"Baker Analyzed" reagent $Zn(NO_3)_2.6H_2O$ was recrystallized from an aqueous solution saturated at 36 °C. $Zn(NO_3)_2.6D_2O$ was prepared as follows: $Zn(NO_3)_2.6H_2O$ was partially dehydrated at 45 °C, dissolved in excess D_2O and slowly concentrated to half volume. D_2O was added and the process repeated twice; crystals obtained after this process were recrystallized from a D_2O solution saturated at 36 °C. Bands attributable to H_2O were absent in the spectra of these crystals. The infrared spectrum of polycrystalline $Zn(NO_3)_2.6H_2O$ (thermostated at 15 °C) (Fig. 1) was recorded against a KRS-5 prism with face angle of 60° placed in a Wilks model-9 M.I.R. attachment. The usefulness of this technique for solid samples has been discussed elsewhere (5). Raman spectra (Fig. 2) were obtained employing the Jarrell-Ash model 25–300 Raman spectrometer. Excitation of samples was achieved with the 4880 Å line of a Spectra Physics model 141 Argon ion laser. Plasma lines were removed with an appropriate narrow band interference filter. Polycrystalline samples were contained in thin-walled Pyrex tubes and thermostated at 25 °C. Raman spectra remained unchanged after prolonged exposure to the laser light. Local heating of the sample and subsequent dehydration did not occur. Excessive grinding of the crystals caused partial dehydration whereas the crystals picked up moisture and melted if exposed to the atmosphere for prolonged periods. Both effects could be detected by spectral changes. Some samples were partially dehydrated in an oven at 40 and 100 °C. No orientational or polarization effects were observed, as expected for polycrystalline samples.

Results and Discussion

$Zn(NO_3)_2.6H_2O$ crystals are orthorhombic, space group D_{2h}^{16}-*Pnma* with 4 molecules per

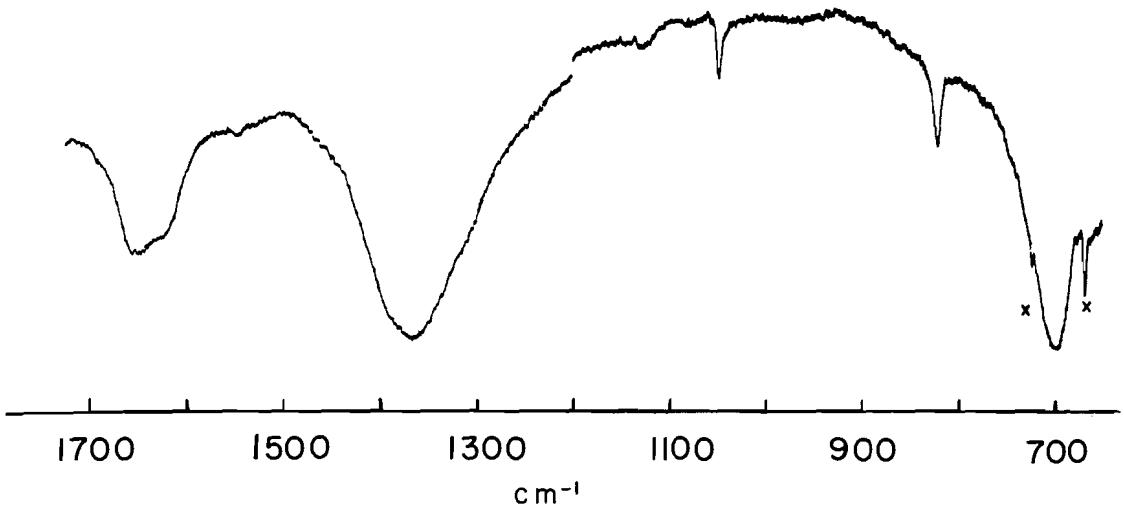

FIG. 1. Photograph of the multiple internal reflection spectrum of $Zn(NO_3)_2.6H_2O$ from 660 to 1750 cm^{-1}.

primitive unit cell. The structure is composed of $[Zn(OH_2)_6]^{2+}$ cations and NO_3^- anions (4). All NO_3^- ions occupy general sites. The hexaquozinc has nearly octahedral symmetry. The two axial water molecules are somewhat closer to zinc, however, and occupy general sites; the four equatorial water molecules occupy C_s sites.

Infrared and Raman spectra are presented in Figs. 1 and 2. Frequencies and tentative assignments for hexaquozinc nitrate crystals are collected in Table 1. Broad Raman bands centered at 376 and 241 cm^{-1} for $Zn(NO_3)_2.6H_2O$ and at 358 and 226 cm^{-1} for $Zn(NO_3)_2.6D_2O$ are assigned to δ(Zn—O) stretching and deformation

vibrations of the hexaquozinc cations (6, 7). A broad Raman band *ca.* 700 cm^{-1} which appears to obscure the ν_4 NO_3^- vibration (Fig. 2) corresponds to a strong infrared absorption *ca.* 690 cm^{-1}, both of which are thought to be due to a water librational mode (8). This band appears weakly in aqueous nitrate solutions (9). In the ν_2 H_2O bending region of the infrared spectrum (Fig. 1) two components can be detected at 1650 and 1625 cm^{-1} which are assigned to water molecules on C_s and C_1 sites, respectively, on the basis of relative intensities.

The occupation of a C_1 site by nitrate ion of D_{3h} point group results in the removal of the degeneracy of the $\nu_3(E')$ and $\nu_4(E')$ modes and the activity of all modes in both infrared and Raman. The lifting of the degeneracy of ν_3 and ν_4, the low intensity of ν_2 in the Raman spectrum (forbidden under D_{3h} selection rules), and ν_1 in the infrared spectrum are clearly visible in Figs. 1 and 2. The spectra do not show sufficient detail to warrant factor group analysis although small differences between infrared and Raman frequencies can be attributed to correlation field coupling. In the infrared spectrum ν_4 was only barely detected even by thick-sample, transmission studies but the ν_3 band at 1362 cm^{-1} is intense and appears to have a shoulder *ca.* 1330 cm^{-1}. The magnitude of the site splitting is less than that observed in other crystalline ionic nitrates in which the NO_3^- ion occupies a general site (5) because the polarizing power of the cation is reduced by the hydration sphere.

The Raman spectrum of the crystal containing D_2O was obtained in order to observe features which could be masked by spectral lines arising from H_2O. In addition to clarification of the spectra in the regions of ν_4 and $2\nu_2$, an intensity reversal of the two components of the ν_3 nitrate vibration was observed (Fig. 2). It is assumed, in the absence of X-ray data and because of similarities in spectra, that the crystal containing D_2O is isomorphous with that containing H_2O, although some expansion of the lattice is probable (Ubbelohde Effect) (10). Strong hydrogen bonds exist in $Zn(NO_3)_2.6H_2O$ (4) and changes in these bond distances probably account for the spectral changes. The possibility that the intensi-

ties of the components of ν_4 (E') are similarly sensitive to deuteration could not be checked because of interference from the H_2O librational mode in this region. No corresponding librational mode was apparent in $Zn(NO_3)_2.6D_2O$.

Infrared and Raman components of ν_1 and ν_2 NO_3^- vibrations are non-coincident (Table 1). Lack of coincidence for the two ν_2 components is emphasized by the presence of two Raman bands at 1642 and 1656 cm^{-1} which correspond to twice the 821 cm^{-1} (infrared) and 828 cm^{-1} (Raman) bands. It is a general rule that overtones of non-degenerate fundamentals are Raman active. Thus the weak 828 cm^{-1} band (forbidden under D_{3h} but activated by the environment) possesses a more intense overtone. Since $Zn(NO_3)_2.6H_2O$ has a centrosymmetric space group the overtones, $2\nu_2$, remain infrared forbidden. Non-coincidence of infrared and Raman bands is required as a consequence of the centrosymmetric crystal structure; this implies that ν_1 and ν_2 vibrations are coupled with similar vibrations of other ions of the unit cell. Dipole–dipole coupling interactions have an inverse cube distance dependence (11). Considering that the minimum nitrogen–nitrogen distance is 6.2 Å in $Zn(NO_3)_2.6H_2O$ (4), it is hard to explain why correlation field coupling is so large compared to that observed for the same vibrations of other nitrates with shorter nitrogen–nitrogen distances (11, 12). Lack of coincidence has also been reported for the saturated aqueous solution (13) with a concentration less than that required to force the NO_3^- ion into the first coordination sphere of the zinc.

Interesting comparisons can be made between the vibrational spectra of solid $Zn(NO_3)_2.6H_2O$ and saturated aqueous $Zn(NO_3)_2$ solutions which are also considered to contain an octahedral hexaquozinc cation (14). Splitting of the ν_3 vibration of NO_3^- in saturated $Zn(NO_3)_2$ at 25 °C (8.2 mol water per mol salt) is 89 cm^{-1} (14) compared to only 20 cm^{-1} in solid $Zn(NO_3)_2.6H_2O$. This difference can partially be accounted for by the increase in the strength of the fluctuating field at the anion site in the more dense fluid state. Only one band has been observed in the ν_4 *ca.* 720 cm^{-1} region of saturated $Zn(NO_3)_2$ at 25 °C, whereas two bands can be resolved in solid $Zn(NO_3)_2.6H_2O$. These latter two bands do not arise from two forms of nitrate ion, however, but from site splitting. The magnitude of the split in the ν_4 region is usually considerably less than in the ν_3 region (5).

Gross changes in the vibrational spectra of solid $Zn(NO_3)_2.6H_2O$ and concentrated aqueous $Zn(NO_3)_2$ solutions only occur when the ratio of the moles of water to moles salt is less than 6 and the NO_3^- ion is allowed to enter the coordination sphere of the cation forming an actual complex *i.e.* an asymmetric field about the NO_3^- ion with a longer lifetime than the time of the measurement. At concentrations less than that required to force cation–anion contact the NO_3^- retains the basic vibrational spectrum of solvated ion modified by the field of the aquated cation environment (14) as noted above.

On dehydration a sharp line at 1047 cm^{-1} was observed in the Raman spectrum in addition to the 1057 cm^{-1} line. As dehydration was continued the new line increased in intensity and shifted to 1015 cm^{-1} at the expense of the 1057 cm^{-1} line. Clearly the new line is characteristic of nitrate ion in the first coordination sphere of zinc (*cf.* ref. 15). Additional Raman bands at 145, 408, 470, 771, 803, 1325, and 1558 cm^{-1} were observed. The 771 cm^{-1} line is higher in frequency than in the concentrated aqueous solution studied earlier (755 cm^{-1} with 2.5 mol water per mol of salt) (14). Hester and Scaife (16) report 775 cm^{-1} for 1.94 mol water per mol of salt at 85 °C. This high value suggests covalence in the zinc–nitrate interaction. The pair of lines, 771 cm^{-1} for inner-sphere nitrate and 718–730 cm^{-1} (site splitting) for outer-sphere, further support the criterion recently advanced for contact ion-pairing in aqueous nitrate solutions (17).

The Adsorption of Tetrachloroethylene and Trichlorofluoromethane on Anhydrous Nickel Sulfate[1]

G. A. KINLOCH[2] AND W. D. MACHIN

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received[3] March 24, 1970

Several anomalous features of the adsorption isotherms obtained with tetrachloroethylene and trichlorofluoromethane on anhydrous nickel sulfate at 20.0, 5.8, and −7.5 °C, have been explained using a parallel plate pore model. Application of the Kelvin equation to the system indicates that adsorption hysteresis is due primarily to contact angle hysteresis, and that the thickness of the adsorbed layer that does not participate in meniscus formation is independent of relative pressure. Heats of immersion calculated from the estimated contact angles, and from heats of adsorption, have provided some support for the model.

Les diverses anomalies des isothermes d'adsorption de tétrachloroéthylène et de trichlorofluorométhane sur sulfate de nickel anhydre à 20.0, 5.8, et −7.5 °C, ont été expliquées à l'aide du modèle à pores en feuillets. L'application de l'équation de Kelvin au système indique que l'hystérésis d'adsorption est principalement dû à l'hystérésis d'angle de contact, et l'épaisseur du film adsorbé, qui ne participe pas à la formation du ménisque, est indépendant de la pression relative. Les chaleurs d'immersion, calculées à partir des angles de contact estimés et des chaleurs d'adsorption tendent à supporter le modèle.

Canadian Journal of Chemistry, 49, 1515 (1971)

Introduction

Hysteresis, when it occurs in adsorbent–adsorbate systems, is generally ascribed to capillary condensation of adsorbate in the pores of the adsorbent (1). The Kelvin equation has been applied to obtain information concerning the size (2), and in some cases, the shape (3) of the pores. The utility of this approach is limited by the necessary assumptions that the molar volume and surface tension of the adsorbate are the same as the bulk liquid, and that the contact angle of the capillary held liquid is zero.

The adsorption of tetrachloroethylene and trichlorofluoromethane on anhydrous nickel sulfate yields isotherms having anomalous features. In particular, the lower closure point of the hysteresis loop is temperature dependent, and may occur within the monolayer region of the isotherm.

Using a relatively simple model for the adsorbent structure, it has been possible to account for these anomalies and to obtain some insight into the applicability of the Kelvin equation.

Experimental

The adsorption system consisted of a vacuum microbalance, similar to that described by Hales and Turner (4), having a sensitivity of ±4 μg and a total capacity of *ca.* 0.5 g; a spoon gauge having a sensitivity of ±0.004 Torr (5), and which, at higher pressures, overlapped with a mercury manometer. Adsorbate purification and storage facilities were also included in the system. Metal valves and O-ring seals were used throughout the equilibrium part of the system.

The sample and counterweight legs of the balance were partially immersed in a large constant temperature bath controlled to ±0.05 °C. At the lowest experimental temperature (−7.5 °C), the water in the bath was replaced with a water–alcohol solution and cooling was provided using a commercial refrigeration unit.

The adsorbent was prepared *in situ* from Reagent Grade $NiSO_4.6H_2O$ by careful dehydration *in vacuo* at temperatures up to 200 °C with most of the water (ca. 90%) being removed below 100 °C. Subsequent degassing of the sample was carried out at 120 °C.

Spectral grade tetrachloroethylene (Eastman Kodak) and trichlorofluoromethane of minimum purity 99.5 mol% (Matheson) were vacuum distilled at least twice, with generous discard of head and tail fractions.

Results

Adsorption isotherms at 20.0, 5.8, and −7.5 °C were determined for both adsorbates. Typical isotherms are shown in Fig. 1. Only those parts of the desorption branches which were reproducible, *i.e.* independent of the point at which desorption was commenced, are shown.

	5.8	44.4	—	0.10	6.00
	−7.5	42.5	—	0.05	2.45
	Average	44.1			

*All data refer to a sample weight of 0.4515 g.

Table 1 summarizes the important features of the isotherms. Monolayer capacities for both adsorbates were determined from B.E.T. plots. Surface areas have been calculated from the $CFCl_3$ isotherms using a molecular area of 29.7 $Å^2$ (6). On this basis, the apparent molecular area of C_2Cl_4 (24.2 $Å^2$) is appreciably lower than the area calculated from liquid density (33.4 $Å^2$). A similar effect has been reported with carbon tetrachloride (7).

Saturation vapor pressures were determined at the various temperatures and are also reported in Table 1. The calculated heats of vaporization are: $CFCl_3$ 6.35 kcal mol^{-1}; C_2Cl_4 9.74 kcal mol^{-1}.

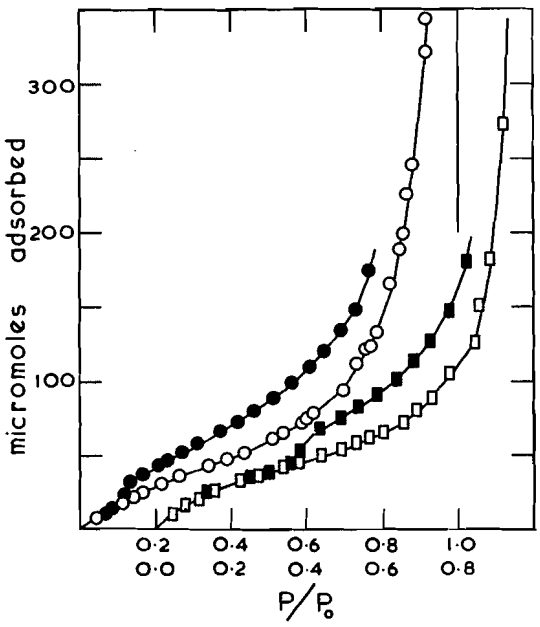

FIG. 1. Adsorption isotherms at 5.8 °C; ○, C_2Cl_4; □, $CFCl_3$. Desorption points are solid. Lower scale P/P_0 refers to $CFCl_3$ data.

Isosteric heats of adsorption, and differential entropies of adsorption are presented in Figs. 2 and 3. The entropies have been calculated according to the procedure given by Young and Crowell (8). Bulk liquid entropies are also shown in Fig. 3.

Discussion

The general form of the Kelvin equation as given by Gregg and Sing (1) is

$$[1] \qquad \frac{dv}{dS} = -\frac{\bar{V}\gamma \cos\theta}{RT \ln (P/P_0)}$$

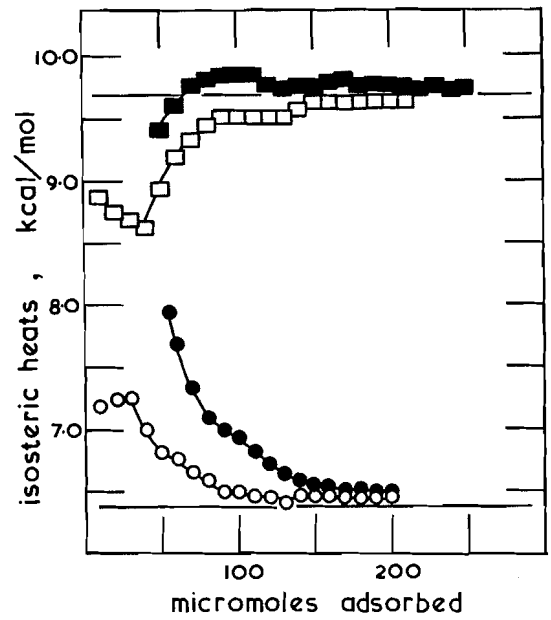

FIG. 2. Isosteric heats of adsorption; □, C_2Cl_4; ○, $CFCl_3$. Desorption points are solid. Latent heats of vaporization as calculated from adsorbate saturation vapor pressures are indicated by solid horizontal lines.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

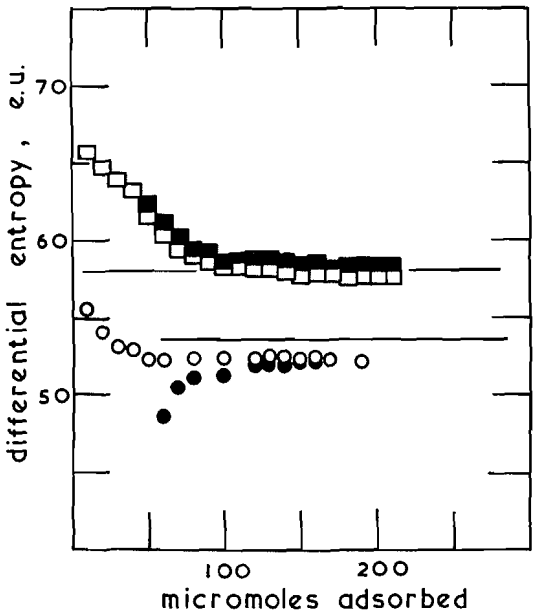

FIG. 3. Differential entropies of adsorption, calculated at 20 °C; □, C_2Cl_4; ○, $CFCl_3$. Desorption points are solid. Solid horizontal lines correspond to entropy of bulk liquid.

where v is the volume and S the surface area of those capillaries capable of inducing capillary condensation at a relative pressure of P/P_0. $\bar{V}$ and γ are the molar volume and surface tension of the adsorbate and θ is the contact angle. These authors also show that, irrespective of the pore geometry, dv/dS is constant, and may be considered a pore size parameter.

The simplest solution to the equation

$$[2] \qquad \left(\frac{\partial v}{\partial S}\right)_d = \text{constant} \quad (\text{at given } P/P_0)$$

is

$$[3] \qquad \left(\frac{\partial v}{\partial S}\right)_d = \frac{v}{S} \quad (\text{at given } P/P_0)$$

and where S is now assumed to be the total surface area, and v is the total volume of adsorbate at P/P_0. This solution defines a particular type of pore structure, the parallel plate model, with the additional condition that the plates are free to move apart in order to accommodate additional quantities of adsorbate, the spaces between all the plates being filled with adsorbate at all relative pressures in the region of hysteresis, and the distance between the plates being variable and dependent on the relative pressure. Some support for this model has been provided by various workers using adsorbents such as montmorillonite clays (9) and boehmite (10) which are known to have parallel plate structures. Isotherms reported by these workers have shapes similar to those reported here.

Accepting this model, we obtain

$$[4] \qquad \frac{v}{S} = -\frac{\bar{V}\gamma \cos\theta}{RT \ln (P/P_0)}$$

and since $v/\bar{V} = M$, the number of moles of adsorbate, and

$$[5] \qquad S = M_m BN$$

where S is the total surface area, M_m is the number of moles of adsorbate required to form a monolayer, and B is the molecular area, we obtain

$$[6] \qquad \frac{-1}{\ln (P/P_0)} = \frac{RT}{BN\gamma \cos\theta} \cdot \frac{M}{M_m}$$

which indicates that a plot of $-1/\ln (P/P_0)$ against M/M_m should be linear. That this is the case is demonstrated in Fig. 4, but the linear portions, when extrapolated, do not pass through the origin.

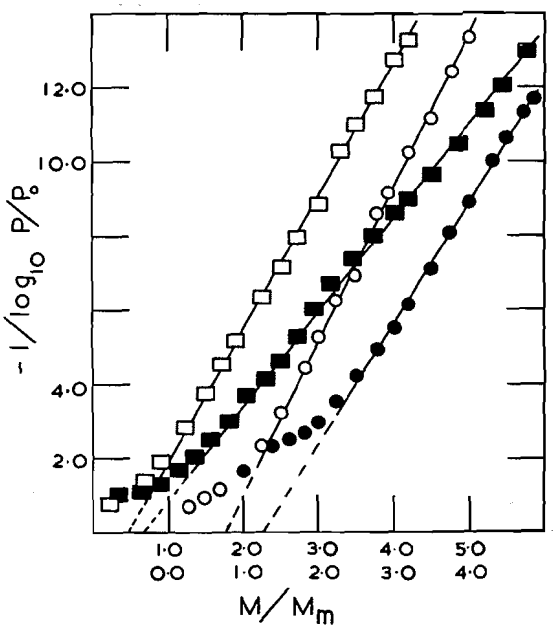

FIG. 4. Inverse Kelvin plots at 5.8 °C; □, C_2Cl_4; ○, $CFCl_3$. Desorption points are solid. Lower M/M_m scale refers to $CFCl_3$ data.

TABLE 2. Contact angles and "t" values

Temperature (°C)	Surface tension (erg cm^{-2})	Adsorption			Desorption		
		cos θ	θ	t	cos θ	θ	t
			$CFCl_3$				
20.0	19.5	0.376	67.9	0.67	0.510	59.3	1.01
5.8	21.4	0.352	69.3	0.63	0.432	64.3	1.22
−7.5	23.1	0.318	71.5	0.69	0.408	65.8	1.36
			C_2Cl_4				
20.0	31.7	0.364	68.7	0.40	0.469	62.0	0.76
5.8	33.3	0.312	71.8	0.43	0.441	63.8	0.62
−7.5	34.9	0.262	74.8	0.38	0.362	68.8	0.91

In our derivation of eq. 6 we have implicitly assumed that all of the adsorbate is present as capillary-held liquid, but both heats and entropies of adsorption indicate that this may not be the case. If we assume that a portion of the adsorbate is not liquid-like, then

$$[7] \qquad v/\bar{V} = M - x$$

where x is the quantity of adsorbate not having liquid properties, and $v/\bar{V}$ is now the quantity of adsorbate having liquid properties.

We now obtain the equation

$$[8] \qquad \frac{-1}{\ln (P/P_0)} = \frac{RT}{BN\gamma \cos\theta}\left[\frac{M}{M_m} - t\right]$$

where $t = x/M_m$, and which provides a satisfactory description of the linear plots in Fig. 4.

Contact angles and values for t calculated from these plots are reported in Table 2. The experimental molecular areas were used in the calculation of cos θ. It is not possible to verify these contact angles by direct measurement, but some measure of support is provided by the following approach.

The heat of immersion, q_{imm}, is related to the contact angle through the equation (11)

$$[9] \qquad q_{imm} = E_L \cos\theta - T\gamma \mathrm{d}\cos\theta/\mathrm{d}T$$

where E_L is the total surface energy and can be evaluated from

$$[10] \qquad E_L = \gamma - T\mathrm{d}\gamma/\mathrm{d}T$$

The heat of immersion may also be calculated (1) from the heat of adsorption, as

$$[11] \qquad \Delta H_i = \Delta H_{SV} - n\Delta H^0 = q_{imm}S$$

where ΔH_i is the net integral heat of adsorption, ΔH_{SV} is the integral heat of adsorption, and ΔH^0 is the latent heat of evaporation of the liquid, and S is the surface area. Unfortunately, both methods of calculation involve small differences between relatively large quantities.

The calculated heats of immersion at 20 °C are: $CFCl_3$ +9.7 erg cm^{-2} (contact angle); +27.8 erg cm^{-2} (heat of adsorption); C_2Cl_4 −10.0 erg cm^{-2} (contact angle); −44.0 erg cm^{-2} (heat of adsorption). While agreement is only qualitative, it should be remembered that the effect of experimental error on these values is large, being *ca.* ±20 erg cm^{-2} for those values calculated from heats of adsorption.

The assumption of contact angle hysteresis provided one of the earliest explanations for the occurrence of hysteresis loops in adsorption isotherms (12), but later work has shown that this cannot be the only reason for their occurrence. We feel that the present work provides some support for the idea that, in the present systems at least, contact angle hysteresis may influence the shape of the adsorption hysteresis loop. In this context, it should be noted that Jones and Wade (13), investigating the adsorption of various *n*-aliphatic alcohols on porous Vycor, found it necessary to assume various contact angles in order to obtain self-consistent pore size distributions.

It is also generally assumed, in pore size calculations, that the thickness of the adsorbed layer that does not participate in meniscus formation (t) is not constant, but increases with increasing relative pressure (2). In the present case, the linearity of the inverse Kelvin plots suggests that t is constant over a large range of relative pressures.

The authors thank the National Research Council of Canada for financial support of this work.

Oxygen Interchange on Vanadium Oxide Catalysts

R. F. MANN

Department of Chemistry and Chemical Engineering, Royal Military College of Canada, Kingston, Ontario

Received September 23, 1970

It is often difficult to compare results for heterogeneous reactions as the data reported in the literature are presented in various ways. A common example of this difficulty is the reporting of oxygen adsorption rate constants in units such as l (g-catalyst)$^{-1}$ s^{-1}, l m^{-2} h^{-1}, g m^{-2} h^{-1}, g-mol m^{-2} h^{-1}, etc. In this paper a number of studies involving oxygen interchange with vanadium pentoxide or vanadium pentoxide – potassium sulfate promoted catalysts are re-examined. Where possible, a first-order oxygen adsorption rate constant is evaluated from published data on rates of oxidation and rates of isotopic exchange, and expressed in units of l h^{-1} m^{-2} of catalyst surface. The rate constants so evaluated and compared as to catalyst composition, temperature, and activation energy show reasonable agreement, even though a variety of catalysts, processes, and techniques are involved.

Dû au fait qu'ils sont souvent présentés sous diverses formes, il est souvent difficile de comparer les résultats rapportés dans la littérature pour des réactions hétérogènes. Un exemple commun de ces difficultés a trait à la façon de rapporter les constantes de vitesses d'adsorbtion de l'oxygène pour lesquelles les unités ont été: l (g-catalyseur)$^{-1}$ s^{-1}, l m^{-2} h^{-1}, g m^{-2} h^{-1}, mol-g m^{-2} h^{-1}, etc. Dans la présente communication, on réexamine un certain nombre d'études au sujet des échanges d'oxygène impliquant des catalyseurs activés par l'oxyde de vanadium ou un mélange d'oxyde de vanadium et de sulfate de potassium. Dans les cas où ce fut possible, nous avons évalué une constante de vitesse du premier ordre pour l'adsorption de l'oxygène; à cette fin, nous avons utilisé les données publiées pour les vitesses d'oxydation et les vitesses d'échanges isotopiques et nous exprimons ces vitesses en litres par heure par m^2 de surface de catalyseur. Quoique les catalyseurs, les procédés de préparation et les techniques employées varient grandement, les constantes de vitesse que nous avons évaluées présentent une corrélation raisonable suivant la composition du catalyseur, la température et l'énergie d'activation.

Canadian Journal of Chemistry, 49, 1520 (1971)

Introduction

Much work has been reported in recent years concerning systems where gas-phase oxygen interacts with vanadium oxide, as well as other metal oxide catalysts. These works involve processes such as catalytic oxidation of a hydrocarbon, oxidation of a reduced catalyst, adsorption of oxygen on a catalyst, and oxygen isotope exchange.

A number of such works, where the catalyst was vanadium pentoxide or vanadium pentoxide promoted with potassium sulfate, were reviewed and, where possible, a first-order oxygen adsorption rate constant was evaluated. It was assumed that the oxygen adsorption stage could be described by

$$[1] \qquad r_{ads} = k_a C_0(1 - \theta)$$

where r_{ads} = rate of oxygen adsorption or uptake by the catalyst surface, in g-mol m^{-2} h^{-1}; k_a = oxygen adsorption first-order rate constant, in l m^{-2} h^{-1}; C_0 = concentration of oxygen in the gas phase, in g-mol l^{-1}; and θ = fraction of the available surface covered by the oxygen being adsorbed.

The k_a values evaluated suffer, of course, from uncertainties. In some cases the values obtained can only be called estimates. The parameters subsequently evaluated, *e.g.* E_a, ln k_0 (E_a = activation energy of k_a, in kcal g-mol^{-1}, k_0 = Arrhenius pre-exponential, in l m^{-2} h^{-1}), will also be in error by varying amounts depending on the source of the original data, the method of k_a estimation, etc. In general the magnitude of these errors is unknown.

The object of this paper, however, is to examine the general characteristics of the various oxygen interchange processes and to discover general similarities in the data.

Data from Catalytic Oxidation of Hydrocarbons

A reaction model was proposed and described by Hinshelwood (1) and Mars and van Krevelen (2) and has been employed by a number of workers as the "steady-state adsorption model". The derivation of this model includes the assumption that eq. 1 describes the interaction between the gas-phase oxygen and the catalyst, and leads to

$$[2] \qquad r_R = \frac{k_a k_r C_0 C_R}{k_a C_0 + n k_r C_R}$$

where r_R = rate of reaction of hydrocarbon reactant, in g-mol m^{-2} h^{-1}; k_r = reaction rate

constant, in l m^{-2} h^{-1}; C_R = concentration of hydrocarbon reactant in the gas phase, in g-mol l^{-1}; and n = stoichiometric number = mol of oxygen required/mol of reacted hydrocarbon. Various units for these variables have been used by various workers. The k_a values have been re-evaluated as described earlier and the results are summarized in Table 1.

Data from Oxidation of Reduced Catalyst

Roiter and Yuza (10) reported rates of oxidation of a V_2O_5 catalyst which had been reduced various amounts with hydrogen. Rates of oxidation were given at various oxygen concentrations so that it was possible to estimate a slope in the low pressure region (*i.e.* as $\theta \rightarrow 0$ in eq. 1) and obtain an estimated k_a. These data are given in Table 2. The degree of reduction, ΔO_2, is expressed in terms of the volume of oxygen that was removed per gram of catalyst by the previous hydrogen oxidation reaction.

Data from Oxygen Isotope Exchange Studies

A number of Russian workers have carried out catalytic activity studies in conjunction with heteromolecular and homomolecular oxygen

isotope exchange measurements. The exchange techniques have been extensively discussed by Boreskov (11) who also presented rate data for exchange on various oxide catalysts. Several of the original papers have been examined and the k_a values in Table 3 were obtained.

Other Work Examined

Other published works on the catalytic oxidation of naphthalene (2, 15), toluene (2), anthracene (2), benzene (2, 16), sulfur dioxide (17), *o*-xylene (18), and methyl alcohol (19) were also examined as were other oxygen adsorption and isotope exchange studies (20, 21). First order adsorption constants k_a could not be evaluated from these works because of insufficient data on oxygen concentrations, catalyst specific areas, units, etc.

Results and Treatment of Data

(1) Arrhenius Correlation

The temperature coefficient of k_a, the apparent Arrhenius activation energy of adsorption E_a, was calculated for each set of k_a values. The accompanying pre-exponential, as ln k_0, was also obtained for each set. The data so obtained are shown in Tables 1, 2, and 3.

(2) Compensation Behavior of ln k_0 with E_a

The great range of k_a values for the first-order adsorption process and the variety of E_a and ln k_0 values are partly explained in Fig. 1, where ln k_0 is plotted against adsorption activation energy, E_a. There appears to be a relationship between the activation energy and the pre-exponential factor for each catalyst, roughly of the form

$$[3] \qquad \ln k_0 = aE_a + b$$

where, in Fig. 1, $a \simeq 0.53$ and $b \simeq 6.0$. As discussed by Ashmore (22) this has been called the "theta rule" by Schwab (23) and the "com-

pensation effect'' by Cremer (24). Cremer called the temperature of intersection of the Arrhenius correlation lines T_s without saying much about the significance of such a temperature. Various possible explanations of the compensation effect were discussed by Cremer (24) but no single explanation was endorsed. Surface heterogeneity of the catalyst is likely a major factor with more than one type of ''active center'' existing. The compensation effect must still be regarded as an empirical relationship, however.

The major objective of the present work is to indicate that oxygen adsorption rate constants obtained by different methods for different processes show some relationship to each other. The present data for V_2O_5 catalysts do illustrate a certain compensation effect as the data for Sets *A*, *G*, *H*, *J*, *K*, *L*, *M*, *N*, and *P* show the general convergence characteristic with the T_s temperature in the range 900 to 1000 °K. (Note that V_2O_5 melts at 963 °K.) As is obvious in Fig. 1, the V_2O_5–xK_2SO_4 data (x = mol K_2SO_4 in catalyst per mol V_2O_5) are not as well correlated as are the V_2O_5 data and, therefore, no clear compensation effect is evident when the k_a values for Sets *B*, *C*, *D*, *E*, *F*, *Q*, *R*, and *S* are plotted on an Arrhenius basis.

Conclusions

While some of the data are admittedly approximate and, therefore, some aspects of the subsequent data analysis must also be approximate, it is concluded that a relationship does exist between k_a data from a variety of sources, for a variety of processes and for a variety of catalysts.

The relationship appears to be of the form described by Cremer as the ''compensation effect'' where an increase in the activation energy of the adsorption rate constant is accompanied (or compensated for) by an increase in the pre-exponential factor. This effect is illustrated most clearly where a number of different processes have been studied on the same catalyst, V_2O_5.

This preliminary examination of data from seventeen different studies of a variety of processes is sufficiently encouraging to warrant continued work. The determination and comparison of k_a data should initially be confined to single catalyst compositions and further information on the relationship between surface and E_a should be a major objective. Re-evaluation of other published work should be continued to give a broader picture of the oxygen interchange process on vanadium oxide catalysts.

On the applied aspects of heterogeneous catalysis, a long-range objective must be the prediction of reactor performance by the proper use of predicted rate equations. This present paper is a further contribution to the problem of predicting the rate of oxygen interaction with a particular family of metal oxide catalysts for catalytic oxidation processes.

The research for this paper was supported in part by the Defence Research Board of Canada, Grant number 9530-64.

Photochemistry of the *cis*- and *trans*-Dichlorobisethylenediamine Chromium(III) Cations in Acidic Aqueous Solutions. Observation of a Stereochemical Change in Photoaquation

A. D. KIRK[1], K. C. MOSS, AND J. G. VALENTIN[2]

Department of Chemistry, University of Victoria, Victoria, British Columbia

Received October 23, 1970

The photoreactions of *cis*- and *trans*-$[CrCl_2(en)_2]^+$ have been investigated in acidic aqueous solution at p*H* 3 and 0 °C. On photolysis in the ligand field bands the *cis* isomer was found to undergo mainly ethylenediamine aquation, apparently to a thermally unstable monodentate protonated ethylenediamine complex, with a quantum yield of 0.13. In addition chloride aquation occurred with $\phi(Cl^-) = 0.02$. In contrast, the *trans* isomer underwent exclusive chloride aquation with quantum yield 0.32. The results are qualitatively, but not quantitatively, in agreement with predictions of Adamson's empirical rules. It was found that for *trans*-$[CrCl_2(en)_2]^+$ photolysis, the reaction product $[CrCl(H_2O)(en)_2]^{2+}$ was produced at least 70% in the *cis* configuration.

Les réactions photochimiques du *cis*- et *trans*-$[CrCl_2(en)_2]^+$ ont été étudiées en solution aqueuse acide à p*H* 3 et à 0 °C. Lors de la photolyse dans les bandes du champ liant, on a trouvé que l'isomère *cis* subit principalement l'hydrolyse de l'éthylènediamine, apparemment pour donner un complexe monodentate protoné de l'éthylènediamine, avec un rendement quantique de 0.13. De plus, l'hydrolyse du chlore a eu lieu avec $\phi(Cl^-) = 0.02$. Par opposition, l'isomère *trans* a subit exclusivement l'hydrolyse du chlore avec un rendement quantique de 0.32. Les résultats sont qualitativement, mais non quantitativement, en accord avec les prévisions des règles empiriques d'Adamson. Il a été trouvé que pour la photolyse du *trans* $[CrCl_2(en)_2]^+$ le produit de réaction $[CrCl(H_2O)(en)_2]^{2+}$ a été produit au moins à 70% dans la configuration *cis*.

Canadian Journal of Chemistry, 49, 1524 (1971)

Introduction

Adamson (1) has proposed a set of empirical rules governing the modes and approximate quantum yields for photolysis of Cr(III) complexes. An interesting prediction of these rules is that for certain *cis*/*trans* complex pairs the photolysis modes and yields for the two isomers would be quite different. To the best of our knowledge the only system of this type previously investigated has been the *cis*/*trans* pair $[Cr(OH)_2(en)_2]^+$ (1, 2). The results of this investigation were rendered somewhat ambiguous by the complexity of the possible reaction modes and ignorance as to the extent of photochemical solvent exchange. Thus although the results are not inconsistent with the rules, they do not allow firm conclusions regarding them.

We wish to report a study of the photochemical reactions of the pair of complexes *cis*- and *trans*-$[CrCl_2(en)_2]^+$. Experimentally this system has the advantage that detailed studies of the thermal reactions have been made (3) and the loss of either ligand from the compounds can easily be followed experimentally. For this pair of compounds, Adamson's rules predict that the *cis* isomer would undergo predominantly ethylenediamine aquation, with a quantum yield of about 0.1 to 0.3, whereas the *trans* compound would undergo predominantly chloride aquation with a low quantum yield of about 0.1 or less. It seemed to us, therefore, that this system offered an excellent opportunity to test critically the extent to which Adamson's rules are valid.

Results and Conclusions

Photolysis of cis-$[CrCl_2(en)_2]^+$

The absorption spectrum of *cis*-$[CrCl_2(en)_2]^+$ is shown in Fig. 1*a*. Photolysis of this compound at p*H* 3.0, 0 °C and at wavelengths (400 and 540 nm) corresponding to absorption into the two ligand field bands Q_1 and Q_2 ($^4T_{2g} \leftarrow {}^4A_{2g}$ and $^4T_{1g} \leftarrow {}^4A_{2g}$ in O_h symmetry, respectively) resulted in hydrogen ion uptake corresponding to the aquation and protonation of the basic ethylenediamine ligand

[1] *cis*-$[CrCl_2(en)_2]^+ + H_2O + H^+ \rightarrow [CrCl_2(H_2O)en(enH)]^{2+}$

[1]To whom correspondence should be addressed.

or

[2] *cis*-$[CrCl_2(en)_2]^+ + H_2O + 2H^+ \rightarrow$
$[CrCl_2(H_2O)_2en]^+ + enH_2^{2+}$

Simultaneously with this reaction, the major thermal reaction

[3] *cis*-$[CrCl_2(en)_2]^+ + H_2O \rightarrow$
cis-$[CrCl(H_2O)(en)_2]^{2+} + Cl^-$

also occurred and was followed by the thermal chloride release. By working at low temperature and maximum possible light intensity it was possible to ameliorate the complicating effects of this process.

Ion exchange chromatography (Rexyn 101) on solutions photolyzed to about 50% decomposition resulted in the elution of a band of compound having the absorption spectrum seen in Fig. 1*c*. This band eluted after the unchanged starting material which was the first observable band off the column. The substance was thermally unstable and, if left on the column at p*H* 0 and 0 °C, decomposed fairly rapidly yielding a compound having the spectrum shown in Fig. 1*d*. It is seen that the long wavelength band maxima in spectra 1*c* and 1*d* are progressively shifted about 500 cm^{-1} towards the red relative to the starting material. Thus, these spectra are close to those expected for the thermally unstable protonated ethylenediamine complex $[CrCl_2(H_2O)en(enH)]^{2+}$ and its ethylenediamine aquation product $[CrCl_2(H_2O)_2en]^+$. Such an identification is also consistent with the chromatographic behavior of the compounds. It was unfortunately not possible to identify the isomers of $[CrCl_2(H_2O)en(enH)]^{2+}$ or $[CrCl_2(H_2O)_2en]^+$ produced. No other significant products were present and the minor amounts of other species found appear to be associated with chloride aquation and secondary photolysis and thermal reactions. In particular *trans*-$[CrCl_2(en)_2]^+$, which would have eluted first in the chromatographic separation, was absent.

The above identification of the major reaction product is rendered somewhat tentative because of the difficulty due to its thermal instability. However, the spectral and chromatographic evidence obtained, the fact of the thermal instability of the product, the absence of other major products, and previous experience with the photolysis of other ethylenediamine complexes (8, 11) all suggest that the major photolysis process occurring in this system is reaction 1. Parallel to this reaction a small yield of photochemical chloride aquation occurred (reaction 3, although the product chloroaquo species may not be *cis*). A small contribution from reaction 2 can not be completely excluded.

On the assumption that reaction 1 is the sole photochemical reaction resulting in proton uptake, one obtains the quantum yields for ethylenediamine aquation shown in Table 1. It is unlikely that any serious error is incurred by neglect of possible thermal aquation of the enH product during the run as this would have caused a curvature in the hydrogen ion time plots and

TABLE 1. Photolysis quantum yields for *cis*- and *trans*-$[CrCl_2(en)_2]^+$ at 0 °C and p*H* 3.0

Complex	Wavelength (nm)	Reaction mode	Quantum yield
cis-$[CrCl_2(en)_2]^+$	400	en	0.13 ± 0.02
		Cl^-	0.011 ± 0.005
	540	en	0.12 ± 0.02
		Cl^-	0.02 ± 0.01
	All	Isomerism	< 0.01
trans-$[CrCl_2(en)_2]^+$	400	Cl^-	0.35 ± 0.02
	424	Cl^-	0.32 ± 0.02
	540	Cl^-	0.32 ± 0.02
	565	Cl^-	0.31 ± 0.02
	All	Isomerism	< 0.05
		en	< 0.001

none was observed. Occurrence of reaction 2 would lead to an error in equating the quantum yield of hydrogen ion uptake to the yield of the species $[CrCl_2(H_2O)en(enH)]^{2+}$, but since no $[CrCl_2(H_2O)_2en]^+$ was observed in the chromatography such error cannot be large.

Direct measurements of the overall chloride yields, corrected for the thermal chloride release, led to the values of Table 1 for the chloride aquation quantum yields. On the assumption of one chloride ion released per photolyzed complex ion, these yields may be taken to be for the primary aquation process, reaction 3. Table 1 also shows a maximum isomerization quantum yield based on our failure to observe any *trans*-$[CrCl_2(en)_2]^+$ amongst the products and our estimate of the maximum amount of the compound that could have gone undetected.

Photolysis of trans-$[CrCl_2(en)_2]^+$

The absorption spectrum of *trans*-$[CrCl_2(en)_2]^+$ is shown in Fig. 1*b*. Because *trans*-$[CrCl_2(en)_2]^+$ is thermally much more stable to aquation than the *cis* isomer, the photochemical work on this complex was uncomplicated by thermal reaction of the starting material. Photolysis of the compound at p*H* 3.0, 0 °C and 400, 424, 540, or 565 nm resulted in chloride ion release, with no detectable hydrogen ion uptake.

Ion exchange chromatography on solutions photolyzed to more than 50% decomposition yielded four substances. Using the Rexyn 101 column and eluting with 0.6 *M* nitric acid one obtained Band 1: *trans*-$[CrCl_2(en)_2]^+$, 39% of the total Cr; Band 2: unidentified, 9% of the total Cr; Band 3, *cis*-$[CrCl(H_2O)(en)_2]^{2+}$, 33% of total Cr; and Band 4, unidentified, 19% of total Cr. Band 2, 9% of the total Cr, was present in too small an amount to allow certain identification by our present techniques. However, since the *trans* isomers of these complexes generally elute before the *cis* it may consist of either or both of *cis*-$[CrCl_2(en)_2]^+$ or *trans*-$[CrCl(H_2O)(en)_2]^{2+}$. The observed color of the band is more consistent with the latter identification. Band 4 was not studied in detail at this juncture. It is almost certainly a secondary product resulting from the high conversion necessary to obtain identifiable amounts of the primary products. Its elution characteristics and color suggest it is $[Cr(H_2O)_2(en)_2]^{3+}$ or $[CrCl(H_2O)_2en(enH)]^{3+}$ arising from secondary photochemical reactions of *cis*-$[CrCl(H_2O)(en)_2]^{2+}$.

These results show that the main process occurring on photolysis of *trans*-$[CrCl_2(en)_2]^+$ in acid aqueous solution is

[4] *trans*-$[CrCl_2(en)_2]^+ \rightarrow [CrCl(H_2O)(en)_2]^{2+} + Cl^-$

where the product $[CrCl(H_2O)(en)_2]^{2+}$ is produced at least 70% in the *cis* configuration.

Because of the latitude allowed by the unidentified Band 4, it remains possible that direct photolysis to $[Cr(H_2O)_2(en)_2]^{3+}$ with loss of both chloride ions also occurs to some extent. This would prevent us from equating the yields of chloride and $[CrCl(H_2O)(en)_2]^{2+}$. However, chromatographic data show that in the worst case, *i.e.*, that Band 4 consists entirely of $[Cr(H_2O)_2(en)_2]^{3+}$ arising from such a direct process, the maximum error incurred by neglect of this process would be 35%. Having recognized this uncertainty, we proceed on the likely assumption that reaction 4 is the only photochemical process releasing chloride and that the ϕ_{Cl} values are equal to $\phi_{[CrCl(H_2O)(en)_2]^{2+}}$.

In all the quantitative work the reactions were

followed continuously by potentiometric chloride determination and by p*H* measurements and the conversions were always $\leqslant 5\%$. Table 1 shows quantum yield data for chloride aquation together with upper limit estimates for other reaction modes based on the chromatographic data and our estimate of observable p*H* changes. The chloride aquation quantum yields for the *trans* complex showed a small increase with decreasing photolysis wavelength while the ethylenediamine yields for the *cis* complex appeared wavelength independent.

Discussion

From the above results it is seen that the photochemistry of the *cis*- and *trans*-$[CrCl_2(en)_2]^+$ complexes illustrates that geometrical configuration can indeed determine the course of chemical reactions undergone by the excited state of a complex ion. The major photoaquation modes are exactly as predicted by Adamson's rules.

The study provides some support for the contention that the photochemical activation of quadrate complexes occurs along the weak-field axis, a suggestion which was not, in our opinion, confirmed by previous reported evidence. Invariably the complexes studied were of such a nature that the results did not allow unequivocal mechanistic conclusions.

For example, for the $[CrX(NH_3)_5]^{2+}$ complexes, the observation that ammonia aquation was the main photochemical reaction did not prove that the ammonia molecule released was that on the weak field axis, but could equally well have arisen from activation of the plane orthogonal to the weak field axis.[3] In fact, the studies of Schläfer and co-workers on the complexes $[CrCl(NH_3)_5]^{2+}$ (4) and $[CrBr(NH_3)_5]^{2+}$ (5) in which the product aquo complex was apparently in the *cis* configuration, could on one interpretation be considered to support such a mechanism. Similar ambiguities of interpretation arise with previous studies of $[Cr(OH)_2(en)_2]^{3+}$ (2) and $[Cr(NCS)_4(NH_3)_2]^-$ (6). In the present work an ambiguity remains for the *cis* isomer but the observation of exclusive chloride aquation in *trans*-$[CrCl_2(en)_2]^+$ unequivocally confines the activation to the weak field axis.

Adamson has suggested that the quantum yields for these photoaquation reactions of non-octahedral complexes should be about the same as for a complex having the same overall average ligand field strength as on the weak field axis. This would suggest a lower quantum yield for the *trans* isomer (about 0.1 to 0.01 by analogy to $[Cr(H_2O)_6]^{3+}$ and $[Cr(urea)_6]^{3+}$ (8) than for the *cis* (about 0.3). Our findings, 0.32 for the *trans* isomer and 0.13 for the *cis*, are very much contrary to this prediction. We conclude that there exists at present little experimental support for any correlation relating the relative magnitudes of quantum yields to the average ligand field on the weak field axis. The pursuit of such quantitative correlations should await the accumulation of much more evidence than is presently available.

As a final aspect of Adamson's rules there is the question as to whether they predict the stereochemistry of the photosubstitution reactions. Earlier work has again been contradictory and equivocal on this point. As stated, Schläfer and co-workers found $[CrCl(NH_3)_5]^{2+}$ and $[CrBr(NH_3)_5]^{2+}$ aquated ammonia to give predominantly the *cis* isomer of the product. It was not, however, completely certain that a post irradiation isomerization was not responsible.[4] In contrast, *trans*-$[Cr(NCS)(H_2O)(NH_3)_4]^{2+}$ (7) appeared to be the product from photoaquation of $[Cr(NCS)(NH_3)_5]^{2+}$.

In the present study it was not possible to identify the isomeric form of the product of the *cis* photoaquation. However, the chloro aquo product complex from photolysis of *trans*-$[CrCl_2(en)_2]$ was found to be at least 70% in the *cis* configuration. Under the temperature and conditions of the experiments the measured rate constants for isomerization (3) exclude any possibility of this amount of thermal isomerization and photochemical *cis*/*trans* isomerization of the reaction product could not occur to this extent. Thus, the photochemical aquation in this complex occurs mainly with stereochemical change, suggesting that the entering water molecule attacks the excited state of the complex *trans* to the leaving chloride ion.

This is in complete contrast to the thermal reaction and, together with our recent findings

[3]We are indebted to Dr. Vincenzo Balzani for useful discussions on this point.

[4]Recent work (12) has confirmed the *cis* configuration of the chloroaquotetraammine product from the photolysis of chloropentaammine Cr(III) ion.

for $[Cren(ox)_2]^-$ (8), represents the first unambiguous demonstration of stereomobility in Cr(III) complex aquation reactions, photochemical or thermal. The result suggests strongly that reaction occurs from some precursor having quite different properties from the ground state, and renders it unlikely that this reaction occurs from vibrationally excited ground state molecules produced by internal conversion.

Experimental

(a) Preparation of Complexes

trans-$[CrCl_2(en)_2]Cl$ was prepared as described in the literature (9), except that it was found necessary to bubble chlorine through the $[Cr(NCS)_2(en)_2]SCN$ slurry overnight in order to obtain good yields.

trans-$[CrCl_2(en)_2]NO_3$ was prepared by adding concentrated nitric acid to a solution of *trans*-$[CrCl_2(en)_2]Cl$ and cooling on ice, filtering and drying.

Anal. Calcd. for *trans*-$[CrCl_2(en)_2]NO_3$: Cr, 17.0. Found: Cr, 16.9.

cis-$[CrCl_2(en)_2]Cl$ was prepared as described in the literature (10).

cis-$[CrCl_2(en)_2]NO_3$ was prepared from the chloride by dissolving in the minimum amount of water at room temperature, adding a large excess of ammonium nitrate, and cooling on ice. The separated salt was filtered and dried.

Anal. Calcd. for *cis*-$[CrCl_2(en)_2]NO_3$: Cr, 17.0. Found: Cr, 16.8.

(b) Photolysis Apparatus and Actinometry

These have been previously described (8). The interference filters for 424 and 565 nm were obtained from Rolyn Corp (Filtraflex B-20) and had half-widths of 9 and 6 nm, respectively. For the ion exchange chromatographic separations, solutions were extensively decomposed using a wide band color filter (CS-496, Corning Glass Co.) to allow greater light intensity. The photolysis cell was a modified 1.0 cm quartz spectrophotometer cell, solutions being stirred by means of a stream of presaturated nitrogen gas along the rear face of the cell.

(c) pH and Chloride Determinations

For the quantitative work, photolysis solutions were prepared at the run temperature 0 °C in semidarkness. Solutions, 5.0×10^{-3} *M*, made up with 1.0×10^{-3} *M* perchloric acid were used for both p*H* and chloride determinations and in addition the solutions were 0.01 *M* in potassium perchlorate.

The p*H* measurements were made using a Fisher microprobe combination electrode in conjunction with a Metrohm Compensator E 388 p*H* meter.

Determinations of the free chloride present in the solutions were made using a concentration cell without transference. The internal reference cell contained 1.00×10^{-2} *M* potassium chloride and the apparatus was calibrated over the range of chloride concentration 1.00×10^{-4} to 2.00×10^{-3}. Silver/silver chloride electrodes were used and that in the photolysis cell was masked to avoid difficulties experienced with photopotentials.

In the quantitative work both p*H* and chloride measurements were made continuously throughout separate series of runs, and percentage conversions were always held to a few percent ($2 \rightarrow 5\%$).

(d) Ion Exchange Chromatography

For both complexes adequate separations of the reaction products were obtained by chromatography on Rexyn 101 with 0.6 *M* nitric acid as eluent. A 1.0 cm diameter, 4.0 cm long column, jacketed at 0 °C was used.

A Study of Cation-exchange Reactions in the System Potassium Durosemiquinone – Potassium Tetraphenylboride – Tetrahydrofuran

T. E. GOUGH[1] AND P. R. HINDLE

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received November 9, 1970

The electron spin resonance (e.s.r.) spectrum of potassium durosemiquinone in tetrahydrofuran has been studied as a function of temperature and found to exhibit line-width alternation indicating the presence of an intramolecular migration of the potassium ion between the oxygens of the semiquinone. The addition of potassium tetraphenylboride to the system produces intermolecular scrambling of potassium, the spectral effects of which are superimposed upon those of the intramolecular exchange. From the spectral line-shapes approximate values of the activation energies and frequency factors were derived. The tetraphenylboride anion did not play a detectable role in the various exchange mechanisms.

On a étudié le spectre r.p.e. du sel de potassium de la durosemiquinone en fonction de la température et on a trouvé qu'ils présentent une alternation des largeurs de raie qui indiquerait que l'ion de potassium effectue des migrations intramoléculaires entre les divers atomes d'oxygène de la semiquinone. L'addition de tétraphénylborure de potassium au système a comme effet de permettre une permutation des ions potassium entre les molécules; ces migrations provoquent des changements spectraux qui se superposent à ceux provoquées par les échanges intramoléculaires. A partir des formes des bandes dans les spectres, on a pu donner les énergies d'activation et les facteurs de fréquence de ces réactions. Il ne semble pas que l'anion tétraphénylborure joue un rôle détectable dans les divers mécanismes d'échange.

Introduction

Electron spin resonance spectroscopy has been used to probe the kinetics of both intra- and intermolecular cation-exchange reactions of systems in which the paramagnetic anion has two sites at which ionic association may occur. The intramolecular case has, to date, received more attention and a number of rate-constants and activation energies have been determined for these processes (1–5); however, the mechanistic details of the exchanges are still somewhat uncertain (6). Intermolecular exchange of cations, occurring in the presence of a second electrolyte, has also been studied, and shown to occur *via* a mechanism in which the incoming cation associates with the uncomplexed site of the anion (7, 8). For semiquinone ion-pairs, these exchanges have been found to proceed *via* the triple ion M_2Q^+ (9, 10), and the role of the anion of the second electrolyte elucidated (10). When this second anion has an affinity for the cation comparable with that of the semiquinone, then the dissociation of the triple ion may be written as

$$[1] \qquad MQM^+ + X^- \rightarrow MQ + MX$$

The principle of microscopic reversibility then demands that MX (rather than M^+) is the attacking species in the intermolecular cation exchange. A quantitative estimation of the kinetic parameters for such an exchange, in the "slow" limit, has been made for the system sodium 2,5-di-*t*-butyl-*p*-benzosemiquinone – sodium iodide – tetrahydrofuran, in which the rate of intramolecular exchange is negligible (9). Here we present the results of a similar kinetic analysis carried through from the "slow" to the "fast" exchange limits for a system showing simultaneous intra- and intermolecular cation exchange.

Experimental

Experimental techniques for the production of samples and the recording of electron spin resonance spectra were as previously described (11). Potassium tetraphenylboride was precipitated *via* the standard literature method (12), from dilute aqueous solutions of sodium tetraphenylboride and potassium chloride.

Results

Electron spin resonance spectra of the system potassium durosemiquinone – potassium tetraphenylboride – tetrahydrofuran were recorded for several concentrations ratios of semiquinone to tetraphenylboride for sample temperatures between −80 and +40 °C. In the absence of potassium tetraphenylboride, spectra of the ion-

−40	1.92	2.50	1.34	0.230
−20	1.91	2.52†	1.32†	0.250
+20	1.90	2.57†	1.26†	0.300

*ΔH, in G, between center of triple ion and ion-pair spectra.
†Extrapolated values, see text.

pair were obtained: at low temperatures this species was locked into a static asymmetric configuration but, as the temperature was increased, line-width alternation, attributed to the intramolecular exchange of potassium, was observed.

Addition of potassium tetraphenylboride to the ion-pair produced spectra which, at low temperatures, contained resonances due to the ion-pair and the triple ion $[K_2\text{-durosemiquinone}]^+$. Since no potassium hyperfine interaction was resolvable, the spectrum of the triple ion was very similar to that of unassociated durosemiquinone, consisting of 13 lines, with binomial intensity distribution and $a_{Me} = 1.92 \pm 0.05$ G; however, the center of this spectrum occurred to high field of the ion-pair spectrum, not to low field as does that of the free ion. Increasing the sample temperature led to intermolecular exchange of potassium ions between the triple ion and the ion-pair. The spectra selected for detailed evaluation of the kinetic parameters characterizing both intra- and intermolecular exchange reactions are given in Fig. 1.

When the intermolecular exchange of potassium nears its "fast" limit, the spectra of mixtures of the triple ion and ion-pair show three interesting features, which we have found to be generally indicative of the participation of triple ions in the intermolecular cation exchange reactions of ion-pairs. These are: (*i*) lines to low field of the center of the spectrum are broader than their high field counterparts (because g and a_{Me} for the triple ion are slightly less than g and $\bar{a}_{Me}$ for the ion-pair); (*ii*) the line shapes are asymmetric; (*iii*) the apparent hyperfine splitting constant varies by as much as 10% across the spectrum in a systematic large–small–large–small pattern. All three features were reproduced in our simulation of such spectra.

In order to extract the required kinetic parameters from the spectra in Fig. 1, it is necessary to know as a function of temperature the difference in magnetic field between the centers of the triple ion and ion-pair spectra, and the values of both methyl hyperfine splitting constants of the ion-pair. Unfortunately, at the higher sample temperatures the ion pair hyperfine splitting constants are not directly obtainable from the spectra. However, for the corresponding system in which potassium is replaced by sodium these parameters are measurable over the range of interest; wherever similar measurements were possible for both systems, trends in these parameters with temperature were independent of cation. Hence, we have used the results for the sodium system to guide the extrapolation of the potassium data to the higher sample temperatures. Table 1 contains the data on hyperfine splitting constants and g-shifts used in the kinetic analysis of the spectra in Fig. 1.

Discussion

We now propose the equilibria depicted in [2] to be occurring in the system potassium durosemiquinone – potassium tetraphenylboride – tetrahydrofuran, and show how this reaction scheme can account quantitatively for the line shapes in Fig. 1.

it to the ion-pair C (or *vice versa*), define τ_A as the residence time as the ion-pairs A or C before reaction with a potassium ion forms the triple ion, and define τ_B as the residence time as the triple ion B before dissociation to an ion-pair. Note then that $2\tau_B$ is the residence time before dissociation to a particular ion pair. Defining G_A, G_B, and G_C as the complex magnetizations of the sites A, B, and C we may then write the Bloch Equations, under slow passage conditions, and modified after the fashion suggested by McConnell (13) as [4].

$$[4]\quad \begin{aligned} \alpha_A G_A &= p_A - G_A(\tau_A^{-1} + \tau_{IP}^{-1}) + G_B/2\tau_B + G_C/\tau_{IP} \\ \alpha_B G_B &= p_B - G_B/\tau_B + (G_A + G_C)/\tau_A \\ \alpha_C G_C &= p_C - G_C(\tau_A^{-1} + \tau_{IP}^{-1}) + G_B/2\tau_B + G_A/\tau_{IP} \end{aligned}$$

where α_j has the usual significance of $1/T_2 - i(\omega_j - \omega)$, p_j represents the fractional population of site j, and the scaling factor $-i\gamma H_1 M_0$ has for simplicity been omitted from the fractional populations. Solution of [4] for G_A, G_B, and G_C gives the result shown in [5].

$$[5]\quad G_A = \frac{(\alpha_C + \tau_A^{-1} + 2\tau_{IP}^{-1})(p_A(\alpha_B + \tau_B^{-1}) + 0.5p_B\tau_B^{-1})}{(\alpha_A + \tau_A^{-1} + 2\tau_{IP}^{-1})[(\alpha_B + \tau_B^{-1})(\alpha_C + \tau_A^{-1} + \tau_{IP}^{-1}) - 0.5\tau_A^{-1}\tau_B^{-1}] - (\alpha_C + \tau_A^{-1} + 2\tau_{IP}^{-1})(0.5\tau_A^{-1}\tau_B^{-1} + (\alpha_B + \tau_B^{-1})\tau_{IP}^{-1})}$$

$$G_C = \frac{(\alpha_A + \tau_A^{-1} + 2\tau_{IP}^{-1})G_A}{(\alpha_C + \tau_A^{-1} + 2\tau_{IP}^{-1})}$$

$$G_B = \frac{(\beta_B + (G_A + G_C)\tau_A^{-1})}{\alpha_B + \tau_B^{-1}}$$

$$G = G_A + G_B + G_C$$

The values of G_A, G_B, G_C may then be added to form the total complex magnetization, G, the imaginary part of which represents the intensity of resonant absorption at the frequency defined by ω. To compute the simulations in Fig. 1 values of ω_A, ω_B, and ω_C, expressed relative to the center of the ion-pair spectrum, were calculated for the 49 nuclear spin wave functions each of which defines a line in the ion-pair spectrum. At each of the 1000 values of ω used to define the spectrum it is then necessary to sum the 49 contributions to the overall signal intensity. The number of parameters to be determined is rather large and so the following assumptions and approximations were made.

The transverse relaxation time of all three species was assumed the same; the fractional populations were taken as independent of temperature, though experimentally we have noticed small variations ($\sim$ 5%) in fractional populations for some ion-pair triple ion equilibria; τ_{IP} and τ_B were assumed independent of the concentration of potassium tetraphenylboride, consistent with the reaction scheme being as shown in [2].

In Fig. 2 Arrhenius plots are used to express the temperature dependences of τ_{IP}, τ_A, and τ_B. The plots are reasonable straight lines which, coupled with the excellent agreement between experimental and computed spectra, indicate that the simple reaction scheme [2] adequately describes the present system. Thus, as previously argued for the triple ion Na_2D^+ (10), the dissociation of the triple ion K_2D^+ in the system potassium durosemiquinone – potassium tetraphenylboride – tetrahydrofuran is not brought about by attack of the tetraphenylboride anion; likewise, the association reaction forming the triple ion does not proceed *via* attack of KPh_4B ion pairs upon KD, but rather K^+ must be the attacking species.

Since the intramolecular cation migration and the dissociation of the triple ion are both first order processes, the intercepts of the appropriate Arrhenius plots may be used to determine frequency factors. For the migration process $\log_{10} A = 12.1$ while for the dissociation $\log_{10} A = 11.7$; for both reactions the activation energy was identical (6.6 kcal/mol) within experimental accuracy. The two reactions are, therefore, kinetically very similar and it is tempting to speculate, on this basis, on the mechanism of the intramolecular migration; however, we feel that it is preferable to examine further systems to see whether the observed kinetic similarity is merely a coincidence.

The association reaction forming the triple-ion

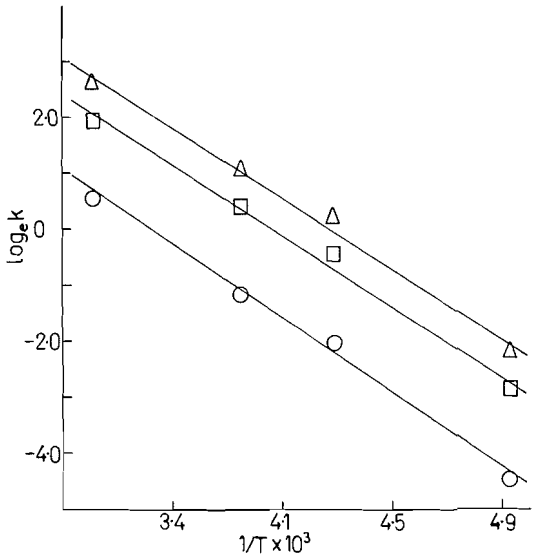

FIG. 2. Arrhenius plots for the system potassium durosemiquinone – potassium tetraphenylboride – tetrahydrofuran; △, intramolecular migration; □, dissociation of triple ion and formation of triple ion at [KPh_4B] *c.* 10^{-3} *m*; ○, formation of triple ion at [KPh_4B] *c.* 2×10^{-4} *m*.

is a second order reaction and so the intercept of the Arrhenius plot is equal to $\log_{10}(A[K^+])$. The concentration of unassociated potassium ions was not determined in the present work, because the dissociation constant of potassium tetraphenylboride in tetrahydrofuran has been measured only at 25 °C (14), and furthermore, there is no guarantee that the species defined by these conductivity measurements as the unassociated potassium ion is in fact the same species as the kinetically significant unassociated potassium ion. However, from a knowledge of the approximate concentration of potassium tetraphenylboride we estimate that $\log_{10} A$ for the association reaction is approximately 14, which is a reasonable value for a positively charged species attacking the negative end of a dipole. The identity of the activation energies for the dissociation and association reaction is, of course, a consequence of our approximation that the fractional populations are independent of temperature.

Thus, using the reaction scheme [2] we are able to account satisfactorily for the observed spectra of the system under discussion and to derive kinetically reasonable parameters characterizing the constituent reactions of the scheme.

Anharmonicity and Hydrogen Bonding. The in-plane OH Bending and its Combination with the OH Stretching Vibration

M. Asselin and C. Sandorfy

Département de Chimie, Université de Montréal, Montréal, Québec

Received December 17, 1970

The infrared spectra of isopropanol, tert-butanol, and their deuterated homologues were measured between 1600 and 1160 cm^{-1} in a mixture of CCl_3F and methylcyclohexane-d_{14} at temperatures ranging from 20 to −182 °C. The assignments of the in-plane OH deformation (δ_{OH}) bands of alcohols are confirmed by these low temperature measurements. An explanation is proposed for the great apparent differences between the δ_{OH} frequencies of primary and secondary alcohols on the one hand, and tertiary alcohols on the other. The effect of temperature on the δ_{OH} frequency of hydrogen bonded alcohols is found to be slight. Hydrogen bonding increases significantly the anharmonic coupling constant between ν_{OH} and δ_{OH}. It remains, however, much smaller than the anharmonicity constant of ν_{OH} itself.

Les spectres infrarouge des l'isopropanol, du tert-butanol et de leurs homologues deutérés ont été mesurés entre 1600 et 1160 cm^{-1} dans un mélange de CCl_3F et méthyl-cyclohexane-d_{14} pour un intervalle de température de 20 à −182 °C. Les attributions des bandes de déformation OH dans le plan (δ_{OH}) des alcools sont confirmées par ces mesures à basses températures. Une explication est proposée pour les grandes différences apparentes entre les fréquences δ_{OH} des alcools primaires et secondaires d'une part et les alcools tertiaires de l'autre. On a trouvé que l'effet de la température sur la fréquence δ_{OH} des alcools liés par liaison hydrogène est faible. La liaison hydrogène augmente de façon significative la constante de couplage anharmonique entre ν_{OH} et δ_{OH}. Elle reste, cependant, beaucoup plus petite que la constante d'anharmonicité de ν_{OH}.

Canadian Journal of Chemistry, **49**, 1539 (1971)

Introduction

The effect of hydrogen bonding on the anharmonicity of the OH stretching vibration (ν_{OH}) of alcohols has been examined previously (1–4) but the anharmonic coupling between ν_{OH} and the in-plane bending vibration (δ_{OH}) of these molecules has not been studied. δ_{OH} is located in a crowded part of the infrared spectrum and is expected to be much less "purely OH" than the stretching vibration. Stuart and Sutherland (5) assigned the free and associated δ_{OH} vibrations to bands observed at about 1250 and 1370 cm^{-1} for primary and secondary alcohols. This was based on isotopic substitution experiments and the great breadth of the 1370 band. Later works by Tarte and Deponthière (6) and Maclou and Henry (7) were basically in agreement with these assignments. It is known that hydrogen bond formation increases the frequency of δ_{OH} (although Ratajczak and Orville-Thomas (8) drew the attention to some exceptions in the case of short hydrogen bonds) but $\Delta\delta$ is much less than $\Delta\nu$.

In the present paper we report results on δ_{OH} and the $\nu_{OH} + \delta_{OH}$ combination band of isopropanol and tertiary butanol. The assignment and anharmonic coupling of these vibrations will be discussed on the basis of low temperature measurements and isotopic substitution.

Outline of the Work

The δ_{OH} bands were measured at 20, −60, −120, and −182 °C in a 1:1 mixture of CCl_3F (freon-11) and methylcyclohexane-d_{14} which is sufficiently translucent between 1600 and 1160 cm^{-1} at thicknesses below 0.1 mm. The location of the free band was ascertained by dilution using a 2.0 mm cell in CS_2 solution at −60 °C. At this temperature most of the OH groups are associated and the free δ_{OH} band disappears. Unfortunately under 2 mm CS_2 is translucent at frequencies lower than 1360 cm^{-1} only.

The $\nu_{OH} + \delta_{OH}$ combination band was measured in a 3 cm cell in a 1:1 mixture of CCl_3F (freon-11) and $C_2Br_2F_4$ (fréon-114-B-2) at 20 and at −193 °C.

Experimental details were given in previous publications (3, 4).

Results

Tertiary Butanol

Figures 1 and 2 show the spectra of C_4H_9OH, C_4D_9OH, C_4D_9OD, and C_4H_9OD at 20 and at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

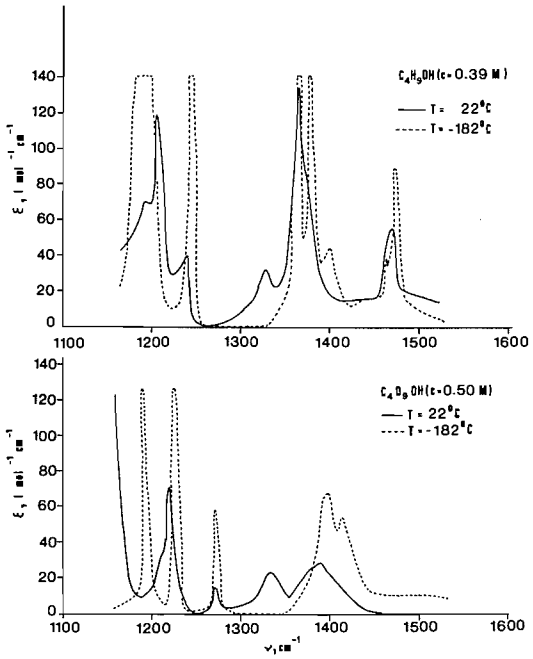

FIG. 1. The infrared spectra (1100–1600 cm^{-1}) of tert-butanol (C_4H_9OH and C_4D_9OH) in a 1:1 mixture of CCl_3F and methylcyclohexane-d_{14} at 22 and −182 °C.

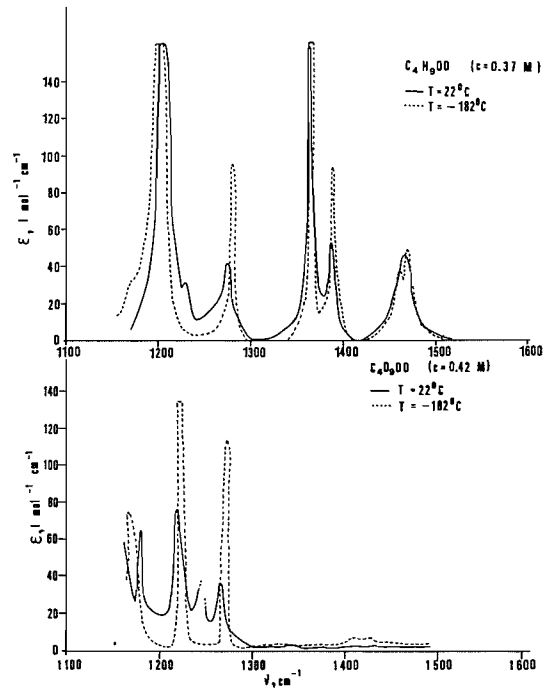

FIG. 2. The infrared spectra (1100–1600 cm^{-1}) of tert-butanol (C_4H_9OD and C_4D_9OD) in a 1:1 mixture of CCl_3F and methylcyclohexane-d_{14} at 22 and −182 °C.

−182 °C. It is seen clearly that the 1328 cm^{-1} band of C_4H_9OH and the 1334 cm^{-1} band of C_4D_9OH disappear in going to low temperature confirming the assignment of this band to the free δ_{OH} vibration. At low temperatures the associated band appears at 1400 cm^{-1} for C_4H_9OH. C_4D_9OH has a doublet at 1415 and 1397 cm^{-1}. The splitting is probably due to Fermi-resonance and since the bands are of nearly equal intensity we used the average, 1406 cm^{-1}, in our calculations.

Unfortunately, solvent problems and near-coincidences with CH bands make it impossible to locate the first overtone of δ_{OH} with any degree of accuracy. We could, however, locate the $\nu_{OH} + \delta_{OH}$ combination tone. Figure 3 shows it for 20 and −193 °C. C_4H_9OH has a sharp band at 4944 cm^{-1} which belongs to the free OH band. It disappears completely at low temperatures. It is replaced by the broad and strong band at 4669 cm^{-1} due to the polymer. C_4D_9OH has these bands at 4949 and 4688 cm^{-1}. They all disappear for C_4D_9OD and C_4H_9OD (Fig. 4). Table 1 contains the frequencies of the fundamentals of ν_{OH} (3, 4), δ_{OH}, and $\nu_{OH} + \delta_{OH}$ for tert-butanol.

Isopropanol

Figures 5 and 6 give the spectra of C_3H_7OH, C_3D_7OH, and $(CH_3)_2CDOH$ at 20 and −182 °C in a 1:1 mixture of CCl_3F and methylcyclohexane-d_{14}. The concentration we had to use to obtain these spectra (0.5 *M*) makes it impossible to identify the bands due to the monomer. We obtained these at 0.1 *M* concentration in CS_2. The associated δ_{OH} band is found at 1397 cm^{-1} for C_3D_7OH and 1400 cm^{-1} for $(CH_3)_2CDOH$

TABLE 1. Wavenumbers of the stretching vibration (ν_{OH}), the in-plane OH bending vibration (δ_{OH}), and of the combination band ($\delta_{OH} + \nu_{OH}$) of free tertiary butanol in solution at 20 °C and of the associated alcohol in solution at −193 °C

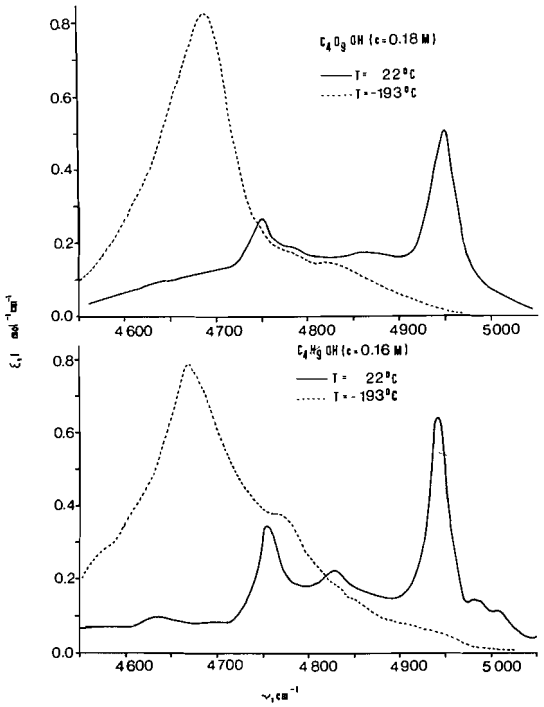

FIG. 3. The infrared spectra (4600–5100 cm^{-1}) of tert-butanol (C_4H_9OH and C_4D_9OH) in a 1:1 mixture of CCl_3F and $C_2Br_2F_4$ at 22 and −193 °C.

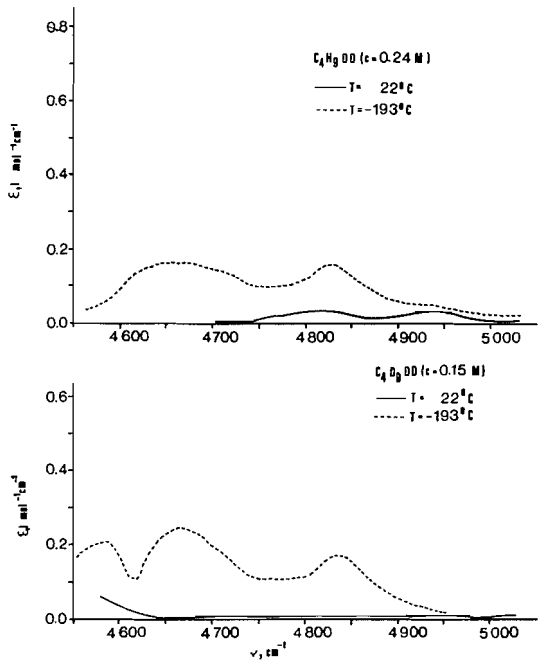

FIG. 4. The infrared spectra (4600–5100 cm^{-1}) of tert-butanol (C_4H_9OD and C_4D_9OD) in a 1:1 mixture of CCl_3F and $C_2Br_2F_4$ at 22 and −193 °C.

while C_3H_7OH has two bands at 1310 and 1415 cm^{-1}. The free bands are at 1328 (C_3D_7OH), 1318 ($(CH_3)_2CDOH$), and 1248 cm^{-1} (C_3H_7OH). According to Krimm, Liang and Sutherland (9), the presence of two bands in the case of associated C_3H_7OH is due to a mixing between δ_{OH} and the CH or CH_2 deformation modes at the same carbon. No explanation was given, however, for the great difference in frequency between the free δ_{OH} of tertiary alcohols (1330 either deuterated or undeuterated), and of primary and secondary alcohols (1256) if the CH hydrogens which are on the same carbon as the OH group are not deuterated.

We observe similar features for the $\nu_{OH} + \delta_{OH}$ combination band of C_3H_7OH. The polymer shows two bands, at 4700 and 4600 cm^{-1}. Both are broad and partly overlap each other (Fig. 7). They are obviously the combinations of ν_{OH} with the bands at 1415 and 1310 cm^{-1}. For the monomer we find a sharp band at 4879 cm^{-1} which is easily assigned to $\nu_{OH} + \delta_{OH} = 3630 + 1248 = 4878\ cm^{-1}$. We find a weaker band at 4995 cm^{-1} which disappears upon association and is absent in the spectra of C_3D_7OH and $(CH_3)_2CDOH$ (Figs. 7, 8). This could be interpreted as a combination between 3630 and a band located at about 1365 which is not observed. It seems logical then to suppose that the strong mixing between OH and CH bending (*cf.* the normal coordinate analysis of Fukushima and Zwolinski (10)) yields two bands for the free species, the one observed at 1248 and one at 1365 assumed coincident with the CH_3 bending bands. This would explain the great difference between the 1250 of the primary and secondary alcohols and the 1330 of tertiary alcohols.

Table 2 summarizes the ν_{OH}, δ_{OH}, and $\nu_{OH} + \delta_{OH}$ frequencies for isopropanol.

Tables 3 and 4 contain the anharmonicity constants for ν_{OH} ($X \equiv \omega_e x_e$ and $Y = \omega_e y_e$; index 1 stands for ν_{OH} and 2 for δ_{OH}) computed from the usual second order formulas. X_{12}* is the anharmonic coupling constant for ν_{OH} and δ_{OH} and the ω are the harmonic frequencies

$$[1] \quad \omega_1 = \nu_1 + 2X_1 + W_1 + (13/4)Y_1 + (1/2)X_{12}^*$$

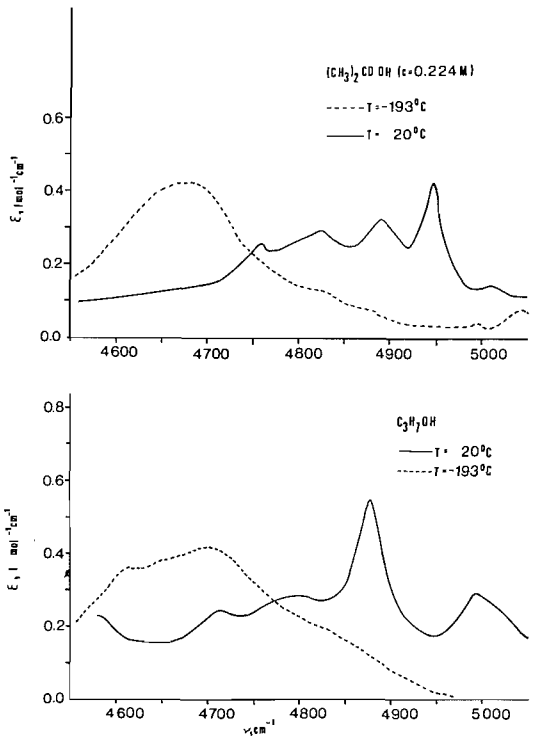

FIG. 7. The infrared spectra (4600–5100 cm^{-1}) of isopropanol (C_3H_7OH and $(CH_3)_2CDOH$) in a 1:1 mixture of CCl_3F and $C_2Br_2F_4$ at 22 and −193 °C.

computed in taking $X_{12}{}^*$ into account (as in eq. 1) and ω_1 without it.

The temperature effect on the associated δ_{OH} band was found to be very slight, between −60 and −182 °C it remains within experimental error. This contrasts with the pronounced temperature shift of ν_{OH} (4). Since vibrations are more sensitive to environmental and temperature effects the more anharmonic they are (11) this indicates a very slight anharmonicity for δ_{OH}. So the shift of δ_{OH} between −182 and −193 °C was neglected in the computation of X_{12} and $\omega_1{}^*$ as well as the very slight differences which might exist between solutions in CS_2, (CCl_3F + methylcyclohexane-d_{14}) and ($CCl_3F + C_2Br_2F_4$). The shift to higher frequencies due to hydrogen bond formation amounts to 72 cm^{-1} for tertiary butanol, 69 cm^{-1} for isopropanol, and 82 cm^{-1} for $(CH_3)_2CDOH$. $\Delta\delta/\Delta\nu$ is of the order of 0.200. As expected $\nu_{OH} + \delta_{OH}$ has a much larger temperature shift, slightly less than ν_{OH} itself.

The coupling constant $X_{12}{}^*$ is only about

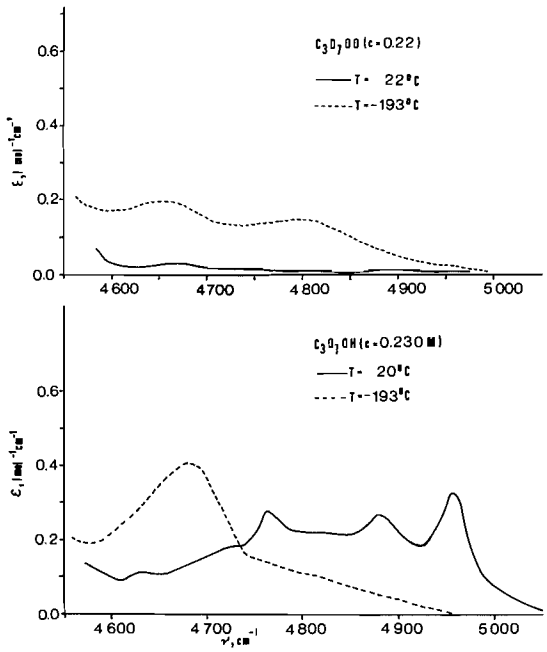

FIG. 8. The infrared spectra (4600–5100 cm^{-1}) of isopropanol (C_3D_7OH and C_3D_7OD) in a 1:1 mixture of CCl_3F and $C_2Br_2F_4$ at 22 and −193 °C.

$-5\ cm^{-1}$ for the monomers. Upon association it increases to 25 ± 5 for tertiary butanol and 52 ± 5 for isopropanol. This means that hydrogen bond formation increases greatly the coupling between OH stretching and in-plane bending vibrations. The value of this coupling constant is relatively low, however, and its effect on the harmonic frequency of ν_{OH} (polymer) is only about 10–20 cm^{-1} compared to about 400 cm^{-1} (Tables 1–4) due to the anharmonicity of the ν_{OH} vibration itself. It can be understood, then, that it can be neglected in computing the isotopic ratios of the frequencies and that the ratios expected in the diatomic approximation can still be obtained (4) as we have shown previously.

Thermodynamic Investigation of the Reaction: $CoSO_{4\,(s)} \rightleftharpoons CoO_{(s)} + SO_{3\,(g,i)}$ by Electromotive Force Measurements

A. W. ESPELUND[1] AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto 5, Ontario

Received November 12, 1970

The thermodynamic properties of the system CoO–$CoSO_4$ have been investigated over the temperature range 560 to 916 °C, by an electrochemical method using a ZrO_2–CaO solid electrolyte and an oxygen reference electrode. The standard free energy change for the reaction

$$CoSO_{4(s)} \rightleftharpoons CoO_{(s)} + SO_{3(1\ atm)}$$

can be expressed by

$$\Delta G^0_R = 69\,213 + 27.631\,T \log T - 137.07\,T$$

and is given with an accuracy of ± 400 cal.

On a étudié les propriétés thermodynamiques du système CoO–$CoSO_4$ entre 560 et 916 °C en utilisant une méthode électrochimique qui fait appel à un électrolyte solide (ZrO_2–CaO) et de l'oxygène comme électrode de référence. Le changement d'énergie libre pour la réaction

$$CoSO_{4(s)} \rightleftharpoons CoO_{(s)} + SO_{3(1\ atm)}$$

peut être exprimé par l'équation

$$\Delta G^0_R = 69\,213 + 27.631\,T \log T - 137.07\,T$$

et est donné avec une précision de ± 400 cal.

Canadian Journal of Chemistry, 49, 1545 (1971)

Introduction

Most previous investigations on simple oxide–sulfate equilibria have been conducted by static methods involving the measurement of the total equilibrium pressure of the gases SO_2, SO_3, and O_2, resulting from thermal decomposition. The partial pressure of SO_3, defining the thermodynamic properties of the reaction

$$[1] \qquad MSO_{4(s)} \rightleftharpoons MO_{(s)} + SO_{3(gas)}$$

(M is a divalent metal cation) was then calculated from the known values of the equilibrium constant of the decomposition reaction

$$SO_{3(g)} \rightleftharpoons SO_{2(g)} + \tfrac{1}{2}\,O_{2(g)}$$

For the calculation the basic assumption was made that at the reaction zone temperature, $P_{SO_2} = 2P_{O_2}$.

The accuracy of the method is usually restricted by the rather low sensitivity of the all glass Bourdon type gauges, which have been employed because of the corrosive nature of the SO_3 gas, and in addition, the validity of the assumption regarding the ratio for the partial pressures given above has not been fully established; the equilibrium between O_2, SO_2, and SO_3 is highly temperature dependent and the actual partial pressures at the sample site could be influenced by the existence of a temperature gradient along the pressure cell. Ingraham and Kellogg (1) demonstrated in one case by circulating the gas with an all glass pump, that such mixing had no influence on the measured total pressure. Warner (2) improved the method by introducing an "oxygen couple" in a position adjacent to the reacting mixture, or as a part of the sample, thus fixing the oxygen pressure. In this way data for the CoO–O–SO_2 system were obtained, using the mixtures of Cu_2O–CuO and CoO–Co_3O_4 as oxygen couples.

In the present investigation, the application of a ZrO_2–CaO type solid electrolyte and an oxygen electrode allows direct determination of the oxygen partial pressures of the reacting mixture at various temperatures. Unambiguous values for the composition of the gas phase at the sample site are obtained by simultaneous measurements of the total gas pressure. The cell design is schematically represented by

$$CoO_{(s)}\text{–}CoSO_{4(s)},\ SO_{2(g)}\ Pt/ZrO_2\text{–}CaO/Pt,\ O_{2(1\ atm)}$$

In this cell the *total* pressure is fixed by using a

For personal use only.

flow of SO_2 gas. The method is similar to that employed recently by Larson and Elliott for the investigation of oxide–sulfide equilibria (3).

In this paper, the results of e.m.f. measurements on the system CoO–$CoSO_4$ are presented and a comparison is made with other available thermodynamic data.

Experimental

The essential features of the cell are shown in Fig. 1. The sample was held in a crucible of silica glass, supported by the SO_2 admission tube. Electrical contact on the sample side of the ZrO_2–CaO electrolyte was provided through a platinum grid, upon which the ZrO_2 + CaO ($\frac{1}{2}$ in. o.d.) tube was resting. Additional material was filled around the tube.

Pure oxygen at atmospheric pressure was utilized in the reference electrode. The gas was admitted through a spring loaded silica tube, that provided good contact between the platinum foil inner electrode and the inner surface of the electrolyte tube.

The platinum leads from each electrode were introduced through the two gas admission tubes. In addition, Pt + 13% Rh leads were welded to the electrodes for temperature measurement. The cell was placed in a vertical position in a conventional tube furnace provided with a grounded Inconel tube for electrical shielding. The temperature of the furnace was controlled with a proportional type controlling unit.

CoO was prepared from the hydrated salt, $CoSO_4 \cdot 7H_2O$ Fisher certified reagent, with a total of 0.12% impurities, by the method used by Ingraham (4): *i.e.* drying to $CoSO_4$ at 400 °C, formation of Co_3O_4 at 850 °C, and conversion of Co_3O_4 to CoO in vacuum at 850 °C. The compositions were verified by X-ray analysis including comparison with the standard ASTM-file.

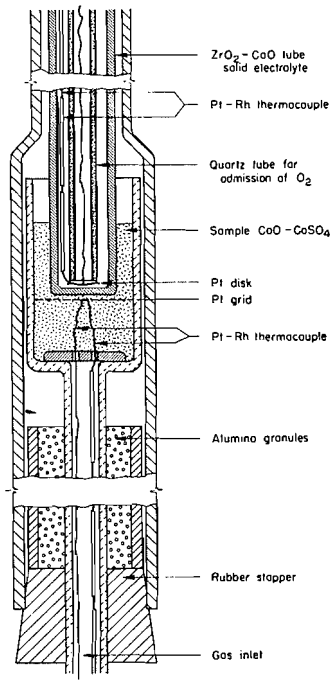

FIG. 1. Apparatus for e.m.f. measurements.

The sulfur dioxide gas was Matheson Anhydrous Grade, with a minimum of 99.98% SO_2. The flow rate was normally varied between 0 and 10 cc/min, and was measured with a calibrated rotameter.

The e.m.f. across the cell was measured with a high impedance p*H*-meter having a scale expander attachment, which could be read to the nearest millivolt.

Results

Electromotive force measurements were taken in the temperature range from 560 to 916 °C. Extension to lower temperatures was not possible because of the erratic behavior of the p*H*-meter, due to the increasing total resistance of the cell.

In the flow rate range of 3 to 10 cc/min of SO_2, the e.m.f. remained independent of flow rate to within ± 1.5 mV. The measurements at the lower flow rate were used for the calculations. The overall calculations involved the following sequence:

(*1*) From the barometric pressure and the measured e.m.f., the partial pressure of oxygen at the reaction site was determined using the equation

$$E_{cell} = \frac{-RT}{4F} \ln \frac{P_{O_2'}}{P_{O_2''}}$$

where $P_{O_2'}$ and $P_{O_2''}$ are the oxygen partial pressures in the reference electrode and at the reaction site, respectively.

(*2*) A preliminary value for p_{SO_2} was obtained, by subtracting the measured oxygen pressure from the total pressure.

(*3*) A preliminary value for p_{SO_2} was determined from the equation for the SO_2/SO_3 equilibrium recommended by Kellogg (5), based upon Evans and Wagman's study of the SO_2–SO_3 system (6).

(*4*) The value obtained was incorporated in the sum of partial pressures, giving a new final value for p_{SO_2}.

(*5*) A second final value for p_{SO_3} was calculated.

At the lowest oxygen pressures, *i.e.* below about 800 °C the first value for p_{SO_3} was sufficiently accurate (less than 20 cal difference between ΔG^0_R resulting from steps (*3*) and (*5*)) and could be calculated from step (*3*) only. Electromotive force measurements and calculated partial pressures in this system are given in Table 1.

The data were fitted into a Σ-plot, using a C_p

value of −12 cal/deg mol, as recommended by Warner (2). The corresponding sigma function is

$$\Sigma = -R \ln p_{SO_3} - 12 \ln T$$

and the plot of Σ vs. $1/T$ is shown in Fig. 2. There is no marked deviation from the straight line given by the equation

$$\Sigma = -137.07 + \frac{69\,213}{T}$$

Accordingly, for the reaction

$$CoSO_{4(s)} = CoO_{(s)} + SO_{3(g,\ 1\ atm)}$$

$$\Delta H^0_R = 69\,213 - 12\,T$$

$$\Delta G^0_R = 69\,213 + 27.631\,T \log T - 137.07\,T$$

$$\Delta S^0_R = 125.07 - 27.63 \log T$$

in the temperature range 833 to 1189 °K. Figure 3 represents the plot of ΔG^0_R *vs.* temperature.

The accuracy in the reported free energy data is subject to the following possible uncertainties. The maximum error due to a fluctuation of ±1 °C in the temperature measurements contributes an error of ±50 cal. The uncertainty of ±1.5 mV in the e.m.f. readings represents an added uncertainty of ±100 cal, and for the SO_2–SO_3 equi-

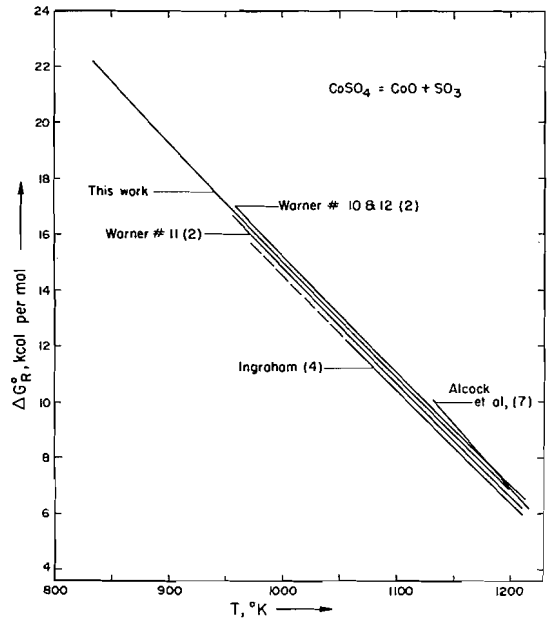

FIG. 3. Plot of ΔG^0_R against T, and comparison of data.

librium Kellogg's equation is given with an accuracy of ± 200 cal. Therefore, the overall accuracy for the free energies calculated from the present results should be better than ± 400 cal/mol.

Discussion

The results shown in Fig. 2 refer to experiments with a sample consisting of the two phases CoO and $CoSO_4$, the latter formed in the apparatus. The source of SO_2 gas was the same for all runs. In order to determine the oxygen potential of the gas in the cylinder, a non-reacting sample of only CoO was used deliberately in the e.m.f. cell at a temperature of 900 °C. The measurements gave an oxygen pressure of $10^{-5.5}$ atm, in good agreement with the gas analysis quoted earlier. This value corresponds to a temperature of about 775 °C at which the CoO–$CoSO_4$ mixture has the same equilibrium oxygen pressure as above. The lack of any abnormal behavior during measurements at temperature below this point of balance indicates that both the sulfation and the decomposition reactions do not have a noticeable kinetic restriction within the range of flow rates and temperatures applied.

In Fig. 3, a comparison is made with the results by Ingraham (4), Warner (2), and Alcock, Sudo, and Zador (7). Ingraham, using direct pressure measurements, obtained as products of decomposition, CoO above 782 °C and Co_3O_4 below this temperature. The values for the $CoSO_4$–CoO equilibrium in the temperature range 700–782 °C (dotted line) were obtained by additional measurements on the Co_3O_4–CoO system.

Warner (2) in his final treatment has averaged his own measurements taken together with those by Ingraham (4), using the Σ-function calculation. However, the application by the former of the oxygen couple with a known oxygen pressure, in addition to a measurement of the total pressure, seems to justify a separate treatment of the data.

The Σ-function equations for experiments #11, and a composite for #10, and #12, reported by Warner (2), are available and have been converted to the ΔG^0_R–T curves shown in Fig. 3. The present results are in excellent agreement with the average of Warner's results, and in addition they extend to a much wider temperature range.

Warner (2) and Ingraham (4) mention the presence of an α–β transition for $CoSO_4$ at 615 ± 5 °C. However, the Σ-plot in Fig. 2 does not show a change in slope below this temperature. This can be explained by the rather low value of ΔH^0_t (600 cal) associated with the phase change according to Ingraham (4), and by the uncertainty of about 400 cal in the present results.

The temperature dependence of the results by Alcock *et al.* (7), obtained over a short temperature range, differs from all others, as shown in Fig. 3. The difference is in the entropy of the reaction and cannot be explained by the use of another equation for the treatment of the SO_2–SO_3 equilibria. The method used by the former was a combination of thermal and gravimetric thermal analysis carried out in a flowing mixture of SO_2, O_2, and N_2 gases and could be limited by nonequilibrium conditions in the gas phase or, during the gas solid reaction. Lack of sensitivity of the equipment registering the onset of reaction in the solid sample could also account for the discrepancy. It is, therefore, proper to question if the present results suffer from the same handicaps. As indicated, in the present method the e.m.f. measurements were practically independent of flow rate of the SO_2 gas, and therefore should represent equilibrium conditions. Furthermore the results were totally reproducible on increasing and decreasing the temperature.

The formation of Co_3O_4 can also be excluded during these measurements, as the oxygen pressures which are required for the oxidation of CoO, in the temperature range 800 to 1100 °K, are of the order of 10^{-8} and 10^{-2} atm, respectively. From the results in Table 1, it may be seen that the partial pressures of oxygen which were present in the reaction site were much lower and oxidation of CoO should not be expected to have taken place.

The authors acknowledge the valuable assistance of Mr. R. Chappell for the construction of the quartz cells used for these experiments.

The financial assistance (A.W.E.) by the Norwegian Science Council is also gratefully acknowledged.

Drop Calorimetric Measurements on some Chlorides, Sulfides, and Binary Melts

W. T. THOMPSON[1] AND S. N. FLENGAS
Department of Metallurgy and Materials Science, University of Toronto, Toronto 181, Ontario

Received September 9, 1970

Enthalpy content measurements on pure KCl, AgCl, CuCl, $PbCl_2$, Ag_2S, and PbS were made at temperatures up to 1000 °C using a sapphire calibrated drop calorimeter. Similar measurements were performed on AgCl–Ag_2S and AgCl–KCl melts. These results determined values for the integral enthalpy of liquid–liquid mixing.

Des mesures d'enthalpie furent faites sur des échantillons purs de KCl, AgCl, CuCl, $PbCl_2$, Ag_2S et PbS à des températures allant jusqu'à 1000 °C utilisant un calorimètre à chute. Des mesures similaires ont été effectuées sur des mélanges fondus de AgCl–Ag_2S et AgCl–KCl. Ces résultats ont permis de déterminer des valeurs pour l'enthalpie intégrale de mélange liquide–liquide.

Canadian Journal of Chemistry, 49, 1550 (1971)

Introduction

The physical chemistry of base metal sulfide – molten chloride solutions, and their use as potential electrolytes in the recovery of metal and elemental sulfur from sulfide minerals, has been under continuous investigation in this laboratory for the past few years. Included in this program are conductivity (1–3), density (3–5), phase diagram (3–6), and electromotive force (e.m.f.) studies (7, 8). Correlation of the complementary e.m.f. and phase diagram investigations requires accurate thermal data for the pure chlorides and sulfides, but it appears that some of the information is lacking or in possible error. The present investigation therefore was undertaken in order to determine or to re-evaluate the enthalpy contents and associated thermodynamic properties of the sulfides and chlorides involved in the previous work of this laboratory. For this purpose, an aluminum block drop calorimeter was designed and constructed commensurate with the accuracy required. After calibration with N.B.S. synthetic sapphire, measurements were made on pure KCl, AgCl, CuCl, $PbCl_2$, Ag_2S, and PbS for temperatures up to about 1000 °C. Approximate measurements of the enthalpy of mixing were also made for the AgCl–Ag_2S melts by determining the enthalpy contents as a function of temperature and composition. This procedure was checked by performing similar measurements and calculations on the AgCl–KCl system for which independent measurements are available.

[1]Present address: Department of Metallurgical Engineering, McGill University, Montreal 110, Quebec, Canada.

Experimental

Calorimeter Design

The essential features of the drop calorimeter constructed for this investigation are shown in Fig. 1. This instrument consists of three main assemblies: a furnace to heat samples to the desired temperature, the calorimeter proper consisting of an aluminum billet, and a mechanism to prevent the transfer of heat by radiation from the furnace to the calorimeter proper.

The heating furnace was made from a Kanthal element wound on a 1 in. diameter Inconel tube. This was insulated with Fiberfrax placed within a copper jacket. The jacket was water cooled to maintain the furnace exterior near room temperature. The furnace assembly was mounted on wheels and located on a track so that it could be rolled away from the calorimeter proper after performing an experiment or during the temperature equilibration of a sample. The drop samples consisted of weighed quantities of the desired compounds sealed within weighed evacuated quartz capsules equipped with quartz hooks. The samples were about 14 mm in diameter and about 6 cm in length. These were suspended within the furnace on 0.005 in. diameter platinum filament strung across thick platinum electrodes. This suspension method made it possible to release the sample by electrically fusing the filament. The small amount of platinum that fell with the sample as a bead attached to the glass hook contributed negligibly to the total heat content. The sample and the suspension assembly are shown in detail A of Fig. 1. The temperature gradient along the length of the sample was reduced to about 1 °C at the average operating temperature of 500 °C by adjusting the furnace insulation. The temperature of the sample was precisely regulated with a proportional electronic controller. The temperature of the sample was measured using a Pt/Pt–13%Rh thermocouple located adjacent to it. The couple was calibrated against the melting points of gold, sodium chloride, tin, and the boiling point of water. Considering the temperature gradient along the sample, the precision of the temperature controller, and the reliability of the calibrated thermocouple, the reported temperatures are within 1 to 1½ °C of the true sample temperatures at the average furnace operating temperature of 500 °C.

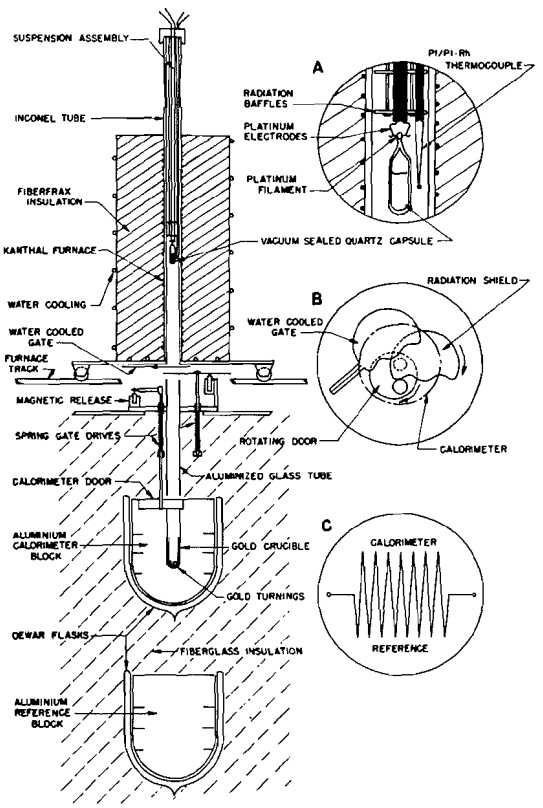

FIG. 1. The drop calorimeter.

The calorimeter proper consisted of a 45 lb aluminum billet suspended within a large Dewar flask. A gold crucible having a $\frac{1}{8}$ in. wall thickness was located at the bottom of a 1 in. diameter hole bored into the billet. This was forced into place so that it made complete thermal contact with the billet. The function of the gold crucible was to prevent the aluminum from oxidizing when the heat from the hot sample was transferred to the calorimeter. Gold turnings placed in the bottom of the crucible absorbed the shock of a falling sample. The calorimeter was equipped with a 1 in. thick disc-shaped aluminum door. This appears in a top view in detail B of Fig. 1. The function of the door was to reduce the loss of heat to the surroundings when a sample was resting within the calorimeter. The door was opened and closed by rotation; it rolled on three small ball bearing wheels located on the bottom face of the disc-shaped door. In the fully closed position, these wheels dropped into small depressions machined into the calorimeter block so that the door made thermal contact with the billet. Before an experiment, the door was rotated manually into the fully open position; however, after releasing a sample from the furnace, it was automatically closed by a relay actuated spring drive mechanism.

The temperature rise of the calorimeter proper, after the admission of a sample, was measured relative to a second block of similar size using a thermopile containing 36 copper–constantan junctions constructed from 0.003 in. diameter insulated thermocouple wire. The thermopile is represented in detail C of Fig. 1. The couples were arranged in three banks of twelve; each couple in each bank was 30° removed from its neighbors, and the banks were displaced 10° from each other. In this way, no matter which way the sample rested in the calorimeter, the signal from the thermopile was the same. The junctions of the thermopile were inserted into snug fitting holes drilled 1 in. into the billet. This depth of penetration assured that at no time during the delivery of heat to the aluminum billet would the thermoelectric signal from the pile rise above the final value when the heat was uniformly distributed in the billet. The shorting of couples through contact with the aluminum was prevented by coating the exposed metal at each junction with lacquer. The output from the thermopile was fed to a Sargent SRG recorder. The chart scale could be adjusted from 0.4 to 2.0 mV for full scale deflection.

Both the calorimeter block and the reference block were insulated from the room with 18 in. of fiberglass wool; a similar quantity of insulation thermally separated the two blocks. Therefore, small changes in the temperature of the room in which the instrument was located resulted in long term monotonic changes in the temperatures of the calorimeter and reference blocks. Heat transfer from the calorimeter to the reference block was negligible during the period following an experiment. This was chiefly a result of the large thermal mass of the calorimeter which resulted in temperature increases of only 0.3 °C during an experiment. Small quantities of heat eventually reached the aluminum reference block. This, however, did not constitute a source of systematic error since heat transfer in this manner is the same for both samples of unknown heat content and known heat content (sapphire) with which the instrument was calibrated.

In order to reduce the transfer of heat from the furnace to the calorimeter and/or make this reproducible from run to run, a radiation shield, shown in detail B of Fig. 1, was incorporated into the design. During temperature equilibration, a water cooled gate closed the bottom of the furnace. This was opened manually just before an experiment when the furnace was over the calorimeter. At this time, the radiation shield prevented short term transfer of heat from the furnace to the calorimeter. When the sample was dropped, an automatic magnetic release allowed this shield to rotate at such a rate that the section removed from the periphery opened the furnace to the calorimeter for a sufficient time interval to allow the sample to pass freely through. As the rotation continued, the shield again passed into a closed position. In coming to rest against a mechanical stop, a microswitch was actuated which released the calorimeter door, thereby enclosing the hot sample within the instrument. The water cooled gate on the furnace was then closed manually and the entire furnace assembly was rolled away from its position over the calorimeter.

Operation

The measurements of the enthalpy contents required compensating for the thermoelectric voltage due to billet temperature differences resulting from previous experiments. In this way, the sensitivity of the recorder could

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

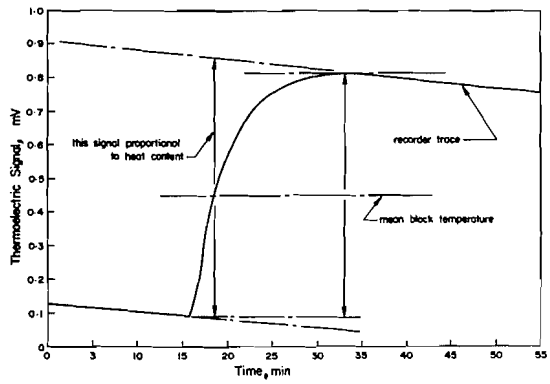

FIG. 2. Typical thermoelectric signal from drop calorimeter.

be used to full advantage. After recording the thermopile output for about 20 min to establish a baseline, the temperature of the calorimeter was measured by withdrawing a mercury thermometer that had been lowered into it 2 or 3 h prior to the experiment. The furnace temperature was then measured and the sample was dropped into the calorimeter. The recorder continued to run for about three quarters of an hour by which time a complete trace of the type shown in Fig. 2 was established. For such behavior, the heat increase of the calorimeter is proportional to the increase in the thermopile output at a point corresponding to half the determined total increase (9). In order to eliminate small errors due to chart paper shrinkage and changes in the electrical characteristics of the recorder, the paper was calibrated at regular intervals using a Leeds and Northrup K-3 potentiometer. The measured thermoelectric signals were all referred to a standard temperature of 25 °C using a simple linear correction (10). This correction gives the signal that would have been measured if the temperature of the sample and calorimeter after an experiment were exactly 25 °C. This correction is quite small since actual final temperatures were generally within 1 or 2 °C of 25 °C.

Calibration

The relationship between the thermopile output and the heat increase of the calorimeter block was determined using U.S. Bureau of Standards synthetic sapphire (11). Since silica glass was used as a container material for the sapphire and compounds studied, a large number of initial experiments were performed to determine the recorded output per gram of silica for temperatures up to 1200 °C. The slugs of silica used in those experiments were similar in surface area to capsules used subsequently to contain compounds. Heat loss by radiation should therefore be similar for slugs and capsules, and hence not lead to a source of systematic error. These results with silica slugs are given in Fig. 3. A smooth curve through these data was determined by the method of least squares. The equation is

$$[1]\quad V_1 = 4.5038\,T^{-1} - 4.3816 \times 10^{-2} + 9.6981 \times 10^{-5}\,T + 1.8370 \times 10^{-9}\,T^2$$

where V_1 is the signal in mV/g SiO_2, and T is the temperature in °K. The standard deviation for this fit is 3.0×10^{-4} mV/g.

A second series of experiments was performed with platinum cuttings sealed in silica capsules. The results are also given in Fig. 3. The equation of the curve is

$$[2]\quad V_2 = -3.037 \times 10^{-3} + 9.629 \times 10^{-6}\,T + 1.751 \times 10^{-9}\,T^2$$

where V_2 is the signal in mV/g Pt. The standard deviation is 5.8×10^{-5} mV/g.

A third series of experiments was performed with the standard sapphire sample sealed in the silica capsule. To prevent possible reaction between the sapphire and silica at high temperature, a platinum foil liner separated the sapphire from the walls of the capsule. The signal corresponding to the enthalpy content of the platinum lined container, obtained by calculating values from eq. 1 and 2, was subtracted from the results of these experiments. The resultant signal corresponded to the enthalpy content of the sapphire.

The enthalpy content of sapphire is known to be the following function of temperature relative to 0 °K (11)

$$[3]\quad H_T - H_0 = 148.5704\,T - 1.7106 \times 10^{-3}\,T^{-2} - 46\,994.87 \log T + 82\,146.1$$

where the enthalpy difference is in absolute J/g-mol. Using this equation, the calorimetric constant was determined. The mean of twelve such determinations from 201 to 1074 °C is 2885 cal/mV with a standard deviation of 34.6 cal/mV. There was no detectable temperature dependence of this factor.

Using this constant, the enthalpy content of silica at 1000 °K relative to 298 °K was calculated from eq. 1 to be 10 320 cal/mol. This compares with 10 280 cal/mol at 1000 °K given by Kelley (12) which is considered accurate to 3% (9). Based on this comparison and the reproducibility of results, it is estimated that the present instrument is capable of measuring enthalpy contents with an absolute accuracy of at least 2%.

Enthalpy Measurements on Pure Compounds

The calorimetric measurements reported on the following materials apply to the condensed state in equilibrium with its vapor. Consequently, the enthalpy change involves an enthalpy effect due to condensing vapor within the silica capsule as the sample cools in the calorimeter, and an enthalpy effect due to changing pressure on the condensed phase as well as that due to the heat capacity of the condensed material. As a result of the small vapor pressure of the compounds studied, and the small volume occupied by the vapor in the capsule, the former effects may be neglected as they contribute collectively no more than about 10 cal/mol of sample to the total enthalpy change. Therefore, to a good approximation and well within the error limits of the present measurements, the enthalpy change may be ascribed entirely to the heat capacity so that

$$[4] \qquad H_T - H_{298} = n \int_{298}^{T} C_p \, dT$$

where H is enthalpy, n is the number of moles of compound, T is temperature, and C_P is the heat capacity at constant pressure.

Of the materials used AgCl, $PbCl_2$, and KCl were vacuum-oven dried Fisher reagent grade materials. CuCl was prepared by SO_2 reduction of $CuCl_2$ as previously described (3). Ag_2S was prepared by precipitation from aqueous $AgNO_3$ solution using $(NH_4)_2S$ solution. The material was washed with distilled water and vacuum dried. To assure crystallinity, Ag_2S was prefused in an evacuated cell before sealing it into a drop capsule. PbS was prepared by reacting stoichiometric quantities of pure lead (five nines) with doubly distilled sulfur in sealed evacuated silica capsules. Heating to 1000 °C resulted in complete reaction; however, to assure crystallinity, the material was prefused in an evacuated double walled silica container. Such a container was necessary because the freezing of the PbS tended to crack the primary container wall.

The experimental measurements for the pure compounds are given in Table 1; for each state of each compound the enthalpy content was expressed as a function of temperature using the least squares method. These data are given in Table 2. Errors quoted represent one standard deviation. The enthalpies of transformation are given in Table 3. The standard deviations were calculated by taking the square root of the sum of the squares of the standard deviations for the enthalpy contents of the high and low temperature phases. The heat capacities of the compounds are given by

$$[5] \qquad C_p = a_1 + 2a_2T$$

where the constants a_i are as in Table 2.

Potassium Chloride

The enthalpy of fusion of potassium chloride has been relatively well established by several investigators using modern instruments calibrated with the sapphire standard. The purpose in studying KCl in this investigation was to provide a further check on the accuracy of the present instrument.

Dworkin and Bredig (13) have determined the enthalpy of fusion of all the alkali halides; for KCl, they give a value of 6340 cal/mol with an estimated accuracy of 1–2%. Douglas of the National Bureau of Standards (14) gives the value of 6270 cal/mol. Earlier literature reports values as high as 6410 and as low as 6100 cal/mol (15, 16). It is evident, therefore, that the enthalpy of fusion is about 6300 ± 100 cal/mol. The results of the present work are shown in Fig. 4. A value of 6250 cal/mol is indicated. This rather good agreement with previous measurements was taken to indicate that the present instrument was free of any gross systematic errors.

The procedure used by Dworkin and Bredig (13) did not give a complete enthalpy content curve, so a detailed comparison of results could not be made. Kelley (12), in his critical review of the older literature, has expressed the enthalpy content of solid KCl as a function of temperature. His evaluation of the thermal data appears in recent tabulations by Blander (17) and Kubaschewski *et al.* (9). At the melting point, the enthalpy content relative to 298 °K and the heat

capacity are given as 10 150 cal/mol and 15.4 cal/°K mol, respectively. The values in the present study are 10 320 cal/mol and 15.5 cal/°K mol. The value for the heat capacity of liquid KCl was estimated by Kelley to be 16.0 cal/°K mol. This value has appeared in recent tabulations in spite of a more up-to-date measurement of 17.6 cal/°K mol (18). The average heat capacity of liquid over the 250 °C range of the present study was 18.4 cal/°K mol. Considering the temperature range and the small random errors in enthalpy contents evident in Fig. 4, this value is probably more reliable than the former values.

Silver Chloride

The enthalpy content of silver chloride was determined by Goodwin and Kalmus (19) and Kobayashi (20). Both investigations were charac-

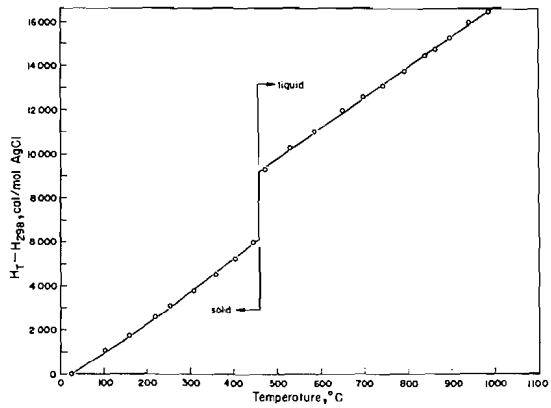

FIG. 5. Enthalpy content of silver chloride.

terized by a limited study of the liquid and were performed before the sapphire standard was available. A value of 3080 cal/mol for the enthalpy of fusion is indicated (12, 21). By way of comparison, a recent estimate of the enthalpy of fusion by Blanc and Petit (22), based on cryoscopic studies with KCl and RbCl, is 2900 cal/mol. Figure 5 shows the results of the present investigation. A value for the enthalpy of fusion of 3160 cal/mol is indicated. There is also good agreement of the present work with previous enthalpy content and heat capacity data on solid AgCl. From Kelley's equation (12), the enthalpy content and heat capacity at the melting point are 6080 cal/mol and 15.1 cal/°K mol, respectively, as compared with 6010 cal/mol and 15.6 cal/°K mol in the present study.

Kelley's reported heat capacity of liquid AgCl of 16.0 cal/°K mol has been generally accepted (9, 17). More recently, a critical appraisal by Lumsden (21) has suggested the value 14.7 cal/°K mol. This, however, is based exclusively on the calorimetric work of Goodwin and Kalmus (19) which shows considerable scatter. The value determined in this investigation of 13.7 cal/°K mol is significantly lower than any value previously reported. In spite of this, the present value is probably more reliable because of the large temperature range studied and the use of sapphire to calibrate the calorimeter. In addition, very recent work independently conducted in this laboratory (23) supports this low heat capacity. From precise e.m.f. measurements of the cell

$$-\text{Ag/AgCl (liquid)/Cl}_2, \text{C}+$$

the free energy of formation of liquid AgCl was determined. The curvature of the ΔG^0 *vs.* T plot requires that the heat capacity of liquid AgCl be about 13.8 cal/°K mol, if the heat capacity of the elements are to be considered correct (12).

Lead Chloride

There is considerable disagreement in the literature concerning the enthalpy of fusion and associated thermal properties of lead chloride. Suggested values for the enthalpy of fusion vary from 3000 to 5800 cal/mol. Using the freezing point depression of $PbCl_2$ with AgCl additions (24) and the e.m.f. data of Salstrom (25) for this system to demonstrate Temkin ideality, Lumsden (21) calculates the enthalpy of fusion of $PbCl_2$ to be 4400 cal/mol. Recent cryoscopic studies of Blanc and Petit (22) using LiCl and NaCl as solutes give an enthalpy of fusion of 5800 cal/mol. Similar work by Bell and Flengas (4), using NaCl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

as a solute, gives a value of 5400 cal/mol. Since Lumsden's calculation involved an old phase diagram, the more recent cryoscopic estimates of the enthalpy of fusion are probably more reliable, although these may be somewhat high as a result of solubility of the solutes in solid $PbCl_2$. Based upon the calorimetric work of Goodwin and Kalmus (19) mainly, and neglecting the study of Krestovnikov and Karetnikov (26) which gives a very low value, Kelley (12) suggested 5800 cal/mol for the enthalpy of fusion. Lumsden (21) in considering the same data reports 5000 cal/mol. With all of the foregoing in mind, the most probable value for the enthalpy of fusion lies between 5000 and 5800 cal/mol. The enthalpy content measurements in the present investigation appear in Fig. 6. These lead to a value of 5560 cal/mol.

Modestova (27) has reported a transformation of lead chloride at 422 °C. This has not been observed by other workers, but may exist and might account for the arrangement of enthalpy content points shown in Fig. 6 just below the melting point. These points show a small systematic deviation with respect to the straight line drawn through them. Since phase diagrams do not show an abrupt change in curvature of the $PbCl_2$ liquidus at 422 °C, the enthalpy of transformation, if the transformation exists, must be quite small. Thus, to evaluate the enthalpy content of solid $PbCl_2$ at the melting point for purposes of determining the enthalpy of fusion, no large error results by drawing a straight line through all the points. The value of the enthalpy content of solid $PbCl_2$, so determined, is 9070 cal/mol at 499 °C. This compares rather poorly with older measurements assessed by Kelley to be 9570 cal/mol.

It is very difficult to make a worthwhile comparison of heat capacities because of the large scatter in the older data. The study of Goodwin and Kalmus (19), however, does substantiate the conclusion of the present study to the extent that the heat capacity of the liquid is considerably greater than that of the solid near the melting point. This feature is most evident in Fig. 6.

Copper(I) Chloride

As with lead chloride there is considerable disagreement in the literature concerning the enthalpy of fusion of CuCl. The appraisals of Kelley (12) and Lumsden (21) refer to Krestovnikov and Karetnikov (26) and give a value of 2620 cal/mol at 430 °C. Considering that the melting point was in error, a more recent value being 423 °C (3), and that the enthalpy of transformation (28) at 407 °C was not detected, this value for the enthalpy of fusion is probably incorrect. The results of the present study are shown in Fig. 7 and indicate two first order transformations at 407 and 423 °C having enthalpy changes 1450 and 1750 cal/mol, respectively. Independent cryoscopic studies (3) using NaCl, KCl, and $BaCl_2$ as solutes, suggest a value of 1800 cal/mol for the enthalpy of fusion, and from the change in slope of the CuCl liquidus at 407 °C, a value of 1500 cal/mol for the enthalpy of the solid state transformation. The higher reported values (3) for the enthalpy of fusion are apparently due to lack of awareness of the 407 °C transformation, causing the apparent enthalpy of fusion to be approximately the sum of the first order enthalpy changes shown in Fig. 7.

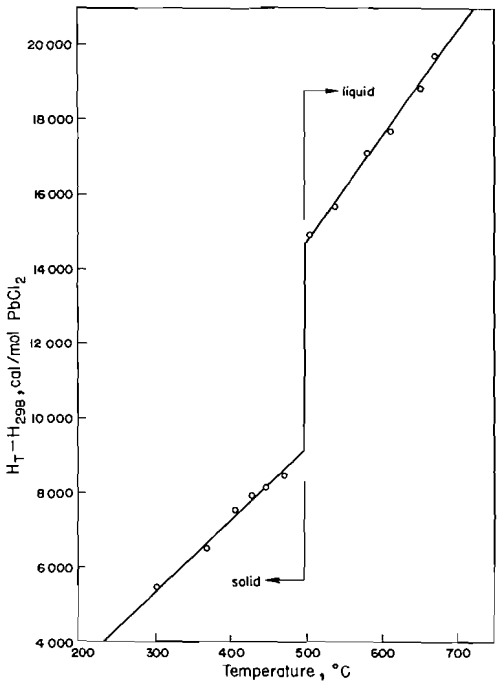

FIG. 6. Enthalpy content of lead chloride.

The determination of the enthalpy content of solid CuCl at the melting point is complicated by the presence of an apparent second order transformation in the low temperature modification of CuCl just prior to the 407 °C transformation. The interesting feature of this phenomenon is its

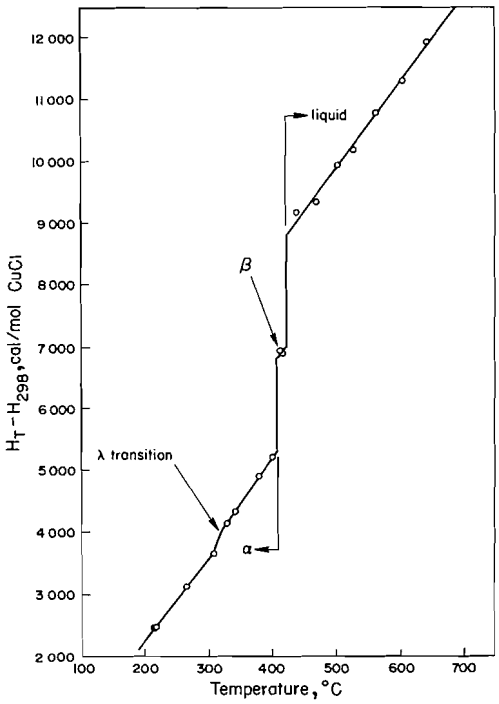

FIG. 7. Enthalpy content of copper(I) chloride.

relation to electrical conductivity measurements on solid CuCl (29). These measurements indicate that cuprous chloride changes from an electronic conductor to an ionic conductor in this temperature range with the transport number of cuprous ion approaching unity at 365 °C. This suggests that at temperatures below the second order transformation, cuprous ions are constrained to a limited number of lattice sites. However, as the temperature rises the lattice expands and cuprous ions are free to occupy all of the tetrahedral positions in the alpha phase (zinc blende). This ability is consistent with an increase in the capacity to store heat over a limited temperature range, a second order transformation.

Because of the numerous transformations taking place near the melting point, the exact heat capacity of the solid phases were difficult to determine with accuracy from the enthalpy content data collected in the present study. For purposes of evaluating the enthalpy of transformation and enthalpy of fusion, a least squares straight line was drawn through the four high temperature points in the alpha phase shown in Fig. 7. A line of the same slope was formed through the points in the beta phase since an adequate temperature range was not available to determine the heat capacity of this phase directly. It is unlikely that the heat capacity of this phase differs significantly enough from 15.5 cal/°K mol to seriously alter the enthalpy of transformation and fusion.

The present heat capacity measurement of liquid CuCl is much lower than that reported by Krestovnikov and Karetnikov (26); their enthalpy content points, spreading over nearly 300 °C, fall on a nearly straight line and would therefore appear to give a reliable mean heat capacity. However, in view of the oversights mentioned previously and the lack of a good calorimetric standard when the work was performed, the determination in the present study of 13.9 cal/°K mol for the heat capacity of liquid CuCl is probably more reliable, particularly since it compares well with that determined for AgCl.

Silver Sulfide

Enthalpy content measurements on silver sulfide are shown in Fig. 8. The solid state transformations are known to be prompt (30); the measurements may therefore be expected to be

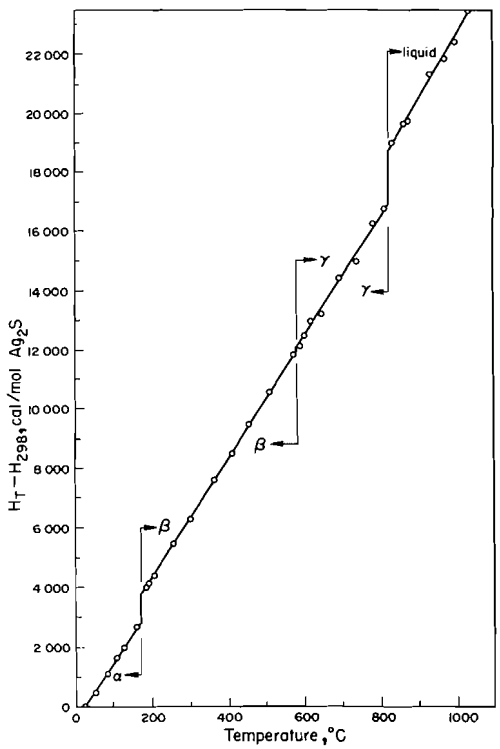

FIG. 8. Enthalpy content of silver sulfide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

reliable. Several values for the enthalpy of the alpha–beta transformation are available in the literature. Kelley (12) suggests 1010 cal/mol based on rather old calorimetric data. Roy *et al.* (31) investigated the pressure effect on this transformation, and from estimates of the volume change on transformation, calculated the enthalpy of transformation to be 1524 cal/mol, using the Clapeyron–Clausius equation. However, this has the rather broad error limit of ±420 cal/mol. Recently, Perrott and Fletcher (32) in an adiabatic calorimeter measured a value of 950 cal/mol ± 100 for this transformation. At 350 °C they observed a second order phase change during which the enthalpy content rose quickly by about 600 cal/mol. The measurements, however, only extended up to 375 °C. This second order transformation was not observed in the present case nor has it been mentioned in previous literature. In particular, the thermal analysis of Kracek (30) reports no such change. It seems that Perrott reports the heat capacity of a metastable compound produced at the time of aqueous precipitation. Therefore, although there is very good agreement of Perrott's enthalpy of alpha–beta transformation with the value of 940 cal/mol in the present study, this may be fortuitous. It is significant to mention here that in early experiments on powdered Ag_2S, which formed part of the present investigation, great difficulty was experienced in obtaining reproducible results, presumably because of structural metastability which could only be alleviated by freezing the sulfide from its liquid state.

It is possible to calculate the enthalpy of alpha–beta transformation from other thermochemical data. From the study of Kiukkola and Wagner (33), the enthalpy of the reaction

[6] $$2Ag_{(s)} + S_{(l)} \rightarrow Ag_2S_{(s,\beta)}$$

is, at 176 °C, −7040 cal/mol. Kubaschewski *et al.* (9) gives the enthalpy of formation of alpha Ag_2S at 298 °K from rhombic sulfur and solid silver to be −7500 cal/mol. Applying the Kirchhoff equation, using the existing enthalpy content data (12) for silver and sulfur, and the present data for alpha Ag_2S, the enthalpy change for the reaction

[7] $$2\,Ag_{(s)} + S_{(l)} \rightarrow Ag_2S_{(s,\alpha)}$$

is, at 176 °C, −7930 cal/mol. The calculated enthalpy of transformation, the difference between the enthalpy of reactions 6 and 7, is thus 890 cal/mol. This value, however, could be in error by as much as ±300 cal/mol. Nevertheless, it is in fair agreement with the present calorimetric determination of the enthalpy of transformation.

The beta–gamma transformation was discovered by Urazov (34) and has been recognized to have a low enthalpy of transformation; however, no direct experimental value appears to have been recorded. The differential thermal analysis of Kracek (30) suggests that this enthalpy change has about one tenth of the magnitude of the alpha–beta transformation. This is in agreement with the present work which gives a value of 120 cal/mol. It is apparent from Table 3 that the error in the measurement of this quantity is as large as the quantity itself, a consequence of subtracting large experimental measurements. Therefore, the present measurement has limited quantitative significance. Qualitatively, the measurement serves to verify that the enthalpy change accompanying this transformation is negligible for most purposes.

The enthalpy of fusion of Ag_2S has been in question for many years with values ranging from 900 to 3600 cal/mol (30, 35). The present work indicates a value of 1880 cal/mol at 830 °C. This is small for such a temperature, but it is consistent with the low entropy change associated with the small alteration in atomic order occurring during fusion of Ag_2S (35).

Lead Sulfide

The experimental measurements are shown in Fig. 9. It appears that no transformations exist in the solid state over the temperature range shown. The enthalpy content was initially expressed as a function of T involving a $1/T$ term. This, however, resulted in a point of inflection which was thought to be statistically meaningless. Accordingly, the simple parabolic form was used. The present measurements are slightly lower than those previously reported. At 900 °K Bornemann and Hengstenberg (36) give 7880 cal/mol. The present measurement at this temperature is 7510 cal/mol. The former value was reported before the sapphire standard was available.

Lead sulfide melts at 1113 °C (6). It is therefore possible, in principle, to make measurements of the enthalpy content of liquid PbS in the present calorimeter, thereby determining the enthalpy of fusion. These experiments were not performed

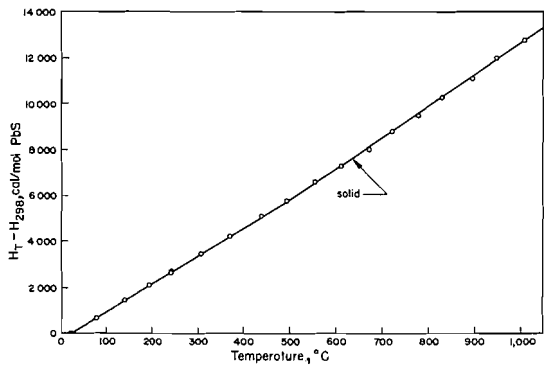

FIG. 9. Enthalpy content of lead sulfide.

because the freezing PbS invariably cracked the silica capsule.

Measurements of Enthalpy Content of Molten Solutions

The enthalpy contents of certain solutions, such as AgCl–KCl and AgCl–Ag_2S melts, include heat effects due to the integral enthalpy of mixing. For such systems, therefore, it is possible to assess the enthalpy of mixing by drop calorimetric methods.

From basic definitions, the integral enthalpy of liquid–liquid mixing ΔH_{mix} of components *1* and *2* at any temperature T is given by

$$[8] \quad \Delta H_{mix} = H_{soln} - X_1 H_1^0 - X_2 H_2^0$$

where H_{soln}, H_1^0, and H_2^0 are the enthalpy of one mole of solution, and pure components *1* and *2*, respectively, and X_1 and X_2 are mole fractions. If the components are not mutually soluble in the solid state at 298 °K

$$[9] \quad (H_{298})_{soln} = X_1(H_{298}^0)_1 + X_2(H_{298}^0)_2$$

where $(H_{298})_{soln}$ is the enthalpy content of a mechanical mixture of the two components at 298 °K having the same composition as the solution in eq. 8. Adding eqs. 8 and 9

$$[10] \quad \Delta H_{mix} = (H_T - H_{298})_{soln} - [X_1(H_T^0 - H_{298}^0)_1 + X_2(H_T^0 - H_{298}^0)_2]$$

The final two terms in eq. 10 are measurable in a drop calorimeter; collectively they represent the additive enthalpy contents of the pure components at temperature T. The first term in this equation may be similarly measured for melts of various compositions. This term represents the enthalpy content per mole of solution at temperature T, and any composition X_1, relative to a mechanical mixture of the two components at 298 °K. Thus the deviation of the enthalpy content of the solution from additivity at temperature T represents the integral enthalpy of mixing.

At constant temperature, the additive enthalpy content of the pure components is given by

$$[11] \quad (H_T - H_{298})_{add} = b_1 + b_2 X_1$$

where b_i are constants. The integral enthalpy of mixing for systems which do not form compounds can generally be adequately expressed as a function of composition using the equation

$$[12] \quad \Delta H_{mix} = b_3 X_1 X_2 + b_4 X_1^2 X_2$$

This form allows for some asymmetry or a change in the sign of the enthalpy effect with respect to composition. Substituting eqs. 11 and 12 into 10, the variation of the enthalpy content of the solution with respect to composition may be represented by the equation

$$[13] \quad (H_T - H_{298})_{soln} = b_1 + b_2 X_1 + b_3 X_1 - b_3 X_1^2 + b_4 X_1^2 - b_4 X_1^3$$

The coefficients in eq. 13 are temperature dependent. The coefficient b_1 is the enthalpy content of pure component *2* at temperature T (X_1 is zero). Similarly $(b_1 + b_2)$ is the enthalpy content of pure component *1* at temperature T (X_1 is one). Previous experiments have shown that the enthalpy contents of pure melts do not detectably vary from linearity with respect to temperature. This is apparent in Figs. 4–8. Therefore

$$[14] \quad b_1 = c_1 + c_2 T$$

and

$$[15] \quad (b_1 + b_2) = c_3 + c_4 T$$

where c_i are constants. The magnitude of the enthalpy of mixing may, in general, vary slightly with temperature. As a first approximation, this dependence will be considered to be linear.

$$[16] \quad b_3 = c_5 + c_6 T$$

The asymmetry term, b_4, may also vary with temperature. The precision of drop calorimetric data, however, does not warrant expressing b_4 as a function of temperature; b_4 may therefore be considered a constant for a particular system. Let

$$[17] \quad b_4 = c_7$$

Substituting eqs. 14, 15, 16, and 17 into eq. 13,

the enthalpy content of the solution becomes, as a function of temperature and composition

$$[18]\quad (H_T - H_{298}{}^0)_{soln} = c_1 + c_2T + (c_3 - c_1 + c_5)X_1 + (c_4 - c_2 + c_6)TX_1 + (c_7 - c_5)X_1{}^2 - c_6TX_1{}^2 - c_7X_1{}^3$$

renaming the coefficients,

$$[19]\quad (H_T - H_{298}{}^0)_{soln} = d_1 + d_2T + d_3X_1 + d_4TX_1 + d_5X_1{}^2 + d_6TX_1{}^2 + d_7X_1{}^3$$

From eqs. 16, 17, 18, and 19

$$[20]\quad b_3 = -d_5 - d_7 - d_6T$$

and

$$[21]\quad b_4 = -d_7$$

Substituting eqs. 20 and 21 into eq. 12

$$[22]\quad \Delta H_{mix} = X_1(1 - X_1)(-d_5 - d_7 - d_6T - d_7X_1)$$

This equation gives the enthalpy of mixing when the enthalpy content of the binary melt can be expressed by eq. 19.

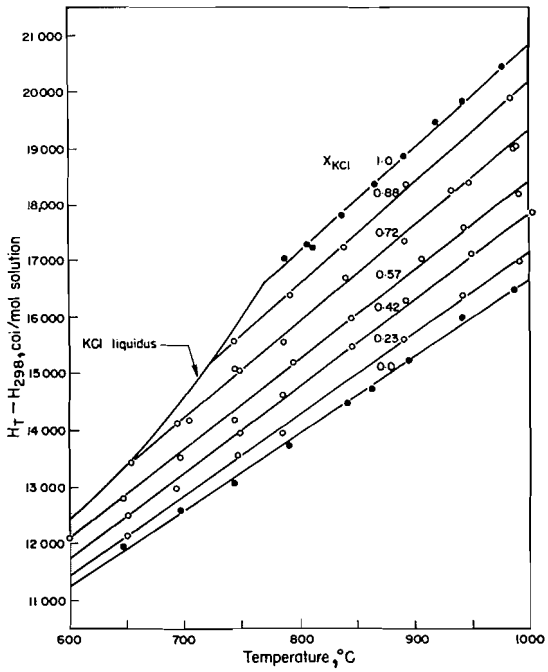

FIG. 10. Enthalpy content of KCl–AgCl melts *vs.* temperature.

The AgCl–KCl System

Enthalpy content measurements of AgCl–KCl melts are given in Table 4. Figure 10 shows these measurements as a function of temperature for solutions of various compositions. The KCl liquidus curve comes from the study of Baboian and Flengas (37). Originally, each of the lines in Fig. 10 was individually constructed by the method of least squares. Isothermal enthalpy contents, interpolated using these equations, yielded the plots in Fig. 11. The deviation from the additivity lines is the integral enthalpy of liquid–liquid mixing. A few measurements on solidified mixtures were made. These are reported in Table 4. There was no detectable deviation from additivity indicating that the salts freeze at the eutectic to form a simple mechanical mixture of nearly pure phases. This is consistent with the phase diagram (37).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

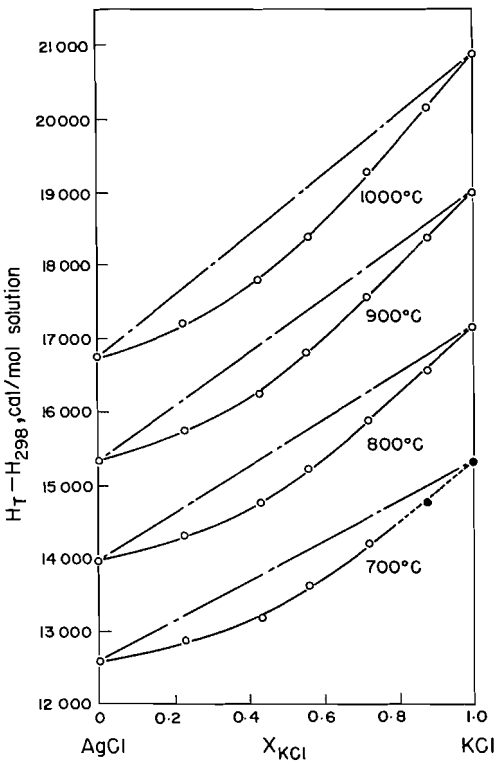

FIG. 11. Enthalpy content of KCl–AgCl melts *vs.* composition.

The actual determination of the position of the lines, shown in Fig. 10, involved fitting the experimental measurements at the various temperatures and compositions to eq. 19 where X_1 is X_{KCl}. The determination of the coefficients d_1 to d_7 was accomplished by multiple linear regression. The coefficients so determined are

$$\begin{aligned} d_1 &= -764.1 \\ d_2 &= 13.68 \\ d_3 &= -3319.0 \\ d_4 &= 3.835 \\ d_5 &= 2031.0 \\ d_6 &= 0.9277 \\ d_7 &= -596.0 \end{aligned} \qquad [23]$$

The standard deviation of the experimental points from the mathematical surface defined by these coefficients was 82 cal/mol. This represents 0.6% of the average total enthalpy content of the salt solution.

From eqs. 22 and 23, the integral enthalpy of mixing for liquid AgCl and liquid KCl is given by

$$\Delta H_{mix} = X_{KCl}(1 - X_{KCl})(-1435 - 0.9277\,T + 596\,X_{KCl}) \qquad [24]$$

Baboian and Flengas (37) measured the integral enthalpy of mixing of this system in an isothermal calorimeter (38) by directly recording the heat liberated when the two liquid salts were mixed. For 0.5 X_{KCl} they report −470 cal/mol at 788 °C and −544 cal/mol at 860 °C. From eq. 24, the values resulting from the present experiments are −531 and −548 cal/mol at the same composition and temperatures, respectively. In addition, the data compare well with respect to the asymmetry of the enthalpy of mixing; both are skewed slightly to the AgCl side of this system. Hersh and Kleppa (39) report integral enthalpies of mixing based on solid–liquid mixing experiments. For 0.5 X_{KCl}, they report −552 cal/mol at 660 °C. In view of the agreement of the present measurements with those previously reported, the present drop calorimetric technique may be considered as a reliable way of quickly determining enthalpies of mixing when great precision is not required.

The AgCl–Ag_2S System

Enthalpy content measurements of AgCl–Ag_2S melts are given in Table 5. These data are plotted in Fig. 12 as a function of temperature for various Ag_2S concentrations; the Ag_2S liquidus was constructed from the phase diagram of Bell and Flengas (4). The straight lines through the data points were determined for each concentration of Ag_2S using eq. 19 in which X_1 was X_{Ag_2S}. The coefficients in this equation were determined by multiple linear regression. Since it was desirable for comparison with other measurements to have average enthalpies of mixing over the temperature range studied, the coefficient d_6 was set equal to zero prior to processing the data. The coefficients are as follows

$$\begin{aligned} d_1 &= -983.7 \\ d_2 &= 13.88 \\ d_3 &= -2223.0 \\ d_4 &= 8.417 \\ d_5 &= -8206.0 \\ d_6 &= 0.0 \\ d_7 &= 5613.0 \end{aligned} \qquad [25]$$

The standard deviation of the enthalpy content measurements from the surface defined by these coefficients was 94 cal/mol. This represents 0.6%

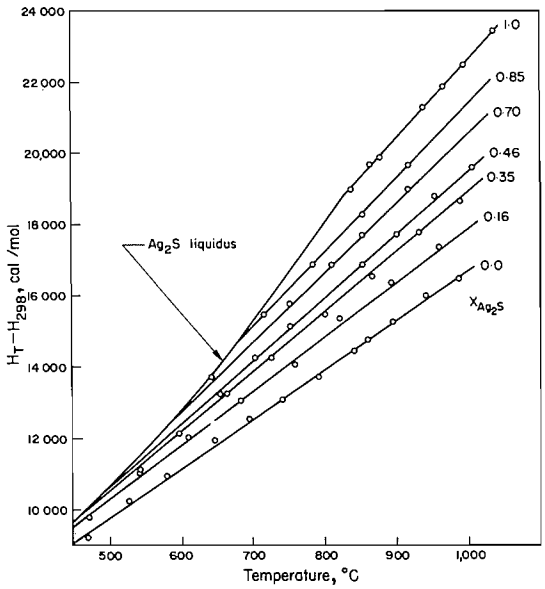

FIG. 12. Enthalpy content of Ag_2S–AgCl melts *vs.* temperature.

of the average total enthalpy content of the solution.

From eqs. 22 and 25, the integral enthalpy of mixing for liquid AgCl and liquid Ag_2S is given by

$$[26] \quad \Delta H_{mix} = X_{Ag_2S}(1 - X_{Ag_2S}) \times (2593 - 5613\, X_{Ag_2S})$$

This equation requires that the integral enthalpy of mixing be endothermic at Ag_2S concentrations less than 0.46 X_{Ag_2S}, and exothermic at higher concentrations. This is uncommon behavior. It is, however, qualitatively consistent with previous e.m.f. measurements on this system (7, 8). These indicate that the partial molar enthalpy of mixing of Ag_2S relative to liquid Ag_2S decreases rapidly from about 2400 cal/mol at 0.0 X_{Ag_2S} to zero near 0.14 X_{Ag_2S}. By differentiating eq. 26, the partial molar enthalpy of mixing of Ag_2S is

$$[27] \quad (\Delta \bar{H}_m)_{Ag_2S} = 2593 - 16\,412\, X_{Ag_2S} + 25\,045\, X_{Ag_2S}^2 - 11\,226\, X_{Ag_2S}^3$$

This equation indicates that the partial molar enthalpy of mixing decreases from about 2600 cal/mol at 0.0 X_{Ag_2S} to zero at 0.23 X_{Ag_2S}. This agreement suggests that the enthalpy of mixing does change sign in this system. Furthermore, it appears that there may be some connection between this effect and the change in mode of electrical conduction (1) although a quantitative model cannot be advanced at this time.

The authors wish to thank the National Research Council of Canada for financial assistance in the form of equipment grants and a fellowship for W.T.T.

NOTES

Semicarbazide Complexes with Metal Chlorides

P. BOLDRINI

Département des Sciences, Université du Québec à Trois-Rivières, Trois-Rivières, Québec

Received[1] March 25, 1970

Complexes of semicarbazide with bivalent metal chlorides were characterized. Crystal data are reported, together with some optical properties and general relations among their crystal structures.

On a caractérisé des complexes formés par réaction de la semicarbazide avec les chlorures de métaux bivalents.

On rapporte les données cristallographiques concernant ces complexes de même que quelques unes de leurs propriétés optiques et les relations générales entre leurs structures cristallines.

Canadian Journal of Chemistry, 49, 1564 (1971)

Semicarbazide (sem), $H_2NNHCONH_2$, is a reagent for identification of aldehydes and ketones, and has applications in medicine as a lathyrogenic (1) and a teratogenic (2). It forms complexes with polynucleotides (3) and enhances growth of Polio (4) and Rubella (5) viruses. The possibility for sem to act as a bidentate ligand has been suggested (6) and verified (7). Sem metal complexes were then prepared as part of an investigation of the reactions of bivalent metal compounds with mono and bidentate ligands (8–10). The synthesis, X-ray crystal data, and some optical properties of 14 salts are reported. Seven of these were previously known (6, 7, 11–13), but their analytical and preparative data were incomplete.

Experimental

Synthesis and Analysis

Sem was isolated from the hydrochloride (11) of Fisher Scientific Co. At room temperature, a cooling of about 30 cal/mol was observed during the solution of the freshly prepared base. The optimum molar ratio for preparing each complex is reported in Table 1, column 2.

Chemical analyses were performed as follows: N by Dumas method; Cl as AgCl after oxidation of sem with H_2O_2; Ni, Cu, Zn by electrolysis; Cd and Pb as sulfates; Mn as pyrophosphates; and Fe as Fe_2O_3.

Densities were obtained, in most cases, by flotation in $CHBr_3$–benzene mixtures at room temperature and then calculated in terms of water at 4 °C.

Density measurements for the two Pb complexes, in contrast, were done pycnometrically. Standard Weissemberg and precession methods, employing CuKα radiation, were used to obtain the X-ray densities; a Co target was used for Co and Mn complexes.

Cell constants were calculated as an average of all axial reflections and, although measured with a calibrated camera, were still affected by absorption. When good crystal forms were available the axial ratio was measured at the optical goniometer and compared with the roentgenographical value. Space groups were deduced from systematic absences of reflections. Results of these analyses are summarized in Table 1, where the density and formula weight for each compound are reported as well. Values in parentheses after each parameter represent calculated root mean square deviations.

Mn(sem)Cl₂ was obtained as dendritic rose microcrystals, orthorhombic and highly soluble in water. The compound showed optical extinction and examination of the cell constants indicated that it was isostructural with $Cd(sem)Cl_2$. $Mn(sem)_2Cl_2$ was always formed when $Mn(sem)Cl_2$ was recrystallized.

Mn(sem)₂Cl₂ was prepared as white needle crystals, orthorhombic and biaxial. They presented orthogonal extinction and appeared isostructural with $Cd(sem)_2Cl_2$. $Mn(sem)_2Cl_2$ showed two equideveloped forms: ((001)) and ((110)) in Buerger's modern symbolism (14). $(a/b)_{goniom.} = 1.527(4)$; $(a/b)_{roentg.} = 1.534(4)$.

Fe(sem)₂Cl₂ was always separated with this stoichiometry, even if prepared from equimolar ratios or solutions richer in sem. Crystals were pale-green, prismatic, monoclinic, optically biaxial, with orthorhombic extinction. They were superficially oxidized when left in the open air and turned brown. Acidic solutions favored the synthesis.

Co(sem)₂Cl₂.2H₂O was crystallized as red-amaranth, pseudohexagonal, tabular crystals; they were monoclinic and highly soluble in water. Preparation of the anhydrous compound (11) was tried without success.

Ni(sem)₂Cl₂ was reprepared (6) as green microcrystals, orthorhombic and easily recrystallizable from water.

Ni(sem)₃Cl₂.3H₂O was obtained as tiny blue-violet needles, aggregated in a sheaf-like manner. These crystals were monoclinic and showed parallel extinction. The

*The ratio is intended as sem:MCl_2. Letters *a*, *b*, *c* after the molar ratio indicate: *a*, preparation from aqueous solutions; *b*, preparation from ethanol 95% solutions; *c*, preparation carried out by slow cooling of aqueous solutions.
†Atomic weights for Mn, Fe, Co are known with higher accuracy and, therefore, the formula weights of these compounds have three decimals.

cell given in Table 2 results from an improvement of single crystal data by a powder diagram. The anhydrous complex (6) was not obtained, but preparation of the trihydrated complex (11) was confirmed.

Cu(sem)Cl₂ crystals were easily obtained (13), frequently as twins. The crystals were decomposed by mild heating and left a white residue of CuCl, thus confirming the known reductive character of sem. Spectra of this compound have recently been studied (12, 15), $(a:b:c)_{\text{gonlom.}} = 0.672(2):1:0.803(3)$; $(a:b:c)_{\text{roentg.}} = 0.675(3):1:0.808(3)$. Other crystal data for this and the three following compounds have been reported (7).

Cu(sem)₂Cl₂ has been studied spectroscopically (12, 15). At room temperature these crystals showed a tendency to be spontaneously reduced, but can be maintained in an unaltered state at 4 °C and are properly prepared under such conditions.

Zn(sem)Cl₂ was monoclinic and presented extinction parallel to the elongation axis. Preparation of this and the following compound was facilitated by adjusting the solutions to p*H* 5 with HCl.

Zn(sem)₂Cl₂ was also found to be monoclinic. A thin lamina, in a tilted direction under the microscope, showed an optical hyperbola which was almost resolved.

Cd(sem)Cl₂ separated as white prismatic crystals, optically biaxial in a direction normal to the elongation axis, and was isostructural with $Mn(sem)Cl_2$. A procedure differing from that devised by Smith (11) was found to be more suitable for the synthesis of this complex and, in addition, led to the formation of $Cd(sem)_2Cl_2$, which could not be prepared by the previous method (11).

Cd(sem)₂Cl₂ was procured as white irregular prisms, orthorhombic and with parallel extinction. The complex was isostructural with $Mn(sem)_2Cl_2$. A p*K* intermediate between the analogous thiosemicarbazide and urea compounds has been measured in solution (16).

Pb(sem)Cl₂ was prepared as thick, short, shining, white crystals which showed inclined extinction and triclinic symmetry. $Pb(sem)_2Cl_2$ was also obtained from the mother liquid.

Pb(sem)₂Cl₂ crystals were prismatic, brittle, shining needles, monoclinic and sometimes 1 in. long. Observed forms were: ((100)), ((111)), ((1̄11)), (14). $(a:b:c)_{\text{gonlom.}}$, 1.860(8):1:1.123(2); $(a:b:c)_{\text{roentg.}}$, 1.856(3):1:1.123(2).

Discussion

A study of the crystal structuresof $Cu(sem)_2Cl_2$ and $Zn(sem)_2Cl_2$ (7) has shown that each metal is surrounded by a trans-planar arrangement of two oxygens and two hydrazinic nitrogens which are found at the corners of a distorted square. Coordination is completed by two chlorines on opposite sites of the square. Such an octahedral coordination, more or less distorted, is also likely to be found in the Cd complexes and in the other disemicarbazide compounds as well.

$M(sem)Cl_2$ complexes have been reported to be polymeric (15). The monosemicarbazide compounds of Fe, Co, and Ni have not as yet been obtained and it has to be expected that such a stoichiometry does not satisfy the stereochemical requirements of these metals (17). Furthermore, success has not been achieved in the preparation of sem complexes with Hg(II) and Ag(I) chlorides. The behavior of Hg(II), however, is somewhat surprising in view of the fact that $Hg(sem)SO_4$ and $Hg(sem)_2SO_4$ have been obtained (18). On the other hand, polymeric complexes of AgCl with thiosemicarbazide are known (19).

There is no doubt that the Co compound of Table 1 differs from the anhydrous compound synthesized by Smith (11). However, existence of both compounds is quite probable as in the case of $Co(thiourea)_4(NO_3)_2$ (9) and that of

*Crystallographic data for $Cu(sem)Cl_2$; $Cu(sem)_2Cl_2$; $Zn(sem)Cl_2$; $Zn(sem)_2Cl_2$ have already been reported (7). Z of column 9 is the number of formula weights in the asymmetric unit.

$Ni(sem)_2Cl_2$ mentioned above. It is in fact the author's experience that such analogous possibilities are more numerous than those reported in the literature.

Finally, the ribbon-like structure of sem (10) is probably responsible for the cooling when sem is dissolved in water.

Financial help for the final stage of the research was provided by Ministère de l'Education, Québec. Thanks are also due to L. Cavalca, M. Nardelli, and A. Perley.

Spectrofluorometric Studies. X. The Photochemistry of Pentafluorobenzene

S. L. LEM, G. P. SEMELUK, AND I. UNGER

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick, Canada

Received September 18, 1970

The vapor phase photochemistry of pentafluorobenzene has been examined at a variety of exciting wavelengths starting at 2540 Å and extending to 2780 Å. Most of the studies were carried out at 2620, 2660, and 2700 Å. Below 2600 Å pentafluorobenzene does not exhibit any detectable fluoroscence, above 2600 Å a very weak fluorescent emission was observed. Addition of biacetyl does not markedly reduce the fluorescent yield, while addition of cyclohexane, CO_2, and *cis*-butene-2 causes an increase in the fluorescent yield. The triplet yield of pentafluorobenzene excited at 2620, 2660, and 2700 Å, measured by the sensitized emission of biacteyl technique, is also very low and is increased by the addition of cyclohexane, CO_2, and *cis*-butene-2. *cis*-Butene-2 is the most effective gas, of the three examined, in increasing the fluorescent and triplet yields of pentafluorobenzene. The fate of the majority of pentafluorobenzene molecules excited in the 2600 Å region is unknown.

La photolyse en phase gazeuse du pentafluorobenzène a été étudiée en fonction de la longueur d'onde de la raie excitatrice entre 2540 et 2780 Å. Pour des longueurs d'onde inférieures à 2600 Å, on n'a pu déceler aucune fluorescence, tandis qu'au-dessus de 2600 Å, on a observé une faible émission. L'addition de biacétyle ne réduit pas le rendement en fluorescence mais l'addition de cyclohexane, de CO_2 et de *cis*-butène-2 l'augmente. Le rendement en triplet, lorsque le pentafluorobenzène est irradié à 2620, 2660, et 2700, tel que mesuré par la technique du biacétyle par émission sensibilisée, est aussi très faible et augmente avec l'addition de cyclohexane, CO_2 et *cis*-butène-2. Des trois gaz examinés, le *cis*-butène-2 est le plus efficace pour accroître le rendement en triplet. On ne sait pas ce qui arrive à la majorité des molécules lorsqu'on photolyse le pentafluorobenzène dans la région de 2600 Å.

Canadian Journal of Chemistry, 49, 1567 (1971)

Introduction

In recent years a number of publications have appeared dealing with various aspects of the photochemical behavior of the fluorinated benzenes (1–6). To date there have been no published reports dealing with the photochemistry of pentafluorobenzene (PFB). Although it is not possible to discern many systematic changes

$Ni(sem)_2Cl_2$ mentioned above. It is in fact the author's experience that such analogous possibilities are more numerous than those reported in the literature.

Finally, the ribbon-like structure of sem (10) is probably responsible for the cooling when sem is dissolved in water.

Financial help for the final stage of the research was provided by Ministère de l'Education, Québec. Thanks are also due to L. Cavalca, M. Nardelli, and A. Perley.

as one progresses from monofluorobenzene to hexafluorobenzene, two trends are worth noting: (*1*) simple HMO calculations (2) predict singlet and triplet energies to decrease as fluorination increases; (*2*) with some exceptions the singlet and triplet yields appear to decrease with increasing fluorination (4, 5) and account for less than 10% of all the excited molecules by the time one reaches hexafluorobenzene (7, 8). An account of the photochemistry of PFB serves to provide a link in this chain and to check on theoretical predictions.

Experimental

The pentafluorobenzene was obtained from Peninsular Chemresearch Incorporated. The v.p.c. showed its purity to be in excess of 99.9%. A comparison of its excitation spectrum with its absorption spectrum indicated no interfering impurities. It was, therefore, used without further purification. Biacetyl (BiA) was obtained from the Aldrich Chemical Company and was purified by bulb-to-bulb distillation "in vacuo" and stored in a blackened reservoir. Fluorometric grade benzene and cyclohexane (CH) obtained from the Hartman Leddon Company and Philips research grade *cis*-butene-2 (*c*-B-2) having less than 0.1% impurity were used without further purification. Dry-Ice was used as the source of CO_2. All chemicals were thoroughly degassed prior to being introduced into the cell.

All experiments were carried out in a conventional grease- and mercury-free high vacuum line equipped exclusively with Hoke packless diaphram metal valves. Pressure measurements were performed by means of a spiral gauge constructed at the National Research Council of Canada in Ottawa. Mixing was effected by flash vaporization followed by circulating the vapors through a flow through cell with an all-glass pump also constructed at the National Research Council of Canada in Ottawa. The flow-through cell was a cuvette-type with dimensions 1 cm × 1 cm × 4.5 cm, polished on all four sides.

All emission measurements were performed on a modified Aminco–Bowman spectrophotofluorometer. Details concerning the light source, phototube, photomultiplier tube, microammeter, recorder and the experimental procedure have been given previously (2). The entrance slit of the excitation monochromator was set at 0.5 mm and the exit slits were set at 1.0, 0.5, and 1.0 mm. The half band pass and spectral distribution at several excitation wave lengths for this combination have been given (9).

Quantum yields of fluorescence and of sensitized emission reported in this paper were based on the singlet and triplet yields of benzene, excited at 2580 Å, being 0.183 (10) and 0.63 (11), respectively.

Results and Discussion

(A) Fluorescence Measurements

The absorption and fluorescent spectrum of PFB is given in Fig. 1. With excitation wavelengths below 2600 Å no fluorescent emission was detected. Above 2600 Å the fluorescent emission is very weak, does not appear to be self-quenched and increases with increasing exciting wavelength; the data are summarized in Table 1. The fluorescent yield with excitation at 2620, 2660, and 2700 Å increases on the addition of CH, CO_2, and *c*-B-2. Cyclohexane and CO_2 exhibit approximately the same efficiency in increasing the fluorescent yield, while *c*-B-2 is the most efficient (see Fig. 2).

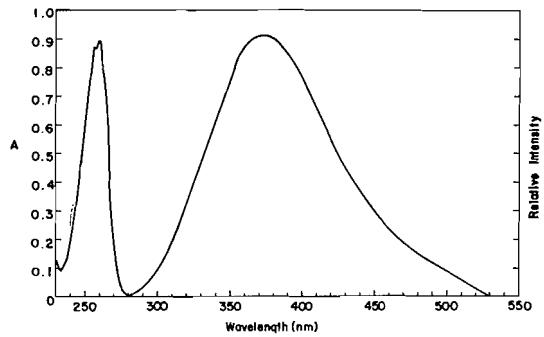

FIG. 1. The absorption and emission spectrum of PFB. The absorption spectrum was recorded on a Hitachi–Coleman Spectrophotometer, Model EPS-3T.

(B) Triplet Yields

The sensitized emission of BiA technique (12) was used to determine triplet yields.[1] The triplet

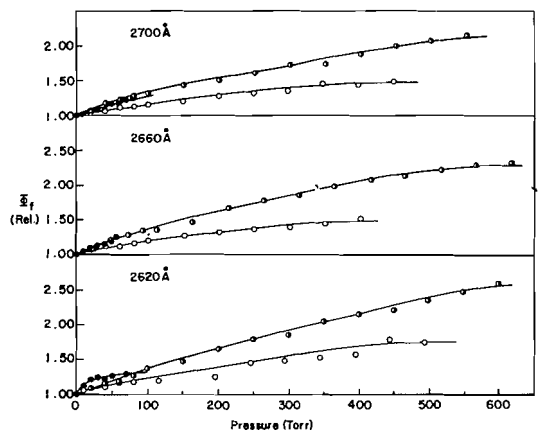

FIG. 2. The effect of CH, ●; CO_2, ○; and *c*-B-2, ◑ on relative fluorescent emission yield of PFB excited at various wavelengths.

[1]Triplet yields reported in this paper are upper limits only, since it is quite probable that excited singlet PFB sensitizes biacetyl emission as well. This phenomenon will be discussed in a forthcoming paper on difluorobenzene photochemistry.

yield of PFB excited at 2620, 2660, and 2700 Å increases with increasing BiA pressure. However, BiA does not markedly quench the fluorescent yield (see Fig. 3). The triplet yields are very low and increase with increasing excitation wavelength. Addition of CH, CO_2, and *c*-B-2 to PFB causes an increase in the triplet yield. These data are summarized in graphical form in Fig. 4.

The two most striking features of the photochemistry of PFB excited in the 2600 Å region are: (*1*) the very low total fluorescent and triplet yield even in the presence of large quantities of inert gas and (*2*) the increase in the sensitized emission, (*i.e.*, triplet yield) on the addition of *c*-B-2.

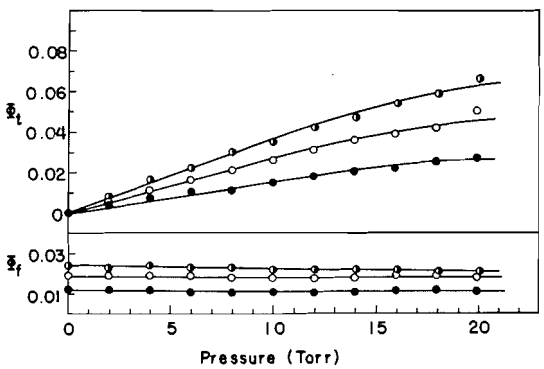

FIG. 3. Triplet and fluorescent yields of PFB excited at various wavelengths as a function of BiA pressure. λ_{ex} = 2620 Å, ●; λ_{ex} = 2660 Å, ○; and λ_{ex} = 2700 Å, ◑. PFB pressure = 20 Torr.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

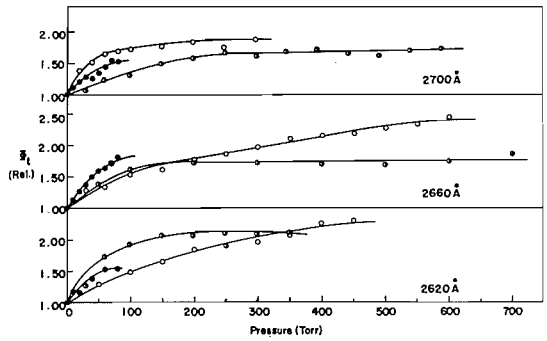

FIG. 4. The effect of CH, ●; CO_2, ○; and *c*-B-2, ◑ on the relative triplet yield of PFB excited at 2620, 2660, and 2700 Å. PFB pressure = 20 Torr, BiA pressure = 10 Torr.

The first phenomenon may be due to any of the following: (*a*) rapid internal conversion from the first singlet to the ground state, a process which has been postulated to account for the very low total singlet and triplet yield in perfluorotoluene (13); (*b*) intramolecular rearrangement occurring from either the singlet or triplet states (14); (*c*) very short PFB triplet lifetime which would require using greater BiA pressures than can be used in order to intercept all the triplet PFB molecules before their radiationless return to the ground state.

Most likely a combination of all of these factors contribute to the low total singlet and triplet yield. Pentafluorobenzene thus follows the pattern observed in the trifluorobenzenes, the tetrafluorobenzenes, and hexafluorobenzene.

With respect to the second phenomenon mentioned above, the "Schenck mechanism" (15) is not operative when aromatics transfer energy to *c*-B-2 (16). Thus when fluorinated aromatics, having triplet energies above the triplet of *c*-B-2, are excited in the presence of BiA and *c*-B-2 is added to the system, it would be expected that the sensitized emission of BiA would decrease. This is indeed the observation for all the fluorinated benzenes up to and including 1,3,5-trifluorobenzene (4). Starting with 1,2,4-trifluorobenzene and continuing to hexafluorobenzene, the triplet energies are predicted theoretically (2) to be lower than that of *c*-B-2 (17, 5). Hence these molecules may not be able to transfer triplet energy to *c*-B-2, and addition of *c*-B-2 to these molecules should then produce the same effect as the addition of any other inert gas. Within the *c*-B-2 pressure range used, this is confirmed for 1,2,4-trifluorobenzene, for all the tetrafluorobenzenes, and in the present case for pentafluorobenzene. However, an alternative explanation involving triplet energy transfer efficiency which seems to apply to 1,2,4-trifluorobenzene (18) cannot be excluded at this time.

Since this work was submitted, a description of some similar experiments has appeared (19). In the case of fluorescent yields where the results are directly comparable there is substantial agreement between the two sets of results.

The authors wish to thank the National Research Council of Canada for financial assistance.

Dissociative Electron Attachment Processes in SO_2 and NO_2

D. A. RALLIS AND J. M. GOODINGS
Centre for Research in Experimental Space Science, York University, Toronto, Ontario

Received October 28, 1970

A trapped electron apparatus has been used to identify the processes involved in negative ion formation for the triatomic oxides SO_2 and NO_2. Two O^- peaks are observed in SO_2 with onset values at $4.2 \pm 0.1_5$ and 6.3 ± 0.2 eV, and peak values at $5.0 \pm 0.1_5$ and $7.4 \pm 0.1_5$ eV, respectively. From kinetic energy analysis of the O^- ions, both peaks are found to have the same dissociation limit involving SO in its ground state. For NO_2, two dissociative electron attachment peaks are observed with onset values at 1.6 ± 0.2 and 7.3 ± 0.3 eV, and peak values at 3.0 ± 0.2 and 8.1 ± 0.2 eV, respectively. The first broad peak is explained by overlapping contributions from two processes having the same dissociation limit involving ground state NO; they differ only in the amount of kinetic energy possessed by the fragments. The second peak appears to involve electronic excitation of the neutral fragment NO* with zero kinetic energy at onset.

Un appareil à électron piégé a été utilisé pour identifier les procédés impliqués dans la formation d'ion négatif pour les oxydes triatomiques SO_2 et NO_2. Deux pics de O^- sont observés dans SO_2 avec des valeurs au commencement de $4.2 \pm 0.1_5$ et 6.3 ± 0.2 eV, et des valeurs pour les pics à $5.0 \pm 0.1_5$ et $7.4 \pm 0.1_5$ eV, respectivement. D'après des analyses d'énergie cinétique des ions O^-, on a trouvé que les deux pics ont la même limite de dissociation impliquant SO dans son état fondamental. Pour NO_2, deux pics d'attachement d'électron dissociatif sont observés avec des valeurs au commencement à 1.6 ± 0.2 et 7.3 ± 0.3 eV, et des valeurs pour les pics à 3.0 ± 0.2 et 8.1 ± 0.2 eV, respectivement. Le premier pic large est expliqué par les contributions qui se recouvrent de deux processus ayant la même limite de dissociation impliquant l'état fondamental NO. Ils diffèrent seulement dans la quantité d'énergie cinétique que possédaient les segments. Apparemment, le second pic implique l'excitation électronique du fragment NO* avec une énergie cinétique nulle au commencement.

Canadian Journal of Chemistry, 49, 1571 (1971)

Introduction

Negative ion formation in both SO_2 (1) and NO_2 (2) has been examined using mass spectrometry in the 0–10 eV range. In both cases, the only appreciable negative ion detected was O^- produced in a number of dissociative electron attachment processes. These unambiguous determinations of the fragments complement the present trapped electron studies in which kinetic energy analysis of the O^- ions is possible: together they serve to identify the processes involved. Possible kinetic energy discrimination in the mass spectrometric results is not a factor in the present work.

For these triatomic oxides, dissociative electron attachment can be represented by

$$[1] \qquad XO_2 + e(E_e) \rightarrow O^- + XO(E') + \text{k.e.}$$

where E_e is the kinetic energy of the electron projectile, E' is the excitation energy of the neutral fragment, and k.e. is the total kinetic energy of the separating fragments. It has been assumed that the thermal energy of the target gas is negligible and that there is no excited state of O^-.

The energetics of the process are given by

$$[2] \qquad E_e = D - A + E' + \text{k.e.}$$

where $D \equiv D(\text{OX—O})$ is the dissociation energy of the OX—O bond and A is the electron affinity of O. In terms of the O^- ion

$$[3] \qquad E_0 = (1 - \beta)[E_e - (D - A + E')]$$

where E_0 is the kinetic energy of the negative ion and β = mass (O^-)/mass (XO_2). A plot of E_0 *vs.* E_e is a straight line of slope $(1 - \beta)$ providing a mass identification of the negative ion. The intercept with the E_e-axis is the quantity $(D - A + E')$ which yields information concerning electron affinities, dissociation energies, and the energy states of the neutral fragment. The present study presents such negative ion data with kinetic energy determinations for SO_2 and NO_2.

Experimental

The trapped electron apparatus combines a retarding potential difference (r.p.d.) electron gun (3) with a Lozier-type collision chamber (4), and is similar to that developed by Schulz (5, 6). The apparatus has been described in detail elsewhere (7); hence, only essential details are given here. A pseudo-monoenergetic electron

beam aligned by a magnetic field (~250 G) traverses the axis of a collision region having the form of a cylindrical potential well. The potential well at the axis is formed by field penetration of an outer cylindrical collector electrode through an inner concentric grid. A pressure ratio of about 100 between the filament and collision chamber was achieved by good differential pumping.

Inelastically scattered electrons are "trapped" and measured at the collector if their residual kinetic energy k.e.$_e \leq W$, where W is the depth of the potential well expressed in eV. The collection mechanism for negative ions is different since their trajectories are not greatly influenced by the weak axial magnetic field; the collection efficiency depends primarily on the solid angle subtended at the outer collector by the collision volume near the axis. By sufficiently reducing W, only the ion current is collected out of a total negative signal comprised of both ions and electrons. By further reducing W to negative values, ion kinetic energy measurements can be made.

Results and Discussion for SO_2

A negative ion spectrum of O^- from SO_2 with a constant well depth $W = 0$ eV is shown in Fig. 1. Two peaks are observed with onset values at $4.2 \pm 0.1_5$ and 6.3 ± 0.2 eV, and with maxima at $5.0 \pm 0.1_5$ and $7.4 \pm 0.1_5$ eV, respectively. These results are in excellent agreement with recent mass spectrometric work by MacNeil and Thynne (1). The narrowness of the first peak supports their suggestion that the cross-section responsible for its production is resonant.

Figure 2 shows a plot of E_0 *vs.* E_e in SO_2. The E_e scale was calibrated against the onset of He^+ formation; the k.e. scale was calibrated from an ion retarding curve for SO_2^+. The line marked "theory" is drawn with a theoretical slope

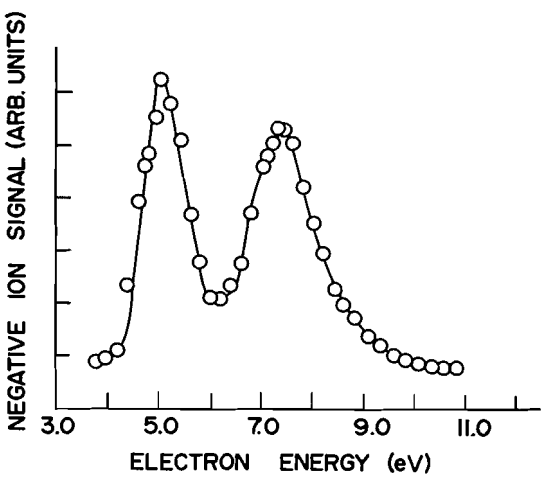

FIG. 1. Negative ion signal as a function of electron energy for SO_2 with $W = 0$.

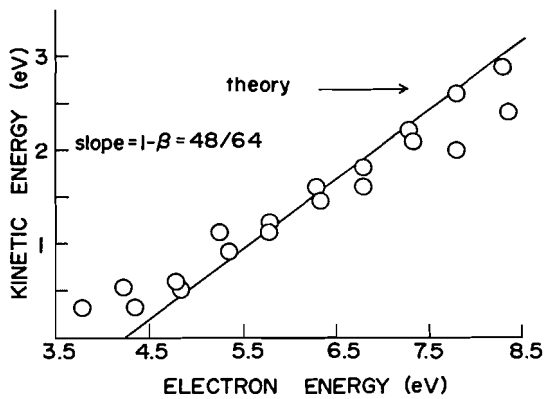

FIG. 2. Kinetic energy as a function of electron energy for the O^- ions produced by dissociative electron attachment processes in SO_2.

$(1 - \beta) = 48/64$ and an intercept $(D - A) = 4.14$ eV, using D(OS—O) = 5.61 eV (8) and A(O) = 1.465 eV (9). These values are consistent with the reaction

[4] $\quad SO_2 + e \rightarrow [SO_2^-]^* \rightarrow SO + O^- + \text{k.e.}$

where SO is in its ground state, and the thermal motion of the target gas has been neglected (10).

The experimental points in the energy range covering both peaks lie approximately along the theoretical line. Thus the products giving rise to the two peaks must be the same at infinite separation. The deviations are greatest at the wings of the peaks where the ion signal is small.

Results and Discussion for NO_2

Figure 3 shows a negative ion spectrum for NO_2 obtained with $W = 0$ eV. Two peaks have been clearly identified with onset values at 1.6 ± 0.2 and 7.3 ± 0.3 eV, and maxima at 3.0 ± 0.2 and 8.1 ± 0.2 eV, respectively. Figure 4 is a plot of E_0 *vs.* E_e for NO_2. The E_e scale was calibrated using the onset for He^+ formation while a retarding curve for NO_2^+ was used to calibrate the k.e. scale. In the range of the broad low-energy peak, the experimental points are in fair agreement with the theoretical line of slope $(1 - \beta) = 30/46$ and E_e-intercept $(D - A) = 1.65$ eV; at higher energy they assume a roughly constant value. A value for $D \equiv D$(ON—O) = 3.114 eV (8) has been assumed, with A(O) = 1.465 eV as before.

In a mass spectrometric study by Fox (2), three O^- peaks were observed in the range 0–10 eV. This work was concerned more with the informa-

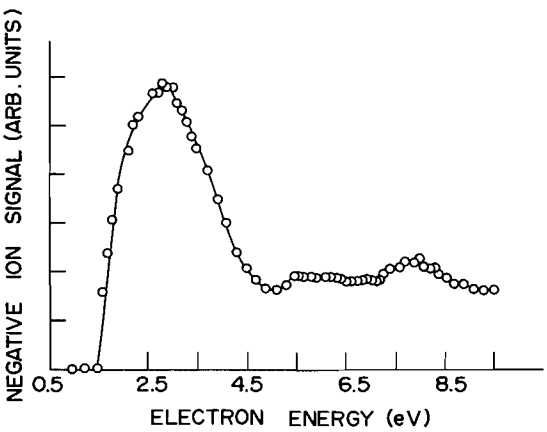

FIG. 3. Negative ion signal as a function of electron energy for NO_2 with $W = 0$.

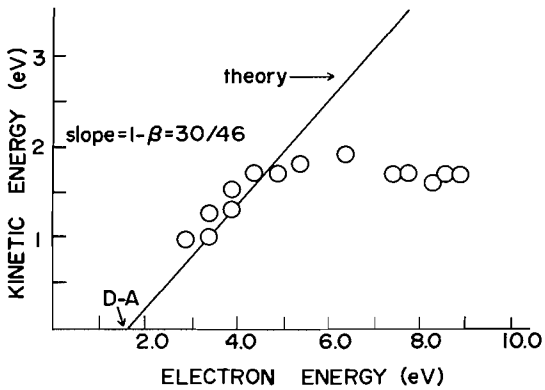

FIG. 4. Kinetic energy as a function of electron energy for the O^- ions produced by dissociative electron attachment processes in NO_2.

tion obtainable from the peak shapes than with the processes involved. The three peaks, designated here by *I*, *II*, and *III* are reported with maxima at 1.90, 3.0, and 8.75 eV, respectively. *I* has an onset at 1.35 eV and is about eleven times as intense as *II* and *III*, which are of comparable magnitude. Using Fig. 4, we believe the relevant processes for *I* and *II* to be

[5] $NO_2 + e \rightarrow [NO_2^-]^* \rightarrow NO + O^- + \text{k.e.}$ (*zero* at onset)

[6] $NO_2 + e \rightarrow [NO_2^-]^{**} \rightarrow NO + O^- + \text{k.e.}$ (*non-zero* at onset)

respectively, involving different excited states of the negative ion intermediate $[NO_2^-]$. Thus the broad low-energy peak in Fig. 3 arises from approximately equal overlapping contributions from [5] and [6]; its onset agrees reasonably well with that of *I* while its maximum is in good agreement with that of *II*. Due to kinetic energy discrimination, Fox's magnetic sector mass spectrometer may have considerably underestimated the relative intensity of *II*. The present results, for which such discrimination is not a problem, indicate that the cross sections for [5] and [6] are comparable, with [6] somewhat in predominance.

Above about 5 eV and in the region of the second peak near 8 eV in Fig. 3, E_0 in Fig. 4 assumes an approximately constant value. A similar behavior was observed by Schulz (11) for N_2O, and attributed to the process

[7] $N_2O + e \rightarrow [N_2O^-]^* \rightarrow N_2\dagger + O^- + \text{k.e.}$

based on his previous observation (12) of the process

[8] $N_2 + e \rightarrow [N_2^-]^* \rightarrow N_2\dagger + e$

where $N_2\dagger$ indicates vibrational excitation. However, a comparable explanation for NO_2 is not reasonable since it would involve the presence of $NO\dagger$ in analogy with eq. 7 for N_2O involving $N_2\dagger$. In a careful investigation by Chantry (13), no mention is made of any peak attributable to $NO\dagger$ in analogy with eq. 8, nor was any evidence obtained during a similar study of NO in these laboratories. Instead, the behavior of Fig. 4 above 5 eV is thought to be instrumental in origin, and indicates that the sensitivity limit of the apparatus has been reached. As noted in Fig. 2 for SO_2, the deviations of the k.e. data are greatest when the O^- signal is small.

Without reliable k.e. data, a conclusive mechanism for the peak near 8 eV in Fig. 3 is not possible. However, of the two probable processes

[9] $NO_2 + e \rightarrow [NO_2^-]^{***} \rightarrow NO(X^2\Pi) + O^- + \text{k.e.}$ (*non-zero* at onset)

[10] $NO_2 + e \rightarrow [NO_2^-]^{***} \rightarrow NO^*(A^2\Sigma^+) + O^- + \text{k.e.}$ (*zero* at onset)

[10] involving electronic excitation of NO is favored for a number of reasons.

(*a*) The separation of the onset values for the two peaks in Fig. 3 is about 5.7 eV. The energy required to excite the NO fragment into its $A(^2\Sigma^+)$ first excited electronic state is 5.45 eV (8) in approximate agreement with the onset separation.

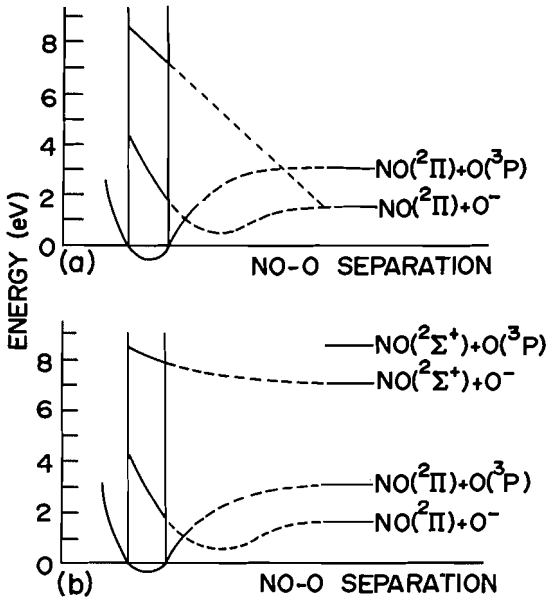

FIG. 5. Hypothetical potential energy curves for NO_2. (*a*) and (*b*) illustrate the behavior for processes [9] and [10], respectively.

(*b*) Fox (2) notes that peak *III* in his work with a maximum at 8.75 eV may be due to an impurity which produces O^- either from NO or from H_2O in this energy range. The peak at 8.1 eV in the present work, believed to arise from NO_2, is not in very good agreement with *III* as to its maximum value. For the present argument, however, suppose the 8.1 eV peak and *III* refer to the same process involving NO_2. *II* and *III* were observed by Fox with comparable low intensity. If [9] is the correct process, the same k.e. discrimination inferred previously for *II* should also be operative for *III* in the mass spectrometric results. In the present work which does not suffer from k.e. discrimination, the 8.1 eV peak should be observed with relatively increased intensity. Since this is not the case, [10] is again the more probable process.

(*c*) Hypothetical potential energy curves are drawn in Figs. 5(*a*) and (*b*) corresponding to [9] and [10], respectively. The points of intersection of the repulsive curves with the vertical Franck–Condon boundaries were taken to be the E_e values at which the peak height decreased to $1/e$ of its maximum value. In Fig. 5(*a*) the Franck–Condon energy range of the $[NO_2^-]^{***}$ state has been stretched somewhat to admit the extreme values possible considering the estimated experimental error; a reasonably shaped repulsive curve terminating at the $NO(^2\Pi) + O^-$ limit is only marginally possible. The smaller Franck–Condon energy range drawn for the $[NO_2^-]^{***}$ state in Fig. 5(*b*) is a more realistic fit to the experimental data. Alternatively, at the experimental onset of 7.3 eV, the total k.e. from eq. 2 of the separating fragments is 5.7 eV if [9] is the correct process. This value corresponds to the Coulomb repulsion of O^- and NO^- considered as point charges 2.5 Å apart. On this comparative basis, it is very unlikely that the repulsion between O^- and *neutral* NO could approach 5.7 eV stemming from a situation where the NO—O^- separation would be expected to exceed 2.5 Å. From either point of view, the process represented in [10] is favored.

A Simple Diffusion Cell for the Determination of Absolute Diffusion Constants using Radioactive Tracers

WILLY DYCK
Geological Survey of Canada, Ottawa, Canada

Received August 10, 1970

Using microscope slides for the diffusion grating, a glass diffusion cell was constructed which permitted the determination of absolute diffusion constants of γ-ray emitting elements in aqueous solutions.

The cell was tested at 25 °C with ^{110}Ag as tracer and gave a bulk-diffusion coefficient of 1.64×10^{-5} cm²/s and a self-diffusion coefficient of 1.48×10^{-5} cm²/s using 0.01 *M* $AgNO_3$.

The hydrogen ion concentration had no detectable effect on the diffusion coefficient of $AgNO_3$ in the p*H* range −0.48 to 7.5. The presence of Na or Fe(III) ions, or sucrose molecules at moderate concentrations (> 0.1 *M*) resulted in a marked decrease in the diffusion coefficient.

En utilisant des plaques de microscope comme grille de diffusion, on a construit une cellule de diffusion en verre qui a permis la détermination des constantes absolues de diffusion en solution aqueuse d'éléments émettant des rayonnements gamma.

La cellule a été testée en utilisant l'argent-110 comme traceur; on a obtenu un coefficient de diffusion globale de 1.64×10^{-5} cm²/s et un coefficient d'autodiffusion de 1.48×10^{-5} cm²/s en utilisant $AgNO_3$ 0.1 *M*.

La concentration d'ions hydrogène n'a pas eu d'effet mesurable sur le coefficient de diffusion de $AgNO_3$ dans la gamme de p*H* −0.48 à 7.5. La présence d'ions Na ou de Fe(III) ou de molécules de sucrose à concentration modérée (> 0.1 *M*) a produit une diminution marquée du coefficient de diffusion.

Canadian Journal of Chemistry, 49, 1575 (1971)

Introduction

The simplest way to determine diffusion coefficients in aqueous solutions is by the McBain–Northrop method (1–4). However, the sintered glass cell used in this method has to be calibrated using an electrolyte such as KCl with known diffusion coefficients. Also adsorption of ions such as silver on the porous diaphragm of sintered glass precludes the use of very dilute solutions. Harned and French (5) and Harned and Blander (6) have developed conductance cells for the measurement of absolute diffusion coefficients of electrolytes. Starik and Yurtov (7) have devised a cell for the measurement of self-diffusion coefficients of radioactive isotopes in dilute solutions. Various modifications of the sintered disc method have been used for diffusion studies (8–10). A capillary method is described by Mills and Godbole (11).

Whiteway *et al.* (12) used the sintered disc and a number of workers (13–17) have used the rotating disc method to measure the diffusion coefficient of Ag^+ in aqueous solutions.

This report describes a diffusion cell suitable for the determination of absolute diffusion coefficients of γ-ray emitting elements in solution and gives the results obtained with silver using ^{110}Ag as a tracer.

Experimental[1]

A sketch of the cell constructed for this work is shown in Fig. 1. The cell grating, or diffusion layer, was constructed as follows:

Approximately 50 to 75 ordinary microscope slides measuring 75 × 25 × 1 mm were encapsuled tightly in a hand-made box and cut approximately to the desired height using a diamond blade. While still in the bakelite box, the exposed edges were ground and polished on a rotating wheel using carborundum powders. The slides were then removed from the bakelite enclosure, their height and thickness measured accurately with calipers, cleaned thoroughly, dried, and cemented together with Canada Balsam using 0.2 mm microscope slide covers as spacers between them. The Canada Balsam cement was diluted with toluene so it would flow freely and give a thin glue line. The spacers were placed near the end of the slides in such a way as to give a series of 0.2 mm parallel slits. The length of these slits was varied to give a grating which approximated a circular opening. The slides and spacers were assembled and glued on an inclined stand and dried at 80 °C. When the cement had hardened the grating was ground into a circular shaped disc. The height of the grating (length of diffusion path), the total thick-

[1]The experiments were carried out by Mr. J. C. Pelchat, Geochemistry Section, Geological Survey of Canada.

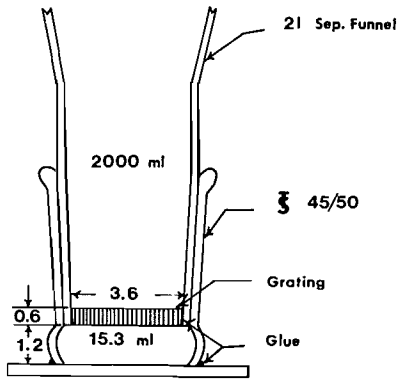

FIG. 1. Cross-section of diffusion cell (all dimensions are in cm).

ness (thickness of all slides plus the thickness of all spaces between them), and the length of each slit were measured accurately. From these measurements a value of a/d = 2.354 cm (eq. 1) was obtained. By weighing the empty and the water filled disc several times and making use of the previously measured d an independent measure of a was obtained. The value for a/d by this method was equal to 2.317 cm. After calibration of the grating it was cemented with epoxy glue into the bottom of a 45/50 male joint and the joint attached to a 2 l separatory funnel. This funnel filled with 2.00 l makes up the volume of the upper compartment. The female part of the joint was cut off about 1.5 cm below the ground surface, ground to a smooth flat edge, and cemented with epoxy glue to a 3 mm thick, 7.5 cm diameter glass disc. When the upper compartment is inserted into this joint the volume below the grating comprises the volume of the lower compartment. This volume was determined by weighing the cell empty and filled with water to the top of the grating and subtracting the volume of the grating as determined earlier.

If the composition in each compartment is kept constant so that diffusion through the grating governs the overall rate, it can be shown that

$$[1] \qquad \ln(\Delta c/\Delta c_0) = -(a/d)(1/v + 1/V)Dt$$

Δc and Δc_0 are the differences in the specific activities in the two compartments at time t and 0, respectively, v and V are the volumes of liquid, a is the total area, and d the length of the diffusion path. Rearranging, the diffusion coefficient is given by

$$[2] \qquad D = \log(\Delta c_0/\Delta c)/(bt)$$

For the cell described here $b = 0.0667\ \text{cm}^{-2}$.

Preliminary tests showed that the assumption that the composition throughout each compartment is constant is not valid (D for 0.01 M $AgNO_3$ fluctuated between 1.4 and 1.7 $\times$ 10^{-5}). Stirring the solutions gently in both compartments gave more reproducible results.

The experiments were carried out as follows: excess silver solution containing ^{110}Ag tracer was poured into the lower compartment making certain that no air remained trapped below or in the grating. After removing the excess tracer solution the upper compartment was filled slowly with 2.00 l of the desired test solution so as not to cause mixing between the compartments. At least once a day the cell was placed on top of a NaI (Tl activated) crystal and the change in γ-ray activity of the 0.656 MeV peak measured using a single channel pulse height analyzer. Between measurements the cell was placed on a stand which permitted gentle stirring of both compartments. A small magnet in glass turning at about 0.3 r.p.s. in the lower compartment and a rod turning at about 2 r.p.s. in the upper compartment were used for stirring. At the end of an experiment (usually one week) the lower compartment was cleaned and the activity of the solution in the upper compartment, still in the diffusion cell, determined giving the background plus upper compartment activity at the end of the experiment. Background plus initial activity of the upper compartment was determined by measuring the activity of the clean cell filled with inactive solution used for that test. A linear interpolation between the above values was used for inbetween values of the activity in the upper compartment. To ascertain that diffusion rather than mechanical mixing was responsible for the transfer of silver between compartments, a plot of $\log(\Delta c)$ *vs.* t was drawn for each experiment. If the points deviated appreciably from the straight line relationship predicted by the above equation, the experiment was rejected. On the few occasions where it was necessary to reject the experiment, it is believed that the solution in the upper compartment had become more dense than in the lower one because of a thermal gradient set up by heat generated by the magnetic stirrer below the cell. Several typical plots of $\log(\Delta c)$ *vs.* t are shown in Fig. 2. D is calculated from the slope of the straight line drawn through the experimental points.

All experiments were carried out at room temperature which was kept fairly constant near 25 °C. It is estimated that over the course of a week (the length of the average experiment) the error in the diffusion coefficient due to

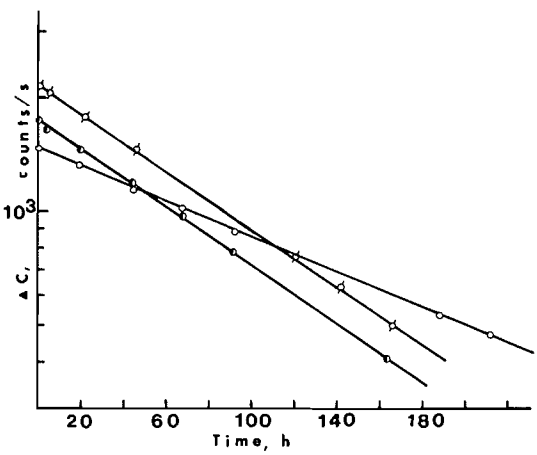

FIG. 2. Relationship between the change in the silver concentration between the cell compartments and time. ○, 0.01 M $AgNO_3$ into H_2O, pH = 0.0; ◐, 0.01 M $AgNO_3$ into H_2O, pH = 3.5; ○, 0.01 M $AgNO_3$ in 0.33 M $Fe(NO_3)_3$ into 0.33 M $Fe(NO_3)_3$, pH = 0.8.

temperature fluctuations was not more than ±3%. Other smaller errors were due to mixing during transport of the cell between counter and stirrers, statistical error in activity measurements (this was easily kept below ±1%), errors in the calibration of the grating, and background interpolations.

Results and Discussion

The results of this work are summarized in Table 1 and Fig. 3. From Fig. 3 we can deduce a bulk-diffusion coefficient of 1.68×10^{-5} cm²/s and a self-diffusion coefficient of 1.48×10^{-5} cm²/s for a 0.01 M $AgNO_3$ solution. These values are in fairly good agreement with those obtained by Whiteway *et al.* (12) using a sintered disc, *i.e.* 1.63×10^{-5} and 1.58×10^{-5}, respectively, except that the difference between the bulk and self-diffusion coefficients as determined in this work is somewhat larger. Other reported values of the diffusion coefficient of Ag^+ range from 1.42×10^{-5} to 1.69×10^{-5} cm²/s (13–17) as determined by the rotating disc and/or the Cottrell method.

The cell described in this report is simple to make, gives absolute diffusion constants, and is simple to use with γ emitting elements. By changing the relative sizes of the two compartments, β emitting elements or nonradioactive elements can be used. In fact, the first working prototype, based on this principle, consisted of two 250 ml beakers facing each other through a grating made from standard 75 × 25 × 1 mm microscope slides which had not been cut or ground at all.

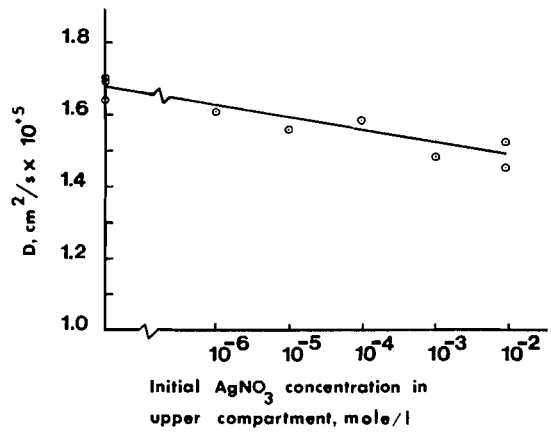

FIG. 3. Relationship between self-diffusion and bulk-diffusion coefficient of silver in aqueous solutions at 25 °C and a pH = 2.0 (initial $AgNO_3$ concentration in lower compartment = 0.01 M).

The use of cements limits its useful life and the type of solutions that can be studied with it. Perhaps a professional glass blower could make such a grating without the use of cements. The cement also offsets somewhat the advantage gained over the sintered disc cell with regard to the adsorption of ions from very dilute solutions.

From the pH series listed in Table 1 a mean

For personal use only.

bulk-diffusion coefficient of $1.64 \pm 0.02 \times 10^{-5}$ cm^2/s for a 0.01 *M* $AgNO_3$ solution is calculated. The hydrogen ion concentration has no noticeable effect on *D* over the p*H* range −0.48 to 7.5 but silver, sodium, iron, and sucrose quite an appreciable one; quite in accord with laws known to govern ionic diffusion processes.

N^{α},N^{im}-Di-*t*-butyloxycarbonyl-L-histidine, N^{α}-benzyloxycarbonyl-N^{im}-*t*-butyloxycarbonyl-L-histidine and poly-L-histidine have been synthesized. The role in peptide synthesis of *t*-butyloxycarbonyl as an imidazole-blocking group is discussed and compared to other currently available imidazole-blocking groups.

On a synthétisé les N^{α},N^{im}-di-*t*-butyloxycarbonyl L-histidine, N^{α}-benzyloxycarbonyl N^{im}-*t*-butyloxycarbonyl L-histidine et poly-L-histidine. On discute du rôle dans les synthèses peptidiques du groupe *t*-butyloxycarbonyl pour bloquer l'imidazole et on le compare avec celui que peuvent jouer d'autres groupes qui sont disponibles présentement pour remplir cette fonction.

Canadian Journal of Chemistry, 49, 1578 (1971)

One of the main requirements associated with the synthesis of histidine-containing peptides has been the selection of a suitable protecting group for the imidazole nitrogen of the amino acid. A useful protecting group should satisfy a number of requirements such as ready availability, stability to the manipulations needed to purify the blocked peptides, stability to the removal conditions of some N and C protecting groups to assure conventional stepwise peptide synthesis, and the selective removal of the protective group under conditions that will not lead to racemization or to the destruction of labile peptide bonds. In addition, it is of great importance that the basicity of the imidazole nitrogen will be minimized while protected.

The benzyl group (1) has been used most often

bulk-diffusion coefficient of $1.64 \pm 0.02 \times 10^{-5}$ cm^2/s for a 0.01 *M* $AgNO_3$ solution is calculated. The hydrogen ion concentration has no noticeable effect on *D* over the p*H* range −0.48 to 7.5 but silver, sodium, iron, and sucrose quite an appreciable one; quite in accord with laws known to govern ionic diffusion processes.

for the protection of the imidazole (im)[3] of histidine but it does not mask the basicity of the ring. In addition, the use of sodium in liquid ammonia for the removal of the benzyl group is drastic, leading in some cases to the cleavage of peptide bonds (2). Removal of the benzyl group from the imidazole group effected by catalytic hydrogenation is very slow, and impossible when sulfur-containing amino acids are present in the peptide. The im-benzyloxycarbonyl (Cbz) group (3) is very labile to basic conditions and to various nucleophilic reagents. Thus the reaction of N^{α},N^{im}-di-Cbz-L-histidine *N*-hydroxysuccinimide ester with L-alanine in a mixture of water and dioxane in the presence of two equivalents of $NaHCO_3$ led to the formation of dipeptide with a free imidazole group.[4] The new imidazole-protecting groups 2,2,2-trifluoro-1-benzyloxycarbonylaminoethyl (4) and 2,2,2-trifluoro-1-butyloxycarbonylaminoethyl (4) which are removed from imidazole by strong acids, the dinitrophenyl which is removed readily from imidazole by thiolysis (5), and the piperidinocarbonyl (6) which is labile to basic conditions and stable to acids, are most promising. However, little information on their use in peptide synthesis is available. The use of *t*-butyloxycarbonyl (*t*-Boc) as an imidazole-blocking group has been briefly described (7, 8). Some further properties of this blocking group have been investigated and its role as a blocking group is discussed.

N^{α},N^{im}-Di-*t*-Boc-L-histidine was obtained in 50% yield on reacting histidine with *t*-Boc azide in the presence of MgO (9). The im-*t*-butyloxycarbonyl (*im*-Boc) group could be removed by strong acids such as HBr in trifluoroacetic acid, HBr in acetic acid, or anhydrous HF, however it is stable to the action of HCl in dioxane. It would thus appear to be compatible with the *t*-Boc or nitrophenylsulfenyl α-amino protecting groups. In addition the *im*-Boc group was found to be much more stable towards alkali than *im*-Cbz group (3, 8). Thus when N^{α},N^{im}-di-*t*-Boc-L-histidine *N*-hydroxysuccinimide ester was coupled with L-alanyl-γ-benzyl-L-glutamic acid the corresponding di-Boc-tripeptide was obtained[4] in 80% yield. Moreover, the basicity of the imidazole ring was reduced markedly by its protection with the *t*-Boc group, since various derivatives such as N^{α},N^{im}-di-*t*-Boc-L-histidine or N^{α}-Cbz-N^{im}-*t*-Boc-L-histidine were not soluble in dilute aqueous acid solutions.

Poly-L-histidine has, in the past, been synthesized by polymerizing N^{im}-benzyl-L-histidine *N*-carboxylanhydride (10). The benzyl group was subsequently removed by treatment with sodium in liquid NH_3. We wish to report here the use of the new imidazole-protecting group, *im*-Boc, in the synthesis of this polymer.

The synthesis of poly-L-histidine is summarized in Scheme 1: N^{im}-*t*-Boc-L-histidine *N*-carboxylanhydride hydrochloride (**2**), prepared from N^{im}-*t*-Boc-N^{α}-Cbz-L-histidine (**1**), was converted to the free base **3** and polymerized in dioxane, using triethylamine as initiator. The blocked polymer, poly-N^{im}-*t*-Boc-L-histidine (**4**), with an average molecular weight of 21 000 as determined by its sedimentation and diffusion constants in dimethylformamide, assuming a partial specific volume ($\bar{v}$) of 0.75, was converted to poly-L-histidine hydrobromide (**5**) with HBr in trifluoroacetic acid.

From these preliminary studies one can conclude that the *t*-Boc blocking group on the imidazole ring has several advantages: (*i*) availability, (*ii*) ease of synthesis, (*iii*) ease of removal with no chance of racemization since carried out under anhydrous HBr treatment, (*iv*) the insolubility of *im*-Boc histidine peptides in aqueous acid solution indicates decreased basicity which results in higher yields in peptide synthesis illustrated by the large poly-L-histidine molecule synthesized (average degree of polymerization is approximately 100 compared to 50 obtained when the imidazole-blocking group was benzyl (10), and (*v*) stable to methods of purification.

Experimental

All melting points are uncorrected. Prior to analysis the compounds were dried at room temperature *in vacuo* over phosphorus pentoxide and NaOH.

N^{α},N^{im}-Di-t-butyloxycarbonyl-L-histidine

Histidine hydrochloride (31.5 g, 0.164 mol) was dissolved in 480 ml of water and added to a solution of *t*-butyloxycarbonyl azide (70 g, 0.49 mol) in 480 ml of dioxane. Magnesium oxide (24 g, 0.62 mol) was then added and the mixture was stirred for 4 days at room temperature. The excess MgO was filtered and the solution was evaporated in high *vacuo* (~25 °C). The oily residue obtained was dissolved in 100 ml of water, cooled

[3]Abbreviations: imidazole, im; benzyloxycarbonyl, Cbz; *t*-butyloxycarbonyl, *t*-Boc; im-*t*-butyloxycarbonyl, *im*-Boc.

Boc = $(CH_3)_3COCO-$; Cbz = $C_6H_5CH_2OCO-$

SCHEME 1

to 0 °C, and acidified with 50% aqueous citric acid. The oily product was extracted into ethyl acetate, the organic solution dried over Na_2SO_4, filtered, and evaporated *in vacuo* to give a colorless amorphous solid; 29 g (50% yield). All attempts to crystallize the product were unsuccessful; m.p. 70° (starts to soften slowly at 53°); $[\alpha]_D^{23}$ +13.9 (*c* 1.1, methanol).

Anal. Calcd. for $C_{16}H_{25}N_3O_6$: C, 54.07; H, 7.09; N, 11.83. Found: C, 54.77; H, 7.37; N, 11.85.

Neutralization equivalent Calcd.: 355. Found: 349, determined by anhydrous titration with sodium methoxide (11); 365, determined by anhydrous titration with perchloric in acetic acid (12).

N^{im}-t-Butyloxycarbonyl-N^{α}-benzyloxycarbonyl-L-histidine

Compound **1** was prepared similarly to the above compound on reaction of N^{α}-benzyloxycarbonyl-L-histidine (3) with *t*-butyloxycarbonyl azide in presence of MgO. Yield of amorphous solid 50%; m.p. 80° (starts to soften slowly at 55°); $[\alpha]_D^{23}$ +16.5 (*c* 1, methanol).

Anal. Calcd. for $C_{19}H_{23}N_3O_6$: C, 58.60; H, 5.95; N, 10.79. Found: C, 59.29; H, 5.75; N, 11.13.

Neutralization equivalent Calcd.: 389. Found: 380 (12) and 383 (11).

N^{im}-t-Butyloxycarbonyl-L-histidine N-Carboxylanhydride Hydrochloride (2)

To a solution of N^{im}-*t*-butyloxycarbonyl-N^{α}-benzyloxycarbonyl-L-histidine (**1**) (1.1 g, 2.8 mmol) in 10 ml of dioxane, thionyl chloride (0.64 ml, 8.5 mmol) was added. The mixture was then stirred at room temperature when the anhydride hydrochloride started to precipitate from the reaction mixture after 30 min. Stirring was effected for an additional 4 h. The product was filtered, and washed with dioxane and ether. It was then suspended in dry acetone, stirred for 15 min, and absolute ether was added. Compound **2** was filtered, washed with ether, and dried *in vacuo* over P_2O_5 and NaOH. Yield 0.80 g (90%); m.p. 260–265° dec. (evolution of CO_2 starts slowly at 200 °C); $[\alpha]_D^{25}$ −34.0 (*c* 1.1, dimethylformamide).

Anal. Calcd. for $C_{12}H_{16}O_5N_3Cl$: C, 45.36; H, 5.08; N, 13.23; Cl, 11.5. Found: C, 44.71; H, 4.81; N, 13.41; Cl, 10.97.

Mol. Wt. Calcd.: 317.6. Found: 330 (11), assuming the presence of two titrable groups per molecule.

Poly-N^{im}-t-butyloxycarbonyl-L-histidine (4)

The anhydride **2** (1 g, 2.5 mmol) was dissolved in dry acetone (75 ml) and dry silver oxide (1 g) was added. The mixture was stirred until it showed negative in a chloride test (~15 min) and then the AgCl and excess of Ag_2O was filtered, washed with acetone, and the combined filtrate and washings were evaporated in high *vacuo* (~30 °C) to yield the neutral anhydride **3**. The oily anhydride **3** was dissolved in absolute dioxane (10 ml) and triethylamine (0.004 ml, 28.8 μmol) was added as an initiator. The polymerization proceeded at room temperature with evolution of CO_2 and a slight precipitate of polymer **4** appeared. After 4 days absolute ether (50 ml) was added, and the polymer which was thus precipitated was filtered, washed with ether, and dried *in vacuo* over P_2O_5 and NaOH. Yield 0.47 g (80%); $[\alpha]_D^{25}$ −8.2 (*c* 0.88, dimethylformamide).

Anal. Calcd. for $(C_{11}H_{15}N_2O_3)_n$: C, 55.68; H, 6.37; N, 17.71. Found: C, 55.63; H, 6.46; N, 17.65.

Neutralization equivalent Calcd.: 237. Found: 242 (12).

The polymer **4** obtained as above is soluble in chloroform, dimethylformamide, acetic acid, 50% aqueous acetic acid, and methanol.

Poly-L-histidine Hydrobromide (5)

Poly-N^{im}-*t*-butyloxycarbonyl-L-histidine (0.24 g, 1 mmol) was dissolved in anhydrous trifluoroacetic acid (10 ml) and HBr gas was passed through the solution for 90 min. The trifluoroacetic acid was removed in high *vacuo* (30° C) and the residue was triturated with dry ether, ethyl acetate and petroleum–ether (b.p. 30–60 °C) and dried *in vacuo* over NaOH and P_2O_5. Yield 0.2 g (90%); $[\alpha]_D^{25}$ −19.3 (*c* 0.6, water).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Anal. Calcd. for $(C_6H_8N_3OBr)_n \cdot n/2\ H_2O$: C, 31.73; H, 4.00; N, 18.50. Found: C, 31.45; H, 4.10; N, 18.00.

Neutralization equivalent Calcd.: 227. Found: 218, determined by titration of the bromide ions (13).

N^{im}-t-Butyloxycarbonyl-L-histidine Dihydrochloride

N^{α},N^{im}-Di-*t*-butyloxycarbonyl-L-histidine was dissolved in 2 *N* HCl in dioxane and after 5–10 min a white precipitate was formed. After another 45 min the mixture was triturated with absolute ether, the precipitate filtered, washed with ether, and dried over NaOH and P_2O_5 *in vacuo*: yield 87%.

Anal. Calcd. for $C_{11}H_{19}N_3O_4Cl_2$: N, 12.80; Cl, 21.65. Found: N, 12.83; Cl, 21.21.

Mol. Wt. Calcd.: 328. Found: 330 (11) assuming the presence of three titrable groups per molecule, and 336 (13) assuming the presence of two titrable groups per molecule.

On reactions of N^{α},N^{im}-di-*t*-butyloxycarbonyl-L-histidine with HBr in TFA or in acetic acid the dihydrobromides of histidine were obtained as shown by paper electrophoresis and nonaqueous titrations.

ET

LOUIS VARFALVY

Département de Chimie, Université de Montréal, Montréal, Québec

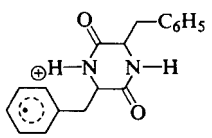
Reçu le 9 novembre, 1970

On rapporte le spectre de masse de la dibenzyl-3,6 dicéto-2,5 pipérazine. On propose et discute un mécanisme général pour expliquer les principaux modes de fragmentation.

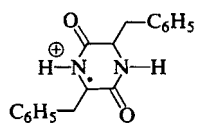
The fragmentation of 3,6-dibenzyl, 2,5-diketo piperazine in the mass spectrometry is presented. The general mechanism is proposed and discussed.

Canadian Journal of Chemistry, 49, 1583 (1971)

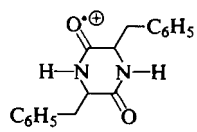
Nos deux dernières publications (1, 2) dans cette série nous a amené aux quelques conclusions générales concernant la fragmentation des dicéto-2,5 pipérazines dans la spectroscopie de masse. La fragmentation de la dibenzyl-3,5 dicéto-2,5 pipérazine (**1**) (anhydride de la phénylalanine) a démontré quelques particularités. D'abord ce produit possède trois centres facilement ionisables: deux hétéroatomes et les noyaux benzéniques. Les trois ions moléculaires formés sont donc par ordre d'importance: **A**, **B**, **C**. On peut noter



A



B



C

[1]Pour les parties I et II voir réfs. 1, 2.

SCHÉMA 5

de nouveau, tout comme pour les anhydrides de la glycine et de l'alanine (1, 2) l'absence totale de fragment correspondant à $P^{\oplus}$-1, et la présence d'ion moléculaire assez abondant (25.5%) (tableau 1).

Ionisation du noyau benzénique conduit aux fragments les plus abondants. Cette ionisation conduit aux fragments connus (4) (schéma 1).

Le transfert de l'hydrogène γ a été supporté par l'obtention des ions 93 et 94 pour le produit **1** *N*-deutérié. On retrouve également le fragment $C_6H_7^{\oplus}$ (*m/e* 79, 0.6%) caractéristique pour le noyau substitué (5).

La fragmentation de schéma 2, élimination d'une molécule d'acéthylène à partir d'ion tropylium, a été supporté par les ions métastables.

Les fragmentations intenses à partir d'ion moléculaire **A** ont dérangé l'interpretation.

A partir de l'ion moléculaire **B** (ionisation de l'azote) on observe uniquement quatre fragments plus intense que 4%. D'abord, avec clivage de la liaison α on observe le transfert d'hydrogène β ou γ (ou γ'), schéma 3.

On peut envisager de différentes façons la formation du fragment à *m/e* 103; surtout qu'on donne les fragments à 104 ($C_8H_8^{\oplus}\cdot$), schéma 4.

SCHÉMA 8

La fragmentation de schéma 5 par clivage de la liaison en α d'azote suivi de rupture simple de liaison.

Le fragment **B**-2 donne par la suite 118, 42, et 28 correspondant aux pertes du H·, C_6H_5·, ou radical benzyl. Les fragments 203, 119, et 118 sont spécifiques pour cette sorte du clivage. Le passage du fragment **B** au **B**-1 est supporté par le pic métastable donné à 140.3 (calculé 140.14).

Ouverture du cycle par clivage de la liaison β

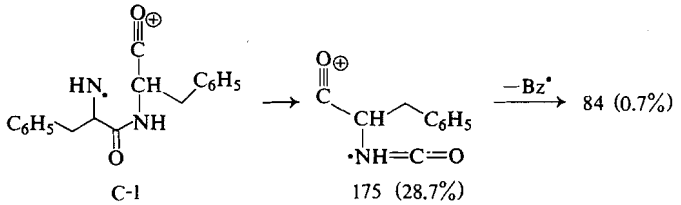

SCHÉMA 9

suivie de la rupture simple des liaisons ne donne aucun pic unique sauf le pic à *m/e* 175, schéma 6.

Les fragments $\overset{\oplus}{N}H{=}\dot{C}O$ ou $\overset{\oplus}{N}\dot{H}_2{=}CO$ (43 et 44) peuvent être également obtenu à partir de la structure **B**-3. Les clivages de la liaison en β de l'azote chargé donne naissance aux fragments déjà observés 147 et 148 (1, 2) suivi par les fragments avec une perte du H·, $\cdot CH_2C_6H_5$, schéma 7.

L'ionisation de l'oxygène du groupement carboxylique donne deux intermédiaires lesquels sont mis en évidence par les fragments de schéma 8.

La fragmentation 132, 131, 130 est analogue à celle pour les *N*-trifluoro acétyl phénylalanate de méthyle (7).

On peut former le fragment 175 à partir de la structure précédente, schéma 9.

Toutefois la fragmentation avec une perte du radical benzyl (203) et le fragment 147 peuvent être également obtenu à partir de cette structure. Une perte du CO, accompagnée par un transfert de charge, conduit à l'obtention du fragment à *m/e* 147, schéma 10.

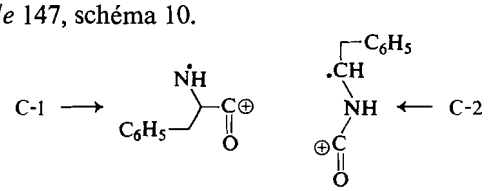

SCHÉMA 10

$\frac{M^{\oplus}}{2} + 1 = 148$

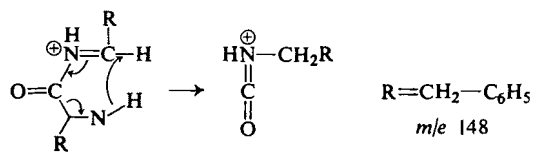

SCHÉMA 11

On a observé aussi le réarrangement qui donne un pic à *m/e* 57 + R. Ce réarrangement est également caractéristique pour les anhydrides de la glycine (à 58) et alanine (à 72) (1). La formule générale du réarrangement est donnée par schéma 11.

Le réarrangement analogue est observé pour les peptides et certains amides (8). Autres fragments non expliqués sont d'intensité plus petite que 3%.

Partie expérimentale

Les spectres de masse ont été enregistrés avec l'aide d'un appareil Hitachi RMU-6D et Picker–AEI MS-30 (200°, 70 eV). La dibenzyl-3,6 dicéto-2,5 pipérazine (**1**) p.f. 279–285° (9) a été obtenu par la cyclisation du NH_2-PhePheOC_2H_5 ou par la dimérisation du phénylalanate d'éthyle dans l'éthylène glycol (1). Le produit **1** a été libéré des fractions polymères par la recristalisation. La phénylalanine racémique a été utilisée. La présence des ions metastables a été prouvée par les méthodes habituellement utilisées.

Orientation in the Crossed Aldol Condensation of Chloral with Unsymmetrical Aliphatic Ketones

EBERHARD KIEHLMANN AND PUI-WAH LOO
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received November 9, 1970

The reactivity of a series of 14 aliphatic ketones in the crossed aldol condensation with chloral has been studied in glacial acetic acid and in dimethoxyethane. The reaction is irreversible and not accompanied by dehydration of the resulting 1,1,1-trichloro-3-hydroxy-4-alkanones. Except for butanone, condensation occurs preferentially at the least-hindered position of an unsymmetrical ketone. The α-methyl/α-methylene condensation product ratio obtained from ketones of the general formula RCH_2COCH_3 is higher in acetic acid than in dimethoxyethane as solvent when sodium acetate is used as catalyst. The steric size and chain length of the alkyl groups of methyl alkyl ketones have a marked effect on the reactivity of the α-methyl group toward chloral. Condensation at the α-methylene group results in the formation of diastereomeric ketols which epimerize under the preparative reaction conditions.

On a étudié la réactivité, dans l'acide acétique et dans le diméthoxyéthane, d'une série de quatorze cétones aliphatiques vis à vis le chloral et conduisant à des produits d'aldolisation mixtes. La réaction est irréversible et les trichloro-1,1,1 hydroxy-3 alcanones-4 formées ne se déshydratent pas. Dans le cas des cétones non symétriques la condensation se fait généralement au niveau de la position la moins empêchée; la butanone est toutefois une exception. Lorsque l'acétate de sodium est utilisé comme catalyseur les quantités de produits provenant d'une condensation sur le méthyle en α par rapport au méthylène α dans des cétones de formule générale RCH_2COCH_3 sont plus grandes dans l'acide acétique que dans le diméthoxyéthane. L'effet stérique et la longueur de la chaîne alkylée des méthylalkylcétones ont un effet marqué sur la réactivité du groupe méthyle sur le chloral. La condensation du chloral sur la position méthylénique conduit à la formation de cétols diastéréoisomères qui s'épimèrisent lorsque des conditions de réaction préparative sont utilisées.

Canadian Journal of Chemistry, 49, 1588 (1971)

Of the numerous reactions leading to the formation of new carbon-to-carbon bonds, the aldol condensation has been studied most extensively. The mechanism of this reaction, scope and limitations, experimental conditions and procedures, and a tabular survey (by reactants) of the literature data through August 1966 have been the subject of a recent comprehensive review by Nielsen and Houlihan (1). Although kinetic and deuterium exchange experiments in protic solvents have firmly established a two-step enolization–addition mechanism, frequently followed by dehydration, for both the acid-catalyzed and the base-catalyzed reaction (2), relatively little is known on the factors determining the orientation of the crossed aldol condensation of aldehydes with unsymmetrical aliphatic ketones, *i.e.*, the relative reactivities of the α-methyl group (C-1) and the α-methylene or α-methine group (C-3) of ketones of the general formula $CH_3COCHRR'$ (R = alkyl, R′ = H or alkyl) toward an aldehydic carbonyl group under kinetically controlled conditions (3, 4).

The reason for the paucity of systematic studies of the effects of ketone structure, aldehyde structure, catalyst, and solvent on the ratio of the isomeric crossed condensation products (ketol *c*/sum of ketols *a* and *b*, Scheme 1) appears to be threefold:

(*a*) The complexity of the reaction sequence makes it extremely difficult to obtain rate constants for all individual steps involved, especially since it has been shown by Noyce and Snyder (5) and Stiles *et al.* (6) that the condensation of certain aromatic aldehydes with butanone is reversible, and that ketol dehydration may be the product-determining step. Thus, neither the ratio of isomeric ketols nor the ratio of isomeric enones were found to be valid measures of the relative reactivities of the two α-carbons of an unsymmetrical ketone toward an aldehydic carbonyl group in these specific cases.

(*b*) The quantitative determination of the ratio of isomeric crossed aldol condensation products is further complicated by the formation of by-products due to self-condensation of aldehydes and ketones containing α-hydrogens. Since isomeric β-ketols differ very little in their spectro-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

scopic properties, spectroscopic methods are not suitable for analytical measurements.

(*c*) Although the aldol addition step is believed to be preceded by enolization, few systematic studies have been reported on the equilibrium composition of enol and/or enolate mixtures formed from ketones of the general structure $CH_3COCHRR'$, and on the relative rates of enolization toward C-1 and -3. The extensive data published by House (7) on relative enolate stabilities in 1,2-dimethoxyethane permit qualitative conclusions on the orientation of base-catalyzed enolization in aprotic solvents. However, attempts to formulate similar rules for the orientation of enolization in protic solvents have met with limited success since the relative rates of deuteration or halogenation[1] at C-1 *vs.* C-3 of $CH_3COCHRR'$ have been found to depend not only on the structure of R and R′ but also on the catalyst and the solvent (10–13).

In the course of our studies on the synthesis and properties of 1,1,1-trichloro-2-hydroxy-4-alkanones we have found that the crossed aldol condensation of chloral with aliphatic ketones is effectively irreversible and not accompanied by dehydration or other side reactions (14, 15). The resulting β-ketols were found to be thermally stable thus permitting determination of the isomer distribution by gas chromatography. On account of these desirable characteristics, we undertook a systematic investigation of the effect of ketone structure and reaction conditions on the composition of the product mixture of isomeric 1,1,1-trichloro-2-hydroxy-4-alkanones in order to gain further insight into the factors determining the orientation in crossed aldol condensations of aldehydes with unsymmetrical aliphatic ketones under kinetically controlled conditions.

Results and Discussion

The condensation of chloral with aliphatic ketones has been reported to give 1,1,1-trichloro-2-hydroxy-4-alkanones in satisfactory yields in glacial acetic acid or propionic acid as solvent and in the presence (14) or absence (16) of the corresponding sodium or potassium carboxylate as catalyst; chloral hydrate is known to undergo the same reaction when acetic anhydride and sodium acetate are used as solvent and catalyst, respectively (15, 17).

In order to optimize the yield of the desired ketol and to minimize the formation of by-products, the condensation of chloral with 4-methyl-2-pentanone as model compound (14) was reinvestigated in a variety of solvent/catalyst systems as well as at various temperatures and reagent concentrations. Dipolar aprotic solvents (DMSO, DMF, and pyridine) and sodium acetate gave large quantities of unidentified black products together with small amounts (yield $< 5\%$) of the desired ketol **6***c*. Dimethyoxyethane (DME)/sodium acetate, acetic acid/sodium acetate and acetic acid (no added base catalyst) were found to be satisfactory to warrant their use for quantitative studies of ketol product ratios as a function of ketone structure.

Gas-chromatographic measurements of the product yield as a function of time (in the acetic acid/sodium acetate system) and graphic determination of the limiting slope at 20% completion of the reaction (for details, see Experimental, kinetic procedures) have shown that the limiting rate of product formation increases approximately linearly with increasing catalyst concentration (Fig. 1). The large positive intercept of this line and the observed ketol formation (although at a slower rate) in the absence of sodium acetate suggest that the reaction is also catalyzed by acetic acid. Although it was shown by further kinetic experiments that the initial rate of ketol formation increases as the temperature is raised (Fig. 2) and as the molar ratio ketone/chloral is increased from 1.00 to 1.50, the following reaction conditions were chosen for subsequent studies with other ketones in order to minimize discoloration due to by-product formation: molar ratio of ketone/chloral/solvent (HOAc or DME)/NaOAc 1.25:1.00:2.00:0.25, temperature 100°, and reaction time 52 h. No significant amounts ($\leq 0.5\%$ if any) of ketol dehydration products and only traces of other by-products were detected by v.p.c. analysis of the crude product mixtures under these conditions.

Kinetic control of the condensation reaction, as suggested by Reeve and Kiehlmann (14), was demonstrated by several types of experiments.

[1]Recent experiments by Rappe (8, 9) on the competitive acid-catalyzed halogenation and deuteration of butanone indicate that, contrary to the generally accepted mechanism, halogenation is not always preceded by rate-determining enolization, *i.e.*, literature reports on enolization kinetics as determined by halogenation experiments must be considered with caution!

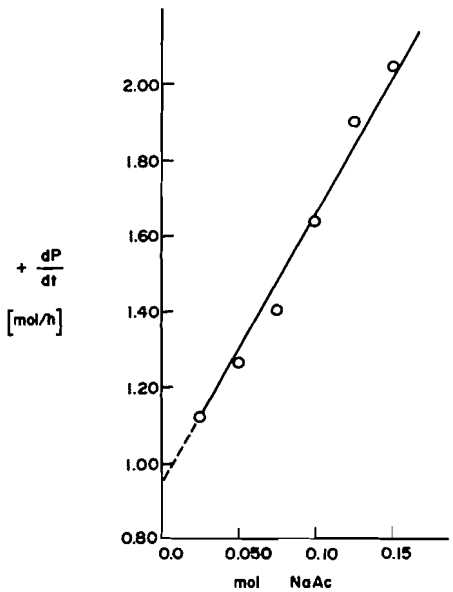

FIG. 1. Effect of catalyst concentration on limiting rate of product (**6***c*) formation. Initial reagent quantities: 0.80 mol chloral, 1.05 mol 4-methyl-2-pentanone, 0.20 mol **6***c*, 2.00 mol HOAc, temperature 100 ± 0.02 °C.

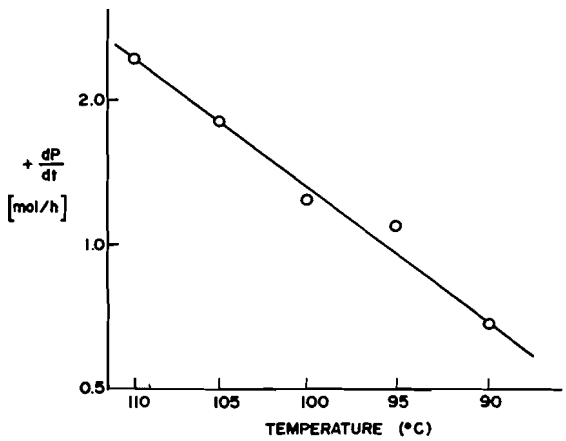

FIG. 2. Effect of temperature on limiting rate of product (**6***c*) formation. Initial reagent quantities: 0.80 mol chloral, 1.05 mol 4-methyl-2-pentanone, 0.20 mol **6***c*, 2.00 mol HOAc, 0.050 mol NaOAc.

involving three different unsymmetrical ketones and their respective chloral condensation products. When pure 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**6***c*) was dissolved in glacial acetic acid and heated at 100° for 15 h in the presence of anhydrous sodium acetate, no 4-methyl-2-pentanone was formed as shown by v.p.c. of the reaction mixture on a Reoplex-400 column at 70°. Ninety percent of the starting material was recovered. No 1,1,1-trichloro-2-hydroxy-3-isopropyl-4-pentanone (isomeric condensation product) was detected in this experiment or in any crude product mixture resulting from the condensation of chloral with 4-methyl-2-pentanone.

Essentially the same result was obtained when mixtures of 1,1,1-trichloro-2-hydroxy-4-hexanone (**2***c*) and the two diastereomeric 1,1,1-trichloro-2-hydroxy-3-methyl-4-pentanones (**2***a* and *b*) containing the three isomeric ketols in various molar ratios were subjected to the preparative reaction conditions: no butanone was formed, 85% of the starting material was recovered after 15 h at 100°, and the ratio of the structural isomers, **2***c*/(**2***a* + **2***b*), remained constant within experimental error. However, the two diastereomeric ketols **2***a* and *b* were found to epimerize slowly via a common enol intermediate (Scheme 1). The v.p.c. analysis of the reaction mixture obtained from chloral and butanone under standard conditions, determination of the total yield of isomeric ketols (**2***a*, *b*, and *c*) formed and empirical comparison of the butanone peak areas before and after the reaction revealed a 94% yield of the desired condensation products based on the amount of ketone consumed. This product balance is considerably higher than the 80% yield reported by Reeve and Kiehlmann for the reaction of chloral with 4-methyl-2-pentanone (14) and provides further evidence that chloral-ketone condensations and the interpretation of the isomeric product ratios are not complicated by retrogression, dehydration, or other undesirable side reactions.

Finally, kinetic studies of the reaction of chloral with 2-heptanone have shown that the ratio of isomeric ketols (78:22) formed by condensation of chloral at C-1 and -3, respectively, does not change as the reaction proceeds (based on 16 kinetic assays taken over a period of 27 h which correspond to 42% completion of the reaction). Since 1,1,1-trichloro-2-hydroxy-4-nonanone (**5***c*) does not isomerize to 1,1,1-trichloro-2-hydroxy-3-(*n*-butyl)-4-pentanone (**5***a* and *b*) under the preparative reaction conditions, this result clearly demonstrates that the condensation reaction is irreversible and that the observed ratio of struc-

turally isomeric ketols reflects the relative reactivities of the α-methylene and the α-methyl group of 2-heptanone toward chloral.

On the basis of these preliminary results, the orientation in the crossed aldol condensation of chloral with 14 aliphatic ketones was studied by quantitative determination of the ratios of isomeric ketols formed under standard conditions of time, temperature, and reagent concentration before completion of the reaction. The results are summarized in Tables 1 and 2.

Although the methyl condensation products of all ketones listed (except **7***c*) have been described in the literature (14–19), the formation and separation of diastereomeric products resulting from the condensation of chloral at the α-methylene group of butanone, 3-pentanone, and cyclohexanone was not reported until 1969 (15). In agreement with the results of configurational and hydrogen-bonding studies reported for these three ketones (15), the low-boiling isomer of each diastereomeric pair (designated "*a*") listed in Tables 1 and 2 has been found to exhibit strong intramolecular hydrogen bonding. The melting points reported by Caujolle *et al.* (17) for the methylene condensation products of butanone, 3-pentanone, and cyclohexanone with chloral indicate that these authors had obtained only the

high-melting (and less volatile) diastereomer in pure form. Although Mastagli and de Champs (19) have recently described a "chelated" and a "non-chelated" isomer of 1,1,1-trichloro-2-hydroxy-3-methyl-4-pentanone (**2***a* and *b*), they have characterized the methylene condensation products of chloral with 2-pentanone and 2-hexanone, respectively, as homogeneous liquids and thus failed to detect the presence of two diastereomers in each case. The same applies to the single chloral-butanone condensation product described by Baluja *et al.* (18). We conclude from this analysis of the literature that **3***a*, **4***a*, **5***a*, **5***b*, **7***c*, **8***a*, **8***b*, **10***a*, **10***b*, **11***a*, **11***b*, **12***a*, and **12***b* are new compounds which have not been characterized before.

Analysis of the percentage yields of the various condensation products listed in Tables 1 and 2 reveals certain trends which permit qualitative conclusions to be drawn with respect to the reaction mechanism.

A comparison of the product yields obtained from the first four ketones in the homologous series $CH_3(CH_2)_nCOCH_3$ shows that methyl condensation becomes more facile as *n* increases from one (31.7% yield) to four (53.3%). Excepting butanone (*vide infra*), the same general trend of increasing reactivity with increasing alkyl chain length is observed for the α-methylene groups. Wamhoff and coworkers (20) have reported similar results for the enol content of acetoacetic esters substituted in the α- or γ-position by alkyl groups of varying chain lengths. They have explained this phenomenon by postulating a high density of σ-electrons at the end of a paraffin chain and delocalization of these electrons into the π-orbital of the enolic C=C double bond which leads to increasing resonance stabilization with increasing alkyl chain length. This analogy suggests that relative enol stabilities (and/or enolization rates) are a determining factor in the crossed aldol condensation of chloral with straight-chain aliphatic methyl ketones.

The effect of alkyl branching on the reactivity of the α-methyl group of aliphatic methyl ketones toward chloral confirms the above conclusion. The data of Table 1 show that the rate of condensation of chloral at the α-methyl group increases from R = *n*-propyl (41.8% yield) via isopropyl (61%) to *t*-butyl (74%) for CH_3COCH_2R, and from R′ = ethyl (31.7%) via isopropyl (38%) to *t*-butyl (48%) for CH_3COR'. Delocalization of the σ-electrons of the alkyl group leads to favorable resonance interaction with the enolic system, and the stability of the 1-enol increases in the indicated order. If one assumes that the energy of activation for the addition of chloral at the unhindered methylene carbon of the 1-enol changes insignificantly from one methyl ketone to another, increasing enol stability would be expected to lead to an increased overall condensation rate.

The observed reactivity sequence is in qualitative agreement with the order of acid-catalyzed deuteration rates reported by Rappe and Sachs (21) for alkyl-substituted methyl ketones but opposite to the order of base-catalyzed deuteration rates of the corresponding ketones (10, 12). We conclude that the mechanism of the acetate-catalyzed condensation of chloral with aliphatic ketones in glacial acetic acid has the characteristics of an acid-catalyzed reaction, and that the transition state of the initial enolization step closely resembles the intermediate enol (22) rather than a negatively charged enolate ion.[2]

It should be pointed out that these trends, as noted by Rappe and Sachs (21), are opposite to what would be predicted on the basis of hyperconjugative enol stabilization. We are presently studying deuteration rates of aliphatic methyl ketones under experimental conditions similar to those employed for the crossed aldol condensation in order to determine whether the formation of 1-enol is the rate-determining step in the enolization–addition sequence.

A qualitative comparison of the relative reactivities of the α-methylene group in ketones of the type CH_3COCH_2R indicates that in most cases the rate of chloral addition is comparable to or slower than the rate of enolization. The reactivity of the methylene group of monoalkyl-substituted acetones drops off rapidly with increasing bulk of the alkyl substituent, *e.g.*, from butanone (R = CH_3, 40.3% yield of ketol) via 2-pentanone (R = Et, 12.2%) to 4-methyl-2-pentanone (R = *i*-Pr, 0%) and 4,4-dimethyl-2-pentanone (R = *t*-Bu, 0%). 3-Methyl-2-butanone, the only 1,1-disubstituted acetone tested, reacts exclusively at the α-methyl group. Apparently the

[2]A study of the relative rates of base-catalyzed enolization of butanone led Warkentin and Tee (11) to suggest that even with bases as strong as $OD^{\ominus}$ in D_2O, the α-carbon does not bear negative charge at the transition state.

aforementioned electron-releasing effect of alkyl groups which leads to increased stabilization of the enol relative to the keto form with an increasing number of carbon atoms in the alkyl residue is superimposed on and swamped by a rate-retarding steric effect in the case of methylene condensation. The same rapid reactivity decrease, in the order shown above, has been reported by Rappe, Warkentin, and coworkers for the acid-catalyzed (21) and base-catalyzed (10,12) deuteration of the α-methylene carbon of methyl alkyl ketones in aqueous solution, and by Wesslén (23) for the acid-catalyzed condensation of formaldehyde at the α-methylene group of methyl alkyl ketones in glacial acetic acid as solvent. These authors have interpreted this behavior in terms of steric hindrance to enolization and of decreasing hyperconjugative stabilization of the "3-enol", $RCH{=}C(OH)CH_3$, with increasing substitution at the β-carbon of butanone.

The failure of the methylene group of 4-methyl-2-pentanone and 4,4-dimethyl-2-pentanone to react with chloral indicates that there is also severe steric hindrance to the addition of chloral at the methylene carbon. When the condensation of chloral with 4,4-dimethyl-2-pentanone was performed in deuterated acetic acid (CH_3COOD) and the condensation product was analyzed by mass spectrometry at 80 meV, a five-fold increase in the $(m + 1)/m$ intensity ratio (1.37) was observed for both the $C_5H_{11}^{\oplus}$ cation and the $(CH_3)_3CCH_2CO^{\oplus}$ acylium ion, relative to the corresponding ratio (0.072) measured for a product sample prepared in non-deuterated acetic acid. Thus deuterium exchange at the methylene group occurs at a measurable rate under the experimental conditions of the crossed aldol condensation. We conclude that both the enolization, as measured by deuteration rates, and the chloral addition step are slow, and that the addition step is rate-determining in the case of ketones with bulky alkyl substituents. The observation by Wesslén (23, 24) that acid-catalyzed deuteration of the methylene carbon of butanone in glacial acetic acid occurs faster than addition of formaldehyde at the same position provides further support for this interpretation. The finding that a significant amount of formaldehyde condenses at the methylene carbon of 4-methyl-2-pentanone (23) and the detection of a trace amount of the methylene condensation product of fluoral with the same ketone under comparable reaction conditions indicate that the overall condensation rate is also retarded by bulky substituents (CF_3, CCl_3) on the aldehydic carbon.

It can be seen from Table 1 that the condensation of chloral at the methylene carbon of the ethyl groups of butanone, 3-pentanone, and 3-heptanone, respectively, is especially facile. Warkentin and Barnett (12), who observed the same phenomenon for deuteration rates, have attributed this exceptionally high reactivity of the methylene group of butanone to a rate-accelerating polar effect of the alkyl group which "opposes the steric effect and is swamped by it in all the ketones except butanone". Our data extend this interpretation to other ethyl alkyl ketones and suggest that in these cases of minor steric hindrance to addition, the enolization step is product-determining. In all other cases, kinetic control favors formation of the least-substituted enol (7) and chloral addition at the least-substituted α-carbon.

The data listed in Table 2 show that similar reactivity trends are observed when the reactions are performed in glacial acetic acid without added base catalyst or in the aprotic solvent dimethoxyethane (DME).[3] In the latter case, the reaction proceeds at a slower rate and generally gives higher ratios of 3-condensation/1-condensation product which may be due to a change in mechanism. In the absence of a proton donor (acetic acid), chloral will not be activated toward nucleophilic addition by protonation of its carbonyl oxygen, and the condensation is likely to proceed via an enolate (rather than enol) intermediate. The lower overall yields and higher 1-condensation/3-condensation product ratios observed in glacial acetic acid without added sodium acetate cannot be meaningfully interpreted in mechanistic terms since the ketols, especially the methylene condensation products, were found to decompose slowly under these conditions.

In summary, our studies of the acetate-catalyzed crossed aldol condensation of chloral with aliphatic ketones in glacial acetic acid as solvent indicate that the following factors govern the rate and orientation of this reaction:

(*1*) The reaction is acid- and base-catalyzed, proceeds via an enol-like transition state, and

[3]Solvent effects on the orientation of the acid-catalyzed deuteration and bromination of unsymmetrical ketones have recently been discussed by Sachs and Rappe (25), and by Gaudry and Marquet (26).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

chloral adds preferentially at the least-highly substituted α-carbon of unsymmetrical dialkyl ketones other than butanone.

(*2*) The rate of condensation at the α-methyl carbon of $CH_3CO(CH_2)_nCH_3$ increases with increasing chain length *n* and thus parallels the stability order of the corresponding 1-enols relative to the keto forms.

(*3*) The rate of condensation at the α-methylene carbon of CH_3COCH_2R decreases with increasing bulk of the alkyl substituent R as a result of steric hindrance to both enolization and rate-determining chloral addition.

(*4*) The rate of condensation at the α-methylene carbon of butanone and other ethyl alkyl ketones is unusually high due to special stabilization of the 2-enol $CH_3CH{=}C(OH)R$ by the polar effect of the methyl group which predominates in these cases over the rate-retarding steric effect.

Experimental

Melting points are uncorrected. The u.v. spectra were run in 95% ethanol using a Unicam SP-200 spectrometer. The n.m.r. spectra were recorded on a Varian A 56/60 spectrometer using TMS as internal standard and $CDCl_3$ as solvent. Chemical shifts are reported in τ units. All spectral measurements were performed at room temperature.

The v.p.c. analyses were carried out on a Varian Aerograph Model 1200-1 HY-FI III gas chromatograph using a 5 ft × 1/8 in. column packed with 5% SE-30 on Aeropak 30 (column temperature 120–140°) and nitrogen as carrier gas (35 ml/min). All quantitative estimates of the composition of product mixtures by g.l.c. analysis (Tables 1 and 2) are based on comparison of integrated peak areas obtained for the various components of a crude product mixture with those obtained for standard mixtures prepared from the pure components. The v.p.c. peak areas were measured by a disc chart integrator. For the purpose of analysis and identification, pure samples of all compounds (except **11***b*) were isolated by fractional distillation, crystallization, and/or liquid partition chromatography on silica (Mallinckrodt, Silicic Acid A.R. 100 Mesh, Chromatographic Grade).

Anhydrous chloral was prepared from the commercially available material (Matheson, Coleman and Bell; Chloral, Practical, Stabilized) by distillation from phosphorus pentoxide under dry nitrogen. All ketones were obtained from commercial sources and purified by fractional distillation. Glacial acetic acid (Baker and Adamson, U.S.P.) and anhydrous sodium acetate (Baker and Adamson, Reagent Grade) were used without further purification in all preparative experiments. For the kinetic studies, reagent grade acetic acid (Baker) was used, and the anhydrous sodium acetate was purified by heating at 160° for 2 h and storage in a desiccator.

Kinetic Procedures

A specific quantity of anhydrous sodium acetate, 4-methyl-2-pentanone (or 2-heptanone), glacial acetic acid, and anhydrous chloral was weighed into each of a series of 10–20 10-ml ampules under the exclusion of atmospheric moisture. The ampules were immediately sealed and immersed in a constant-temperature oil bath (±0.02°). Timing was started after 1 min of temperature equilibration. At room temperature, no discernible reaction was found to occur inside the ampule over a period of 10 days.

Ampules were withdrawn from the oil bath at appropriate time intervals and immediately chilled in ice water. Each sample was then quantitatively transferred and rinsed with chloroform into a 50-ml calibrated volumetric flask which was allowed 2 h to reach temperature equilibrium (23.0 ± 0.01°) before filling up to the mark. Using a 10-μl syringe, at least three aliquots of 5.0 ± 0.02 μl each were withdrawn from each volumetric flask for v.p.c. analysis. In each case, the average reading of all integrated peak areas was used to determine graphically the product yield by comparison with a calibration curve prepared under the same experimental conditions using known quantities of product. The limiting rate of product formation at 20% completion was determined graphically from a plot of the product yield *vs.* reaction time. (The peak area *vs.* concentration plot was found to deviate from linearity at product concentrations corresponding to less than 13% yield.)

Condensation of Chloral with Ketones

Reaction Procedure

A mixture of 36.9 g (0.25 mol) of anhydrous chloral, 0.31 mol of ketone, 5.1 g (0.063 mol) of anhydrous sodium acetate (where required), and 0.50 mol of glacial acetic acid or dimethoxyethane was heated at 100° for 52 h in a 500-ml flask equipped with reflux condenser and calcium chloride tube. Solvent, unreacted starting materials, and acetic acid were removed by vacuum distillation. The residue was dissolved in 200 ml of ether and 100 ml of water, and the layers were separated. The aqueous layer was extracted with 50 ml of ether, and the combined organic extracts were washed with 5% aqueous sodium bicarbonate solution and water and dried with anhydrous magnesium sulfate. Evaporation of the ether gave the crude product quantities listed in Table 2 which were analyzed by v.p.c. as described before. The experiments performed in acetic acid in the absence of sodium acetate resulted in black crude product mixtures which were found by v.p.c. analysis to contain up to 10% of unidentified products.

Product Isolation and Purification

The single condensation product (Scheme 1, structure *c*) formed from chloral and acetone, 4-methyl-2-pentanone, 4,4-dimethyl-2-pentanone, 3-methyl-2-butanone, and 3,3-dimethyl-2-butanone, respectively, was isolated from the crude product mixture and purified by recrystallization from carbon tetrachloride and cyclohexane. In all other cases, *i.e.*, where mixtures of two, three, or four isomeric ketols were formed, small samples of the individual components were isolated by liquid partition chromatography on silica using 20% (by volume) petroleum ether (30–60°) in benzene as eluent. Larger quantities of the pure isomers melting above 30° were obtained by fractional distillation of the product mixture through a Vigreux

column at high vacuum, v.p.c. analysis of each of the fractions collected, seeding of selected fractions with the appropriate pure compound and recrystallization from cyclohexane. Crystallization of **2***a*, **8***b*, 9*a*, and **13***a* was extremely slow and inhibited by small amounts of impurities. The mixture of four isomeric ketols (**11***a*, **11***b*, **12***a*, **12***b*) formed from chloral and 3-heptanone was resolved by partition chromatography on silicic acid using 10% petroleum ether (65–110°) in benzene as eluent. Although this procedure gave only **11***a*, **12***a*, and **12***b* in pure form, the n.m.r. of a fraction containing 65% **11***b* and 35% **12***b* allowed a satisfactory structure assignment for this isomer.

Physical Constants

The melting points, boiling points, and chemical shifts of the reaction products are summarized in Table 3. The 1,1,1-trichloro-2-hydroxy-4-alkanones were found to exhibit two weak u.v. absorption maxima at 210–219 (ε 40–60) and 275–285 mμ (ε 25–30). 1,1,1-Trichloro-2-hydroxy-6-methyl-4-heptanone showed an additional peak at 239 mμ (ε 32).

Reaction of Chloral with 2,4-Dimethyl-3-pentanone

Following the standard condensation procedure, 3.6 g of crude product was obtained from 0.31 mol (35.6 g) of 2,4-dimethyl-3-pentanone and the appropriate quantities of chloral, acetic acid and sodium acetate. The product mixture which exhibited five major peaks in the gas chromatogram was not further investigated since none of the desired condensation product was detected by spectroscopic analysis.

Epimerization of Diastereomeric 1,1,1-Trichloro-2-hydroxy-4-alkanones

A mixture of 5.50 g (0.025 mol) of 1,1,1-trichloro-2-hydroxy-3-methyl-4-pentanone (**2***a*), 0.43 g (0.0060 mol) of butanone, 0.51 g (0.0063 mol) of anhydrous sodium acetate and 3.00 g (0.050 mol) of glacial acetic acid was heated at 100° for 15 h. The standard work-up procedure gave a product mixture containing the two diastereomeric ketols **2***a* and *b* in the approximate ratio 4:5 but no detectable amount of the structural isomer **2***c* (analysis by v.p.c.). Application of the above procedure to **2***b* (instead of **2***a*) gave the same result. When 1,1,1-trichloro-2-hydroxy-4-hexanone (**2***c*) was subjected to these reaction conditions, v.p.c. analysis of the product did not disclose any **2***a* or *b*. The same type of experiment was performed with **9***a*, **9***b*, **13***a*, **13***b*, **5***c*, and mixtures of **5***a* and *b*, respectively, replacing **2***a* in the above procedure. In all cases, epimerization of diastereomers but no structural isomerization was observed.

The following specific heats of combustion (kcal/g) were determined calorimetrically to estimate relative thermodynamic product stabilities (product structure in parentheses): 3.66 (**2***a*), 3.63 ± 0.01 (**2***b*), 3.73 ± 0.03 (**2***c*), 4.20 ± 0.03 (**9***a*), and 4.15 ± 0.02 (**9***b*).

The authors wish to express their gratitude to the National Research Council of Canada for providing the financial support for these investigations, and to Miss N. McGillivray for her assistance in the performance of laboratory experiments.

Studies on Acyl Alkyl Diimides

THOMAS R. LYNCH,[1] FREDERICK N. MACLACHLAN, AND YUM KUEN SIU[2]
Chemistry Department, Scarborough College, University of Toronto, West Hill, Ontario

Received November 26, 1970

A number of acyclic acyl alkyl diimides have been obtained by oxidation of the corresponding alkyl hydrazides. A new method for the synthesis of α-cyanoalkyl hydrazides, the reaction of acid hydrazides with ketones in the presence of sodium cyanide, has been explored. All the acyl alkyl diimides so obtained exhibit a medium to weak i.r. band at *ca.* 1550 cm^{-1}; evidence supporting the assignment of this band to the —N=N— stretch is given. The results of oxidation of 5-methyl and 5-phenyl-pyrazolidin-3-one are reported, together with the synthesis and oxidation of tetrahydro-6-methyl-3(2*H*)-pyridazinone.

Par l'intermédiaire de l'oxydation des hydrazides alkylées correspondantes, on a obtenu un certain nombre de diimides acycliques substituées par des groupes acylés et alkylés. On a de plus exploré une nouvelle méthode de synthèse d'hydrazides substituées par des groupes α cyanoalkyles qui fait appel à la réaction d'hydrazides d'acides avec des cétones en présence de cyanure de sodium. Toutes les diimides ainsi préparées montrent, dans leur spectre i.r., une bande légèrement faible à environ 1550 cm^{-1}; on présente des données permettant d'attribuer cette bande à la vibration de fréquence du groupe —N=N—. On rapporte aussi les résultats obtenus lors de l'oxydation des méthyl-5 et phényl-5 pyrazolidinone-3 ainsi que la synthèse et l'oxydation de la tétrahydro méthyl-6 pyridazinone 3(2*H*).

Canadian Journal of Chemistry, 49, 1598 (1971)

Introduction

Whereas the chemistry of diacyl and dicarbalkoxy diimides and related compounds have been widely investigated (1), that of acyl alkyl diimides has received less attention since the early studies of Wieland *et al.* (2). Chaco and Rabjohn have synthesized the carbethoxy alkyl diimides **1** and **1***a* by oxidation of the corresponding hydrazides with bromine water, and silver oxide in benzene, respectively (3). The diimide **1** tautomerized readily to the corresponding hydrazone at room

R—N=N—CO_2Et

temperature, whereas **1***a*, lacking an α-H, decomposed only on heating to 170°; both diimides exhibited n–π* bands in their u.v. spectra at *ca.* 375 mμ. Hoffmann and Eicken (4) have found lead tetraacetate (LTA) to be a convenient reagent for oxidation of benzohydrazides to the corresponding diimides, a number of which were obtained as unstable red oils, with n–π* bands of unspecified extinction coefficient in the 395–420 mμ region, but no further spectral information was given. The alkoxide-induced decomposition of these (4) and of benzoyl *t*-butyl diimide (5) have been investigated, carbanionic intermediates being suggested, with the possible additional intervention of radicals in the latter case. In the present work we reported on the synthesis of a variety of acyl alkyl diimides, including some acetyl cases which have not previously been reported, together with some discussion on their i.r. and u.v. spectra.

Results and Discussion

The hydrazides **2***a*, **2***b*, **4***a*, and **4***b* were synthesized by catalytic hydrogenation of the corresponding hydrazones over 5% Pt/C in alcohol (6). Reaction of a 4.1 *M* excess of phenyl-

extend this reaction to obtain the hydrazides **2***d*, **4***c*, and **4***d*, using phenylmagnesium bromide, methyl lithium, or methylmagnesium bromide were unsuccessful.

The benzoyl diimides **3***a–c* and the acetyl diimides **5***a* and *b* were obtained by LTA oxidation of the corresponding hydrazides essentially according to the method of Hoffmann and Eicken. The diimides thus obtained were, with the exception of **3***c*, unstable red oils, which tautomerized to the hydrazones on standing at room temperature, the acetyl cases being more unstable in this regard than the benzoyl examples. However, satisfactory n.m.r., i.r., and u.v. spectra could be obtained (*vide infra*). As expected, **3***c* was more stable, an analytically pure sample being obtained by two molecular distillations at 70°/0.5 mm.

Azobisnitriles have been widely investigated as sources of free radicals, due to their inability to tautomerize, and their clean decomposition on mild heating. We therefore attempted the synthesis of some acyl α-cyanoalkyl hydrazides by modification of the method of Overberger *et al.* (8) for the preparation of symmetrical α-cyanoalkyl hydrazines. Reaction of benzohydrazide and acetohydrazide with cyclohexanone, acetone, and butanone, in the presence of aqueous sodium cyanide and 1 equiv of mineral acid, gave the hydrazides **2***e–g* and **4***e–g* respectively, in yields of 50–88%. Compound **2***f* has previously been prepared by addition of liquid hydrogen cyanide to the corresponding hydrazone (9). Oxidation of **2***e* and *f* was conveniently accomplished with yellow mercuric oxide; the acetylhydrazides **4***e* and *f* were resistant to this reagent, but could be oxidized with activated manganese dioxide (10) in methylene chloride. Of these four diimides so formed, only **3***e* was obtained analytically pure, being isolated as yellow–orange crystals, m.p. 66.5–67.5°. Diimide **3***f* was obtained spectroscopically pure as an oil, but could not be obtained crystalline; attempted molecular distillation appeared to cause decomposition. Samples of **4***e* and *f* obtained by oxidation either with manganese dioxide at 25°, or with *N*-chlorobenzotriazole at −20°, in methylene chloride, exhibited in their i.r. spectra an additional carbonyl band at *ca.* 1710 cm^{-1} of varying intensity. Also, during manganese dioxide oxidations of **4***e* and *f*, mild effervescence of a gas was observed, suggesting that some decomposition was occurring on the surface of the metal oxide.[3]

We have also examined the oxidation of some cyclic hydrazides. Kent and Anselme (12) observed that mercuric oxide oxidation of **8** afforded styrene, and assumed, without identification, the intermediacy of the substituted 1-pyrazolin-3-one **9**. In our hands, LTA oxidation of **8** at −70° afforded a yellow solution with $\lambda_{max}(CH_2Cl_2)$ 430 mμ, consistent with the presence of **9**. When allowed to warm up, this absorption disappeared, and styrene, as the dibromide, was isolated. Similar oxidation of **10** (13), gave a solution with $\lambda_{max}(CH_2Cl_2)$ 443 mμ, consistent with the presence of **11**; however, attempts to isolate **11**, or trap it with 2,3-dimethylbutadiene or diphenylketene (14) were unsuccessful. After completion of our work in this area, Nagata and Kamata (15) reported the successful isolation of **13** and **15**, as unstable solids, having $\lambda_{max}(CH_2Cl_2)$ 448 (ε 190), 436 (ε 251), 445 (sh), and 460 mμ (sh), respectively, in agreement with our values.

Reduction of the previously known 4,5-dihydro-6-methyl-3(2*H*)-pyridazinone (**16**) (16), in methanol containing a slight excess of acetic acid occurred smoothly to give the previously unknown tetrahydro-6-methyl-3(2*H*)-pyridazinone (**17**), m.p. 71–72°. Oxidation of **17** with mercuric oxide at room temperature gave only **16**. Oxidation with LTA or with activated manganese

[3]While this manuscript was in preparation, the chlorine oxidation of hydrazides **2***e–g* and **4***e–g* to **3***e–g* and **5***e–g* respectively, was reported (11).

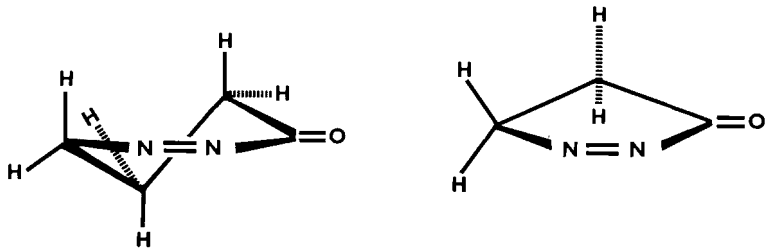

FIG. 1. Dihydro-1-pyridazin-3-one and 1-pyrazolin-3-one conformations.

dioxide at −70° gave purple solutions with $\lambda_{max}(CH_2Cl_2)$ 512 mμ, not considered consistent with the presence of **18**. It is possible that the product with λ_{max} 512 mμ arises by rapid tautomerism of **18** to **16**, followed by subsequent oxidation of **16**, since LTA oxidation of **16** alone yields the same purple solution. The rapid tautomerism of **18** to **16** compared to the stability of the 1-pyrazolin-3-ones is perhaps interpretable in terms of the conformations of the molecules. In the dihydro-1-pyridazin-3-ones effective overlap of a developing p orbital on C-6 is aided by the near axial orientation of one of the C_6—H bonds, a situation which is not so favorable in the 1-pyrazolin-3-one cases[4] (Fig. 1).

The i.r. spectra of the acetyl and benzoyl diimides obtained above exhibit carbonyl absorptions at 1755–1762 and 1710–1725 cm^{-1}, in good agreement with the carbonyl band positions of diacetyl diimide (1762 cm^{-1}) and dibenzoyl diimide (1726 cm^{-1}). In addition, the spectra of the acetyl and benzoyl diimides, with the exception of **3***c*, obtained by LTA oxidation contain bands of variable intensity at 1825–1827 and *ca.* 1810 cm^{-1}, respectively, which may be due to the presence of traces of acetic anhydride and acetyl benzoyl anhydride, formed by nucleophilic attack of acetate ion or acetic acid on the diimides. The n.m.r. spectra of the diimides indicate the percentage of these anhydrides to be very small.

In dialkyl diimides, the stretching frequency of the N=N group is fairly well established to lie in the region 1540–1576 cm^{-1} from Raman (17) and i.r. (18, 19) studies. However, with substituents other than alkyl, a variety of i.r. frequencies have been proposed, *e.g.*, in *trans*-diaryl diimides, 1410–1440 (20), *cis*-diphenyldiimide, 1511 (20), a variety of aromatic azo compounds, *ca.* 1406 or 1577 (21), formazans, 1450 (22), and aryl azo naphthols, *ca.* 1450 cm^{-1} (23). In a recent review (1) it has been stated that "the position of the N=N stretching band of α-carbonyl azo compounds has not yet been determined." Raman spectra of esters and the potassium salt of azodicarboxylic acid (24, 25) attribute this vibration to a band at 1553–1562 cm^{-1}, whereas Chaco and Rabjohn (3) appear to assign bands at 1610 and 1635 cm^{-1} to this vibration in the i.r. spectra of diethyl azodicarboxylate, and ethyl *t*-butylazocarboxylate, (**1***a*), respectively, while Le Fèvre *et al.* (26), in the i.r. spectra of esters of azodicarboxylic acid, has suggested that it lies at *ca.* 1780 cm^{-1}.

It was therefore with some interest that we observed that the i.r. spectra of all the acyclic diimides obtained above exhibited a sharp band of weak to medium intensity between 1545 and 1551 cm^{-1}. It is difficult to attribute this band to any common structural feature in these diimides other than the —N=N— group. Further support for this assignment comes from examination of the i.r. spectra of dibenzoyl diimide and diacetyl diimide; the spectra of these symmetrically substituted diimides exhibit no absorption between 1500 and 1580 cm^{-1}. To provide further information, we have also examined the laser Raman spectrum of a crystalline sample of dibenzoyl diimide.[5] This spectrum exhibits two intense sharp bands at 1712 and 1600 cm^{-1}, attributable, respectively, to carbonyl and aromatic absorptions. In addition, there occurs a much weaker sharp band at 1545 cm^{-1}, which can be assigned, in the light of the evidence above, to the —N=N—stretching vibration.

[4]This explanation follows that of R. Moore in a somewhat similar system (R. Moore, Ph.D. Thesis. University of Alberta, Edmonton, Alberta, 1967).

[5]The authors are indebted to Prof. G. A. Ozin for obtaining the Raman spectrum and for helpful discussions. The instrument used was a Spex 1401 Raman spectrometer.

*For comments on the purities of these compounds, see Discussion.

It was of interest to determine whether direct attachment of an aromatic ring to the diimide functional group might affect the position of the —N=N— stretching band. Indeed, in the spectrum of phenyl benzoyl diimide one observes no absorption in the region between 1510 and 1580 cm^{-1}. Sharp bands are observed at 1450, 1501, and 1600 cm^{-1}, the last absorption having a weak shoulder at 1585 cm^{-1}. It would thus appear, as has already been shown in the case of diaryl diimides (20), that direct attachment of an aromatic ring to the diimide group does have a profound effect on the position of the —N=N— stretching vibration.

The u.v. spectra for the diimides prepared here are collected in Table 1. Intensity data for **5***e* and *f* are not given due to the presence of impurities. All exhibit broad weak n–π* bands in the 396–410 mμ region; these bands undergo hypsochromic shifts of 1–3 mμ on increasing the polarity of the solvent. The acetyl cases exhibit additional, relatively weak, maxima at *ca.* 226 and 275 mμ. The benzoyl diimides have more intense bands below 400 mμ, characteristic maxima occurring at *ca.* 240 and 312–325 mμ. All benzoyl cases exhibit shoulders at *ca.* 286 mμ, some cases having shoulders at 330 mμ.

Experimental

Melting points were determined on a Fisher–Johns apparatus, and are uncorrected. The i.r. spectra were obtained in chloroform solution unless otherwise stated, on a Beckman IR-10, n.m.r. spectra in deuterochloroform using a Varian T-60 instrument, u.v. spectra on a Bausch and Lomb 505 recording spectrophotometer, and mass spectra on a CEC 490 instrument. A Series 3910 Shaker Type Hydrogenation Apparatus (Parr Instrument Co.) was used for the hydrogenations. Microanalyses were performed either by A. B. Gygli, Toronto, Ontario, or by Bernhardt Mikroanalytisches Laboratorium, 5251 Elbach uber Engelskirchen, Fritz-Pregl-Strasse 14–16, West Germany.

2-Isopropyl acetohydrazide (**4***b*), m.p. 55–56° (lit. (27) m.p. 54°) and 2-ethyl benzohydrazide (**2***a*), m.p. 85–87° (lit. (28) m.p. 86–87°) were obtained by catalytic reduction of the corresponding hydrazones.

2-Acetyl Acetaldehyde Hydrazone

A mixture of 29 g (0.39 mol) acetohydrazide and 60 g (1.36 mol) acetaldehyde was stirred at room temperature for 2.5 h. The excess acetaldehyde was removed and the crude product (31.7 g, 81%), m.p. 94–96°, was recrystallized from benzene–hexane to give pure material, m.p. 107.5–109°; ν_{max} 3328 (w) and 1666 cm^{-1} (s); n.m.r.: δ 7.25 (q, 1, J = 5.4 Hz), 2.20 (s, 3) and 1.90 (d, 3, J = 5.4 Hz).

Anal. Calcd. for $C_4H_8N_2O$: C, 47.98; H, 8.05; N, 27.98. Found: C, 48.14; H, 8.24; N, 28.05.

*2-Ethyl Acetohydrazide (**4***a*)*

A solution of 17 g (0.17 mol) 2-acetyl acetaldehydehydrazone in 200 ml absolute alcohol with 3 g 5% platinum-on-carbon was hydrogenated under 50 p.s.i. for 2 days. The catalyst was removed by filtration and washed with additional absolute alcohol. Removal of the solvent and recrystallization of the residue from benzene–pentane yielded white needles (13.29 g, 77%) m.p. 42–46°; b.p. 67–68° (0.5 mm); ν_{max} 3447 (w) and 1675 cm^{-1} (s); n.m.r.: δ 4.51 (br s, 1), 2.90 (q, 2, J = 7.2 Hz), 1.99 (s, 3) and 1.10 (t, 3, J = 7.2 Hz).

Anal. Calcd. for $C_4H_{10}N_2O$: C, 47.03; H, 9.87; N, 27.43. Found: C, 47.18; H, 9.63; N, 27.22.

*2-Isopropyl Benzohydrazide (**2***b*)*

A solution of 18.32 g (0.104 mol) 2-benzoyl acetonehydrazone in 400 ml absolute alcohol with 4 g 5% platinum-on-carbon was hydrogenated under 50 p.s.i. overnight. The catalyst was removed by filtration and washed with additional absolute alcohol. The filtrates were combined, the solvent was removed, and the residue was recrystallized from benzene – petroleum ether (b.p. 60–80°) to give pure material (17.5 g, 98%) m.p. 116–117°; ν_{max} 3443 (w) and 1656 cm^{-1} (s); n.m.r.: δ 7.88–7.27 (m, 5), 3.31 (sept, 1, J = 6.2 Hz) and 1.11 (d, 6, J = 6.2 Hz).

refluxed with stirring for 2.5 days, cooled, and hydrolyzed with water. The mixture was extracted with three 600 ml portions of chloroform, and the combined chloroform extracts were dried and concentrated. The residue solidified on cooling and was recrystallized from benzene – petroleum ether (b.p. 60–80°) to give pure material (1.63 g, 25%) m.p. 115.5–116.5°; ν_{max} 3430 (w) and 1650 cm^{-1} (s); n.m.r.: δ 7.65–7.15 (m, 10), 5.2 (broad, 1), and 1.41 (s, 6).

Anal. Calcd. for $C_{16}H_{18}N_2O$: C, 75.56; H, 7.13; N, 11.02. Found: C, 75.26; H, 7.26; N, 10.79.

Benzoyl 1,1-Dimethylbenzyl Diimide (3c)

A solution of 1.2 g (2.7 mmol) LTA in 30 ml methylene chloride was added dropwise to a stirred solution of 0.52 g (2.05 mmol) 2-(1,1-dimethylbenzyl)-benzohydrazide in 20 ml methylene chloride cooled to −20°. When addition of the oxidant was complete, stirring was continued at −20° for 30 min. The red-orange solution was poured into 20 ml ice water. The organic phase was separated and washed four times with 20 ml ice water, once with 20 ml saturated aqueous sodium bicarbonate solution, and finally with 20 ml ice water. After drying, the solvent was removed at ice-bath temperature to give the crude product as a red-brown oil (0.47 g, 90%); the product was purified by two molecular distillations at 70°/0.5 mm; ν_{max} (CCl_4) 1723 (s), 1600 (m), 1540 cm^{-1} (w). n.m.r.: δ 7.97–7.21 (m, 10) and 1.69 (s, 6).

Anal. Calcd. for $C_{16}H_{16}N_2O$: C, 76.16; H, 6.39; N, 11.10. Found: C, 76.01; H, 6.29; N, 11.00.

The diimides **3***a*, **3***b*, **5***a*, and **5***b* were similarly obtained in 18–90% yield and were not further purified (for comments on their purity, see Discussion); i.r. and n.m.r. data for these are as follows: **3***a*, ν_{max} 1810 (m), 1715 (s), and 1550 cm^{-1} (w); n.m.r.: δ 8.08–7.08 (m, 5), 4.10 (q, 2, J = 7.2 Hz), and 1.34 (t, 3, J = 7.2 Hz); **3***b*, ν_{max} 1810 (m), 1712 (s), and 1550 cm^{-1} (w); n.m.r.: 7.98–7.28 (m, 5), 4.07 (sept, 1, J = 6.0 Hz), and 1.40 (d, 6, J = 6.0 Hz); **5***a*, ν_{max} 1825 (s), 1756 (s) and 1550 cm^{-1} (vw); n.m.r.: δ 4.07 (q, 2, J = 7.6 Hz), 2.24 (s, 3), and 1.35 (t, 3, J = 7.6 Hz); **5***b*, ν_{max} 1825 (w), 1758 (s), and 1549 cm^{-1} (m); n.m.r.: δ 3.83 (sept, 1, J = 6.6 Hz), 2.18 (s, 3), and 1.26 (d, 6, J = 6.6 Hz).

The pyrazolidin-3-ones, **8** (29) and **10** (13) were obtained by previously reported procedures.

Tetrahydro-6-methyl-3(2H)-pyridazinone (17)

4,5-Dihydro-6-methyl-3(2*H*)-pyridazinone (**16**) (7 g, 0.06 mol) was dissolved in 100 ml methanol containing glacial acetic acid (7 g, 0.12 mol) and hydrogenated in the presence of 7 g 5% platinum-on-carbon under 50 p.s.i. for 2 days. After filtration to remove the catalyst, the methanol was evaporated. The residue was dissolved in 10 ml chloroform and neutralized with saturated sodium bicarbonate solution. After drying, the solvent was removed to give the crude product (3.49 g, 49%). Recrystallization from benzene – petroleum ether (b.p. 60–80°) gave white crystals (1.8 g, 25%), m.p. 71.5–72.5°; ν_{max} 3410 (w) and 1655 cm^{-1} (s); n.m.r.: δ 3.09 (m, 1), 1.36–2.60 (m, 4) and 1.10 (d, 3, J = 6 Hz).

Synthesis of the α-Cyanoalkyl Hydrazides, 2e–g and 4e–g

The general method of synthesis was as follows; a solution of sodium cyanide (1 mol) in water (10 ml/g sodium cyanide) containing the ketone (1 mol) (with butanone and cyclohexanone, 4 and 10 ml, respectively, of dioxane/g ketone were added), was poured into a mixture of the acylhydrazide (1 mol) in water (10 ml/g benzohydrazide, 7 ml/g acetohydrazide; in the case of benzohydrazide, 8 ml alcohol/g benzohydride were also added). The combined solutions were stirred in tightly stoppered flasks for several days, and the products were isolated by filtration or extraction with chloroform. Yield, m.p., i.r., n.m.r., and analytical data for these hydrazides are as follows: **2***e*, 88%, 131–132.5°, ν_{max} 3410 (m), 2220 (vw), and 1666 cm^{-1} (s); n.m.r.: δ 7.25–7.8 (m, 6), 3.6 (br s, 1), 1.2–2.2 (br m, 10).

Compound **4***f*, 50%, 79.5–82°, ν_{max} 3410 (m), 3290 (m), 2220 (vw), and 1685 cm^{-1} (s); n.m.r.: δ 8.1 (br s, 1), 5.0 (br s, 1), 2.0 (s, 3), 1.5 (s, 6).

Anal. Calcd. for $C_6H_{11}N_3O$: C, 51.05; H, 7.85; N, 29.77. Found: C, 51.03; H, 8.07; N, 29.84.

Compound **4***g*, 55%, 69–72°, ν_{max} 3410 (m), 3290 (m), 2220 (vw), and 1685 cm^{-1} (s); n.m.r.: δ 7.95 (br s, 1), 4.4 (br s, 1), 2.0 (s, 3), 0.9–1.9 (m, 8).

Anal. Calcd. for $C_6H_{13}N_3O$: C, 66.34; H, 6.96; N, 19.34. Found: C, 66.33; H, 6.74; N, 19.19.

Oxidation of 2e to 3e

2-α-Cyanocyclohexyl benzohydrazide (**2***e*, 0.50 g) was stirred in benzene (25 ml) with anhydrous sodium sulfate (0.50 g) and yellow mercuric oxide (0.886 g) for 0.5 h. After filtration, the solvent was removed to give crude **3***e* (0.122 g, 25%), which was crystallized from pentane, m.p. 66.5–67.5°, ν_{max} 2220 (w), 1721 (s), and 1550 cm^{-1} (m); n.m.r.: δ 7.4–8.0 (m, 5), 1.3–2.3 (m, 10).

Anal. Calcd. for $C_{14}H_{15}N_3O$: C, 69.69; H, 6.27; N, 17.41. Found: C, 69.45; H, 6.07; N, 17.33.

Compound **2***f* was similarly oxidized to give **3***f* as a yellow oil, ν_{max} 2220 (w), 1721 (s), and 1552 cm^{-1} (m); n.m.r.: 7.28–8 (m, 5), 1.8 (s, 6). Attempted purification of the oil by molecular distillation was unsuccessful.

Compounds **4***e* and *f* were oxidized to **5***e* and *f*, respectively, by stirring with excess manganese dioxide (10) in methylene chloride at room temperature. Mild effervescence of a gas was observed to occur. Oxidation of **4***e* was also accomplished using *N*-chlorobenzotriazole at −20° in methylene chloride. Spectral measurements were made on the samples of **5***e* and *f* so obtained; **5***e*, ν_{max} 2220 (vw), 1760 (s), 1710 (sh, w), 1550 cm^{-1} (m); **5***f*,

For personal use only.

ν_{max} 1760 (s), 1710 (sh, m), 1555 cm^{-1} (w); n.m.r.: δ 2.15 (s), 1.70 (s).

*5-Phenylpyrazolin-3-one (**9**)*

A solution of 0.29 g (0.65 mmol) LTA in 15 ml methylene chloride was added dropwise to a stirred solution of **8** (0.073 g, 0.45 mmol) in 5 ml methylene chloride cooled to −70°. When addition of the oxidant was complete, stirring was continued at −70° for 10 min; the u.v. spectrum of this solution exhibited a maximum at 430 mμ.

In a subsequent preparation, 0.98 g **8** was oxidized at −20°, and when oxidation was complete, the solution was poured into water, and the organic phase was separated, washed successively with 40 ml portions of water, saturated aqueous sodium bicarbonate, and water, dried, and evaporated to give styrene (0.5 g, 67%), identified as the dibromide, m.p. 72–73° (lit. (32) m.p. 73–74°).

*5-Methylpyrazolin-3-one (**11**)*

A solution of 0.94 g (2.1 mmol) LTA in 30 ml methylene chloride was added to a stirred solution of **10** (0.178 g, 1.7 mmol) in 10 ml methylene chloride cooled to −70°. Stirring was continued at −70° for 10 min after addition of the oxidant was complete. The u.v. spectrum of the solution exhibited a maximum at 443 mμ.

Diacetyl diimide was prepared by iodine oxidation of the mercuric salt of 1,2-diacetylhydrazine according to the literature method (30). The product was once distilled.

Dibenzoyl diimide, m.p. 119–121° (lit. (31) m.p. 119.5–121.5°) was conveniently obtained by oxidation of 1,2-dibenzoylhydrazine with an equimolar quantity of *N*-chlorobenzotriazole in methylene chloride at room temperature.

We thank the National Research Council of Canada and the Ontario Department of University Affairs for support of this research.

Preparations of Some Tetrahydronaphthalenone and Dihydroindanone Derivatives of Potential Value as Intermediates for the Synthesis of Steroids and Related Compounds

J. Bryan Jones, Jeffrey D. Leman,[1] and Peter W. Marr

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

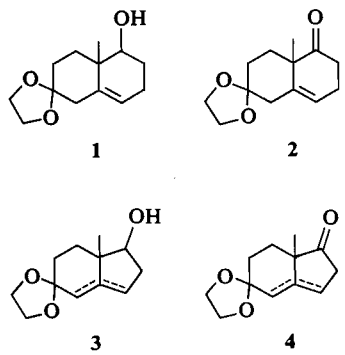
Received December 17, 1970

The difficulties which in the past have precluded the preparation of some synthetically potentially useful ethylenedioxy-tetrahydronaphthalenone and -dihydroindanone derivatives have been overcome. The proclivity of the tetrahydronaphthalenone compounds to undergo acid- and base-catalyzed rearrangements has been shown to be paralleled to some extent by the analogous dihydroindanone compounds.

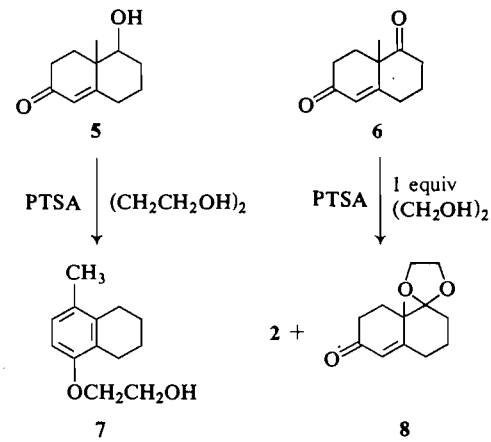
On a pu surmonter les difficultés qui dans le passé ont empêché la préparation de certains dérivés éthylenedioxitétrahydronaphtalènone ou -dihydroindanone qui sont potentiellement utiles au point de vue synthétique. On a démontré que les dihydroindanones en milieux acide ou basique, se réarrangent pratiquement avec autant de facilité que les tétrahydronaphtalénones.

Canadian Journal of Chemistry, 49, 1604 (1971)

During synthetic studies on androgen analogues the need arose to prepare the tetrahydronaphthalenone and dihydroindanone derivatives **1**, **2**, **3**, and **4**. Such compounds have



obvious potential as intermediates in steroid and related syntheses and in view of their desirability in this regard it was somewhat surprising to discover that their preparations had not been reported. However, examination of the pertinent literature revealed that the parent ketones of **1** and **2**, the hydroxynaphthalenone **5**, and the dione **6** respectively, and related compounds were extremely susceptible to rearrangement under acidic, basic, and photochemical conditions (1–4) and that a previous attempt to effect the ketalization of **5** with ethylene glycol and toluene-*p*-sulfonic acid (PTSA) had yielded only the tetrahydronaphthyloxyethanol **7** and related rearrangement products (3) (Scheme 1). We have subsequently reinvestigated the latter reaction and our results confirm the rearrangement product **7** to be the major isolable product.



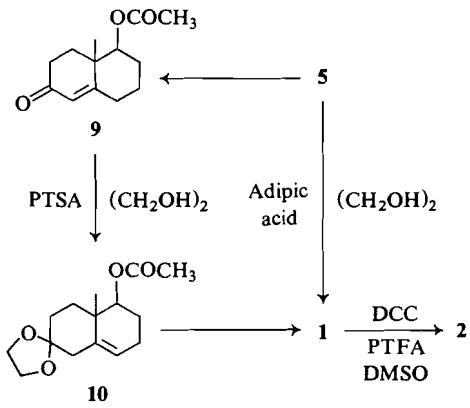
Scheme 1

Attention was then turned towards the possibility of selective ketalization of the unsaturated ketone function of **6** by using one equivalent only of ethylene glycol in the presence of an appropriate acid. This method had proven valuable for a variety of steroid ketals (5) and it was found that using toluene-*p*-sulfonic acid

[1]Abstracted in part from the Ph.D. thesis of J.D.L., University of Toronto, Toronto, Ontario, 1969.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

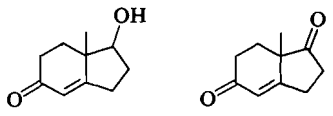
catalysis, the dione **6** could be converted into a mixture containing up to 40% of the desired ketal **2**.[2] However, although separation of **2** from the other ketal product **8** was readily effected by chromatography, the reaction proved to be a very temperamental one and considerable variations in the ratios of the ketals formed were observed from one run to another. Reproducible results were not attainable even under very carefully controlled conditions and no satisfactory procedure could be developed. Substitution of oxalic acid as the catalyst (5) gave some 6,6-ethylenedioxy-8*a*β-methyl-3,4,8,8*a*-tetrahydro-1(2*H*,7*H*)-naphthalenone[2] but application of the method as an acceptable route to this desirable synthetic intermediate was precluded by the low (<12%) yields obtained. Attempted ketalizations of **6** using adipic acid catalysis (5) were not successful and the starting tetrahydronaphthalenedione was recovered unchanged.



SCHEME 2

The preparations of **1** and **2** in sufficient quantities for our future synthetic studies were finally achieved by the two methods outlined in Scheme 2. Acetylation of the hydroxyl group of **5** prior to ketalization precluded the possibility of the previously observed (3) rearrangement reactions and the acetate **9** was readily converted into the ethylene ketal **10** under normal ethylene glycol toluene-*p*-sulfonic acid conditions (5, 7). Hydrolysis of **10** with methanolic sodium hydroxide yielded the desired hydroxyethylene ketal **1** in 69% overall yield from **5**. Subsequently, it was discovered that rearrangement of **5** under ketalization conditions could be prevented by using a weaker acid catalyst. In the presence of adipic acid, the reaction of **5** with ethylene glycol proceeded smoothly to give **1** in 30% yield. However, owing to the presence of the hydroxyl group, the ketal **1** retained its potential for rearrangement and proved to be a relatively unstable compound.

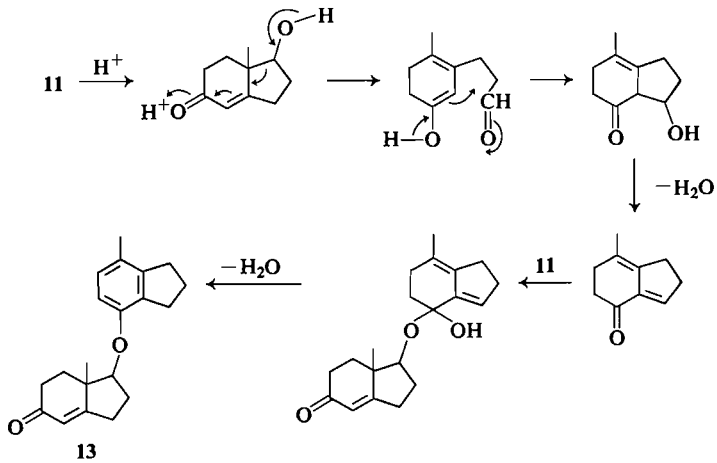
In refreshing contrast to the difficulties encountered with the other reactions in this series oxidation (8) of the hydroxy ketal **1** into the ethylenedioxynaphthalenone **2** was effected very readily in 58% yield. The oxoketal **2** obtained by this method was identical with the samples obtained by the less satisfactory selective ketalization route. Unlike its hydroxy analogue **1**, it was a stable solid which could be fully characterized and its structure was further verified by conversion into its oxime and by hydrolysis back to its parent dione **6**.



11 **12**

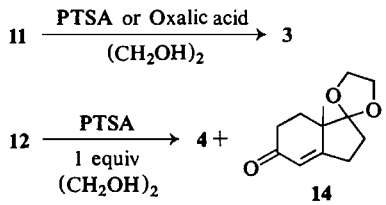
With the problems regarding ketalization in the tetrahydronaphthalenone series having been overcome, the study was then extended to the corresponding indanone ketals **3** and **4**. In view of the well documented sensitivity of the above naphthalenones to acids and bases (1–4), the stability of the analogous dihydroindanones **11** and **12** under similar conditions was investigated prior to any attempted ketalization experiments. Treatment of the hydroxyindanone **11** and the dione **12** with a variety of bases, including triethylamine, sodium hydroxide, and potassium-*t*-butoxide afforded complex reaction mixtures which contained no residual starting material. Disappointingly, no rearrangement products analogous to those reported previously in the naphthalenone series (1–4) could be isolated. However, the effect of toluene-*p*-sulfonic acid in refluxing benzene on the hydroxyindanone **11** paralleled the octalone results very closely and a 36% yield of the rearranged "dimer" **13** was obtained. One of the possible pathways which accounts for the formation of **13** is outlined in Scheme 3 (*cf.* ref. 3).

[2]The designations of the double bonds of **1** and **2** as Δ^4 and of the oxalic acid derived product as Δ^{4a} were made on the basis of comparisons of the p.m.r. spectra with those of analogous steroid ketals (6).



SCHEME 3

Very unexpectedly, when ethylene glycol was added to the above reaction mixture, the anticipated rearrangement (*cf.* **7**) did not occur and we were able to isolate the desired ketal **3**[3] in 30% yield (Scheme 4). Use of oxalic acid to promote ketalization gave a similar yield of **3** but adipic acid proved to be ineffective as a catalyst.



SCHEME 4

The ethylenedioxy indanone **4** was prepared from the dione **12** by the selective ketalization procedure. Following chromatographic purification a 22% yield of **4** was obtained and in addition, 41% of the isomeric ketal **14** was isolated. Since our particular interest in **4** as a synthetic intermediate was minimal at this time, no further studies of this reaction nor on the preparation of **4** by oxidation of **3** were considered warranted. However, if in the future the indanone **4** is required in quantity, our experiences in the tetrahydronaphthalenone series suggest that oxidation of the hydroxyindanone ketal **3** should be the preferred method.

[3]Comparisons of the vinylic proton peak widths and multiplicities in the p.m.r. spectra of **1**, **2**, and **8** with those of **3** and **4** indicated that the position of the double bonds of the latter two compounds is Δ^{3a}. However, the possibility that **3** and **4** possess the isomeric Δ^{3}-olefin structures cannot be eliminated (*cf.* ref. 6) and at present an unequivocal decision in this regard cannot be made. In the Experimental section, **3** and **4** have been named as Δ^{3a}-olefins in order to avoid the complexities inherent in either/or type nomenclature.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were obtained on a Perkin–Elmer 237B spectrophotometer using chloroform solutions. The p.m.r. spectra were measured on deuterochloroform solutions with Varian T-60 or HA-100 instruments and with tetramethylsilane as internal standard. A Varian Aerograph 1740 gas chromatograph equipped with a 6′ × 2 mm, 3% SE-30 glass column, and with temperature programming in the range 130–230°, was used to monitor most of the ketalization reactions. The t.l.c. and preparative layer chromatographic separations were effected on phosphor-containing silica gel G. Chromatograms were visualized both with u.v. light and with 5% ceric sulfate in 2 *N* sulfuric acid. Mass spectra were obtained on Bell and Howell 21-490 (low resolution) and AEI MS 902 (high resolution) mass spectrometers. All compounds reported were purified until no impurities could be detected by either t.l.c. or g.l.c. analysis.

8*a*β-Methyl-3.4,8 8*a*-tetrahydro-1,6(2*H*,7*H*)-naphthalenedione (**6**, catalogue name 9-methyl-$\Delta^{5(10)}$-octalin-1,6-dione) was purchased from Aldrich.

Acid-catalyzed Rearrangement of 1β-Hydroxy-8aβ-methyl-3,4,8,8a-tetrahydro-6(2H,7H)-naphthalenone (5) in the Presence of Ethylene Glycol

A solution of 1β-hydroxy-8*a*β-methyl-3,4,8,8*a*-tetrahydro-6(2*H*,7*H*)-naphthalenone (**5**, 1.17 g, 6.5 mmol, prepared by reduction of 8*a*β-methyl-3,4,8,8*a*-tetrahydro-1,6(2*H*,7*H*)-naphthalenedione (**6**) with recrystallized

sodium borohydride as described by Boyce and Whitehurst (9*a*)) and ethylene glycol (10 ml) in toluene (60 ml) containing toluene-*p*-sulfonic acid (10 mg) was slowly distilled with the addition of fresh toluene at intervals to maintain the starting volume. Distillation for 5 h afforded approximately 200 ml of distillate. The mixture was cooled, washed thoroughly with saturated sodium hydrogen carbonate solution, and dried ($MgSO_4$). The solvent was evaporated and the resulting yellow oil (1.40 g) was shaken with warm petroleum ether (40–60°). The solvent was decanted off and was kept overnight at −10°. 2-(1,2,3,4-Tetrahydro-8-methyl-5-naphthyloxy)ethanol (**7**) was obtained as a crystalline powder (240 mg, 18%), m.p. 72–73° (lit. (3) m.p. 73–74°).

1β-Acetoxy-8aβ-methyl-3,4,8,8a-tetrahydro-6(2H,7H)-naphthalenone (9)

1β-Hydroxy-8aβ-methyl-3,4,8,8*a*-tetrahydro-6(2*H*,7*H*)-naphthalenone (**5**, 320 mg, 1.8 mmol) was treated with acetic anhydride (1 ml) and pyridine (1.4 ml) and allowed to stand overnight at 20°. The solvent was removed under reduced pressure and the residue was recrystallized from petroleum ether (30–60°) to give the acetate (**9**, 360 mg, 91%), m.p. 82–85° (lit.(9*a*) 89°); i.r. 1730 and 1664 cm^{-1}; p.m.r. δ 1.28 (3H, s, CCH_3), 2.08 (3H, s, $COCH_3$), 4.67 (1H, m, *H*COCOCH_3), and 5.80 p.p.m. (1H, structured s, vinyl H).

1β-Acetoxy-6,6-ethylenedioxy-8aβ-methyl-2,3,8,8a-tetrahydro-(5H,7H)-naphthalene (10)

A mixture of 1β-acetoxy-8aβ-methyl-3,4,8,8*a*-tetrahydro-6(2*H*,7*H*)-naphthalenone (**9**, 1.45 g, 65 mmol), ethylene glycol (25 ml), benzene (300 ml), and a few crystals of toluene-*p*-sulfonic acid was heated under reflux with stirring for 12 h, and water which formed during the reaction was removed by a Dean–Stark moisture trap containing molecular sieves. The mixture was then washed with saturated aqueous sodium hydrogen carbonate solution (3 × 50 ml) and dried ($MgSO_4$). The solvent was evaporated and the residue (1.72 g) was recrystallized from petroleum ether (40–60°). The acetate **10** was obtained as plates (1.40 g, 80%), m.p. 95–97°; i.r. 1730, 1104 and 1093 cm^{-1}; p.m.r. δ 1.15 (3H, s, C-8*a* CH_3), 2.16 (3H, s, $OCOCH_3$), 3.93 (4H, s, OCH_2CH_2O), 4.83 (1H, "t", J = 7.0 Hz, *C*HOCOCH_3), and 5.35 p.p.m. (1H, m, vinyl H).

Anal. Calcd. for $C_{15}H_{22}O_4$: C, 67.65; H, 8.33. Found: C, 67.47; H, 8.16.

6,6-Ethylenedioxy-1β-hydroxy-8aβ-methyl-2,3,8,8a-tetrahydro-(5H,7H)-naphthalene (1)

(a) From the Ketal (5)

A mixture of 8aβ-methyl-3,4,8,8*a*-tetrahydro-1,6-(2*H*,7*H*)-naphthalenedione (**6**, 0.80 g, 4.4 mmol), ethylene glycol (2.4 ml), adipic acid (80 mg, 4.4 mmol), and benzene (160 ml) was stirred and heated under reflux for 12 h, the water formed during the reaction being removed by molecular sieves contained in a Dean–Stark moisture trap. The cooled reaction mixture was diluted with benzene (200 ml) and was then washed with saturated aqueous sodium hydrogen carbonate solution (2 × 50 ml). The aqueous phase was extracted with benzene (2 × 20 ml) and the combined benzene solutions were washed with water (2 × 100 ml) and filtered through Celite. The dried ($MgSO_4$) benzene solution was evaporated to yield a yellow oil which was then shaken with petroleum ether (40–60°). The supernatant was decanted and evaporated to give the ethylene ketal **1** as a clear colorless oil (300 mg, 30%); i.r. 3623, 3497, and 1089 cm^{-1}; p.m.r. δ 1.09 (3H, s, CH_3), 3.48–3.81 (1H, m, HOC*H*); 3.96 (4H, s, OCH_2CH_2O), and 5.34 p.p.m. (1H, m, vinyl H).

(b) From the Acetate (10)

A solution of 1β-acetoxy-6,6-ethylenedioxy-8aβ-methyl-2,3,8,8*a*-tetrahydro(5*H*,7*H*)-naphthalene (**10**, 200 mg, 0.75 mmol) in methanol (6 ml) containing sodium hydroxide (140 mg, 3.5 mmol) was kept at 20° for 16 h and was then poured into water (50 ml). The mixture was reduced to half volume under reduced pressure and was then extracted with ether (3 × 10 ml). The combined ether extracts were dried ($MgSO_4$) and evaporated to produce the hydroxyketal **1** as a yellow oil (160 mg, 95%) identical in all respects to the material obtained above.

6,6-Ethylenedioxy-8aβ-methyl-2,3,8,8a-tetrahydro-1(5H,7H)-naphthalenone (2)

(a) By Oxidation of the Hydroxyketal 1

6,6-Ethylenedioxy-1β-hydroxy-8aβ-methyl-2,3,8,8*a*-tetrahydro-(5*H*,7*H*)-naphthalene (**1**, 0.43 g, 1.9 mmol), dicyclohexyl carbodiimide (1.18 g, 1.9 mmol), and pyridinium trifluoroacetate (0.19 g, 0.95 mmol) were dissolved in dimethyl sulfoxide (5 ml) and benzene (5 ml) and the solution heated at 50° for 2 h. Ethyl acetate (25 ml) was then added and the precipitated dicyclohexylurea (m.p. 235–236°) was removed by filtration. The solution was extracted with phosphate buffer (0.01 *M*, p*H* 7.0, 2 × 25 ml) and was then washed with water (2 × 25 ml). The dried solution ($MgSO_4$) was evaporated to give a yellow oil (1.10 g) which was chromatographed on neutral alumina. Elution with benzene – petroleum ether (40–60°) (3:1) gave the ethylenedioxy ketone (**2**, 0.15 g, 58%), m.p. 63–64.5°; i.r. 1706, 1110 and 1092 cm^{-1}; p.m.r. δ 1.30 (3H, s, CH_3), 1.77 (2H, d, superimposed on other proton signals, J_{AX} = 0.5 Hz, $O_2CCH_2^AC{=}CH^X$), 3.99 (4H, s, OCH_2CH_2O), and 5.61 p.p.m. (1H, m, vinyl H).

Anal. Calcd. for $C_{13}H_{18}O_3$ (mol. wt. 222.1256): C, 70.14; H, 8.16. Found (222.1254 (mass spectrum)): C, 69.92; H, 8.09.

The oxime (prepared in 58% yield by treatment of **2** with hydroxylamine hydrochloride in aqueous ethanolic pyridine) recrystallized from ethanol as feathery plates, m.p. 175–175.5°; i.r. (KBr) 3257, 1675, 1099, and 1089 cm^{-1}; p.m.r. δ 1.32 (3H, s, CH_3), 1.81 (2H, s, superimposed on other proton signals, O_2CCH_2), 3.93 (4H, s, OCH_2CH_2O), 5.52 (1H, m, vinyl H), and 9.02 p.p.m. (1H, s, C=C—OH). Mass spectrum *m/e* 237 (molecular ion).

Anal. Calcd. for $C_{13}H_{19}NO_3$ (mol. wt. 237): C, 65.80; H, 8.07; N, 5.90. Found: C, 66.03; H, 8.03; N, 5.99.

Toluene-*p*-sulfonic acid catalyzed hydrolysis of **2** in aqueous acetone-chloroform solution regenerated the parent dione **6** in 75% yield.

(b) By Selective Ketalization of the Dione 6

8aβ-Methyl-3,4,8,8*a*-tetrahydro-1,6(2*H*,7*H*)-naphthalenedione (**6**, 100 mg, 0.6 mmol), ethylene glycol (37

mg, 0.6 mmol), and toluene-*p*-sulfonic acid (12 mg) in dry benzene (5 ml) were refluxed under a molecular sieve containing Dean–Stark trap for 1 h. The reaction mixture was cooled, diluted with benzene (5 ml), and washed with saturated aqueous sodium bicarbonate solution (2 ml) followed by water (2 ml). The dried ($MgSO_4$) benzene solution was evaporated and the yellow oil (130 mg) obtained was preparative layer chromatographed using 60% diethyl ether – 40% petroleum ether (b.p. 40–60°) as developing solvent. The higher R_f band was extracted to give the ethylenedioxy ketone **2** (50 mg) which was identical with the sample obtained above.

The lower R_f band yielded 1,1-ethylenedioxy-8*a*β-methyl-3,4,8,8*a*-tetrahydro-6(2*H*,7*H*)-naphthalenone (**8**) as a colorless oil (26 mg) which decomposed on attempted distillation[4]; i.r. 1665 and 1070 cm^{-1}; p.m.r. δ 1.35 (3H, s, CH_3), 3.96 (4H, s, OCH_2CH_2O), and 5.78 (1H, s, vinylic H).

Mol. wt. Calcd. for $C_{13}H_{18}O_3$: 222.1256. Found (mass spectrum): 222.1254.

*7,7a-Dihydro-7a*β*-methyl-1,5(6H)-indanone (12)*

The indandione **12** was prepared in 45% yield from 2-methylcyclopentane-1,3-dione (synthesized[5] by the method of Schick and co-workers (11)) and methyl vinyl ketone according to the procedure of Boyce and Whitehurst (9*b*); it formed prisms from diethyl ether – *n*-hexane, m.p. 68.5–70° (lit. (9*b*) m.p. 72–73°)

*Acid-catalyzed Rearrangement of 7,7a-Dihydro-1*β*-hydroxy-7a*β*-methyl-5(6H)-indanone (11)*

7,7*a*-Dihydro-1β-hydroxy-7*a*β-methyl-5(6*H*)-indanone (**11**, 500 mg, prepared in 76% yield by reduction of the indandione **12** with recrystallized sodium borohydride as described by Boyce and Whitehurst (9*c*)) and toluene-*p*-sulfonic acid (30 mg) in dry benzene (15 ml) were refluxed under a Soxhlet extractor containing molecular sieves for 20 h. The cooled solution was then washed with saturated aqueous sodium bicarbonate (5 ml) followed by water (5 ml). The dried ($MgSO_4$) benzene solution was evaporated and the residue (307 mg) column chromatographed on Florisil. Elution with diethyl ether – benzene (1:2) yielded 7,7*a*-dihydro-7*a*β-methyl-1β-(7-methyl-4-indanoxy)-5(6*H*)-indanone(**13**,180 mg, 36%). Preparative layer chromatography (diethyl ether development) followed by recrystallization from ethanol afforded an analytical sample m.p. 101.5–102.5°; i.r. 1680 and 1082 cm^{-1}; p.m.r. δ 1.30 (3H, s, CH_3), 2.18 (3H, s, $C_6H_5CH_3$), 4.30 (1H, t, J = 4 Hz, *H*CO), 5.84 (1H, s, vinylic H), 6.66 (1H, d, J = 4 Hz, aromatic H) and 6.93 p.p.m. (1H, d, J = 4 Hz, aromatic H). Mass spectrum *m/e* 296 (molecular ion).

Anal. Calcd for $C_{20}H_{24}O_2$ (mol. wt. 296): C, 81.08; H, 8.11. Found: C, 81.19; H, 8.14.

*5,5-Ethylenedioxy-1*β*-hydroxy-7a*β*-methyl-7,7a-dihydro-(6H)-indane (3)*[3]

7,7*a*-Dihydro-1β-hydroxy-7*a*β-methyl-5(6*H*)-indanone (**11**, 100 mg, 0.6 mmol), ethylene glycol (37 mg, 0.6 mmol), and toluene-*p*-sulfonic acid (or oxalic acid) (12 mg) were heated under reflux for 4 h with a Dean–Stark trap containing molecular sieves. The cooled, discolored solution was then washed with saturated aqueous sodium bicarbonate (2 ml), then with water (2 ml), and the dried ($MgSO_4$) benzene layer evaporated. Preparative layer chromatography of the residual oil (96 mg) with diethylether as the developing solvent yielded the hydroxy indane ketal **3** (38 mg, 30%) m.p. 82–83.5° which decomposed on attempted recrystallizations from a variety of solvents; i.r. 3640, 3480, 1090, and 1110 cm^{-1}; p.m.r. δ 1.00 (3H, s, CH_3), 2.4 (2H, "s", C-3 or -4 CH_2), 3.96 (4H, s, OCH_2CH_2O), 4.12 (1H, t, J = 4 Hz, C*H*-OH) and 5.26 (1H, "s", vinylic H).

Anal. Calcd. for $C_{12}H_{18}O_3$ (mol. wt. 210.1256): C, 68.54; H, 8.62. Found (210.1253): C, 68.64; H, 8.77.

*5,5-Ethylenedioxy-7a*β*-methyl-7,7a-dihydro-1(6H)-indanone (4)*[3]

7,7*a*-Dihydro-7*a*β-methyl-1,5(6*H*)-indandione (**12**, 100 mg, 0.6 mmol) and ethylene glycol (37 mg, 0.6 mmol) were reacted and worked-up as described above for the preparation of **3** by selective ketalization of the dione **6**. The higher R_f preparative layer chromatography band contained the ketal **4** (26 mg) which recrystallized from *n*-hexane as small prisms m.p. 54–56°;[6] i.r. 1740 and 1090 cm^{-1}; p.m.r. δ 1.10 (3H, s, CH_3), 2.36 (2H, broad s), and 2.83 (2H, m, C-2 and -3, or -4 CH_2), 3.83 (4H, s, OCH_2CH_2O) and 5.60 p.p.m. (1H, "s", vinylic H).

Anal. Calcd. for $C_{12}H_{16}O_3$ (mol. wt. 208.1099): C, 69.20; H, 7.74. Found (208.1105); C, 68.73; H, 7.72.

The preparative layer chromatography band of lower R_f yielded the isomeric 1,1-ketal **14** as an oil (48 mg) which decomposed on attempted purification by distillation; i.r. 1660, 1160, and 1135 cm^{-1}; p.m.r. δ 1.28 (3H, s, CH_3), 2.45 (2H, "s") and 2.95 (2H, m, C-2 and -3, or -4 CH_2).

Mol. Wt. Calcd. for $C_{12}H_{16}O_3$: 208.1099. Found (mass spectrum): 208.1105.

Reaction of 1-Nitroso-2-naphthylamine with 3-Aroylaziridines

J. W. LOWN AND M. H. AKHTAR[1]

Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received December 21, 1970

Reaction of 1-nitroso-2-naphthylamine with a series of 3-aroylaziridines affords (*a*) 3-arylbenzo[*f*]-quinoxalines, (*b*) cyclohexylimino derivatives of 2-aroylnaphtho[1,2-*d*]imidazoles, and (*c*) a 2-aryl-naphtho[1,2-*d*]imidazole. Electron-withdrawing substituents in either the 2 or 3 aryl moieties of the aziridine lead to preferential formation of products of type *a* whereas electron-donating substituents in either of these positions result in the formation of products of type *b*. The results of deuterium labelling and unambiguous synthetic studies in support of the proposed 1,3-dipolar cycloaddition mechanism are discussed.

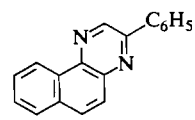
La réaction de la nitroso-1 naphtylamine-2 avec une série de benzoyl-3 arizidines conduit à (*a*) des phényl-3 benzo[*f*]quinoxalines, (*b*) des dérivés cyclohéxylimino des benzoyl-2 naphto[1,2-*d*]imidazoles, et (*c*) une phényl-2 naphta[1,2-*d*]imidazole. Si le noyau aromatique de l'aziridine porte des substituants électro-affinitaires en positions 2 ou 3, les produits formés d'une façon préférentielle sont ceux du type *a*; par ailleurs si des substituants sont électro-répulsifs les produits formés d'une façon préférentielle sont ceux du type *b*. On discute de nos résultats-molécules marquées par du détérium et synthèses non-ambigues-en fonction d'un mécanisme de cycloaddition dipolaire-1,3.

Canadian Journal of Chemistry, 49, 1610 (1971)

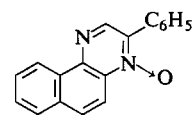
We recently described the reaction of 3-aroylaziridines with 1-nitroso-2-naphthol to produce both 2-aryl and 2-aroylnaphtho[1,2-*d*]oxazoles in good yield (1, 2). The reaction was interpreted as proceeding via initial 1,3-dipolar addition of an azomethine ylide, derived by thermal cleavage of the aziridine, to the nitrogen–oxygen bond in both orientations. Spontaneous 1,3-cleavage of the intermediate oxadiazolidines produced nitrones which cyclodehydrate to produce the observed products. In these reactions the aziridines behave as ylides and the reactions parallel the classic work of Krohnke and Gerlach on the chemistry of pyridinium ylides with nitrosonaphthols (3, 4). The latter type of reaction was used to prove the structure of the 2-aroylnaphtho-[1,2-*d*]oxazoles obtained in the aziridine reactions. 2-Nitroso-1-naphthol behaves differently with 3-aroylaziridines than with pyridinium ylides however and affords in the former case 2-arylnaphtho[2,1-*d*]oxazoles, 2,2′-azodi-1-naphthol, and examples of the hitherto undescribed naphtho[2,1-*f*]-1,3,5-oxadiazepine system (5), whereas in the latter case only naphtho[2,1-*d*]oxazoles are produced.

The simplicity and versatility of the reactions of aziridines with nitroso compounds suggested an extension to include other participating groups to be worthwhile. We describe the reaction of 1-nitroso-2-naphthylamine with 3-aroylaziridines to produce 3-arylbenzo[*f*]quinoxalines, cyclohexylimino derivatives of 2-aroylnaphtho[1,2-*d*]-imidazoles, and a 2-arylnaphtho[1,2-*d*]imidazole.

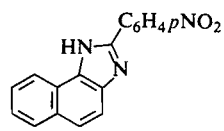
Treatment of 3-benzoyl-1-cyclohexyl-2-*p*-nitrophenylaziridine with an equimolar quantity of 1-nitroso-2-naphthylamine in refluxing benzene for 24 h and chromatographic separation of the product on alumina gave 3-phenylbenzo[*f*]quinoxaline (**1**), $C_{18}H_{12}N_2$, in 49% yield and 2-*p*-nitrophenylnaphtho[1,2-*d*]imidazole(**3**),$C_{17}H_{11}N_3O_2$, in 16% yield.



1



2



3

The structure of **1** was proven by oxidation to the known 3-phenylbenzo[*f*]quinoxaline-4-oxide (**2**) (6) in 53% yield with *m*-chloroperbenzoic acid. Owing to the existence of tautomerism in the

[1]NRCC Postdoctorate Fellow, 1970 to present.

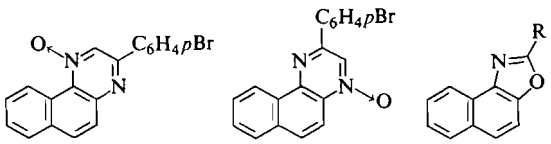
For personal use only.

2-*p*-nitrophenylnaphtho[1,2-*d*]imidazole (**3**) the position of the NH proton (clearly indicated by a band at 3330 cm^{-1} in the i.r. spectrum) cannot be assigned (7). Such structures had been considered for the sole products obtained in the parallel reaction of nitrosonaphthylamines with pyridinium ylides by Krohnke which were formulated as the benzo[*f*]quinoxaline-*N*-oxides *e.g.* **4** and **5** obtained by reaction of pyridinium



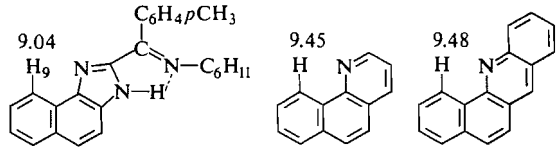
4 **5** **6**

p-bromophenacylide on 1-nitroso-2-naphthylamine and 2-nitroso-1-naphthylamine respectively (3, 4). In our reactions therefore the azomethine ylides derived from thermal cleavage of the 3-aroylaziridines behave quite differently from their pyridinium ylide analogs in contrast to their parallel behavior in their reactions with 1-nitroso-2-naphthol to produce 2-arylnaphtho-[1,2-*d*]oxazoles **6** (1, 2).

The obvious pathway to benzoquinoxalines such as **1** in the reaction with 3-aroylaziridines, namely, initial formation of a benzoquinoxaline-*N*-oxide analogous to **4** followed by deoxygenation, does not apply. While aromatic nitroso compounds can effect oxygen transfer reactions in many instances especially at elevated temperatures (8) nevertheless representative benzo[*f*]-quinoxaline-1-oxides prepared separately with pyridinium ylides proved to be completely unreactive towards 1-nitroso-2-naphthylamine under conditions in which **1** and similar compounds are formed readily.

The 3-*p*-bromophenylbenzo[*f*]quinoxaline-1-oxide (**4**) (4) could however be deoxygenated with lithium aluminum hydride to 3-*p*-bromophenylbenzo[*f*]quinoxaline which was shown to be identical with the product obtained from the reaction of 3-*p*-bromobenzoyl-1-cyclohexyl-2-phenylaziridine with 1-nitroso-2-naphthylamine.

Reaction of 1-cyclohexyl-2-phenyl-3-*p*-toluoylaziridine with 1-nitroso-2-naphthylamine in refluxing benzene for 24 h followed by chromatographic separation afforded a third type of product, 2-(cyclohexylimino-2-*p*-toluoyl)naphtho[1,2-*d*]imidazole (**7**), $C_{25}H_{25}N_3$, in 35.3% yield.



7 **8** **9**

The i.r. spectrum of **7** showed an NH absorption at 3440 cm^{-1} [compared with reported values of 3470–3400 cm^{-1} for hydrogen bonded NH in solution for benzimidazoles (9)]. The n.m.r. spectrum showed two bands at 5.08 and 5.21 δ, together equal to one proton, and both exchangeable in deuterium oxide and assigned to the NH proton in tautomeric hydrogen-bonded forms such as **7**; and a band at 3.83–4.50 characteristic of cyclohexyl methine adjacent to a C=N bond (10). The strongly shifted aromatic proton at 9.04 δ is ascribed to proton-9 *peri* to the aza-nitrogen of the imidazole ring by comparison with model compounds **8** and **9** (11).

The benzo[*f*]quinoxalines and cyclohexylimino 2-aroylnaphtho[1,2-*d*] imidazoles produced by reaction of 1-nitroso-2-naphthylamine with a variety of 3-aroylaziridines are listed in Tables 1 and 2 together with analytical data. In several instances the same naphthoimidazole or benzoquinoxaline was obtained from reactions with different aziridines when the appropriate groups were common.

The formation of the three types of products benzo[*f*]quinoxalines, cyclohexylimino-2-aroylnaphtho[1,2-*d*]imidazoles, and 2-arylnaphtho-[1,2-*d*]imidazoles is rationalized in Scheme 1.

The reactions are interpreted in terms of initial 1,3-dipolar cycloadditions in both orientations of the azomethine ylide (derived by cleavage of the aziridine) to the N—O bond of the nitrosonaphthylamine although most of the products correspond to one particular orientation of addition **10**. Formation of products of types **16** and **17** are envisaged as involving cleavage (*y*) of the intermediate oxadiazolidines **10** and **11** to the nitrones **13** and **14** respectively (a reaction for which precedents and strong analogies exist (1, 2)) and cyclodehydration of the latter to **16** and **17** respectively. Although Schiff bases have occasionally been isolated from 1,3-dipolar cycloaddition reactions of 4-oxazolines, they are more often hydrolyzed to aldehyde and cyclohexylamine during the reaction (12) and so cyclohexylamine would be available for condensation to form **16**.

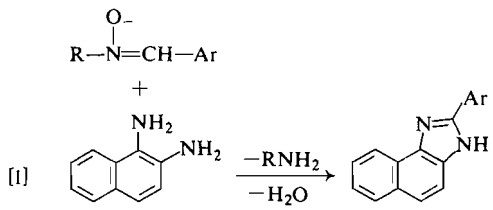
Formation of **16** and **17** from the nitrones **13** and **14** is the intramolecular counterpart of the reaction of aromatic 1,2-diamines with nitrones to form naphtho[1,2-*d*]imidazoles and benzimidazoles described by Krohnke and Leister (13) (see eq. 1). In the case of **13** the initially formed 2-aroylnaphtho[1,2-*d*]imidazole condenses with cyclohexylamine to form **16**.



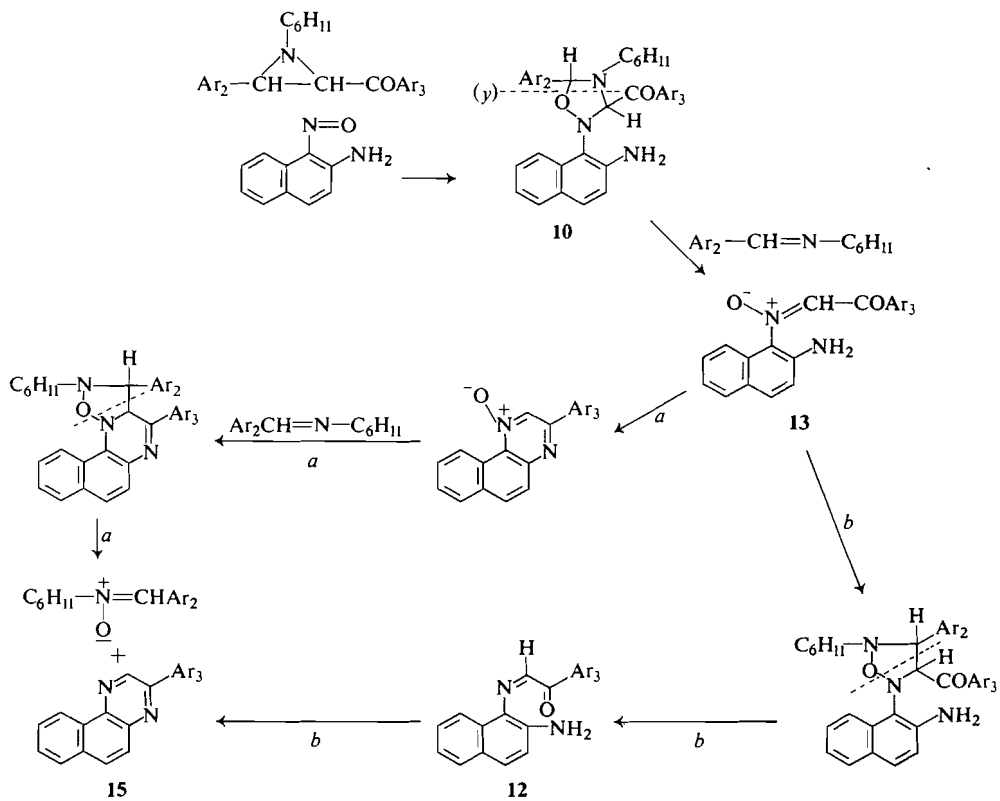
[1]

An alternative rationale for the formation of benzo[*f*]quinoxalines rather than benzo[*f*]-quinoxaline-1-oxides in these reactions suggested by a referee involves the reversible cycloaddition of Schiff bases to the *N*-oxide 1,3-dipoles (see Scheme 2).

However two benzo[*f*]quinoxaline-1-oxides were found to be completely unreactive towards benzal cyclohexylamine eliminating route *a*. Similarly route *b* is unlikely in view of the observed rapid cyclization of **13** (generated with pyridinium ylides at 15°) to the benzo[*f*]quinoxaline-1-oxide in contrast to the known sluggish dipolarophilic activity of Schiff bases (19) even at high temperatures.

1 - Nitroso - 2 - methylaminonaphthalene (**18**), when allowed to react with 3-benzoyl-1-cyclohexyl-2-*p*-nitrophenyl aziridine, gave the 1-*N*-methyl-2-*p*-nitrophenylnaphtho[1,2-*d*]imidazole (**19**), $C_{18}H_{13}N_3O_2$, m.p. 246–248° as the only isolable product. Compound **19** showed a singlet at 3.99 δ in the n.m.r. spectrum for the *N*-methyl group but showed no NH absorption in the i.r. spectrum. The benzo[*f*]quinoxaline is not formed in this reaction since condensation to the carbonyl group as in **12** is precluded.

Formation of products of type **15** without the intermediacy of the benzo[*f*]quinoxaline-1-oxide

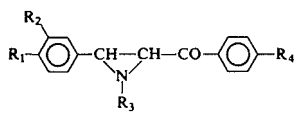


SCHEME 2

TABLE 3. Reaction of 3-aroylaziridines with *p*-nitrosodiphenylamine

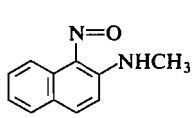
Aziridine substituents*				Schiff base formed†		Yield (%)	Melting point (°C)	Reference
R_1	R_2	R_3	R_4	R_1	R_2			
(*cis*)H	NO_2	C_6H_{11}	H	H	NO_2	30.0	120	15
(*trans*)H	NO_2	C_6H_{11}	H	H	NO_2	26.3	121	15
NO_2	H	C_6H_{11}	H	NO_2	H	34.0	172	15
H	H	CH_3	CH_3	H	H	26.0	105	15
OCH_3	H	C_6H_{11}	H	OCH_3	H	33.9	103	16

*Refers to structure:

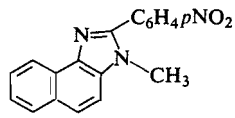


†Refers to structure: $C_6H_5NHC_6H_4-N=CH-C_6H_3(R_2)-R_1$

implies a second mode of cleavage (*x*) of intermediate **10** in which the substituted Schiff bases **12** are formed and subsequently cyclodehydrate to the benzo[*f*]quinoxalines **15**. At this latter stage the reaction becomes the counterpart of the



18



19

reaction of 1,2-diamines with α-diketones to form quinoxalines. The latter reaction would be favored over formation of an imidazole ring since the C=N bond in **12** is less susceptible to nucleophilic attack than the strongly polarized $C=\overset{+}{N}-O^{\ominus}$ bond in **13** or **14**. This reaction pathway to **15** receives confirmation by the reaction of 1-nitroso-2-naphthylamine with specifically deuterium labelled 3-benzoyl-1-cyclohexyl-3-deutero - 2 - *p* - nitrophenylaziridine (containing 54% deuterium incorporation) which gave 2-deutero-3-phenylbenzo[*f*]quinoxaline in which 56% of the original label was incorporated into the 2 position (see Scheme 1).

To support the above proposal involving cleavage of the intermediate oxadiazolidine by mode (*x*), examples were sought in which Schiff bases were isolable directly. Such should be the case if cyclization were prevented by a suitable positioning of substituents.

p-Nitrosodiphenylamine reacted readily with either *cis* or *trans* 3-benzoyl-1-cyclohexyl-2-*m*-nitrophenylaziridine to give the known *N*-[*m*-nitrobenzal]-4-phenylaminoaniline (**20**), m.p. 121°, in 30 and 26% yields respectively. Similarly *p*-nitrosodiphenylamine reacted with 2-*p*-anisyl-3-benzoyl-1-cyclohexylaziridine to give *N*-[4-methoxybenzal]-4-phenylaminoaniline in 34% yield (see Table 3).

$$pC_6H_5NHC_6H_4N{=}CHC_6H_4mNO_2$$

20

It is very improbable that a nitrone comparable with **14** is an intermediate in the formation of **20** and similar Schiff bases. Nitrones like the *N*-oxides **2**, **4**, and **5** may be deoxygenated to imines but require reagents such as triphenylphosphine (14).

It may be noted from Table 4 that electron-withdrawing substituents in either the 2 or 3 aryl moieties of the aziridine lead to a clear preference for formation of the benzo[*f*]quinoxalines. In contrast electron-donating substituents in either the 2 or 3 positions of the aziridine result in formation of the naphtho[1,2-*d*]imidazole derivative and groups which have zero (H) or small inductive effects (Br) lead to mixtures of the two principal products. The 2-arylnaphtho[1,2-*d*]-imidazole was isolated in only one instance. The marked effects of the substituents on the mode of cleavage of the intermediate oxadiazolidine **10** indicate a highly polar transition state for the reaction and suggest heterolytic cleavage.

Reactions of 3-aroylaziridines with 1-nitroso-naphthalenes bearing other neighboring groups in the 2 position are currently under investigation.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were

*2-*p*-Nitrophenylnaphtho[1,2-*d*]imidazole.

recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (W/V) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Absorption spectra were recorded in 'spectro'-grade solvents on a Beckman DB recording spectrophotometer. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for t.l.c. Microanalyses were carried out by Mrs. D. Mahlow of this department.

General Preparation of 3-Aroylaziridines

The aziridines used in this study were prepared by the Gabriel synthesis involving Claisen–Schmidt condensations to form chalcones, addition of bromine to form the dibromochalcones, and treatment of the dibromochalcones with an excess of a primary aliphatic amine to provide 3-aroylaziridines (17).

Preparation of 1-Nitroso-2-naphthylamine

1-Nitroso-2-naphthylamine was prepared by dissolving 1-nitroso-2-naphthol (technical grade, Eastman Organic Chemicals) in water, adding an equimolar quantity of 0.88 aqueous ammonia, and heating the mixture on the steam bath for 2 h. 1-Nitroso-2-naphthylamine formed as a moss-green precipitate which was collected and purified by recrystallization from aqueous ethanol m.p. 150–152° in 69% yield (lit. m.p. 150–152° (18)).

Preparation of 1-Nitroso-2-(N-methyl)-naphthylamine

To a suspension of 8.6 g (0.05 mol) of 1-nitroso-2-naphthol in 40 ml of water were added 10 ml of methylamine (40% in water, Eastman Organic Co). The reaction mixture was heated in a pressure bottle in a steam bath for 30 min. On cooling a greenish-brown precipitate deposited, which was filtered, boiled in water twice (20 ml), filtered, dried *in vacuo* to give 5.4 g (69% yield) of 1-nitroso-2-(*N*-methyl)-naphthylamine, m.p. 135–137 °C.

Anal. Calcd. for $C_{11}H_{10}N_2O$ (mol. wt. 186.0793): C, 70.96; H, 5.38; N, 15.05. Found (186.0790 (mass spectrum)): C, 70.82; H, 5.08; N, 14.73.

The i.r. spectrum, $\nu_{max}(CHCl_3)$: 3410 cm^{-1} (N—H); n.m.r. spectrum: $\delta_{TMS}(CDCl_3)$: 2.85 (3H, doublet, —N—CH_3, J = 5.0 Hz); 4.18–5.18 (1H, broad, —NH, D_2O-exchangeable); 6.55–7.62 (5H, multiplet, aromatic protons); 8.81–8.95 (1H, multiplet, *peri*-proton at C-8 position).

General Procedure for the Reaction of 3-Aroylaziridines with 1-Nitroso-2-naphthylamine

Representative examples of the preparation of 3-arylbenzo[*f*]quinoxalines, 2-cyclohexyliminoaroylnaphtho[1,2-*d*]imidazoles, and 2-arylnaphtho[1,2-*d*]imidazoles are described in detail. The analytical and spectral data on further examples prepared in a similar fashion are summarized in Tables 1–3.

Reaction of 3-Benzoyl-1-cyclohexyl-2-p-nitrophenylaziridine with 1-Nitroso-2-naphthylamine

A solution of 1.75 g (5 mmol) of 2-*p*-nitrophenyl-1-cyclohexyl-3-benzoylaziridine and 0.86 g (5 mmol) of 1-nitroso-2-naphthylamine in 40 ml of dry benzene was stirred and heated under reflux for 24 h. The reaction mixture was concentrated *in vacuo*, and the dark oil was subjected to chromatography on 60 g of alumina (BDH) with hexane–benzene (8:2) as eluant. Removal of the solvent afforded white flakes of 3-phenylbenzo[*f*]quinoxaline, 0.632 g (49.4% yield), m.p. 163–164 °C [from 95% ethanol (lit. m.p. 163–164° (6)].

Anal. Calcd. for $C_{18}H_{12}N_2$ (mol. wt. 256.1001): C, 84.50; H, 4.70; N, 10.83. Found (256.0997 (mass spectrum)): C, 84.48; H, 4.57; N, 10.93.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 7.16–8.22 (10H, multiplet, aromatic protons); 9.03–9.18 (1H, multiplet, *peri*-proton at C-10), and 9.25 (1H, singlet, proton at C-2).

Further elution with benzene gave after removal of the solvent *in vacuo* a brownish solid of 2-*p*-nitrophenylnaphtho[1,2-*d*]imidazole 0.224 g (15.5% yield), m.p. 290–293 °C.

Anal. Calcd. for $C_{17}H_{11}N_3O_2$ (mol. wt. 289.0851): C, 70.58; H, 3.83; N, 14.52. Found (289.0858 (mass spectrum)): C, 70.57; H, 4.19; N, 13.69.

The i.r. spectrum ν_{max}(KBr) 3330 (—N—H); 1510 and 1335 cm^{-1} (aromatic nitro group).

Reaction of 3-Benzoyl-1-cyclohexyl-3-deutero-2-p-nitrophenylaziridine with 1-Nitroso-2-naphthylamine

A solution of 0.88 g (2.5 mmol) of 3-benzoyl-1-cyclohexyl-3-deutero-2-*p*-nitrophenylaziridine (54% D incorporation) (11) and 0.43 g (2.5 mmol) of 1-nitroso-2-naphthylamine in 30 ml of dry benzene was heated under reflux for 24 h. The reaction mixture worked-up exactly as described above affording 2-deutero-3-phenylbenzo-[*f*]quinoxaline, m.p. 162–163°, 0.240 g (36% yield) m.p. of protium analog 163–164°.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 7.16–8.22 (10H, multiplet, aromatic protons), 9.03–9.18 (1H, multiplet, *peri*-protons at C-10), and 9.25 (0.67H, singlet, proton at C-2, 33% deuterium incorporation at C-2 position *i.e.* overall incorporation 55.5%).

Reaction of 1-Cyclohexyl-2-phenyl-3-p-toluoylaziridine with 1-Nitroso-2-naphthylamine

A solution of 1.59 g (5 mmol) of 1-cyclohexyl-2-phenyl-3-*p*-toluoylaziridine and 0.87 g (5 mmol) of 1-nitroso-2-naphthylamine in 40 ml of dry benzene was stirred and heated under reflux for 24 h. The reaction mixture was concentrated *in vacuo*, and the oil was subjected to chromatography on 60 g of alumina (BDH) with hexane–benzene (9:1) as eluant. Removal of the solvent and trituration of the resulting yellow oil with petroleum ether (30–60) gave the cyclohexylamino adduct of 2-toluoylnaphtho[1,2-*d*]imidazole as a yellow solid, 0.645 g (35.3% yield), m.p. 134–135.5° (95% ethanol).

Anal. Calcd. for $C_{25}H_{25}N_3$ (mol. wt. 370.2049): C, 81.70; H, 6.85; N, 11.45. Found (367.2045 (mass spectrum)): C, 81.52; H, 6.83; N, 11.49.

The i.r. spectrum ν_{max}($CHCl_3$): 3440 cm^{-1} (—NH). The n.m.r. spectrum δ_{TMS}($CDCl_3$): 0.83–2.33 (10H, multiplet, cyclohexyl protons); 2.42 (3H, singlet, methyl protons); 3.83–4.50 (1H, multiplet, methine proton), 5.08 and 5.21 (1H, 2 singlet, D_2O exchangeable, —NH). 7.18–7.96 (9H, multiplet, aromatic protons), and 8.96–9.12 (1H, multiplet *peri*-proton at C-9).

Oxidation of 3-Phenylbenzo[f]quinoxaline with m-Chloroperbenzoic Acid

To a solution of 0.256 g (1 mmol) of 3-phenylbenzo-[*f*]quinoxaline in 10 ml chloroform was added 0.207 g (1.2 mmol) of *m*-chloroperbenzoic acid (80%). The reaction mixture was stored at 0 °C for 4 days, concentrated, made alkaline with 2 *N* aqueous sodium carbonate, and extracted with chloroform to give the yellow 3-phenylbenzo[*f*]quinoxaline-4-oxide, 0.144 g (53% yield), m.p. 231–233 °C (lit. m.p. 234–235° (6)).

Deoxygenation of 3-p-Bromophenylbenzo[f]quinoxaline-1-oxide with Lithium Aluminum Hydride

To a suspension of 0.38 g (10 mmol) of lithium aluminum hydride in 125 ml of dry benzene was added 0.9 g (2.5 mmol) of 3-*p*-bromophenylbenzo[*f*]quinoxaline-1-oxide prepared from published procedures (4) and the suspension was heated under reflux for 24 h. The usual work-up procedure afforded a cream-colored solid of 3-*p*-bromophenyl-benzo[*f*]quinoxaline, 0.078 g (8%), m.p. 199–201 °C. The n.m.r. and i.r. spectra of this compound were identical to those prepared by reaction of 3-*p*-bromobenzoyl-1-cyclohexyl-2-phenylaziridine with 1-nitroso-2-naphthylamine. The mixed melting points of 3-*p*-bromophenylbenzo[*f*]quinoxaline from these two sources were undepressed. In comparable reactions between 3-*p*-bromophenylbenzo[*f*]quinoxaline-1-oxide and an equimolar quantity of 1-nitroso-2-naphthylamine, the benzo-[*f*]quinoxaline-1-oxide was recovered unchanged, even after prolonged refluxing in benzene.

Reaction of 3-Benzoyl-1-cyclohexyl-2-p-nitrophenylaziridine with 1-Nitroso-2-(N-methyl)-naphthylamine

A solution of 1.75 g (5 mmol) of 3-benzoyl-1-cyclohexyl-2-*p*-nitrophenylaziridine and 0.93 g (5 mmol) of 1-nitroso-2-(*N*-methyl)naphthylamine in 40 ml of dry benzene was stirred and heated under reflux for 24 h during which time the solution turned dark brown. Upon cooling of the reaction mixture, a green–brown solid which had precipitated, 0.982 g (65% yield) was collected and purified by extraction of the impurities with benzene–acetone (8:2) to give yellow solid, m.p. 246–248 °C.

Anal. Calcd. for $C_{18}H_{13}N_3O_2$ (mol. wt. 303.1008): C, 71.28; H, 4.31; N, 13.85. Found (303.1004 (mass spectrum)): C, 70.80; H, 3.70; N, 13.91.

The i.r. spectrum, ν_{max}($CHCl_3$): ν_{max} 1515 and 1340 cm^{-1} (aromatic nitro group); n.m.r. spectrum δ_{TMS} ($CDCl_3$): 3.99 (3H, singlet, CH_3), and 7.20–8.94 (10H, multiplet, aromatic protons).

Reaction of p-Nitrosodiphenylamine with 2-Anisyl-3-benzoyl-2-cyclohexylaziridine

A solution of 1.675 g (5 mmol) of 2-anisyl-3-benzoyl-1-cyclohexylaziridine and 0.99 g (5 mmol) of *p*-nitrosodiphenylamine in 40 ml of dry benzene was heated under reflux for 24 h when a red–brown color developed. After removal of the solvent *in vacuo*, the residual brown oil was subjected to chromatography on 80 g of B.D.H. alumina. Elution with benzene afforded a yellow oil after evaporation of the solvent. The oil crystallized upon trituration with hexanes yielding *N*-[4-methoxybenzal]-4-phenylaminoaniline 0.51 g (34% yield), m.p. 103° (lit. m.p. 105° (16)).

Reaction of cis-3-Benzoyl-1-cyclohexyl-2-p-nitrophenylaziridine with p-Nitrosodiphenylamine

A solution of 1.75 g (5 mmol) of *cis*-3-benzoyl-1-cyclohexyl-2-*p*-nitrophenylaziridine and 0.99 g (5 mmol) of *p*-nitrosodiphenylamine in 50 ml of dry benzene was heated under reflux for 24 h. After removal of the solvent *in vacuo*, the residual oil was subjected to chromatography on 85 g of B.D.H. alumina. Elution with benzene afforded a red oil which crystallized upon trituration with hexanes yielding *N*-[3-nitrobenzal]-4-phenylaminoaniline as deep yellow plates, 0.464 g (30% yield), m.p. 120° (lit. m.p. 123° (14)).

Reaction of trans-3-Benzoyl-1-cyclohexyl-2-p-nitrophenylaziridine with p-Nitrosodiphenylamine

A similar reaction between 1.75 g (5 mmol) of *trans*-3-benzoyl-1-cyclohexyl-2-*p*-nitrophenylaziridine and 0.99 g (5 mmol) of *p*-nitrosodiphenylamine afforded *N*-[3-nitrobenzal]-4-phenylaminoaniline, 0.402 g (26% yield), m.p. 121° identical with that obtained above.

Reaction of other 3-aroylaziridines with *p*-nitrosodiphenylamine to give Schiff bases were carried out in a similar fashion and the results are summarized in Table 4.

Reaction of 3-Phenylbenzo[f]quinoxaline-1-oxide with Benzal Cyclohexylamine

A solution of 1.36 g (0.05 mmol) of 3-phenylbenzo-[*f*]quinoxaline-1-oxide [prepared from 1-nitroso-2-

naphthylamine and pyridinium phenacylide (4) [Mol. Wt. Calcd. for $C_{18}H_{12}N_2O$: 272.0950. Found (mass spectrum): 272.0944)] and 0.91 g (0.05 mol) of benzal cyclohexylamine (20) in 40 ml of benzene was heated under reflux for 24 h. Upon cooling the solution the *N*-oxide precipitated unchanged as an orange–red solid which was collected, 1.31 g (98% recovery), m.p. 222–224° (mixed m.p. with authentic sample 222–224°).

Reaction of 3-p-Bromophenylbenzo[f]quinoxaline-1-oxide with Benzal Cyclohexylamine

Similarly a suspension of 1.75 g (0.05 mol) of 3-*p*-bromophenylbenzo[*f*]quinoxaline and 0.91 g (0.05 mol) of benzal cyclohexylamine in 40 ml of benzene was heated under reflux for 24 h. Upon cooling the solution, the unchanged *N*-oxide was recovered 1.72 g (99% recovery), m.p. 301° (mixed m.p. with authentic sample 301°).

This research was supported by a National Research Council of Canada grant to J. W. Lown. We thank Mr. R. Swindlehurst and Dr. A. Hogg for the n.m.r. spectra and Mr. J. P. Moser and Miss B. Cole for able technical assistance.

Photolysis of 1,1-Diphenylsilacyclohexanone in Diethyl Fumarate. The Trapping of a Siloxycarbene by an Electron-Deficient Olefin

A. G. Brook, H. W. Kucera, and Ronald Pearce
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received December 4, 1970

Photolysis of diphenylsilacyclohexanone in diethyl fumarate yields a product shown to be the cyclopropane resulting from trapping of a siloxycarbene by the alkene.

On montre que le produit formé lors de la photolyse de la diphénylsilacyclohexanone dans le fumarate d'éthyle est un cyclopropane provenant de la condensation d'un syloxycarbène sur l'alcène.

Introduction

In our investigations of the photochemistry of acylsilanes, we have obtained evidence for a ready photoisomerization of acylsilanes to siloxycarbenes, these latter species being trapped in the presence of alcohols (1) (eq. 1). Confirmation of the formation of the siloxycarbenes in these photolyses was required, and since the formation of cyclopropanes by the addition of carbenes to the double bond of olefins is characteristic of such species (2) the photolysis of acylsilanes in alkenes was investigated. This report describes the isolation and characterization of the spirocyclopropane obtained from the photolysis of 1,1-diphenyl-1-silacyclohexan-2-one (**1**) in the presence of diethyl fumarate.

$$[1]\quad R_3SiC(=O)R' \xrightarrow{h\nu} R_3SiO\ddot{C}R' \xrightarrow{R''OH} R_3SiOCHR'(OR'')$$

Results and Discussion

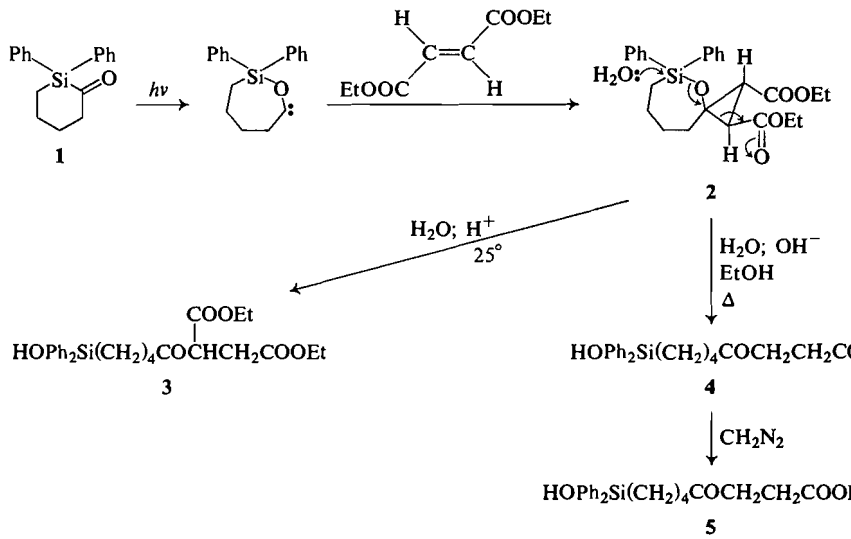
Photolysis of **1** in diethyl fumarate solution proceeded readily to give the adduct, *trans*-1,2-dicarbethoxy-4,4-diphenyl-3-oxa-4-silaspiro-[2.6]nonane (**2**) in 78% yield (Scheme 1). Its n.m.r. spectrum showed two doublets at δ 2.29 and 2.72 (J = 7 Hz) assigned to the cyclopropyl protons, in addition to other expected features. No evidence of the presence of other isomers was noted.

Mild acid hydrolysis of **2** afforded the acyclic ester, **3**, while a more vigorous, basic hydrolysis gave the acyclic acid, **4**, which was characterized as its methyl ester, **5**, after reaction with diazomethane. The formation of **3** presumably takes place via attack of water (or hydroxide ion) at silicon. Saponification of **3**, and decarboxylation of the resulting β-keto acid, accounts for the formation of **4**.

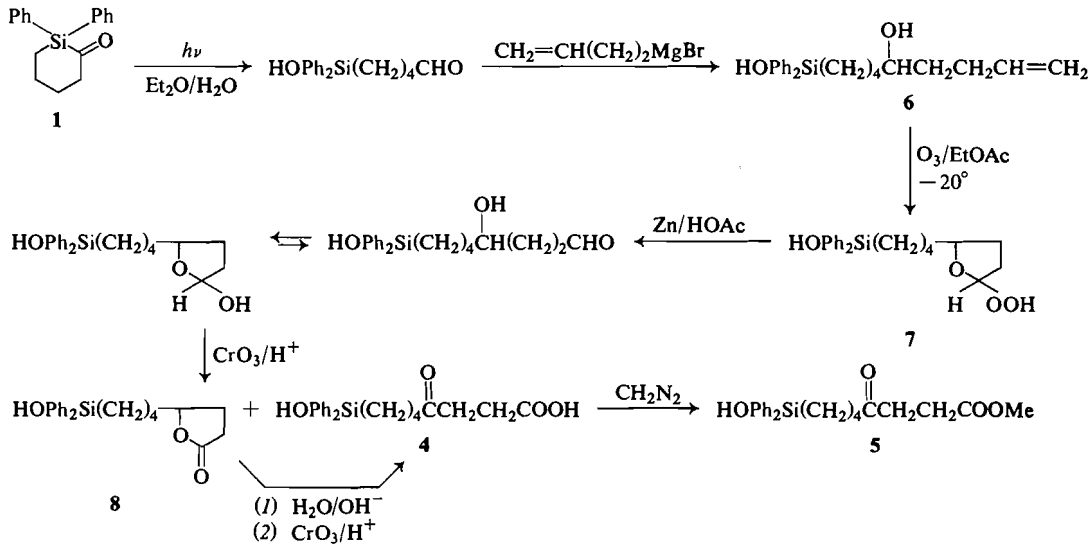
The structure of the methyl ester, **5**, was confirmed by the alternate synthesis outlined in Scheme 2. 5-(Diphenylhydroxysilyl)pentanal (3) prepared by photolysis of **1** in wet ether, was treated with 3-butenylmagnesium bromide to give 9-diphenylhydroxysilyl-5-hydroxynon-1-ene (**6**). Ozonolysis of this alkene gave a product believed to be the 2-hydroperoxytetrahydrofuran, **7** (4). Without being isolated this was reduced with zinc in acetic acid and oxidized with chromic acid to give the γ-lactone, **8**, along with a small quantity of the γ-keto acid, **4**. The predominance of the γ-lactone in the oxidation product is not unexpected since it is known that 4-hydroxybutanals exist mainly as their tautomeric cyclic hemi-acetals (5). Hydrolysis of **8**, followed by oxidation with chromic acid, afforded the γ-keto acid, **4**, which was converted to its methyl ester, **5**, on treatment with diazomethane. The spectra of **5** obtained from this synthesis and from the material obtained by the degradation of the spiro compound, **2**, were identical.

The isolation of the adduct **2** is, therefore, good evidence for the intermediacy of a siloxycarbene, **1***a*, in the photolysis of **1**.

Photolysis of **1** in the presence of a number of other olefins failed to give significant quantities of the expected spiro adducts. The olefins used were cyclohexene, 2,3-dimethylbut-2-ene, 1,1-dimethoxyethene, *cis*- and *trans*-1,2-dichloroethene, and tetracyanoethene (this olefin appeared



SCHEME 1



SCHEME 2

to form a charge-transfer complex with **1**). The presence of very small quantities of what may be the expected adducts with *cis*- and *trans*-1,2-dichloroethene was indicated by weak signals in the n.m.r. spectra of the crude products: absorptions at δ 3.28 and 2.77 p.p.m. were observed with the *cis*-olefin and a pair of doublets (AB system, $J = 4$ Hz) at δ 2.89 and 3.27 p.p.m. were observed with the *trans*-olefin.

The facile reaction with diethyl fumarate and the lack of reactivity with electron-rich olefins such as cyclohexene or tetramethylethylene suggest that the cyclic siloxycarbene behaves as a nucleophile, a behavior observed previously with a variety of other oxacarbenes (2, 6). The nucleophilic properties of oxacarbenes can be ascribed to the importance of contributions from the canonical form **9*a*** of the hybrid. If this interpre-

For personal use only.

$$R—O—\ddot{C}—R' \leftrightarrow R—\overset{+}{O}=\bar{C}—R'$$
9 **9a**

tation is correct then the siloxycarbenes may be expected to be more nucleophilic than their carbon analogues since electron release by the relatively electropositive silyl group R should stabilize this contribution. The results presented here are in accord with this order of relative nucleophilicity.

Experimental

Photolysis of 1,1-Diphenylsilacyclohexan-2-one (1) in Diethyl Fumarate

A solution of **1** (5.0 g, 0.019 mol) in freshly distilled diethyl fumarate (31 g, 0.18 mol) was irradiated under nitrogen for 6 h using a low pressure mercury lamp.[1] Fractionation afforded *trans*-1,2-dicarbethoxy-4,4-diphenyl-3-oxa-4-silaspiro[2.6]nonane (**2**), 6.5 g (78%); b.p. 190–200°/0.01 mm (Kugelröhr); n_D^{22} 1.5462; i.r. (film) λ_{max} 5.78 (C=O) μ; n.m.r. (CCl_4) δ 7.7–7.1 (Ar, m, 10), 4.0 (OCH_2—, two overlapping q (J = 7 Hz), 4), 2.72, 2.29 (cyclopropyl, AB system (J = 7 Hz), 2), 2.2–0.9 (aliphatic and O—C—CH_3, m with two overlapping t at 1.1 (J = 7 Hz), 14), p.p.m.

Anal. Calcd. for $C_{25}H_{30}O_5Si$: C, 68.45; H, 6.90. Found: C, 68.24; H, 6.91.

Acid Hydrolysis of 2

A solution of **2** (1.11 g, 0.0025 mol), acetone (15 ml), and 2 *M* hydrochloric acid (1 ml) was stirred at room temperature for 24 h. The solvent was removed on a rotary evaporator and the residue was extracted with ether. The ethereal extract was washed with sodium carbonate solution and dried ($MgSO_4$). Evaporation of the ether gave 0.90 g (80%) of viscous oil. Elution with 5% acetone in chloroform from silica gel gave pure ethyl-8-diphenylhydroxysilyl-3-carbethoxy-4-oxooctanoate (**3**); i.r. (film) λ_{max} 2.7–3.1 (OH), 5.77, 5.85 (C=O) μ; n.m.r. (CCl_4) δ 7.7–7.2 (Ar, m, 10), 3.98 and 4.02 (OCH_2, two overlapping q, (J = 7 Hz), 4), 3.8 (—COCH(COOEt)-CH_2—, t (J = 8 Hz), 1), 2.70 (CH_2COOEt, two d (J = 8 Hz), 2), 2.5 (CH_2CO—, m, 2), 1.7–0.9 (aliphatic OH and O—C—CH_3, m with two overlapping t at 1.1 (J = 7 Hz), 13) p.p.m.

Anal. Calcd. for $C_{25}H_{32}O_6Si$: C, 65.75; H, 7.06. Found: C, 66.16; H, 7.09.

An n.m.r. spectrum in DMSO showed a singlet at δ 6.48 p.p.m. (—SiOH) which disappeared on addition of D_2O.

Base Hydrolysis of 2

A solution containing **2** (1.64 g, 0.0036 mol), potassium hydroxide (1.3 g, 0.023 mol), ethanol (20 ml), and water (4 ml) was heated at reflux for 2 h. The solution was acidified and the crude γ-keto acid, **4**, was isolated by extraction with sodium bicarbonate solution. To a solution of **4** in ether was added dropwise a solution of diazomethane in ether until the yellow color of the diazomethane was no longer rapidly discharged. Work-up gave a viscous oil (0.95 g, 50%) which was eluted with chloroform from silica gel to give methyl-8-(diphenylhydroxysilyl)-4-oxooctanoate (**5**); i.r. (film) λ_{max} 2.7–3.1 (OH), 5.74, 5.81 (C=O) μ; n.m.r. (CCl_4) δ 7.6–7.1 (Ar, m, 10), 4.9 (OH, broad, s, 1), 3.45 (OMe, s, 3), 2.4 ($COCH_2CH_2CO$, broad, s, 4), 2.4–2.1 (CH_2CO, m, 2), 1.6–0.8 (aliphatic, m, 6) p.p.m.

Anal. Calcd. for $C_{21}H_{26}O_4Si$: C, 68.08; H, 7.07. Found: C, 67.91; H, 7.03.

An n.m.r. spectrum in DMSO showed a singlet at δ 6.36 p.p.m. attributed to the silanol proton.

Synthesis of Methyl 8-(Diphenylhydroxysilyl)-4-oxooctanoate

To a solution of 5-(diphenylhydroxysilyl)pentanal (**3**) (prepared from **1** (4.4 g, 0.0165 mol in ether (50 ml)) was added at −70° a solution of 3-butenylmagnesium bromide (excess) in ether. After the addition the solution was allowed to warm to room temperature. Work-up gave an oil which was purified by elution with 7% acetone in chloroform from silica gel to give 8-(diphenylhydroxysilyl)-5-hydroxynon-1-ene (**6**), 4.6 g, 82%; i.r. (CCl_4) λ_{max} 2.70 (SiOH), 2.75 (C—OH), 6.10 (C=C) μ; n.m.r. (CCl_4) δ 7.7–7.1 (Ar, m, 10), 6.0–4.6 (CH_2=CH, m, 3), 4.2 (OH, broad, s, 2), 3.5–3.1 (C*H*—OH, m, 1), 2.1–0.8 (aliphatic, m, 12) p.p.m.

Anal. Calcd. for $C_{21}H_{28}O_2Si$: C, 74.08; H, 8.29. Found: C, 74.01; H, 8.41.

Ozone in dry oxygen was bubbled through a solution of **6** (3.78 g, 0.0112 mol) in dry ethyl acetate (100 ml) at −20° until the effluent gases liberated iodine on passage through a solution of potassium iodide in aqueous acetic acid. The solvent was removed on a rotary evaporator and the residual oil was dissolved in glacial acetic acid (50 ml). To this solution was added zinc dust (8.0 g, 0.12 g atom) and water (25 ml) and the resulting mixture was stirred for 3.5 h. Work-up gave 3.11 g of a viscous oil, believed to be 8-(diphenylhydroxysilyl)-4-hydroxyoctanal and its tautomeric cyclic hemi-acetal. To this product (2.45 g, 0.0072 mol) in acetone (25 ml) at 0° was added dropwise 1.67 *M* chromic acid solution (12.5 ml, 0.021 mol). The mixture was warmed to ambient temperature over 15 min. The solvent of the organic layer was removed on a rotary evaporator, and the residue was taken up in ether and extracted with sodium bicarbonate solution. Reacidification of the bicarbonate extracts gave an oil (0.22 g, 10%) which contained some of the γ-keto acid, **4**. The ethereal extracts afforded the γ-lactone, **8**, as a crude oil. An analytical sample was separated by elution with chloroform from silica gel; i.r. (CCl_4) λ_{max} 2.70 (OH), 5.60 (C=O) μ; n.m.r. (CCl_4) δ 7.7–7.2 (Ar, m, 10), 4.3 (CH—O, m, 1), 3.7 (OH, broad, s, 1), 2.5–2.0 (CH_2C=O, m, 2), 2.0–0.9 (aliphatic, m, 10).

Anal. Calcd. for $C_{20}H_{24}O_3Si$: C, 70.55; H, 7.10. Found: C, 70.77; H, 7.30.

A solution of the crude γ-lactone in ethanol (10 ml) and 3 *M* sodium hydroxide (10 ml) was heated at reflux for 15 min. The mixture was acidified, and the crude

Nucleophilic Attack of Siloxycarbenes on Carbonyl Groups. The Formation of Oxiranes

A. G. Brook, Ronald Pearce, and J. B. Pierce
Department of Chemistry, University of Toronto, Toronto 181, Ontario

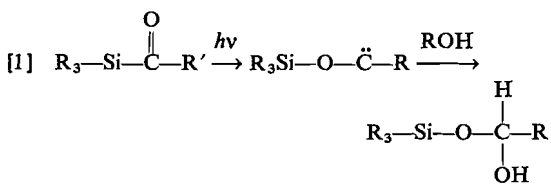
Received December 24, 1970

Siloxycarbenes, formed by the photolysis of dimethyl- or diphenylsilacyclohexanone have been trapped as oxiranes or as the ring-opened hydrolysis products of oxiranes, with simple aldehydes and ketones such as acetaldehyde, or cyclohexanone. The reactions are interpreted as arising from the nucleophilic attack of the siloxycarbene on the carbonyl group. The structures of the oxiranes and their hydrolysis products have been established.

La photolyse de diméthyl- ou diphénylsilacyclohexanones fournit des siloxycarbènes qui réagissent avec les aldéhydes et les cétones simples comme l'acétaldéhyde et la cyclohexanone pour fournir des oxirannes ou les produits provenant d'une hydrolyse de ces hétérocycles. Ces produits proviendraient d'une attaque nucléophile du siloxycarbène sur les groupes carbonylés. On a bien établi la structure des oxirannes et de leurs produits d'hydrolyse.

Canadian Journal of Chemistry, 49, 1622 (1971)

It has recently been shown that acylsilanes yield siloxycarbenes on photolysis which can be trapped with alcohols as mixed acetals (eq. 1)



[1] $R_3Si-\overset{\overset{O}{\|}}{C}-R' \xrightarrow{h\nu} R_3Si-O-\ddot{C}-R \xrightarrow{ROH} R_3Si-O-\underset{OH}{\overset{H}{\underset{|}{\overset{|}{C}}}}-R$

(1). A cyclic siloxycarbene has also been trapped as a spirocyclopropane by reaction with diethyl fumarate (2). These and other studies suggest that siloxycarbenes display nucleophilic character.

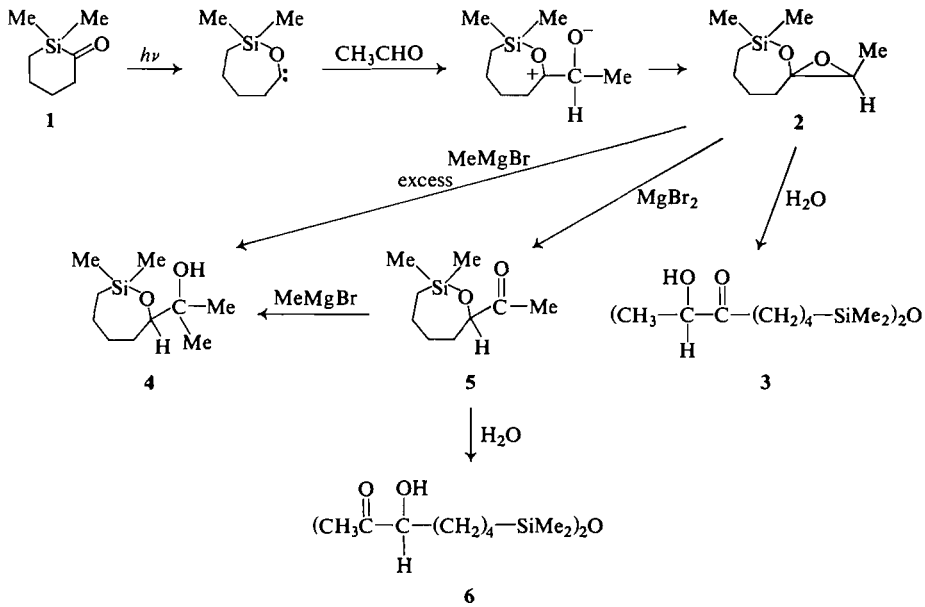
Additional support for this concept is now provided by the finding that siloxycarbenes, generated by photolysis of acylsilanes, will react with acetaldehyde or a simple ketone to give the oxirane, or compounds formally derivable therefrom, as reaction products.

Photolysis of 1,1-dimethyl-1-silacyclohexanone (**1**), in cyclohexane at 0° in the presence of excess acetaldehyde using a low pressure mercury floodlamp with λ_{max} about 360 nm gave the oxirane **2**, as a mixture of two isomers (Scheme 1). The mixture was unstable and hence the isomers could not be separated nor the mixture analyzed but the structures of the major components were confirmed by spectral data and derivatization reactions. The methyl group and hydrogen atom on the oxirane ring appeared as two sets of doublets and quartets in the ratio of 1 to 1.6, in the δ 1.2 and 2.8 p.p.m. regions of the n.m.r. spectra, compared with 1.3 and 3.0 p.p.m. for propylene oxide (3). The i.r. spectrum showed a doublet at 7.95–8.0 μ, corresponding to overlapping absorptions by the epoxide and Si—Me groups in the molecule.

Oxirane **2** slowly decomposed spontaneously, or rapidly in the presence of added water, being hydrolyzed to the acyloin **3**, which was characterized by analysis, the presence of a methyl doublet, hydrogen quartet and broad singlet in the n.m.r. spectrum, and OH, C=O, and SiOSi absorption in the i.r.

When treated with methylmagnesium bromide the carbinol **4** was formed almost quantitatively. This reaction appears surprising at first, but the isomerization of trisubstituted oxiranes in ring opening reactions is known to be facile (4). Further, treatment of the oxirane **2** with anhydrous magnesium bromide, a mild Lewis acid, gave the rearranged product, the methyl ketone **5**, in almost quantitative yield. This showed the expected carbonyl absorption at 5.82 μ. On treatment with methyl Grignard reagent, **5** also gave **4** as expected. On exposure to moisture **4** gave the acyloin **6**, isomeric to that given by **2**, as shown by the methyl ketone singlet at δ 2.13 p.p.m. together with the other expected spectral features.

The above data fully support the structure of **2** as that of the oxirane. While the reaction of carbenes with carbonyl groups is relatively



1 2 3 4 5 6

SCHEME 1

unknown, recent studies by Seyferth and Tronich (5) have shown that dihalocarbenes will form oxiranes only with highly fluorinated ketones such as hexafluoroacetone: the mechanism of this reaction has not been thoroughly established.

Attempts to trap the siloxycarbene using benzaldehyde were unsuccessful, and the fact that almost no decomposition of the acylsilane had occurred after 6 h irradiation, double that required for complete reaction with acetaldehyde, suggests that the benzaldehyde is acting as a quenching agent. Preliminary studies using pivaldehyde indicated that a mixture of products was formed. The n.m.r. data of the mixture could be interpreted as containing a mixture of the two diastereomeric oxiranes corresponding to **2**, with Me replaced by *t*-Bu.

When diphenylsilacyclohexanone **7** was photolyzed in acetone, related behavior was observed (Scheme 2). The sole product isolated was the acyloin **10**, which is derivable at least formally from the oxirane **9**, which was not detected in this case. It seems probable that sufficient water to hydrolyze the oxirane (or other intermediate) was present in the excess acetone used as solvent.

The structure of **10** was confirmed by analysis, by the presence of Si—OH, C—OH, and C=O absorption in the i.r., by a six-proton singlet signal for the two methyl groups and by two sharp singlets (in DMSO) at δ 6.48 and 5.10 p.p.m. in the n.m.r. spectrum corresponding to the Si—OH and C—OH signals. Diphenylmethylsilanol also has OH absorption at 6.48 p.p.m. (6). The structure of **10** was further confirmed by its reduction to the diol–silanol **11**, which on cleavage with lead tetraacetate gave the known 5-diphenylhydroxysilylpentanal, **12** (7) which can be produced also by photolysis of **7** in damp ether, or by photolysis in methanol to give the acetal **8** which readily hydrolyzes to **12** on treatment with dilute acid.

A similar photochemical reaction appeared to take place when 2-butanone was used as the solvent for the diphenylsilacyclohexanone photolysis, as judged by the similar spectroscopic properties of the product isolated to those of **10**. However, somewhat different behavior was observed when cyclohexanone was employed as the solvent (Scheme 3). In addition to the acyloin **16** obtained in about 50% yield, a second compound, **15**, was obtained in 25% yield. This compound is isomeric with the oxirane, **14**, which would have been formed had ring closure of **13**, the dipolar product of nucleophilic addition to the carbonyl group, occurred. It is not clear why **15** is formed in this case instead of the

oxirane **14**, since molecular models do not suggest that **14** is unduly sterically hindered. Indeed, it is possible that **14** is formed and transformed into **15** during the course of the reaction or its work-up.

The structure of **16** was confirmed by its reduction to the silanol–diol **17**, which on cleavage with lead tetraacetate gave the known compound **12**, and cyclohexanone, isolated as the 2,4-dinitrophenylhydrazone. The structure of **15** was inferred from the presence of OH, Si—O—C, and C=C stretching absorption in the i.r., and the n.m.r. spectrum showed a single vinyl proton, as a triplet centered at 4.98 p.p.m. On treatment with acetone containing a drop of aqueous 5% hydrochloric acid, **15** was rapidly converted to **16**. This facile hydrolysis, observed before for siloxyalkenes (8), is consistent with **15** being the precursor of **16**, hydrolysis being accomplished by traces of water introduced with the cyclohexanone.

The reactions described above are all consistent with the photochemical generation, from an acylsilane, of a siloxycarbene which possesses nucleophilic character. While all acylsilanes readily undergo photolysis in polar reagents such as alcohols (1), within our limited experience cyclic acylsilanes appear to yield siloxycarbenes which react as nucleophilic carbenes more rapidly and cleanly with other kinds of electrophiles than do their acyclic analogs. The scope of this nucleophilic reactivity is being explored further.

Experimental

General

The n.m.r. spectra were run on either an A-60 or T-60 Varian spectrometer, using TMS as internal standard in most cases. The i.r. spectra were recorded on a Perkin–Elmer Model 237B instrument. Melting points and boiling points are uncorrected.

It was important to carry out the photolyses in the absence of oxygen, since in at least some cases its presence diverted the reaction and other products were formed.

The Oxirane 2 from Dimethylsilacyclohexanone 1 and Acetaldehyde

A solution of 1,1-dimethyl-1-silacyclohexan-2-one (9) (2.0 g, 0.014 mol), freshly distilled acetaldehyde (2 ml), and cyclohexane (80 ml) was placed in a vessel, flushed with nitrogen, sealed, and irradiated with a 100 W low pressure mercury floodlamp for about 3 h while being cooled in ice-water. The solution became colorless. After removal of the solvent by rotary evaporation, the residual liquid was distilled to give 1.1 g (43%) of colorless material, **2**, b.p. 35–36° (0.8 mm), 62–64° (2.5 mm). Freshly distilled material had the following spectral characteristics: i.r.; 7.0 (Si—Me), 9.3 (Si—O—C) μ; n.m.r.; δ (CCl_4), (isomer **1***a*, relative amount 1) 2.94 (Me—C*H*, q, J = 5.5 Hz, 1H), 1.13 (*Me*—CH, d, J = 5.5 Hz, 3H) and (isomer **1***b*, relative amount 1.6) 2.64 (Me—C*H*, q, J = 5.0 Hz, 1H), 1.22 (*Me*—CH, d, J = 5.0 Hz, 3H) together with 1.65 (CH_2, m), 0.73 (CH_2Si, poorly resolved t), 0.05 (Me_2Si, m) p.p.m. in relative ratio 6:2:6; δ (C_6H_6) (isomer **1***a*) 3.17 (J = 5.5 Hz, q), 1.00 (J = 5.5 Hz, d), and (isomer **1***b*) 2.65 (J = 5 Hz, q), 1.33 (J = 5 Hz, d) together with 1.73 (CH_2, m), 0.80 (s, CH_2, poorly resolved triplet), and 0.17 (three peak multiplet with separations of about 5 Hz due to nonequivalent Me groups on Si) p.p.m.

Formation of $(CH_3CHOHCO(CH_2)_4SiMe_2)_2O$ (3) by Hydrolysis of 1

When 0.5 g of **2** in ether was shaken with water for 30 min, or when exposed to air for 12 h, a pale-yellow liquid **3** was obtained on removal of the solvent, n_D^{21} 1.4597; i.r. (film) 2.7–3.2 (OH), 5.84 (C=O), 9.5 (SiOSi) μ; n.m.r. (CCl_4 with benzene as internal standard) δ 4.15 (C*H*OH, q, J = 7 Hz, 1H), 3.6 (OH, s (broad), 1H), 2.5 (CH_2CO, t (partially resolved) 2H), 2.0–0.9 (CH_2CH_2, m with d centered at δ 1.33, J = 7 Hz due to CH_3—CHOH, 7H), 0.7–0.3 (CH_2Si, m, 2H), 0.10 ($SiMe_2$, s, 6H) p.p.m.

Anal. Calcd. for $C_{18}H_{38}Si_2O_5$: C, 55.34; H, 9.80. Found: C, 55.34; H, 9.77.

Reaction of Oxirane 2 with Methylmagnesium Bromide

The oxirane produced from photolysis of 2.5 g (0.018 mol) of the acylsilane with acetaldehyde was added to excess methylmagnesium bromide in ether. After stirring for 15 min the reaction was worked-up rapidly with aqueous ammonium chloride solution to give 3.0 g (85%) of crude carbinol **4**. Distillation gave a colorless liquid in 50% yield, $n_D^{22.5}$ 1.4538; b.p. 54–55° (0.8 mm); i.r. (film) 2.7–3.1 (OH), 9.25 (Si—O—C) μ; n.m.r. (CCl_4 with benzene as internal standard) δ 3.3 (CH, m, 1H), 2.0–0.5 (CH_2 and OH, m, 9H), 1.1 (CMe_2, s (broad), 6H), 0.13 ($SiMe_2$, s, 6H) p.p.m.

Anal. Calcd. for $C_{10}H_{22}O_2Si$: C, 59.35; H, 10.96. Found: C, 59.48; H, 11.06.

Isomerization of Oxirane 2 to Siloxyketone 5

The photolysate from 3.0 g (0.021 mol) of **1** in acetaldehyde was poured into a solution of anhydrous magnesium bromide in ether (prepared from excess magnesium and 0.5 ml of 1,2-dibromoethane). The solution was stirred for 1 h and worked-up rapidly using aqueous ammonium chloride to give 3.45 g (91%) of pale-yellow liquid. Distillation gave 2.8 g (64%) of pure **5**, b.p. 85–88°/10 mm, n_D^{22} 1.4488; i.r. (film) 5.82 (C=O), 7.41 (COMe) μ; n.m.r. (CCl_4 with benzene as internal standard) δ 4.0 (C*H*COMe, m, 1H), 2.08 (MeCO, s, 3H), 2.1–0.5 (CH_2, m, 8H), 0.15 and 0.10 (Me_2Si, two s, 6H) p.p.m.

Anal. Calcd. for $C_9H_{18}O_2Si$: C, 58.02; H, 9.74. Found: C, 57.99; H, 9.96.

Formation of the Dimethylcarbinol 4 from Methyl Ketone 5 with Methyl Grignard Reagent

A solution of 0.5 g (0.0027 mol) of the ketone **5** was added to excess methylmagnesium bromide in ether. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solution was stirred for 15 min and then was rapidly worked-up with aqueous acid to give 0.52 g (85%) of material identical in all respects to the dimethylcarbinol **4** described above.

Hydrolysis of the Methyl Ketone 5 to Give Acyloin 6

Hydrolysis of **5** could be rapidly accomplished by shaking with water or with aqueous sodium hydroxide but exposure to air over a period of 4 weeks gave the purest product. The mixture, a pale-yellow liquid, n_D^{21} 1.4647 had i.r. (CCl_4) 2.85 (OH), 5.84 (C=O) μ; n.m.r. (CCl_4 with benzene as internal standard) δ 4.0 (C*H*OH, m (broad) 1H), 3.2 (OH, broad, 1H), 2.13 (MeCO, s, 3H), 1.4 (CH_2, m, 6H), 0.6 (CH_2Si, m, 2H), 0.06 (Me_2Si, s, 6H) p.p.m.

Anal. Calcd. for $C_{18}H_{38}Si_2O_5$: C, 55.34; H, 9.80. Found: C, 55.18; H, 10.04.

Photolysis of Dimethylsilacyclohexanone 1 in Benzaldehyde

Photolysis of 1.0 g of **1** in excess freshly redistilled benzaldehyde in cyclohexane was examined after 6 h. Spectra of the crude material indicated much **1** was still present and only traces of unidentified material (n.m.r. (CCl_4): δ 4.2, 3.8 p.p.m., both singlets of unequal intensity) were observed.

Photolysis of Dimethylsilacyclohexanone in Pivaldehyde

When the material obtained from a photolysis similar to the above but using pivaldehyde in place of benzaldehyde was examined, little **1** remained. The n.m.r. spectrum in CCl_4 showed absorptions at δ 3.4 (broad singlet), 1.10 and 0.90 (singlets), and 0.10 (m) assignable to the C—H, *t*-Bu, and Si—Me signals of a mixture of oxiranes like **2**, where *t*-Bu replaces Me on the three-membered ring. Other signals were also present indicating the presence of at least one other compound. The mixture could not be separated.

Photolysis of 1,1-Diphenylsilacyclohexane-2 in Methanol

Twenty-five milliliters of dry methanol (freshly distilled from MeOMgI) were placed in a flask and dry nitrogen was bubbled through for about 1/2 h to displace all the dissolved oxygen. Then 1.0 g (0.00377 mol) of 1,1-diphenylsilacyclohexanone-2 (**7**) was added in one lot and the 100 W mercury floodlamp was turned on. The solution was irradiated for 1/2 h while maintaining a constant flow of nitrogen. After this time the solution was blown over into a receiving flask with nitrogen and the photolysis flask was rinsed once with dry methanol. The methanol was removed under reduced pressure to give the cyclic acetal (**8**). The product was not absolutely pure as judged by the presence of a small carbonyl peak at 5.78 μ. It was distilled under high vacuum to give 0.404 g or 36% of **8**, b.p. 130–132° (0.04 mm) but little purification was obtained: i.r. (CCl_4) 3.51 (OMe), 7.0, 9.0 (Si—Ph) μ; n.m.r. (CCl_4) δ 7.10–7.75 (Ar, m, 10H), 4.80–5.00 (C*H*OMe, m, 1H), 3.23 (OMe, s, 3H), 0.91–2.15 (CH_2, m, 8H) p.p.m.

Anal. Calcd. for $C_{18}H_{22}SiO_2$: C, 72.46; H, 7.43. Found: C, 72.93; H, 7.47.

Hydrolysis of the Cyclic Acetal 8

To 0.40 g (0.00134 mol) of the cyclic acetal **8** (prepared in the above photolysis) in 20 ml of THF was added a solution consisting of 2 ml of a 1% solution of KOH in water and 10 ml of THF. After stirring for 15 min 5% HCl was added and the mixture was extracted with diethyl ether. The ether phase was washed with water, dried, and the solvent was then removed. The residue was chromatographed on silica gel using benzene, 50:50 benzene–chloroform, and then chloroform as eluents. Isolated in the benzene fractions was 0.12 g or 30% of the starting acetal. The aldehyde, 5-(diphenylhydroxysilyl)-pentanal, 2.5 g (68%), was eluted with benzene–chloroform and gave an i.r. spectrum identical to that of authentic material (**7**): n.m.r. (CCl_4) δ 9.44 (CHO, t, 1H), 6.80–7.70 (Ar, m, 10H), 1.90–2.34 ($COCH_2$ + OH, m, 3H), 0.81–1.80 (CH_2, m, 6H).

Photolysis of 1,1-Diphenylsilacyclohexanone-2 in Acetone Saturated with Nitrogen; Isolation of 10

Nitrogen was bubbled through a solution of 0.200 g (0.000753 mol) of 1,1-diphenylsilacyclohexanone-2 in 40 ml of dry acetone (freshly distilled from anhydrous $MgSO_4$) while maintaining the solution in the dark. After 15 min the lamp was started and the photolysis was continued for 2 h with a constant stream of nitrogen passing through the solution. An i.r. spectrum of a small aliquot taken 2 h after the start of the photolysis indicated that none of the starting acylsilane remained. The solution was collected under nitrogen in the conventional way and after removal of the solvent gave a residue which was purified by chromatography on silica gel. The majority of the material was eluted with chloroform to give 0.130 g (54%) of **10**: i.r. (CCl_4) 2.70 (Si—OH), 2.85 (C—OH), 5.85 (C=O), 7.0, 8.95 (Si—Ph) μ; n.m.r. (CCl_4), δ 7.18–7.67 (Ar, m, 10H), 3.60–3.82 (Si—OH + COH, broad, 2H), 2.13–2.50 (CH_2CO, m (broad), 2H), 1.0–2.02 (CH_2, m), with 1.19 (CMe_2, s, 6H) superimposed p.p.m.; (DMSO) δ 7.22–7.33 (Ar, m, 10H), 6.48 (Si—OH, s, 1H), 5.10 (C—OH, s, 1H) p.p.m.

Reduction of 10 with Lithium Aluminum Hydride

A mixture consisting of 0.089 g (0.000260 mol) of 7-(diphenylhydroxysilyl)-2-hydroxy-2-methylheptanone-3 (**10**) and 50 mg (0.00132 mol) of lithium aluminum hydride in 20 ml of dry ether was stirred for 20 min at room temperature. An aqueous solution of 5% HCl was added to destroy the excess lithium aluminum hydride and the mixture was then extracted with ether. The ether phases were dried and the solvent was removed under reduced pressure. An i.r. spectrum of the isolated material indicated that reduction had been complete (no carbonyl band). A total of 72 mg or 81% of the diol **11** was obtained; i.r. (CCl_4) 2.70 (Si—OH), 2.91, very broad (C—OH), 7.00, 8.96 (Si—Ph) μ.

Cleavage of 7-(Diphenylhydroxysilyl)-2-methylheptane-2,3-diol (11) with Lead Tetraacetate

A sample of lead tetraacetate was recrystallized from glacial acetic acid and dried under high vacuum. A mixture of 100 mg (0.000226 mol) of this purified material and 72 mg (0.000209 mol) of the above-produced 7-(diphenyl-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hydroxysilyl)-2-methylheptane-2,3-diol in 75 ml of dry benzene was allowed to stand for 1½ h. After this time the mixture was poured onto a saturated solution of sodium bicarbonate and was extracted with ether. The organic phases were washed with water and were then dried with $MgSO_4$. Evaporation of the solvents left an oily residue which gave spectra identical in every way to those of authentic 5-(diphenylhydroxysilyl)-pentanal (**12**) (7).

Photolysis of 1,1-Diphenylsilacyclohexanone-2 in Butanone-2 Saturated with Nitrogen

Purified butanone-2 was distilled from phosphorus pentoxide and a central cut was stored over Drierite for 2 days. After this time it was again distilled and a central cut was taken. The oxygen was displaced from a solution consisting of 0.200 g (0.000753 mol) of 1,1-diphenylsilacyclohexanone-2 in 30 ml of this purified solvent by bubbling nitrogen through the solution while maintaining it in the dark. An i.r. spectrum, taken 1 h after the beginning of the irradiation, indicated that no starting material remained. The solution was collected under nitrogen and the solvent was removed. Attempts to crystallize the residue from dry hexane failed. An i.r. spectrum of the material indicated that it was probably 8-(diphenylhydroxysilyl)-3-methyl-3-hydroxyoctanone-4. The n.m.r. spectra in CCl_4 and dimethyl sulfoxide confirmed this structure: i.r. (CCl_4) 2.70 (Si—OH), 2.85 (C—OH), 5.85 (C=O), 7.00, 9.00 (Si—Ph) μ; n.m.r. (CCl_4) δ 6.95–7.72 (Ar, m, 10H), 0.78–2.52 (complex), 1.12 (broad, possibly a singlet superimposed on band above) p.p.m.; n.m.r. (DMSO) δ 7.16–7.75 (Ar, m, 10H), 6.48 (Si—OH, s, 1H), 5.11 (C—OH, s, 1H) p.p.m.

*Photolysis of 1,1-Diphenylsilacyclohexanone-2 in Oxygen-Free Cyclohexanone; Isolation of **15** and **16***

Purified cyclohexanone was distilled at atmospheric pressure and a central cut retained. This cut was redistilled under nitrogen in "flamed out" apparatus and another central cut collected. A solution of 1.0 g (0.00377 mol) of 1,1-diphenylsilacyclohexanone-2 in 35 ml of this purified solvent was freed from oxygen and then was photolyzed for 8 h while a stream of nitrogen was constantly bubbled through the solution. The solution was collected after 8 h of irradiation and the solvent was removed by distillation under high vacuum. Two methods of purification of the residue were attempted. About half of the residue was distilled under high vacuum through a short column and three fractions boiling in the range 180–190 °C (0.05 mm) were collected. However, i.r. spectra of these fractions were all identical with the i.r. spectrum of the crude material indicating that no separation had occurred. Chromatography on silica gel collecting 75 ml fractions and using a series of solvents was more successful. With benzene as eluent, fractions 7 to 15 yielded compound **15** and after using 375 ml of chloroform, which eluted nothing, fractions 22 and 23 using ether as eluent gave compound **16**. The yields of **15** and **16** were approximately 25 and 51% respectively, as observed from a second experiment. Samples of **15** and **16** were pumped down under high vacuum at 100 °C for 18 h to prepare them for analysis. Both compounds were viscous oils. The cyclic siloxyalkene **15** had: i.r. (CCl_4) 2.76 (Si—OH), 6.01 (C=C) 7.00, 9.00 (Si—Ph) μ; n.m.r. (CCl_4) δ 7.20–7.65 (Ar, m, 10H), 4.97 (=CH, t, J = 7 Hz, 1H), 0.90–2.40 (m, 17H) p.p.m.

Anal. Calcd. for $C_{23}H_{28}SiO_2$: C, 75.77; H, 7.74. Found: C, 75.80; H, 7.82.

The hydrolysis product of **15**, the acyloin **16** had: i.r. (CCl_4); 2.70 (Si—OH), 2.85 (C—OH), 5.87 (C=O), 7.00, 8.97 (Si—Ph) μ; n.m.r. (CCl_4) δ 7.10–7.68 (Ar, m, 10H), 3.68–4.10 (C—OH + Si—OH, broad, 2H), 2.10–2.55 (CH_2CO—, m (broad), 2H), 0.82–1.95 (m, 16H) p.p.m.

Anal. Calcd. for $C_{23}H_{30}SiO_3$: C, 72.18; H, 7.90. Found: C, 72.62; H, 8.12.

*Reduction of Acyloin **16** with Lithium Aluminum Hydride*

A solution consisting of 120 mg (0.000314 mol) of compound **16** and 100 mg (0.00264 mol) of lithium aluminum hydride in 10 ml of dry ether was stirred for 1/2 h. A solution of 5% HCl was then added and the mixture was extracted with ether. The ether phases were dried and then evaporated to leave a residue whose i.r. spectrum indicated that reduction of the carbonyl group was complete. The yield of crude reduction product **17** was 112 mg or 93%: i.r. (CCl_4) 2.70 (Si—OH), 2.99 (C—OH, very broad), 7.00, 9.00 (Si—Ph) μ.

*Treatment of **17** with Lead Tetraacetate*

A solution consisting of 112 mg (0.000293 mol) of **17** as isolated from the experiment above and 129 mg (0.000293 mol) of freshly crystallized lead tetraacetate in 10 ml of dry benzene was stirred for 1/2 h at room temperature. It was then poured onto a saturated solution of sodium bicarbonate and was extracted with ether. After drying, the solvents were distilled from the products at atmospheric pressure. The flask containing the residue was then connected to a vacuum apparatus and all volatile material was collected in a cold trap. The volatile material (cyclohexanone + benzene) gave an i.r. spectrum (using benzene in the reference cell) which compared very favorably with an i.r. spectrum of authentic cyclohexanone. The 2,4-dinitrophenylhydrazone of this isolated ketone was prepared by the method of Parrick and Rasburn (10) by adding 2 ml of dimethyl sulfoxide and 100 mg of 2,4-dinitrophenylhydrazine followed by 1 drop of concentrated HCl to the residue. After 15 min the benzene was removed from the sample under reduced pressure and 0.049 g or 65% of the crystalline 2,4-dinitrophenylhydrazone of cyclohexanone was deposited. This material was filtered off, washed with dilute HCl, water, and then 95% ethanol, m.p. 161–163 °C, mixed m.p. with an authentic sample 162–163 °C. The non-volatile material consisted of 0.076 g or 91% of 5-(diphenylhydroxysilyl)-pentanal **12**, whose i.r. and n.m.r. spectra were identical to those of authentic material.

*Hydrolysis of Siloxyalkene **15***

A small sample of chromatographically pure **15** as isolated from the photolysis above was dissolved in acetone and about 5 drops of a 5% v/v HCl solution was added. After standing at room temperature for 1/2 h the sample was added to water and extracted with ether. The ether phases were dried and the solvents were then

removed to leave a residue which gave an i.r. spectrum identical to that of authentic **16**. An n.m.r. spectrum taken in dimethyl sulfoxide confirmed the structure of the product.

Refinement of the Structure of $Mg_3(VO_4)_2$

N. KRISHNAMACHARI AND C. CALVO

Department of Chemistry and Institute for Materials Research, McMaster University, Hamilton, Ontario

Received June 29, 1970

Magnesium orthovanadate crystallizes in the orthorhombic space group *Cmca* with $a = 6.053(3)$, $b = 11.442(6)$, $c = 8.330(3)$ Å, and $Z = 4$. The structure was refined by full matrix least square methods to a final R value of 0.047 using 1697 reflections measured by a quarter circle General Electric automatic diffractometer. The structure was assumed to be isomorphous with that of $Ni_3(VO_4)_2$, reported by Durif and Bertaut (2), and the refinement started using the same fractional atomic coordinates. The structure consists of nearly cubic closest packing of oxygen atom layers roughly normal to the [01$\bar{1}$] direction with the Mg ions in two types of octahedral sites and the V ion in a tetrahedral site. The VO_4 group has a crystallographic mirror plane. The cations lying on sites of C_m symmetry show an average Mg—O bond length of 2.092 Å, compared to 2.098 Å for cations lying at sites of C_{2h} symmetry. The anion deviates significantly and substantially from regularity with the three oxygen atoms shared with only two cations showing V—O bond lengths within 0.015 Å of their mean, 1.70 Å, whereas the remaining oxygen atom, which is shared with three Mg ions, lies 1.809 Å from the V ion. The structure has characteristics similar to those of spinel.

L'orthovanadate de magnésium cristallise dans le système orthorhombique avec une maille de dimensions: $a = 6.053(1)$, $b = 11.422(2)$ et $c = 8.330(1)$ Å. Le groupe d'espace est *Cmca* et $Z = 4$.

L'affinement de la structure, par moindres-carrés (matrice complète), conduit à un facteur d'accord final $R = 0.047$ pour les 1697 réflexions mesurées sur un diffractomètre automatique General Electric. On a admis que la structure était isomorphe de celle de $Ni_3(VO_4)_2$, telle que rapportée par Durif et Bertaut, et on a utilisé les mêmes coordonnées fractionnaires pour commencer l'affinement.

La structure consiste en un arrangement compact presque cubique de couches d'atomes d'oxygène approximativement paralléles à la direction [01$\bar{1}$]. Les ions magnésium sont répartis sur deux sites octaèdriques tandis que le vanadium occupe un site tétraèdrique. Le groupe VO_4 possède un plan de symétrie cristallographique. La longueur de liaison moyenne Mg—O est de 2.092 Å pour les cations dans la position de symétrie C_m, et de 2.098 Å pour ceux qui sont sur les sites de symétrie C_{2h}. L'anion est fortement déformé: les distances du vanadium aux trois oxygènes communs à deux cations chacun diffèrent de 0.015 Å de la moyenne de 1.70 Å, tandis que la distance du vanadium à l'oxygène commun à trois ions Mg est de 1.809 Å. La structure a des caractéristiques semblables à celles des spinelles.

Canadian Journal of Chemistry, 49, 1629 (1971)

Introduction

Pope and Dale recently indicated "a detailed structure of a crystalline orthovanadate has yet to appear in the literature" (1). However, approximate atomic positions have been reported for $Ni_3(VO_4)_2$ by Durif and Bertaut (2). The powder pattern of $Mg_3(VO_4)_2$ has been indexed on the basis of a cell similar to that of $Ni_3(VO_4)_2$ (3) as has $Zn_3(VO_4)_2$ and the high temperature form of $Co_3(VO_4)_2$ (4). Joubert and Durif have shown that the low temperature form of $Co_3(VO_4)_2$ is cubic probably transforming to a spinel structure with disordered vacancies and finally becomes orthorhombic at high temperature (5).

The average V—O bond lengths in $Cd_2V_2O_7$ (6) and $Mn_2V_2O_7$ (7) suggest that for orthovanadates showing tetrahedrally coordinated V ions, the V—O bond length should be near 1.70 Å. For closest packing of oxygen atoms as spheres of radii 1.40 Å, the tetrahedral holes would give rise to V—O bond lengths of 1.71 Å. In $Co_3(AsO_4)_2$ (8), where the mean As—O bond length is 1.69 Å the oxygen atom pack as layers with an *ABCB* arrangement while the $Ni_3(VO_4)_2$ structure is based upon an *ABC* stacking sequence. Thus the structure of $Mg_3(VO_4)_2$ has been refined in order to examine the source of the detailed difference between the packing in $Co_3(AsO_4)_2$ and $Co_3(VO_4)_2$. As a prototype of the latter structure, $Mg_3(VO_4)_2$, containing the lightest cation of the series, has been examined.

Experiments

Crystals of $Mg_3(VO_4)_2$ were grown in a Pt crucible by slowly cooling a melt of hydrated $Mg_3(VO_4)_2$ obtained from Alpha Inorganic, Inc. Several crystals with dimensions of the order of $0.1 \times 0.1 \times 0.2$ mm^3 were chosen for study. Unit cell parameters were obtained from a least squares refinement using 2θ values of 17 lines measured with the quarter circle General Electric XRD6

Diffractometer with MoKα radiation ($\lambda_\alpha = 0.71069$ Å). The cell parameters obtained are $a = 6.053(3)$, $b = 11.442(6)$, $c = 8.330(3)$ Å where the estimated standard deviations in the parentheses represent 3 × the values obtained from the refinement. The crystals are orthorhombic with reflections *hkl* extinct when $h + k$ is odd, *h0l* absent for *l* odd and *hk*0 absent for *h* and/or *k* odd. Hence the space group is D_{2h}^{18}-*Cmca* or C_{2v}^{15}-*C2ca*. The former space group, that of $Ni_3(VO_4)_2$ (3), was chosen for the initial trial. *Z* was taken as four in agreement with the value assigned to $Ni_3(VO_4)_2$. The calculated density is 3.486 g/cm³. It cannot be compared to an experimental one since the product did not appear uniform. A total of 1697 symmetry independent reflections were collected with the diffractometer from a crystal, with dimensions 0.08 × 0.08 × 0.23 mm³, mounted parallel to the long axis. Filtered Mo radiation was used and the peaks were scanned at a rate of 1°/min through 2 to 3° in 2θ depending upon this angle. The total counts for each peak were corrected for the average background, counted at fixed angles on either side of the peak for a time period of 40 s. The 113 reflections with background intensity greater than that of the reflection were ignored. If the net counts were less than that three standard deviation above background but greater than zero, the intensities were considered as unobserved. The intensities were corrected for Lorentz and polarization but not for absorption. The linear absorption coefficient, μ, equal to 37 cm^{-1} leads to transmission factors that vary by less than 10% for the range of angles used. The structure was refined initially using the atomic positional parameters of $Ni_3(VO_4)_2$ together with measured photographic intensity data and the results of this refinement used as the trial model for the diffractometer data. Weights, $w = (10.5 - 0.476|F_o| + 0.006|F_o|^2)^{-1}$, were chosen so that the value of $w(|F_o| - |F_c|)^2$ would be independent of the local average $|F_o|$. Zero weights were assigned to those reflections whose calculated structure was less than the local minimum observed value. Scattering factor curves for Mg^{2+}, V^{5+} corrected for dispersion, and for O^-, were obtained from the International Tables for X-Ray Crystallography (10). The structure was refined to a minimum in

$$R_W = \left\{\frac{\sum w||F_o| - |F_c||^2}{\sum w|F_o|^2}\right\}^{1/2}$$

using a full matrix least squares program and the refinement terminated when the calculated shifts were less than 1/3 of the estimated standard deviations. The final *R* and R_W values are 0.047 and 0.031, respectively. The final atomic positional coordinates are listed in Table 1, $|F_o|$ and $|F_c|$ in Table 2. Structure factors were calculated for those 113 reflections whose derived intensities were negative. Only one appeared to be larger than the estimated minimum observable value obtained from the examination of the unobserved limit in the same region of reciprocal space.

Description of the Structure

The structure of $Mg_3(VO_4)_2$ is based upon a pseudocubic, that is *ABC*, arrangement of close packed layers of oxygen atoms, as seen in Fig. 1. The normal to these layers nearly parallel the $-2b^* + c^*$ direction which lies within 2° of the [011] in the direct lattice. The oxygen atom layers alternate between pairs containing tetrahedrally coordinated V ions and pairs devoid of such ions. Some of the Mg(1) ions occur between the same layers as do the V ions. All the Mg ions have nearly regular octahedral coordination.

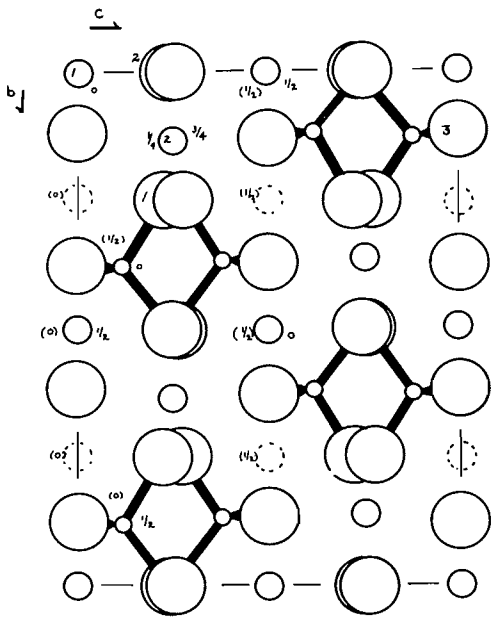

FIG. 1. The projection of the structure of $Mg_3(VO_4)_2$ onto the *bc* plane. Large circles represent oxygen atoms, smaller circles the Mg ions while the smallest circles are vanadium ions. The dotted circles, are the cations to be added. These together with the changes in *x* coordinates indicated by parentheses and small shift in oxygen atom positions will generate the spinel structure.

The Mg(1) site has 2/*m* symmetry with four equal, symmetry related Mg—O(3) bond lengths of 2.130(1) Å and two equal, symmetry related Mg—O(2) bond lengths of 2.034(1) Å. Mg(2) lies at a site with two fold symmetry with independent Mg—O bond lengths of 2.022(1), 2.118(1), and 2.135(1) Å. The independent bond lengths and angles can be found in Table 3. The two V—O bonds lying in the mirror planes, V—O(1) and V—O(2), are 1.716(1) and 1.809(1) Å long, respectively, while the two mirror planes related V—O(3) bonds are 1.695 Å in length. Since the estimated standard deviations in these bond lengths are of the order of 0.001 Å all these differences appear to be significant. The cause of the large difference of the V—O(2) bond and the other V—O bonds lies in the fact that O(2) is shared with three cations while the remaining oxygen atoms are shared with only two Mg ions. The bond angles also show substantial deviations from tetrahedral symmetry. The major distortion from a regular tetrahedron arises from the displacement of O(2) from the ideal position and not the displacement of V from the center.

The Mg(2)—O_6 groups form chains of O(1)—O(2) edge sharing octahedra running parallel to the *a* axis.

		—O(3)	90.98		

*Estimated standard deviations in parentheses. Transformations: $a = x, 1/2 + y, 1/2 - z$; $b = 1/2 + x, 1/2 - y, -z$; $c = x, -y, -z$; $d = 1/2 + x, y, 1/2 - z$; $e = 1/2 - x, y, 1/2 - z$.

The O(1)—Mg(2)—O(2) angle, subtending this edge, is contracted to 86.0°, presumably as a result of cation repulsion. Between these chains lie rows of octahedral sites which are either alternately filled or empty as shown in Fig. 2. The Mg(1)—O_6 and Mg(2)—O_6 share O(2)—O(3) edges which are also contracted (89.8 and 87.5°, respectively). The unshared edges of Mg(2)—O_6, involving O(1) and O(1′), and O(2) and O(2′) are both larger than 90° and substantially so in the former case. The O(3)—O(3′) edge subtended at Mg(1) shows the greatest contraction (77.8°) and involves oxygen atoms which are separately shared with two Mg(2) ions lying in an x = constant plane. The reason for this contraction is a greater net Mg(1)–Mg(2) and Mg(1)–V repulsion compared to the Mg(2)–Mg(2) repulsion.

The three dimensional packing can be appreciated by a comparison of the $Mg_3(VO_4)_2$ structure with that of spinel whose stoichiometry is M_2TO_4. The spinel structure is shown in a projection analogous to that of $Mg_3(VO_4)_2$ in Fig. 1. Here we note that octahedral sites at (0,1/4,0) are filled, leading to octahedral layers as seen in Fig. 2. The chains of filled octahedral sites alternate with chains where half the octahedral sites are filled. These layers alternate with layers of oxygen atoms where both octahedral and tetrahedral sites are occupied. In $Mg_3(VO_4)_2$, the Mg(1) and V both alternate between lying at $x = 0$ and 1/2 along b while in spinel these ions are colinear with the b axis.

Figures 3*a* and *b* compare the relative disposition of the filled octahedral and tetrahedral sites in a double layer of close packed oxygen atoms in $Mg_3(VO_4)_2$ and spinel. Both structures contain double rows of filled tetrahedral sites with the apexes of adjacent tetrahedra directed oppositely with respect to the normal to the oxygen atom layers. These rows run parallel to the a axis of the diagram with adjacent double rows equivalent and related either by a translation perpendicular to the original row or a diagonal to this row. In spinel every double row is related to its neighbors by this latter translational operation while in $Mg_3(VO_4)_2$ the two translational operations alternate. The maximum stoichiometry for these layers obtainable in spinel is one filled octahedral site for every two filled tetrahedral sites while for the magnesium orthovanadate the maximum stoichiometry is a filled octahedral site for every four filled tetrahedral sites. We will assume that the tetrahedral groups do not share oxygen atoms, and that face sharing between octahedra or

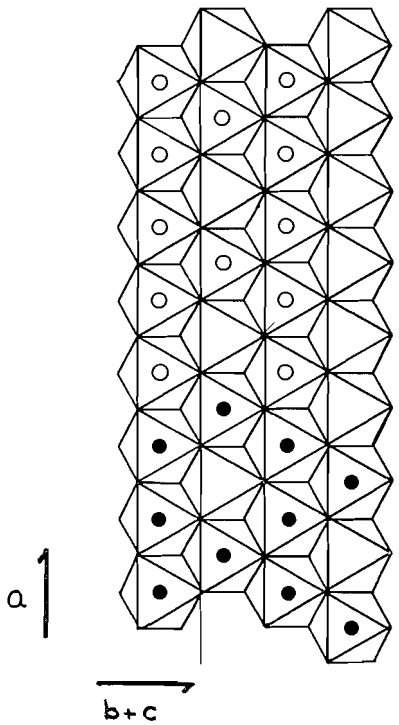

FIG. 2. The octahedrally coordinated cation layers in $Mg_3(VO_4)_2$ and spinel. The open circles are the filled cation sites in $Mg_3(VO_4)_2$. The rows parallel to a, where the cation sites are filled half the time, correspond to those containing Mg(1) and the filled rows to Mg(2). The black circles represent the filled cation sites in spinel for these types of layers.

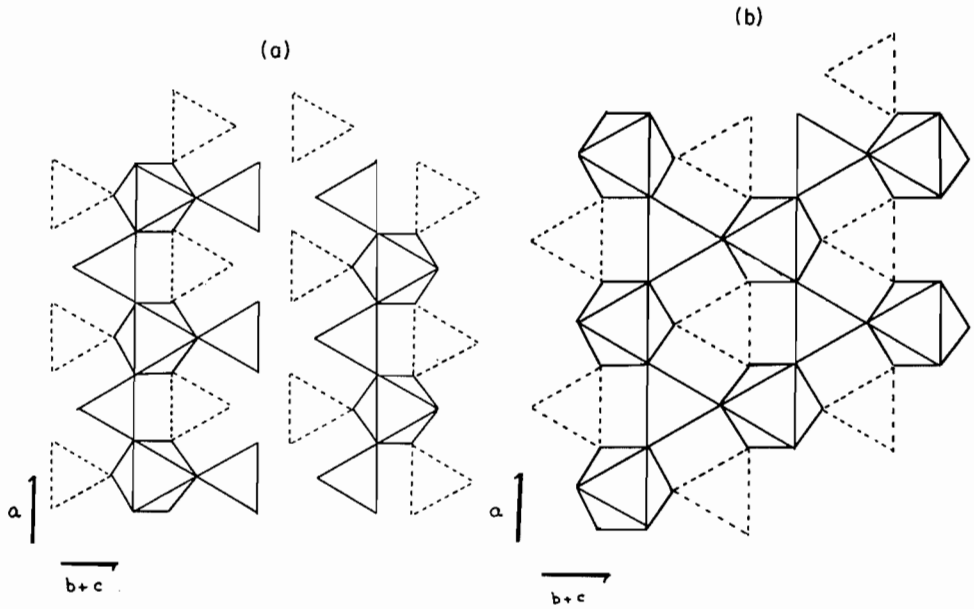

FIG. 3. (*a*) The oxygen atom layer containing tetrahedrally coordinated cations in $Mg_3(VO_4)_2$. The broken triangles represent three oxygen atoms bonded tetrahedrally to the fourth oxygen atom in the layer of the oxygen atoms represented with solid lines. The tetrahedra shown in projection with solid lines have their fourth oxygen atom in the plane of the broken triangles. Only occupied tetrahedral and octahedral sites are shown. (*b*), The oxygen atom layers containing tetrahedrally coordinated cations in spinel.

between tetrahedra and octahedra are not acceptable. The oxygen layer adjacent to the two layers depicted in Fig. 3 can either form a hexagonally close packed oxygen arrangement (*ABA*) or a cubically close packed arrangement (*ABC*). By applying the above restrictions and by disallowing edge sharing between filled octahedra and tetrahedra, a stoichiometry greater than one filled octahedral per filled tetrahedral site can be achieved only when the third layer is added cubically. For this packing the maximum stoichiometry obtainable corresponds to that of spinel, M_2TX_4, when the motif of Fig. 3*b* is used and $M_{7/4}TX_4$ when that of Fig. 3*a* is employed.

Discussion

The average V—O bond length in VO_4^{3-} is 1.729 Å and is slightly larger than that recently determined for other structures containing VO_4^{3-} tetrahedra with non-bridging oxygen atoms. In $Zn_3(VO_4)_2$, an isostructure of $Mg_3(VO_4)_2$, and YVO_4 the average V—O bond lengths are 1.71 Å (11, 12). In $Ca_3(VO_4)_2$ the average bond lengths for the three independent VO_4 groups are 1.69, 1.69, and 1.70 Å (13), with individual V—O bond lengths ranging from 1.67 to 1.72 Å. In YVO_4 the V ion lies on a $\bar{4}$ axis and thus all the V—O distances are equivalent. In $Zn_3(VO_4)_2$ the situation is quite parallel to that in $Mg_3(VO_4)_2$ with the V—O(2) bond length at 1.78(1) Å while V—O(1) and V—O(3) are 1.74(1) and 1.67(1) Å long, respectively. The bridging bond lengths in the meta-vanadates are of the same order as those found for V—O(2) in the ortho-vanadates. Thus in NH_4VO_3 (14) and $CsVO_3$ (15) the bridging V—O bond length is 1.81 Å and in KVO_3 it is 1.80 Å long (16). The V—O(2) bond with O(2) shared with three cations (Zn or Mg) have bond orders of 1.00, based upon a scale proposed by Evans (17) while the remaining bonds, involving oxygens shared with only two cations, have bond orders near 1.5. The high sensitivity of X—O bond lengths to their environment have been noted for X = P (18) and silicate systems are described in some detail by Brown and Gibbs (19).

The relationship between the spinel and $Mg_3(VO_4)_2$ structures has been considered above. Kamb (20) has recently discussed the conditions favoring the appearance of a spinel or olivine form for a M_2TX_4 compound where X ions are close-packed spheres. These compounds show an almost universal deviation from the ideal close-packed arrangement of X ions, resulting in an enlarged occupied tetrahedral site in the spinel form and a contracted occupied

†Reference 11.
‡Reference 22.

tetrahedral site in the olivine form. In the latter case a contraction of the tetrahedral T—X bond length leads to a shortening of the shared edges between the tetrahedron and octahedron. A similar phenomenon occurs in spinel with the pertinent edges being shared between MX_6 groups. It is the shortening of shared edges separating the positively charged cations which Kamb claims explains the relative stability of these phases. The boundary defining the stability limit of the two phases should lie near an ideal ratio of the M—X to T—X bond lengths. However, Kamb finds that the spinel structure is stable to progressively larger values of this ratio as the charge on the T ion increases. For pentavalent T ions the value of this ratio seems to be near 1.22.

Kamb's concepts should find application to other stoichiometries in addition to M_2TX_4. The appearance of the $Mg_3(VO_4)_2$ structure for the ortho-vanadates of Co, Ni, and Zn while a structure based upon an olivine-like packing for the ortho-arsenates of Ni(21) and Co(8) provide some test data. Table 4 summarizes the value of this ratio for the known vanadates and arsenates in this series. The mode of oxygen atom packing is indicated together with the number of filled tetrahedral sites out of *N* possible filled sites. Filled tetrahedral sites sharing bridging X ions are excluded. The layer sequence in spinel and $Mg_3(VO_4)_2$ both have the tetrahedral sites showing *N*, 0, *N*, 0, · · · sequence while in olivine the sequence is *N*/2, *N*/2, · · ·. This datum provides support for the extension of Kamb's criterion to these stoichiometries with the ratio at the boundary near 1.24.

Stereochemistry of Hexahydrocarbazoles; the Temperature-dependent Nuclear Magnetic Resonance Spectra of *N*-Acetyl Derivatives

STEWART MCLEAN, U. O. TROTZ, C. J. MACDONALD, W. F. REYNOLDS, AND D. J. WOOD
Department of Chemistry, University of Toronto, Toronto 181, Ontario

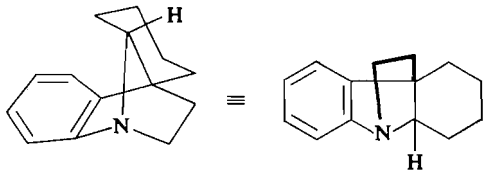
Received November 25, 1970

The configuration of certain substituted hexahydrocarbazoles **2**, of significance in connection with earlier work, has been established. A study of the temperature dependence of the n.m.r. spectra of *N*-acetyl derivatives, initiated with the intention of distinguishing between *cis*- and *trans*-fused isomers, has led to the conclusion that the distinction could not be made on this basis since all of the temperature-dependent phenomena, even in cases where the *cis*-fusion had been established by other means, could be associated with rotational isomerism of the *N*-acetyl group and no observable effects in the temperature range studied could be related to conformational mobility of the ring system. Nevertheless, the results obtained provide information of value and interest regarding the stereochemistry of hexahydrocarbazoles.

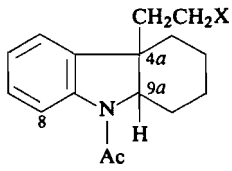
On a établi la configuration de certaines hexahydrocarbazoles substituées **2** qui présentaient de l'intérêt en fonction de nos travaux antérieurs dans ce domaine. Nous avons examiné les spectres r.m.n. des dérivés *N*-acétylés en fonction de la température afin d'évaluer s'il est possible de déterminer la configuration-*cis* ou -*trans* de la jonction entre les cycles; nous avons été amenés à conclure que cette méthode ne peut être utilisée parce que, dans les limites des températures examinées, toutes les variations spectrales dépendantes de la température qui sont observées peuvent être reliées à l'isomérie rotationnelle du groupe *N*-acétyle et que de plus aucune variation détectable ne peut être attribuée à la mobilité conformationnelle et ce même dans les cas où on a pu établir par d'autres méthodes que la jonction entre les cycles est *cis*. Malgré ces limitations nos résultats fournissent des informations importantes et intéressantes concernant la stéréochimie des hexahydrocarbazoles.

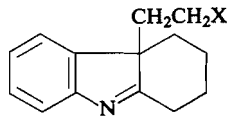
Canadian Journal of Chemistry, 49, 1638 (1971)

Recently we reported on the results of our studies which led to the synthesis of certain derivatives of 2,3-benzo-1-azabicyclo[2.2.1]hept-2-ene and the discovery that compounds of this structure underwent an unusual ring opening on treatment with acetic anhydride; for example, compound **1**, formally derived from hexahydrocarbazole by the introduction of a two-carbon bridge, afforded **2***a* (1). In contrast to the case of the analog formally derived from 2,3-dimethylindoline, where two stereoisomers were obtained and confident stereochemical assignments could be made both to the ring-closed isomers, analogs of **1**, and to the ring-opened isomers, analogs of **2***a*, only one isomer was obtained in the hexahydrocarbazole case and it was not possible to present conclusive evidence for the stereochemistry of either the ring-closed or ring-opened compounds. We did, however, point out that the burden of the evidence, mainly based on the n.m.r. spectroscopic characteristics of the ring-closed and the ring-opened compounds, favored a configuration, as depicted in **1** and **2***a*, based on a *cis*-hexahydrocarbazole parent structure.[1]



1





2

a X = OAc
b X = H
c X = OTs
d X = OH
e X = Br

3

a X = Br
b X = H

In order to establish conclusively the configuration in this series, we undertook two simultaneous lines of investigation. In the first we converted **2***a* to the 4*a*-ethyl derivative, **2***b*, by borohydride reduction of the tosylate **2***c* obtained from the alcohol **2***d*, the hydrolysis product of **2***a*. Compound **2***b* was then subjected to an X-

[1]Since the major part of this paper concerns hexahydrocarbazole derivatives, locants based on this system will be used throughout.

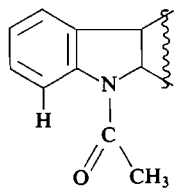
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ray analysis which established unequivocally that its configuration was that shown (2), and since none of the reactions used to effect the interrelationship are expected to affect position 9*a*, the configuration of **1** and that of each of the compounds of formula **2** are also firmly established. It can be noted at this point that one chemically significant conclusion that follows from this result is that the reaction which formed **1**, the reduction of **3***a* by either borohydride or catalytic hydrogenation, delivered hydrogen to C-9*a* exclusively from the side of the molecule carrying the C-4*a* side chain; in contrast the reduction of the corresponding 2,3-dimethylindolenine led to both stereoisomers, but with delivery of hydrogen to the other side of the molecule as the predominant path (1). No good explanation for the stereochemical outcome of the reduction of **3***a*, particularly by catalytic hydrogenation, is apparent, but it can be shown that the presence of bromine in the molecule is not a significant factor since catalytic hydrogenation of the 4*a*-ethyl derivative **3***b* in the presence of acetic anhydride also leads to the *cis* product **2***b*. (Under these conditions **3***a* is transformed directly into **2***e*.)

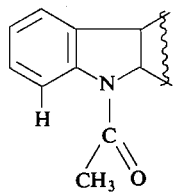
Our second line of investigation involved a more careful examination of the n.m.r. spectra of the ring-opened compounds since our original tentative stereochemical assignment (1) was based on the appearance of the spectra of a number of derivatives, but in each case only one member of a pair of epimers was available. It was our intention, therefore, to prepare suitable model *cis*- and *trans*-hexahydrocarbazoles and compare their behavior with that of our compounds. However, it became apparent that the original assignments of configuration to the model compounds were made a number of years ago on an empirical basis (3) and some element of doubt existed about them; the assignments have not been challenged, but very recently others have also noted the need for placing them on firmer ground (4), and, once **2***a* proved amenable to X-ray analysis, one outcome of our present study has been to do that, the converse of what we had originally intended.

It is well known that a fused ring system such as *cis*-hexahydrocarbazole is flexible and can adopt two extreme conformations, one with the 4*a* substituent axial and the 9*a* substituent equatorial and the other with the relationship reversed, but, with suitable substitution, one conformation may be predominantly or exclusively populated; in contrast, the *trans*-fused isomer is rigid and both 4*a* and 9*a* substituents are axial. Our previous studies (1) had led us to conclude that the 9*a* proton in our compounds of structure **2** was axial, indicative of a *trans*-hexahydrocarbazole or a *cis* isomer in which one conformation was populated predominantly, and of these two possibilities we favored the latter. (It may be noted that the X-ray study (2) has now shown that the molecule does in fact adopt this conformation, with the hydrogen at 9*a* axial, in the crystal.) It was our intention to verify this conclusion by examining the temperature dependence of the n.m.r. spectra of compounds of formula **2**, since it was anticipated that the conformational mobility of the ring system, if *cis*-fused, would exhibit some temperature dependent feature in these spectra. However, we recognized that the compounds of interest to us all carried an *N*-acetyl group which could also lead to temperature dependent changes in the spectra (5), and the conclusion we now draw from our present study is that the temperature dependence of the n.m.r. spectra in the range in which we have studied it can be entirely attributed to the conformational mobility of the *N*-acetyl group.

When the spectra of compounds of formula **2** were examined, three features showing a significant temperature dependence could be associated with each compound: the signals concerned were those attributed to the protons at C-8 and -9*a* and those of the *N*-acetyl group. In the best cases where there was a minimum of overlap with other signals, each set of protons gave rise at the low temperature limit to two groups of signals of appropriate multiplicity, indicative of the presence of two species in the sample; the abundance ratio, as judged by the relative intensities of the signals, depended primarily on the specific compound examined, but was also affected by variables such as solvent and temperature. As the temperature was raised, the signals associated with each set of protons broadened and converged on an average position, coalesced, and, at the upper temperature limit, appeared as one signal, again showing the appropriate multiplicity. It is clear that rotation of the *N*-acetyl group, for which two rotamers, **A** and **B**, are favored by π-orbital stabilization, can affect the signals associated with all three sets of protons, while conformational inversion of the ring system is highly unlikely to have any effect on the signals of the C-8 proton. If both conformational variations were occurring together, it would be expected that the temperature dependence of each set of



A



B

signals would be different, and ideally a precise analysis of each would be required. Unfortunately, the system in hand is a complex one; the chemical shift differences at the low temperature limit are different in each set of protons, signals are often obscured by overlap of other signals, and it is difficult to obtain data with the precision required for a quantitative analysis. Nevertheless, by making use of observable values and by interpolating or extrapolating where necessary, we have concluded that the presence of the two interconverting *N*-acetyl rotamers is sufficient to provide an explanation for all of the temperature dependent phenomena in the range we have studied, and that any conformational mobility of the ring system has a minimal effect. In terms of our original aim of using this technique to study the configuration of the ring fusion, this result is not helpful, but since the X-ray analysis has provided the answer to this question, we can simply state that the conformational mobility of a *cis*-fused hexahydrocarbazole does not lead to observable temperature-dependent phenomena in the n.m.r. spectrum, at least in the temperature range we have studied, while rotation of an *N*-acetyl substituent has a pronounced effect.

Results were obtained for the 4*a*-ethyl derivative **2***b* as a solution in toluene-d_8 over the temperature range -84 to $+96°$. The C-8 proton (6) was associated at the lowest temperatures with a doublet, $J = 8$ Hz, at τ 1.20, which moved upfield as the temperature was raised, began to collapse at about 0° (at intermediate temperatures better resolution was obtained and the doublet showed further fine structure), and at $+40°$ appeared as a broad featureless envelope; at the higher temperatures a doublet, $J = 8$ Hz, again appeared and at 96° it was centered at τ 1.94. The doublet at the highest temperature is clearly the time-averaged signal for the C-8 proton in both rotamers, while at the lowest temperatures interconversion of rotamers is sufficiently slow that two sets of signals are obtained, the τ 1.20 doublet being attributed to the C-8 proton of rotamer **A**, but the corresponding signal for rotamer **B** being lost among the other aromatic signals near τ 3. The signals we attributed to the C-9*a* proton at the lowest temperatures were a smaller multiplet centered near τ 5.5 and a larger multiplet centered near 6.9 (which in well resolved spectra appeared as a symmetrical three-peak pattern with 8 Hz spacing and further fine structure); as the temperature was raised these signals moved together and collapsed, appearing at about $+40°$ as a very broad envelope, and at the highest temperature the three-peak pattern reappeared, centered at τ 6.2. The signal for the *N*-acetyl protons appeared at the lowest temperatures as an unresolved peak at τ 8.15, but at $-60°$, where resolution was generally better, two components could be discerned, a smaller singlet at τ 8.09 and a larger singlet at 8.14; by the time 0° was reached only one singlet, at τ 8.10, was visible and at the highest temperature this appeared at 8.01. These observations are again compatible with the existence of two rotamers, **A** and **B**, which are seen separately at low temperatures but lead to a time-averaged signal at high temperatures. (The appearance of the *N*-acetyl signal at the lowest temperatures may result from poorer resolution at these temperatures, an accidental convergence arising from a different temperature dependence of the chemical shift of the protons in the two rotamers, or a combination of both effects.) In these cases the relative peak areas indicated the rotamer ratio **A**:**B** is roughly 3:1; the value based on the C-8 protons is not directly available because of overlap, but the signal strength of the observed doublet is compatible with this figure.

An approximate free energy of activation ($\Delta G^{\ddagger}$) for the interconversion between rotamers **A** and **B** was obtained by observation of the broadening of the individual components of the low field C-8 doublet in the slow exchange limit. At 10 °C, the individual lines were broadened beyond the limiting value in the absence of exchange by between 3 and 4 Hz. Since, in the slow exchange limit (8),

$$\pi(\Delta\nu - \Delta\nu_0)_A = 1/\tau_A$$

where $\Delta\nu$ and $\Delta\nu_0$ are line widths in Hz (at half height) in the presence and absence of exchange and τ_A is the lifetime at site A. Therefore, $\tau_A \simeq 10^{-1}$ s. This corresponds to $\Delta G^{\ddagger} = 15$ kcal/mol. In addition, values of $\Delta G^{\ddagger}$ of 14 to 15 kcal/mol were obtained from the coalescence temperatures for C-8, -9*a*, and the *N*-acetyl protons. While both sets of measurements are only approximate, the

former because the above equation should strictly only be applied to a system in which protons at sites A and B are not coupled to other protons and the latter because the temperature dependence of the chemical shift was ignored, it is believed that at least the former value is accurate to within 1 kcal/mol since this would allow for an error of greater than a factor of 5 in the measurement of line width and lifetime.[2] The value of 15 kcal/mol is of the same order of magnitude as has been obtained by others for related processes (5); this combined with the relative constancy of the value obtained from different processes provides support for the conclusion that the temperature dependence of all three sets of signals can be attributed to interconversion of *N*-acetyl rotamers and that it is not necessary to invoke further effects arising from the conformational mobility of the ring system.

Other derivatives of formula **2** have been examined less extensively as chloroform-*d* solutions and they show behavior corresponding to that of **2***b*. For the bromo compound **2***e*, the relevant data are that the C-8 proton produces a sharp doublet, $J = 8$ Hz, at τ 1.80 (a second component is presumably lost in the aromatic multiplet between τ 2.5 and 3.0) at $-60°$, the coalescence temperature is about $+30°$, but at 65°, the highest temperature used, the upper limiting condition is not reached and the signal appears as an unresolved multiplet centered at τ 2.05; the C-9*a* proton produces two signals at $-60°$, a smaller multiplet at τ 5.55 and a larger at 6.10 (both are three-peak patterns with fine structure and the ratio of areas is approximately 1:4), which have coalesced by $+40°$, but still appear as an unresolved multiplet centered at τ 5.90 at 65°; the two components of the *N*-acetyl signal at the lowest temperature, the smaller singlet at τ 7.54 and the larger at 7.67, appear as one singlet at 7.70 at the highest temperatures; in addition, the CH_2Br protons which form a simple three-peak pattern centered at 6.85 at the highest temperatures appear as a much more complex multiplet at the lowest temperatures, but with very little change in chemical shift. The C-8, -9*a*, and *N*-acetyl protons of the alcohol **2***d*, show the same behavior with only very small chemical shift differences; in addition the OH proton moves from about τ 5.45 to 8.0 as the temperature is raised over the range -60 to $+70°$.

The parent *N*-acetylhexahydrocarbazole to which the *cis* configuration was previously assigned on empirical grounds (3) shows a marked correspondence in behavior to that of our 4*a*-substituted derivatives. In toluene-d_8 at $-73°$ the C-8 proton appears at τ 1.30 as a doublet, $J = 8$ Hz, which moves upfield and broadens with increasing temperature, has its maximum width at about $+30°$, and then sharpens to a doublet at τ 2.00, $J = 8$ Hz, at 97°; the *N*-acetyl protons, which are unresolved at $-73°$, form two singlets at $-56°$, the smaller at τ 8.17 and the larger at 8.23 (in this case the ratio of areas is two or three times greater than in the case of **2***b*), coalesce by $+10°$, and appear as a singlet at τ 8.05 at the highest temperatures. The behavior of the C-9*a* proton signals is made somewhat more difficult to follow in this case by the presence of peaks associated with the C-4*a* proton, and a rational explanation of the observed spectra is as follows: the C-4*a* proton is responsible for a multiplet that appears at τ 7.20 at $-73°$ and moves slowly downfield without significant broadening as the temperature is raised, appearing at τ 6.88 at $+97°$, while the C-9*a* proton is associated with a multiplet at τ 6.90 at $-73°$ which moves downfield and broadens as the temperature is raised, having its greatest width at $+30°$, and then sharpens to a multiplet at τ 6.04 at $+97°$; at low temperatures a small, broad, and very poorly defined signal can be discerned against the background noise near τ 5.2, and is consistent with the description already given (which requires the C-9*a* proton signal from rotamer **B** to appear in this region and to move upfield to meet the signal associated with rotamer **A** as the temperature is raised). It follows that the stereochemistry of the *cis* isomer is analogous to that of **2***b* with the C-9*a* proton axial and with no conformational inversion involving the ring fusion giving rise to a temperature-dependent change in the spectra, despite the fact that it could be anticipated that this conformational equilibrium might be significantly affected by the

[2]In principle, a more accurate value for ΔG^* could be obtained from the temperature dependence of the *N*-acetyl signals, by use of total line shape analysis. In practice, this would be extremely difficult for this system. Firstly, exchange rate, chemical shift, and rotamer populations would all be adjustable parameters in the calculation (previous calculations have involved no more than two parameters). Secondly, the signal-to-noise ratio is poor due to limited solubility at low temperature and the peaks of interest partially overlap with other spectral peaks. Consequently, we believe that a detailed total lineshape analysis would not give a significantly more accurate value for ΔG^*.

presence or absence of a bulky substituent at C-4*a*. The account given for the *cis*-*N*-acetylhexahydrocarbazole case does require that the preponderance of rotamer **A** over rotamer **B** be significantly greater than in the case of **2***b* in the same solvent, and no good explanation for this difference is apparent at present. Although it does not appear to bear directly on this question, we can note that the **A**:**B** ratio does have a solvent dependence and the corresponding spectra in chloroform-*d* show signals, albeit at slightly different positions because of the effect of the solvent on the chemical shift, which are consistent with a smaller **A**:**B** ratio; moreover, in support of the case made above, the signal at lower field associated with the C-9*a* proton of rotamer **B** is now more clearly visible.

The spectrum of *trans*-*N*-acetylhexahydrocarbazole (3) shows a temperature dependence that is related to those already described but is sufficiently distinctive in detail that it serves to support the assignments made previously. In toluene-d_8 at $-73°$, the C-8 proton of rotamer **A** gives rise to a doublet, $J = 8$ Hz, at τ 1.18 and in this case the corresponding signal from rotamer **B**, the minor component, appears at τ 3.54, to high field of the other aromatic resonances; as the temperature is raised, these signals converge and broaden, coalesce at about $-30°$, reappear as a doublet at about $+30$, and, at $+77°$, appear as a sharp doublet, $J = 8$ Hz, at τ 2.35. The *N*-acetyl protons give rise to two singlets at $-73°$, the smaller at τ 8.11 and the larger at 8.32, which coalesce near $-45°$, and appear as a sharp singlet at τ 8.03 at $+77°$. These features are consistent with a rotamer ratio **A**:**B** of between 2:1 and 3:1 at the lowest temperatures and a rotational barrier significantly lower (by 3 to 4 kcal/mol) than in the *cis* case; no ready steric explanation for this difference can be discerned from molecular models. As with the *cis* isomer, an account of the behavior of the C-9*a* proton is made more difficult by the presence of the C-4*a* proton, and a further difficulty becomes apparent when the spectra of the *trans* isomer are examined. At $-73°$ two multiplets are clearly visible, centered at τ 6.47 and 6.93, in the region where the C-4*a* and -9*a* resonances may be expected and a further multiplet appears to be present near τ 7.8 at the edge of the envelope to higher field (which includes solvent peaks); at $+77°$ two three-peak patterns with further fine structure appear in this region, one at τ 6.92 and one at 7.63 and a two-peak pattern appears at 7.30, and each of these patterns appears to correspond to one proton; since the multiplets are both broadened and shifted at intermediate temperatures and a considerable amount of overlap of signals occurs, it is difficult to follow their progress in detail, but it is possible that the multiplet near τ 6.9 is associated with the C-4*a* proton and does not move significantly as the temperature is varied, while the τ 7.63 multiplet at high temperatures is the time-averaged signal for the C-9*a* proton; the τ 7.30 multiplet at higher temperatures must then be associated with another proton in the cyclohexane ring, such as the equatorial proton at C-1, which experiences an unusually strong deshielding effect from the acetyl group (time-averaged at this temperature); at the lowest temperature the low field pattern at about τ 6.47 would, if this explanation were correct, correspond to a superimposition of signals from the latter proton and the C-9*a* proton in one rotamer, the corresponding signals from the other rotamer being at τ 7.8 or higher. A 220 MHz spectrum obtained at 60° supports these conclusions; each set of peaks is more clearly resolved than in the 100 MHz spectrum and the integrated areas of the peaks are in accord with the proposals made. As we have already stated, the assignments are not considered to be rigorously established, but it is clear that any analysis requires the assignment of some rather unusual chemical shift values, and it is a judgment of the probable pattern of behavior of the chemical shifts over the temperature range studied that has led us to the assignments we have made.

We have also examined the spectra of *cis*-*N*-ethylhexahydrocarbazole (obtained by reduction of the *N*-acetyl derivative), in which *N*-acetyl rotation is obviously no longer a factor but the possibility still exists of conformational inversion associated with the ring fusion, and the spectra of aspidocarpine, in which hydrogen bonding between the *N*-acetyl group and a hydroxyl group at the position corresponding to C-8 holds the molecule in a conformation corresponding to rotamer **A** (7). In neither case did the spectra show appreciable variation with temperature over a range of about 100°, particularly with respect to the signals arising from protons corresponding to those on which the present discussion has centered.

In summary, we have established that the 4*a*-

substituted hexahydrocarbazoles that we isolated previously are *cis*-fused and this information has been used to deduce the stereochemistry of the azabicycloheptene from which they were derived and the steric course of the reduction of the precursor tetrahydrocarbazolenine. No temperature-dependent phenomena in the n.m.r. spectra of the hexahydrocarbazoles could be traced to conformational mobility of the ring fusion, but *N*-acetyl substituents led to temperature-dependent effects which could be associated with the interconversion of two rotamers. Comparison of this behavior with that of *cis*- and *trans*-hexahydrocarbazole provided supporting evidence for the configurational assignments originally made for these isomers.

Experimental

The n.m.r. spectra were recorded on a Varian HA-100 spectrometer operating in frequency sweep mode at a sweep rate of 1 Hz/s. Spectra were calibrated by measuring the difference between sweep and manual (lock) oscillators. The variable temperature unit was calibrated with standard Varian samples before each run.

All solute concentrations were approximately 0.5 *M*; 5% tetramethylsilane was added as a lock and internal reference. Sample tubes were degassed and sealed under vacuum before use.

The 220 MHz spectrum of *trans*-*N*-acetylhexahydrocarbazole was recorded on a Varian HR-220 at the Canadian 220 MHz N.M.R. Center.

Model compounds were synthesized by standard procedures (3).

9-Acetyl-4a-ethyl-1,2,3,4,4a,9a-hexahydrocarbazole (2b)

Preparation A

A solution of the tosylate **2***c* (1) (65 mg; 0.16 mmol) in 6 ml dimethyl sulfoxide was stirred with excess sodium borohydride (800 mg) for 10 h at room temperature. The solution was diluted with water and extracted with methylene chloride; the extract afforded an oil (35 mg; 0.14 mmol) which, on recrystallization from hexane, was isolated as colorless crystals, m.p. 63.5–64.5°.

Preparation B

A solution of 4*a*-ethyl-1,2,3,4-tetrahydrocarbazolenine (**3***b*) (1) (2.40 g; 12 mmol) in 6 ml acetic anhydride was hydrogenated in the presence of prereduced platinum oxide at room temperature and atmospheric pressure for 10 h (11.3 mmol hydrogen was consumed). This afforded **2***b* (2.92 g; 12 mmol) identical with that described above. Repeated recrystallization afforded an analytical sample, m.p. 65.5–66.5°.

The Effect of Pressure on the Aquation of Chromium(III) Complexes

DAVID L. GAY AND ROBERT NALEPA[1]

Received December 21, 1970

The effect of pressure on the rates of aquation of $Cr(NCS)_6^{3-}$ and $Cr(NH_3)_2(NCS)_4^-$ has been studied over the pressure range 1 to 2043 atm, at 50 °C. The activation volumes for these reactions are found to be 16 ± 2 and −2.4 ± 0.8 ml/mol, respectively. The pressure dependence of the activation volumes, $(\partial\Delta V^*/\partial P)_T$, are 15 ± 5 and 0 ± 1 ml/katm mol, respectively. These results are consistent with a dissociative interchange (I_d) process for the aquation of $Cr(NCS)_6^{3-}$ and an S_N2 front-side process for the aquation of $Cr(NH_3)_2(NCS)_4^-$.

On a étudié, à 50 °C et à différentes pressions entre 1 et 2043 atmosphères, l'effet de la pression sur les taux d'hydratation de $Cr(NCS)_6^{3-}$ et $Cr(NH_3)_2(NCS)_4^-$. On a trouvé que les volumes d'activation de ces réactions sont respectivement de 16 ± 2 et de −2.4 ± 0.8 ml/mol; on a aussi établi pour chacune de ces réactions que la dépendance de leur volume d'activation sur la pression, $(\partial\Delta V^*/\partial P)_T$, est de 15 ± 5 et de 0 ± 1 ml/katm mol. Ces résultats seraient consistants avec l'hypothèse que l'hydratation du $Cr(NCS)_6^{3-}$ se fait par un processus d'échange dissociatif alors que l'hydratation du $Cr(NH_3)_2(NCS)_4^-$ se produit par une substitution S_N2 impliquant le devant de la molécule.

Canadian Journal of Chemistry, 49, 1644 (1971)

Introduction

The aquation reactions 1 and 2,

[1] $Cr(NCS)_6^{3-} + H_2O \rightarrow Cr(NCS)_5(H_2O)^{2-} + NCS^-$

[2] $Cr(NH_3)_2(NCS)_4^- + H_2O \rightarrow Cr(NH_3)_2(NCS)_3(H_2O) + NCS^-$

are thought to proceed via transition states involving one and two molecules of water, respectively (1, 2). However, it is believed that the role of solvent water is not that of a nucleophile (1–3). In addition, it assumed that a fair degree of Cr...NCS bond stretching is involved in the activation processes of these reactions, but no direct evidence for this has been presented (1, 2).

This study was therefore performed to obtain evidence which would clarify the role of Cr... NCS bond stretching as well as the role of water in these reactions.

Experimental

Materials

Reagent grade $K_3Cr(NCS)_6$, Alpha Inorganics stock No. 24115, and Fisher Certified grade $NH_4Cr(NH_3)_2(NCS)_4$ were used without further purification. Deionized water was obtained from boiled out distilled water by passing it through a mixed bed, acid–base, ion-exchange resin column. The mixed bed resin was Fisher certified, Rexyn H–OH resin, analytical grade.

[1]Summer student, 1970.

Kinetics

The rates of the aquation reactions 1 and 2 were estimated from the rate of production of free thiocyanate. The free thiocyanate was measured spectrophotometrically as $FeSCN^{2+}$ complex ion, by Adamson's method (3).

All rate studies were carried out in the high pressure vessel using the sampling technique outlined previously (4). For studies at atmospheric pressure, the reaction vessel inside the pressure bomb was not pressurized. The reaction vessel was a 5 ml hypodermic syringe with the barrel sawed off. In order to minimize complications from photolysis, a photographic red light replaced the normal fluorescent room lights. All solutions were 10^{-3} *M* in complex and 6×10^{-3} *M* in perchloric acid. Reactions were followed for no more than 3 h and less than 25% completion. In all experiments no deviations from first order kinetics were observed.

First order rate constants, reproducible to ±1%, were obtained for the aquation of $Cr(NCS)_6^{3-}$ and $Cr(NH_3)_2(NCS)_4^-$ as a function of pressure at 50 °C (see Table 1). The activation volume, ΔV^*, is usually extracted from the pressure dependence of the rate constant by eq. 3.

$$[3] \qquad \Delta V^* = -2.303RT(\partial \log k/\partial P)_T$$

However, this can only be used in cases where the activation volume is independent of pressure,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

TABLE 1. Rate constants for the aquation of $Cr(NH_3)_2(NCS)_4^-$ and $Cr(NCS)_6^{3-}$ in 6×10^3 *M* perchloric acid solution at 50 °C as a function of pressure

	Rate constant, 10^4k, min^{-1} at 50 °C	
P (atm)	$Cr(NH_3)_2(NCS)_4^-$	$Cr(NCS)_6^{3-}$
1	0.93_1	9.7_4
340	—	8.0_5
681	0.97_0	7.4_6
1362	1.00	6.8_2
2043	1.11	7.1_9

as exhibited by the linearity of log *k vs. P* plots. This is illustrated for the aquation of $Cr(NH_3)_2(NCS)_4^-$ in Fig. 1. When the activation volume is dependent of pressure, that is the plot of log *k vs. P* is non-linear, resort to other approaches in extracting ΔV^* from pressure-rate data becomes essential (5, 6). The approach taken here will be that of Baliga and Whalley (6). Thus the activation volume of reaction 1 was obtained by plotting the mean activation volumes given by eq. 4

$$[4] \quad \Delta V^* = -(2.303RT \log k_2/k_1)/(P_2 - P_1)$$

in the pressure interval P_1 and P_2, against the mean pressure $(P_1 + P_2)$, and extrapolating to zero pressure; k_1 and k_2 are the first order rate constants at pressures P_1 and P_2, respectively.

The activation volumes are found to be -2.4 ± 0.8 and 16 ± 2 ml/mol for the aquation of $Cr(NH_3)_2(NCS)_4^-$ and $Cr(NCS)_6^{3-}$, respectively. The activation volume for the $Cr(NH_3)_2(NCS)_4^-$ aquation is independent of pressure (*i.e.* $(\partial\Delta V^*/\partial P)_T = 0$), whereas the activation volume for the $Cr(NCS)_6^{3-}$ aquation is strongly pressure dependent $(\partial\Delta V^*/\partial P)_T = 15 \pm 5$ ml/katm mol.

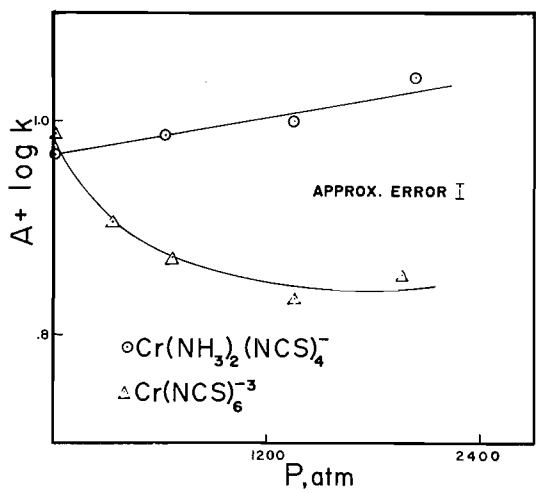

FIG. 1. Plot of log *k* against pressure for the aquation reactions 1 and 2.

Discussion

As far as the mechanistic interpretation of activation volumes is concerned, by far the simplest and most straightforward approach would be to compare the activation volumes of the reactions concerned with those for reactions of known mechanism. This approach becomes more acceptable since theory does not allow *a priori* calculation of activation volumes (4).

Suppose the aquation reactions 1 and 2 proceed via a dissociative interchange process (I_d) involving the non-nucleophilic participation of water molecule, as stated by Langford and co-workers (1, 2), then the only important activational process will be that involving Cr...NCS bond stretching, according to eqs. 5 and 6.

$$[5] \quad (NCS)_5CrNCS^{3-} \rightarrow (NCS)_5Cr^{2-}...NCS^-$$

$$[6] \quad (NH_3)_2(NCS)_3CrNCS^- \rightarrow (NH_3)_2(NCS)Cr...NCS^-$$

Since in neither of these cases is there a net creation nor destruction of charge, it is reasonable to assume that the formation of the transition states does not involve appreciable changes in the electrostriction of the solvent. Therefore, the ΔV^* of $+16 \pm 2$ ml/mol for the $Cr(NCS)_6^{3-}$ aquation can be attributed to Cr...NCS bond stretching. Furthermore, this value falls in the range (about +12 ml/mol) found for unimolecular dissociative reaction of both anions and cations (7–9). However, complications arising from charge dispersal in the transition state of reaction 5 may not be unimportant and could result in a positive contribution to the activation volume. If this is so, then a rough estimate of this given in ref. 15 of +5 ml/mol may be used. The net positive contribution to the activation volume due to Cr...NCS bond stretching is found to be +11 ml/mol. Using a value of 4.9 Å for the radius of the $Cr(NCS)_6^{3-}$ ion (10), the observed ΔV^* is the result of 5 to 8% stretching in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Cr...NCS bond.[2] This value is in the range (10%) estimated for unimolecular processes (11, 12). On the other hand ΔV^* of -2.4 ml/mol is not in keeping with a unimolecular dissociative aquation for $Cr(NH_3)_2(NCS)_4^-$. In any case a process involving the estimated "normal" amount of bond stretching is not involved.

The only other mechanism worth exploring, for the aquation of $Cr(NH_3)_2(NCS)_4^-$, is the one proposed by Langford and White (1). In this mechanism, one of the two water molecules involved is hydrogen bonded to the leaving NCS^- anion in the activation process; the other water molecule has a non-nucleophilic role and is not important from an energy point of view. If this is so then the ΔV^* should be about -1 to -3.6 ml/mol; this being the volume difference between a water molecule in the bulk solvent and the first coordination (4, 13). The value of -2.4 ml/mol found for the aquation of $Cr(NH_3)_2(NCS)_4^-$ is in good agreement with this estimate. This mechanism is in effect the S_N2 front-side mechanism proposed by Adamson (3). However, a small amount of Cr...NCS bond stretching facilitated by the NCS...H_2O hydrogen bonding cannot be ruled out.

Lateef and Hyne (14) have correlated the value of $(\partial\Delta V^*/\partial P)_T$ found for many solvolytic reactions of organic substrates with reaction mechanism. Large values (of about 45 ml/katm mol) are associated with unimolecular solvolytic processes and small values (of about 10 ml/katm mol) with bimolecular processes. If this type of analysis is at all applicable here, then the implication is that a molecule of water may be involved in the activation processes of reactions 1 and 2, since the values of $(\partial\Delta V^*/\partial P)_T$ for these aquations are 15 ± 5 and 0 ± 1 ml/katm mol, respectively. These small values may then be a result of the small differences between the volume of a water molecule in the bulk solvent and the first coordination sphere (13).

From this study the authors conclude that the aquation of $Cr(NH_3)_2(NCS)_4^-$ proceeds via a mechanism involving at least one molecule of water. It is assumed on the basis of previous studies (13) that the role of this water molecule is non-nucleophilic but rather facilitates Cr...NCS bond cleavage through hydrogen bonding to the leaving NCS^- anion (3). However, the presence of another water molecule in the transition state, as indicated by the studies of Langford and White (1), cannot be ruled out completely. It may also be concluded that the aquation of $Cr(NCS)_6^{3-}$ goes by a mechanism involving at least one molecule of water. In this mechanism the Cr...NCS bond is thought to be excessively broken and the H_2O...Cr bond only very slightly formed. This mechanism is taken to be the dissociative interchange (I_d) mechanism proposed by Langford and co-workers (2), for this aquation process. This study, therefore, essentially confirms the conclusions of Langford and co-workers (1, 2) and Adamson (3). However, it provides direct evidence for a large degree of Cr...NCS bond stretching involved in the $Cr(NCS)_6^{3-}$ aquation which had been previously assumed without proof (2). Also, no significant amount of Cr...NCS bond stretching seems to be involved in the aquation of $Cr(NH_3)_2(NCS)_4^-$, as previously proposed (1), but this is not absolutely certain.

[2]A crude calculation of ΔV^* is given by the product of the effective cross-sectional area of the molecule and the amount of bond stretching (15). Therefore, the amount of bond stretching, x, is obtained as follows

$$x = \frac{\Delta V^*}{\text{cross-sectional area}}$$

$$= \frac{16 \times 10^{24}}{\pi \times (4.9)^2 \times 6 \times 10^{23}}$$

$$= 0.4 \text{ Å}$$

If the Cr...NCS bond length is assumed to be 4.9 Å (10), then the percentage bond stretching is about 8%. This value is based on the assumption that all 16 ml/mol found for ΔV^* is due to bond stretching. However, if the value corrected for electrostriction changes (11 ml/mol) is used, then the percentage bond stretching is found to be about 5%.

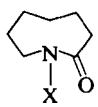
Received November 5, 1970

High yield peroxide initiated and photochemical conversion of *N*-chloroazacyclooctanone to 5-chloroazacyclooctanone and of *N*-chloroazacyclononanone to a mixture of azabicyclo[4.3.0]nonan-2-one and azabicyclo[4.3.0]nonan-9-one is described. *N*-Chloro-2-azabicyclo[2.2.2]octan-3-one gave 4-chlorocyclohexylamine derivatives under similar conditions, while *N*-chloro-*N*-methylpentanoamide gave γ-valerolactone. An apparent ionic, silver ion, and base-catalyzed cyclization of *N*-chloroazacyclononanone was observed.

On décrit une réaction photochimique et initiée par les péroxydes qui permet de transformer avec de bons rendements la *N*-chloroazacyclooctanone en chloro-5 azacyclooctanone et la *N*-chloroazacyclononanone en un mélange d'azabicyclo[4.3.0]nonanone-2 et d'azabicyclo[4.3.0]nonanone-9. Dans des conditions expérimentales semblables, la *N*-chloro aza-2 bicyclo[2.2.2]octanone-3 fournit des dérivés de la chloro-4 cyclohexylamine alors que la *N*-chloro *N*-méthylpentanoamide donne la γ-valéro lactone. On a aussi observé une cyclisation de la *N*-chloroazacyclononanone qui s'effectue en présence d'ion argent et de base et qui serait apparemment ionique.

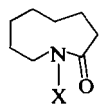
Canadian Journal of Chemistry, 49, 1648 (1971)

Some time ago it was reported (1) that when the medium ring *N*-chloro lactams, *N*-chloroazacyclooctan-2-one (**1***a*) and *N*-chloroazacyclononan-2-one (**2***a*), were heated with silver perchlorate in aqueous dioxane. they cyclized, in low yield, to bicyclic lactams. We now report conditions under which these cyclizations can be effected in high yield. The reaction was initially considered to involve the generation of nitrenium ions ($R—\overset{+}{\underset{\cdot\cdot}{N}}COR'$). However, experimental evidence is now presented that these efficient cyclizations proceed by a radical-chain mechanism.



1

a X = Cl
b X = H



2

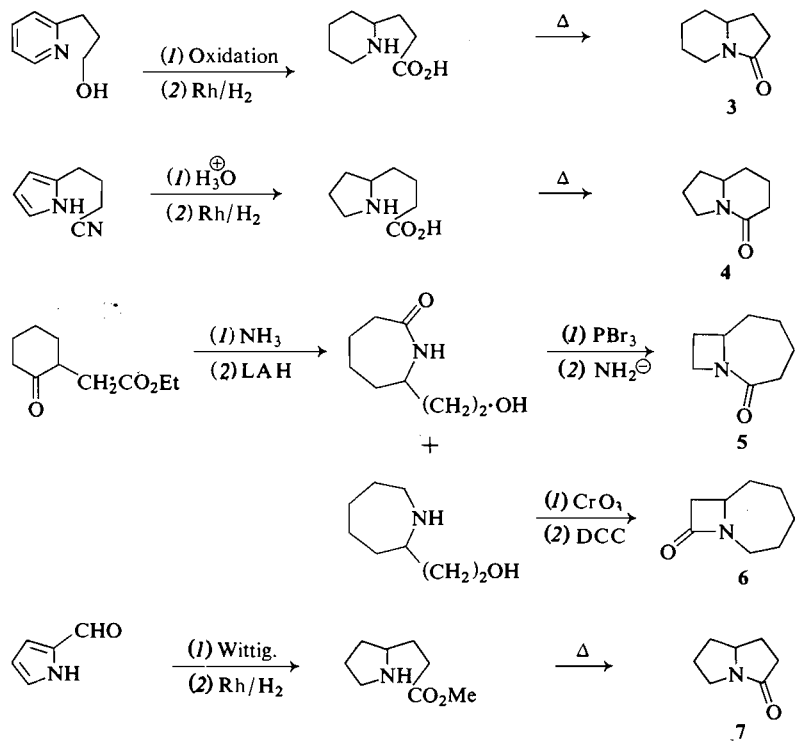
a X = Cl
b X = H

In our further investigations of the reactions of medium ring chloro lactams, we first endeavored to optimize conditions for the cyclization of the nine-membered *N*-chloro lactam **2***a*, a compound which had, in the original investigation, given a better yield (13%) of bicyclic products than the eight-membered **1***a* (5%). It was discovered that: (*a*) the *N*-chloro lactams were inert to silver ions in peroxide-free solvents; (*b*) traces of peroxide in the dioxane used as solvent, catalytic amounts of benzoyl peroxide, or metallic silver initiated the reaction; (*c*) in order to obtain reasonable yields of bicyclic products the presence of bases such as silver oxide, silver carbonate or calcium carbonate was needed to prevent accumulation of acid during reaction; (*d*) the presence of water in the solvent markedly reduced the amount of parent lactam produced, and led to high yields of bicyclic products.

In 1 h at 80° in 80% dioxane – 20% water in the presence of 1.5 mol % of benzoyl peroxide and calcium carbonate, *N*-chloroazacyclononane was converted into a mixture of **3** (34%), **4** (63%), and **2***b* (3%). A similar result was obtained in aqueous dimethylformamide. Neither of the bicyclo[5.2.0] compounds **5** or **6** was produced. The preparation of authentic reference lactams is outlined in Scheme 1.

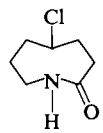
Under comparable conditions *N*-chloroaza-

[1]Submitted as NRCC No. 11695.
[2]NRCC Postdoctorate Fellow.



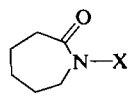
SCHEME 1

cyclooctan-2-one (**1***a*) was converted in over 70% yield into 5-chloroazacyclooctan-2-one (**8**). The structure of this product was proven by base or silver ion promoted conversion into 1-azabicyclo[3.3.0]octan-2-one (**7**).



8

Under the above conditions, *N*-chloroazacycloheptan-2-one (**9***a*) gave only the parent lactam **9***b* (*ca.* 100%).

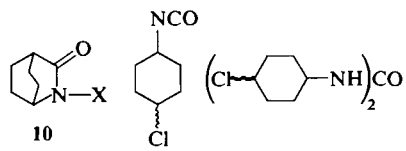


9

a X = Cl

b X = H

A further and remarkable variation in behavior was provided by the reaction of *N*-chloro-2-azabicyclo[2:2:2]octan-3-one (**10***a*) in aqueous dioxane, which yielded a urea, to which we ascribe structure **12**. The intermediacy of the isocyanate **11** could be demonstrated when the reaction was carried out in anhydrous dioxane.[3] Small amounts of the lactam **10***b* were also formed, in both cases.



10 **11** **12**

a X = Cl

b X = H

Thus we have a set of observations in which, under the same reaction conditions, *N*-chloro lactams produce predominantly either the parent lactam (**9***a* → **9***b*), a *C*-chloro lactam

[3]This is in accord with the report that *N*-bromosuccinimide is converted to 3-bromopropionyl isocyanate when it is heated with benzoyl peroxide in the presence of allyl halides in chloroform, or bromoform, solution (2). Similarly several *N*-bromo-α-haloamides gave chlorobromoalkanes in a chain reaction that appeared to be homolytic in character. However *N*-chloromandelamide gave comparable fission in an apparent ionic process (3).

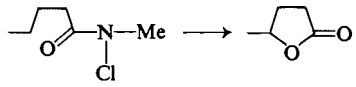
(**1***a* → **8**), bicyclic lactams (**2***a* → **3** + **4**), or fragment to an isocyanate (**10***a* → **11**). This diversity of products implies that the reaction must be very sensitive to substrate structure.

Under our optimum cyclization conditions an acyclic chloramide *N*-chloro-*N*-methylpentanoamide **13** gave the γ-lactone **14**. This parallels



13 **14**

the observation of Neale *et al.* (4) on the photolysis of the *N*-bromo analogue of **13** followed by thermal cyclization *i.e.* the internal nucleophilic displacement in the intermediate *C*-haloamide was by oxygen rather than nitrogen.

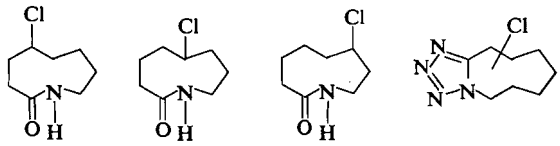
The above reactions appeared to be homolytic chain reactions. In agreement with this, photolysis of **1***a* or **2***a* in aqueous dioxane resulted in rapid conversion into the same products as in the peroxide catalyzed process. The yield of bicyclic products was near 90% from **2***a*. However, photolysis in *dry* dioxane gave only 29% of bicyclic products.

Since metallic silver has been shown to produce nitrogen radicals from chloramines (5) at room temperature, we examined its action on **1***a* and **2***a*. The reaction proved to be very slow at room temperature, but fairly rapid at 80°. The yield of transannular product was much lower than in the photochemical or peroxide-initiated reaction (25% for **1***a*, 15% for **2***a*), the main product being the parent lactams.

In the light of our initial interest in the generation of nitrenium ions (1) we made attempts to find ionic conditions for cyclizing *N*-chloro lactams to bicyclic ones. Since silver ions alone were inert, it was argued that both a base and silver ions might provide a push–pull mechanism. The system chosen, silver oxide – $Ag(NH_3)_2^+$ – ammonia did indeed give a rapid room temperature reaction. Chloro lactam **2***a* was converted into **2***b* (37%), **3** (16%), and **4** (47%) when aqueous dioxane was used as solvent. In aqueous acetonitrile 50% of bicyclic products was obtained. Blank runs showed that **2***a* was inert to ammonia or silver oxide under these conditions.

In contrast to the case of the nine-membered ring, *N*-chloroazacyclooctanone gave less than 5% of bicyclic products when treated with silver oxide – ammonia at room temperature.

It seemed probable (see Discussion) that 5- and 6-chloroazacyclononan-2-one (**15** and **16**) were being formed as primary products from the corresponding *N*-chloro lactam in the reactions initiated by peroxide or metallic silver, and that these were spontaneously cyclizing to the bicyclic derivatives **3** and **4**. To test this we attempted to synthesize authentic **15**.



15 **16** **17** **18**

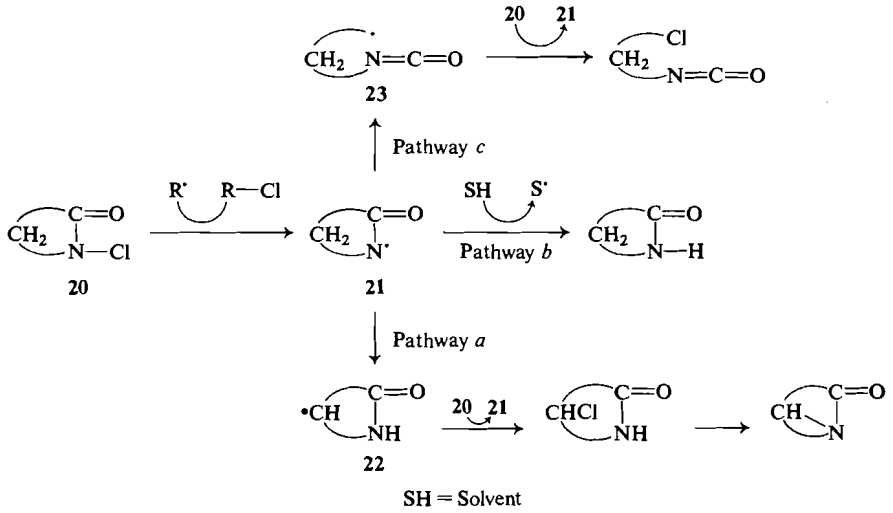
A Schmidt reaction on 4-chlorocyclooctanone gave one of the expected 5- or 7-chloro lactams as a crystalline product. However this proved to be the 7-isomer (**17**) since it could be cyclized cleanly with potassium amide in liquid ammonia to **5**. Investigation of the non-crystalline product from the Schmidt reaction showed it to be rich in **3**, hence cyclization of **15** had already occurred. Another product isolated was the tetrazole **18**.

Discussion

The present work, and our related study of the reaction of medium ring chloramines with silver ions (5), has provided no evidence for the formation of discrete nitrenium ions [see however the special cases studied by Gassman (6)].

Although no previous transannular replacement of unactivated hydrogen in *N*-halo lactams seems to have been observed, the intramolecular analogues for *N*-iodo (7), *N*-bromo, and *N*-chloro amides (4, 8) and *N*-halo imides (9) have been studied. Photolysis (4, 7–9) or initiation by one-electron reducing agents (8) converted these to 4-halo amides or imides.

The fact that dioxane peroxides or benzoyl peroxide at 80° were sufficient to catalyze the decomposition of the medium ring chloro lactams suggested that a homolytic chain reaction was involved. Scheme 2 outlines three pathways open to an initially formed amidyl radical. Pathway (*a*) leads to a *C*-chloro lactam. In the case of **1***a* this could be isolated, but **15** and **16** cyclized below room temperature to the bicyclic lactams. Pathway (*b*) gives solvent radicals and parent lactams. The former give rise to products such as **19** and **19***a* (via 2-



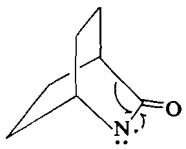
SCHEME 2

chlorodioxane). Pathway (*c*) is the course followed by amidyl radicals from **10***a* and from *N*-bromosuccinimide (2).

The high yield of parent lactam formed at the expense of transannular products in the silver initiated reactions contrasts sharply with the results of the peroxide initiated reactions. We assume that the silver produces the same amidyl radicals (see eq. 1) as are formed in the peroxide catalyzed reaction. Hence we are faced

[1] 
with the puzzle why a very small amount of chain reaction ensues (more than 90 mol % of silver chloride formed) and why hydrogen abstraction from solvent now is favored over transannular hydrogen abstraction followed by chlorine abstraction. A possible explanation of the difference is that the amidyl radical or corresponding carbon radical (see **22**) remains associated with the silver surface for some time, and that access to solvent as a source of hydrogen in this state is better than access to a chloro lactam molecule.

The ring fission undergone by **10***a* seems to be a consequence of the inaccessibility of internal hydrogen in the most probable configuration **24** of the derived radical (amide resonance), and the fact that its geometry is ideal for ring opening.



24

One striking factor affecting the course of the homolytic reactions is the solvent composition. In *dry* dioxane or dimethyl formamide, the radical **24** and the medium ring ones (see **21**) derived from **1***a* and **2***a* abstract the reactive hydrogens of the solvent in preference to the unactivated transannular ones. However in all cases, the presence of 20% water in the solvent reverses this nearly completely. A possible explanation is that the amidyl radicals are exclusively water-solvated, and that this shields the nitrogen radical from attack on the dioxane or dimethylformamide. It is reasonable to expect that the carbon radicals (**22**) formed by transannular hydrogen abstraction would then abstract chlorine from another molecule of *N*-chloro lactam, in preference to hydrogen abstraction from other species, and thus promote a chain reaction. As expected from the above results, in the photochemical decomposition of **2***a* in dioxane, the presence of 20% water

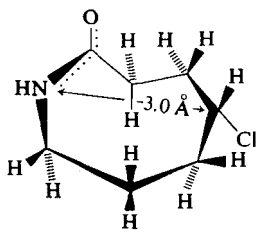
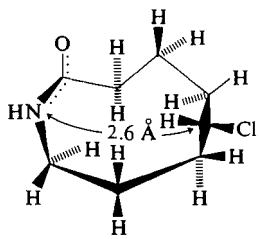
dramatically suppressed hydrogen abstraction from solvent.[4] The peroxide initiated reaction in dry dimethylformamide was much slower than in dry dioxane, perhaps because of solvent shielding of the chloro lactam.

The striking difference between the ease of cyclization of the nine-membered and eight-membered *C*-chloro lactams must be of purely geometric origin. Indeed, if one assumes that the reactions involve overlap of the π electrons of the planar amide function with the rear lobe of the C—Cl bond, Courtauld molecular models do show a significant difference between the proximity in the two cases (see **25** and **26**).



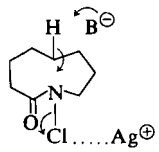
25



26

The apparent ionic reaction between *N*-chloroazacyclononanone and silver oxide–ammonia combination in aqueous dioxane or acetonitrile can be formulated as a push–pull process (eq. 2). However the other main product

[2]



was parent lactam, and with the eight-membered ring this was the main product. These are certainly formed by a homolytic process. Since the chloro lactams were inert to dioxane peroxide at room temperature, and no peroxide was present in the acetonitrile, it appears possible that colloidal metallic silver produced in some oxidation–reduction reaction may be the initiator of radical chains leading to these lactams.

Experimental

The i.r. spectra were recorded on a Perkin–Elmer Model 257 grating spectrometer and n.m.r. spectra on a Varian A60A spectrometer using deuterochloroform as solvent and tetramethylsilane as internal standard unless otherwise specified. Mass spectra were obtained using a Hitachi–Perkin Elmer RMU-60 instrument. Intensities are given in parentheses.

Solvents

Acetonitrile used throughout was of spectroscopic quality. Dioxane was distilled after refluxing over sodium and was stored under nitrogen in the presence of sodium. Elimination of traces of peroxide was achieved by the passage of the solvent through a column of alumina (activity 1) prior to use.

Silver Oxide

This was prepared by the addition of 10% sodium hydroxide solution to an aqueous solution of silver nitrate until precipitation was complete. The oxide was repeatedly washed with water until the washings were free of base, filtered, and used immediately.

Silver

The silver oxide prepared as described above was dissolved in the minimum volume of ammonia solution (28%). Formaldehyde solution was added with rapid stirring until precipitation was complete. The silver was washed repeatedly with water until free of base, filtered, and used immediately.

Gas–Liquid Chromatography

The lactams were analyzed by g.l.c. on 4′ glass columns of 10% versamid 900 on HMDS treated Chromosorb W (60/80 mesh) at 200° using a flame ionization detector. The response of this detector towards azacyclononan-2-one, and the azabicyclononanones was determined using the authentic compounds, and the analyses reported for these compounds are estimated as having a maximum error of 5%.

Parent Lactams

With the exception of azacycloheptan-2-one which was a commercial product, and the mixed *C*-chloroazacyclononan-2-ones (see below), the monocyclic lactams used in this study were prepared by the sulfuric acid induced (10) Beckmann rearrangement of the oximes of the corresponding cyclic ketones. 2-Azabicyclo[2.2.2]-octan-3-one was prepared from *cis*-4-aminocyclohexanecarboxylic acid (11).

N-Chloro Lactams

These were conveniently prepared by the addition of excess 10% sodium hypochlorite solution to a stirred aqueous solution of the medium ring lactams at 10 °C. A reaction time of 1 h was sufficient for an almost quantitative conversion to the *N*-chloro derivative, which conveniently separated as an oil. The reaction mixture was extracted with hexane–dichloromethane (7:3), and the extracts washed (H_2O), dried (Na_2SO_4), and the solvents removed *in vacuo* at < 50°. The colorless chloro lactams, whose iodometric assay gave a purity > 95% (traces of solvent remain), were used without further purification.

Alternatively a 10% excess of freshly prepared *t*-butyl hypochlorite was added to a solution of lactam in benzene, or chloroform, and the reaction mixture kept in the dark, at room temperature for 6–12 h (t.l.c. analysis

[4]We are grateful to a referee for suggesting this experiment.

For personal use only.

indicated that *N*-chlorination was essentially complete within 1 h). Evaporation under reduced pressure then yielded the *N*-chloro lactams as oils which usually crystallized spontaneously when stored overnight at 0°. As before, the purity of the products was determined by iodometry, and t.l.c. Certain of the *N*-chloro lactams were recrystallized and further characterized.

N-Chloro-*N*-methylpentanoamide. This chloramide was prepared from the parent amide by the *t*-butyl hypochlorite procedure, and obtained as an oil, homogeneous by t.l.c. analysis; ν_{max}(film) 1675 cm^{-1}; n.m.r. (CCl_4) τ 6.72 (3H, s, NCH_3), 7.30 (2H, tr. J = 7 Hz, CH_2CO), 8.2–8.8 (4H, broad multiplet, H-3 and -4), and 9.05 (3H, tr. J = 6 Hz, CH_3CH_2).

Preparation of Reference 1-Azabicyclo[m.n.o]alkanones

(1) 1-Azabicyclo[4.3.0]nonan-2-one (3-Ketooctahydropyrrocoline) (3)

This compound was prepared, in 80% yield, by the thermal cyclization of 3-(2-piperidyl)propionic acid (12), and obtained as a colorless oil, homogeneous by g.l.c. analysis, b.p. 70°/0.02 mm (lit. (12) b.p. 126–127°/12 mm).

(2) 1-Azabicyclo[4.3.0]nonan-9-one (5-Ketooctahydropyrrocoline) (4)

Mixed methyl 4-(2′- and 3′-) pyrrolylbutyrates (13) (70% 2′-isomer by g.l.c.) were dissolved in hot aqueous ethanol (1:1 v/v) and saponified by titration with 2.5 *N* aqueous sodium hydroxide to a persistent (1 h) phenolphthalein end point. The solution was concentrated to small volume, diluted with water, and extracted with ether. The aqueous phase was then brought to p*H* 2 with 2 *N* hydrochloric acid and extracted with ether. Evaporation of the combined, dried ($MgSO_4$) ether extracts afforded a golden, crystalline residue of the mixed 4-(3′- and 2′-pyrrolyl) butyric acids which was used without further purification.

A solution of the acids (7.5 g, 49 mmol) in water (100 ml) containing concentrated aqueous ammonia (5 ml, *d* 0.88) was shaken with 5% rhodium-on-alumina (2.5 g) at room temperature in an atmosphere of hydrogen (50 p.s.i.). Hydrogen uptake appeared complete in 1 h. The suspension was filtered, the catalyst washed with water, and the filtrate and washings were evaporated (bath 50°) under reduced pressure. The syrupy residue was dried by azeotropic distillation with benzene under reduced pressure, and finally over P_2O_5, *in vacuo*, yielding the 4-(3′- and 2′-pyrrolidyl) butyric acids as a colorless solid m.p. 112–115°.

These mixed acids (7 g) were heated for 10 min (bath 125–130°) under a slow current of nitrogen. After cooling, the resulting oil was partitioned between 1 *N* aqueous sulfuric acid (5 ml) and ether (10 ml). The aqueous phase was then re-extracted with ether (4 × 10 ml), and then with chloroform (5 × 5 ml). Evaporation of the dried ($MgSO_4$) extracts yielded an oil which was distilled to give 5-ketooctahydropyrrocoline, as a colorless liquid b.p. 66–67°/0.15 mm (4.26 g, 98% based on 2′-pyrrolyl isomer content of the starting ester): ν_{max}(film) 1650 cm^{-1}; n.m.r. τ 8.9–7.5 (10H, complex) and 6.8–6.2 (3H, complex, $-CH_2-\underset{|}{N}-CH\langle$).

Anal. Calcd. for $C_8H_{13}NO$: C, 69.04; H, 9.42; N, 10.07. Found: C, 69.28; H, 9.71; N, 10.05.

(3) 1-Azabicyclo[5.2.0]nonan-9-one (5)

(*a*) Ethyl (2-oxocyclohexyl) acetate (44 g, 240 mmol) dissolved in chloroform was submitted to a Schmidt reaction with hydrazoic acid (190 ml of a 1.55 *M* solution in chloroform, 290 mmol) at 3–5° (14). After 3 h the reaction mixture was worked-up by the standard procedure (14) to give a crystalline product, which recrystallized from ethanol–hexane to give ethyl 2-oxohexahydro-7-azepinyl acetate as colorless prisms, m.p. 113–114°; n.m.r. τ 3.30 (1H, br. singlet, NH), 5.81 (2H, quartet, J = 7 Hz, $-CO_2CH_2CH_3$), 6.22 (1H, br. multiplet $NHCHCH_2CO_2$), 7.45 (2H, doublet, J = 7 Hz, $CHCH_2CO_2$), 7.52 (2H, broad multiplet, $-CH_2CO$), 8.0–8.6 (6H, broad complex multiplet, ring CH_2), and 8.73 (3H, triplet, J = 7 Hz, $CO_2CH_2CH_3$).

Anal. Calcd. for $C_{10}H_{17}NO_3$: N, 7.03. Found: N, 6.87.

This ester (5.0 g, 25 mmol) was reduced with lithium aluminum hydride (1.5 g) in refluxing dioxane (50 ml) for 4 h. Excess reagent was decomposed by the dropwise addition of water (2 ml), and then 15% aqueous sodium hydroxide (4.5 ml) to the cold, stirred, reaction mixture. The precipitated inorganic salts were removed by filtration, and the filter-cake was washed well with methylene dichloride. The combined, dried ($MgSO_4$) filtrate and washings were evaporated to yield a solid residue, which recrystallized from chloroform–benzene to give 7-(2-hydroxyethyl)hexahydroazepin-2-one as fine colorless needles, m.p. 138° (2.9 g, 74%); ν_{max}($CHCl_3$) 3400, 3325 (br.), and 1660 cm^{-1}; n.m.r. τ 3.15 (1H, br. singlet, NH) 6.22 (3H as a 2H triplet, J = 5 Hz, plus a 1H singlet which disappeared upon addition of D_2O, $-CH_2OH$), 6.47 (1H, broad complex, $-CHCH_2$), 7.53 (2H, multiplet, CH_2CO), and 7.9–8.7 (8H, broad complex signal, hydrogens at C-4, -5, -6, and -1′); m/e 157 (16) (M^+), 112 (100) $(M-CH_2CH_2OH)^+$.

Anal. Calcd. for $C_8H_{15}NO_2$: N, 8.91. Found: N, 9.16.

Phosphorus tribromide (0.8 g, 2.95 mmol) was added to the alcohol (1.2 g, 7.5 mmol). The mixture was stirred, and kept at 40–50° for 2 h, then poured into ice-water (10 ml), and extracted with chloroform (3 × 25 ml). The chloroform extracts were washed with saturated aqueous sodium bicarbonate (2 × 5 ml) and water (5 ml). The crystalline residue (1.5 g), which remained after removing the solvent from the dried chloroform extracts, was recrystallized from benzene – hexane to yield 7-(2-bromoethyl)hexahydroazepin-2-one, m.p. 121–122° (1.3 g, 5.9 mmol) (77%); ν_{max}(KBr) 3200 and 1670 cm^{-1}; n.m.r. τ 3.2 (1H, br. singlet, NH), 6.48 (3H, triplet, [2H, J = 7 Hz (CH_2Br) superimposed on 1H multiplet ($-CH-$N)], 7.52 (2H, br. multiplet, CH_2CO) and 7.6–8.6 (8H broad complex multiplet, H

For personal use only.

at C-4, -5, -6 and -1′); *m/e* 121 (3) and 119 (3) (M^+), and 112 (100) ([$M—CH_2CH_2Br^+$]).

Anal. Calcd. for $C_8H_{14}BrNO$: C, 43.64; H, 6.37; N, 6.36. Found: C, 43.98; H, 6.19; N, 6.71.

The bromoethyl compound (1.2 g, 5.4 mmol) was added to a solution of potassium amide (from 0.21 g, 5.4 mmol potassium) in liquid ammonia (30 ml), and the reaction mixture was stirred overnight, while the ammonia was allowed to evaporate. The residue was extracted with benzene (3 × 25 ml), and the extracts were washed successively with 0.01 *N* aqueous hydrochloric acid (5 ml) and then with water (5 ml). Removal of solvent from the dried ($MgSO_4$) extract left a residual oil which was distilled to yield 1-azabicyclo[5.2.0]nonan-9-one as a colorless liquid, b.p. 132°/15 mm (0.47 g, 3.4 mmol) (63%); ν_{max}(film) 1630 cm^{-1}; n.m.r. τ 5.7 (1H, broad multiplet, H-7), 6.15 (2H, triplet J = 7 Hz, H-9), and 7.3–9.0 [10H, broad overlapping signals at *ca.* 7.6 (H at C-3) and 7.7–9.0 (H at C-4, -5, -6, and -8)]; *m/e* 137 (84) (M^+), and 56 (100).

Anal. Calcd. for $C_8H_{13}NO$: N, 10.07. Found: N, 9.93.

(*b*) To a solution of potassium amide (prepared from 0.14 g, 3.6 mmol of potassium) in liquid ammonia was added 7-chloroazacyclononan-2-one (0.53 g, 3.0 mmol). The reaction mixture, protected by a soda-lime tube, was stirred overnight while the solvent was allowed to evaporate. The residue was extracted with benzene (3 × 50 ml) and the extracts were washed with dilute hydrochloric acid, and water, then dried ($MgSO_4$), and evaporated under reduced pressure to yield a residual oil (0.31 g, 74%) (> 95% (**5**) by g.l.c.).

(4) 1-Azabicyclo[5.2.0]nonan-2-one (6)

The mother liquors from the lithium aluminum hydride reduction of ethyl (2-oxohexahydro-7-azepinyl) acetate (see preparation of reference 1-azabicycloalkanones) upon evaporation yielded a residual oil which was part-soluble in cold ether. Evaporation of the ether solution, followed by fractional distillation, gave 2-(2′-hydroxyethyl)-hexahydroazepine as an oil b.p. 71°/0.03 mm; $\nu_{max}(CHCl_3)$ 3200 cm^{-1} (very broad), no C=O absorption; n.m.r. τ 3.15 (1H, br., NH), 6.22 (3H, 2H triplet J = 6 Hz, H at C-2′, with a superimposed 1H singlet, OH), 6.45 (1H, br. multiplet, H at C-2), 7.53 (2H, multiplet, H at C-7), and 8.1–8.6 (8H, H at C-1′, -3, -4, -5, and -6). The 1H signals at τ 3.15, and 6.22 were removed upon addition of D_2O.

The imino alcohol (1.0 g) was dissolved in a solution of sulfuric acid (2.0 g) and chromium trioxide (1.2 g) in water (17 ml), and the reaction mixture was kept at 80° for 30 min. Excess chromic acid was reduced by passing SO_2 through the mixture, which was then boiled briefly with a slight excess of aqueous barium hydroxide solution. The mixture was filtered, and the filtrate evaporated to dryness to leave a syrupy residue which solidified upon storage under vacuum. This hygroscopic material was extracted with ethanol (3 ml), and the ethanol extract was then diluted with ether (200 ml). Hexahydro-2-azepinylacetic acid separated as a non-hygroscopic white solid (0.35 g) with m.p. 173–174°, ν_{max} 3115 and 1580, together with broad absorption in the region 2780–2325 cm^{-1}.

Anal. Calcd. for $C_8H_{15}NO_2$: C, 61.15; H, 9.55; N, 8.92. Found: C, 60.69; H, 10.16; N, 8.70.

The identity of this acid was further confirmed by its conversion with diazomethane to a methyl ester, b.p. 75°/0.3 mm; ν_{max} 3350 and 1725 cm^{-1}; n.m.r. τ 6.30 (3H, s, CO_2CH_3), 6.70–7.20 (3H, overlapping broad multiplets for H at C-2′, and -7′), 7.62 (2H, doublet J = 7 Hz, H at C-2), and 9.0 (8H, multiplet, H at C-3′, -4′, -5′, and -6′); *m/e* 171 (M^+) with base peak at 98 corresponding to α-cleavage and loss of $CH_2CO_2CH_3$.

A solution of the hexahydroazepinylacetic acid (150 mg) in dry nitromethane (8 ml) was treated with dicyclohexylcarbodiimide (120 mg), and the reaction mixture was stirred at room temperature for 4 days. The *N,N′*-dicyclohexylurea which separated was removed by filtration. Evaporation of the filtrate yielded an oil (125 mg) which was subjected to t.l.c. on alumina with chloroform–hexane (1:1) as the developing solvent. The major band yielded 1-azabicyclo[5.2.0]nonan-2-one as an oil (51 mg); $\nu_{max}(CHCl_3)$ 1745 cm^{-1}; mass spectrum, M^+ 139 (base peak); n.m.r. τ 6.39 (1H, br. singlet, H-7), 7.15 (1H, dd, J = 5 and 14 Hz, H-8), and 7.70 (1H, dd, J = 3 and 14 Hz, H-8).

(5) 1-Azabicyclo[3.3.0]octan-2-one (Pyrrolizidin-3-one) (7)

Methyl *trans*-2-(2-pyrrolyl) acrylate was prepared from pyrrole-2-aldehyde and carboethoxymethyltriphenylphosphorane as described for the ethyl ester (15) and obtained as pale yellow crystals, m.p. 88–89°, b.p. 110°/0.1 mm (64%).

This ester (5.4 g, 36 mmol), dissolved in ethanol (100 ml), was hydrogenated over 5% rhodium-on-alumina (5g) at atmospheric pressure for 20 h. The reaction mixture was then filtered and the filtrate evaporated to yield a dark oil, fractionation of which gave 3-ketopyrrolizidine b.p. 107–108°/12 mm, > 99% pure by g.l.c. (80%);[5] ν_{max}(film) 1680 cm^{-1}, (lit. (16) b.p. 90–100°/10 mm).

Schmidt Reaction on 4-Chlorocyclooctanone

A 1.0 *M* solution of hydrazoic acid in chloroform (30 ml, 30 mmol), containing 4-chlorocycloöctanone (17) (4.4 g, 27 mmol) was added dropwise to a mixture of chloroform (25 ml) and concentrated sulfuric acid (10 ml). The temperature of the reaction mixture was maintained at 3–5° by external cooling. After addition was complete the reaction mixture was stirred for 30 min, then poured into ice-water (200 ml) and neutralized with sodium carbonate. The chloroform phase was separated, and the aqueous phase extracted with chloroform (2 × 30 ml). The combined chloroform extracts were dried ($MgSO_4$) and evaporated under reduced pressure to yield an oil (*ca.* 6 g), which was shown by t.l.c. to consist of some unchanged ketone (R_f 0.70) together with two other major products, R_f 0.33 and 0.45 (chloroform:methanol:hexane, 85:5:10).

The material with R_f 0.33 crystallized out from the crude reaction product when this was stored at 0°. Recrystallization from benzene and ether gave 7-chloroazacyclononan-2-one (**17**) (0.80 g, 17%) as colorless

[5]We also obtained this product, in poorer yield, and less pure, by treating pyrrolyl magnesium chloride with propiolactone, at 0°. The mixed 2- and 3-pyrrolylbutyric acids so obtained were methylated with diazomethane, the methyl ester purified by distillation (b.p. 125–128°/15 mm), and hydrogenated as described above for the acrylate.

For personal use only.

prisms, m.p. 109–111°; ν_{max} 3400 and 1600 cm^{-1}; *m/e* 175 and 177 (*ca.* 2.5:1) M^+, with M + 1 ions of comparable intensity at *m/e* 176 and 178; n.m.r. τ 5.7–6.0 (1H, multiplet, CHCl).

Anal. Calcd. for $C_8H_{14}ClNO$: C, 54.70; H, 8.03; N, 7.97. Found: C, 54.77; H, 8.11; N, 8.21.

The mother liquors from the original crystallization were evaporated to a residual oil which was subjected to t.l.c. (chloroform:methanol:hexane 85:5:10) by which means the component with R_f 0.45 was separated as an oil, free of the lower R_f product. If had ν_{max}(film) 1685 cm^{-1}. Its n.m.r. was complex, but had no significant absorption at τ 5.5–6.0 for CHCl. The identity of the product with 1-azabicyclo[4.3.0]nonan-2-one (**3**) was established by comparison of mass spectra and g.l.c. retention time.

In other cases, the crude Schmidt product was subjected, directly, to fractional distillation, yielding a material with b.p. 60–65°/0.01 mm rich in **3** (g.l.c. analysis), followed by the *C*-chloro lactam **18**, b.p. 85–125°/0.02 mm which crystallized in the receiver.

Also isolated in small amounts, from some reactions conducted in acetic acid containing sulfuric acid and sodium azide at 60–65°, was a substance R_f 0.57 (chloroform:methanol:hexane 85:5:10), m.p. 72–74°, identified as the tetrazole derivative, **18**; ν_{max}(KBr) no NH or CO absorptions; *m/e* 200 and 202 (*ca.* 3:1, M^+); n.m.r. τ 5.40 (2H, br. triplet, *J ca.* 6 Hz), 5.90 (1H, width *ca.* 14 Hz), 2.87 (2H, broad multiplet), 6.5 (2H, AB quartet, J = 6 Hz), 8.15 (4H, broad complex), and 8.5 (2H, broad multiplet).

Anal. Calcd. for $C_8H_{13}ClN_4$: N, 27.78. Found: N, 27.77.

(A) Reaction of the N-Chloro Lactams "under Ionic-reaction Conditions"

(1) N-Chloroazacyclononan-2-one

To a solution of the *N*-chloro lactam (0.72 g, 4.1 mmol) in dioxane–water (4:1, 15 ml) was added ammonia solution (0.56 ml of 30%; 10 mmol), followed by freshly prepared silver oxide (from 4.74 g silver nitrate), and the resultant mixture stirred at room temperature under nitrogen. The reaction rate was determined by iodometric assay of 0.5 ml samples, withdrawn from the flask at appropriate intervals. After the reaction was completed (2 h), sodium chloride solution was added to precipitate any silver remaining in solution, and the mixture was filtered and the cake washed with dioxane. The filtrates were evaporated to low bulk; taken up in chloroform, dried (Na_2SO_4), evaporated, and the residue distilled on the oil pump. The distillate (b.p. 70–95°/0.01 mm, 0.5 g) was analyzed by g.l.c. The products, the lactams **3**, **4**, and **2***b* were found in the ratio 1:2.8:1.85, which corresponded to a yield of 63% of bicyclic products.

When the above reaction was carried out in acetonitrile–water (9:1) the following result was obtained. After 3 h reaction, the product analysis showed the lactams **3**, **4**, and **2***b* to be in the ratio 1:2.8:3.6, corresponding to a 50% yield of bicyclic products.

When a solution of the *N*-chloro-2-azacyclononanone (1.23 mmol) in acetonitrile–water 9:1 (5 ml) containing ammonia (0.14 cc, 30%, 2.5 mmol) was left under nitrogen at room temperature for 3 days, the concentration of *N*-chloro amide remained unchanged (iodometric assay).

(2) N-Chloroazacyclooctan-2-one

The reaction of the *N*-chloro compound with silver oxide – ammonia, under the standard conditions described previously was complete in 3 h in aqueous dioxane, and 4.5 h in aqueous acetonitrile. Product analysis by g.l.c. and n.m.r. showed the parent lactam **1***b* (90% recovery) to be the sole product of reaction in the case where aqueous acetonitrile was used as solvent. A trace (< 5%) of 1-azabicyclo[3.3.0]octanone-2 was detected in the reaction mixture when aqueous dioxane was used as solvent (95% recovery).

(3) N-Chloroazacycloheptan-2-one

Under the reaction conditions described previously, the parent azacycloheptan-2-one was the sole product of reaction (90%).

(B) Reaction of the N-Chloro Lactams "under Free-radical Conditions"

(1) N-Chloroazacyclooctan-2-one

(*a*) This *N*-chloro lactam (1.01 g, 6.3 mmol) was dissolved in 4:1 (v/v) peroxide-free dioxane–water (75 ml) containing precipitated calcium carbonate (3.0 g) and benzoyl peroxide (20 mg, 0.01 mmol). The reaction mixture was stirred and heated at 80°, under nitrogen. The reaction was complete in 1.5 h, and the mixture was then filtered and the filter-cake washed with dioxane. The combined filtrate and washings were evaporated to small bulk and the residue taken up in chloroform. Removal of solvent from the dried solution yielded an oil which was taken up in acetone–hexane. The solution deposited white prisms of the *C*-chloro lactam **8**, m.p. 85–87° (750 mg, 75%), ν_{max}($CHCl_3$) 1660 and 3400 cm^{-1}; n.m.r. τ 2.8–3.5 (broad, 1H, NH), 5.5–5.9 (multiplet, 1H, CH—Cl), 6.4–6.85 (multiplet, 2H, —CONH—CH_2—), and 7.1–8.5 (complex multiplet, 8H, ring protons).

Anal. Calcd. for $C_7H_{12}ClNO$: C, 52.02; H, 7.48; N, 8.64. Found: C, 52.37; H, 7.51; N, 8.78.

The g.l.c. behavior of the *C*-chloro lactam **8** on two columns, versamid at 200°, and SE30 at 165°, provided evidence of the thermal cyclization of **8** to the bicyclic lactam **7** *i.e.* retention times of **8** and **7** were identical on versamid at 200°, but **8** on SE30 at 165° gave two peaks (R_t = 4 min: 12 min), the faster peak corresponding to bicyclic lactam **7**.

(*b*) The above reaction could be duplicated using dioxane containing traces of hydroperoxides instead of benzoyl peroxide (*i.e.* by using dioxane distilled from sodium, but not percolated through alumina). Calcium carbonate could also be replaced by silver carbonate without altering the course of the reaction.

(*c*) *N*-Chloroazacycloöctan-2-one (0.465 g, 2.9 mmol) in 4:1 (v/v) peroxide-free dioxane – water (25 ml) containing calcium carbonate was heated at 80° under nitrogen. After 6 h no decrease in *N*-chloro lactam concentration could be detected, as judged by iodometry.

(*d*) The reaction at 80° in pure dioxane containing added peroxide, but no water or calcium carbonate, was very fast (complete in under 30 min), and gave a mixture of products; the major being the parent lactam **1***b*, with less than 5% of the *C*-chloro lactam, as estimated by the intensity of the *H*—C—Cl signal in the n.m.r. spectrum of the crude product. Further analysis of the n.m.r. spectrum revealed a singlet at τ 6.3 (dioxane hydrogens) together with a doublet at τ 5.1 (J = 3 Hz),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

consistent with the presence of a coupled product **19** formed by combination of amidyl and dioxanyl radicals.

(*e*) When the reaction was run as in (*a*) or (*b*), but without calcium carbonate, the reaction mixture became slightly acidic, and the rate of reaction decreased considerably. Addition of calcium carbonate accelerated the reaction. In cases where the reaction was allowed to go to completion in the absence of carbonate, lower yields (30–40%) of *C*-chloro lactam **8** were obtained.

(*f*) When the reaction was conducted as in (*a*), but in pure dry dioxane, the reaction was fast (complete within 1 h) but gave lower yields of the desired *C*-chloro lactam. Examination of the n.m.r. spectrum of the crude product revealed absorptions similar to those described in (*d*) *i.e.* products such as **19** were again forming.

(*g*) When the reaction was conducted as in (*a*), but in dimethylformamide–water (4:1) an 80% yield of the *C*-chloro lactam **8** was obtained. In contrast, a comparable run in anhydrous dimethylformamide, showed that only 20% of the *N*-chloro lactam had decomposed in 1 h (*c.f.* 100% in the aqueous DMF case). Further additions of benzoyl peroxide (up to 25 mol %) were required over a period of 25 h to complete the decomposition in the dry solvent.

Cyclization of the C-Chloro Lactam 8

(*a*) The crystalline lactam (1.0 g, 6.2 mmol) was dissolved in dioxane–water (7:3, 200 ml), containing silver perchlorate (2.5 g, 12 mmol), and the mixture refluxed with stirring for 4 h, during which time silver chloride precipitated. Saturated sodium bicarbonate was added to precipitate the silver remaining in solution and the mixture was filtered; the filtrate was reduced to low bulk, taken up in chloroform, dried (Na_2SO_4), and the residue on evaporation distilled in vacuum. The fraction b.p. 60–70°/3 × 10^{-2} mm (500 mg, 58%) had ν_{max} ($CHCl_3$) 1680 cm^{-1} (5 ring lactam).

Anal. Calcd. for $C_7H_{11}NO$: C, 67.16; H, 8.85. Found: C, 67.06; H, 8.81.

The mass spectrum, M^+ = 125 (78); 97 (100) ($M^+ - 28$); 69 (61) (97–28), was consistent with the formulation of the product as 1-azabicyclo[3.3.0]octan-2-one (**7**).

Lithium aluminum hydride reduction of the bicyclic lactam **7** in dioxane, afforded a base whose picrate, m.p. 254–256° was identical (m.p. and mixed m.p. 253–255°) with an authentic sample of pyrrolizidine picrate (lit. (16) m.p. 255–258°).

(*b*) A solution of potassium amide in liquid ammonia was prepared from potassium metal (22 mg, 0.57 mmol) and liquid ammonia (25 ml). To this solution was added **8** (81 mg, 0.5 mmol) and the reaction mixture was stirred overnight while the ammonia was allowed to evaporate. The residue was extracted with a little benzene, and the benzene solution was washed with dilute hydrochloric acid, and dried ($MgSO_4$). Removal of solvent under reduced pressure left a residual oil which was >95% 3-ketopyrrolizidine by g.l.c. analysis, and comparison with the above sample.

(2) N-Chloroazacycloheptanone

(*a*) The *N*-chloro compound (0.42 g, 2.86 mmol) was dissolved in 4:1 (v/v) pure dioxane–water (40 ml), containing calcium carbonate (2 g) and benzoyl peroxide (20 mg, 0.01 mmol). Reaction was complete within 1 h at 80° under nitrogen, and work-up as before gave a product (%Cl = 0.07) whose i.r. spectrum was almost identical with that of azacycloheptan-2-one. The n.m.r. spectrum of the crude product revealed significant absorptions at τ 6.3 (singlet) and 5.1 (doublet, J = 3 Hz) consistent with products such as **19** derived from radical attack on dioxane.

(*b*) *N*-Chloro lactam (from 0.51 g, (4.41 mmol) of lactam) dissolved in 4:1 v/v dioxane–water (25 ml) in which was suspended silver carbonate (4 g), was stirred and heated at 100° (bath) for 3 h (reaction was complete after 1 h as judged by iodometry). The reaction mixture was filtered (Celite) and the filter-cake was washed with hot dioxane. Upon cooling, the combined filtrate and washings deposited colorless micro-needles (200 mg), soluble in water, insoluble in chloroform, containing silver but no nitrogen ν_{max}(KBr) 3400–3200, 1610, 1125, and 1075 cm^{-1}; n.m.r. (D_2O) τ 6.30 and 6.27 (4H, apparently the superposition of two triplets, J = 3 Hz, $HOCH_2CH_2O$—) and 5.97 (2H, singlet, —OCH_2CO_2) consistent with this material being silver 2′-hydroxyethoxyacetate, presumably derived by the further oxidation of **19***a*.

Evaporation of the aqueous dioxane filtrates, followed by partitioning of the residue between chloroform and water, gave a chloroform extract which was dried ($MgSO_4$) and evaporated to yield an oil (500 mg). The g.l.c. analysis revealed that this product was more than 90% azacycloheptan-2-one, and crystallization of the material from solution in petroleum ether afforded **9***b* as colorless plates. Its i.r. spectrum was superimposable upon that of authentic material.

(3) N-Chloroazacyclononan-2-one

(*a*) The *N*-chloro lactam (1.02 g, 5.75 mmol) was dissolved in 4:1 (v/v) "sodium-dry" dioxane–water (30 ml) containing calcium carbonate (2 g), and the reaction mixture was stirred and heated at 85° under nitrogen. The reaction appeared complete (iodometric assay) after 3 h. The reaction mixture was worked-up in the usual manner to yield an oil (0.96 g) which was shown by g.l.c. analysis to consist of the three lactams (**3**) (32%), (**4**) (63%), and (**2***b*) (5%).

(*b*) In a similar experiment, in which silver carbonate was used instead of the calcium salt, the products were fractionated by distillation under reduced pressure on a micro spinning-band column, yielding pure 5-ketooctahydropyrrocoline (**3**) (b.p. 96°/0.003 mm, n_D^{24} 1.4879) and 3-ketooctahydropyrrocoline (**4**) of greater than 90% purity (b.p. 110°/0.001 mm, n_D^{24} 1.5003). The i.r. spectra of these preparations were superimposable upon those of authentic specimens of the bicyclic lactams.

(*c*) The decomposition of *N*-chloroazacyclononan-2-one in wet, and dry dimethylformamide containing calcium carbonate and benzoyl peroxide, was also investigated.

As usual, the *N*-chloro lactam was completely destroyed within 20 min at 88°, in the wet solvent. The major products, as determined by g.l.c. analysis consisted of **3**, **4**, and **2***b* (*ca.* 1:3.3:1).

In anhydrous DMF the reaction was complete within 4 h at 88°, and the major products were the same as in the aqueous solvent, but with increased amounts of **2***b* (**3**:**4**:**2***b* *ca.* 1:1.9:2.0).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(4) N-Chloro-2-azabicyclo[2.2.2]octan-3-one ("Isoquinuclidone")

(*a*) The *N*-chloroazabicyclolactam (3.0 g, 18.8 mmol) was dissolved in 4:1 "sodium-dry" dioxane–water (150 ml), containing 12 g of suspended calcium carbonate, and heated at 80° under nitrogen. After all the *N*-chloro lactam had disappeared, the reaction mixture was worked-up in the usual fashion. However in this instance, a white precipitate separated from the filtrate, and considerable amounts of organic material were present in the filter-cake, which was therefore washed thoroughly with hot chloroform. The chloroform washings were used to extract the original filtrates, and the combined, dried chloroform extracts were then evaporated to yield a white solid which was recrystallized from acetone–hexane, m.p. 225–226° (1.9 g, 69%); ν_{max}(KBr) 3340 and 1635 cm^{-1}, *m/e* 292:294:296 *ca.* 9:6:1 corresponding to "M^+" species for $C_{13}H_{22}Cl_2N_2O$.

Anal. Calcd. for $C_{13}H_{22}Cl_2N_2O$: C, 53.06; H, 7.58; N, 9.58. Found: C, 53.29; H, 7.84; N, 9.49.

The mother liquors contained, in addition to this *N,N'*-di-(4'-chlorocyclohexyl) urea, a little parent 2-azabicyclo[2.2.2]octan-3-one, as judged by t.l.c. and g.l.c. (*ca.* 10%).

(*b*) When the *N*-chlorobicyclolactam was heated in "sodium-dry" dioxane, reaction was again rapid. The solution became acid. Evaporation, with exclusion of moisture, gave an oil containing some suspended solids. The i.r. spectrum of this crude product had ν_{max}(film) 2265 (—N=C=O), as well as 3200 and 1700 cm^{-1}.

Freshly distilled aniline was added to a solution of the crude product in dry ether. A mildly exothermic reaction ensued. The reaction mixture was kept for several hours at room temperature, then washed with dilute aqueous sulfuric acid, and then with bicarbonate solution. Evaporation of the dried ether extracts gave a solid which consisted of two major components (t.l.c.). Separation was achieved by fractional recrystallization from benzene–hexane to give the less-soluble substance as colorless crystals m.p. 179–183°; *m/e* 284:286 (*ca.* 3:1) as required for $C_{14}H_{21}ClN_2O_2$.[6]

The other substance was obtained by t.l.c. of the residues obtained upon evaporation of the mother liquors as colorless crystals m.p. 243°; *m/e* 252 and 254 (*ca.* 3:1) as required for *N*-(4-chlorocyclohexyl)-*N'*-phenylurea.

(*c*) The reaction was repeated in dry dioxane, with the addition of silver carbonate. After 1 h the reaction was complete, and work-up under anhydrous conditions gave an oily product which was distilled under reduced pressure to give a colorless liquid, b.p. 67–70°/14 mm (65%); ν_{max}(film) 2265 cm^{-1}.

Addition of aniline to a solution of this oil in ether gave a quantitative yield of the *N*-(4-chlorocyclohexyl)-*N'*-phenylurea; flat-sided needles from ethanol–hexane, m.p. 237–238° raised to 241–242° on further recrystallization; *m/e* 252 and 254 (*ca.* 3:1); n.m.r. (DMSO-d_6) τ 1.72 (1H, singlet, NH Ar), 2.5–3.2 (5H, multiplet, ArH), 3.95 (1H, doublet, J = 8 Hz, N*H*—CH), 5.92 (1H, very broad "singlet" (width *ca.* 24 Hz), C*H*Cl)), 6.47 (1H, very broad singlet (width *ca.* 20 Hz) C*H*—NH)), and 7.65–9.0 (8H, overlapping multiplets, ring CH_2). Irradiation at τ 6.47 collapsed the signal at τ 3.95 to a singlet, but the reverse operation, although it sharpened the τ 6.47 signal, did not resolve its structure. From the width of the τ 6.47 and 5.92 signals it seems most likely that the urea has a *trans*, diequatorial arrangement of the chloro and ureido groups.

Anal. Calcd. for $C_{13}H_{17}ClN_2O$: C, 61.78; H, 6.78; N, 11.09. Found: C, 61.66; H, 6.71; N, 10.98.

(5) N-Chloro-N-methylpentanoamide

A solution of the *N*-chloramide (1.49 g, 0.01 mol) in aqueous dioxane (100 ml, 1:4 v/v) containing benzoyl peroxide (*ca.* 20 mg) and suspended calcium carbonate (1.1 g, 0.011 mol) was stirred and heated at 85° (bath) for 18 h, after which time the *N*-chloro amide had been completely decomposed.

The reaction mixture was cooled, filtered, and evaporated to small volume (*ca.* 20 ml). Aqueous sodium bicarbonate solution was added, after which the mixture was extracted with chloroform (4 × 50 ml). The combined dried ($MgSO_4$) extracts were then evaporated to yield a residual yellow oil (1.21 g), shown by t.l.c. analysis (silica gel G, ethyl formate – benzene 4:1 v/v) to consist of two major, and one minor products. The crude reaction product had ν_{max} 3300, 1770, and 1650 cm^{-1}.

Fractional distillation gave two fractions: b.p. 75–80°/14 mm (290 mg), and b.p. 110–120°/*ca.* 14 mm (529 mg). The first fraction had ν_{max} 1790 cm^{-1} (v. strong), n.m.r. τ 5.35 (m) (1H), 7.65 (m) (2H), 7.9–8.5 (br. m.) (2H), and 8.65 (d, J = 7 Hz) (3H); this was identified as γ-valerolactone.

The second fraction had ν_{max} 3310 (strong) and 1655 cm^{-1} (strong); n.m.r., τ 2.15 (1H, broad), 5.8 (1H, multiplet), 7.3 (3H, d, J = 5 Hz), 7.8 (2H multiplet), 8.55 (2H multiplet) and 9.10 (3H, d, J = 6 Hz) consistent with it being γ-chloro-*N*-methylpentanoamide. The fraction also contained a small amount of *N*-methylpentanoamide.

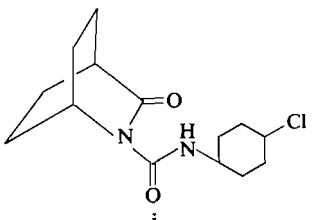
Photolyses

The *N*-chloro amides were photolyzed at 5 °C in aqueous dioxane solutions (peroxide-free) under an atmosphere of nitrogen in a Vycor apparatus with a central well using a Hanovia (8A36) lamp (254 mμ).

N-Chloro-2-azacyclooctanone

The *N*-chloro amide (0.467 g, 2.9 mmol) in peroxide-free dioxane–H_2O (4:1, 50 ml) was completely photolyzed in 15 min (iodometric assay). The solution was evaporated to dryness at low temperature and the residue taken up in methylene chloride, dried (Na_2SO_4), and evaporated. The gum so obtained (0.51 g) was shown by n.m.r. and halogen analysis (%Cl = 16.24) to contain the *C*-chloro lactam **8**, in a yield of 75%.

[6]We ascribe structure **i** to this material.



i

N-Chloro-2-azacyclononanone

The *N*-chloro amide (0.41 g, 2.34 mmol) in dioxane–water (4:1, 50 ml) was completely photolyzed in 10 min. The resulting acidic solution was stirred at 0 °C with a little calcium carbonate, filtered, and worked-up at ice temperature in the manner described previously. All attempts to isolate the suspected intermediate *C*-chloro lactams failed, the bicyclic lactams **3** and **4** being the major products isolated in all cases in yields of 70–80%.

Comparison of Photolysis in Wet and Dry Dioxane

Solutions of *N*-chloroazacyclononan-2-one in aqueous dioxane (1:4 v/v) and dry dioxane (both peroxide-free) were photolyzed under nitrogen at 0–5° using a 450 W Hanovia high pressure mercury lamp in a quartz well. The reaction in aqueous dioxane was complete in 20 min and gave a ratio of **3** to **4** to **2***b* of 1:2:0.3. The reaction dry dioxane was complete in 30 min and gave a ratio of **3** to **4** to **2***b* of 1.5:1:6.

Reaction of the N-Chloroamides with Silver

N-Chloro-2-azacyclooctanone (0.505 g, 3.13 mmol) was dissolved in dioxane–water (4:1, 40 ml), containing calcium carbonate (2 g). Silver (prepared from 7.5 g silver nitrate) was then added and the stirred reaction mixture heated at 80° under nitrogen. After the reaction was completed (5 h) the solids were removed by filtration and washed well with dioxane. The filtrates, on working-up in the manner described previously, gave an oil whose chlorine analysis (8.62%) and n.m.r. spectrum indicated a yield of *C*-chloro lactam **8** of around 25%. Extraction of the dried filter-cake (3x) with aqueous ammonia, and acidification of the extracts gave a precipitate of silver chloride (0.271 g, 1.91 mmol). *N*-Chloro-2-azacyclononanone under the above conditions gave a low yield (*ca.* 10–15%) of the bicyclic lactams **4** and **5**, the major product being the parent lactam **2***b* (over 90 mol % of silver chloride was found in this case).

Reaction of the N-Chloro amides with Silver Oxide

The following experiment was conducted using dioxane which had been stored over sodium wire, but which contained traces of peroxide. *N*-Chloro-2-azacyclononanone (0.405 g, 2.3 mmol) in dioxane–water (4:1, 20 ml) containing silver oxide (prepared from 3 g silver nitrate), was heated at 90° under nitrogen. Complete reaction occurred in 4 h, and the reaction mixture was worked-up in the manner described previously. The distilled residue (0.26 g) contained the lactams **3**, **4**, and **2***b* in the ratio 1:2.8:0.4, the total yield of bicyclic lactams being in the region of 85%.

The Reaction of S(^{3}P) Atoms with Molecular Oxygen

R. W. Fair,[1] A. Van Roodselaar, and O. P. Strausz
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received November 27, 1970

The rate constant of the reaction of ground state S(^{3}P) atoms with molecular oxygen, S(^{3}P) + $O_2(X^3\Sigma_g^-) \rightarrow SO(X^3\Sigma^-) + O(^3P)$, has been determined as $(1.7 \pm 0.2) \times 10^{12}$ cm^3 mol^{-1} s^{-1} at 298 °K by means of kinetic spectroscopy in the vacuum ultraviolet region. The source of S(^{3}P) atoms was the isothermal flash photolysis of COS in the presence of Ar or CO_2.

On a déterminé par spectroscopie cinétique dans l'ultraviolet lointain que la constante de vitesse à 298 °K de la réaction des atomes S(^{3}P) dans leur état fondamental avec de l'oxygène moléculaire, S(^{3}P) + $O_2(X^3\Sigma_g^-) \rightarrow SO(X^3\Sigma^-) + O(^3P)$, est de $(1.7 \pm 0.2) \times 10^{12}$ cm^3 mol^{-1} s^{-1}. On a utilisé la photolyse éclair de COS en présence de Ar ou de CO_2 comme source d'atomes S(^{3}P).

Canadian Journal of Chemistry, **49**, 1659 (1971)

The spin and symmetry allowed reaction of ground state $^3P_{2,1,0}$ atomic sulfur with molecular oxygen

[1] $S(^3P) + O_2(X^3\Sigma_g^-) \rightarrow SO(X^3\Sigma^-) + O(^3P)$

has often been postulated as an elementary process occurring in the oxidation of simple sulfur compounds (1–6). Two conflicting rate constants have been reported for this reaction. Homan *et al.* (7) obtained the relation

$$k_1 = 1 \times 10^{13} \exp(-5600 \text{ cal/mol})/RT \quad \text{cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

in the temperature range 675–1090 °K, but extrapolation of this expression to 298 °K yields a value which is three orders of magnitude lower than the value $(1.2 \pm 0.3) \times 10^{12}$ cm^3 mol^{-1} s^{-1} obtained by Fair and Thrush (8). In view of this discrepancy it was considered desirable to reinvestigate reaction 1.

Experimental

The technique of flash photolysis with kinetic spectroscopy in the vacuum ultraviolet region was used in this work. The reaction cell, made of quartz with LiF end windows, was 17.6 cm long and 1.9 cm in diameter. It was positioned parallel to the limbs of a U-shaped flash lamp and the cell-lamp assembly surrounded by an aluminum reflector. The lamp was filled with 2–6 Torr N_2 to prevent firing during the charging period, and the total pressure was made up to 50 Torr with Kr. It was discharged at 3–9 kV from a 30 μF capacitor. Maximum flash intensity was reached at 14 μs and half peak intensity at 20 μs after initiation. Over 90% of the flash energy was dissipated by 40 μs after initiation, which was the shortest time delay used in the kinetic runs. The spectroscopic source was a conventional quartz capillary discharge lamp which was filled with 10 Torr Kr and discharged at 12–16 kV from a 2.5 μF capacitor; its intensity rose to a maximum in 4 μs and had a duration of 10 μs at half peak intensity. Light from the spectroscopic lamp was focused onto the entrance slit of the spectrograph by a LiF lens placed between the reaction cell and the slit. The LiF end windows of the cell also served as the windows for the spectroscopic lamp and the spectrograph, thus minimizing the number of optical components in the light path.

The spectrograph was a 1 m McPherson 225 normal incidence vacuum scanning instrument fitted with a 30 000 grooves/in. grating, which provided a dispersion of 8.3 Å/mm. A slit width of 20 μ was used. Spectra were recorded on Kodak SWR film which was developed in half strength Kodak D-19 developer for 5 min. The plates were photometered with a Joyce Loebl double beam recording microdensitometer. The three multiplets of S(3^{3}P) were detected by the absorption lines at 1807 ($^3P_2$), 1820 ($^3P_1$), and 1826 Å ($^3P_0$). The dependence of the microdensitometer peak heights, h, of these transitions on the concentrations, c, of the species and the path length, l, was assumed to be of the form

$$h = kc^n l^n$$

The value of n was determined by comparing the peak heights obtained by flashing half the cell length and the full cell length. For the $^3P_2$ line at 1807 Å, n was found to be 0.5 ± 0.1 (Fig. 1). The same value was obtained for the $^3P_1$ line, but the $^3P_0$ line was too weak for quantitative measurements.

Carbonyl sulfide (Matheson) was purified by the procedure of Wiebe *et al.* (9) and carbon dioxide by passing it over P_2O_5 and outgassing at 77 °K. Airco assayed reagent grade argon and oxygen were used without further purification.

[1]Present address: Department of Chemistry, University of Essex, Colchester, Essex, England.

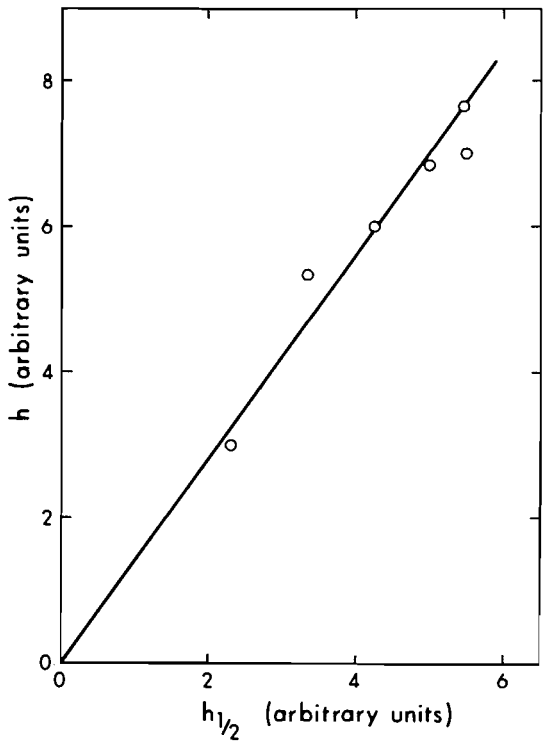

FIG. 1. Determination of Beer–Lambert exponent for the $S(4s^3S_1 \leftarrow 3p^3P_2)$ transition at 1807 Å. h and $h_{\frac{1}{2}}$ are microdensitometer peak heights for path lengths of 17.6 and 8.8 cm, respectively.

Results

The flash photolysis of mixtures containing 0.1 Torr COS with 200 Torr of CO_2 or of Ar was investigated briefly. $S(3^3P_{2,1,0})$ atoms were observed and they decayed over a period of a few milliseconds. The fraction of COS decomposed by flashing COS + Ar mixtures was estimated to be $(2 \pm 1)\%$ by monitoring the intensity of the COS absorption in the wavelength region 1730–1785 Å. Similar measurements were not carried out with COS + CO_2 mixtures since CO_2 also absorbs at these wavelengths. The $S(^3P_2)$ decay fitted first order plots, Fig. 2, with first order rate constants of $(1.1 \pm 0.3) \times 10^3$ and $(0.7 \pm 0.3) \times 10^3$ s^{-1} in the presence of CO_2 and of Ar, respectively. First order $S(^3P_1)$ decay plots showed rather more scatter since the microdensitometer peak heights of the $S(^3P_1)$ absorption were a factor of about 4.5 lower than the corresponding $S(^3P_2)$ line, but the first order rate constants obtained were the same as those for the $S(^3P_2)$ decays.

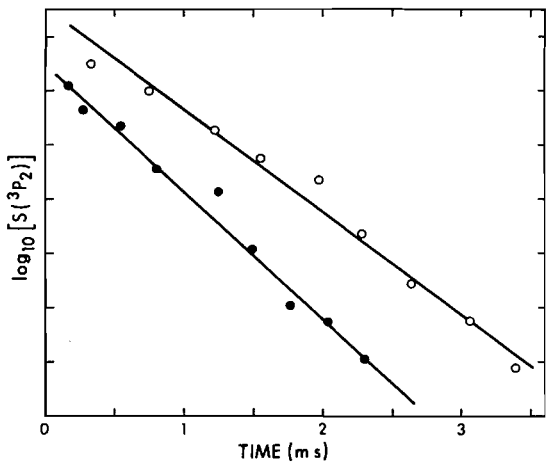

FIG. 2. First order plots of $S(^3P_2)$ decay from flash photolysis of 0.1 Torr COS with: ○, 200 Torr Ar; ●, 200 Torr CO_2. The ordinate axis is marked in intervals of 0.2.

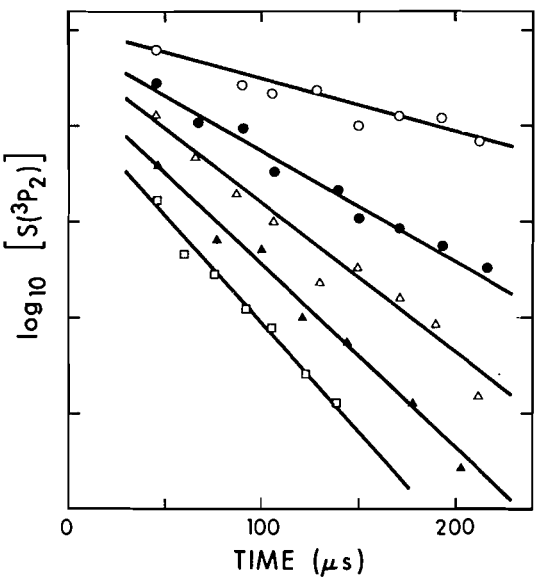

FIG. 3. First order plots of $S(^3P_2)$ decay. $10^9[O_2]$-(mol cm^{-3}): ○, 3.3; ●, 6.7; △, 9.9; ▲, 13.8; □, 15.5. Total pressure = 200 Torr. The ordinate axis is marked in intervals of 0.5.

The addition of 0.06–0.29 Torr of O_2 to COS (0.1 Torr) + CO_2 (200 Torr) mixtures considerably enhanced the rate of removal of atomic sulfur. Typical first order plots obtained for the $S(^3P_2)$ decays are shown in Fig. 3 and the pseudo first order rate constants, k_{uni}, are given in Table 1. Figure 4 shows that k_{uni} is linearly related to the oxygen concentration. A three-fold variation

TABLE 1. Kinetic data for the reaction of $S(^3P)$ with O_2

$10^8[O_2]$ (mol cm^{-3})	$S(^3P)$ species monitored	No. of runs	$10^{-4}k_{uni}$* (s^{-1})
0.33	$^3P_2$	4	0.66
0.33	$^3P_1$	2	0.60
0.67	$^3P_2$	2	1.31
0.69	$^3P_2$	1	1.20[a]
0.99	$^3P_2$	4	1.80
0.99	$^3P_1$	1	1.84
1.11	$^3P_2$	4	2.02[b]
1.38	$^3P_2$	4	2.24[c]
1.38	$^3P_1$	4	2.40[c]
1.55	$^3P_2$	3	2.66

*Listed values of k_{uni} are averages from the number of runs given in column 3. All experiments were carried out with 0.1 Torr COS and 200 Torr CO_2 except: (*a*) 0.05 Torr COS, 70 Torr Ar, 30 Torr CO_2; (*b*) 0.1 Torr COS, 60 Torr CO_2; (*c*) 0.1 Torr COS, 140 Torr Ar, 60 Torr CO_2.

in the flash energy did not affect the value of k_{uni}. The latter was also unaltered when the total pressure was reduced to 60 Torr and when a mixture of CO_2 and Ar in the ratio 1:2.4 was used instead of CO_2 as the thermalizing gas.

The ratio of the microdensitometer peak heights of $S(^3P_2)$ and $S(^3P_1)$ in flashed COS + O_2 + CO_2 mixtures was (4.5 ± 1):1 and was independent of the reaction time. The $S(^3P_1)$ decay was measured in some of the runs and its kinetics were identical with those of the $S(^3P_2)$ decay (*cf.* Table 1 and Fig. 4). The line in Fig. 4 is drawn as the best fit to all the data. Its slope is $(1.7 \pm 0.2) \times 10^{12}$ cm^3 mol^{-1} s^{-1}. Since the oxygen consumed was always less than 5% of the initial $[O_2]$, no correction was made for the concentration change during the reaction.

SO could not be detected under the conditions used for the kinetic runs (0.1 Torr COS). However, when the COS pressure was increased to 0.3 Torr the (14,0), (15,0), (16,0), (17,0), (18,0), (19,0), and (21,0) bands of the $B^3\Sigma^- \leftarrow X^3\Sigma^-$ system of SO were observed weakly in the region 1950–2040 Å. Quantitative measurements of the kinetics of the SO formation were not possible due to the low intensity of the bands, but the rise in the SO concentration appeared to correspond to the decay of atomic sulfur.

A very weak diffuse band centered at 1831.5 Å was observed in flashed COS (0.1 Torr) + O_2 + CO_2 mixtures. Its intensity increased during the period of the atomic sulfur decay. With 0.3 Torr COS additional bands centered at 1838 and 1844 Å were observed. These are the most intense members of a set of six bands which McGarvey and McGrath (3) attributed to an isomeric form of sulfur dioxide. More recently, however, this assignment has been questioned by two independent groups of workers (10, 11) who concordantly suggest that the band system in fact is due to the $D^3\Pi \leftarrow X^3\Sigma^-$ transition of the SO molecule.

Discussion

The absorption spectrum and photodissociation of carbonyl sulfide have been discussed in detail in the literature (12–15). The quartz cell and photo lamp used in the present work limited photolysis to the first absorption band, which lies in the region 1900–2600 Å. The predominant primary process occurring at these wavelengths is

[2*a*] $COS(\tilde{X}^1\Sigma^+) + h\nu \rightarrow CO(X^1\Sigma^+) + S(^1D_2)$

with possibly a small contribution from the spin forbidden process

[2*b*] $COS(\tilde{X}^1\Sigma^+) + h\nu \rightarrow CO(X^1\Sigma^+) + S(^3P_{2,1,0})$

The $^1D_2$ sulfur atoms are removed by reaction with COS and collision-induced relaxation to the ground state (14, 16)

[3*a*] $S(^1D_2) + COS(\tilde{X}^1\Sigma^+) \rightarrow S_2(a^1\Delta_g) + CO(X^1\Sigma^+)$

[3*b*] $S(^1D_2) + COS(\tilde{X}^1\Sigma^+) \rightarrow S(^3P_{2,1,0}) + COS$

[4] $S(^1D_2) + M \rightarrow S(^3P_{2,1,0}) + M$

The half-lives of the decay of $S(^1D_2)$ under our conditions would be ~ 4 μs for reactions 3 with 0.1 Torr COS (16) and ~ 0.1 μs for reaction 4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

with 200 Torr Ar (17). Removal of $S(^1D_2)$ by [4] in the presence of 60 Torr CO_2 would have a half-life of approximately 0.01 μs since the data of Wiebe *et al.* (9) indicate that k_3 and k_4 have comparable magnitudes for $M = CO_2$. Hence with the pressures used in the present work, the $S(^1D_2)$ atoms generated by [2*a*] were almost exclusively quenched to the ground state, and the rate of this quenching was extremely rapid on our time scale. This was also the case in the flash photolysis of the $COS + CO_2 + O_2$ mixtures since the oxygen would remove negligible amounts of $S(^1D_2)$ even if the reaction occurred with unit collision efficiency. The photolysis of COS under our conditions therefore provides a clean source of $S(3^3P_{2,1,0})$ atoms.

The low intensity of the $S(^3P_0)$ line and the constant ratio of the intensities of the $S(^3P_1)$ and $S(^3P_2)$ lines strongly suggest that a Boltzmann distribution was maintained among the three triplet components. An alternative explanation is that the chemical reactivities of the triplet components are equal; provided the $S(^3P)$ decay is first order in [S], the intensities of the multiplets would then represent the relative amounts initially formed by reaction 4. However, in view of Donovan's observation (17) on the rapidity of the thermalization process for sulfur atoms and of the reported high efficiency of spin–orbit relaxation of $Se(4^3P_0)$ (18), a species for which the triplet splitting is much larger than for sulfur, the latter explanation is improbable. Hence, it was not possible in the present work to determine the relative reactivities of the different *J* states of $S(^3P)$, but monitoring the $S(^3P_2)$ line or the $S(^3P_1)$ line yields the total reaction rate of all the *J* states.

Previous studies (19, 20) have shown that $S(^3P)$ atoms generated by the isothermal flash photolysis of COS decay by a recombination process rather than by the abstraction reaction

[5] $S(^3P) + COS(\tilde{X}^1\Sigma^+) \rightarrow S_2(X^3\Sigma_g^-) + CO(X^1\Sigma^+)$

The apparent first order decay of $S(^3P)$ observed in the present work in flashed $COS + CO_2$ and $COS + Ar$ mixtures demonstrates that simple atomic recombination

[6] $S(^3P) + S(^3P) + M \rightarrow S_2 + M$

is not the dominant process removing $S(^3P)$. In order to contribute significantly to the observed rate, this reaction would require an improbably high rate constant of $k_6 \sim 2 \times 10^{17}$ cm^6 mol^{-2} s^{-1}. A mechanism involving strong, irreversible complexing

[7] $S + COS + M \rightarrow COS_2 + M$

with $k_7 = 1.4 \times 10^{16}$ cm^6 mol^{-2} s^{-1} (M = Ar), followed by

[8] $COS_2 + COS_2 \rightarrow 2COS + S_2$

would be consistent with the observed first order decay of S-atoms. However, more work is clearly required on this problem and with the limited data available, further speculation about the mechanism is not justified.

In the presence of molecular oxygen, the pseudo first order rate constant, k_{uni}, for the $S(^3P)$ decay increased linearly with the concentration of O_2 added (Fig. 4). The intercept of the line in Fig. 4 at $[O_2] = 0$ is 1.0×10^3 s^{-1} and is identical within experimental error with the value of $k_{uni} = (1.1 \pm 0.3) \times 10^3$ s^{-1} ($M = CO_2$) determined directly in the absence of oxygen. Therefore, the $S(^3P)$ decay rate due to the oxygen and the decay which occurs in the absence of oxygen are strictly additive with no interaction between the two processes.

According to correlation rules the following reactions are possible within the confines imposed by energy limitations

[1] $S(^3P) + O_2(X^3\Sigma_g^-) \rightarrow SO(X^3\Sigma^-) + O(^3P)$

[9*a*] $\rightarrow SO_2(X^1A_1)$

[9*b*] $\rightarrow SO_2(a^3B_1)$

[9*c*] $\rightarrow SO_2(A^1B_1)$

To date no evidence has been found for the formation of SO_2 and it is doubtful if reactions 9 occur at all. Therefore the most likely structure for the reaction complex is SOO. Correlation rules predict nine states for this molecule: three singlets, three triplets, and three quintets. The latter would probably lie too high to be attainable energetically. This leaves three singlets and three triplets possible, none of which appears to possess a finite lifetime. Decomposition of the complex should preferentially follow the lower energy path SOO → SO + O, according to the sequence

[1] $S(^3P) + O_2(X^3\Sigma_g^-) \rightarrow SOO\dagger(2^1A' + 2^3A'' + {}^1A'' + {}^3A'') \rightarrow SO(X^3\Sigma^-) + O(^3P)$

where the dagger signifies vibrational excitation.

Thus we assign the rate constant, $(1.7 \pm 0.2) \times 10^{12}$ cm^3 mol^{-1} s^{-1}, measured at 298 °K to reaction 1. The possibility of the intervention of other reactions removing S atoms were considered. The combination reactions

[10] $S + SO + M \rightarrow S_2O + M$

[11] $S + O + M \rightarrow SO + M$

[12] $S + SO_2 + M \rightarrow S_2O_2 + M$

were insignificant under our conditions since rate constants of $\sim 10^{19}$ cm^6 mol^{-2} s^{-1} would be required. The bimolecular reactions

[13] $S(^3P) + SO(X^3\Sigma^-) \rightarrow S_2(X^3\Sigma_g^-) + O(^3P)$

[14] $S(^3P) + SO_2 \rightarrow 2SO$

would also require unreasonably large rate coefficients. Additional evidence against the occurrence of these steps is the lack of light intensity dependence of the S atom decay (and the 22 kcal/mol endothermicity of step 13). Although oxygen does absorb light weakly at wavelengths above the quartz cut-off (21), any decomposition products or excited intermediates formed by this photolysis did not remove S(³P) since k_{uni} was independent of the flash energy. Reactions such as

[15] $O + O_2 + M \rightarrow O_3 + M$

[16] $S + O_3 \rightarrow SO + O_2$

or

[17] $O + SO + M \rightarrow SO_2 + M$

[18] $S + SO_2 + M \rightarrow S_2O_2 + M$

could not proceed at a rate sufficient to remove significant amounts of S(³P) atoms.

The rate constant obtained in the present study for the removal of S(³P) atoms by O_2 shows satisfactory agreement with the value of $(1.2 \pm 0.3) \times 10^{12}$ cm^3 mol^{-1} s^{-1} which Fair and Thrush (8) measured by monitoring the formation of the products of reaction 1. The maximum value of the activation energy consistent with these values of the rate constant is 2.8 kcal if the A factor is equal to the gas kinetic collision frequency. Therefore, the high activation energy reported by Homann *et al.* (7) is in error. The overall reaction, step 1, is exothermic by 6 kcal and its activation energy would not be expected to be higher than that of the thermoneutral isotopic exchange reaction (22–24)

[19] $^{18}O(^3P) + {}^{16}O_2 \rightarrow {}^{18}O{}^{16}O + {}^{16}O(^3P)$

which is reported to have $E_a = 1.1$ kcal (22).

Considering the analogous sequence for the reaction of O(³P) atoms with O_2 (25)

$$O + O_2 \underset{}{\overset{a}{\rightleftarrows}} O_3^* \begin{cases} \nearrow O_2 + O \\ \xrightarrow{M} O_3 \end{cases}$$

the calculated value of $k_a = 0.9 \times 10^{12}$ cm^3 mol^{-1} s^{-1} corresponds closely with our results on the S + O_2 reaction. In this case, however, the reaction complex, the excited ozone molecule has a finite lifetime and can be deactivated by collision to the stable ground state.

From the measured rate coefficient, the upper limit for the activation energy of the reverse reaction of [1],

$$SO(X^3\Sigma^-) + O(^3P) \rightarrow O_2(X^3\Sigma_g^-) + S(^3P)$$

may be estimated to be < 9 kcal.

We wish to thank the National Research Council of Canada for continuing financial support and Mr. R. Kadlecz for help in electronics.

Anionic Dimerization in Reductive Cleavage of an Allyl Ether with Sodium–Potassium Alloy

D. H. HUNTER AND D. W. MOORE
Department of Chemistry, University of Western Ontario, London, Ontario

Received September 30, 1970

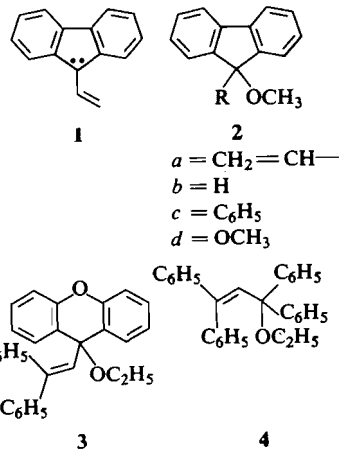
The reaction of 9-methoxy-9-vinylfluorene (**2a**) with sodium–potassium alloy does not yield the expected 9-vinylfluorenylanion (**1**). The anions derived from the reaction were characterized by carbonation and subsequent methylation. Four esters (**5**, **6**, **7**, and **8**) accounting for about two-thirds of the starting material were isolated and characterized. Structures were assigned on the basis of mass spectra and n.m.r. spectra in particular using decoupling experiments. A brief mechanistic scheme is presented.

La réaction du méthoxy-9 vinyl-9 fluoréne (**2a**) avec un alliage sodium–potassium ne conduit pas à l'anion vinyl-9 fluorényle (**1**). On a caractérisé les anions dérivés de cette réaction en effectuant successivement une carbonatation et une méthylation. On a pu isoler et caractériser quatre esters (**5**, **6**, **7** et **8**) qui permettent de tenir compte d'environ les deux tiers du produit de départ. On a attribué des structures à ces composés en se basant principalement sur les spectres de masse et de r.m.n. en faisant appel aux techniques de découplage. On présente un bref mécanisme réactionnel.

Canadian Journal of Chemistry, 49, 1665 (1971)

Introduction

Reductive cleavage of ethers by alkali metals has proved to be one of the more successful routes to organic derivatives of the alkali metals. The presence of a site of unsaturation in the ether, often a phenyl ring, facilitates the reaction and allyl- and benzyl-type carbanides have been prepared most commonly (1–6). In an attempt to prepare and study restricted rotation in the alkali metal derivatives of anion **1**, a sample of 9-methoxy-9-vinylfluorene **2a** was prepared and reacted. Unlike analogous 9-substituted-9-methoxy-fluorenes (**2b** (7), **2c** (8), and **2d** (8)), the expected anion was not observed (**1** in this case). Other analogous ethers which have been reacted successfully to produce their potassium salts are **3** and **4** (9).



1 **2** **3** **4**

Results

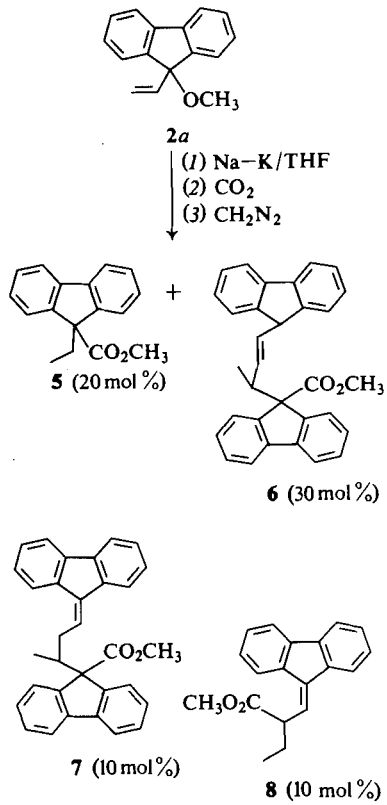
A sample of 9-methoxy-9-vinylfluorene (**2a**) was prepared as described in the Experimental section. A dilute solution (*ca.* 0.1 *M*) of **2a** in freshly distilled tetrahydrofuran was stirred under an argon atmosphere for two days with a slight excess over the stoichiometric amount of sodium–potassium alloy. During the course of the reaction a dissolving deep-red coloration developed on the surface of the alloy and the final solution was deep red. In an attempt to characterize the organometallics present, this solution was passed into a room temperature solution of carbon dioxide in tetrahydrofuran. The acids accounted for 85 wt% of the total isolated materials and no **2a** could be detected in the neutral fraction.

Instead of a mixture of the two acids expected upon carbonation of the desired anion, thin layer chromatography indicated a mixture of at least nine components and n.m.r. suggested that neither of the predicted products was present. This result proved to be reproducible. The acids were converted to their methyl esters on treatment with diazomethane and again both thin layer chromatography and n.m.r. showed about nine components. By a combination of thick layer chromatography and vapor phase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

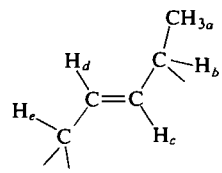
chromatography (v.p.c.), four components of the mixture were isolated and characterized as described in the Experimental section.

Structures **5**, **6**, **7**, and **8** have been assigned

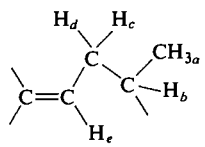


on the basis of their n.m.r. and mass spectra. The structure assigned to **5** has been verified by mixed melting point with an authentic sample.[1] All the esters proved to be crystalline solids except **8** which remained a viscous oil. Both the n.m.r. and analytical results for **8** suggest the presence of a small amount of impurities which, however, do not interfere with the structural assignment.

Integration of the 100 MHz n.m.r. spectrum of **6** (Fig. 1) indicated the presence of two fluorenyl groupings and this was substantiated by the mass spectrum parent peak at $m/e = 442$. A first order analysis of this and the decoupled n.m.r. spectra yielded $\delta a = 0.81$, $\delta b = 3.47$, $\delta c = 5.53$, $\delta d = 5.14$, $\delta e = 4.14$, and $J_{ab} = 6.8$ Hz, $J_{bc} = 8.0$ Hz, $J_{cd} = 15.0$ Hz, $J_{de} = 8.8$ Hz. The structure of the carbon chain was clarified by proton–proton decoupling experiments. The high field methyl doublet (protons *a*) collapsed to a singlet when proton *b* was irradiated. At the same time the low field quartet due to a vinyl proton (*c*) collapsed to a doublet. Irradiation of the doublet at $\delta = 4.14$ (proton *e*) collapsed the upfield vinyl proton (*d*) to a doublet. These results require a carbon chain of the following type. The large coupling ($J_{cd} = 15.0$ Hz) between the vinyl protons is consistent with a *trans* geometry. Introduction of two fluorenyl ring systems and a carbomethoxy group lead to structure **6**.



The n.m.r. spectrum of **7** is shown in Fig. 2 along with the results of integration. The mass spectrum (parent peak at $m/e = 442$) show that **6** and **7** are isomers. The n.m.r. again suggests the presence of two fluorenyl rings and a carbomethoxy grouping. Again homonuclear decoupling experiments proved very useful in the assignment of the structure of the carbon chain. The methyl doublet (protons *a*) collapsed to a singlet when the signal at $\delta = 3.14$ due to a single proton (*b*) was irradiated. Furthermore the multiplet due to two protons (*c* and *d*) at $\delta = 2.4$ simplified to an unsymmetrical triplet. Irradiation at $\delta = 2.4$ caused the triplet due to a single vinyl proton (*e*) to collapse to a singlet. These results are consistent with the following skeleton.



Further decoupling experiments showed that irradiation of the signal due to the vinyl proton *e* changed the character of the multiplet due to protons *c* and *d* so that it appeared as the AB part of an ABX. The multiplet at $\delta = 3.14$ (proton *b*) could be changed to a quartet by irradiation of either protons *a* or protons *c*

[1]The authors wish to thank F. A. L. Anet for providing a sample of 9-ethyl-9-carbomethoxyfluorene for comparison.

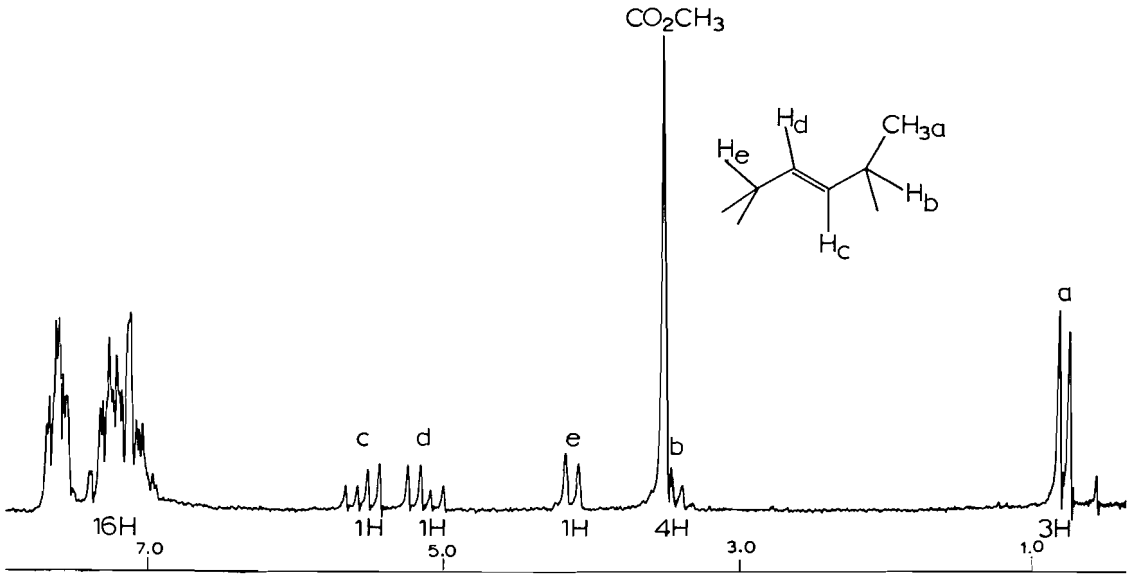


FIG. 1. The 100 MHz n.m.r. spectrum of ester **6**.

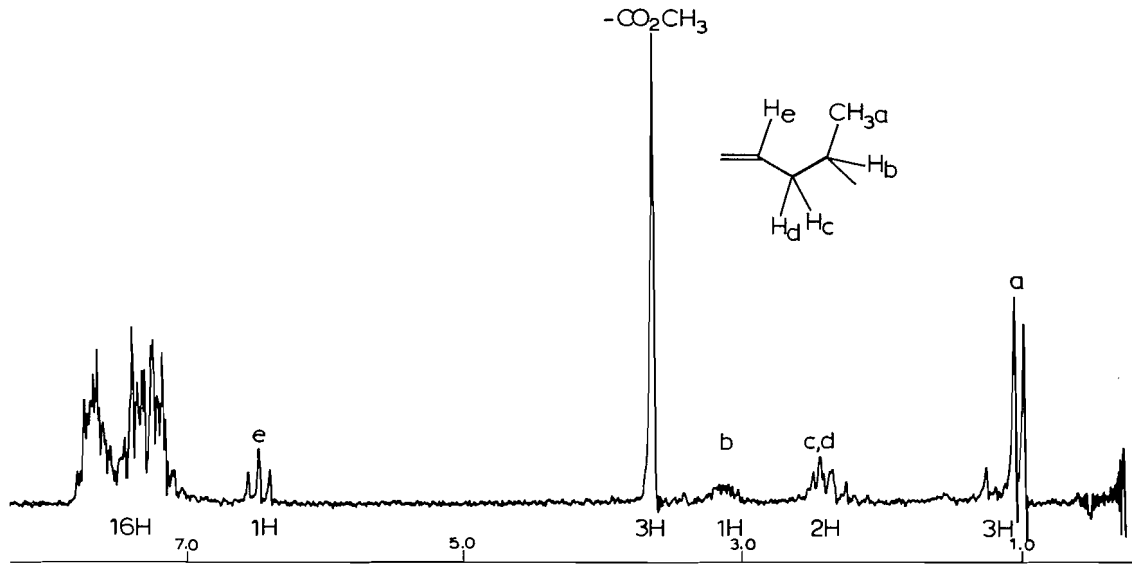

FIG. 2. The 100 MHz n.m.r. spectrum of ester **7**.

and *d*. This latter piece of evidence and the complex pattern due to protons *c* and *d* show that protons *c* and *d* are magnetically nonequivalent due to the asymmetric center. Inclusion of the fluorenyl rings and the carbomethoxy group leads to structure **7**. The signals formed by protons *b*, *c*, and *d* on successive irradiation of protons *a* and *e* were analyzed as an ABC pattern. The following parameters were obtained for the entire system: $\delta_a = 1.02$, $\delta_b = 3.16$, $\delta_c = 2.32$, $\delta_d = 2.50$, $\delta_e = 6.49$ and $J_{ab} = 6.9$, $J_{bc} = 10.3$, $J_{bd} = 4.1$, $J_{cd} = -14.8$, and J_{ce}, $J_{de} = 7.9$.

It can be seen that **6** and **7** are just double bond isomers. An attempt was made to determine which is the thermodynamically more stable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

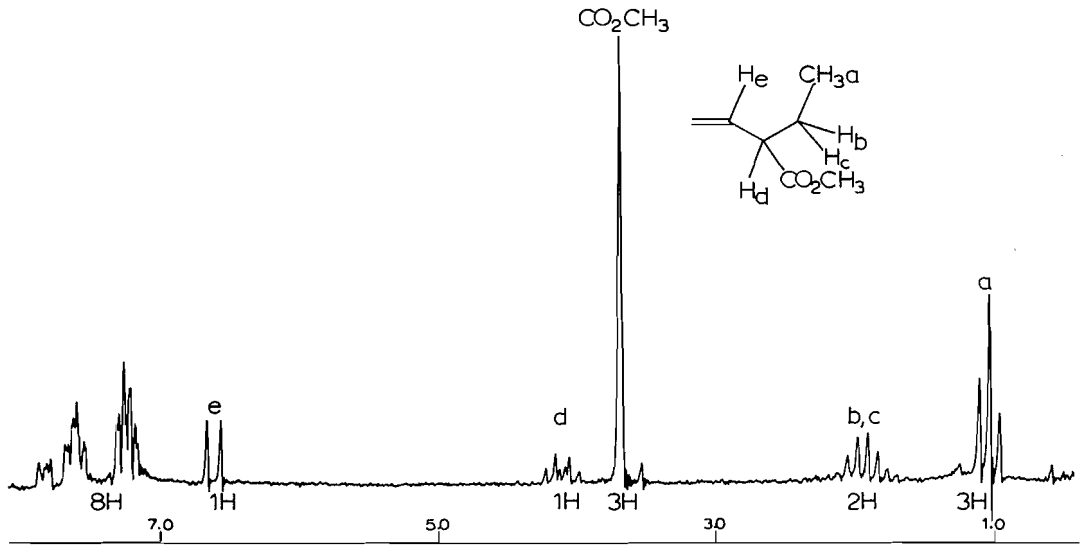

FIG. 3. The 100 MHz n.m.r. spectrum of ester **8**.

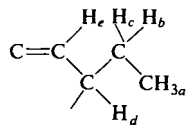
isomer and to provide further evidence on the interrelationship of the structures. Treatment of **6** in methanol with 0.4 *M* potassium methoxide at 60° led to nearly complete conversion of **6** to **7**. Further reaction led to the complete disappearance of **7** and the formation of new and unidentified products. This result requires that the isomer with the conjugated double bond (**7**) is the more stable of the two.

Unlike esters **6** and **7**, the mass spectrum (parent peak at $m/e = 278$) and the integrated n.m.r. spectrum (Fig. 3) of ester **8** are consistent with the presence of just one fluorenyl nucleus and one carbomethoxy group. The structure of the attached carbon chain for this compound also was elucidated with decoupling experiments.

Irradiation in the region of the signals due to the two protons labelled *b*, *c* resulted in the collapse of the perturbed methyl triplet (proton *a*) at high field to a singlet and the collapse of the one proton doublet of triplets (proton *d*) at $\delta = 4.13$ into a doublet. This same multiplet (*d*) at $\delta = 4.13$ changes to a triplet when irradiation is applied to the signal at $\delta = 6.62$ (proton *e*). Conversely irradiation of the signal at 4.13 p.p.m. collapses the doublet at 6.62 (proton *e*) to a singlet and the character of the two proton multiplet (proton *b*, *c*) at 1.96 p.p.m. alters but to more than four lines. The following carbon skeleton is suggested.



From the complexity of both the decoupled and undecoupled signal due to protons *b*, *c* it is apparent that the methylene protons are magnetically nonequivalent. On the basis of a first order analysis, the spectral parameters have been partially assigned: $\delta_a = 1.24$, $\delta_{b,c} \approx 1.96$, $\delta_d = 4.13$, $\delta_e = 6.62$, and $J_{ab} = 7.4$, $J_{bd} = 7.0$, and $J_{ed} = 9.8$ Hz. The structure of ester **8** is completed by attaching the fluorenyl ring and the carbomethoxy grouping.

The separation of these four esters (**5**, **6**, **7**, and **8**) was sufficiently involved that only low yields of purified materials were obtained. The yields of the various esters, indicated under their formulas, were estimated from the n.m.r. spectrum of the original ester mixture and account for about two-thirds of the original material.

Discussion

The unique feature of the reaction of **2a** is the apparent absence of the monomeric anion **1**, as judged by n.m.r. of the anions and of the CO_2 quenched material. Instead, significant amounts of dimeric products were produced. As was mentioned in the Introduction section, reductive cleavage of unsaturated ethers by alkali metals usually succeeds and has been applied fairly widely (1). Reagents commonly

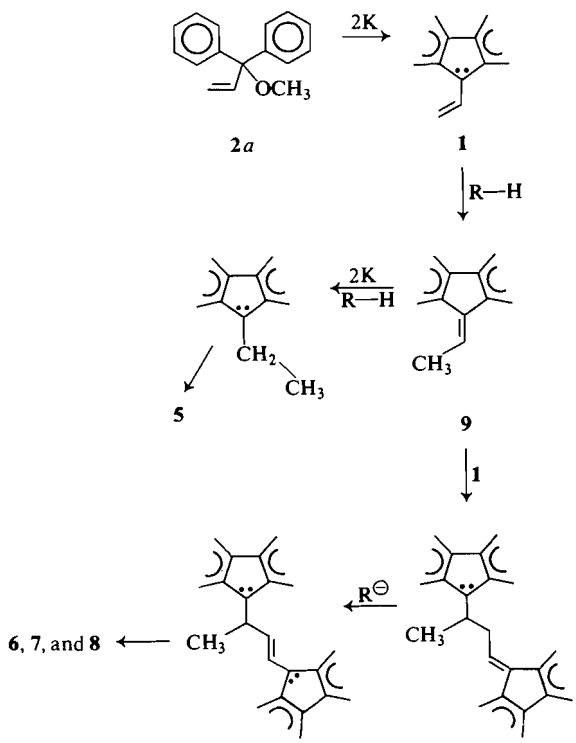
used are potassium, sodium, sodium–potassium alloy, lithium or magnesium in ether, tetrahydrofuran, or hexamethylphosphoramide (2). Thus allylmagnesium phenoxide (3), allyllithium (4), allylsodium (5), and allylpotassium (6) have all been prepared in reasonable yield from allylphenylether or diallylether.

Unlike ethers **2b–d**, **3**, and **4**, ether **2a** produces an anion which reacts further to eventually dimerize. Aside from ester **5**, the other isolated products, **6**, **7**, and **8**, seem to have arisen from an end to middle coupling of the original carbon skeleton. This structural feature can be accommodated if 9-ethylidenefluorene **9** is generated as an intermediate in the reaction (see Scheme 1).



This olefin **9** could arise by protonation of **1** (10) as the monoanion or in a more highly charged form (11–13). Reduction of **9** to the 9-ethylfluorenylanion with eventual production[2] of ester **5** and addition of **1** across the double bond (14) of **9** could follow. The polymerization reaction could terminate at the dimeric stage with formation of the dianion. Ester **8** apparently arises following carbon–carbon bond cleavage (1) of one of the dimeric species. Esters **6** and **7** arise upon carbonation and methylation of the dimeric anions. While a variety of ions and radicals can be involved as intermediates, the present results do not bear on this feature and only a simplified mechanism is included.

Polymerization has been reported for cinnamylethers and 2-phenylallylphenylether during reductive cleavage by alkali metals (2, 3). Unlike **2a**, these ethers could be viewed as substituted styrenes and thus are prone to polymerize in the presence of carbanions (15). Ether **2a** first required a double bond shift and then reaction in a manner similar to the styrenes.

Experimental

Infrared spectra were obtained of carbon tetrachloride solutions with a Beckman IR-10. The n.m.r. spectra (CCl_4 or $CDCl_3$) were run on a Varian HA-100 spectrometer using internal TMS. Mass spectra were obtained using a Varian M-66 mass spectrometer. Melting points and boiling points are uncorrected. Microanalyses were run by A. B. Gygli, Toronto.

The tetrahydrofuran used as solvent was freshly distilled from lithium hydride onto sodium–potassium alloy. The tetrahydrofuran-d_8 (Stohler Isotope Chemicals) was dried with sodium–potassium alloy before use.

9-Methoxy-9-vinylfluorene

Reaction of 90 g (0.5 mol) of 9-fluorenone with a 300 ml tetrahydrofuran solution of vinylmagnesium bromide prepared from 14.6 g (0.6 g-atoms) of magnesium turnings and 70 g (0.65 mol) of vinylbromide yielded 9-vinyl-9-fluorenol. Recrystallization from ether-ligroin gave 121 g (0.45 mol, 90%) of material (m.p. 89–90°, lit. (16) m.p. 91°).

The methyl ether was prepared (17) by stirring a mixture of 50 g (0.25 mol) of 9-vinyl-9-fluorenol, 60 ml (0.96 mol) of methyl iodide, 129 g of barium oxide and 0.8 g of water in 20 ml of dimethylformamide for 40 h at 20 °C. Water–methylene chloride extraction was followed by elution chromatography on alumina using 5% ether in pentane. Recrystallization from 2:1 methanol–water yielded 49 g (88%) of colorless crystals, m.p. 50–51°.

The infrared (i.r.) showed band at 1186 cm^{-1} attributable to the ether C—O stretch. The n.m.r. spectrum in CCl_4 appeared consistent with the expected structure. The aromatic protons appeared as a multiplet δ 7.04 to 7.52 (8H), the methoxy protons appeared as a singlet δ 2.75 (3H) and the vinyl protons (3H) appeared as a multiplet which was analyzed as an ABC pattern with $\delta_A = 5.83$, $\delta_B = 5.42$, $\delta_C = 5.04$, and $J_{AB} = 17.2$ Hz, $J_{BC} = 1.7$ Hz, and $J_{AC} = 10.6$ Hz.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.45; H, 6.34. Found: C, 86.34; H, 6.41.

Reaction of 9-Methoxy-9-vinylfluorene

Sodium–potassium alloy (5.7 wt% sodium; 6 ml, 108 mmol) was added to a solution of 9-methoxy-9-

[2]Treatment of a sample of **9** with sodium–potassium alloy under the reaction conditions followed by carbonation and methylation produced **5** in about 15% yield.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

vinylfluorene (12 g, 54 mmol) in 450 ml of tetrahydrofuran. The tetrahydrofuran solution was degassed and the atmosphere exchanged for argon before addition of the alloy. The solution was stirred at room temperature for 48 h and acquired a deep red color.

The anions were carbonated by slow addition of the deep red solution to 100 ml of tetrahydrofuran saturated with dried carbon dioxide. The reaction mixture was stirred at room temperature and carbon dioxide was constantly bubbled into the solvent. The resulting pale green solution was stirred for another hour and the majority of the tetrahydrofuran removed with a rotary evaporator.

The reaction products were extracted with dilute sodium hydroxide – ether. The aqueous layer was acidified and extracted with ether to yield 10.2 g (85 wt%) of acids, and neutrals amounting to 1.2 g were obtained.

Thin layer chromatography of the neutral fraction indicated the absence of 9-methoxy-9-vinylfluorene while t.l.c. of the acid fraction using 3% acetic acid in chloroform on silica gel suggested at least 9 components.

The mixture of acids was methylated using both diazomethane and boron trifluoride etherate-methanol. The ester mixture prepared by either route appeared to be of the same composition as judged by t.l.c. on silica gel using 30% ether-pentane and contained about nine components. The conversion of acids to esters appeared to be complete on the basis of weight (103 wt.% yield) and n.m.r.

Separation of the Esters

A gross separation of the ester mixtures from the diazomethane reactions was obtained with elution column chromatography. The esters were chromatographed on silica gel eluting with 30% ether in pentane. Two major components, labelled esters **6** and 7, were collected in a purified state. Further purification with thick layer chromatography, eluting three times with 10% ether–pentane yielded nearly pure samples of both esters. Each ester was then recrystallized from methanol to yield sharp melting colorless crystals.

Ester **6**: m.p. 118–119°. The i.r. peak due to the ester carbonyl appeared at 1730 cm^{-1}.

Anal. Calcd. for $C_{32}H_{26}O_2$: C, 86.86; H, 5.93. Found: C, 86.76; H. 5.92.

Ester 7: m.p. 162–163°. The i.r. carbonyl peak appeared at 1730 cm^{-1}.

Anal. Calcd. for $C_{32}H_{26}O_2$: C, 86.86; H, 5.93. Found: C, 86.61; H, 5.90.

The less pure fractions containing ester **6** from the column chromatography showed three carbomethoxy signals in the n.m.r. spectrum. The remaining ester **6** was removed from this material by thick layer chromatography eluting three times with 10% ether–pentane. The remaining band was extracted and n.m.r. indicated a mixture of two esters. These were separated and collected using g.l.p.c. ($\frac{1}{4}$ in. × 6 ft column of 10% SE-30 on 45-60 Chromosorb W) with a column temperature of 220 °C.

The two components were labelled esters **5** and **8**. Ester **8** was a liquid which was distilled using a molecular still (b.p. 60–63° @ 0.05 mm of Hg). The i.r. showed an ester carbonyl at 1727 cm^{-1}.

Anal. Calcd. for $C_{19}H_{18}O_2$: C, 81.98; H, 6.52. Found: C, 80.42; H, 6.73.

Ester **5** was a solid which was sublimed under vacuum to yield material of m.p. 77–78°. Admixture with an authentic sample **1** of the methyl ester of fluorene-9-ethyl-9-carboxylic acid gave m.p. 77–78°.

A comparison of the n.m.r. spectra of the separated esters **5** and **8** with the mixture before g.l.p.c. indicated that no chemical changes had occurred during the separation.

The Effect of Trace Impurities on Condensed Electrode and Microwave Discharges through Nitrogen

R. R. BAKER, A. JACOB,[1] AND C. A. WINKLER
Department of Chemistry, McGill University, Montreal, Quebec

Received November 26, 1970

Traces of various gases have been added to a stream of purified nitrogen gas prior to entering either a microwave or a condensed electrode discharge, and the effect of the presence of these gases on the steady flow rate of nitrogen atoms obtained from the discharge has been measured. Suggestions for the effect of the impurity gases on the possible reactions occurring in the discharge have been put forward. It seems probable that an important feature of the presence of the impurities may be their effect on the electron temperature in the discharge.

A un jet d'azote purifié qui est ensuite soumis à une décharge soit de micro-ondes ou soit d'électrode condensé, on ajoute des traces de divers gaz et l'on mesure leur effet sur le débit constant des atomes d'azote qui sont obtenus. On propose des suggestions concernant les effets possibles de ces impuretés sur les réactions se produisant au cours de la décharge électrique. Il semble probable qu'une caractéristique importante de la présence de ces impuretés soit leur effet sur la température des électrons dans la décharge.

Canadian Journal of Chemistry, 49, 1671 (1971)

Introduction

It has been known for many years that very small amounts of certain impurities increase the extent of dissociation of diatomic molecules (H_2, O_2, N_2) in electrical discharges. Although one report indicated that the yellow afterglow in pure nitrogen which has been activated by an electrical discharge was not produced in the presence of a trace of hydrogen (1), there seems little doubt that the afterglow is more intense when traces of gaseous "dissociation catalysts" such as H_2, O_2, or H_2O have been added to the nitrogen before or after the discharge tube (2–4). As a result of previous investigations on the subject, it has been suggested (ref. 5, pp. 25–27, ref. 6) that the effect of the impurities is to increase the afterglow mainly by inhibiting the wall destruction of a precursor to the afterglow, probably by their adsorption onto the wall of the discharge tube and reaction vessel, with reduction in the heterogeneous recombination of N atoms (7).

The present report records some related observations on the effect of catalysts on the behavior of continuous and discontinuous discharges through nitrogen. The corresponding results were reproducibly observed over a period of months on more than one apparatus, and it is believed that such studies should help to define operating conditions most conducive to meaningful data.

[1]Present address: Trapelo Division of L.F.E. Corporation, 1601, Trapelo Road, Waltham, Mass., 02154.

Experimental

The systems were of the fast flow type, similar to those described in earlier studies (*e.g.* refs. 8, 9). Linde "Bone Dry" nitrogen was purified by passing it over copper turnings at 500 °C and copper oxide at 750 °C to remove oxygen, and hydrogen and hydrocarbon impurities respectively, and finally through two traps surrounded by liquid nitrogen, to remove condensible impurities. The purified nitrogen stream either entered the discharge tube directly, or was premixed with measured traces of catalyst gases before entering the discharge tube. The condensed electrode discharge occurred between aluminum electrodes in a tube of new design, shown in Fig. 1. When glass wool was introduced into the "U" bends, and these were immersed in cooling water, no aluminum dust accumulated in any part of the reactor or product traps, even after prolonged operation of the discharge unit. The pulse rate in the systems used could be varied from a distinctly discontinuous discharge to a virtually continuous one by changing the time constant of the electric circuit for a constant input voltage at a given pressure. The microwave discharges occurred in vycor tubing using a Raytheon diathermy unit of 125 W power output at 2450 Mcs^{-1} continuous wave radiation.

The reaction vessels used were straight Pyrex tubes, about 70 cm long and having internal diameters in the range 2.0 to 2.6 cm. The average nitrogen atom flow rates at points 12 to 16 cm downstream from the discharge tube were determined with the NO gas-phase titration (10).

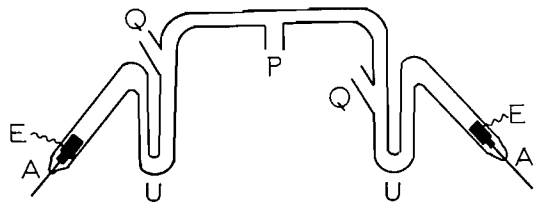

FIG. 1. Diagram of modified discharge tube. A, tungsten-to-glass seal; E, aluminum electrode; P, inlet to reaction vessel; Q, feed lines; U, bends packed with glass wool and cooled in water.

Results

With a flow of pure nitrogen and a distinctly discontinuous condensed discharge, at total pressures of 2.0 to 3.5 Torr, the NO titration (*i.e.* the N atom flow rate) continued to decrease for as long as 2.5 h before it became constant at about one half its initial value. On the other hand, with a microwave discharge and a flow of pure nitrogen, a constant value for the N atom flow rate was reached in only about 10 min.

In the presence of trace amounts of catalysts, constant levels of atomic nitrogen were usually attained much more quickly than in the absence of a catalyst. For instance, with H_2O vapor as catalyst at flow rates of 0.1×10^{-6} and 5×10^{-6} mol s^{-1} in a discontinuous condensed discharge, the N atom flow rate reached a steady value within 30 min of operation at about 10 and 18 times, respectively, the level without catalyst present. However, when the H_2O flow rate was changed from the higher to the lower value without interrupting the discharge, the decrease in N atom flow rate from one level to the other required up to 3 h of operation.

Similar results were obtained using other catalysts. When the pulse rate was increased until the condensed discharge operated almost continuously ("pseudo-continuous"), steady N atom flows were usually obtained in 5–15 min. When the catalyst flow was stopped in either the discontinuous or pseudo-continuous discharges, it required several hours for the N atom flow to decrease to the steady value in the absence of catalyst. However, when I_2 was used as catalyst, it required only 15 min for the N atom flow to decrease to the steady uncatalyzed value, after the I_2 flow was stopped (11). With a microwave discharge, on the other hand, a steady N atom flow was reached after only 10 to 15 min operation of the discharge in the presence of the various catalysts. When the flow of the catalyst was stopped, the steady condition corresponding to its absence was restored in about the same short time of operation, except with catalysts containing F atoms, when about 1 h of operation was required. This could be due to the strong adsorption onto the walls of the discharge tube and reaction vessel of species derived from the F-containing compounds, probably F atoms.

Some typical plots of N atom flow against the flow of the added catalyst are shown in Figs. 2 and 3 for the microwave and continuous condensed electrode discharge units, respectively. In all cases, the points on the plots are the steady values of the N atom flow rate for the corresponding flow of the catalyst. The temperature and total pressure in the reaction vessel, and the flow of molecular nitrogen through the reaction vessel, were kept constant at the values given in Table 1 for all the catalysts used. These data show an initial linear dependence of N atom flow rate on the flow rate of the catalyst, and in all cases, either a plateau value of N atom flow is reached with a sufficiently high catalyst flow rate, or the gradient falls towards a plateau value (zero gradient) at high catalyst flow rates. The plateau values appear to be reached either sharply, as with H_2S and CH_3Cl, for example (Fig. 2), or gradually, as with C_2H_2 (Fig. 2). The effects of the various catalysts are summarized in Table 1. In the table, $(\Delta[N]/\Delta[M])_i$ is the initial gradient of the plot of N atom flow rate against catalyst flow rate, for a given catalyst M, $N_{plateau}$ is the value of the N atom flow rate at the plateau in the curve, and $M_{plateau}$ is the minimum flow rate of the catalyst that gives the plateau value of the N atom flow. The latter quantity is obtained for a given catalyst from a plot of the gradient of the catalyst curve (Figs. 2 and 3), $\Delta[N]/\Delta[M]$, against the flow rate of the catalyst. $M_{plateau}$ is then the value of the intercept where the plot cuts the catalyst flow rate axis. The approximation signs ($\sim$) in Table 1 indicate that $N_{plateau}$ or $M_{plateau}$ for that particular catalyst has been obtained by extrapolation. Table 1 shows that, with the exceptions of Ar, He, and SF_6, the value of $(\Delta[N]/\Delta[M])_i$ for a given catalyst is much smaller in the microwave discharge than in the condensed discharge, the value in the microwave discharge being about 30% that in the condensed discharge, on average. To a first approximation, the value of $(\Delta[N]/$

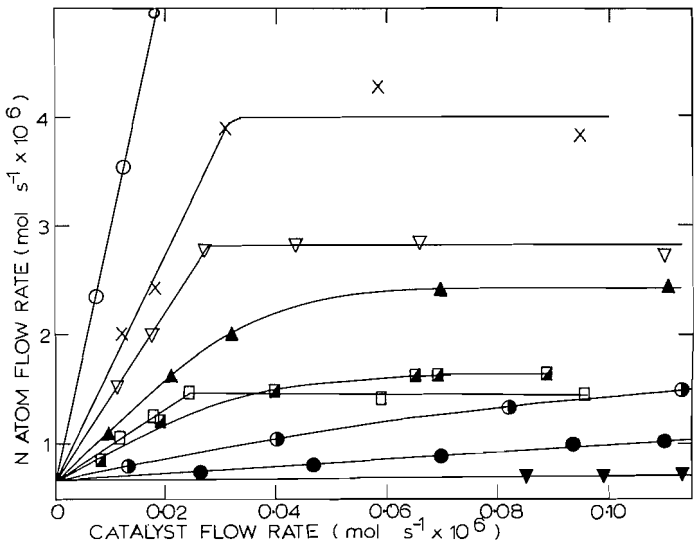

FIG. 2. Effect of different catalysts in the microwave discharge. ○ = CF_4, × = CH_3F, ▽ = H_2S, ▲ = C_2H_2, □ = CH_3Cl, ◪ = HBr, ◑ = NH_3, ● = N_2O, ▼ = He.

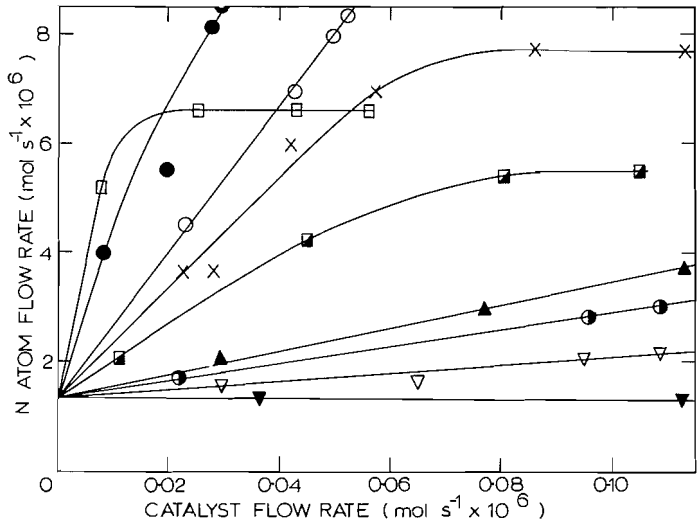

FIG. 3. Effect of different catalysts in the condensed electrode discharge. □ = CF_4, ● = CH_3Cl, ○ = SF_6, × = CH_4, ◪ = HCl, ▲ = CO_2, ◑ = H_2, ▽ = O_2, ▼ = Ar.

$\Delta[M])_i$ in either discharge depends on the electronegativity of the molecule, and the number of degrees of freedom in the molecule. Thus large, electronegative molecules such as SF_6, CF_4, and CCl_3F give large values of $(\Delta[N]/\Delta[M])_i$, while smaller and more electroneutral molecules such as O_2, CO, and NO have small values. For molecules with the same number of degrees of freedom, such as CH_4, CH_3Cl, CCl_4, CH_3F, CCl_3F, and CF_4, the value of $(\Delta[N]/\Delta[M])_i$ increases with the overall electronegativity of the molecule. The inert gases Ar and He are virtually without any catalytic effect.

The effect of using O_2, NO, and SF_6 as catalysts has also been investigated by Young, Sharpless, and Springham (12), who used a microwave discharge and measured the concentration of N atoms produced in an electron spin resonance

SF_6	240	230

*Young *et al.* (12) used a N_2 flow of 872×10^{-6} mol s^{-1}, and the N flow in the absence of catalyst was about 0.1×10^{-6} mol s^{-1}.

(e.s.r.) cavity well removed from the discharge. Their results are compared to those of the present investigation with a microwave discharge in Table 2. The results with NO and SF_6 are very similar, indicating that the effect of these catalysts is very reproducible, but the results with O_2 differ for some yet inexplicable reason.

It was also observed in the present study that the short-lived, energetic pink afterglow observed downstream from the microwave discharge was increased from a distance corresponding to a flow time of 5 ms in the absence of a catalyst to distances corresponding to about 30, 40, and 70 ms in the presence of H_2S, SF_6, and CF_4, respectively. With the other catalysts, the pink afterglow was reduced, usually to zero seconds.

Discussion

When the flow of catalyst is stopped in the microwave discharge, the steady N atom flow rate reverts back to the uncatalyzed condition in a few minutes (1 h for compounds containing F atoms), whereas several hours are usually required to produce the same effect in a condensed discharge. This suggests that the effect of the catalyst is unlikely to be due solely to heterogeneous reactions (*cf.* ref. 7). It appears that traces of catalyst are involved in some way in the dissociation process to increase the yield of N atoms. This is indicated also by the observation that a condensed discharge could be initiated and sustained at a lower voltage in the presence of traces of catalyst than in a system containing pure N_2.

The main problem in interpreting the effect of catalysts on the steady concentration of N atoms is that the fundamental processes occurring in the discharge are not known. Young and

St. John have shown that under appropriate conditions electrical discharges both produce and destroy N atoms (13). Their results (14) indicate that, in the discharge, the dissociation of pure N_2 results from stepwise excitation involving intermediate excited states susceptible to deactivation. The suggested mechanism below gives various possible reactions that may contribute to the final concentration of N atoms.

[1] $e_{fast} + N_2 \rightarrow N_2^* + e_{slow}$

[2] $e_{slow} + N_2^* \rightarrow N_2 + e_{fast}$

[3] $N_2^* \rightarrow$ (N atoms)

[4] $N + N_2^* \rightarrow N_2 + N$

[5] $e + N_2^* \rightarrow N_2^+ + 2e$

[6] $e + N_2 \rightarrow N_2^+ + 2e$

[7] $N_2 + N_2 + N_2^+ \rightleftarrows N_4^+ + N_2$

[8] $N + N_4^+ \rightarrow N_3^+ + N_2$

[9] $N + N_3^+ \rightarrow N_2^+ + N_2$

Reaction 3 represents some unspecified reaction of N_2^* that gives N atoms, possibly reaction with an electron, $e + N_2^* \rightarrow 2N + e$. The radiative lifetime of N_2^* must be sufficient, of course, so that reaction 3 is reasonably probable before radiation to a lower level occurs, and metastable species such as $N_2(A^3\Sigma_u^+)$ might be particularly effective. In reaction 1, e_{fast} represents an electron with sufficient energy to produce metastable N_2^* molecules from molecules in the $X^1\Sigma_g^+$ state. The deactivation of N_2^* by N atoms in reaction 4 has been postulated previously (15, 16), in this case with N_2^* identified as $N_2(A^3\Sigma_u^+)$.

Since N_2^* is probably a metastable species, the cross section for reaction 1 will be a maximum for some specific electron energy, and the production of N_2^* will be most efficient over a relatively narrow range of electron energy (ref. 17, pp. 196–228). By the principle of detailed balancing (ref. 17, pp. 57–58, ref. 18) the deactivation of N_2^* by electron attachment (reaction 2) peaks near 0 eV (18). Thus reactions 1 and 2, which both govern the concentration of N_2^* and hence N atoms, will be very sensitive to the electron temperature in the discharge.

The presence of small amounts of impurities is known to affect the electron temperature in electrical discharges (19, 20), with polyatomic molecules causing large decreases in the electron temperature, and the inert gases having a small effect. The degree of effect on the electron temperature is very approximately similar to the degree of effect which impurities have on the steady state concentration of N atoms (Table 1). While this correlation should not be unduly emphasized, perhaps, it does suggest the possibility that added impurities in the present systems might exert their effects primarily through an influence on the electron energy in the discharge. Four possible effects that traces of impurities can have on reactions 1–9 are given below.

(*1*) Polyatomic molecules, with many degrees of freedom, can undergo a wide variety of low energy (< 1 eV), inelastic collisions with very energetic electrons. These collisions may lead to electrons with energy in the range where reaction 1, and hence the production of N atoms by reaction 3, is most efficient.

(*2*) Low energy electrons may be removed from the system by forming negative ions with electronegative catalysts, thus lowering the possibility of reaction 2. This should promote an increase in the steady concentration of N_2^* in the system, and hence in the production of N atoms by reaction 3. SF_6, in particular, can readily form SF_6^- by a highly resonant process in which an electron of energy 0 ± 0.05 eV can be attached without radiation, the process having the very high attachment cross section of at least 10^{-15} cm^2 (ref. 17, pp. 285–286; ref. 20, pp. 417–419). Dissociative attachment to form SF_5^- is also possible (21) with the process peaking around 0.1 eV.

(*3*) N atom consumption by reactions 8 and 9 will be minimized if the nitrogen ionic species are removed by the following types of charge transfer reactions with the impurity, M (13),

[10] $N_2^+ + M \rightarrow N_2 + M^+$ (or $m_1 + m_2^+$)

[11] $N_4^+ + M \rightarrow 2N_2 + M^+$ (or $m_1 + m_2^+$)

where m_1 and m_2 are decomposition products of M. These types of reactions explain the supression of the first negative bands of N_2^+ ($B^2\Sigma_u^+ \rightarrow X^2\Sigma_g^+$) in the pink afterglow in the presence of traces of H_2, O_2, and C-containing compounds (ref. 5, pp. 48–50, ref. 22). However, they cannot explain the catalytic effects of H_2, CF_4, and SF_6 since the ionization and appearance potentials for these gases are larger than for N_2 (23). Furthermore, they cannot be important catalytic reactions for the other gases, since there is no apparent correlation between the observed value

of $(\Delta[N]/\Delta[M])_i$ for a catalyst, and its ionization or appearance potential.

(*4*) A reduction in the breakdown potential in the presence of a catalyst might be due to a sequence of reactions, such as

[12] $$N_2^* + M \rightarrow m_1 + m_2 + N_2$$

[13] $$e + m_1 \text{ (or } m_2) \rightarrow m_1^+ \text{ (or } m_2^+) + 2e$$

where m_1 and m_2 possess ionization potentials lower than that of N_2. By such a process, the same extent of positive ion formation (m_1^+ or m_2^+) might be maintained by electrons that have enough energy to create metastable N_2 (by reaction 1) but not N_2^+. In this way, one molecule of M introduces more than one extra electron into the system, which, if they have the correct energy, could then produce more than one N_2^* by reaction 1.

The much smaller effect which catalysts usually have on the N atom yield in a microwave discharge than in a condensed electrode discharge (Table 1) might then simply reflect a lower concentration of excited molecular nitrogen species in the microwave discharge. This would be in accord with the observations that active nitrogen from a condensed discharge is capable of promoting chemical changes that do not seem to occur significantly with active nitrogen from a microwave system, *e.g.* the decomposition of NH_3 and SO_2 (ref. 5, pp. 505–511, refs. 6, 24). Presumably, the condensed discharge produces a higher concentration of excited molecular species capable of initiating such reactions.

Thus, the possible ways in which a particular catalyst may influence the steady concentration of N atoms are varied and complex, and probably more complex than is indicated above. However, they provide a ready interpretation, for example, of the observation that He and Ar have virtually no catalytic effect on the production of N atoms. Since these gases have no vibrational and rotational degrees of freedom, the first possible effect enumerated above cannot operate; formation of negative ions as required by *2* is unlikely; their high ionization potentials make *3* energetically improbable; and *4* cannot occur for monatomic species. On the other hand, electronegative polyatomic molecules, such as SF_6, have large catalytic effects since the first two possibilities above are readily available. However, it is not possible as yet to resolve the varied and complex ways in which a given impurity may exert its catalytic effect from its possible inhibition of N-atom recombination (homogeneously or heterogeneously), and the final yield of N atoms may be strongly affected by both.

The authors would like to thank Dr. J. S. Bulger for helpful discussion.

Radiolysis of Hydrogen Sulfide at Very High Dose Rates. The Effect of SF_6[1]

C. WILLIS, A. W. BOYD, AND O. A. MILLER

Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received November 26, 1970

Gaseous H_2S has been irradiated with electron pulses from a Febetron 705 at a dose rate of $\sim 2 \times 10^{27}$ eV g^{-1} s^{-1}. For single pulse experiments, the yield of hydrogen is $G(H_2) = 12.0 \pm 0.5$, independent of pressure from at least 350 to 1600 Torr. Addition of SF_6 reduces the yield to $G(H_2) = 7.9 \pm 0.3$ which is fairly close to that observed for pure H_2S at low dose rates. The reduction, $\Delta G(H_2) = 4.1 \pm 0.3$, agrees very well with the ion pair yield based on a W value of 25.3 eV.

In multi-pulse irradiations, for pure H_2S, the yield falls off with dose giving a limiting yield close to $G(H_2) = 8.0$. No similar fall-off is observed for H_2S–SF_6 mixtures. It is proposed that at high absorbed doses and at low dose rates, there is no contribution to the hydrogen yield from neutralization processes; and that this is due to neutralization of H_3S^+ by an ion of the type S_n^- rather than a free electron.

L'hydrogène sulfuré a été irradié en phase gazeuse par pulsations électroniques au moyen d'un Febetron 705 à une dose de 2×10^{27} eV g^{-1} s^{-1}. A pulsation unique, le rendement en hydrogène est $G(H_2) = 12.0 \pm 0.5$, et ne dépend pas de la pression entre 350 et 1600 Torr. L'addition de SF_6 réduit le rendement à $G(H_2) = 7.9 \pm 0.3$, ce qui est très proche du rendement observé pour H_2S pur, irradié à faibles intensités. Cette diminution de $\Delta G(H_2) = 4.1 \pm 0.3$ est en excellent accord avec le rendement en paires d'ions basé sur une valeur de $W = 25.3$ eV.

Pour des irradiations à pulsations multiples de H_2S pur le rendement décroît avec la dose jusqu'à une valeur limite proche de $G(H_2) = 8.0$. Pour des mélanges H_2S–SF_6, une telle décroissance n'est pas observée. Il est suggéré que des processus de neutralisation ne contribuent pas au rendement en hydrogène pour l'absorption de fortes doses, ou à faibles intensités à un taux de doses faibles; ceci pouvant être attribué à la neutralisation de H_3S^+ par un ion du type S_n^- plutôt que par un électron libre.

Canadian Journal of Chemistry, **49**, 1677 (1971)

Introduction

The γ-radiolysis of H_2S has been the subject of several recent papers. Meissner and Henglein (1) γ-irradiated solid, liquid, and gaseous H_2S and report $G(H_2) = 9.3$ at 1 atm and that N_2O had little or no effect on this H_2 yield. Perner and Franken (2) in a pulse radiolysis study of gaseous H_2S, devoted mainly to the formation and reactions of SH radicals, reported $G(H_2) = 11.5 \pm 0.7$[2] at high dose rates. They also reported that this yield is reduced by the addition of SF_6, although they did not state by how much. Huyton and Woodward (7, 8) γ-irradiated gaseous H_2S and measured the dose by ion chamber measurements. They report $G(H_2) = 7.0 \pm 0.2$ at 800 Torr and that neither N_2O nor SF_6 has any effect on this yield (7).

The α-radiolysis of gaseous H_2S also has been studied recently by Forys and Jezierska (9) and by Torrey (10). The former (9) obtained $G(H_2) = 7.9$ based on a series of dosimeter systems and the latter (10) obtained a hydrogen yield of $M/N = 1.82$ molecules per ion pair relative to $W_{H_2S} = 23.4$ eV per ion pair giving $G(H_2) = 7.8$. As with the γ-radiolysis, both refs. 9 and 10 report no effect of electron scavengers on the hydrogen yield.

The difference between the hydrogen yields of Meissner and Henglein and of Huyton and Woodward may be due to dosimetry as the former give no details of their dose measurements. The difference between the yields and the effect of electron scavengers at high and low dose rates is more fundamental.

Perner and Franken propose the following mechanism for the primary processes and subsequent neutral reactions in irradiated H_2S.

[1] Primary processes: $H_2S \rightsquigarrow H + SH$

[2] Primary processes: $H_2S \rightsquigarrow H_2 + S$

[1] AECL No. 3848.

[2] These authors used a Febetron 706 pulsed electron accelerator and we can assume a dose rate of $\sim 10^{25}$–10^{27} eV g^{-1} s^{-1}. Perner and Franken reported $G(H_2) = 8.8$ based on N_2O dosimetry assuming $G(N_2) = 10$. As we have pointed out (3–6), at these dose rates $G(N_2) = 12.4$ and the yields of Perner and Franken have been corrected using this value. These authors also used a stopping power for H_2S relative to air which is 6% too high.

[5] $H + H_2S \rightarrow H_2 + SH$

[6] $SH + SH \rightarrow H_2S_2^*$

[7] $S' + H_2S \rightarrow H_2S_2^*$

[8] $H_2S_2^* + M \rightarrow H_2S_2$

[9] $H_2S_2^* \rightarrow H_2 + S_2$

As Perner and Franken point out there is some uncertainty as to the importance of reactions 7 to 9. However, because of the large rate constant for reaction 5, $k_5 = 7 \pm 2 \times 10^8\ M^{-1}\ s^{-1}$,[3] and the inherent high concentration of H_2S it can be assumed that all H atoms formed in the system, even at dose rates as high as 10^{28} eV $g^{-1}\ s^{-1}$, will react to form hydrogen. The reaction of H atoms with SH radicals, [10],

[10] $H + SH + M \rightarrow H_2S + M$

would have to have the improbably high rate constant of k_{10} [M] $= 5 \times 10^{10}\ M^{-1}\ s^{-1}$ at 1000 Torr to compete measurably with [5] at 10^{28} eV $g^{-1}\ s^{-1}$.

It appears then that the effect of dose rate on the H_2 yield is due to a change in the ionic reactions and this is supported by the change in behavior with electron scavengers. Huyton and Woodward (7) suggested from their low dose rate work that the neutralization process in H_2S–SF_6 mixtures is [11]

[11] $H_3S^+ + SF_6^- \rightarrow H + H_2S + SF_6$

giving the same H atom yield as in pure H_2S where they suggested the neutralization process is [12]

[12] $H_3S^+ + X^- \rightarrow H + H_2S + X$

where X^- may be H_2S^- or some other negative species. Clearly, reaction 11 contradicts the earlier observation of Perner and Franken that at high dose rates SF_6 does reduce the hydrogen yield.

Because of this contradiction, we have irradiated H_2S at dose rates similar to those of Perner and Franken and have measured quantitatively the effect of SF_6 and of dose. We have also examined the ionic processes grouped in reaction 4.

[3]Perner and Franken (2) report $k_5 = 7.7 \pm 1.5 \times 10^8\ M^{-1}\ s^{-1}$ giving D. Mihelcic and R. N. Schindler's (private communication) value of $k_5 = 8.3 \pm 0.4 \times 10^8\ M^{-1}\ s^{-1}$ as supporting evidence. Dzantiev and Shiskov (11) report $k_5 = k_{H+C_2H_4}$ and a recent reliable value for this reaction at high pressures is $k_H + C_2H_4 = 5.5 \pm 0.5 \times 10^8\ M^{-1}\ s^{-1}$ (12).

Experimental

Radiation Source and Dosimetry

The accelerator used in the present experiments was a Febetron 705. This is a high intensity, pulsed electron accelerator and we have described previously its use in high dose rate studies (13–15). The gas samples were irradiated in quartz cells (13) fitted with Teflon O ring type stopcocks (Ace Glass Company Inc.).

The mean absorbed dose in the cell, measured using nitrous oxide dosimetry with $G(N_2) = 12.4$ (3–6), was 1×10^{20} eV g^{-1} per pulse. The mean dose rate was $\sim 2 \times 10^{27}$ eV $g^{-1}\ s^{-1}$. The stopping power correction in going from N_2O to H_2S is 1.006 g^{-1} (16).

Materials and Analyses

The H_2S and SF_6, Matheson C. P. grade, were used without further purification other than the elimination of impurities non-condensible at 77 °K by several freeze–pump–thaw cycles. The volume of gas non-condensible at 77 °K produced by the radiolysis was measured with a McLeod gauge and its composition determined by mass spectrometry.

Results

The hydrogen yield from single pulse irradiations of H_2S at different pressures is shown in Fig. 1. The yield of hydrogen is independent of pressure over the range shown at $G(H_2) = 12.0 \pm 0.5$.

Figure 2 shows the effect of SF_6 at 350 and 1000 Torr H_2S. The yields are not corrected for the slight increase in dose due to the SF_6 addition. Although there is a more rapid initial decrease in $G(H_2)$ at the higher pressure both give the same limiting yield of $G(H_2) = 7.9 \pm 0.3$, giving a reduction in yield of $\Delta G(H_2) = 4.1 \pm 0.3$.

The amounts of hydrogen formed in multipulse irradiations for pure H_2S are shown in Fig. 3*A* for 350 and 1000 Torr. There is marked

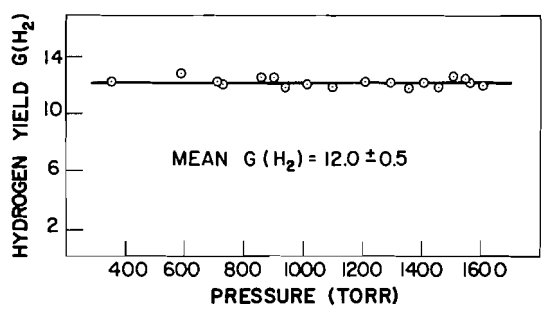

FIG. 1. Hydrogen yields from radiolysis of H_2S at a dose rate of $\sim 2 \times 10^{27}$ eV $g^{-1}\ s^{-1}$ as a function of pressure of H_2S.

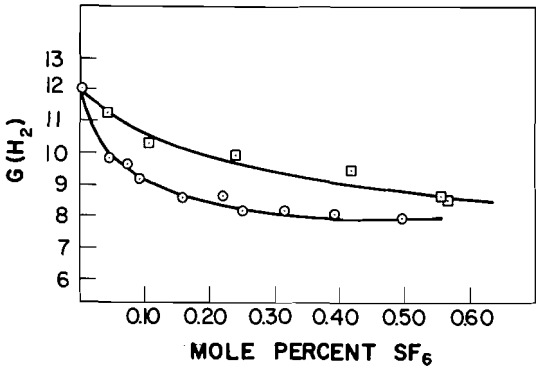

FIG. 2. Effect of added SF_6 on the hydrogen yield from the radiolysis of H_2S at a dose rate of $\sim 2 \times 10^{27}$ eV g^{-1} s^{-1}. ○, 1000 Torr pressure; □, 350 Torr pressure.

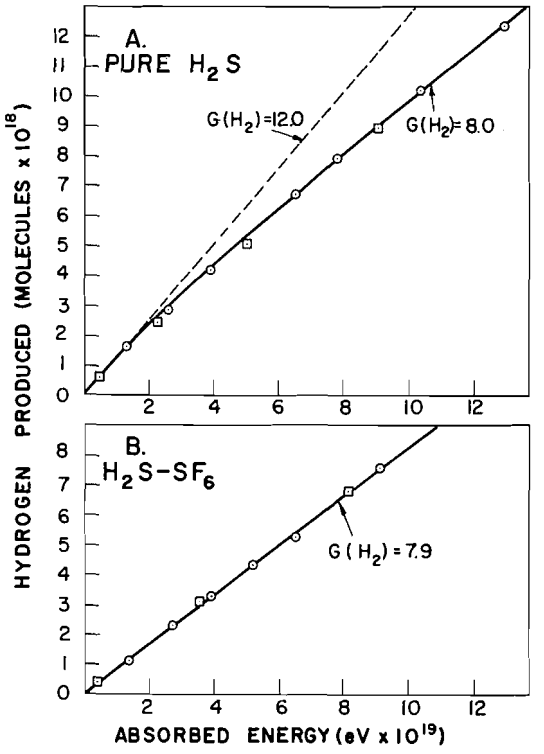

FIG. 3. Amount of hydrogen produced as a function of absorbed energy. Increase in absorbed dose was achieved by use of several pulses. decrease in yield at higher doses for both pressures. The results for H_2S–SF_6 mixtures are given in Fig. 3*B*. In direct contrast to pure H_2S there is no fall-off in yield at the higher doses.

Discussion

The hydrogen yield, $G(H_2) = 12.0 \pm 0.5$, we observe in the radiolysis of H_2S at a dose rate of $\sim 2 \times 10^{27}$ eV g^{-1} s^{-1} is in good agreement with that of Perner and Franken (2) of $G(H_2) = 11.5 \pm 0.7$ for similar conditions.

We also agree with the qualitative observations of these authors in that SF_6 reduces the hydrogen yield. The decrease we observe is in good agreement with the ion pair yield for H_2S based on the value of $W = 25.3$ eV per ion pair (8). This value of W measured by Huyton and Woodward is probably more reliable than the lower value used in ref. 9.

Primary Ionic Processes

From mass spectrometric studies (17), the predominant positive ions formed in the radiolysis of H_2S will be H_2S^+ (52%), SH^+ (22%), S^+ (23%), and H^+ (3%). Accepting the energy required to form an ion pair as $W_{H_2S} = 25.3$ eV (8), the yields of these should then be $G(H_2S^+) = 2.08$, $G(SH^+) = 0.88$, $G(S^+) = 0.92$, and $G(H^+) = 0.12$. These ions are presumably formed in reactions such as [13]–[16].

[13] $H_2S \rightsquigarrow H_2S^+ + e$

[14] $H_2S \rightsquigarrow SH^+ + H + e$

[15] $H_2S \rightsquigarrow S^+ + H + H + e$

[16] $H_2S \rightsquigarrow H^+ + SH + e$

Both H_2S^+ and SH^+ will react very rapidly with H_2S to form H_3S^+ (18–20)

[17] $H_2S^+ + H_2S \rightarrow H_3S^+ + SH$
$k_{17} \simeq 8 \times 10^9\ M^{-1}\ s^{-1}$

[18] $SH^+ + H_2S \rightarrow H_3S^+ + S$
$k_{18} \simeq 1 \times 10^{10}\ M^{-1}\ s^{-1}$

as we shall assume does the trace of H^+,

[19] $H^+ + H_2S + M \rightarrow H_3S^+ + M$

The fate of S^+ is not as clear. Since SF_6 reduces the hydrogen yield by ~4 G units, each neutralization reaction must give an H atom. Thus some reaction sequence involving S^+ which can be suppressed by SF_6 must be capable of producing H atoms. A possibility is charge exchange with H_2S, reaction 20. This is slightly endothermic (i.p.$_{H_2S}$ = 10.47 eV, i.p.$_S$ = 10.36 eV (21))

[20] $S^+ + H_2S \rightarrow H_2S^+ + S$

but is possible if the S^+ ion is formed with a slight excess of energy. The H_2S^+ ion would then form H_3S^+ by reaction 17. Reaction with H_2S to yield S_2^+, reaction 21, would be favored on grounds of ionization potentials (i.p.$_S$ = 10.36 eV, i.p.$_{S_2}$ = 8.3 eV (21))

[21] $$S^+ + H_2S \rightarrow S_2^+ + H_2$$

but this reaction would not be suppressed by SF_6.

Assuming S^+ reacts as in [20] then [17], or by some other reaction sequence, to yield H_3S^+, the net yields from primary ionic processes before neutralization are predicted to be: $G(H_3S^+)$ = 4.0 = G(e), $G(SH)_i$ = 3.12, $G(H)_i$ = 2.72, and $G(S)_i$ = 1.80.

Neutralization Processes

At high dose rates, for single pulse experiments in pure H_2S, the fate of H_3S^+ and e must be to neutralize each other. The predominant neutralization reactions most probably are

[12] $$H_3S^+ + e \rightarrow H + H_2S$$

[22] $$H_3S^+ + e \rightarrow H_2 + SH$$

Since H atoms react so rapidly with H_2S, [5], we are unable to distinguish between these two reactions.

Sulfur hexafluoride will rapidly attach thermal electrons (22), [23]

[23] $$e + SF_6 \rightarrow SF_6^-$$
$$k_{23} = 1.8 \times 10^{14}\, M^{-1}\, s^{-1}$$

and this can suppress contributions from dissociative neutralization reactions. Since addition of SF_6 reduces the hydrogen yield and since SF_6 does not react rapidly with hydrogen atoms, we must assume the reduction is due to reaction 24 competing with reaction 12

[24] $$H_3S^+ + SF_6^- \rightarrow H_2S + HF + SF_5$$

[12] $$H_3S^+ + e \rightarrow H\cdot + H_2S$$

or reaction 25 competing with reaction 26.

[25] $$H_3S^+ + SF_6^- \rightarrow H\cdot + HF + SH + SF_5$$

[26] $$H_3S^+ + e \rightarrow 2H + SH$$

Both these competitions lead to a reduction in hydrogen yield of $\Delta G(H_2) = G(e) = 4.0$. Reactions 25 and 26, however, are an improbable sequence. It is unlikely that four product fragments arise from a single neutralization. Even less likely is the small yield of H atoms from neutral excitation processes that these reactions would require. The maximum possible yield of H atoms is $G(H)_{total}$ = 12.0. If reaction 26 occurred it would yield $G(H)_{26} = 2G(e) = 8.0$. The yield from ion–molecule reactions is $G(H)_i$ = 2.72 leaving 12.0 − 8.0 − 2.72 = 1.28 from direct neutral excitation processes. This gives an unreasonably low value for the ratio of $G_{excitation}$ to $G_{ionization}$. Thus it appears that one H atom is formed per neutralization as in [12] and that this can be suppressed by SF_6, as in [24].

The effect of pressure on the decrease in the yields with SF_6 shown in Fig. 2 cannot be precisely explained. A reduction in the effectiveness of SF_6 at lower pressures has been observed in Febetron irradiations of N_2O and HCl (5, 6). It was proposed that this was due to an increase in electron energy at low pressures. The rate constant of reaction 23 decreases rapidly for electrons above thermal energies (22–24). This should be reflected by an inverse dependence of k_{23} on pressure. A measure of the reduction in k_{23} can be obtained from a reciprocal plot of the yields given in Fig. 2. These plots are shown in Fig. 4 and are based on the expression

$$\frac{1}{G(H_2)_0 - G(H_2)_s} = \frac{1}{G(H_2)_0 - G(H_2)_\infty}\left[1 + \frac{\text{constant} \times [H_2S]}{k_{23}[SF_6]}\right]$$

From the slopes in the figure, SF_6 is seen to be more than three times as effective at 1000 Torr

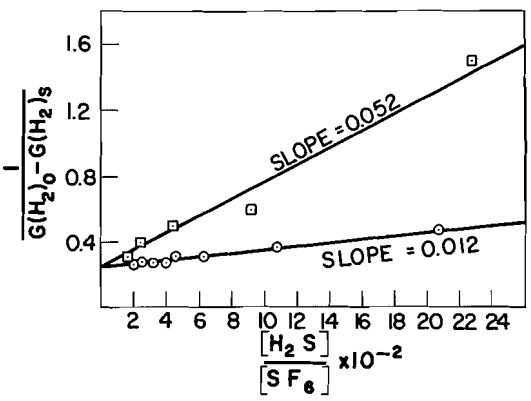

FIG. 4. Reciprocal plot of reduction in hydrogen yield *vs.* amount of SF_6 added. ○, 1000 Torr H_2S; □, 350 Torr H_2S.

as it is at 350 Torr. Using a computer program[4] to test the system and assuming $k_{12} = 1 \times 10^{15}$ M^{-1} s^{-1}, even at 1000 Torr, k_{23} (effective) is more than 10 times smaller than that given in the literature for thermal electrons (22).

Low Dose Rate Yields

As discussed in the previous section, the fair agreement between the low dose rate yield of $G(H_2) = 7.0$–7.9 (7, 9, 10) and the limiting yield of $G(H_2) = 7.9 \pm 0.3$ with SF_6 at high dose rates suggests that there is no contribution from neutralization at low dose rates. This is confirmed by the absence of an effect of SF_6 and N_2O on $G(H_2)$ at low dose rates (1, 7, 9, 10) and it is further confirmed by the limiting yield in multipulse irradiations at high dose rates where $G(H_2) \approx 8$, and is unaffected by SF_6, Figs. 3*A* and 3*B*.

For conditions where no neutralization contribution to $G(H_2)$ is observed, there must be some neutralization process other than reaction 12. At low dose rates this could be due to clustering or charge transfer reactions of the H_3S^+ ion. Because of the high proton affinity of H_2S (p.a. $\geqslant$ 7.6 eV (25)), however, charge transfer is unlikely. Because reaction 26 is unlikely, neutralization of H_3S^+ should only give one H atom and this should not be affected by clustering. The fall-off in yield at high doses at high dose rates, Fig. 3, also eliminates clustering as an explanation for the difference in yields. The amount of clustering will be the same for any number of pulses as the life-time of ions with respect to neutralization is essentially independent of absorbed dose.

The reduction in yield at low dose rates or at high doses in high dose rate experiments is probably due to electron attachment to products. Perner and Franken (2) have reported that H_2S_2 has no effect on the H_2 yield and therefore the most likely product involved is sulfur. Assuming that a negative ion of the type S_2^-, S_4^- etc. is formed, the neutralization reaction could be

$$[27] \qquad H_3S^+ + S_n^- \rightarrow H_2S + HS_n$$

Whatever the species responsible, it must attach electrons very efficiently. From Fig. 3, at a dose of $\sim 6 \times 10^{20}$ eV g^{-1}, $G(H_2) \simeq 10$ and therefore electrons are disappearing equally by neutralization [12] and by attachment to this species. Assuming the species to be S_2, its maximum concentration at this dose is 8×10^{-5} M. Since the mean lifetime of the electron with respect to neutralization is ~ 10 ns at a dose rate of 2×10^{27} eV g^{-1} s^{-1} (6), the attachment rate constant must be $k_{28} \geqslant 3 \times 10^{12}$ M^{-1} s^{-1}.

$$[28] \qquad e + S_2 \rightarrow S_2^-$$

Conclusions

The initial hydrogen yield of $G(H_2) = 12.0$ obtained at high dose rates is reduced to $G(H_2) \simeq 7.9 \pm 0.3$ either by the addition of SF_6 or increasing the absorbed dose. This reduction, which is equal to the ion pair yield, is due to the replacement of the neutralization of H_3S^+ with an electron by the SF_6^- ion or a negative ion of the type S_n^-. The fair agreement between this and the yield observed at low dose rates of $G(H_2) = 7.0$–7.9 and the lack of effect of SF_6 at low dose rates is probably due to similar neutralization processes.

[4]The program was WR16 and we have previously described its use in similar calculations, *e.g.* ref. 6.

Kinetics of Reactions of 8-Quinolinol and Acetate with Hydroxyaluminum Species in Aqueous Solutions. 1. Polynuclear Hydroxyaluminum Cations[1]

R. C. TURNER AND WAN SULAIMAN[2]

Soil Research Institute, Research Branch, Canada Department of Agriculture, Ottawa, Canada

Received[3] April 27, 1970

The effect of varying 8-quinolinol and acetate concentration on the rate of decomposition of polynuclear hydroxyaluminum cations was studied. It was found that the concentration of the undissociated 8-quinolinol and acetic acid molecules determined the magnitude of the first order rate constant for the decomposition of the polynuclear hydroxyaluminum cations, except when the acetate concentrations were relatively high. With high acetate concentrations, it appeared that polynuclear acetate species were involved in the reactions. An empirical equation was developed showing the effect of 8-quinolinol and acetic acid molecule concentrations on the pseudo first order rate constant for the decomposition reaction.

L'effet de la variation de la concentration de l'hydroxy-8 quinoléïne et de l'acétate sur la vitesse de décomposition des cations hydroxy-aluminium polynucléaires a été étudié. Il a été trouvé que la grandeur de la constante de vitesse d'ordre un est déterminée par la concentration de l'hydroxy-8 quinoléïne et de l'acide acétique non dissociés, excepté à relativement haute concentration en acétate. A haute concentration en acétate, il est apparu que la réaction impliquait des complexes polynucléaires contenant de l'acétate. On a développé une équation empirique qui donne l'effet de la concentration de l'hydroxy-8 quinoléïne et de l'acide acétique sur la constante de vitesse d'ordre un de la réaction de décomposition.

Canadian Journal of Chemistry, **49**, 1683 (1971)

Introduction

It was shown in an earlier publication (1) that three forms of Al could be determined in partially neutralized $AlCl_3$ solutions by 8-quinolinolate extraction procedures. The three forms of Al were mononuclear and polynuclear hydroxyaluminum cations (mono- and polynuclear with respect to Al) and an initial solid phase. The rate of the reaction with the mononuclear cations was essentially instantaneous, while with the polynuclear cations it could be represented by a first order process and with the initial solid phase it could be represented reasonably well by a 2/3 order process, which went to completion because the reaction mixtures were swamped with 8-quinolinol.

Goto and Yotsuyanagi (2) studied the effect of 8-quinolinol and acetate concentrations on the initial rate of the reaction with hydroxyaluminum material. They concluded that the reaction was first order but that the rate constant was affected to a great extent by the 8-quinolinol concentration and to a lesser extent by the acetate concentration. They found that the rate of the reaction with varying acetate concentrations (but with the 8-quinolinol and pH kept constant) could be represented by the equation

$$[1] \quad \frac{d[Al]}{dt} = k_2[Ac_T]^n[Al_p] + k_2^0[Al_p]$$

where [Al] is the concentration of mononuclear Al, $[Ac_T]$ the total concentration of acetate, $[Al_p]$ the concentration of polynuclear material expressed as Al, k_2 and k_2^0 are constants and the experimental value of n was 2. Similarly, when the 8-quinolinol was varied but the acetate concentration and pH kept constant the rate of the reaction was

$$[2] \quad \frac{d[Al]}{dt} = k_3[OX_T]^m[Al_p] + k_3^0[Al_p]$$

where $[OX_T]$ is the total concentration of 8-quinolinol, k_3 and k_3^0 are constants, and the experimental value of m was 2. Goto and Yotsuyanagi (2) did not differentiate between polynuclear hydroxyaluminum cations and the initial solid phase, thus it is uncertain whether their results referred to the two forms together or to only one of them.

The objective of the work reported here was to determine the effect of the concentrations of 8-quinolinol and acetate on the rate of the

[1]Contribution No. 332.

reaction with the polynuclear hydroxyaluminum cations and to determine whether it was the undissociated 8-quinolinol and acetic acid molecules or their ions that determined the magnitude of the first order rate constant for the reaction.

Experimental

The polynuclear hydroxyaluminum cations were prepared by titrating a solution of $AlCl_3$ slowly with NaOH to an NaOH/Al mole ratio of 2.4, the time required for titration being about 24 h. The final total concentration of Al in a system was usually 10^{-3} *M* although in some experiments higher concentrations were used. After ageing for at least 24 h, aliquots were filtered through VS Millipore filters under suction and the filtrates were used in the rate studies.

The method for determining the concentration of mononuclear Al ions was based on the fact that the complex formed between this form of Al and 8-quinolinol was essentially instantaneous. The complex was extracted into chloroform and its concentration determined colorimetrically.

Before presenting the procedures followed, it is important to point out that rather small concentrations of phosphate in the reaction mixtures increased the rate of the reactions. It was found, however, that this source of error was eliminated by ensuring that the phosphate concentration was less than 3×10^{-7} *M*.

The standard procedure was as follows: 25 ml of 8-quinolinol stock solution (which was prepared by dissolving 10 g 8-quinolinolate in 25 ml acetic acid and diluting to 1000 ml with H_2O) was added to 150 ml of H_2O, followed by 25 ml of 1 *N* NaOAc. This solution was then added to 50 ml of an aqueous test solution in which the Al concentration was between 5×10^{-5} and 2×10^{-4} *M*. The reaction flask was suspended in a constant-temperature water bath at 26 °C and $NaOH–H_2SO_4–H_2O$ washed air was bubbled through the solution. Twenty-five ml aliquots were pipetted from the flask at predetermined time intervals and extracted with exactly 10 ml of chloroform. Extraction with chloroform consisted of shaking the mixture in a separatory funnel for 10 s allowing the chloroform to separate from the aqueous layer and drawing the chloroform off through the drainage tube which contained a cotton plug to remove H_2O. This procedure gave a reaction mixture with 8-quinolinol and acetate concentrations of 6.9×10^{-3} and 1.44×10^{-1} *M*, respectively, with a p*H* of 5.05 ± 0.02.

Variations in the concentrations of 8-quinolinol and acetate were made by varying the amounts of the stock solutions used, adjusting the p*H* by adding acetic acid or NaOH but keeping the volume of the reaction mixture constant by varying the amount of H_2O added. When the desired acetate concentration in the reaction mixture was less than that in the stock solution of the 8-quinolinol, it was necessary to use a special stock solution of 8-quinolinol dissolved in perchloric acid rather than acetic acid.

With both 8-quinolinol and acetate present the reactions went to completion via a first order process. When the concentration of either 8-quinolinol or acetate was zero, the reactions did not go to completion via a first order process. In fact, the reactions appeared to reach equilibria when there was an appreciable concentration of the polynuclear hydroxyaluminum cations remaining in solution. Consequently, when the acetate concentration was zero, the rates were determined during the first minute of reaction, and when the 8-quinolinol concentration was zero the rates were determined over the first 35% of reaction. In both cases the rates were proportional to the concentration of polynuclear cations present. It was assumed therefore that the processes were first order and the rate constants were calculated on the basis of the concentration of polynuclear cations present.

Results and Discussion

The concentrations of both OX_T and Ac_T, except when either was zero, were much greater than the total concentrations of Al in the reaction mixtures so that their concentrations remained essentially constant during the reactions. Thus the reactions appeared to be first order processes with respect to $[Al_p]$.

The effect of acetate concentration on the reaction with constant p*H* and 8-quinolinol concentrations is shown in the upper section of Fig. 1 as the plot of first order rate constant *k vs.* $[Ac_T]^2$. These plots are essentially the same as those used by Goto and Yotsuyanagi (2) and show, in agreement with their results, that the plots could be represented by straight lines over the entire range of $[Ac_T]$ used including zero. Thus *n* in eq. 1 is equal to 2. When the 8-quinolinol concentration was 6.9×10^{-3} *M*, however, *k* was equal to 3.0 min^{-1} M^{-2} whereas when $[OX_T]$ was zero *k* was 3.3 min^{-1} M^{-2} which indicates that the two reactants did not react independently with the polynuclear hydroxyaluminum cations.

The results in Fig. 1*b* show that when the first order rate constant *k* was plotted against $[OX_T]^2$ with constant p*H* and $[Ac_T]$, the plots could not be represented by a straight line. This is contrary to the conclusion reached by Goto and Yotsuyanagi (2) but they did not use the low concentrations of 8-quinolinol which were necessary to show the definite curves in the plots. The upper curve is included to show the increased rates over those in the middle curve due to phosphate in the reaction mixture. It is ignored in the following treatment. Before proceeding with the effect of $[OX_T]$ on the first order rate constant, eqs. 1 and 2 will be combined into one equation.

Equations 1 and 2 imply that 8-quinolinol and acetate react independently with the polynuclear

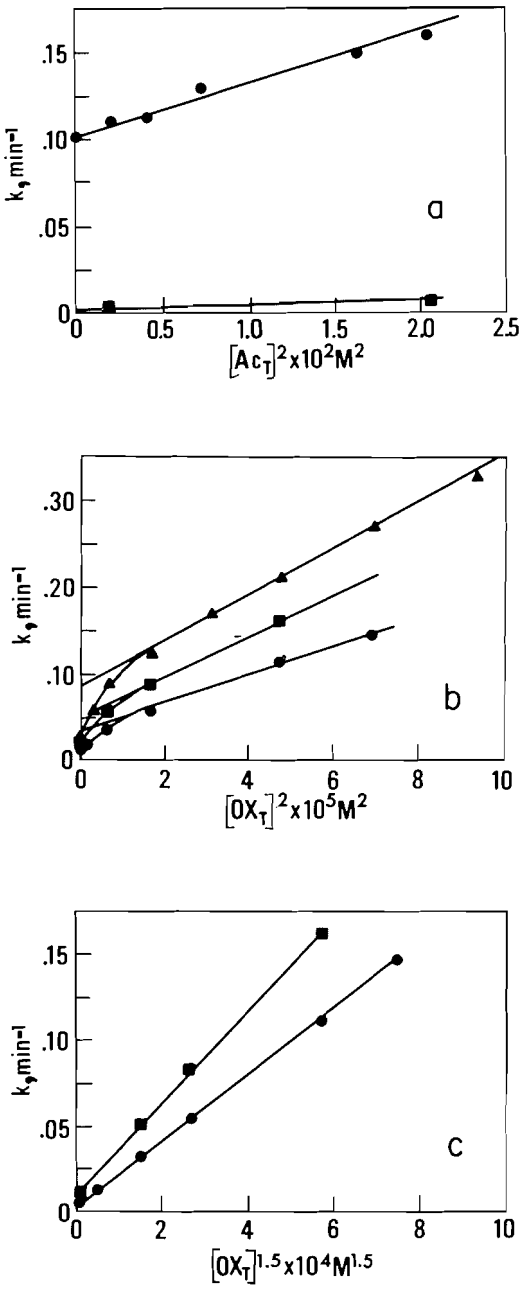

FIG. 1. Effect of 8-quinolinol and acetate concentrations on the rate constant for the decomposition of polynuclear hydroxyaluminum cations. (*a*) Varying $[Ac_T]$: ●, $[OX_T] = 6.9 \times 10^{-3}$ *M*; ■, $[OX_T] = 0$. (*b*) Varying $[OX_T]$: ▲, $[Ac_T] = 1.44 \times 10^{-1}$ and $[P] = 1.6 \times 10^{-5}$; ■, $[Ac_T] = 1.44 \times 10^{-1}$; ●, $[Ac_T] = 4.4 \times 10^{-2}$ *M*. (*c*) Varying $[OX_T]$: ■, $[Ac_T] = 1.44 \times 10^{-1}$; ●, $[Ac_T] = 4.4 \times 10^{-2}$ *M*.

cations and they therefore can be combined to give

$$[3] \quad \frac{d[Al]}{dt} = (k_2[Ac_T]^n + k_3[OX_T]^m)[Al_p]$$

which shows that $k_2[Ac_T]^n$ is equal to k_2^0 when $[OX_T]$ is zero and $k_3[OX_T]^m$ is equal to k_3^0 when $[Ac_T]$ is zero. According to eq. 3 the pseudo first order rate constant k at constant pH is expressed by the equation

$$[4] \quad k = k_2[Ac_T]^n + k_3[OX_T]^m$$

where n is equal to 2.

The value of m was determined from the experimental results represented in Fig. 1*b* by plotting the log k minus $k_2[Ac_T]^2$ *vs.* log $[OX_T]$. The slopes of the straight lines of best fit drawn through the experimental points showed m equal to 1.5. Figure 1*c* shows the same plots as Fig. 1*b* but with m equal to 1.5. The experimental values follow a straight line over the entire range of $[OX_T]$ used including zero. The slopes of the lines were different, however, for the two concentrations of $[Ac_T]$ so that the value for k_3 with $[Ac_T]$ equal to 14.4×10^{-2} was 2.7×10^{-2} $M^{-1.5}\,min^{-1}$, while with $[Ac_T]$ equal to 4.4×10^{-2} it was 2.0×10^{-2}. It appeared, therefore, as was the case when $[Ac_T]$ was varied with $[OX_T]$ and pH constant, the 8-quinolinol and acetate did not react independently with the polynuclear cations.

Since the acetate and 8-quinolinol did not react independently with the polynuclear cations, it was necessary to modify eq. 4 by adding at least one term which involved both reactants. Furthermore, this new term or terms must be consistent with the experimental fact that the plot of k *vs.* $[Ac_T]^2$ at constant $[OX_T]$ and k *vs.* $[OX_T]^{1.5}$ at constant $[Ac_T]$ both gave straight lines (Fig. 1). The simplest equation that was consistent with the experimental facts was

$$[5] \quad k = k_2[Ac_T]^2 + k_4[Ac_T]^2[OX_T]^{1.5} + k_3[OX_T]^{1.5}$$

The constants k_2, k_3, and k_4 in eq. 5 can be readily evaluated graphically. Specifically, the slope of k *vs.* $[Ac_T]^2$ plot in which $[OX_T]$ and the pH are held constant (Fig. 1*a*) is equal to $k_2 + k_4[OX_T]^{1.5}$. Likewise, the slope of the plot of k *vs.* $[OX_T]^{1.5}$ with $[Ac_T]$ and pH held constant, (Fig. 1*c*) is equal to $k_3 + k_4[Ac_T]^2$. The value of k_2 obtained from the intercept of the plot in Fig. 1*c*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where $[OX_T] = 0$ and $[Ac_T] = 1.44 \times 10^{-1}$ was 3.4×10^{-1} min^{-1} M^{-2}. Also, the value of k_3 from the intercept at $[Ac_T] = 0$ and $[OX_T] = 6.9 \times 10^{-3}$ in Fig. 1*a* was 1.8×10^{-2} min^{-1} $M^{1.5}$. With these values for k_2 and k_3 and the slopes from the same plots the calculated value of k_4 was 4.5×10^3 min^{-1} $M^{-3.5}$.

The equations developed above as well as the values for k_2, k_3, and k_4, are based on the total concentrations of acetate and 8-quinolinol in the reaction mixtures. This is legitimate regardless of the specific species derived from the acetate or 8-quinolinol which may be rate determining because at constant p*H* a specific species is proportional to the total concentrations, except in special cases, which will be discussed later.

To determine whether it was the concentration of protonated 8-quinolinol $[OX^+]$, 8-quinolinol [OX], dissociated quinolinolate $[OX^-]$ or the sum of the three, *i.e.*, $[OX_T]$, that controlled the rate of the reaction, experiments were made with $[OX_T]$ and $[Ac_T]$ kept constant at 6.9×10^{-3} and 4.4×10^{-2} *M*, respectively, and the p*H* of the reaction mixture was varied from 4.8 to 5.6. At this concentration of acetate the solution was strongly buffered so that the p*H* was not affected by the reactions and the concentration was too low relative to that of 8-quinolinolate to have an appreciable effect on the rate of the reaction. When the p*H* was raised from 4.8 to 5.6 the rate constant increased from 0.06 to 0.21 min^{-1}, a 3.5-fold increase. Thus, according to eq. 5, the concentration of the species controlling the magnitude of the rate constant must have increased 2.3 fold. The value of $[OX_T]$ is independent of p*H* and can therefore be ruled out. Using $10^{-9.89}$ (3) and $10^{-5.13}$ (3) as the equilibrium constants for $OX \rightleftharpoons OX^- + H^+$ and $OX^+ \rightleftharpoons OX + H^+$, respectively, it can be shown that increasing the p*H* from 4.8 to 5.6 decreases $[OX^+]$ by a factor of 2.7 but increases $[OX^-]$ and [OX] 15 and 2.3-fold, respectively. Since a 2.3-fold increase in concentration corresponds to a 3.5-fold increase in the rate constant, it is obvious that the concentration of OX controls the rate of the reaction. Consequently, eq. 5 was modified to

$$[6] \quad k = 3.4 \times 10^{-1}[Ac_T]^2 + 1.47 \times 10^4[Ac_T]^2[OX]^{1.5} + 5.88 \times 10^2[OX]^{1.5}$$

In the case of acetate there were a number of possibilities including polynuclear forms of acetic acid. Providing relatively low concentrations of acetate were involved, however, only three possibilities needed to be considered, *i.e.*, that it was the concentration of total acetate $[Ac_T]$, acetate ion $[Ac^-]$, or undissociated acid [Ac] that governed the rate of the reaction. In all experiments in which 8-quinolinol was absent and $[Ac_T]$ was constant, decreasing the p*H* increased the rate constant. When the p*H* was decreased from 5.05 to 4.70 the rate constant increased 3.3-fold which corresponds to an increase of 1.8-fold in the concentration of the reacting species (eq. 6). Using $10^{-4.75}$ (4) for the dissociation constant of acetic acid, it can be shown that this decrease in p*H* would decrease $[Ac^-]$ by a factor of 1.4 but increase [Ac] 1.6-fold. It was concluded therefore that it was the concentration of undissociated acid, *i.e.*, [Ac] that controlled the rate of the reaction. Consequently, eq. 6 was modified to

$$[7] \quad k = 3.09[Ac]^2 + 1.32 \times 10^5[Ac]^2[OX]^{1.5} + 5.88 \times 10^2[OX]^{1.5}$$

Equation 7 was tested by either varying $[OX_T]$ and $[Ac_T]$ simultaneously while keeping $[OX_T]/[Ac_T]$ and p*H* constant or by keeping $[OX_T]$ and $[Ac_T]$ constant and varying p*H*. The upper part of Table 1 shows that there was excellent agreement between the calculated and experimental results when the p*H* was kept constant, and, although much of the total calculated rates came from the third term of the equation which involves only [OX], as much as 40% was contributed by the second term which involves [Ac] as well as [OX]. The second section of the table shows that there was also excellent agreement between calculated and experimental results when the p*H* was varied but in these experiments the acetate concentration was low with the result that practically all of the calculated values were derived from the last term of the equation which involves only [OX]. In both of these experiments, the first term of the equation which involves [Ac] alone contributed essentially nothing to the total calculated values. To have conditions in which the first term of the equation contributed materially to the total values, it was necessary to either increase the concentration of acetate to relatively high values or to decrease the 8-quinolinol concentration to zero. The first two rows of the third section of the table show that when only acetate was present, changing the p*H* from 5.05 to 4.70 increased the

*First, second, and third term on the right-hand side of eq. 7.

experimental rate constant. The next two rows show that the experimental values agreed with those calculated by the equation when the pH was either 5.05 or 4.87 and $[OX_T]$ and $[Ac_T]$ were respectively 6.9×10^{-3} and 2.88×10^{-1} M. At these concentrations decreasing the pH increased the contribution from the $[Ac]^2$ term and decreased the contribution from the $[OX]^{1.5}$ term with the result that rate constant was the same at the two pH values. The final three rows of the table show that increasing the acetate concentration beyond 2.88×10^{-1} M caused the experimental values to be significantly greater than the calculated ones.

The very real discrepancy observed between the calculated and experimental values of the first order rate constant with relatively high acetate concentration is probably due to a simplifying assumption made in the derivation of eq. 7. This assumption was that only the two mononuclear forms, undissociated acid and acetate ion, would be involved. At acetate concentrations greater than 5×10^{-2} M, however, the polynuclear forms $H_2(OAc)_2$ and $H(OAc)_2^-$ cannot be ignored (5). Since at constant ionic strength and pH the concentrations of these two species are proportional to $[Ac]^2$, their concentrations increase with increasing $[Ac_T]$ much more rapidly than [Ac].

Regardless of the discrepancies between calculated and experimental rate constants at the higher total acetate concentrations, the evidence is convincing that it is the 8-quinolinol and acetic acid molecules, rather than the charged ions derived from them, that react directly with the polynuclear hydroxyaluminum cation. The polynuclear acetate species have very little effect at the concentration of acetate used in the proposed method (1).

The phosphorus analyses were done by Ian Duncan.

Kinetics of Reactions of 8-Quinolinol and Acetate with Hydroxyaluminum Species in Aqueous Solutions. 2. Initial Solid Phases[1]

R. C. TURNER

Soil Research Institute, Research Branch, Canada Department of Agriculture, Ottawa, Canada

Received[2] April 27, 1970

The effects of p*H* and concentrations of 8-quinolinol and acetate on the rate of release of mononuclear Al from an initial solid phase formed by the rapid precipitation of mononuclear Al cations and from another formed by the precipitation of polynuclear hydroxyaluminum cations with NaOH were determined. With the solid formed by precipitation of the mononuclear Al cations, the rate was governed by the rate of dissolution of the solid. Dissolution occurred because the solution was undersaturated with respect to the solid. With the solid formed by the precipitation of the polynuclear cations the reaction behaved as if the rate determining step in the release of the mononuclear Al was the decomposition of the polynuclear cations after dissolution of the solid, indicating that the polynuclear cations persisted as such in the precipitate.

Independent evidence that the two initial solid phases were entirely different was indicated by the fact that the one formed by precipitation of mononuclear cations developed into gibbsite in a few days whereas the other did not.

L'influence du p*H* et de la concentration de l'hydroxy-8 quinoléïne et de l'acétate sur la formation de Al mononucléaire à partir d'une phase solide initiale, obtenue par précipitation rapide de cations Al mononucléaires, et d'une autre, formée par la précipitation de cations hydroxy-aluminium polynucléaires par NaOH, a été déterminée. Avec le solide, formé par précipitation des cations Al mononucléaires, la vitesse a été contrôlée par la dissolution du solide. La dissolution a eu lieu parce que la solution était insaturée par rapport au solide. Avec le solide formé par précipitation de cations polynucléaires, la réaction s'est comportée comme si l'étape déterminante de la vitesse de formation de Al mononucléaire était la décomposition des cations polynucléaires après dissolution du solide, indiquant que les cations polynucléaires sont restés comme tels dans le précipité.

Une preuve supplémentaire que les deux phases solides initiales sont différentes peut être apporteé par le fait suivant : celle obtenue par précipitation des cations mononucléaires se développe sous une forme gibbsite en quelques jours tandis que l'autre phase ne se développe pas sous cette forme.

Canadian Journal of Chemistry, **49**, 1688 (1971)

Introduction

It was shown in a previous publication (1) that the reaction between 8-quinolinol plus acetate at p*H* 5.05 and the initial solid phase formed by the rapid precipitation of $Al(OH)_3$ from an $AlCl_3$ solution with NaOH could be represented reasonably well by a 2/3 order process. It was assumed that the reaction was irreversible and went to completion via a 2/3 order process because the reaction mixture contained a high concentration of 8-quinolinol which remained essentially constant during the reaction. This implied that there was a direct reaction between the 8-quinolinol and the surface of the solids. Later (2) it was shown that both the 8-quinolinol and the acetic acid in the reaction mixture reacted with polynuclear hydroxyaluminum cations. Thus, the acetate played a double role; it not only acted as buffer to keep the reaction mixture at a constant p*H* but also was a source of acetic acid molecules which entered into the reaction. Studies similar to those made with the polynuclear hydroxyaluminum cations were therefore made with the initial solid phase.

It has been shown that, whereas the initial solid phase formed by the rapid precipitation from an $AlCl_3$ solution occurs near p*H* 4.5 (3, 4), the precipitation resulting from the neutralization of the polynuclear hydroxyaluminum cations occurs near p*H* 6.0 (4). The reaction between the initial solid formed in the latter way and 8-quinolinol plus acetate was also studied.

The object of the study, besides determining the kinetics of the reactions, was to see whether there was any real difference between the two initial solid phases, one formed by precipitation of mononuclear Al cations and the other by the precipitation of polynuclear hydroxyaluminum cations.

Experimental

Initial solid phases were prepared by titrating Al salt solutions to pH 7.0 with NaOH solutions. In some cases the Al in the salt solution was in the form of mononuclear cations while in others it was in the form of polynuclear hydroxyaluminum cations. The solid formed from mononuclear cations will be referred to as ISP(M) and the other, formed from the polynuclear cations, will be referred to as ISP(P). The NaOH, in both cases, was added rapidly while the solutions were stirred vigorously. The final total Al concentrations in the suspensions were either 10^{-3} or 5×10^{-3} M. These suspensions were used in the rate studies without filtering. The procedure for the determination of the rate of release of mononuclear Al was the same as that used with the polynuclear cations (2).

Results and Discussion

It was shown previously (1) that the reaction of 8-quinolinol plus acetate at pH 5.05 with the initial solid phase ISP(M) could be represented by the equation

$$[1] \qquad C_0^{1/3} - C^{1/3} = k_c t$$

where C_0 is the concentration of ISP(M) expressed as Al^{3+} at t equals zero, C is the concentration at time t, and k_c is a constant for any given value of C_0 and temperature.

The experiments made to determine the effect of 8-quinolinol concentration on the rate constant k_c were done with the acetate concentration 1.44×10^{-1} M in the reaction mixture at pH 5.0 or 6.0 at 35 °C. As shown in the lower section of Fig. 1, the reaction at pH 5.0 or 6.0 could be represented reasonably well by eq. 1 with k_c equal to 3.3×10^{-4} $M^{-1/3}$ min^{-1} when the 8-quinolinol concentration was varied from 1.38×10^{-3} to 6.9×10^{-3} M. When the 8-quinolinol concentration was zero the reaction was somewhat faster than in the presence of 8-quinolinol when the pH was 5.0, but when the pH was raised to 6.0 the reaction rate was reduced to almost zero.

Calculations showed that at pH 5.0 when all of the solid was dissolved even if no complexing occurred between mononuclear Al and 8-quinolinol and/or acetate, the ion activity product $(Al)(OH)^3$ would be less than $10^{-31.7}$, the solubility product of the initial solid phase (3, 4). When the pH was 6.0, however, the solution would be saturated with respect to the initial solid phase after very little dissolution unless considerable complexing of the mononuclear Al occurred. Apparently with only acetate present there was not sufficient complexing of mononuclear Al at pH 6.0 to maintain the solution undersaturated with respect to the solid and therefore dissolution did not occur. On the other hand, when 8-quinolinol was present as well as the acetate there was apparently sufficient complexing of the mononuclear Al ions to maintain the solution undersaturated with respect to the solid at pH 6.0 and dissolution occurred as fast at pH 6.0 as at 5.0. The conclusion, on the basis of this interpretation, is that there is no direct reaction

between 8-quinolinol or acetate and the solid phase; dissolution occurs because the solution is undersaturated with respect to the solid. The 8-quinolinol and acetate play an indirect role, *i.e.*, they contribute to maintaining the solution undersaturated by complexing the mononuclear aluminum cations. Thus the assumption made in the earlier publication (1) that the dissolutions of the ISP(M) goes to completion via a 2/3 order process because there is a direct reaction between 8-quinolinol and the surface of the solid must be modified.

Figure 1*a* shows the effect of ageing the ISP(M) on the rate of the reaction. When the length of time of ageing was as short as it was physically possible to make it, less than 1 min from the beginning of addition of NaOH to the $AlCl_3$ solution to the beginning of the rate experiment, $k_c/C_0^{1/3}$ was 7.8×10^{-3} min^{-1} at 26 °C whereas when the length of time ageing was 40 min it was 3.9×10^{-3} min^{-1}. With 24 h ageing the rate was very slow and could not be represented by eq. 1, and after nine days ageing only a very small fraction of the solid was dissolved in 5 h.

When the initial solid phase was ISP(P), *i.e.*, when it was formed by precipitation of polynuclear hydroxyaluminum cations rather than mononuclear Al cations, its reaction with 8-quinolinol plus acetate was entirely different. As shown in Fig. 2 the rate of release of mononuclear Al from the solid was not affected by ageing and was similar to that which occurred with polynuclear hydroxyaluminum cations, *i.e.*, it approximated a first order process with rate constant equal to 0.16 min^{-1} (2). It appeared therefore that the rate determining step was the decomposition of the polynuclear cation resulting from dissolution of the solid. To check this possibility the following experiments were made.

An aliquot of the suspension containing the ISP(P) was filtered through a VS Millipore filter and the filtrate was found to contain only a trace of Al showing that the precipitation was essentially complete. Another aliquot was suspended in 0.1 *N* NaOAc which had been adjusted to p*H* 5.0 and filtered immediately through a VS Millipore filter. All of the solid was dissolved and the Al passed through the filter but only a very small fraction of it was measured as mononuclear cations. The remainder reacted with the 8-quinolinol plus acetate reaction mixture at p*H* 5.0 via a first order process with rate constant 0.16 min^{-1} (Fig. 2). Thus, although the dissolution

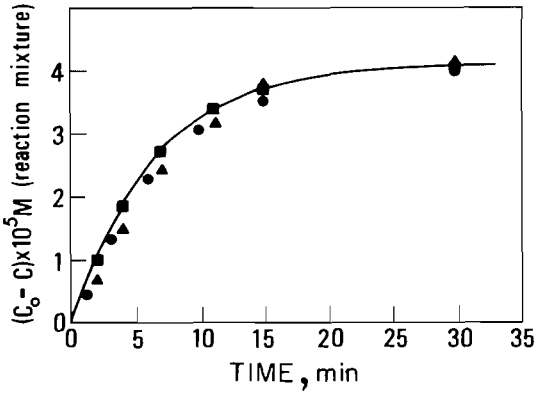

FIG. 2. Rate of decomposition of initial solid phase formed by precipitation of polynuclear hydroxyaluminum cations. ●, Immediately after precipitation; ▲, 8 days after precipitation; ■, filtrate from acetate treatment of precipitate. Smooth curve is the first order rate curve with $k = 0.16$ min^{-1}.

of the solid in the acetate solution at p*H* 5.0 was very rapid, the result of dissolution was polynuclear hydroxyaluminum cations. The polynuclear cations could not have been formed from mononuclear Al cations in the 0.1 *N* NaOAc at p*H* 5.0 because it has been shown that they are destroyed under these conditions (2). Furthermore, when the initial solid phase formed by the precipitation of mononuclear Al cations ISP(M), was suspended, immediately after precipitation, in 0.1 *N* NaOAc adjusted to p*H* 5.0, only about 20% of the solid dissolved and passed through a VS Millipore filter; and this 20% was in the mononuclear Al form. It must be concluded, therefore, that the polynuclear hydroxyaluminum cations are sufficiently stable to go through precipitation by NaOH and redissolution as well as exchange reactions with clays (5) and resins (6).

Further evidence that the two initial solid phases were entirely different was the fact that at the end of the 8 days ageing, the one formed from precipitation of the polynuclear cations was amorphous to X-rays whereas the other showed a good gibbsite pattern.

The X-ray analysis was done by N. M. Miles.

Carbon Disulfide. V. Reaction with Azibenzil[1,2]

PETER YATES,[3] B. G. CHRISTENSEN, AND L. L. WILLIAMS
The Departments of Chemistry, Harvard University, Cambridge, Massachusetts 02138, and the University of Toronto, Toronto 5, Ontario

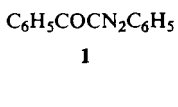
Received December 8, 1970

The product formed by the reaction of azibenzil (2-diazo-2-phenylacetophenone) with carbon disulfide has been shown to be 2-(α-phenylphenacylidene)-5,5-diphenyl-1,3-dithiolan-4-one (**9**).

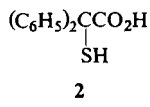
On démontre que le produit de la réaction entre l'azibenzil (diazo-2 phényl-2 acétophénone) et le sulfure de carbone est la (α-phénylphénylacylidène)-2 diphényl-5,5 dithiolanone-1,3,4 (**9**).

Canadian Journal of Chemistry, 49, 1691 (1971)

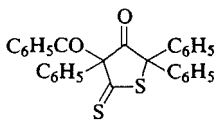
The reaction of carbon disulfide with azibenzil (2-diazo-2-phenylacetophenone, **1**) was first described by Meyer (4). He found that when a solution of **1** in carbon disulfide was boiled under reflux, a yellow crystalline product, $C_{29}H_{20}O_2S_2$, was formed readily in high yield. Basic hydrolysis of this material was found to give benzoic, phenylacetic, and diphenylacetic acids, together with another acid that was considered to be thiobenzilic acid (**2**). On this basis Meyer proposed **3** as the structure of the reaction product.



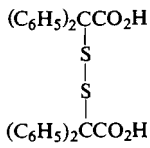
1



2

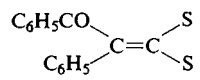


3

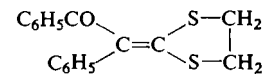


4

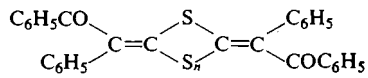
In our hands Meyer's experimental results were reproduced, except that in the basic hydrolysis 2,2,5,5-tetraphenyl-3,4-dithiaadipic acid (**4**) was isolated rather than **2**. This product is doubtless produced by air oxidation of **2**, and the structural implications of its formation are the same as for **2**. However, the i.r. and u.v. spectra of the compound $C_{29}H_{20}O_2S_2$ were not in accord with structure **3**. Its i.r. spectrum showed bands at 5.86(s), 5.98(w), and 6.17 μ (mw), in addition to bands associated with the phenyl ring vibrations. Its u.v. spectrum showed maxima at 254 (ε 17 000) and 347 mμ (ε 13 800) and very strong end absorption. These spectra strongly suggested the presence of the part structure **5**; they may be compared with the spectra of **6** (5*a*): λ_{max} 6.20 μ; 257 (ε 10 700) and 350 mμ (ε 15 800).[4] A further spectroscopic analogy supports this conclusion: a set of strong bands in the 7.4–7.9 μ region of the i.r. spectra of the product $C_{29}H_{20}O_2S_2$, compound **6**, the desaurin **7**[5] (5), and both the trithiolane **8** and one of its *cis* isomers (1).



5



6



7 $n = 1$
8 $n = 2$

Given the part structure **5**, two structures must be considered for the compound $C_{29}H_{20}O_2S_2$, *viz.* **9**[6] and **10**. Of these, **9** may be preferred on the

[1]For Paper IV see ref. 1.

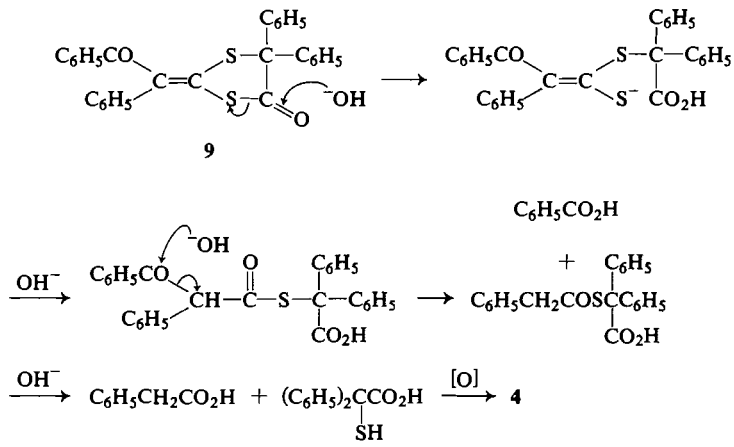
[2]Preliminary reports of this work have appeared (2, 3).

[3]Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 5, Ontario.

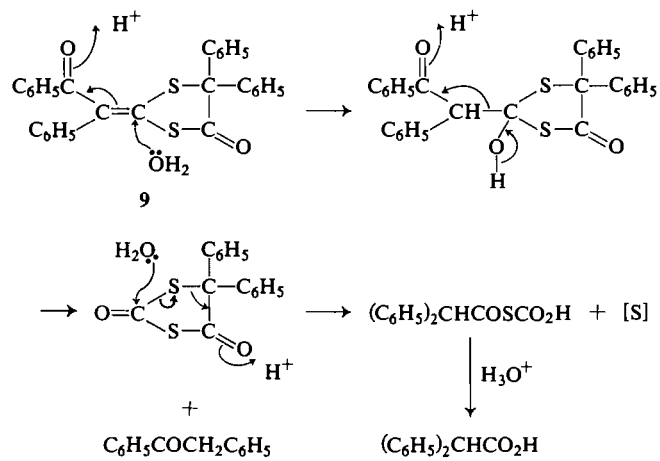
[4]The differences in these spectra may be attributed to the presence of an additional chromophore in the compound $C_{29}H_{20}O_2S_2$.

[5]The stereochemical assignment for the desaurin is provisional (5).

[6]No stereochemical assignment is implied by this and subsequent structures, unless specifically discussed.



SCHEME 1



SCHEME 2

basis of the formation of products with geminal phenyl groups in several of the degradation reactions of the compound $C_{29}H_{20}O_2S_2$ now to be discussed.

It may first be noted that the products obtained on basic hydrolysis can readily be interpreted in terms of structure **9** (Scheme 1).[7]

Acidic hydrolysis of the compound $C_{29}H_{20}O_2S_2$ gave diphenylacetic acid, deoxybenzoin, and sulfur, products whose formation can again be readily interpreted in terms of structure **9** (Scheme 2).

Desulfurization of the compound $C_{29}H_{20}O_2S_2$ with deactivated Raney nickel in ethanol gave principally ethyl diphenylacetate and α-methyldeoxybenzoin (**11**), together with a small amount of diphenylmethane. These products could arise from **9** as shown in Scheme 3; alternatively, ethyl diphenylacetate could be formed via diphenylketene.

Reduction of the compound $C_{29}H_{20}O_2S_2$ with zinc in boiling acetic acid gave a colorless dihydro product, whose i.r. spectrum showed a broad band at 5.94 μ. Its u.v. spectrum had a maximum at 252 mμ (ε 15 900), and its p.m.r. spectrum showed an AB signal system (δ 4.62 and 5.28, J = 11 Hz, 2H). Basic hydrolysis gave deoxybenzoin and diphenylacetic acid, and desulfurization with

[7]This and the following schemes are illustrative only; it is clear that many variations in detail are possible.

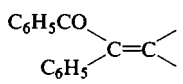
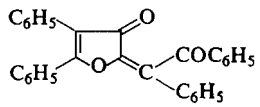
Raney nickel in ethanol gave ethyl diphenylacetate, methyldeoxybenzoin (**11**), and a trace of 1,1,2,2-tetraphenylethane. These data can be interpreted in terms of structure **12** for the dihydro product, derived by reduction of the ethylenic double bond of the α,β-unsaturated carbonyl system of **9**. The broad carbonyl-stretching band can be assigned to overlapping absorption of the benzoyl and thio lactone groups, and the u.v. maximum to the former group.[8] The degradation products can arise by the routes shown in Scheme 4 (the formation of the tetraphenylethane as a minor product on treatment with Raney nickel is probably related to the formation of diphenylmethane from **9**, proceeding via the diphenylmethyl radical).

Ozonolysis of the compound $C_{29}H_{20}O_2S_2$ followed by hydrolytic work-up gave benzil and benzoic acid, together with a small amount of diphenylacetic acid. When reductive work-up with zinc and hot aqueous acetic acid was used, the neutral product was benzoin rather than benzil. The formation of benzoic acid from a compound with the structural feature **13** can proceed via benzoic anhydride, whose formation finds analogy, for example, in the ozonolysis of **14** (7). The failure to isolate more than small amounts of geminal diphenyl derivatives may be due to the incorporation of water-soluble sulfonic acid residues. Evidence was obtained that indicated the formation of sulfuric acid in the reaction, but this accounted for only a small fraction of the sulfur in the starting material.

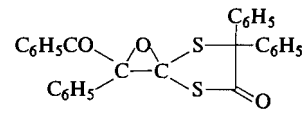


13

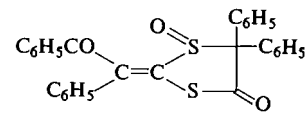


14

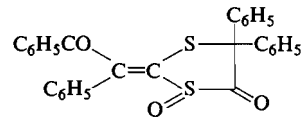
Oxidation of the compound $C_{29}H_{20}O_2S_2$ with perphthalic acid led to the formation of a compound $C_{29}H_{20}O_3S_2$. Since this product regenerates the compound $C_{29}H_{20}O_2S_2$ on treatment with zinc and acetic acid at room temperature, it is highly probable that it has been formed without skeletal change. Three structures then come into consideration on the basis of structure **9** for the compound $C_{29}H_{20}O_3S_2$, *viz.*, **15**, **16**, and **17**. Of these **17** may be rejected, since it is most unlikely that the electron poorer of the two sulfur atoms of **9** would undergo preferential attack by peracid. Treatment of the compound $C_{29}H_{20}O_3S_2$ with aqueous ethanolic sodium hydroxide gave benzophenone and the desaurin **7**. The formation of these products can be interpreted in terms of structure **16** as shown in Scheme 5. The cleavage of the sulfenic acid **18** to give thiobenzophenone finds analogy in the observation that the disulfide **4** undergoes partial conversion to thiobenzophenone (**20**) in aqueous base (8); the further conversion of **20** to benzophenone with aqueous ethanolic sodium hydroxide has also been observed previously. The conversion of the thioketene **19** to the desaurin **7** may well not involve simple dimerization, but may proceed via attack of hydroxide or methoxide ion to give a β-keto thio acid or ester as an intermediate (*cf.* ref. 5*b*).



15



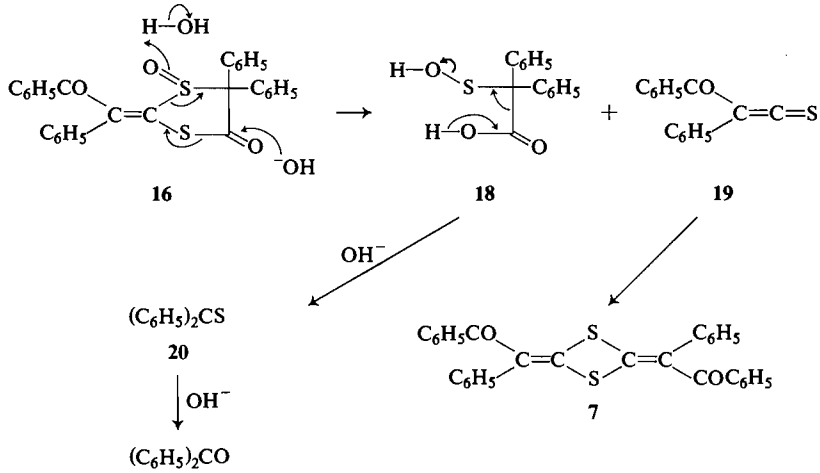
16



17

The formation of these products is more difficult to interpret in terms of structure **15** in that the segment of the molecule that would have to serve as the source of the desaurin is in too high an oxidation state, while that which must serve as the source of the benzophenone is in too low an oxidation state. Furthermore, the i.r. and u.v. spectra of the compound $C_{29}H_{20}O_3S_2$ are in better accord with structure **16**. Thus, its i.r. spectrum ($CHCl_3$) showed carbonyl-stretching bands at 5.83 and 5.97 μ that may be assigned to the thio lactone and benzoyl carbonyl groups in **16**, respectively. The conversion of the thio ether function to a sulfoxide function should inhibit the

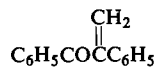
[8]Thiol esters have absorption maxima at *ca.* 235 mμ (ε 4000) (6) and thus the thio lactone absorption would be expected to be masked by the maximum due to the benzoyl group and the intense end absorption.



SCHEME 5

interaction of this sulfur atom with the benzoyl carbonyl group and also partially inhibit the interaction of this carbonyl group with the ethylenic double bond, thus accounting for the fact that the carbonyl-stretching band due to the benzoyl group occurs at a wavelength only slightly longer than that observed for simple benzoyl groups [*cf.* methylenedeoxybenzoin (**21**): $\lambda_{max}(CCl_4)$ 5.95 μ (10)].[9] The sulfoxide function could also be responsible for the observed small hypsochromic shift of the thio lactone band relative to that of **9**. Finally, it may be noted that a strong band occurs at 9.27 μ, close to the range assigned to the sulfoxide group (9). On the other hand, it is unlikely that the benzoyl group in structure **15** would have its carbonyl-stretching band at longer wavelength than that for simple benzoyl compounds, and it would be expected that the thio lactone carbonyl-stretching band would occur at longer rather than shorter wavelength than that for **9**.

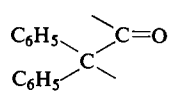
The u.v. spectrum of the perphthalic acid oxidation product showed a maximum at 263 mμ (ε 23 400) with a shoulder at 287 mμ (ε 16 500). This spectrum is in good accord with structure **16**; the considerable hypsochromic shift relative to the long wavelength maximum in the spectrum of **9** being again attributable to inhibition of the interaction between the thio ether sulfur atom and the α,β-unsaturated carbonyl system upon oxidation of this sulfur to a sulfoxide function. The spectrum may be compared with that of **21**, which shows a maximum at 247 mμ (ε 20 900) (10). Although models are lacking for the epoxy ketone structure **15**, it seems unlikely that this would show such strong absorption at 287 mμ.



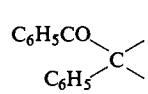
21

Thus, although no single observation rigorously excludes structure **15**, the weight of the evidence favors the assignment of structure **16**. It may be noted that in simpler cases it has been found that oxidation of vinyl sulfides with peracids gives sulfoxides rather than epoxides (11).

As pointed out earlier, the formation of geminal diphenyl derivatives in several of the degradation reactions of the compound $C_{29}H_{20}O_2S_2$ favors the assignment of **9** rather than **10** as its structure. However, most of these reactions were carried out under vigorous conditions, and the possibility existed that the residue **22** arose by rearrangement of the residue **23**. Furthermore, in none of the degradation reactions had products been isolated that provided direct evidence of the environment of both sulfur atoms. A very mild method of degradation was therefore sought.



22



23

[9]As has been noted earlier, it is anticipated that the other sulfur atom would not interact strongly with the α,β-unsaturated carbonyl system because of its incorporation into a thio lactone function.

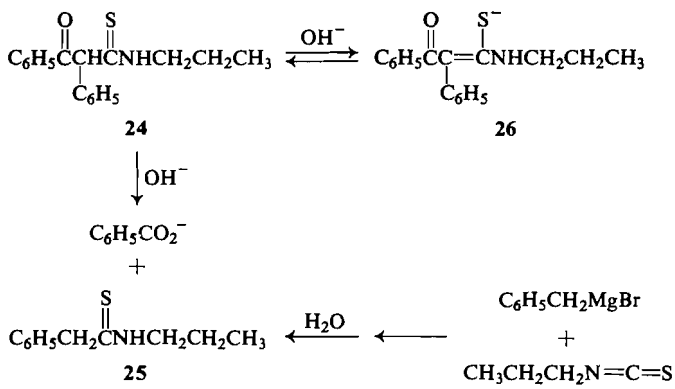
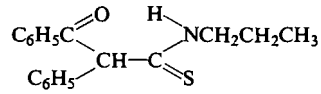


SCHEME 6

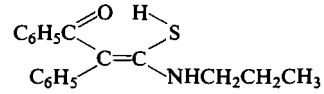
Treatment with propylamine in chloroform solution at room temperature provided such a method. The reaction mixture rapidly assumed a bright red color, which slowly faded; further addition of amine resulted in regeneration of the red color until 2 molar equivalents had been added. The characteristic odor of hydrogen sulfide indicated its formation during the reaction. Two compounds were isolated by fractional crystallization of the product mixture.

The lower melting, more soluble compound, $C_{18}H_{19}NOS$, is assigned structure **24** on the following basis. On treatment with dilute aqueous sodium hydroxide at room temperature, it slowly dissolves, after which an oily product separates from solution. The latter product was shown to be the thio amide **25** by direct comparison with a sample prepared from the reaction of benzylmagnesium chloride with propyl isothiocyanate. Acidification of the basic solution from the hydrolysis reaction gave benzoic acid. Thus the compound $C_{18}H_{19}NOS$ must be a benzoyl derivative of **25**; the only such derivative that would be expected to be base-soluble is **24**, which could form the anion **26** (Scheme 6). In accord with this assignment, a solution of the compound rapidly gave a black precipitate when treated with mercuric oxide, indicating the presence of a thiocarbonyl group (12).

The spectroscopic data for compound **24** are in good accord with the assigned structure and show that this compound has the preferred conformation ***24a*** in solution. Its i.r. spectrum showed a single carbonyl-stretching band at 5.98 μ, assigned to the hydrogen-bonded benzoyl carbonyl group in ***24a***; it also showed a band at 3.01 μ (with shoulder at 2.95 μ) attributable to a hydrogen-bonded N—H stretching vibration (the shoulder may result from the presence of conformations other than ***24a***). Its u.v. spectrum in methanol showed maxima at 249 (ε 15 900) and 265 mμ (infl., ε 12 300), attributable to the benzoyl and thio amide groups, respectively [*cf.* thioacetamide λ_{max}(EtOH) 265 mμ (ε 13 800) (13)].



24a

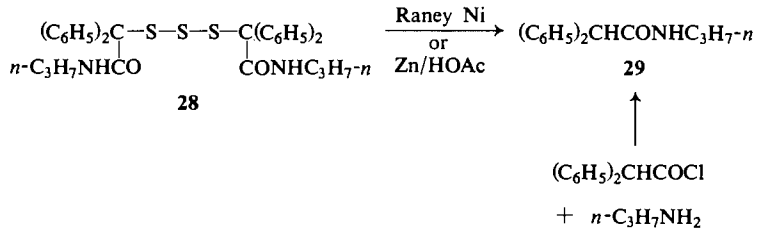


24b

When the u.v. spectrum was recorded in methanolic sodium methoxide these maxima were shifted to 273 (ε 7800) and 340 mμ (ε 15 100), a change that can be attributed to formation of the anion **26**. Its p.m.r. spectrum showed signals at δ 0.9(t), 1.55(m), and 3.42(m), assigned to the *N*-propyl protons, a singlet at 6.30, assigned to the benzylic proton, multiplets at 7.33 and 8.05, assigned to the phenyl protons, and a broad signal at 9.30, in good accord with the presence of a strongly hydrogen-bonded thio amide proton.

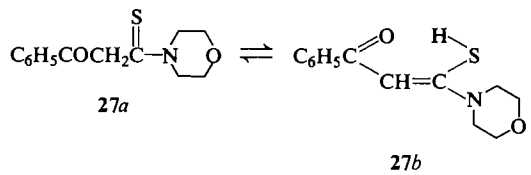
The spectral data exclude the possibility that **24** exists in solution as the enethiol tautomer ***24b***. This would be expected to show i.r. and u.v. bands at much longer wavelengths than those observed (1, 5, 10). Further, the p.m.r. spectrum of such a species would be expected to show a signal at $\delta \gg 10$, due to chelate-type hydrogen bonding. Although β-keto dithio acids and their derivatives

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.



SCHEME 7

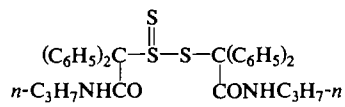
often exist to a significant extent as the corresponding enethiol tautomers (5, 10), it is not surprising in the present case that **24***a* should be favored over **24***b*. Gompper and Schaefer (14) have found that the β-keto thioamide **27** exists in the solid state in the unenolized form **27***a*, and that in solution in chloroform the tautomer ratio **27***a*:**27***b* is 6:4. It would be expected in the case of



27*a* **27***b*

24 that the unenolized form **24***a* would be considerably more favored than in the case of **27***a*, both because **24***a* derives additional stabilization from hydrogen bonding and because **24***b* is destabilized more than **24***a* by steric interactions between the phenyl groups.

The second compound isolated from the aminolysis of the compound $C_{29}H_{20}O_2S_2$ was found to have the formula $C_{34}H_{36}N_2O_2S_3$. It is assigned structure **28** on the basis of the following data. Reduction with either Raney nickel or zinc and acetic acid gave 2 molar equivalents of the amide **29**, whose structure was established by direct comparison with a sample prepared from diphenylacetyl chloride and propylamine (Scheme 7). The compound $C_{34}H_{36}N_2O_2S_3$ was insoluble in dilute aqueous sodium hydroxide and failed to give a sodium nitroprusside test, indicating the absence of sulfhydryl groups (15); it also failed to react with mercuric oxide, indicating the absence of thione groups (12). The sulfur atoms must then be present as sulfide or polysulfide linkages joining two residues related to **29**. The removal of all three sulfur atoms by treatment with zinc and acetic acid can then only be interpreted in terms of the structural assignment **28** or the closely related branched trisulfide **30**. Although the latter structure cannot be excluded rigorously, structure **28** is preferred since branched bonding at sulfur appears to occur only in those cases in which the sulfur atom to which the branch is attached is also bonded to a highly electronegative atom (16).



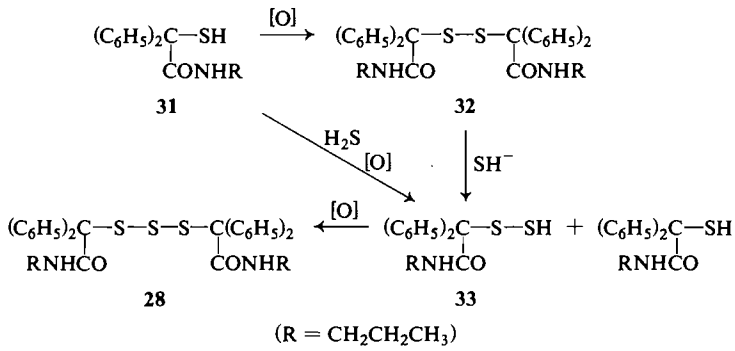
30

The i.r. and u.v. spectra of the compound $C_{34}H_{36}N_2O_2S_3$ are in good accord with the assignment of structure **28**. The former showed all the bands of **29** and no others of appreciable intensity. This is in agreement with expectation since neither C—S nor S—S single bonds give rise to bands of high intensity (17). The u.v. spectrum showed no clear cut maxima but medium intensity absorption at 300 mμ rising steadily to high intensity end absorption with an inflection at *ca.* 270 mμ (ε 6500). In appearance it is strikingly similar to the u.v. spectrum of dibenzyl disulfide (18), although greater in intensity. It can be interpreted in terms of overlap of absorption due to geminal phenyl groups (19) and the trisulfide group (*cf.* ref. 20).

The three-sulfur compound **28** must have arisen in a secondary reaction after the primary aminolysis (Scheme 8). Its precursor is clearly the thiol **31**. It could be formed from this via air oxidation to the disulfide **32** (*cf.* the formation of the disulfide **4** during the hydrolysis of **9**) followed by attack of hydrosulfide ion (the formation of hydrogen sulfide during the reaction has already been noted) to give **33** and oxidative coupling of this with **31**; alternatively, **33** might arise via oxidative coupling of **31** with hydrogen sulfide. The yield of **28** was only 39%, and it is possible that the reaction mixture also contained **32** and the tetrasulfide corresponding to **33**.

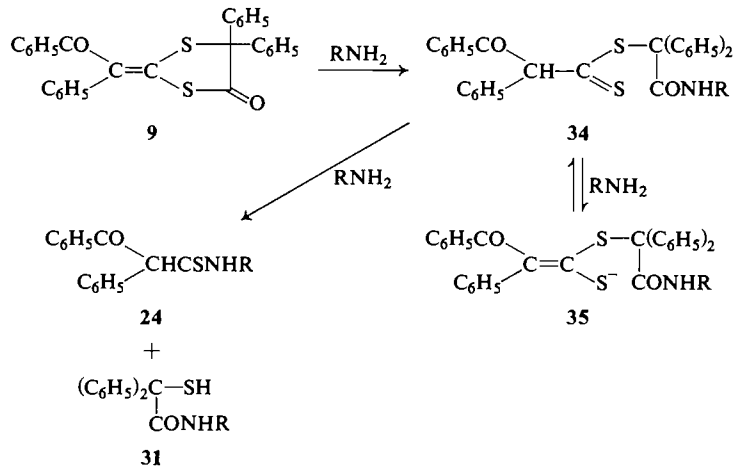
The formation of **24** and **31** on treatment of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.



(R = $CH_2CH_2CH_3$)

SCHEME 8



(R = $CH_2CH_2CH_3$)

SCHEME 9

compound $C_{29}H_{20}O_2S_2$ is readily interpretable in terms of structure **9** for that compound as shown in Scheme 9. This scheme accounts for the formation of a red-colored species during the course of the reaction, the anion **35** of the β-keto dithio ester **34**. The hydrogen sulfide observed to be formed could arise by reaction of **24** or **35** with propylamine (*cf.* ref. 21).

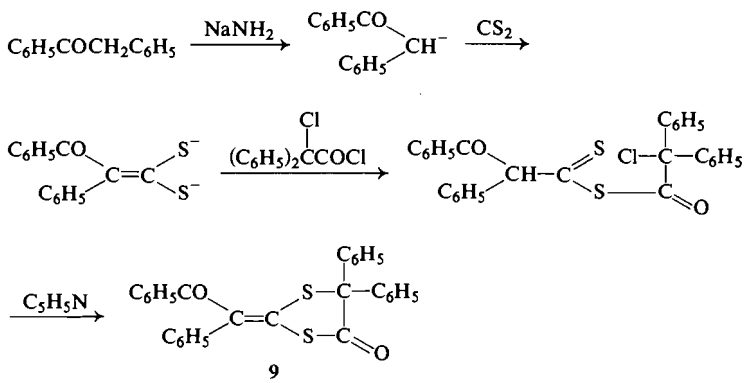
The isolation of the product **28** from a reaction carried out under such mild conditions supports the earlier conclusion that a geminal phenyl grouping is present in the compound $C_{29}H_{20}O_2S_2$ and that its structure is better represented by **9** than by **10**.

The choice of structure **9** was finally vindicated by an alternative synthesis of the compound $C_{29}H_{20}O_2S_2$, albeit in very low yield, by the route shown in Scheme 10. This route was adopted in analogy to that used for the synthesis of **6** (5). The product obtained in this way was identical in all respects with that formed in the reaction of azibenzil with carbon disulfide.

The degradative and synthetic evidence presented in favor of the assignment of structure **9** do not exclude the closely related structure **36**, a valence bond isomer of **9** containing a tetracovalent sulfur atom. This might account for the apparent [10] relatively low intensity of the band assigned to the carbonyl-stretching vibration of the benzoyl group in **9**. However, X-ray crystallographic studies in related cases of compounds with the *s-cis* grouping **37** have shown that although the S—O distances are considerably

[10]No quantitative intensity measurements have been made; *cf.* refs. 1 and 5.

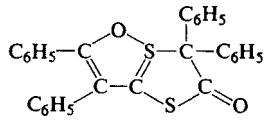
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.



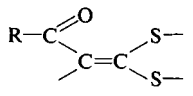
9

SCHEME 10

shorter than the sum of the van der Waals' radii of sulfur and oxygen, they are appreciably longer than the normal S—O covalent bond length (22). Furthermore, Kapecki and Baldwin (23) have concluded from extended Hückel molecular orbital calculations that covalent bonding between sulfur and oxygen is negligibly weak in related cases. Thus structure **9** is considered to be the best representation of the compound $C_{29}H_{20}O_2S_2$, although there may be weak bonding between the oxygen atom of the benzoyl group and one of the sulfur atoms.[11]



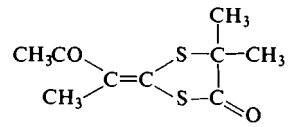
36



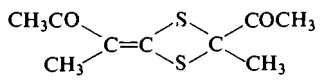
37

A variety of pathways can be envisaged for the formation of **9** from azibenzil and carbon disulfide. All must involve at some stage the rearrangement of one of the two azibenzil residues that are incorporated into the product. In one type of mechanism this is accomplished by a Wolff rearrangement of azibenzil to diphenylketene. However, it has been found that addition of diphenylketene to the reaction mixture of azibenzil and carbon disulfide does not increase the yield of the product, and it thus appears unlikely that diphenylketene is an intermediate. An alternative type of mechanism is illustrated in Scheme 11. Electrophilic attack by carbon disulfide on azibenzil could give **38**; loss of nitrogen would then give **39**. Alternatively, this could be formed via **40**, whose formation would find analogy in the reaction of aliphatic diazo compounds with thiones (24). Reaction of **39** with a second molecule of azibenzil would give **42**, either directly or via **41**. Elimination of nitrogen from **42** accompanied by phenyl group migration would give **9**.[12]

The reaction of two other α-diazo ketones with carbon disulfide have been reported recently. 3-Diazo-2-butanone (**43**) was found to react with carbon disulfide to give a product, $C_9H_{12}O_2S_2$, that was originally assigned structure **44** by analogy with the case of azibenzil (25). However, its structure was subsequently shown to be **45** by



44



45

X-ray crystallography (22*b*). It is possible to interpret this behavior in terms of Scheme 11. In the case of 3-diazo-2-butanone the rearrangement corresponding to the step **42** → **9** requires the migration of a methyl group rather than a phenyl group as in the case of azibenzil. It may be anticipated that such a migration will be less ready,

[11]It should be reemphasized here that the geometry depicted about the ethylenic double bond in **9** is arbitrary and no evidence is available regarding the configuration or conformation of the product.

[12]It is not excluded that the processes depicted in Scheme 11 occur in a more concerted fashion.

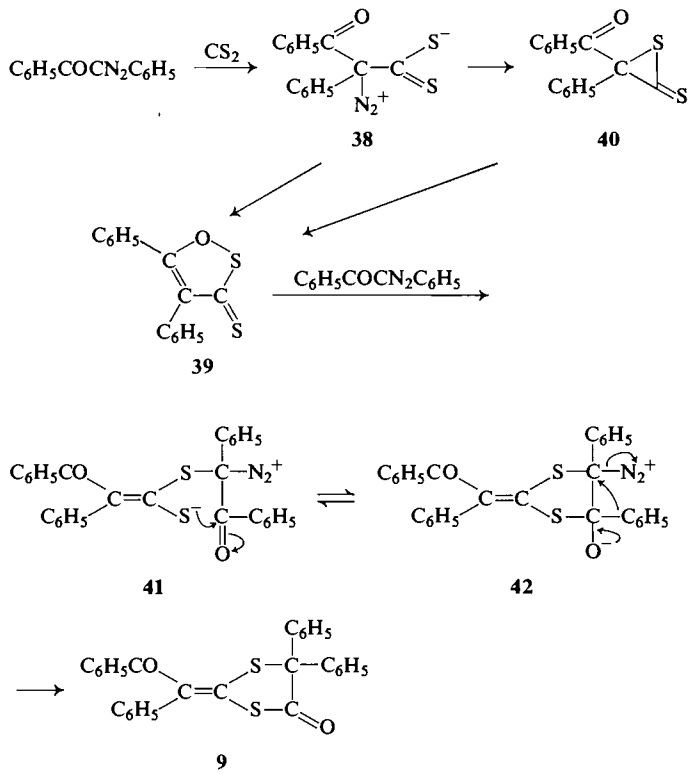
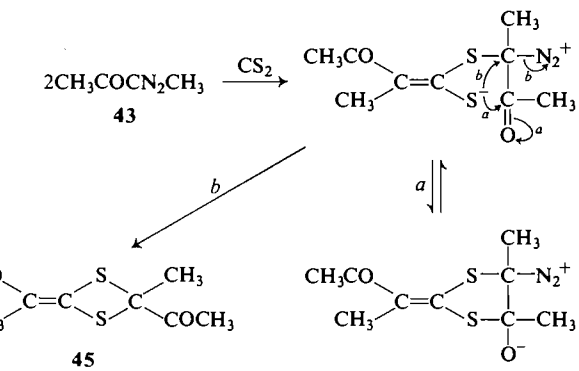


SCHEME 11



SCHEME 12

and, if the intermediate corresponding to **42** is formed reversibly from that corresponding to **41**, an alternative pathway could be traversed from the latter, leading to the formation of **45** (Scheme 12).

Baldwin and Kapecki (26) have investigated the reaction of *p*-fluorobenzoyl-*p*-fluorophenyldiazomethane (**46**) with carbon disulfide. They obtained as the major product a compound $C_{29}H_{16}F_4O_2S_2$, analogous in composition to **9** and **45**. They concluded that this product was better represented by structure **47**, analogous to **9**, than by a structure analogous to **45**, on the basis of its ^{19}F n.m.r. spectrum, which showed three signals with an intensity ratio of 1:1:2 in both tetrahydrofuran and bromoform solution [*cf.* **45**, which shows in its p.m.r. spectrum four methyl proton signals (25)]. The preferential for-

46 47

mation of **47** can again be interpreted in terms of the above rationale.

Experimental

Solutions in organic solvents were dried over anhydrous sodium sulfate, unless otherwise indicated. The i.r. spectra were taken in chloroform solution unless otherwise indicated.

Reaction of Azibenzil with Carbon Disulfide (4). Formation of 9

Azibenzil (22.0 g, 106 mmol), prepared by the method of Nenitzescu and Salomonica (27), was dissolved in carbon disulfide (120 ml, 1.99 mol). The solution was boiled under reflux for 36 h. Carbon disulfide was removed by heating the solution on the steam bath at water aspirator pressure until the product began to crystallize. The mixture was then cooled in an ice bath, and the product was filtered. It was washed with ether and recrystallized from carbon disulfide to give **9** as a pale yellow crystalline solid (22.5 g, 92%), m.p. 154–155° [lit. (4) m.p. 153–154°]; λ_{max} 5.86, 5.98 (w), 6.17 μ (mw); $\lambda_{max}(CHCl_3)$ 254 (ε 17 000), 347 mμ (ε 13 800).

Anal. Calcd. for $C_{29}H_{20}O_2S_2$: C, 74.97; H, 4.34; S, 13.80. Found: C, 74.83; H, 4.46; S, 13.71.

Compound **9** was recovered unchanged after treatment with yellow mercuric oxide in boiling benzene for 30 min and with boiling 2% alcoholic silver nitrate for 15 min.

Basic Hydrolysis of 9

A mixture of **9** (12.0 g, 25.8 mmol) and a solution of potassium hydroxide (16.0 g, 285 mmol) in 95% ethanol (50 ml) was boiled under reflux for 7 h. It was cooled to room temperature, diluted with a four-fold excess of water, and acidified to p*H* 1 with concentrated hydrochloric acid, when hydrogen sulfide was evolved. The mixture was heated on the steam bath for a few minutes, cooled, neutralized with aqueous 10% sodium bicarbonate, and filtered. The filtrate was acidified (p*H ca.* 1) and extracted three times with ether. The combined ethereal extracts were dried and evaporated on the steam bath to give a solid (10.4 g). This was extracted three times with petroleum ether (b.p. 30–60°). The red oil (4.8 g) that remained undissolved was extracted with benzene. Evaporation of the benzene from this extract afforded a white solid (100 mg), m.p. 194–196° (dec.). This product was soluble in aqueous 5% sodium bicarbonate with evolution of carbon dioxide and after several recrystallizations from carbon disulfide had m.p. 199.5–200.5° dec.; λ_{max}(KI) 5.99 μ.

Anal. Calcd. for $C_{28}H_{22}O_4S_2.H_2O$ (mol. wt. 504): C, 66.64; H, 4.80; S, 12.71. Found (neut. equiv. 247): C, 66.32; H, 4.76; S, 13.13.

The m.p. of authentic 2,2,5,5-tetraphenyl-3,4-dithiaadipic acid (**4**) (*vide infra*) was undepressed on admixture with this product; the i.r. spectra of the two samples were identical.

An ethereal solution of diazomethane (5.9 mmol) was added to a solution of the degradation product (100 mg, 2.0 mmol) in dioxane. The dioxane was evaporated at oil pump pressure on the steam bath, and the resulting methyl ester was crystallized from benzene: m.p. 130.5–131.5°; λ_{max} 5.79 μ.

Anal. Calcd. for $C_{30}H_{26}O_4S_2$: C, 70.01; H, 5.09; S, 12.46. Found: C, 69.65; H, 5.08; S, 12.12.

The m.p. of the methyl ester was undepressed on admixture with authentic dimethyl 2,2,5,5-tetraphenyl-3,4-dithiaadipate (*vide infra*); the i.r. spectra of the two samples were identical.

The petroleum ether - soluble fraction from the basic hydrolysis of **9** weighed 5.0 g. Examination of the i.r. spectra of this fraction in both carbon disulfide and chloroform corroborated Meyer's earlier observation (4) that this was a mixture of benzoic and phenylacetic acid. Quantitative analysis by means of i.r. spectroscopy demonstrated that it was composed of 2.2 g (70%) of benzoic acid and 2.8 g (80%) of phenylacetic acid.

It was subsequently found that such drastic conditions are not necessary to effect the basic hydrolysis of **9**, which was completely hydrolyzed in a 2.5% sodium hydroxide solution in dioxane–water at room temperature overnight.

2,2,5,5-Tetraphenyl-3,4-dithiaadipic Acid (4)

2,2,5,5-Tetraphenyl-3,4-dithiaadipic acid was prepared by the method of Becker and Bistrzycki (28) from thiobenzilic acid (28) in 70% yield; m.p. 192.0–193.5° (dec.).

Dimethyl 2,2,5,5-Tetraphenyl-3,4-dithiaadipate

Dimethyl 2,2,5,5-tetraphenyl-2,4-dithiaadipate was prepared by reaction of **4** with ethereal diazomethane as above; m.p. 130.5–131.5°.

Acidic Hydrolysis of 9

Compound **9** (10.0 g, 21.5 mmol) was added to a mixture of glacial acetic acid (300 ml), concentrated sulfuric acid (50 ml), and water (50 ml). The mixture was boiled under reflux for 2 days, poured into water (2 l), and extracted six times with ether. The combined ethereal extracts were extracted with aqueous 5% sodium bicarbonate until carbon dioxide was no longer evolved. The sodium bicarbonate extract was acidified to p*H ca.* 1 with concentrated hydrochloric acid and extracted six times with ether. Both the acidic and neutral fractions were dried and evaporated to dryness on the steam bath.

The acidic fraction, which contained much acetic acid, was kept in a vacuum desiccator over potassium hydroxide pellets until the odor of acetic acid was absent. It was crystallized from aqueous ethanol to give colorless crystals of diphenylacetic acid (3.10 g, 68%), m.p. 145–147°, undepressed on admixture with an authentic sample. The neutral fraction yielded sulfur (1.30 g, 94%) as yellow needles, m.p. 116–118.5° [lit. (29) m.p. of monoclinic sulfur, 119°]. Its identity was confirmed by the fact that it burned with a blue flame, liberating sulfur dioxide and leaving no residue.

For personal use only.

The remainder of the neutral fraction (5.30 g) showed all the bands of deoxybenzoin in its i.r. spectrum. It was converted to its 2,4-dinitrophenylhydrazone by the method of Shriner *et al.* (30). This was recrystallized from ethyl acetate to give orange crystals (3.60 g, 50%), m.p. 200–201°, undepressed on admixture with an authentic sample of the 2,4-dinitrophenylhydrazone of deoxybenzoin.

Desulfurization of **9** *with Raney Nickel*

The W-2 Raney nickel catalyst was prepared by the method of Mozingo (31). This was deactivated by a modification of the procedure of Spero *et al.* (32). The W-2 Raney nickel catalyst (50.0 g) was washed twice by decantation with acetone and heated in boiling acetone (150 ml) under reflux for 2 h. The catalyst was then washed twice by decantation with ethyl acetate, heated in boiling ethyl acetate (150 ml) under reflux for 2 h, and washed twice by decantation with ethanol.

The deactivated W-2 Raney nickel catalyst (50.0 g, 1.78 g-atoms) was suspended in ethanol (250 ml), **9** (5.00 g, 10.8 mmol) was added, and the mixture was boiled under reflux in a nitrogen atmosphere for 24 h. Examination of the i.r. spectrum of an aliquot of the reaction mixture showed that all of the starting material had been consumed. The mixture was filtered free of the catalyst and evaporated to dryness on the steam bath at water aspirator pressure to give an oil (4.70 g).

A solution of this oil (4.35 g) in petroleum ether (b.p. 30–60°; 75 ml) was chromatographed on Merck alumina (150 g). The column was developed with petroleum ether, and 50 ml fractions were collected. Fractions 1 and 2 gave diphenylmethane (190 mg), which was purified by vacuum distillation; b.p. 70–75° (1 mm); n_D^{24} 1.5761. This was identified by its characteristic odor and the identity of its i.r. spectrum with that of an authentic sample; n_D^{24} 1.5763.

Further elution of the column gave an oil (fractions 13–15). One gram of this oil was subjected to a series of seven successive chromatographic separations. In each case Merck alumina (40 g) was used, and 10 ml fractions were collected. The oil was thus separated into two components. The i.r. spectra of these two compounds were identical in every respect to those of methyldeoxybenzoin and ethyl diphenylacetate.

To corroborate the identification of these products, the oil (1.00 g) was heated for 3 h with boiling aqueous 5% sodium hydroxide (25 ml) and ethanol (10 ml) under reflux. The reaction mixture was diluted three-fold with water and extracted three times with ether to give the neutral fraction. The aqueous layer was acidified to p*H ca.* 1 with concentrated hydrochloric acid and extracted three times with ether to give the acidic fraction. Both fractions were dried and evaporated to dryness on the steam bath. The acidic fraction was crystallized from aqueous ethanol to give diphenylacetic acid (300 mg, 66%), m.p. 144–145.5°, undepressed on admixture with an authentic sample; the i.r. spectra of the two samples were identical.

The neutral fraction (410 mg, 73%) was a colorless oil. This was converted to its 2,4-dinitrophenylhydrazone by the method of Shriner *et al.* (30). The orange crystalline product was recrystallized from ethyl acetate: m.p. 151.5–152.5°, undepressed on admixture with an authentic sample of the 2,4-dinitrophenylhydrazone of methyldeoxybenzoin (*vide infra*).

When W-6 Raney nickel catalyst (33) was used for the desulfurization in place of the less reactive deactivated W-2 Raney nickel catalyst, a product mixture of different composition was obtained. Reaction with **9** (5.00 g) yielded 640 mg of diphenylmethane, and the amount of methyldeoxybenzoin was greatly reduced. The product mixture was separated by chromatography and vacuum distillation. Ethyl diphenylacetate was isolated and crystallized from aqueous ethanol: m.p. 57–58°, undepressed on admixture with an authentic sample; the i.r. spectra of the two samples were identical.

Methyldeoxybenzoin 2,4-Dinitrophenylhydrazone

Methyldeoxybenzoin was prepared by the method of Meyer and Oelkers (34) in 65% yield; b.p. 140–145° (5 mm); λ_{max} 5.95, 7.28 μ (m). It was converted to its 2,4-dinitrophenylhydrazone by the method of Shriner *et al.* (30); m.p. 151.5–152.5°.

Anal. Calcd. for $C_{21}H_{18}O_4N_4$: C, 64.60; H, 4.65; N, 14.35. Found: C, 64.78; H, 4.86; N, 14.81.

Reduction of **9** *by Zinc and Acetic Acid. Formation of* **12**

To a boiling solution of **9** (1.00 g, 2.15 mmol) in glacial acetic acid (15 ml), zinc dust (1.00 g, 15.3 mg-atoms) was added with swirling over a period of 20 min. The solution was filtered, and three drops of concentrated hydrochloric acid were added to the filtrate (p*H ca.* 1). The solution was added to a large excess of water, and the mixture was extracted with dichloromethane. The extract was washed three times with saturated aqueous sodium bicarbonate and three times with water, dried, and evaporated on the steam bath. The residual oil (700 mg) was crystallized from benzene – petroleum ether (b.p. 30–60°) to yield **12** (140 mg, 14%) as a colorless, crystalline solid, m.p. 209.5–210.5°; λ_{max} 5.94 μ (br), λ_{max}(EtOH) 252 mμ (ε 15 900); δ ($CDCl_3$) 4.62 (d, J = 11 Hz, 1H), 5.28 (d, J = 11 Hz, 1H), 7.2–7.5 (m, 18H), 7.67 (m, 2H).

Anal. Calcd. for $C_{29}H_{22}O_2S_2$: C, 74.67; H, 4.75; S, 13.72. Found: C, 74.69; H, 5.03; S, 13.90.

Although the i.r. spectrum of the oil showed only the bands of the reduction product **12**, attempts to obtain further crystalline product from it failed.

Basic Hydrolysis of **12**

A mixture of **12** (1.00 g, 2.15 mmol) and a solution of potassium hydroxide (1.50 g, 26.7 mmol) in 95% ethanol (10 ml) was boiled under reflux for 7 h. The reaction mixture was diluted with water, acidified to p*H ca.* 1 with concentrated hydrochloric acid, heated on the steam bath for 10 min, and allowed to cool to room temperature. It was then extracted three times with ether, and the combined ethereal extracts were extracted three times with aqueous 5% sodium bicarbonate. The bicarbonate extract was acidified with concentrated hydrochloric acid to p*H ca.*1 and extracted three times with ether to obtain the acidic fraction. Both acidic and neutral fractions were dried and evaporated on the steam bath.

The neutral fraction (330 mg, 79%) showed all of the bands of deoxybenzoin in its i.r. spectrum. A 2,4-dinitrophenylhydrazone of this fraction was made (30) and crystallized from ethanol: m.p. 200–201°, undepressed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.

upon admixture with authentic deoxybenzoin 2,4-dinitrophenylhydrazone.

The acidic fraction (420 mg, 91%), whose i.r. spectrum was identical with that of diphenylacetic acid, was crystallized from aqueous ethanol to yield colorless crystals of diphenylacetic acid, m.p. 145–146°, undepressed on admixture with an authentic sample.

Desulfurization of ***12*** *with Raney Nickel*

A mixture of **12** (1.00 g, 2.14 mmol), W-2 Raney nickel catalyst (31) (2.00 g), and ethanol (50 ml) was stirred under a nitrogen atmosphere for 2 days. The mixture was filtered, and the filtrate was stripped of ethanol on a steam bath under vacuum. The resulting oil had an i.r. spectrum identical with that of the oil from the Raney nickel desulfurization of **9**. It was heated with a boiling mixture of aqueous 5% sodium hydroxide (15 ml) and ethanol (3 ml) for 3 h. After cooling to room temperature, the mixture was poured into a three-fold excess of water and extracted with ether to give the neutral fraction. The aqueous layer was acidified with concentrated hydrochloric acid to p*H ca.* 1 and extracted with ether three times to give the acidic fraction. Both fractions were dried and evaporated on the steam bath.

The acid fraction on crystallization from aqueous ethanol gave diphenylacetic acid (160 mg, 36%) m.p. 144–146°, undepressed on admixture with an authentic sample.

Lixiviation of the partially crystalline neutral fraction with ethanol yielded *sym*-tetraphenylethane (30 mg) as colorless crystals, m.p. 210–211° after recrystallization from benzene. The m.p. was undepressed upon admixture with authentic *sym*-tetraphenylethane.

Excess ethanol was evaporated from the filtrate to give an oil (400 mg, 89%) whose i.r. spectrum showed all of the bands of methyldeoxybenzoin. Its 2,4-dinitrophenylhydrazone was prepared (30) and crystallized from ethanol; m.p. 151–152.5°. A mixture melting point with an authentic sample of the 2,4-dinitrophenylhydrazone of methyldeoxybenzoin showed no depression.

Ozonolysis of ***9***

A solution of **9** (1.00 g, 2.15 mmol) in dichloromethane (50 ml) was cooled to 0°, and maintained at this temperature throughout the ozonolysis. Ozone from a Welsbach ozonizer was bubbled through the solution for 3 h.The ozonide was decomposed by the addition of water (20 ml). The dichloromethane was removed under water aspirator pressure, first at room temperature and finally on the steam bath. The aqueous solution was extracted four times with ether, and the combined ethereal extracts were extracted six times with aqueous 5% sodium hydroxide. The ethereal layer was dried and evaporated on the steam bath to give the neutral fraction. The aqueous layer was neutralized with concentrated hydrochloric acid to p*H ca.* 1 and extracted four times with ether. The combined ethereal extracts were dried and evaporated on the steam bath to give the acidic fraction.

The original aqueous solution was allowed to stand at room temperature until it had evaporated. The residue (150 mg) was dissolved in water to give an acidic solution (p*H ca.* 1). Neutralization of this solution to the methyl red end-point with aqueous 5% barium hydroxide gave a precipitate of barium sulfate (20 mg).

The neutral fraction (630 mg) was distilled at 100° (1 mm) to give an oil (410 mg) that showed all of the bands of benzil in its i.r. spectrum. This was treated with 2,4-dinitrophenylhydrazine reagent (30), and the product was crystallized from ethanol to give benzil 2,4-dinitrophenylhydrazone, m.p. 194–195°, undepressed on admixture with an authentic sample.

The acidic fraction (170 mg) was sublimed at 50° (1 mm) for 6 h. The sublimate (110 mg) was crystallized from water to give benzoic acid, m.p. 120–121.5°, undepressed on admixture with an authentic sample. Distillation of the sublimation residue from the acidic fraction at 150° (1 mm) gave an oil (30 mg). This oil showed all of the bands of diphenylacetic acid in its i.r. spectrum; however, it contained benzoic acid since all of the bands of the latter were also present in the spectrum.

In another ozonolysis, the ozonide was decomposed with zinc and acetic acid by the method of Noller and Adams (35). Glacial acetic acid (10 ml) was added to the ozonide, and the dichloromethane was removed at water aspirator pressure and room temperature. Ether (40 ml) was added, and the mixture was stirred and treated with zinc dust (1.00 g) and three drops of water. Further zinc dust (9.00 g) was added in small portions, followed by water (1 ml). The mixture was boiled under reflux until it gave a negative test with starch–iodide paper (*ca.* 15 min). It was then filtered, and the zinc salts were washed several times with ether. The combined filtrate and washings were washed several times with aqueous 10% sodium carbonate and once with water. The sodium carbonate extract was acidified to obtain the acidic fraction. The ethereal layer was dried and evaporated on the steam bath to give the neutral fraction (250 mg), which was crystallized from benzene to give benzoin, m.p. 132–134°, undepressed on admixture with an authentic sample; the i.r. spectra of the two samples were identical.

Oxidation of ***9*** *with Perphthalic Acid. Formation of* ***16***

Compound **9** (5.00 g, 10.8 mmol) was added to a solution of perphthalic acid (33.5 mmol) in ether (500 ml). The mixture was stirred at room temperature for 2 days. The solution was evaporated at water aspirator pressure without the application of external heat. The residue was digested with chloroform (250 ml) that had stood over anhydrous sodium sulfate for 3 h. The mixture was filtered, and the filtrate was evaporated to dryness. The product was crystallized from ethanol to give **16** (4.10 g, 79%), m.p. 148–150° (dec.); λ_{max} 5.83, 5.97 μ; λ_{max} 263 (ε 23 400), 287 mμ (sh, ε 16 000).

Anal. Calcd. for $C_{29}H_{20}O_3S_2$: C, 72.47; H, 4.20; S, 13.35. Found: C, 72.28; H, 4.19; S, 13.14.

Reduction of ***16*** *with Zinc and Acetic Acid*

A mixture of **16** (82 mg, 0.17 mmol), acetic acid (10 ml), and zinc dust (39 mg, 0.70 mmol) was stirred at room temperature for 30 min. The solution was decanted into ether (30 ml), and the ethereal solution was washed twice with water, three times with aqueous 5% sodium bicarbonate, and again with water. It was dried over anhydrous magnesium sulfate and evaporated to give a yellow glass (80 mg). This was crystallized from ether to give **9** as pale yellow crystals (10 mg, 13%), m.p. 153–155°. One recrystallization from carbon disulfide gave material, m.p. 153.5–155°, undepressed on admixture with an authentic sample of **9**, the i.r. spectra of the two samples were identical.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.

Basic Hydrolysis of ***16***

A mixture of compound **16** (1.00 g, 2.09 mmol), ethanol (25 ml), and aqueous 5% sodium hydroxide (25 ml) was boiled under reflux for 3 days. The mixture was poured into an excess of water, acidified to p*H ca.* 1 with concentrated hydrochloric acid, and extracted three times with ether, with filtration to remove the insoluble yellow precipitate that appeared. This precipitate was crystallized from chloroform to give **7** (220 mg, 45%), m.p. 300.5–302.5° (dec.), undepressed on admixture with an authentic sample (*5b*).

The ethereal extract was dried and evaporated to give a liquid (330 mg, 87%) that showed all of the bands of benzophenone in its i.r. spectrum. Its 2,4-dinitrophenylhydrazone was prepared (30) and crystallized from ethyl acetate – ethanol; m.p. 238–240°, undepressed on admixture with an authentic sample of the 2,4-dinitrophenylhydrazone of benzophenone.

Acidic Hydrolysis of ***16***

A mixture of **16** (1.00 g, 2.09 mmol), ethanol (25 ml), and concentrated hydrochloric acid (25 ml) was boiled under reflux for 2 days. The mixture was poured into a four-fold excess of water and extracted four times with ether, and the combined ethereal extracts were extracted four times with aqueous 10% sodium bicarbonate. The sodium bicarbonate extract was acidified to p*H ca.* 1 with concentrated hydrochloric acid and extracted four times with ether. These ethereal extracts were combined, dried, and evaporated on the steam bath to give the acidic fraction (160 mg). This was crystallized from aqueous ethanol to give benzilic acid, m.p. 148–149°, undepressed on admixture with an authentic sample; the i.r. spectra of the two samples were identical.

The neutral fraction showed all of the bands of the starting material **16** in its i.r. spectrum.

Reaction of ***9*** *with n-Propylamine. Formation of* ***24*** *and* ***28***

To a solution of **9** (5.00 g, 11.0 mmol) in chloroform (50 ml) was added *n*-propylamine (2.0 ml, 1.4 g, 24 mmol). The pale yellow solution rapidly acquired a bright red color, which faded to pale orange after the solution had stood for 2 h at room temperature, when the characteristic odor of hydrogen sulfide could be detected. Addition of further *n*-propylamine (0.50 ml, 350 mg, 6.0 mmol) produced only a slight intensification of the orange color. After a further 4 h at room temperature the chloroform and excess amine were removed by evaporation at room temperature and water aspirator pressure. The residual orange oil was dissolved in a small amount of ether, and the solution was stored at −10°. After 2 days the solid (750 mg) that had separated was filtered and washed well with ether; the mother liquor was concentrated and again cooled to −10°. After a further 3 days a second crop of solid (600 mg) was separated as before. The first crop had m.p. 164–166°, and the second had m.p. 166–168°; their i.r. spectra were virtually identical. Combination and recrystallization from benzene–ligroin gave fine colorless needles of **28** (1.30 g, 39%), m.p. 167–168°. Two more recrystallizations from benzene–ligroin gave an analytical sample, m.p. 167–168°; λ_{max} 2.91 (w), 2.94 (sh), 2.98 (sh), 6.01 μ; λ_{max}(MeOH) *ca.* 270 mμ (inflexion, ε 6500); ε_{235} 25 000.

Anal. Calcd. for $C_{34}H_{36}N_2O_2S_3$: C, 68.02; H, 6.03; N, 4.65; S, 15.98. Found: C, 67.87; H, 5.98; N, 4.67; S, 16.20.

A benzene solution of **28** on treatment with yellow mercuric oxide underwent no reaction in 30 min.

Crystallization of the remainder of the original reaction product from ether yielded a yellowish solid (1.05 g) whose i.r. spectrum suggested that it was a mixture. The remaining product was crystallized from ether – petroleum ether by cooling at −10° to give **24** as a faintly yellow solid (1.20 g, 37%), m.p. 62–64°. Four more recrystallizations from ether – petroleum ether gave fluffy white needles, m.p. 66–67°; $\lambda_{max}(CCl_4)$ 2.95 (sh), 3.01 (m), 5.98 μ; λ_{max}(MeOH) 249 (ε 15 900), 265 (inflexion, ε 12 300) mμ; λ_{max}(MeOH–MeONa) 273 (ε 7800), 340 mμ (ε 15 100); δ 0.90 (t, J = 7 Hz, 3H), 1.55 (m, 2H), 3.42 (m, 2H), 6.30 (s, 1H), 7.33 (m, 8H), 8.05 (m, 2H), 9.30 (br, s, 1H).

Anal. Calcd. for $C_{18}H_{19}NOS$: C, 72.70; H, 6.44; N, 4.71; S, 10.76. Found: C, 72.76; H, 6.63; N, 4.52; S, 10.65.

A benzene solution of **24** on treatment with yellow mercuric oxide developed a black precipitate within 10 min.

Reaction of ***24*** *with Aqueous Base*

A mixture of **24** (271 mg, 0.91 mmol) and aqueous 5% sodium hydroxide (20 ml) was stirred vigorously at room temperature. After 20 min all but a few crystals had dissolved to give a yellow solution, from which an oil soon began to separate. After 3 h the mixture was extracted with two 20 ml portions of ether. The extracts were combined, dried over anhydrous magnesium sulfate, and evaporated to give a pale yellow oil (105 mg) that crystallized on standing; the i.r. spectrum of this material showed only very weak absorption in the 5.8–6.1 μ region. Two recrystallizations from ether – petroleum ether gave α-phenyl-*N*-*n*-propylthioacetamide (**25**) as colorless needles (49 mg, 28%), m.p. 55.5–57°, undepressed on admixture with an authentic sample (*vide infra*); the i.r. spectra of the two samples were identical.

In another run **24** (192 mg, 0.65 mmol) was stirred for 3 h with aqueous 5% sodium hydroxide (10 ml). After separation of the neutral product, the solution was acidified with hydrochloric acid and extracted with two 20 ml portions of ether. These were dried over magnesium sulfate and evaporated to give an off-white solid (86 mg), whose i.r. spectrum was very similar to that of benzoic acid. Sublimation of the solid at 50° (1 mm) gave colorless crystals (55 mg), m.p. 106–113°. Recrystallization first from aqueous ethanol and then cyclohexane gave benzoic acid as colorless crystals (14 mg, 18%), m.p. 120–122°, undepressed on admixture with an authentic sample.

*α-Phenyl-N-n-propylthioacetamide(****25****)*

n-Propyl isothiocyanate was prepared by the method used previously for the preparation of methyl isothiocyanate (36). It was obtained in 73% yield as a colorless liquid, b.p. 150–152° [lit. (37) b.p. 153°]; $\lambda_{max}(CCl_4)$ 4.60 (sh), 4.71 (sh), 4.82 μ.

n-Propyl isothiocyanate was converted to **25** by treatment with benzylmagnesium bromide following the method described by Blicke and Zinnes (38) for the preparation of α-phenyl-*N*-ethylthioacetamide. Com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 188.143.235.115 on 09/06/12
For personal use only.

pound **25** was obtained in 43% yield as off-white needles, m.p. 51.5–53.5°. Four recrystallizations from ether – petroleum ether gave colorless needles, m.p. 55.5–56.5°; $\lambda_{max}(CCl_4)$ 2.89 (m), 6.25 (w), 6.63, 7.16, 9.36 μ; λ_{max}(MeOH) 267.5 (ε 12 700), 271 (sh, ε 12 400) mμ; λ_{max}(MeOH–MeONa) 268 (ε 11 500), 271 mμ (sh, ε 11 300).

Anal. Calcd. for $C_{11}H_{15}NS$: C, 68.37; H, 7.82; N, 7.25; S, 16.56. Found: C, 68.55; H, 8.01; N, 7.45; S, 16.59.

When a benzene solution of **25** was treated with yellow mercuric oxide a black precipitate developed within 10 min.

*Reduction of **28** with Nickel*

A solution of **28** (52 mg, 0.087 mmol) in ethanol (20 ml) was boiled under reflux for 20 h with a large excess of sponge nickel catalyst (Davison). The solution was cooled to room temperature, the catalyst was separated by gravity filtration, and the solvent was evaporated at the water aspirator. The residual solid (45 mg) had m.p. 86–88°; crystallization from benzene-ligroin gave α,α-diphenyl-*N*-*n*-propylacetamide (**29**; 28 mg, 64%) as colorless needles, m.p. 94–94.5°. One further recrystallization gave **29** (21 mg), m.p. 94.5–95°, undepressed on admixture with an authentic sample (*vide infra*).

*Reduction of **28** with Zinc and Acetic Acid*

A solution of **28** (69 mg, 0.120 mmol) in acetic acid (5 ml) was boiled under reflux for 3 h with zinc dust (100 mg). The supernatant solution was poured into ice-water, and the mixture was extracted with three 10 ml portions of ether. The extracts were combined, washed well with aqueous 5% sodium bicarbonate, and dried over anhydrous magnesium sulfate. The ether was evaporated at reduced pressure, and the solid residue was sublimed at 120° (1 mm) to give a white solid (42 mg), m.p. 87–90°. Recrystallization from cyclohexane gave **29** as colorless needles (32 mg, 55%), m.p. 94–94.5°, undepressed on admixture with an authentic sample (*vide infra*).

*α,α-Diphenyl-N-n-propylacetamide (**29**)*

The preparation of **29** was accomplished by the general method of Shriner *et al.* (39). Diphenylacetic acid (500 mg, 2.40 mmol) was dissolved in a large excess of thionyl chloride (10 ml), and the solution was boiled gently under reflux for 30 min. The excess thionyl chloride was evaporated at the water aspirator, and a solution of *n*-propylamine (1.0 ml, 0.70 g, 12 mmol) in benzene (15 ml) was added to the residual oil. The resulting solution was boiled under reflux for a few minutes, cooled to room temperature, and washed once with 5% hydrochloric acid, once with water, and twice with aqueous 5% sodium hydroxide. Drying over anhydrous magnesium sulfate followed by evaporation of the benzene under reduced pressure gave a tan solid (500 mg). Recrystallization from benzene–ligroin gave **29** as off-white needles (400 mg, 67%) m.p. 94–95°. Six recrystallizations from benzene–ligroin gave colorless needles, m.p. 95–95.5°; λ_{max} 2.84 (m), 5.97, 6.66 μ.

Anal. Calcd. for $C_{17}H_{19}NO$: C, 80.57; H, 7.56; N, 5.53. Found: C, 80.58; H, 7.36; N, 5.58.

*Alternative Synthesis of **9***

To a stirred suspension of sodium amide (400 mg, 10.0 mmol) in dry benzene (75 ml) was added a solution of deoxybenzoin (2.00 g, 10.0 mmol) in benzene (40 ml), and the mixture was stirred and boiled under reflux under nitrogen for 10 h. The yellow suspension was cooled to room temperature, and to it was added carbon disulfide (0.65 ml, 820 mg, 11.0 mmol). The mixture rapidly acquired a bright red color, which intensified during an additional 24 h of stirring. Addition of a solution of α-chlorodiphenylacetyl chloride (40) (2.70 g, 10.0 mmol) in benzene (20 ml) rapidly discharged the red color, after which the mixture was stirred for 1 h. Dry pyridine (1 ml) was added, and the mixture was boiled under reflux for 5 h, during which time a heavy precipitate formed. The mixture was cooled to room temperature, and the precipitate was filtered and washed with benzene. The benzene was evaporated from the filtrate at reduced pressure leaving a viscous reddish oil. This was triturated with a small amount of ether, and the brownish solution was decanted, leaving a sticky solid (600 mg).

The ethereal solution was evaporated, and the residual oil (3.0 g) was dissolved in benzene – petroleum ether (3:2) and chromatographed on silica gel (Davison, 300–400 mesh; 50 g); 80 ml fractions were collected. Elution with benzene – petroleum ether (9:1) gave fractions that appeared from their i.r. spectra to be largely mixtures of deoxybenzoin and **9**. These were combined and rechromatographed on silica gel (50 g). The column was eluted with benzene – petroleum ether (7:3), and 80 ml fractions were collected. Fractions 3 and 4 were combined and recrystallized from carbon disulfide to give a first crop of yellow prisms (97 mg), m.p. 154–156°, and a second crop (57 mg), m.p. 153–155°, undepressed on admixture with **9**.

The residue from evaporation of the mother liquors from the recrystallizations was combined with fractions 2, 5, and 6 of the second chromatogram, and this material was again chromatographed on silica gel (18 g). The column was eluted with benzene – petroleum ether (3:2), and 50 ml fractions were collected. Recrystallization of fraction 4 from ether – carbon disulfide gave yellow crystals (14 mg), m.p. 153–155°, while a combination of fractions 3 and 5 gave yellow solid (20 mg), m.p. 142–147°. Trituration of the residues from evaporation of the mother liquors with ether and cooling gave more yellow solid (14 mg), m.p. 151–153°. The last two, low-melting crops were recrystallized from carbon disulfide to give yellow prisms (20 mg), m.p. 154–155°, undepressed on admixture with **9**. The i.r. spectra of all four crops were identical with the spectrum of **9**; the total combined product (188 mg) represents a yield of 8%.

Reaction of Azibenzil with Carbon Disulfide in the Presence of Diphenylketene

Diphenylketene (5.00 g, 25.7 mmol), prepared by the method of Smith and Hoehn (41), azibenzil (5.72 g, 25.7 mmol), and carbon disulfide (55 ml) were boiled under reflux in a nitrogen atmosphere overnight. The excess carbon disulfide was removed by evaporation on the steam bath at the water aspirator, and the residue was crystallized from acetic acid to give **9** (5.00 g, 84% based on azibenzil alone); m.p. 152–154°, undepressed on admixture with a sample of **9** prepared by the reaction of azibenzil with carbon disulfide in the absence of diphenylketene. The i.r. spectrum of the product showed all of the bands of **9**.

The Reaction of Hydroperoxides with Triphenylphosphine

R. HIATT, R. J. SMYTHE, AND CHRISTINE MCCOLEMAN
Chemistry Department, Brock University, St. Catharines, Ontario

Received September 9, 1970

The reductions of *n*-butyl, *sec*-butyl, and *tert*-butyl hydroperoxides by triphenylphosphine in ethanol have been shown to follow second-order kinetics with k_2's equal, respectively to $10^{7.2}e^{-8.4/RT}$, $10^{9.0}e^{-10.8/RT}$, $10^{8.8}e^{-11.2/RT}$. Similar results obtain in CH_2Cl_2, but in hexane the rate equation requires an additional term, $k_3[Ph_3P][RO_2H]^2$, though the overall reaction is somewhat faster than in the other solvents.

Retardation, apparently by adventitious impurities, has been observed in some cases, but attempts to inhibit the reaction by free radical traps were unsuccessful. Parallels with reduction of hydroperoxides by organic sulfides suggest a similar non-radical mechanism.

On a établi que la réduction des hydropéroxydes de *n*-butyle, *sec*-butyle et *tert*-butyle par la triphénylphosphine dans l'éthanol est d'ordre deux et que les constantes de vitesses sont de $10^{7.2}e^{-8.4/RT}$, $10^{9.0}e^{-10.8/RT}$ et $10^{8.8}e^{-11.2/RT}$ respectivement pour chacun de ces composés. On a obtenu des résultats semblables dans le CH_2Cl_2 mais dans l'hexane l'équation de vitesse nécessite un terme supplémentaire et devient $k_3[Ph_3P][RO_2H]^2$ quoique dans l'ensemble la réaction devient plus rapide que dans les autres solvants.

On a observé que la réaction est ralentie dans certains cas, apparemment par des impuretés, mais on n'a toutefois pas pu inhiber la réaction par addition de substances susceptibles d'éliminer les radicaux libres. Les parallèles qui peuvent être faits avec la réaction de réduction des hydropéroxydes par les sulfures organiques permettent de suggérer que le mécanisme de la réaction sous considération n'est pas de nature radicalique.

Canadian Journal of Chemistry, 49, 1707 (1971)

Introduction

The facile reduction of hydroperoxides to alcohols by phosphines (1, 2) or phosphites (3) has been used extensively in the analysis of autoxidation products (4). The 1:1 stoichiometry of the reaction provides a method for quantitative analysis (5, 6). Stereochemical studies have shown that

[1] $$RO_2H + R'_3P \rightarrow ROH + R'_3PO$$

the phosphine abstracts the hydroxyl oxygen (7); the cleanness of reduction and the absence of inhibition by trinitrobenzene (3) have suggested a polar rather than radical mechanism (3, 7).

Nonetheless the reaction occurs extremely rapidly in non-polar solvents, "instant" reduction in hexane solution at $-40°$ (7) being an oft quoted claim. There is evidence that the reduction *can* be inhibited, or at least retarded, by adventitious impurities (8), and misgivings about its cleanness when applied to non-tertiary hydroperoxides have been expressed (4). Such findings suggested a free radical chain mechanism propagated by steps [2] and [3].

[2] $$RO_2^{\cdot} + R'_3P \rightarrow RO^{\cdot} + R'_3PO$$

[3] $$RO^{\cdot} + RO_2H \rightarrow ROH + RO_2^{\cdot}$$

Differences between tertiary and non-tertiary hydroperoxides could thus be ascribed to the much faster self-termination of non-tertiary peroxy radicals acting in competition with reaction 2.

The following describes what we believe to be the first rate studies of the phosphine–hydroperoxide reaction, undertaken in the hope that a kinetic analysis would settle the mechanistic question conclusively.

Experimental

Triphenylphosphine obtained from Eastman Organic Products, Limited, (m.p. 74–80 °C) was purified by chromatography on alumina followed by recrystallization from ethanol; m.p. 79–80°. Simple sublimation of the crude material did not improve its melting range.

t-Butyl hydroperoxide (Lucidol 90%) was purified by vacuum distillation. *n*-Butyl and *s*-butyl hydroperoxides were synthesized by the method of Williams and Mosher (9) and used as the 80–81% pure materials (by iodometric titration) afforded by this procedure.

t-BuO_2D was obtained by hydrolysis of the potassium salt of *t*-BuO_2H with D_2O. The recovered hydroperoxide (by ether extraction and vacuum distillation) was 90.5% pure and contained 88% O—D (by i.r.). *The dry t-$BuO_2^-K^+$, prepared by reaction of KNH_2 with t-BuO_2H in liquid ammonia, was found to be considerably more hazardous than expected.* While small quantities did not explode even on scratching or hammering, a 70 g batch

left unattended for several minutes detonated violently and without warning.

Methylene chloride and *n*-hexane to be used in solvents for kinetic runs were fractionally distilled and dried over molecular sieves. Ethanol was dried with the magnesium ethoxide. EtOD (99.5%) was obtained from Merck, Sharp and Dohme, Ltd.

Rates of reaction were measured by scanning the disappearance of the triphenylphosphine maximum absorbance at 2600–2800 Å (10) using a Hitachi–Perkin–Elmer model 124 u.v. spectrophotometer. Since both hydroperoxides and triphenylphosphine oxide absorb weakly in this region, reactions using approximately equal concentrations of RO_2H and Ph_3P were difficult to analyze. Consequently all kinetic runs were carried out with at least a 10 fold excess of peroxide, using plots of log [Absorbance$_t$ − Absorbance$_\infty$] *vs.* *t* to obtain pseudo first-order rate constants. These latter were independent of the actual wave length followed over the range of 2500–2800 Å.

Results

Exclusion of a Free Radical Mechanism

The reaction of triphenylphosphine with *t*-BuO_2H in styrene solution at 0 °C resulted in a virtually quantitative yield of Ph_3PO and *t*-BuOH but *no* polystyrene. Attempts to inhibit the reaction in benzene or methylene chloride solution using either hydroquinone or the stable free radical galvinoxyl (11) were unsuccessful.[1] The products of reaction of *n*-BuO_2H or *s*-BuO_2H with Ph_3P were shown by g.l.c. to be the corresponding alcohols exclusively. No traces of the aldehydes or ketones resulting from self-termination of peroxy radicals could be detected.

While none of these tests in itself is conclusive, they together tend to substantiate the generally held view (3, 7) that the reaction is non-radical.

Rates and Kinetics of Reaction, t-Butyl and n-Butyl Hydroperoxides

Reductions were carried out in three solvents, ethanol, methylene chloride, and hexane, using initial concentrations of 0.5–2.0 × 10^{-4} *M* Ph_3P and 0.001–0.1 *M* hydroperoxide. Rates of reaction were sufficiently slow for convenient measurement by following the decrease in u.v. absorption due to triphenylphosphine. With the uniformly large excess of hydroperoxide, disappearance of the phosphine followed first order kinetics; plots of log [Ph_3P] *vs.* time were linear to at least 95% reaction (Fig. 1), with slopes that were independent of [Ph_3P]$_0$ (Table 1).

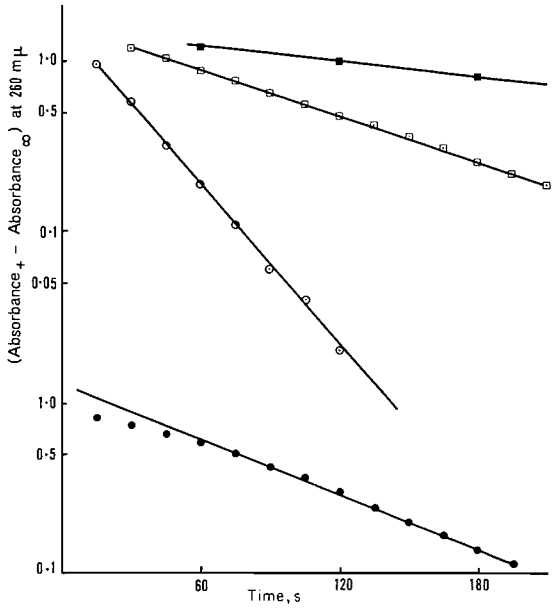

FIG. 1. Pseudo-first order plots for the reduction of hydroperoxides by 2 × 10^{-4} *M* Ph_3P. ■, 0.01 *M* *t*-BuO_2H at 23.5° in EtOH; □, 0.013 *M* *n*-BuO_2H at 20.0° in EtOH; ○, 0.013 *M* *n*-BuO_2H at 21.5° in *n*-hexane; ●, 0.010 *M* *s*-BuO_2H at 21.5° in *n*-hexane.

In ethanol[2] or methylene chloride the pseudo-first order rate constants ("k_1") were directly proportional to hydroperoxide concentration,[3] (Table 1), *i.e.*,

$$[4] \qquad -\partial[Ph_3P]/\partial t = k_2[Ph_3P][RO_2H]$$

Reactions in *n*-hexane were not second order, however. Plots of log "k_1" *vs.* log [RO_2H] showed a close fit to 3/2-order in hydroperoxide, but the data could be fitted equally well to an ex-

[1]These tests were necessarily qualitative since the u.v. absorption of the inhibitors was so intense as to preclude the following reaction by the decrease of the Ph_3P maximum. Instead a crude form of differential thermal analysis was used. Mixing 0.001 mol each of Ph_3P and *t*-BuO_2H in 30 ml of solvent at 20–22 °C caused a rapid temperature rise of 2.5 °C. The pattern was completely unaffected by the presence of the free radical traps.

[2]The reaction of *t*-BuO_2H in ethanol was scrutinized particularly for the effect of impurities. Hydroperoxide and Ph_3P in all stages of purification were used, but in no case did the rate of reaction differ significantly from that using the purest starting materials.

[3]For *t*-BuO_2H, k_2's increased slightly as RO_2H was decreased from 0.1 to 0.001 *M*. The increase was, however, barely outside the limits of reproducibility for individual runs at a given concentration. Since the hundredfold change in peroxide concentration produced a hundredfold change in rate, approaching the high and low limits for accurate measurement, the variation can probably be ascribed to experimental error.

pression, "k_1" = $k_2[RO_2H] + k_3[RO_2H]^2$ (Table 2, Fig. 2), an analysis which we prefer.[4]

[4]A 3/2-order reaction might be explained on the assumptions (*a*) that the hydroperoxide is extensively dimerized in this solvent and (*b*), reaction in aprotic solvents requires both RO_2H monomer and a proton transfer agent, which could be hydroperoxide dimer. (The parallel with reductions by organic sulfides is discussed in a later section.) However, this interpretation falls short on several grounds; even in hexane, the hydroperoxide is probably not dimerized to the necessary extent at the concentrations used. Assuming the association constant for *t*-BuO_2H in CCl_4 (12) is a satisfactory approximation, dimer would account only 8% of the hydroperoxide at 0.02 M and 0.5% at 0.001 M; in methylene chloride, also aprotic, higher order kinetics are not observed; reduction by organic sulfides are second order, not 3/2-order, in hydroperoxide under similar circumstances (13, 14).

For *t*-BuO_2H, $k_2 = 0.185 \pm 0.008$ and $k_3 = 37.77 \pm 0.50$ at 22 °C. For *n*-BuO_2H, $k_2 = 1.25 \pm 0.15$ and k_3, 207 ± 17 at 27.6 °C. The constants in Table 1 were computed as if the reaction were simple second order, owing to insufficient data at other temperatures to compute the second- and third-order constants.

Deuterium Isotope Effects

Reduction of partially deuterated hydroperoxide (*t*-BuO_2D (H), 88% O—D) in hexane gave an overall rate about 0.6 times as fast as the undeuterated material. (Table 2, shown arbitrarily as an effect on "k_2", but readily translatable to the pseudo-first order rate since the comparable run with *t*-BuO_2H is at the same initial concen-

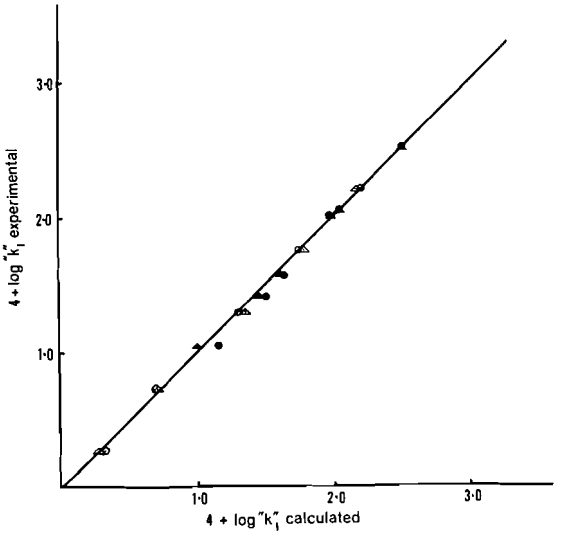

FIG. 2. "k_1" experimental *vs.* "k_1" calculated for reduction of hydroperoxides by Ph_3P in *n*-hexane. "k_1" = $k_2[RO_2H] + k_3[RO_2H]^2$; ●, *t*-$BuO_2H$, ○, *n*-$BuO_2H$; "$k_1$" = $k_{3/2}[RO_2H]^{3/2}$, ▲, *t*-BuO_2H, ○, *n*-BuO_2H.

tration.) While it would have been nice to have a more accurate estimate of the isotope effect and to have resolved the separate contributions to the bimolecular and termolecular parts of the reaction in hexane, work in this direction was abandoned when efforts to prepare 100% *t*-BuO_2D proved unexpectedly hazardous (Experimental section).

To see whether solvent deuteration had any effect, *t*-BuO_2H was reduced in EtOD (Table 1). The reacting species was, of course, *t*-BuO_2D, due to the rapid exchange with solvent. However, rates were the same within experimental error as for *t*-BuO_2H in EtOH.

s-Butyl hydroperoxide in ethanol or methylene chloride gave results consistent with those obtained using *n*- or *t*-BuO_2H (Table 1). In hexane, however, rates were not reproducible, and in some cases reactions exhibited induction periods (Fig. 1). (Rates given in Table 1 are typical and reliable, perhaps, to ±50%.) The variability appeared linked to impurities in the hydroperoxide.[5] Different batches having approximately the same peroxide titer (80–83%) gave different results which could not be traced to known or suspected contaminants such as 2-butanol, methyl-ethyl-ketone, acetaldehyde, or 2-butyl methanesulfonate.

Differing purities of triphenylphosphine had no effect on the results with a given batch of hydroperoxide, a surprising result since slow and incomplete reductions of hydrocarbon solutions of *s*-BuO_2H on a large scale (prior to g.l.c. analysis of reaction mixtures) have been traced to the use of unpurified Ph_3P more than once (8).

Discussion

Generally speaking, these results confirm earlier contentions (3, 7) that phosphine reduc-

[5]Impurities were much less important when ethanol was the solvent; hydroperoxide which had been allowed to deteriorate on standing over several months to a titer of 30% gave rates of reduction only 10% less than those obtained for the purest material.

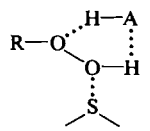
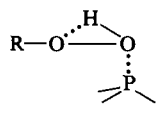
tions belong to a sizable class of nucleophilic displacements on the peroxide bond. Examples include reactions with I^-, organic sulfides and sulfones, amines and olefins (15), all of which require for ease of accomplishment either a readily transferred proton (hydroperoxides), generation of a stable anion (acyl peroxides), or both (peroxy acids).

Of these examples cited the reaction of hydroperoxides with organic sulfides, though much less rapid (13, 14), bears the most resemblance to that with Ph_3P (Table 3). Similarities include relative insensitivity to solvent, cleanness of reduction without the need for added catalysts, and large negative entropies of activation. The sulfide reduction appears to require a greater degree of assistance in transferring the proton from one oxygen to the other (14), since in non-polar, aprotic solvents the reaction is strictly second order in hydroperoxide, whereas, as we have shown, for Ph_3P the $[RO_2H]^2$ contribution is



1



2

balanced by an almost equally rapid reaction which is unimolecular in hydroperoxide.[6] Likewise the effect is greater for reduction by sulfides, insofar as effects in D_2O *vs.* H_2O and EtOD *vs.* EtOH are comparable (Table 3). (The reduction of RO_2D by sulfides in aprotic solvents seems not to have been investigated.)

The lower sensitivity of the RO_2H–Ph_3P reaction to such factors need not be interpreted as a concerted proton shift, as in **2**; more likely it reflects a transition state closely related to the reactants in which there is little weakening of the O—H bond. The low activation energy and the insensitivity to solvent polarity would tend to support this conclusion.

The relative reactivities of the three hydroperoxides t-Bu < s-Bu < n-Bu are line with both expected steric effects and relative electrophilicities of the peroxidic oxygen. The differences are so small, however, as to discourage any detailed rationalization.

The inhibition or retardation of the reduction of s-BuO_2H by small amounts of as yet undefined species has some peculiar aspects, to say the least, and will be the subject of continuing research.

Catalysis of the Reduction of Hydroperoxides by Triphenylphosphine

R. HIATT AND CHRISTINE MCCOLEMAN

Chemistry Department, Brock University, St. Catharines, Ontario

Received September 9, 1970

The reaction of hydroperoxides with triphenylphosphine is catalyzed by the addition of strong acid. Likewise in hydroxylic solvents, the log of the bimolecular rate constant increases linearly with the solvents' autoprotolysis constants. Soluble salts of molybdenum or vanadium are 10^4 to 10^5 times more effective catalysts than H^+. The reaction shows promise as a method for quantitative comparison of the effectiveness of these compounds in augmenting the electrophilic character of hydroperoxides.

On observe que la réaction entre les hydropéroxydes et la triphénylphosphine est catalysée par les acides forts. Il en est de même dans les solvants hydroxyliques où le log de la constante de vitesse bimoléculaire augmente d'une façon linéaire avec les constantes d'autoprotolyse des solvants. Les sels solubles de molybdène ou de vanadium sont des catalyseurs de 10^4 à 10^5 fois plus efficaces que H^+. Il semble que cette réaction pourrait éventuellement être utilisée pour déterminer d'une façon quantitative l'efficacité de ces composés pour augmenter le caractère électrophile des hydropéroxydes.

Canadian Journal of Chemistry, 49, 1712 (1971)

Introduction

The reduction of hydroperoxides by triphenylphosphine has been shown not to involve a free radical chain, and to have similar characteristics to reductions by organic sulfides (1). It seemed useful to determine whether this similarity extended to catalysis by strong acids and by more protic solvents (2), even though the reaction itself is fast enough to scarcely require added acceleration. In the same vein we have explored the effect of compounds of molybdenum, vanadium, and tungsten, metal ions known to catalyze the reaction of hydroperoxides with olefins (3), amines (4), and sulfoxides (5).

Experimental

Hydroperoxides and triphenylphosphine were obtained or prepared as previously reported. Solvents were Reagent Grade, used without further purification. Perchloric acid was used as the 70% solution in water. Compounds of Mo, V, or W were used as obtained from K & K Laboratories, molarities for naphthenate solutions being calculated on the basis of their containing 3%, by weight, of metal ion.

Rate studies were based on the u.v.-monitored, unimolecular disappearance of Ph_3P, hydroperoxide being in uniformly large excess, as previously described (1). Excellent first-order plots for Ph_3P disappearance were obtained in every case. Most constants reported are averages of duplicate runs.

Results and Discussion

Acid Catalysis

Table 1 shows second-order rate constants for the reaction of n-BuO_2H with Ph_3P in ethanol with added amounts of 70% $HClO_4$. The constants increase linearly with $HClO_4$ up to 0.1 M. At higher concentrations of acid there is a slight tailing off (Fig. 1), due possibly to the activity of $HClO_4$ (or H^+) in ethanol not being a linear function of concentration at these higher values. Alternatively sufficient protonation of the phosphine may be occurring to reduce the effective concentration of the active species.

TABLE 1. Reduction of n-BuO_2H by Ph_3P in ethanol,* effect of added $HClO_4$

ready interpretation (1), those of a structurally similar series fall nicely into line (Table 2, Fig. 2); log k_2's for reaction in alcohols being correlated with their autoprotolysis constants (6). While no such correlation coefficient is available for 80% ethanol, the increase in rate over that in 100% ethanol is clearly in the right direction.

Determination of the effect of added acetate ion on the rate in acetic acid was limited to the extent that no attempt was made to maintain a constant ionic strength. However, it is clear from the slight increase in rate constant that there is no common ion effect, as should be the case if the accelerating effect of acetic acid were due to protonation of the hydroperoxide. It may be noted that acetic acid as solvent exerts a levelling effect on rate differences due to hydroperoxide

[2] $$HOAc + RO_2H \rightleftharpoons RO_2H_2^+ + {}^-OAc$$

structure. While the differences between *n*-BuO_2H and *t*-BuO_2H in ethanol, CH_2Cl_2 or hexane are small, a factor of 3–4 (1), in HOAc their rates are the same within experimental error (Table 2).

TABLE 2. Reduction of *t*-BuO_2H by Ph_3P in protic solvents*

*At 25 °C, [Ph_3P]$_0$ = 1 × 10^{-4} mol/l.
†Containing 0.10 *M* KOAc.
‡*n*-BuO_2H.

The effects of different protic solvents and of strong acid on the reaction of Ph_3P with hydroperoxides are strikingly similar to those for the hydroperoxide – organic sulfide reaction (2), not only as to direction and lack of common ion effect, but even approximate magnitude of the correlation constants. Thus for catalysis by $HClO_4$ at 25 °C, k_3 for *t*-BuO_2H + thioxolane is 14.1 times as large as k_2 for the uncatalyzed component (2), whereas for *n*-BuO_2H + Ph_3P at 25°, $k_{3[HClO_4]}$ is 18 times as large as k_2. While the differences in solvent (H_2O *vs.* EtOH) and hydroperoxide might argue that this agreement is coincidental, the effects of different alcohols as solvents on the bimolecular rate constant for

t-BuO_2H (Fig. 2) are directly comparable and are about half as large for Ph_3P as for the sulfide.

Catalysis by Metal Ions

A select group of metal ions, molybdenum, vanadium, and to a lesser extent, tungsten, have been shown to increase the electrophilicity of hydroperoxides, via complexation (3–5), to the extent that hitherto unknown reactions are possible (vide infra). Such compounds in exceedingly low concentrations have been found to exert a profoundly accelerating effect on the rate of reaction of hydroperoxides with Ph_3P (Table 3). Over the admittedly small range of concentrations experimentally available, catalysis was reasonably close to first order in metal ion (Table 3 and Fig. 1); *i.e.*, conforming to

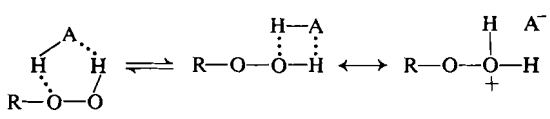
$$-d[Ph_3P]/dt = [Ph_3P][RO_2H][k_2 + k_3[M^{n+}]]$$

The low concentrations were only in part dictated by the necessity of keeping the reaction rate within measurable bounds. The high coloration imparted to their solutions extended into the u.v. region and interfered with the method of Ph_3P analysis. In fact, solutions containing carbonyls of the mentioned metals, as well as the acetyl acetonate of vanadium could not be used due to absorbtion changes of the metal compound during the course of reaction. This was doubly unfortunate, since catalysis of the RO_2H–Ph_3P reaction appears to offer a clean method for quantitatively assessing the effect of these substances on hydroperoxide reactivity. That is, reactions appeared to suffer little of the autoretardation (Fig. 3) commonly noted for other reactions catalyzed by these species (3*b*, 4*b*). (This has led to as yet unresolved difficulties in making other than qualitative comparisons of catalyst efficiency in those cases.[1])

It is particularly interesting that the effectiveness of molybdenum is independent of whether it is added as naphthenate or oxyacetylacetonate, and is some ten times greater than that of vanadium (Table 3). It would be precipitous and doubtless an oversimplification to assert that ligands had no effect, and that previous ratings of Mo over V and *vice versa* were entirely due to extraneous effects. However, further experiments in the Ph_3P–RO_2H system would appear to offer a profitable avenue for ascertaining the true situation.

Catalysis

Generally speaking, catalysis of the electrophilic reactions of hydroperoxides can be ascribed to two factors, not always easily separable, facilitation of hydrogen transfer, and increase in the electrophilic character of the hydroperoxide. Both are easily visualized in terms of a hydroperoxide–catalyst complex.



[1]This is not to say that catalyst solutions were not subject to degradation. They were, and were consequently made up fresh immediately prior to reactions. Most noticeably, solutions of MoO_2acac_2 in hexane deteriorated to the point of virtual inactivity over the course of a few hours. This was perhaps not surprising in view of the low concentration and the tendency of acetylacetonates to autoxidize rapidly (7).

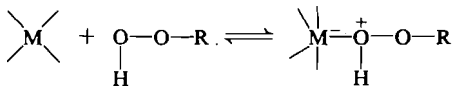
For personal use only.

The present data suggest that whatever its effect, complexation is in itself the most important factor. That is, acetic acid which probably has low steric requirements for complex formation tends to level out differences between n-BuO_2H and t-BuO_2H, while metal ion aggregates, undoubtedly more bulky, tend to exaggerate them (Table 3).

While the catalytic influence of complexing with molybdenum or vanadium certainly derives from an increased electron demand of the peroxidic oxygen (3*b*), this is not to say all, if indeed any, of the effect of acids or protic solvents



is similarly founded. Factors affecting electrophilic reactions of peroxides require better understanding, and will be the subject of continued research in these laboratories.

Hydrates of Tetra-*n*-butylammonium Picrate in Benzene and Chlorobenzenes

SAUL GOLDMAN AND G. C. B. CAVE
Department of Chemistry, McGill University, Montreal, Quebec
Received[1] December 23, 1969

The first two hydration constants of the ion pair tetra-*n*-butylammonium picrate in the solvents *o*-dichlorobenzene, chlorobenzene, and a binary mixture benzene–chlorobenzene (1:1 *v/v*) at 25.0, 35.1, and 45.1 °C were determined by an isopiestic method. In addition, algebraic treatment of the data permitted evaluation of the hydration constants of the dimer and higher aggregates known to co-exist with the monomer in the solutions. The effect of bulk dielectric constant of the solvent on the hydration constants of the monomer is discussed.

Les deux premières constantes d'hydratation de la paire d'ion, picrate de tétra-*n*-butylammonium, dans l'*o*-dichlorobenzene, le chlorobenzene et le mélange binaire benzène–chlorobenzène (1:1 *v/v*) à 25, 35.1 et 45.1 °C ont été déterminées par une méthode isopiestique. De plus le traitement algébrique des données a permis une évaluation des constantes d'hydratation des agrégats dimères et polymères qui existent en solutions avec le monomère. L'effet de la constante dielectrique globale du solvant sur les constantes d'hydratation du monomère est discutée.

Canadian Journal of Chemistry, **49**, 1716 (1971)

Introduction

Ion pairs (monomers) and co-existing ion-pair aggregates occur in many solvent extraction systems of analytical importance. At least partial hydration of these species in the organic phase of such systems is expected. Characterization of the species extracted in a solvent extraction system and evaluation of their thermodynamic properties in the organic phase require, therefore, similar knowledge of these hydrates.

The thermodynamic properties ΔG^0, ΔH^0, and ΔS^0 of the aggregation reactions of the monomer of tetra-*n*-butylammonium picrate in benzene and in substituted benzenes have been evaluated from solvent extraction data (1). These evaluations required prior evaluation of the hydration constants of the monomer and its aggregates, as well as the activity values of the unbound water in the organic phase.

The sought-for hydration constants were evaluated from isopiestic data. Thus, standard nonaqueous solutions of tetra-*n*-butylammonium picrate (hereafter usually abbreviated Bu_4NPi) were equilibrated in closed, thermostatted vessels with the water vapor from an adjoining standard aqueous solution of calcium chloride. The equilibrium stoichiometric concentrations of water in the nonaqueous solutions, together with the stoichiometric concentrations of Bu_4NPi, as well as the activities of the water in the aqueous solutions gave on algebraic treatment the required constants.

The use of an isopiestic technique, rather than direct equilibration of the two liquid phases, avoided the possibility of chemical reaction between the solutes Bu_4NPi and $CaCl_2$. In the case of solutes Bu_4NPi and $CaBr_2$, preliminary experiments showed that reaction was extensive.

Experimental

Apparatus

Karl Fischer Titration Assembly

The stoichiometric concentrations of water in the equilibrated nonaqueous solutions of Bu_4NPi were determined by a conventional Karl Fischer dead-stop back-titration (2). The titration was carried out in a standard, completely closed Radiometer Titration Assembly (type TTA1); and the two platinum electrodes in the electrode head of this Assembly were connected to a Radiometer Titrator (type TTT1a), for determination of the dead-stop end point.

Isopiestic Assembly

The apparatus was similar to that described by Christian *et al.* (2). The equilibration flasks were 250 ml, conical, ground-glass stoppered iodine flasks, dried before use. The nonaqueous solution of Bu_4NPi for equilibration was contained in the bottom of the iodine flask. The aqueous solution of $CaCl_2$ was in an open 10 cm × 1 cm test tube which rested obliquely inside the stoppered flask. The upper rim of the ground-glass stopper was lightly greased. The flask and its contents were then placed in a water thermostat maintained to within ±0.1 °C.

Materials

The tetra-*n*-butylammonium picrate (Bu_4NPi) was prepared by a method similar to that of Flaherty and Stern (3). The product was re-crystallized 3 times from hot ethanol solutions, by adding a large excess of cold, distilled water. The resulting product was dried in vacuo over P_2O_5, for 12 h at 65 °C: m.p. 89.3–89.8 °C; lit. 89.5 °C (4). This final product was also assayed for pic-

[1]Revision received December 1, 1970.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

rate, by means of a potentiometric titration with a standard 0.1 *N* solution of $HClO_4$ in glacial acetic acid (5); the product was thereby found to be 100.0 ± 0.1% pure.

Reagent grade benzene, chlorobenzene, and *o*-dichlorobenzene were further purified by washing each of them successively with concentrated sulfuric acid, water, 1 *N* NaOH solution for benzene and 1 *N* $NaHCO_3$ solution for the chlorobenzenes, and finally with water. Each resulting product was then fractionally distilled over silica gel, the center two-thirds cut being kept for use. These final products were stored over silica gel. Their densities at 25.0 °C were found to be: benzene, 0.8734 (lit. 0.8734 (6)); chlorobenzene, 1.1010 (lit. 1.1008 (3)); *o*-dichlorobenzene, 1.3005 (lit. 1.3007 (6)).

Conventional, stabilized Karl Fischer reagent and diluent (Fisher So-K-3 and So-K-5) were used for the dead-stop determination of water in the nonaqueous solutions of Bu_4NPi. Spectrophotometric grade methanol (Fisher A-408) containing approximately 0.1% water was the titrant for the back-titration step.

Calcium chloride was anhydrous reagent grade (Fisher C-76). Distilled water was used to prepare the aqueous solutions of $CaCl_2$.

Silver nitrate was reagent grade (Engelhard 99.98%), dried at 120 °C before use.

Sodium chloride was best quality reagent grade (Fisher 271), dried at 120 °C before use.

Linde dry nitrogen was used to flush the Karl Fischer titration vessel before use.

Procedures

Preparation of Solutions

The nonaqueous solutions of Bu_4NPi were prepared by accurately weighing the salt, considered as a primary standard, into calibrated volumetric flasks, and diluting to volume with the solvent (*o*-dichlorobenzene, chlorobenzene, and the mixed solvent benzene–chlorobenzene (1:1 *v/v*)).

The aqueous solutions of $CaCl_2$ were prepared by suitable dilutions of a near-saturated aqueous stock solution of $CaCl_2$. Those resulting working solutions that were used at 25 °C were standardized after the isopiestic equilibration experiments.

Equilibration

Approximately 20–50 ml of the nonaqueous solution of Bu_4NPi were placed in the dried iodine flask. The 10 cm × 1 cm test tube containing 7 ± 0.5 ml of water or a standard aqueous solution of $CaCl_2$ was then placed in the iodine flask so that the rim of the test tube rested against the upper inside wall of the flask. The flask was then stoppered, the upper rim of the stopper having been lightly greased. The flask and its contents were then placed in a water thermostat maintained to within ±0.1 °C. Care was taken to ensure that the water level in the thermostat was kept above the bottom of the stopper in the iodine flask; condensation inside the flask was thereby prevented.

Trials showed that the stoichiometric concentration of water in the nonaqueous solution did not change after equilibration for 2 days. In the present work, 5 days were allowed. As further proof of equilibrium, pure benzene equilibrated at 25 °C with water by the isopiestic method had the same water content as benzene equilibrated with water by direct liquid–liquid extraction.

Water Content of the Nonaqueous Solutions of Bu_4NPi

The stoichiometric concentration of water in a nonaqueous solution of Bu_4NPi after the isopiestic equilibration was determined by a Karl Fischer titration. Thus, the Karl Fischer reagent was dispensed by using a dried pipet, into the dried titration cell of the Radiometer Titration Assembly. Then an aliquot of the nonaqueous solution for analysis was added via a pipet which had been prerinsed with the same solution. The volume of this aliquot was so chosen that only a small excess of Karl Fischer reagent remained unreacted. This small excess was then back-titrated with the methanol–water titrant, which consisted of approximately 0.1% water in pure methanol.

In practice, the following sequence of operations was followed, for every water determination: (*i*) The titre of the methanol–water titrant was determined with respect to the Karl Fischer reagent; (*ii*) the Karl Fischer reagent itself was standardized against a stock standard solution that for convenience consisted of water-saturated benzene kept at 25.0 °C; (*iii*) a measured aliquot of the nonaqueous solution for analysis was titrated by the procedure outlined in the preceding paragraph.

The water content of the water-saturated benzene at 25.0 °C was also found by Karl Fischer titration. In this case, the Karl Fischer reagent was first standardized against a standard solution of water in methanol, prepared by adding an accurately measured amount of water to methanol. The solubility of water in benzene at 25.0 °C was found in this way to be 0.0347 *M* (standard deviation 0.0015 for 5 replicates), in good agreement with the literature value (2) of 0.0349 *M* (standard deviation 0.0005 for 4 replicates).

Trials had shown that even virtually anhydrous solvents showed, on Karl Fischer titration, measurable traces of water. The source of water was attributed to a small amount of atmospheric moisture believed to have entered the titration cell during addition of the sample solution. Therefore this small blank correction (0.017 mmol of water) was determined in replicate by using very carefully dried benzene as the sample, and the correction found was applied to all subsequent titrations.

Trials also showed that dried Bu_4NPi had no effect on the titration results.

Equilibrium Water Activities

The molality of each aqueous solution of $CaCl_2$, after the isopiestic equilibration at 25 °C, was determined by titration of a diluted aliquot with a standard aqueous solution of silver nitrate. Dichlorofluorescein was the indicator. The silver nitrate solution was standardized against dried sodium chloride (the primary standard).

The molalities of the equilibrium calcium chloride solutions were found to be within 1% of the initial molalities, as a result of the small volumes of the nonaqueous solutions used in the isopiestic studies, and the low solubility of water in those solutions.

From the measured molalities of those calcium chloride solutions which were at 25.0 °C, the corresponding water activities at 25.0 °C were found from published tabulations (7).

Results

The equilibrium data for the isopiestic systems are summarized in Table 1. Literature values for

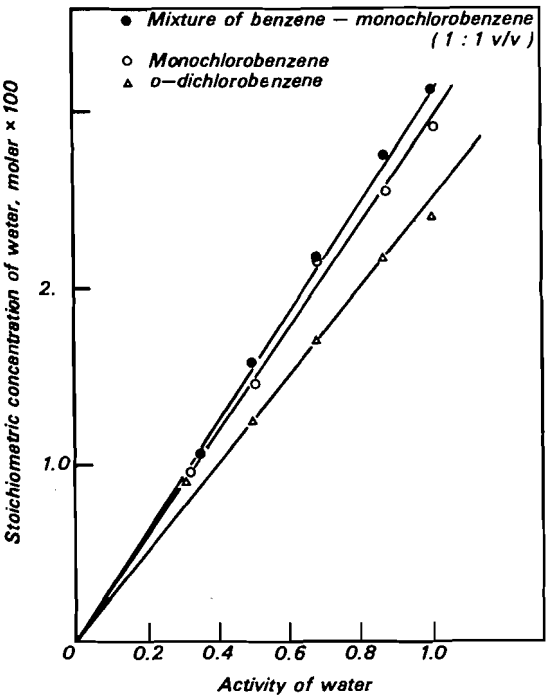

FIG. 1. Concentration of water *vs.* its activity, in three solvents at 25.0 °C, from isopiestic experiments.

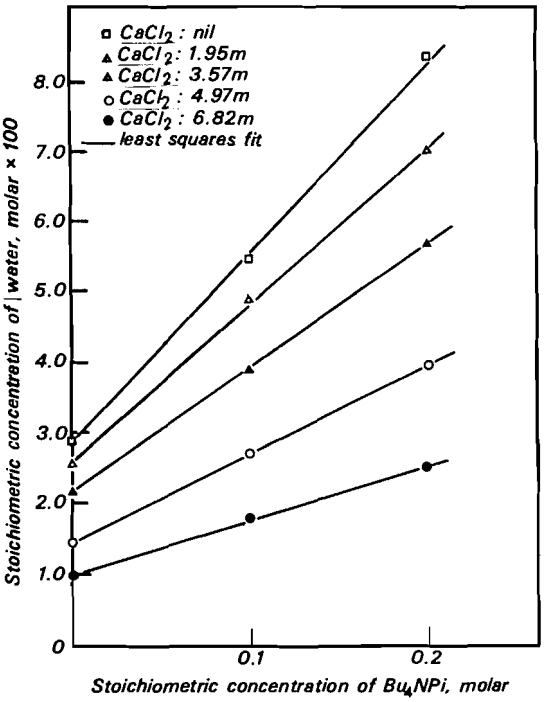

FIG. 2. Stoichiometric concentration of water *vs.* stoichiometric concentration of Bu_4NPi in chlorobenzene at 25.0 °C, in equilibrium with five aqueous solutions of $CaCl_2$ (isopiestic experiments).

the activity of water in aqueous solutions of calcium chloride were available only for 25 °C. Therefore only at this temperature were the equilibrium calcium chloride molalities measured; at 35.1 and 45.1 °C the molalities given in Table 1 are initial values calculated from the known dilution of a stock solution of calcium chloride.

In Fig. 1, the stoichiometric concentration of water in each of the pure nonaqueous solvents is plotted against the activity of water, for 25.0 °C. For each solvent, the graphs are linear. Consequently Henry's law was obeyed by water. This conclusion is in accord with similar results reported (8) for water in benzene, toluene, carbon tetrachloride, and cyclohexane. It was considered reasonable to assume that the unbound water (*i.e.* water not bound as hydrates to the Bu_4NPi monomer and its aggregates) was monomeric in the three solvents and in their Bu_4NPi solutions, at the three temperatures studied.

From the data in Table 1, it was found that for a fixed temperature, solvent, and water activity, a linear relationship exists between the equilibrium stoichiometric concentration of water in the nonaqueous solution, and the stoichiometric concentration of Bu_4NPi in that solution. All systems showed this linear relationship. In Fig. 2 it is illustrated for the chlorobenzene solutions at 25.0 °C. The intercept of each of these straight-line plots represents the concentration of unbound water, $[H_2O]_f$, that was present in all the solutions that belong to that particular straight line. The slope of each line represents the average number ($\bar{n}$) of bound moles of water per stoichiometric mole of Bu_4NPi (monomers and aggregates, anhydrous and hydrated).

Actually, $\bar{n}$ and $[H_2O]_f$ were evaluated for each system by a conventional least squares treatment of the relevant data from Table 1. The resulting values and their standard deviations are entered in Table 2, and are used in the following section. Plots of $\bar{n}$ *vs.* $[H_2O]_f$ are illustrated in Fig. 3 for the chlorobenzene systems; similar curves were obtained for the other two solvent systems.

Treatment of the Data

Solvent extraction studies of Bu_4NPi between water and each of the solvents benzene, chlorobenzene, and *o*-dichlorobenzene have been carried out (1). These data showed that Bu_4NPi in the organic phase of the solvent extraction system existed as an equilibrium mixture of several

*s.d. means standard deviation for 1 degree of freedom.

species, namely ions, ion pair (monomer), dimer (aggregate of two pairs), trimer (aggregate of three pairs), and others. A proportion of each of these species was considered to be hydrated. However, the charged species were found (1) to contribute only very slightly to the stoichiometric concentration of Bu_4NPi, in the range of concentrations studied in the present work. Therefore, their existence is ignored in the following treatment.

A treatment of the isopiestic data is now described which allows calculation of the step-wise hydration constants of the coexisting uncharged species in the organic phases.

Let $[X_i(H_2O)_j]$ denote the molar concentration of any neutral species in the solution of Bu_4NPi. For example, $[X_1(H_2O)_0]$ will denote the molarity of the anhydrous monomer; and $[X_2(H_2O)_2]$ will denote the molarity of the dihydrated dimer

Let $\bar{n}$ denote the total number of moles of bound

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

water per stoichiometric mole of Bu_4NPi (monomers and aggregates, anhydrous and hydrated). Then

$$[1] \qquad \bar{n} = \frac{\sum_{j=0}^{m} \sum_{i=1}^{n} j[X_i(H_2O)_j]}{\sum_{j=0}^{m} \sum_{i=1}^{n} i[X_i(H_2O)_j]}$$

Let ${}^{j}k_i$ denote the stepwise hydration constants where

$$[2] \qquad {}^{j}k_i = \frac{(X_i(H_2O)_j)}{(H_2O)_f(X_i(H_2O)_{j-1})} \qquad i, j \geq 1$$

and where round brackets denote activity, and $(H_2O)_f$ denotes the activity of the unbound water in the organic phase. Since this unbound water was shown to obey Henry's law, it is permissible to write $(H_2O)_f = [H_2O]_f$. If the assumption is made that $(X_i(H_2O)_j) = [X_i(H_2O)_j]$, then

$$[3] \qquad {}^{j}k_i = \frac{[X_i(H_2O)_j]}{[H_2O]_f[X_i(H_2O)_{j-1}]} \qquad i, j \geq 1$$

Substitution of eq. 3 into eq. 1 gives, on rearrangement,

$$[4] \qquad \sum_{i=1}^{n} C_i(\theta_i - \bar{n}i\psi_i) = 0$$

where

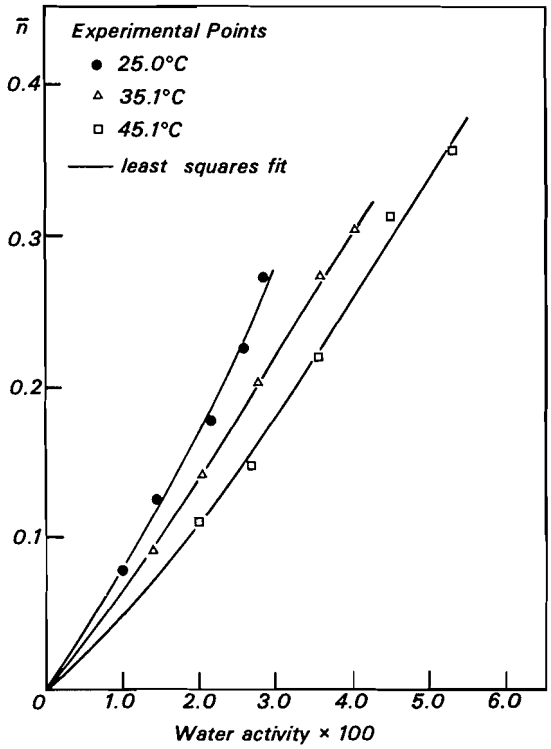

FIG. 3. Activity of water *vs.* $\bar{n}$ for solutions of Bu_4NPi in chlorobenzene at three temperatures.

$C_i = [X_i(H_2O)_0]$, the molarity of anhydrous species X_i

$$\theta_i = {}^{1}k_i[H_2O]_f + 2{}^{1}k_i{}^{2}k_i[H_2O]_f{}^{2} + \cdots + m\prod_{r=1}^{m} {}^{r}k_i[H_2O]_f{}^{m}$$

$$\psi_i = 1 + {}^{1}k_i[H_2O]_f + {}^{1}k_i{}^{2}k_i[H_2O]_f{}^{2} + \cdots + \prod_{r=1}^{m} {}^{r}k_i[H_2O]_f{}^{m}$$

For the present systems, it was shown experimentally, from the data in Table 1 (vide Fig. 2), that the value of $\bar{n}$ was independent of the stoichiometric concentration of Bu_4NPi. Moreover, for a fixed temperature, solvent, and water activity θ_i and ψ_i were also constants. Under those conditions

$$[5] \qquad (\theta_i - \bar{n}i\psi_i) = 0 \qquad \text{for all } i$$

That is,

$$[6] \qquad \bar{n} = \frac{\theta_1}{\psi_1} = \frac{\theta_2}{2\psi_2} = \cdots = \frac{\theta_n}{n\psi_n}$$

Equation 6 was used in order to evaluate the hydration constants for these species present in significant concentrations in the organic phase of the isopiestic experiments. These species are considered in turn.

Monomer (Ion Pair)

For the monomer, eq. 6 becomes

$$[7] \qquad \bar{n} = \frac{\theta_1}{\psi_1} = \frac{{}^{1}k_1[H_2O]_f + 2{}^{1}k_1{}^{2}k_1[H_2O]_f{}^{2} + \cdots + n\prod_{r=1}^{n} {}^{r}k_1[H_2O]_f{}^{n}}{1 + {}^{1}k_1[H_2O]_f + {}^{1}k_1{}^{2}k_1[H_2O]_f{}^{2} + \cdots + \prod_{r=1}^{n} {}^{r}k_1[H_2O]_f{}^{n}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The sought-for constants ${}^1k_1$ to ${}^n k_1$ inclusive can be evaluated for each solvent system by applying eq. 7 to the values of $\bar{n}$ and $[H_2O]_f$ in Table 2.

If only one hydrate of the monomer were formed, eq. 7 would reduce to

$$[8] \qquad \bar{n} = \frac{{}^1k_1[H_2O]_f}{1 + {}^1k_1[H_2O]_f}$$

However, eq. 8 did not fit the data.

If only a mono- and a dihydrate of the monomer were formed, then

$$[9] \qquad \bar{n} = \frac{{}^1k_1[H_2O]_f + 2{}^1k_1{}^2k_1[H_2O]_f{}^2}{1 + {}^1k_1[H_2O]_f + {}^1k_1{}^2k_1[H_2O]_f{}^2}$$

The same results may be obtained by analogy with B.E.T. theory for the special case of a maximum of two adsorption layers (9).

Equation 9 can be written as

$$[10] \qquad Y = {}^1k_1 + {}^1k_1{}^2k_1X$$

where

$$Y = \bar{n}/[H_2O]_f(1 - \bar{n})$$

$$X = [H_2O]_f(2 - \bar{n})/(1 - \bar{n})$$

Plots of X *vs.* Y resulted in straight lines (within experimental error) for all the solvent systems. Therefore it was concluded that the monomer formed a monohydrate and a dihydrate. However, the data are not accurate enough to permit the unequivocal exclusion of small concentrations of higher hydrates.

The constants ${}^1k_1$ and ${}^2k_1$ were evaluated for each system by a conventional least-squares fit of eq. 10 to the data in Table 2. The resulting values and their standard deviations are entered in Table 3.

Dimer

Based on the monomer forming only the mono- and dihydrate, eq. 6 becomes

$$[11] \qquad \frac{{}^1k_1[H_2O]_f + 2{}^1k_1{}^2k_1(H_2O)_f{}^2}{1 + {}^1k_1[H_2O]_f + {}^1k_1{}^2k_1[H_2O]_f{}^2} = \frac{{}^1k_2[H_2O]_f + 2{}^1k_2{}^2k_2[H_2O]_f{}^2 + \cdots + m\prod_{r=1}^{m} {}^rk_2[H_2O]_f{}^m}{2\left[1 + {}^1k_2[H_2O]_f + {}^1k_2{}^2k_2[H_2O]_f{}^2 + \cdots + \prod_{r=1}^{m} {}^rk_2[H_2O]_f{}^m\right]}$$

Equation 11 led to chemically and mathematically consistent values of ${}^1k_2$ to ${}^m k_2$ inclusive only if $m = 4$. With $m = 4$, then on cross-multiplying eq. 11 and equating the coefficients of $[H_2O]_f{}^1$, $[H_2O]_f{}^2$, . . . , $[H_2O]_f{}^6$, 6 simultaneous equations resulted, which were solved to give the following 4 relationships

$${}^1k_2 = 2{}^1k_1$$

$${}^2k_2 = {}^2k_1 + \frac{{}^1k_1}{2}$$

$${}^3k_2 = \frac{2{}^1k_1{}^2k_1}{2{}^2k_1 + {}^1k_1}$$

$${}^4k_2 = \frac{{}^2k_1}{2}$$

From those 4 relationships and the values already found for ${}^1k_1$ and ${}^2k_1$, the 4 stepwise hydration constants for the dimer can be calculated.

Trimer

The same mathematical method was used in treating the trimer case, as that described for the dimer. Consistent values for ${}^jk_3$ for the trimer hydrates were obtained when the first 6 hydrates of the trimer were taken into account, and no others. The method then led to the following 6 relationships, from which the 6 stepwise hydration constants of the trimer can be calculated from the values already found for ${}^1k_1$ and ${}^2k_1$

$${}^1k_3 = 3{}^1k_1$$

$${}^2k_3 = {}^1k_1 + {}^2k_1$$

described for the dimer and used for the trimer can in fact be applied to any neutral aggregate of the monomer, provided that (*i*) the stoichiometric concentrations of water and of salt (Bu_4NPi here) are related in a linear way, and (*ii*) the species of interest is present as a significant proportion of the total salt concentration.

Discussion

Equation 6 may be written as

$$[12] \qquad \bar{n} = \frac{\theta_i C_i}{i\psi_i C_i}; \qquad i = 1, 2, \ldots, n$$

where C_i is the stoichiometric concentration of the unhydrated species i, which is either the monomer Bu_4NPi, or one of its neutral aggregates. The numerator represents the stoichiometric concentration of water bound to species i, and the denominator the stoichiometric concentration of monomer present as species i (*e.g.* $2\psi_2 C_2$ is the stoichiometric concentration of monomers present as dimers). Therefore eq. 12 shows that the average number of mol of bound water per mol of monomer is constant, and therefore independent of whether the monomer is free or combined in an aggregate. That is, the tendency (as measured by ΔG^0) of water to hydrate the Bu_4NPi monomer is unaffected by self-association of the monomer.

By assigning two hydrates to the monomer Bu_4NPi, exactly the first $2n$ hydrates could then be found for a given aggregate of n monomers. The stepwise formation constants for these $2n$ hydrates are algebraically related through eq. 6 to the two stepwise hydration constants ($^1k_1$ and $^2k_1$) of the free monomer. Therefore only these latter two constants will be discussed; their values are in Table 3. The standard deviations of these values are too large to justify the evaluation of the standard enthalpies and entropies of the two hydration reactions, from the measured temperature dependence of the two constants.

The relationship between the standard free energy of hydration of the monomer, and the bulk dielectric constant (D) of the solvent was studied. Thus, the values of $\log {}^1k_1$ taken from Table 3 were plotted against $1/D$ for the three solvents, at each of the 3 temperatures; corresponding plots were also made for $\log {}^2k_1$. On taking into account the standard deviations found for $^1k_1$ and $^2k_1$, the plots were linear in every case. Least squares equations were calculated for the lines, together with the standard deviations of their slopes. Conventional statistical tests then showed that of the 6 slopes none was significantly different from the others, nor were they significantly different from zero, at the 95% confidence level.

Resonance forms of the models we postulate for the monohydrate and the dihydrate of the

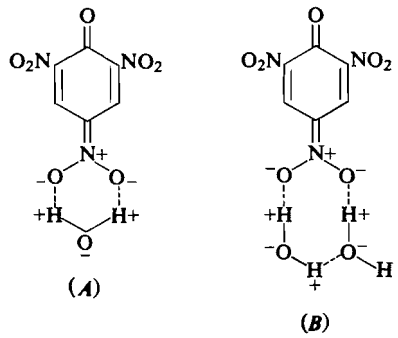

FIG. 4. One resonance form for the monohydrate (*A*) and the dihydrate (*B*) of the picrate anion.

For personal use only.

Bu_4NPi monomer are illustrated in Fig. 4. Nitrobenzene has been reported (10) to form a monohydrate and a dihydrate through its nitro group, with the dihydrate forming a ring. Moreover, any other possible site for the addition of the water to the monomer would appear to be sterically less favorable due to the *n*-butyl groups on the cation.

The formation of rings, as shown in Fig. 4, makes possible the enhancement of those inductive effects that would normally exist. Thus, a cooperative inductive effect would then operate all around the rings. Such an enhanced effect due to ring formation has already been postulated (11) in order to explain the greater stability of trimers over dimers of alcohol in chloroform solutions.

The creation of these extra charges due to ring formation would require an amount of electrostatic energy proportional to $1/D$. Hence this electrostatic term in the standard free energy of formation of a hydrate would decrease linearly with $1/D$. If in addition the formation of a hydrate is considered to result from dipole–dipole (water–nitro group) interaction, then this electrostatic contribution to the standard free energy of formation of the hydrate would increase linearly with $1/D$. The overall contribution to ΔG^0 of hydrate formation would then be the difference between these two energies of interaction. If the other contributions to ΔG^0, including the standard entropy of formation of the hydrate are considered to depend only slightly or not at all on $1/D$, then plots of ΔG^0 *vs.* $1/D$ will provide information on the relative values of the two opposing electrostatic terms in ΔG^0. As noted above, the values of ΔG^0 for formation of the monohydrate and of the dihydrate were in fact found statistically not to depend on the solvent. These results therefore do not indicate any difference in the magnitude of the two opposing electrostatic terms in ΔG^0; but the large standard deviations of the values of ΔG^0 in Table 3 would enable only gross differences to be detected.

We are grateful to the National Research Council of Canada for financial support, and for a Scholarship to one of us (S.G.).

Ions and Aggregates of Tetra-*n*-butylammonium Picrate in Nonaqueous Solvents at 25 °C: A Solvent Extraction Study

SAUL GOLDMAN AND G. C. B. CAVE
Department of Chemistry, McGill University, Montreal, Quebec

Received[1] December 23, 1969

The values of ΔG^0 at 25 °C were determined for the ionization, dimerization, and trimerization of tetra-*n*-butylammonium picrate (**1**) in benzene, chlorobenzene, and *o*-dichlorobenzene by a solvent extraction method. Corrections were applied for the presence of hydrates in the organic phase, in order to report ΔG^0 values for the anhydrous solvents. In chlorobenzene, hexamers of **1** were also indicated in measurable concentrations. The various values of ΔG^0 are related in a simple way to the bulk dielectric constant of the solvent.

La valeur de ΔG^0 à 25 °C pour l'ionisation, la dimérisation et la trimérisation du picrate du tétrabutylammonium (**1**) a été déterminée par une méthode d'extraction par solvants dans le benzène, le chlorobenzène et l'*o*-dichlorobenzène. De façon à pouvoir rapporter des valeurs de ΔG^0 pour des solvants anhydres des corrections ont été faites pour tenir compte de la présence d'hydrates dans la phase organique. Des concentrations mesurables de l'hexamère de **1** semblent présentes dans le chlorobenzène. Les diverses valeurs de ΔG^0 sont reliées d'une façon simple avec la constante diélectrique globale du solvant.

Canadian Journal of Chemistry, 49, 1726 (1971)

Introduction

Ion association in solvents of low dielectric constant to form ion pairs (monomers) and higher aggregates has been known for several decades. Cryoscopy (1), conductance measurements (2, 3), and dielectric studies (4) were the techniques most widely used in the earlier studies of ion association phenomena.

In cryoscopy neither the solvent nor the temperature can conveniently be altered. Therefore, it is difficult to measure the variation of equilibrium constants with changes in temperature, and with changes in the dielectric constant of the solvent.

Conductance measurements (2, 3) provided the first (and only) evidence for the existence of triple ions and higher charged aggregates in ion-pairing systems. However, the total concentration of these charged aggregates in low-dielectric solvents is small (5).

Dielectric studies have been interpreted (6) to indicate that monomers associate to form aggregates of two main types. One type results from lateral association of the monomer, to produce an aggregate with a dipole moment lower than that of the monomer. The second type results from end-to-end association of the monomer, to produce an enhanced dipole moment. Without prior knowledge of the shapes of the aggregates, dielectric studies alone cannot yield the equilibrium constants of aggregation reactions.

Solvent extraction was used in the present work, in order to evaluate ΔG^0 at 25 °C for the aggregation reactions of an ion pair in low dielectric solvents. This equilibration technique was well suited to the purpose; both the temperature, and the dielectric constant of the solvent could readily be varied. In addition, by appropriate choice of the concentration range several different aggregation reactions could be studied in turn.

Tetra-*n*-butylammonium picrate was the salt chosen for study. It has suitable solubilities in the solvents. Moreover, the cation is important in analytical solvent extraction procedures. The solvents chosen were benzene, chlorobenzene, and *o*-dichlorobenzene. They are geometrically similar, are relatively immiscible with water, and they covered a particularly convenient range of dielectric constants (2.27, 5.63, and 10.1, respectively at 25 °C).

The solvent extraction technique consisted in measuring at 25 °C the distribution ratio of tetra-*n*-butylammonium picrate between an aqueous phase and the nonaqueous phase, over a wide range of stoichiometric concentrations of the salt. The data, after applying corrections for the presence of hydrates in the organic phase, were fitted to a derived polynomial. Thereby, the species present were identified, and their standard free energies of formation from the monomer were evaluated.

Experimental

Apparatus

Equilibration Vessels

The two phases in the solvent extraction system were equilibrated in 165-ml "milk-dilution" bottles fitted with bakelite screw caps having Teflon inserts. The rim of the opening in each bottle had been ground flat with emery paper, so that a tight, leak-proof fit with the cap was attained. Plastic tape wound around the neck and tightly screwed cap of each bottle was an additional precaution against leakage while the bottles were in a water thermostat.

Thermostat

The water thermostat used for the solvent extraction equilibrations was 70 cm long, 40 cm wide, and 37 cm deep. The temperature was maintained to within ± 0.1 °C of the required value. Stirring was by a centrifugal pump and a rotor.

The 165-ml bottles for equilibration were clamped lengthwise on a Plexiglass rotor immersed in the water thermostat, with the axis of rotation horizontal. The rotor was driven at 15 r.p.m. from an external motor and gear-reduction box, and gave the bottles an end-over-end rotation.

Dielectric Constant

The dielectric constant of the three solvents presaturated by isopiestic equilibration with pure water were measured. A Sargent Model V Oscillometer with a Sargent cell compensator was used. The temperature of the sample in the Sargent cell was maintained to within ± 0.1 °C of the required temperature by a snug-fitting, hollow brass jacket through which constant-temperature water was circulated.

A calibration curve was prepared by using benzene, chlorobenzene, and *o*-dichlorobenzene purified and dried by a previously described procedure (7), then further dried by storage over Drierite for at least 2 weeks (8). Literature values (9, 10) were used for the dielectric constants.

Materials

The preparation, purification, and analysis of the tetra-*n*-butylammonium picrate (hereafter abbreviated to Bu_4NPi), and the purification and densities of the solvents benzene, chlorobenzene, and *o*-dichlorobenzene have been described elsewhere (7). The Bu_4NPi was found to be $100.0 \pm 0.1\%$ pure. Distilled water was used as the aqueous phase in the solvent extraction experiments.

Procedures

Preparation of Solutions

Stock standard solutions of Bu_4NPi were prepared both in water and in the water-saturated organic solvents by weighing the salt to ± 0.1 mg, into calibrated volumetric flasks, and diluting to the mark with the solvent. Aqueous stock solutions under 10^{-3} *M*, and nonaqueous stock solutions under 10^{-2} *M* were prepared by accurate dilution of more concentrated stock solutions.

The titre of nonaqueous stock solutions more dilute than 10^{-4} *M* was found to drop slowly with time, when anhydrous solvent had been used. A comparable phenomenon with phenolate-type indicators has been reported (11), and interpreted then as being due to an adsorption reaction. Specifically, the indicator was presumed to form with the sodium compounds in the glass of the container, an insoluble coating of the sodium salt. However, it was also found in the present work that aqueous solutions of Bu_4NPi even as dilute as 10^{-5} *M* retained their original titre for at least 2 years and possibly longer. This fact suggested that a strongly adsorbed water layer on the glass wall prevented the adsorption reaction observed for the anhydrous nonaqueous solvent. This in turn suggested in the present work that Bu_4NPi in a water-saturated organic solvent would also not lose salt to the glass wall; the activity of water in the solvent would be almost that of pure water. It was indeed found that when the nonaqueous solutions of Bu_4NPi had been prepared with water-saturated solvents, their titre remained constant to within 1% for at least 1 month. The publications on conductance and dielectric studies on Bu_4NPi in anhydrous solvents performed during the past 35 years appear not to mention this adsorption effect. The repetitive rinsing of the cells with solution, prior to the actual measurements of conductance or dielectric constant, evidently conditioned the cell walls.

Equilibration of Solutions

Equal volumes (10 ml–50 ml) of the two phases were transferred by pipet into the 165 ml equilibrating bottle. One phase contained a known concentration of Bu_4NPi, the other none. The capped bottle was fastened to the Plexiglass rotor in the water thermostat, and it received one end-over-end rotation every 4 s.

This gentle rotor motion was superior to mechanical shaking. When a shaker was tried, precision of the measured distribution ratios of Bu_4NPi was poor. This was attributed to the formation of a copious suspension of the organic phase in the aqueous phase. Precision by using the rotor method, on the other hand, was good.

An equilibration period of 1 h was allowed, although extensive tests had shown that 15 min were enough, regardless of which phase the Bu_4NPi was initially in.

Analysis of Equilibrated Phases

After the 1-h equilibration, the bottle was removed from the rotor, and was suspended vertically in the water thermostat, with only the cap and the neck above the water surface; the upper level of the lighter phase was well under the surface.

An aliquot of the required phase was transferred from the uncapped bottle still in the water thermostat, into a centrifuge tube. In sampling the heavier phase, air was always bubbled through the pipet during its descent through the lighter phase. The aliquot was centrifuged for 15 min to remove any droplets of the other phase present; but in practice the invariable absence of such droplets made centrifugation apparently only a precaution.

When an aliquot of the organic phase containing a low concentration of Bu_4NPi was being processed for analysis, the glassware used was pre-rinsed several times with the solution. Thereby, loss of Bu_4NPi due to adsorption on the glass walls was avoided.

The stoichiometric concentration of Bu_4NPi in the centrifuged aliquot was then determined with a Unicam SP 500 spectrophotometer, by measuring the absorbance at the wavelength of the absorption peak. The concen-

TABLE 1. Absorptivity of tetra-*n*-butylammonium picrate in four solvents at 25.0 °C

Solvent	λ_{max} (mμ)	Molar absorptivity × 10^{-4} Mean	Standard deviation	Degrees of freedom
Water	353	1.43	0.01	20

o-Dichlorobenzene*	377	1.83	0.01	5

*Water-saturated solvent.

tration was then found from the value of the molar absorptivity previously determined from standard solutions.

The wavelength of maximum absorption of Bu_4NPi depended on the solvent, as shown in Table 1. For the organic phases and the corresponding solutions for calibration, the spectrophotometric blank was the water-saturated solvent. For the aqueous phases, the blank was distilled water except when *o*-dichlorobenzene was the organic phase. In that case only did solvent-saturated water have a very slightly different absorptivity than that of pure water at the wavelength used. For the case of all 3 solvents, the molar absorptivity of Bu_4NPi in an aqueous solution, in which the water had been pre-saturated with the solvent, was the same as the molar absorptivity of Bu_4NPi in pure water, using the designated blanks.

Beer's law was obeyed by the Bu_4NPi both in water and in the water-saturated organic solvents over the tested concentration ranges of interest, namely 1×10^{-6} to 5×10^{-4} *M* for water, and 1×10^{-6} to 1×10^{-4} *M* for the organic solvents. The molar absorptivities are in Table 1.

Results and Treatment of the Data

All the distribution experiments were in triplicate. The standard deviation of most measured concentrations was within 1% of the mean, and never more than 2%.

In some experiments, both equilibrium phases were analyzed for Bu_4NPi content in order to check mass balance. Systems were chosen for which the distribution ratio was in the range 0.4–3. For all three solvents, it was found that mass balance was attained to within 1%.

For most systems, only the equilibrium phase containing the lesser concentration was analyzed for Bu_4NPi. The equilibrium concentration in the other phase was then found from the known total initial amount of Bu_4NPi, and the volumes.

The results of the distribution experiments at 25.0 °C are entered in Table 2.

A polynomial expression was derived which related the stoichiometric concentration of Bu_4NPi in the equilibrated organic phase, to its stoichiometric concentration in the equilibrated aqueous phase. A least squares fit of the data in Table 2 to that polynomial permitted the evaluation of sought-for equilibrium constants of the various species in the nonaqueous solutions.

In deriving the polynomial, three assumptions were made:

(*i*) In the concentration range studied, the aqueous phase contained only the simple ions Bu_4N^+ and Pi^-, and negligible concentrations of all other species. This assumption is supported by conductivity experiments (12, 13) in water, with salts similar to Bu_4NPi, namely Et_4NPi (12), Me_4NPi (13), $(n\text{-Am})_4NBr$ (13), $(n\text{-Bu})_4NBr$ (13), and $(n\text{-Pr})_4NI$ (13). The Onsager equation was found (12, 13) to be obeyed by these aqueous solutions at salt concentrations below 10^{-3} *M*, which indicated that dissociation was virtually complete in them. The maximum concentration of Bu_4NPi in the aqueous phases of the present extraction systems was 8×10^{-4} *M*.

(*ii*) The total contribution to the stoichiometric concentration of Bu_4NPi in the organic phase, made by charged species other than the simple ions Bu_4N^+ and Pi^- was negligibly small. This assumption is supported by the low conductivity of salts of the type used in the present work, in solvents of low dielectric constant (2, 3, 14). That charged aggregates contribute only slightly to the stoichiometric concentration of salts in such systems has been previously deduced (5) from conductivity data.

(*iii*) The monomer and neutral aggregates of Bu_4NPi in both phases had activity coefficients of unity (but the activity coefficients of the ions in both phases were not taken to be unity). The justification for this assumption is that the potential energy of interaction of two dipolar species falls off fairly rapidly with distance. The

*Mean of triplicates.

interaction at close distance is interpreted solely in terms of aggregation of monomers, and numerically is reflected in the calculated formation constants of the aggregates.

A previously reported (7) hydration study showed that Bu_4NPi and its aggregates were partially hydrated in the solvents used in the present work, when the solvent also contained dissolved water. Moreover, in that study it was considered reasonable to suppose that only the picrate ion was hydrated in the organic phase, and not the cation. This supposition is made in the present work.

Then for the organic phases of the present extraction systems,

$$[1] \qquad C_T = [X_{ion}]\psi_{ion} + \sum_{i=1}^{n} i[X_i]\psi_i$$

where C_T = stoichiometric concentration of Bu_4NPi in the equilibrium organic phase of the extraction system; $[X_{ion}]$ = molar concentration of unhydrated picrate ion in the equilibrium organic phase; $[X_i]$ = molar concentration of the unhydrated species X_i in the equilibrium organic phase, where X_i ($i = 1, 2, \cdots$) represents respectively the monomer and the neutral aggregates of Bu_4NPi; ψ_{ion}, ψ_i = water-correction factors for species X_{ion} (picrate ion) and X_i, respectively, in the organic phase.

$$[2] \qquad \psi_i = 1 + \sum_{m=1}^{n} [H_2O]_f^m \prod_{m=1}^{m} {}^mk_i$$

where $[H_2O]_f$ = molar concentration of unbound (to Bu_4NPi aggregates, and ions) water in the equilibrium organic phase; ${}^mk_i$ = mth stepwise hydration constant for species X_i in the organic phase.

Thus

$$[3] \qquad {}^mk_i = \frac{[X_i.mH_2O]}{[X_i.(m-1)H_2O][H_2O]_f}$$

In the previous study (7) on hydration, the values of ${}^mk_i$ for Bu_4NPi and its aggregates were determined for three solvents, *o*-dichlorobenzene, chlorobenzene, and a mixture of benzene and chlorobenzene (1:1 *v/v*). The plots of log ${}^mk_i$ *vs.* $1/D$ were linear for that sequence of solvents, D being the bulk dielectric constant. Therefore the values of ${}^mk_i$ for benzene as solvent were readily found from the least squares equation of the lines. Moreover, it was shown (7) that Henry's law was obeyed by the water in those solvents; and the activity of water in the nonaqueous solutions of Bu_4NPi was measured there by an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

isopiestic method. Those activity values were applicable to the present extraction systems. Therefore these previous data (7) were used in eq. 2, and each ψ_i except ψ_{ion} was thereby evaluated. The evaluation of ψ_{ion} for the solvents is considered separately below.

Let the subscript T denote the stoichiometric concentration of Bu_4NPi in a particular phase. Let the subscript w denote the aqueous phase, and let the absence of a subscript denote the organic phase.

The notations used for eqs. 1 and 2 will be used, including square brackets to denote molarities. Then, with assumption (*iii*) above applied, the partition coefficient p of species X_1 (the monomer Bu_4NPi) is given by

$$[4] \qquad p = [X_1]/[X_1]_w$$

Let k denote the ion-pair formation constant of Bu_4NPi in the aqueous phase and $\gamma_{\pm w}$ the mean activity coefficient. Then

$$[5] \qquad k = \frac{[X_1]_w}{[X_{ion}]_w^2 \gamma_{\pm w}^2}$$

Let K denote the ion-pair dissociation constant of Bu_4NPi in the organic phase, and $\gamma_\pm$ the mean activity coefficient, for the case of unhydrated monomer and ions. Then

$$[6] \qquad K = [X_{ion}]^2 \psi_{ion} \gamma_\pm^2 / [X_1]$$

Let K_n be the aggregation constant for aggregation of unhydrated Bu_4NPi monomer to unhydrated aggregate $(Bu_4NPi)_n$.

$$[7] \qquad K_n = [X_n]/[X_1]^n$$

On combining eqs. 1 with 4 to 7 inclusive, and on recognizing that assumption (*i*) above indicates that $[X_{ion}]_w = C_{Tw}$ (the stoichiometric concentration of Bu_4NPi in the aqueous phase), then

$$[8] \quad C_T = \frac{\psi_{ion}^{\frac{1}{2}} (Kkp)^{\frac{1}{2}} C_{Tw} \gamma_{\pm w}}{\gamma_\pm} + \sum_{i=1}^{n} i \psi_i K_i (kp)^i (C_{Tw} \gamma_{\pm w})^{2i}$$

where $K_1 = 1$.

Equation 8 can be written

$$[9] \qquad C_T = \frac{A_{ion} x}{\gamma_\pm} + \sum_{i=1}^{n} A_i x^{2i}$$

where $x = C_{Tw}\gamma_{\pm w}$ and A_{ion}, A_i $(i = 1, 2, \cdots, n)$ are constants.

The C_T and C_{Tw} data required for least squares evaluation of the constants in eq. 9 are in Table 2. The values of $\gamma_{\pm w}$ and $\gamma_\pm$ were calculated by using the Debye–Hückel expression for activity coefficients. In the case of $\gamma_\pm$, the computation was necessarily an iterative one (15).

The standard deviation in C_T was a function of the value of C_T. Therefore, evaluation of the constants in eq. 9 from the data in Table 2 required the use of a weight function. For a given point, this weight function will be given by the reciprocal of the variance. However, in the present work only 3 independent replicates were available for each point, and the estimates of variance found therefrom proved inadequate to give the best fit of eq. 9 to the data. Therefore a weight function was derived, which was a function of x and of the constants in eq. 9. It was based on the vertical distance (C_T axis) of the experimental point (C_T, $C_{Tw}\gamma_{\pm w}$) from the curve of best fit, being taken as the standard deviation of that particular value of C_T. This weight function was of necessity obtained by using an iterative technique, because the constants in eq. 9 were initially unknown. Evaluation of these constants by a least squares treatment and the concomitant evaluation of the weight function and of $\gamma_\pm$ were carried out by several iterations. The detailed technique has been described elsewhere (15).

It proved to be the case that for the benzene system and the *o*-dichlorobenzene system, inclusion of the species simple ions, monomer (ion pair), dimer, and trimer resulted in a satisfactory fit of eq. 9 to the data in Table 2. Inclusion of additional, higher aggregates did not significantly improve the goodness of fit. Therefore, for these two solvents, eq. 9 was used with $n = 3$.

For the chlorobenzene system, eq. 9 with $n = 3$ did not provide a satisfactory fit to the data. In the high concentration region, the curve of best fit consistently lay below the upper experimental points (C_T, x). This fact indicated that for the chlorobenzene system, simple ions, monomers, dimers, trimers, and at least one still higher aggregate were present. The present data do not permit the unequivocal identification of this higher aggregate. Indeed, there may be more than one such aggregate higher than the trimer.

However, Rutgers and de Smet (16) reported the presence of hexamers of tetra-isoamylammonium picrate, in equilibrium with monomers and trimers in low-dielectric solvents. Therefore eq. 9 was written to include not only ions, monomers, dimers, and trimers, but also hexamers, as follows

$$[10] \quad C_T = \frac{A_{ion}x}{\gamma_\pm} + \sum_{i=1}^{3} A_i x^{2i} + A_6 x^{12}$$

When eq. 10 was fitted to the chlorobenzene data in Table 2, a good fit resulted, and in particular the above-described negative deviations in the high-concentration range disappeared.

The least squares values of the parameters A_{ion} and A_i in eqs. 9 and 10 together with their standard deviations are given in Table 3, for the three solvent systems at 25.0 °C. As an illustration of the goodness of the fit, the data in Table 2 are plotted as individual points in Figs. 1 and 2 for the *o*-dichlorobenzene system. The solid curve in each case is the least squares curve. The corresponding curves for the benzene system and the chlorobenzene system were similar in shape to those in Figs. 1 and 2, and they also fitted the experimental points equally well.

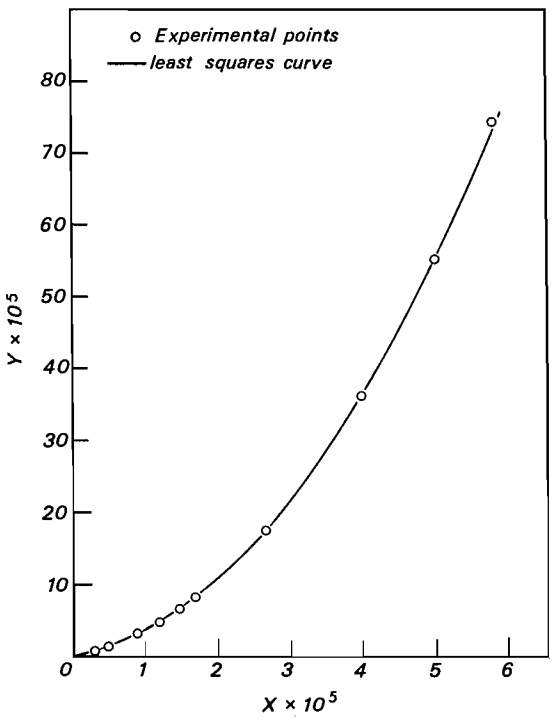

FIG. 1. Solvent extraction data for the system Bu_4NPi–H_2O–*o*-dichlorobenzene at 25.0 °C; low concentration range.

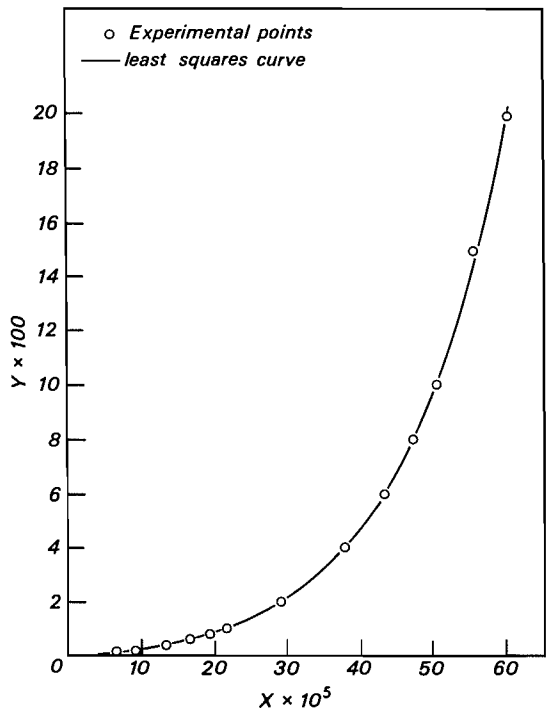

FIG. 2. Solvent extraction data for the system Bu_4NPi–H_2O–*o*-dichlorobenzene at 25.0 °C; entire concentration range.

From eqs. 8 and 9 it is seen that the sought-for equilibrium constants K, K_2, K_3, K_6, and pk could be evaluated at once from the values of A_{ion}, A_1, A_2, A_3, and A_6, provided the ψ values were available. A previous hydration study (7) had provided values for ψ_1, ψ_2, ψ_3, and ψ_6, but not for ψ_{ion}. Therefore for the present study it was assumed that $\psi_{ion} = \psi_1$. This assumption is equivalent to assuming that in the organic phase the simple ion Pi^- was hydrated to the same extent as was the monomer Bu_4NPi. This assumption is discussed below. The equilibrium constants were then evaluated, and the values are entered in Table 3. The term water-corrected equilibrium constant is used there, to emphasize that the equilibria involved are for the unhydrated species in the organic phases. The standard deviations tabulated for the benzene systems are larger percentage-wise than the corresponding values for the other two solvent systems. This

*Standard deviation for 5 degrees of freedom.

reduced precision is due partly to the fact that for the benzene systems the values of ψ_i were obtained from extrapolated values of the hydration constants (7), and partly to the relative scarcity of monomers and dimers in the benzene phase.

Discussion

The values found in the present work for the dissociation constants of the Bu_4NPi monomer are compared in Table 4 with literature values obtained from conductance data in anhydrous systems. Agreement for the *o*-dichlorobenzene system is reasonably good, but for the chlorobenzene it is poor. For the benzene system the large standard deviation (due to the relative scarcity of single ions in the benzene phase, even at the lowest concentrations studied) makes comparison of the two values of the dissociation constant of little value, even though statistically they agree.

The solvent systems in the present work were water-saturated, whereas the literature values in Table 4 were for anhydrous solvents. Therefore, the dielectric constants of the water-saturated solvents were measured, and the values are compared in Table 5 with values reported for the anhydrous solvents. Clearly, the presence of unbound water produced an increase in dielectric constant that was much too small to cause a measurable increase in the dissociation constants. Presumably the presence of hydrated species of Bu_4NPi and its aggregates and ions did not affect the dissociation constant of the anhydrous monomer. Therefore, another explanation was sought for the difference between the present and the literature values of that dissociation constant in chlorobenzene.

In treating the data for all the present systems, the somewhat arbitrary assumption had been made that $\psi_{ion} = \psi_i$ (see eq. 1). For the *o*-dichlorobenzene system, the agreement between present and literature values for the dissociation constant of Bu_4NPi suggests that the assumption was valid. To obtain similar agreement for the chlorobenzene system requires that $\psi_{ion} \sim 10\psi_1$. This indicates that the degree of hydration of the ions, compared to that of the monomer, was greater in chlorobenzene than in *o*-dichlorobenzene. A reasonable explanation for this difference in hydration is as follows. The dissociation constant of Bu_4NPi is approximately 1000 times greater in anhydrous *o*-dichlorobenzene than in anhydrous chlorobenzene. Hence *o*-dichlorobenzene is a stronger solvator of ions relative to monomers, than is chlorobenzene. Therefore *o*-dichlorobenzene would more successfully compete with dissolved water to solvate the ions, than would chlorobenzene. Moreover, hydration of ions would be expected to exceed hydration of the monomer, in both solvents; ion–dipole (ion–water) interactions are stronger than dipole–dipole (monomer–water) interactions. In addition, the phenolate oxygen on the picrate ion is exposed for hydration in the ion, but not in the monomer. These two factors would be less important in *o*-dichlorobenzene than in

chlorobenzene if the former solvent solvates the ions more strongly than does the chlorobenzene.

The standard free energy of transfer of the pair of ions Bu_4N^+ and Pi^- from the aqueous phase to the organic phase, there to exist as the monomer, was calculated for the three solvents from the values of pk given in Table 3.

These values of ΔG^0 at 25 °C are plotted in Fig. 3 as a function of $(1 - 1/D)$, where D is the bulk dielectric constant of the water-saturated solvent. The values of ΔG^0 at 25 °C for the dimerization and the trimerization of the monomer in the three solvents were calculated from the values of K_2 and K_3 respectively, listed in Table 3. Plots of ΔG^0 of dimerization and of trimerization *vs.* $1/D$ are also shown in Fig. 4. Each plot in Figs. 3 and 4 is a straight line. The theoretical basis for this linearity is the subject of a separate communication.

Measurable concentrations of the hexamer did not appear in the benzene system, although benzene has a lower dielectric constant than chlorobenzene. No doubt the reason is that the highest stoichiometric concentrations $[C_T]$ of Bu_4NPi in the benzene phase were an order of magnitude lower (due to solubility limitations) than those in the upper concentration range of the chlorobenzene system.

Hexamers were also not detected in the *o*-dichlorobenzene systems. The highest stoichiometric concentrations of Bu_4NPi in that solvent were about twice those in the chlorobenzene phases. However, the dielectric constant of *o*-dichlorobenzene is also about twice that of chlorobenzene.

At higher concentrations of Bu_4NPi in benzene and in *o*-dichlorobenzene, hexamers would be expected, and no doubt, other higher aggregates as well.

A ^{19}F Nuclear Magnetic Resonance and Raman Spectroscopic Study of Complex Formation between Antimony Pentafluoride and the Pentafluorides of Niobium and Tantalum

P. A. W. DEAN AND R. J. GILLESPIE

Department of Chemistry, McMaster University, Hamilton, Ontario

Received August 12, 1970

The low temperature ^{19}F nuclear magnetic resonance (n.m.r.) spectra of NbF_5–SbF_5–SO_2ClF and TaF_5–SbF_5–SO_2ClF systems appear to indicate ionization of the pentafluorides to form niobium (tantalum) fluorocations and antimony polyfluoroanions, but the solutions show an unusual distribution of species and have very low conductivities. It is concluded that neutral "fluxional" MF_4–Sb_nF_{5n+1} molecules are formed. The ^{19}F n.m.r. spectra and conductivities of the liquid systems NbF_5–SbF_5 and TaF_5–SbF_5 are consistent with the formation of neutral fluorine-bridged polymers with mixed transition metal and antimony units. These polymers may be "fluxional" on the n.m.r. time scale. The Raman spectra of the liquid systems and the crystalline pentafluoride mixtures show that both contain mixed *cis* fluorine-bridged units. The Raman spectrum of crystalline SbF_5 and the ^{19}F n.m.r. spectrum of the $NbSbF_{11}^-$ ion are reported.

Les spectres r.m.n. de fluor à basse température pour les systèmes NbF_5–SbF_5–SO_2ClF et TaF_5–SbF_5–SO_2ClF semblent indiquer que les pentafluorures s'ionisent pour former des fluorocations de niobium (tantale) et des polyfluoroanions d'antimoine; les solutions sont toutefois composés par une distribution surprenante des entités et ont de très basses conductivités. On en conclut que des molécules "fluxionnelles" neutres du type MF_4–Sb_nF_{5n+1} se forment. Les spectres r.m.n. du fluor et les conductivités des systèmes liquides NbF_5–SbF_5 et TaF_5–SbF_5 sont consistants avec la formation de polymères neutres comportant des ponts fluorés reliant des unités comportant des métaux de transition et de l'antimoine; par rapport à l'échelle de temps de la r.m.n., ces polymères peuvent être considérés comme fluxionnels.

Les spectres Raman des systèmes liquides et des mélanges cristallins de pentafluorures montrent que chacun des systèmes comporte des unités avec des ponts mixtes avec le fluor *cis*. On rapporte aussi le spectre Raman du SbF_5 cristallin et le spectre r.m.n. du fluor de l'ion $NbSbF_{11}^-$.

Canadian Journal of Chemistry, 49, 1736 (1971)

Liquid antimony pentafluoride and solid niobium and tantalum pentafluorides are all known to have fluorine-bridged structures which indicates that, in addition to their well-known Lewis acidity or acceptor properties, they also possess some basicity or donor strength. It was felt that it should be possible to obtain some information about the relative acceptor and donor strengths of these pentafluorides by studying mixtures of them. The formation of an unsymmetrical fluorine bridge would in the limit lead to ionization, for example

$$NbF_5 + SbF_5 \rightarrow NbF_4^+ + SbF_6^-$$

and the possible formation of such fluorocations was also of interest. We have, therefore, studied the mixtures NbF_5–SbF_5 and TaF_5–SbF_5 both in SO_2ClF and as liquids in the absence of a solvent using ^{19}F n.m.r. Raman spectra were obtained for the liquid and solid mixtures with no solvent; the Raman spectrum of crystalline SbF_5 is also reported. Some conductimetric measurements were made on solutions of $(n\text{-}Bu)_4NBF_4$, NbF_5–SbF_5, and TaF_5–SbF_5 in SO_2ClF and also on solutions of Et_4NSbF_6, NbF_5, and TaF_5 in SbF_5.

Recently Davies and Moss (1) reported the fluorine-on-antimony region of the ^{19}F n.m.r. spectrum of a dilute solution of NbF_5 in SbF_5. On the basis of this spectrum they concluded that simple dissolution of NbF_5 in SbF_5 occurred, but alluded to a change in the ^{19}F chemical shift of fluorine-on-niobium which led them to suggest that solute–solvent interactions were strong. Subsequently, since the completion of the present study, Edwards (2) has reported the preparation and crystal structure of a 1:1 NbF_5:SbF_5 adduct. The complex was obtained by sublimation from a mixture containing a slight excess of NbF_5. The structure consists of zig-zag chains of alternating antimony and niobium atoms linked asymmetrically by *cis*-bridging fluorine atoms in such a way that an important contribution to the structure from the ionic form $NbF_4^+SbF_6^-$ is indicated.

Results and Discussion

^{19}F n.m.r. Spectra and Conductivities of NbF_5–SbF_5–SO_2ClF and TaF_5–SbF_5–SO_2ClF

NbF_5–SbF_5 and TaF_5–SbF_5 mixtures are quite soluble in sulfuryl chlorofluoride at room temperature, but become much less so at the low temperatures required to obtain fine structure in the ^{19}F n.m.r. spectra of the solutions. Low temperature n.m.r. spectra can be obtained, however, by cooling the solutions quickly and recording the spectra rapidly.

We have investigated solutions with compositions $NbF_5/SbF_5/SO_2ClF$ = 1/1.94/4.03 and $TaF_5/SbF_5/SO_2ClF$ = 1/2.22/7.76. The ^{19}F n.m.r. spectra of both these solutions show broad lines at room temperature probably due to fast fluorine exchange, but at low temperatures fine structure can be observed in the spectra of the rapidly quenched solutions. Figure 1*a* shows the fluorine-on-antimony region of the −95° 56.4 MHz ^{19}F n.m.r. spectrum of the NbF_5 solution. Outside this region there is a single broad line (110 Hz half-width) from fluorine-on-niobium, at ϕ −278.4, and also a sharp single line from the solvent together with a smaller line +228 Hz from the solvent line which has been shown (3) to be due to SO_2ClF in the complex $SbF_5.SO_2ClF$. Figure 1*b* shows the fluorine-on-antimony region of the ^{19}F n.m.r. spectrum of the TaF_5 solution under the same conditions. The total spectrum of this solution includes a single line from the solvent, a line +215 Hz from the solvent arising from SO_2ClF in $SbF_5.SO_2ClF$, and a second line +150 Hz from the solvent line which is known (3) to result from SO_2ClF in the 2:1 complex $(SbF_5)_2.SO_2ClF$. The signal from fluorine-on-tantalum is a single broad line (240 Hz half-width) at ϕ −170.1.

The fluorine-on-antimony region of the n.m.r. spectra of both solutions are similar and the same assignments apply to both. By comparison with previous studies using SO_2ClF as solvent (3, 4) the doublet *H* and quintet *J* can be assigned to $SbF_5.SO_2ClF$ and *A*, *C*, and *F* to $Sb_2F_{11}^-$ (in Fig. 1*a* *C* is not observed due to the high intensity of *D*). *E* is part of the previously reported (4) spectrum of *cis*-$Sb_3F_{16}^-$ as is the quintet *G* which is overlapped by quintet *J* in Fig. 1*b* (other components of the spectrum of *cis*-Sb_3F_{16} are overlapped by more intense resonances and not observed); *K* may be part of the spectrum of $(SbF_5)_2.SO_2ClF$ (3). The broad signal *D* at ~ϕ 110 may reasonably be assigned to SbF_6^-.

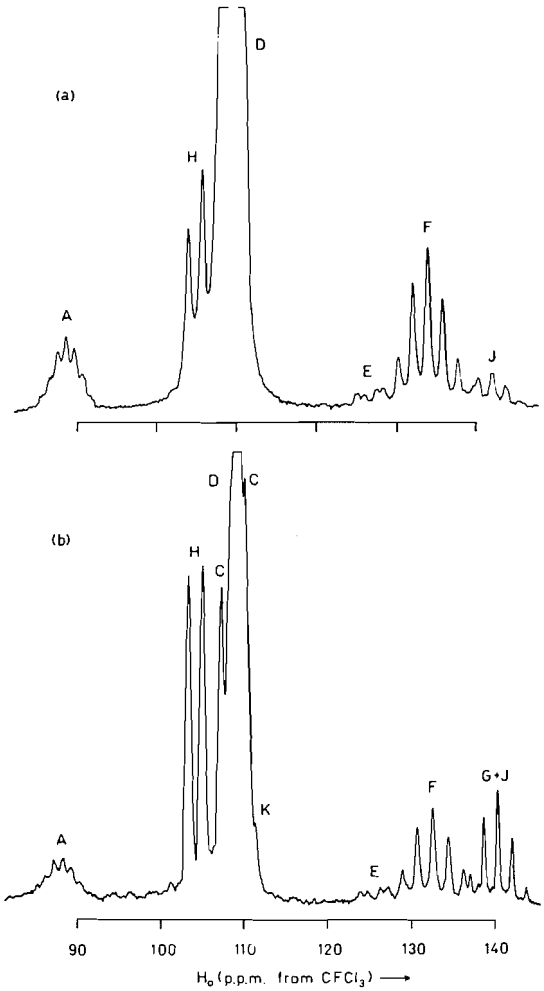

FIG. 1. The −95° 56.4 MHz ^{19}F n.m.r. spectra (F-on-Sb region only) of (*a*) a solution with $NbF_5/SbF_5/SO_2ClF$ = 1/1.94/4.03, and (*b*) a solution with $TaF_5/SbF_5/SO_2ClF$ = 1/2.22/7.76.

The n.m.r. spectra of the solutions appear to indicate ionization of the MF_5–SbF_5 mixtures to give the anions SbF_6^-, $Sb_2F_{11}^-$, and *cis*-$Sb_3F_{16}^-$, together with quite appreciable formation of $SbF_5.SO_2ClF$ which arises from solvolysis reactions such as $Sb_3F_{16}^- + SO_2ClF \rightleftarrows Sb_2F_{11}^- + SbF_5.SO_2ClF$. There must also be a cation, presumably MF_4^+, which gives rise to the broad line observed to low applied fields in these spectra. The distribution of the anions, and the amount of solvolysis product formed in the solu-

TaF_5(0.462 *m*)	SbF_5	25	1.63

[a]Specific conductivity of SO_2ClF used $< 10^{-8}$ ohm^{-1} cm^{-1} (0°).
[b]0.512 *m* $Et_4NSbF_6 \equiv$ 0.460 *m* Et_4NF.
[c]This solution becomes inhomogeneous at lower temperatures.
[d]Specific conductivity of SbF_5 used $= 0.23 \times 10^{-6}$ ohm^{-1} cm^{-1} (25°).

tions are, however, somewhat anomalous in the light of an investigation (4) of the systems *t*-BuF–SbF_5–SO_2ClF and $(n\text{-Bu})_4NSbF_6$–SbF_5–SO_2ClF. In this study it was shown that solvolysis of the anions $Sb_nF_{5n+1}^-$ is negligible up to $n = 3$, and that *cis-cis*-$Sb_4F_{21}^-$, which *is* partly solvolyzed, is not produced in solutions containing appreciable amounts of the SbF_6^- ion. For instance, in a solution where *t*-BuF/SbF_5/SO_2ClF = 1/2.5/2.2, there is an almost equimolar mixture of the anions $Sb_2F_{11}^-$ and *cis*-$Sb_3F_{16}^-$, a much smaller amount of SbF_6^- and an extremely small amount of $SbF_5.SO_2ClF$. Significant amounts of $SbF_5.SO_2ClF$ are formed only in solutions with higher SbF_5/F^- ratios, and in the spectra of these solutions there is no observable SbF_6^- signal.

Changing the cation from $C(CH_3)_3^+$ or $(n\text{-Bu})_4N^+$ to MF_4^+ clearly produces a change in the distribution of the fluorine-containing species in the SO_2ClF solutions. Whereas the *t*-BuF/SbF_5/SO_2ClF solutions contain predominately $Sb_2F_{11}^-$ and $Sb_3F_{16}^-$ and no $SbF_5.SO_2ClF$ or SbF_6^- all four species are present in the MF_5–SbF_5 solutions.

Changes of cation could produce changes in the distribution of a series of anions in equilibrium if there were a significant change in one or more cation–anion interactions with variation in cation. To assess the importance of cation–anion interactions in the SO_2ClF solutions of MF_5–SbF_5, conductivity measurements were made. The results are given in Table 1, together with a measurement on $(n\text{-Bu})_4NBF_4$ as a standard electrolyte. (Neither of the more desirable standards Et_4NSbF_6 or $(n\text{-Bu})_4NSbF_6$ showed sufficient solubility in SO_2ClF to be useful.) The MF_5–SbF_5 mixtures have conductivities very much lower than that of the tetrafluoroborate salt. Although the dielectric constant of SO_2ClF has not been reported, it is presumably low, and it is therefore expected that extensive ion-multiplet formation will occur in the BF_4^- solution. In the pentafluoride mixtures ion-multiplet formation must be even more extensive or alternatively a different type of interaction must be involved. Both NbF_4^+ and TaF_4^+ are expected to be extremely strong Lewis acids and it would not be surprising, therefore, if the cation–anion interaction in MF_5–SbF_5 took the form of strong fluorine bridging between MF_4^+ and $Sb_nF_{5n+1}^-$. We conclude that neutral fluorine bridged MF_4–Sb_nF_{5n+1} molecules are formed which are ionized to the extent of a few percent only.

The fluorine-on-antimony region of the ^{19}F n.m.r. spectrum of a neutral fluorine-bridged molecule MF_4–Sb_nF_{5n+1} would normally be expected to differ from that of an $Sb_nF_{5n+1}^-$ anion due to association of the MF_4 entity with some of the fluorines in the Sb_nF_{5n+1} section of the molecule but not with others. However, the n.m.r. spectra of the MF_5–SbF_5–SO_2ClF solutions (Fig. 1) show what appear to be the spectra of unperturbed $Sb_nF_{5n+1}^-$ ions and thus the n.m.r. measurements are apparently at variance with the above interpretation of the conductivity experiments.

It is possible to reconcile the conductivity and n.m.r. results if the molecules MF_4–Sb_nF_{5n+1} are "fluxional". In these "fluxional" molecules there occurs very rapid (on an n.m.r. time scale) intramolecular exchange of potential MF_4^+ cations between various fluorine positions on the potential $Sb_nF_{5n+1}^-$ anion, in such a way that the ^{19}F n.m.r. spectrum of the potential anion is indistinguishable from that of the free anion. Such an intramolecular exchange could be rapid and facile if the MF_4 moiety were fluorine-bridged to antimony as in **1**, the exchange then taking place by continued fission of one M···F bond at a time,

followed by formation of another such bond to a different fluorine on the antimony.

As the structures of crystalline NbF_5 and TaF_5 (5) and of $NbF_5.2SbF_5$ (2) involve two *cis* fluorine-bridges per niobium or tantalum it is most probable that in the present case the number of fluorine-bridges per M is also two. As the MF_4 unit is strongly electron withdrawing it is reasonable to expect that the molecule $MF_4.Sb_3F_{16}$ will be more easily solvolyzed than the free $Sb_3F_{16}^-$ ion. Therefore the unusually large amount of solvolysis observed in the MF_5–SbF_5 solutions is consistent with the proposed model.

Formation of "fluxional" molecules has recently been postulated to explain the ^{19}F and ^1H n.m.r. spectra of MeF–SbF_5 (6, 7) and EtF–SbF_5 (7) solutions in SO_2 and SO_2ClF. In these systems the fluorine n.m.r. showed what were apparently the spectra of the free anions $Sb_nF_{5n+1}^-$, but the proton n.m.r. showed the absence of ionization. It is noteworthy that the "fluxional" molecule Et-Sb_3F_{16} is apparently more easily solvolyzed in SO_2ClF than the free *cis*-$Sb_3F_{16}^-$ anion (7).

^{19}F n.m.r. Spectra and Conductivities of SbF_5–NbF_5 and SbF_5–TaF_5

Mixtures of NbF_5 and SbF_5 are stable as liquids or supercooled liquids at room temperature when $NbF_5/SbF_5 \gtrsim 0.7$, as are mixtures of TaF_5 and SbF_5 when $TaF_5/SbF_5 \gtrsim 0.5$. In systems containing more of the transition metal pentafluoride, crystallization occurred fairly rapidly but it was nevertheless possible to obtain some information from ^{19}F n.m.r. spectra recorded quickly on the melts supercooled to room temperature. Low temperature n.m.r. spectra could be obtained for both NbF_5–SbF_5 and TaF_5–SbF_5 mixtures in which $MF_5/SbF_5 \leq 0.3$.

The room temperature n.m.r. spectra of the MF_5–SbF_5 mixtures showed, to low applied fields, a broad resonance from the fluorine-on-transition element, and, in the fluorine-on-antimony region, either a single broad resonance or a more incompletely resolved set of several resonance. Table 2 gives details of the room temperature spectra of the NbF_5–SbF_5 mixtures; Table 3 presents similar information for TaF_5–SbF_5 mixtures. The intensity measurements for both systems indicate extensive transfer of fluorine from the transition element to antimony. In addition there is considerable variation in the chemical shift of the fluorine-on-Nb(Ta) signal

with composition, whereas the fluorine-on-Sb resonance, when a single line, is always in the range ϕ 107–112 (as noted above this part of the spectrum was more complex in some solutions). For compositions with small amounts of antimony the F-on-Nb(Ta) chemical shifts approach those of MF_5, and limiting values in the antimony-rich region are observed when the mole fraction of $SbF_5 \geqslant 0.8$. The total variation of the F-on-Nb(Ta) chemical shifts, about 100 p.p.m. for the NbF_5–SbF_5 system and 65 p.p.m. for the TaF_5–SbF_5 system,[1] provides good evidence for strong interaction between the components of the mixtures.

Figure 2 shows the fluorine-on-Sb region of the low temperature ^{19}F n.m.r. spectra of NbF_5–SbF_5 mixtures with $0.324 \geqslant NbF_5/SbF_5 \geqslant 0.093$. The fluorine-on-niobium chemical shifts of these mixtures did not change significantly from their room temperature values though there was some variation in half-width of the signal, probably resulting mostly from changes in viscosity. Essentially identical spectra were obtained for liquid TaF_5–SbF_5 mixtures with the same mole ratios. The spectrum of a dilute NbF_5–SbF_5 (or TaF_5–SbF_5) solution (Fig. 2*a*) is very similar to the ^{19}F n.m.r. spectrum of SbF_5 which shows three regions of resonance, *A*, *B*, and *C*, with intensities 1:2:2 (1, 4, 8). Davies and Moss (1) have previously remarked upon this similarity for a dilute solution of NbF_5 in SbF_5; however, they did not notice the distortion (compared to the spectrum of SbF_5) of the resonance *B* which arises from the growth of a new resonance *D* beneath the high field side of *B*. As the amount of solute is increased the intensity of the broad line *D* increases but the intensity ratio *C*/*A* remains equal to two as it is in SbF_5 itself, strongly suggesting that some free SbF_5 or another SbF_5-like species is present even at the highest M/Sb ratios studied (there is some loss in resolution of *C* which most probably results from increased viscosity at the higher M/Sb ratios). Over the range of composition studied at low temperatures, the ratio of the intensity of the signal *D* to that of the F-on-M resonance is approximately two.

Although the intensities given in Tables 2 and 3 suggest extensive ionization in these systems, with donation of fluoride ion from the transition element to antimony, the relatively good resolution obtained in the low temperature spectra is not consistent with an ionic model. In the system Et_4NSbF_6–SbF_5, which *must* be ionic, very broad lines are observed in the ^{19}F n.m.r. spectrum at all temperatures studied, almost certainly as a result of rapid fluorine exchange (9). In view of this apparent anomaly and the unusual results obtained for solutions of MF_5–SbF_5 in SO_2ClF (see above), conductivity measurements were made on the SbF_5 solutions of MF_5. The results are shown in Table 1, together with a measurement for Et_4NSbF_6 as a standard electrolyte. It is clear by comparison with the ionic Et_4NSbF_6–SbF_5 system that the MF_5–SbF_5 mixtures can be at most slightly ionized.

[1]As the solutions showed no electron spin resonance (e.s.r.) signals these cannot be contact shifts.

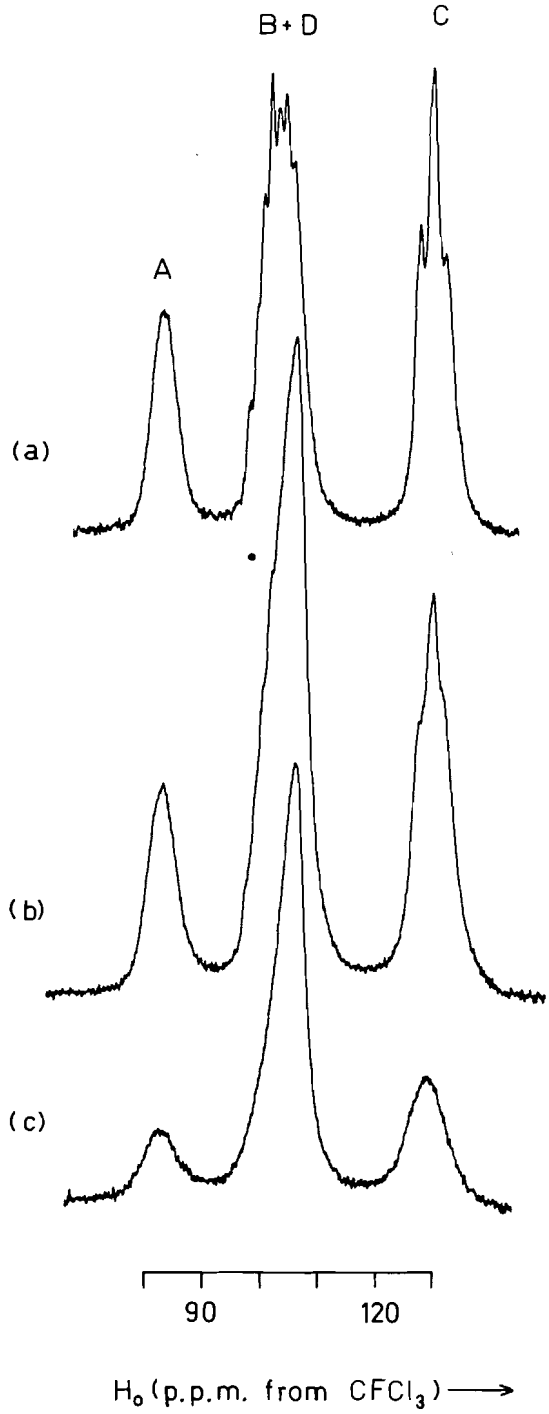

FIG. 2. The 56.4 MHz ^{19}F n.m.r. spectra (F-on-Sb region only) of liquid NbF_5/SbF_5 mixtures: (*a*) $NbF_5/SbF_5 = 0.093$, and $-36°$; (*b*) $NbF_5/SbF_5 = 0.200$, at $-36°$; (*c*) $NbF_5/SbF_5 = 0.324$, at $-28°$.

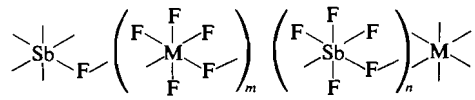
The NbF_5 solution was blue (as were those used for n.m.r.) apparently due to a very small amount of highly colored impurity;[2] thus part of the difference between the conductivities of the NbF_5 and TaF_5 solutions could be due to impurities.

The n.m.r. and conductivity measurements show that the MF_5–SbF_5 systems are essentially covalent, and the n.m.r. spectra also show that free SbF_5 is probably present at least up to MF_5/SbF_5 ratios of *ca.* 0.3. It seems very likely that $NbF_5.SbF_5$ has a polymeric structure in the liquid state similar to that found for the solid (2). However, our results cannot be satisfactorily accounted for in terms of the formation of a 1:1 mixed polymer only [*e.g.*, the ^{19}F chemical shift of F-on-Nb or F-on-Ta is, at the 1:1 point, considerably different from its value in dilute SbF_5 solution (Tables 2 and 3)] and we suggest that polymers of the general type **2** are formed.



2

Like $NbF_5.SbF_5$ (2), these contain both antimony and transition metal units linked by *cis*-fluorine bridges. In principle **2** could also contain *trans*-fluorine bridges, but the Raman spectra discussed below provide no evidence for *trans* bridging. As SbF_5 is present at some compositions, completely random mixing of Sb and M cannot occur over the whole range of composition, but apparently the antimony-rich polymers tend to disproportionate to give the SbF_5 polymer and a less antimony-rich Nb(Ta)–Sb polymer, *i.e.*, there is a limiting value for *n*, the average antimony chain length in the mixed polymer. This situation resembles that in the system Et_4NSbF_6–SbF_5, where $Sb_nF_{5n+1}^-$ ions are not formed indefinitely but at higher values of *n* disproportionation occurs to give SbF_5 and a smaller polyfluoroanion (9). Since the intensities of *A* and *C* show quite a large amount of SbF_5 to be present in mixtures with $Nb(Ta)/Sb \simeq 0.3$, the average limiting value for *n* must be small, probably two or less.

In the polymers containing a maximum amount of antimony we can reasonably expect that few M—F—M bridges are present, *i.e.*, the value of

[2]We note that solutions of NbF_5 in ethanol are reported to be purple (10).

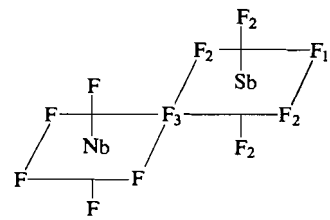
For personal use only.

m, the average MF_5 chain length in the polymer, is close to unity. On increasing the M/Sb ratio the value of n, the average SbF_5 chain length approaches unity, and simultaneously the value of m increases. Both these factors probably affect the chemical shift of F-on-M. As the transition metal positions are averaged by fast exchange, we might expect a smooth variation in the average chemical shift of F-on-M, from a limiting value in solutions with a low M/Sb ratio towards the value for MF_5 itself as m increases with increasing M/Sb. Such variation is indeed observed (Tables 2 and 3). The rapid exchange which averages the F-on-M chemical shifts could occur by homo- or heterolytic cleavage and reformation of Sb—F—M or M—F—M bridges (or both).

There still remains the problem of the inconsistency between the apparently extensive ionization indicated by the intensities in the ^{19}F n.m.r. spectra and the very limited ionization indicated by the conductivity measurements. In view of the results for MF_5–SbF_5–SO_2ClF, one possible explanation is that polymers of the type **2** are "fluxional". Unfortunately we were unable to obtain spectra at a low enough temperature to observe the definitive n.m.r. spectra of the $Sb_nF_{5n+1}^-$ ions and so confirm that the polymers are "fluxional". We presume that, at the temperatures we could reach, the chemical shifts of the various fluorines-on-antimony in the M—Sb polymers are averaged to the single line D, just as the chemical shifts of F-on-M are averaged. If the value of n is between one and two then in the most antimony-rich polymers, where for reasons given above $m \simeq 1$, the intensity ratio of D to the F-on-M signal should be between 1.5 (for MF_4–SbF_6) and 2.75 (for MF_4–Sb_2F_{11}) and the ratio is found to be about two experimentally.

An alternative explanation for the apparent ionization is that not all the intensity attributed to fluorine-on-antimony is in fact due to fluorine bonded solely to antimony. To investigate this possibility further we studied the spectrum of another system containing a fluorine bridge between niobium and antimony. $(n\text{-Bu})_4NSbF_6$ has very low solubility in SO_2ClF but dissolves in the presence of an equimolar amount of NbF_5. At $-135°$, the 94.1 MHz ^{19}F n.m.r. spectrum of the mixture showed, in addition to the solvent line, a broad (approximately 225 Hz half-width) line at ϕ -157.1 which can be attributed to fluorine-on-niobium, and three broad structureless lines of intensity 1:4:1 at ϕ 101.7, 117.7, and 131.5 (half widths $\simeq$479, $\simeq$280, and $\simeq$470 Hz, respectively) in the region normally attributable to fluorine-on-antimony. The ratio of the intensities F-on-Nb/F-on-Sb was found to be 5/6. The spectrum may be assigned to the $NbSbF_{11}^-$ ion (**5**). By comparison with the spectra of the $Sb_2F_{11}^-$ ion (9, 11) and the $AsSbF_{11}^-$ ion (12),



5

we can probably assign the line at ϕ 131.5 to the fluorine F_1. The intense signal at ϕ 117.7 must arise from the fluorines F_2, and hence we conclude that the resonance at ϕ 101.7 is due to the fluorine F_3, *bonded to both niobium and antimony*, even though it appears in the "fluorine-on-antimony" region. (Note that reversal of the assignments for F_1 and F_2 does not alter the conclusion.) This result probably signifies considerable asymmetry of the Nb—F—Sb bridge, the fluorine lying much closer to the antimony than to the niobium just as the bridging fluorines do in $NbF_5.SbF_5$ (2). The lack of fine structure in the lines in the F-on-Sb region may be due to residual coupling with the Nb nucleus ($I = 9/2$). The single signal from fluorine-on-niobium is probably a result of fast inter- or intramolecular exchange of the terminal fluorines attached to niobium.

Raman Spectra

In order to be able to interpret the Raman spectra of the pentafluoride mixtures, a knowledge of the individual Raman spectra of SbF_5, NbF_5, and TaF_5 as liquids and crystalline solids is desirable. Raman spectra have been reported for liquid SbF_5 (13–15), liquid (13, 16) and solid (13) NbF_5, and liquid (13, 16) and solid (13) TaF_5. We have now obtained the Raman spectrum of crystalline SbF_5 which can be obtained by cooling a solution of SbF_5 in C_4F_8, SO_2F_2 or SF_6 and removing the solvent at low temperature. We have also found that some samples of SbF_5 crystallize on cooling after having been stored in

glass tubes for a period of months. Details of the Raman spectrum of crystalline SbF_5 are given in Table 4. The high frequency region of the −100° spectrum of the material is shown in Fig. 3*a*; Fig. 3*b* shows the same region for liquid SbF_5 supercooled to −100°. The spectra of crystalline and liquid pentafluoride show marked differences; in particular more and sharper bands are observed in the high frequency (antimony-terminal fluorine stretching) region of the spectrum of the solid than of the liquid. Nevertheless the two most intense bands observed in the spectrum of the liquid (717 and 668 cm^{-1}) are essentially unchanged in position in the solid (718 and 670 cm^{-1}) which must therefore have a structure based on *cis* fluorine-bridged SbF_5 units, as has been shown by ^{19}F n.m.r. to be the case for the liquid (1, 4, 8). The two most likely structures for the solid are the infinite *cis* fluorine-bridged chain structure of liquid SbF_5 and crystalline VF_5 (17) or the cyclic fluorine-bridged tetrameric structure of crystalline NbF_5 and TaF_5 (5), but we cannot definitely assign either structure on the basis of the Raman spectrum alone.

TaF_5–SbF_5 and NbF_5–SbF_5

Table 4 gives the details of the Raman spectrum of a system with TaF_5/SbF_5 = 1/1.13 both as a crystalline solid at room temperature, and as a

liquid at 65°. It also includes the spectra of solid and liquid SbF_5 and TaF_5 for comparative purposes. The spectrum of the system is complicated and it is difficult to make definite assignments. However, useful information can be obtained from the region above 600 cm^{-1}. In this region the spectrum of the solid closely resembles a superimposition of the spectra of solid SbF_5 and TaF_5 having strong bands at 764, 713, 695, and 668 cm^{-1} compared with 755 and 699 cm^{-1} for TaF_5 and 717 and 668 cm^{-1} for crystalline SbF_5. By variation of the composition of the mixtures studied, it was possible to associate increased intensity of the bands at 764 and 695 cm^{-1} with increased amount of TaF_5 in the system, and increased intensity of the bands at 743, 713, and 695 cm^{-1} with increased SbF_5.

The formation of crystalline products melting above room temperature (*e.g.*, 50–56° and 40–45° when TaF_5/SbF_5 = 1/1.13 and 1/2.01, respectively) and therefore well above the melting point of crystalline SbF_5 of 5–10 °C is good evidence that in the solid there is more than a simple mixture of the components with no interaction. In view of the similarity of bands in the Raman spectrum to those of either crystalline SbF_5 or crystalline TaF_5, both of which contain *cis* fluorine-bridging between MF_6 units (4, 5), it is reasonable to conclude that in the present case we also have *cis* fluorine-bridged MF_6 units but with some alternation of Sb and Ta as the central atom. The structure is presumably that of an infinite chain, similar to the structure of $NbF_5.SbF_5$ (2), though we cannot, on the basis of the Raman spectrum alone, rule out a cyclic fluorine-bridged structure.

The 65° Raman spectrum of the liquid of composition TaF_5/SbF_5 = 1/1.13 (Table 4) is similar to that of the solid with like composition, and also to a combination of the spectra of liquid SbF_5 and liquid TaF_5. Thus the liquid shows an intense strongly polarized band at 668 cm^{-1} where SbF_5 alone has a similar band, and a second intense strongly polarized band at 762 cm^{-1} close to the frequency (755 cm^{-1}) where such a band is observed in the spectrum of liquid TaF_5. The single rather broad polarized band at 705 cm^{-1} in this TaF_5–SbF_5 mixture must be a composite of two bands: in the spectrum of a liquid with TaF_5/SbF_5 = 1/2.01 a higher frequency band (712 cm^{-1}) with a lower frequency shoulder (~700 cm^{-1}) is observed, both bands being polarized. (These most probably correspond to the two distinct bands observed at 713 and 695 cm^{-1} in the solid.) Bands occur at 718 and 690 cm^{-1} in the spectra of liquid SbF_5 and TaF_5, respectively. Comparison of the spectra of mixtures of different composition shows that the band at 762 cm^{-1} increases in intensity with increasing mole ratio of TaF_5 and the band at 668 cm^{-1} with increasing amount of SbF_5.

As in the case of the solid product, the Raman spectrum of the liquid mixture is close to that expected for no interaction of the components. However, the ^{19}F n.m.r. spectra of the pentafluoride mixtures (see earlier) show that reaction does occur, a conclusion strengthened by the Raman evidence presented above for mixing of TaF_6 and SbF_6 units in the solid. It seems certain that if such mixing occurs in the solid it will also occur in the liquid. In view of the Raman spectra of the solids, the bands at 764 and 668 cm^{-1} in the spectrum of the liquid indicate the presence of *cis* fluorine-bridged TaF_6 and SbF_6 units, respectively, in the liquid also. We conclude that our results are consistent with formation of a mixed fluorine-bridged polymer of the type **2** with *cis* fluorine bridges on both Ta and Sb.

Since the bands observed at 755, 762, and 764 cm^{-1} in the Raman spectra of crystalline TaF_5, and the crystalline and liquid TaF_5/SbF_5 mixture, respectively, are diagnostic of the presence of *cis* fluorine-bridged TaF_6 octahedra, it seems highly probable that the observation of a band at 755 cm^{-1} in the spectrum of liquid TaF_5 also show the presence of such units, and is therefore consistent with the polymeric structure proposed by Beattie *et al.* (13) for this material. In view of our results for the mixed pentafluoride systems, we conclude that the monomeric structure proposed by other authors (16, 18) for liquid TaF_5 is highly unlikely.[3] Such a structure is in any case doubtful in view of the high Trouton's constants of 25.9 cal/°K for TaF_5 and of 25.4 cal/°K for NbF_5, (20).

We were able to obtain good Raman spectra of liquid NbF_5–SbF_5 mixtures and no spectra at all were obtained from the corresponding solids.

[3]In the only proven case of depolymerization of a fluorine-bridged material in the liquid phase, that of VF_5 (20), the Raman frequencies of the monomer differ significantly from those of the polymer, whereas the frequencies of the liquid and solid polymer are almost identical (13, 20).

The spectra of the liquid mixtures were generally similar to those of the TaF_5–SbF_5 mixtures. Detailed frequencies for a typical spectrum (NbF_5/SbF_5 = 1/2.13) are given in Table 5, together with those of the spectra of liquid and solid NbF_5. All three spectra show an intense band in the region 763–770 cm^{-1} which, by the same arguments used for TaF_5–SbF_5, must be diagnostic of *cis* flourine-bridged NbF_6 units, known to occur in crystalline NbF_5; the spectrum of the mixture also shows an intense polarized band at 667 cm^{-1} shown above to be diagnostic of *cis*-bridged SbF_6 units. We conclude that, as in the TaF_5–SbF_5 system, the liquid has a polymeric structure involving mixed *cis* fluorine-bridged antimony and transition element MF_6 octahedra. It is reasonable to suppose that solids isolable from the system NbF_5–SbF_5 will have structures similar to $NbF_5.SbF_5$ (2) even when of different stoichiometry.

Experimental

Fluorine n.m.r. spectra were obtained using a Varian DA-60 operating at 56.4 MHz in the field sweep unlock mode described previously (3). The spectrometer was equipped with a Varian variable temperature probe and controller. Spectra were calibrated using sidebands from an audio oscillator, and referencing to external $CFCl_3$ was made either by sample interchange (in samples with no SO_2ClF solvent) or, in SO_2ClF solutions, by measuring relative to the internal SO_2ClF solvent line and applying the appropriate conversion ($\delta(CFCl_3) = \delta(SO_2ClF) - 99.1$ p.p.m.). Areas were measured by cutting out lines and weighing them; at least four spectra were averaged.

Raman spectra were taken with a Spex Industries Model 1400 spectrometer using argon ion (5145 Å) excitation from a Spectra Physics Model 140 laser. The 90° viewing technique of Gillespie and Pez (21) was used. Low temperature spectra were obtained using a Dewar insert cooled by boiling liquid nitrogen as already described (22). For high temperature work the same Dewar insert was used and heating was provided by directing the thrust of a hot air blower through the insert *via* a cone of aluminum foil. Temperatures were measured using a thermocouple which lay next to the sample in the Dewar insert. Samples were contained in either melting point capillary tubes or in 5 mm o.d. glass tubes.

Conductivity measurements were made using an Industrial Instruments Incorporated Bridge, model R.C. 18. The cell was like that previously used (11) with anhydrous hydrogen fluoride; it was calibrated in the normal manner.

Antimony pentafluoride (Ozark Mahoning Co.) was purified by double distillation under an atmosphere of dry nitrogen in a glass apparatus. Niobium and tantalum pentafluorides (Ozark Mahoning Co.) were purified by triple sublimation in vacuo in a Vycor apparatus. Sulfuryl chlorofluoride was synthesized from KSO_2F and chlorine by the method of Seel and Riehl (23). Sulfur dioxide impurity in the product was removed by condensing the SO_2ClF onto SbF_5 using a vacuum line, then distilling off the SO_2ClF *in vacuo*, leaving the SO_2 behind as the relatively involatile $SbF_5.SO_2$. The absence of SO_2 was confirmed by the absence of the characteristic ^{19}F n.m.r. spectrum of either $SbF_5.SO_2$ or $(SbF_5)_2.SO_2$ (3) in the n.m.r. spectra of the SO_2ClF solutions, and also by the absence of the band at 1361 cm^{-1} (24) in the infrared spectrum of the gas.[4]

Samples in 5 mm o.d. n.m.r. and Raman tubes were prepared by adding weighed amounts of the pentafluorides under a nitrogen atmosphere in a dry box. SbF_5 was transferred to the tubes using an all-glass syringe. The tubes were closed with detachable tops and attached to a standard glass vacuum line. If no solvent was to be added the tubes were evacuated and sealed, otherwise the SO_2ClF was condensed in prior to sealing and the sealed tube with top weighed afterwards. The samples with no solvent were homogenized by heating to *ca.* 100° in an oven with frequent shaking and turning. Thereafter these samples were kept molten until used since they exhibited a frustrating tendency to crack the container on crystallization. Raman samples in capillary tubes were prepared by carefully allowing the larger molten samples to crystallize, cracking open the 5 mm tube in the dry box, and transferring the solid to the capillary which was sealed immediately on leaving the box.

Antimony pentafluoride samples sometimes crystallized spontaneously on cooling in Dry Ice. Alternatively SbF_5 was added to a U-shaped apparatus, the arms of which were 5 mm o.d. glass tubes, *via* a 1/4 in. o.d. tube attached at the bend. SO_2F_2 was condensed into the apparatus on a vacuum line and the 1/4 in. opening sealed. On warming and shaking, a homogeneous solution was formed at room temperature and tipped into one arm. This arm was cooled in a chloroform slush bath and the other arm in an ethyl acetate slush bath. After some time all the solvent had condensed in the low temperature arm and

[4]This band has previously been incorrectly assigned (25) to a combination band of SO_2ClF.

crystalline SbF_5 remained in the higher. Last traces of SO_2F_2 were removed by cooling the low temperature arm to $-196°$. The tube containing the *crystalline* SbF_5 was sealed off and kept at low temperature until used.

For conductivity measurements in SO_2ClF, weighed amounts of antimony pentafluoride and the other pentafluoride, or of $(n\text{-Bu})_4NBF_4$, were added to the cell in the dry box. The cell was closed with a teflon "Swagelock" valve and attached to the vacuum line. On the vacuum line an appropriate amount of SO_2ClF was collected in a preweighed vessel closed by a teflon-in-glass stopcock. This vessel was removed from the line and weighed; it was then reconnected and the solvent was condensed into the conductivity cell.

Conductivity samples with no SO_2ClF were made up in glass tubes as for the similar n.m.r. and Raman samples, but on a larger scale. Following homogenization, the tubes were opened in the dry box and the fluid transferred to the conductivity cell.

Though both the niobium and antimony pentafluorides used were colorless, mixtures of these two, with or without solvent, were blue, presumably due to a small amount of highly colored impurity. TaF_5–SbF_5 mixtures were colorless.

We thank the United States Air Force Office of Scientific Research and the National Research Council of Canada for financial support of this work.

Evidence for a Radical Chain Mechanism in the Autoxidation of Triethylbismuth

R. V. WINCHESTER[1]

School of Natural Resources, University of the South Pacific, P.O. Box 1168, Suva, Fiji

Received December 11, 1970

The autoxidation of triethylbismuth in cyclohexane at 25 °C produces as major products ethanol, acetaldehyde, and a solid suggested to be Bi_2O_3 with oxygen atoms randomly replaced by $=CHCH_3$ or $—CH_2CH_2—$ groups. Minor products include diethyl peroxide, diethyl ether, acetic acid, and probably ethylene. The reaction is strongly inhibited by diphenylamine and a radical chain reaction is proposed to account for the observed products.

L'autoxydation du triéthyle de bismuth, dans le cyclohexane à 25 °C, conduit principalement à l'éthanol, l'acétaldéhyde et un produit solide qui serait du Bi_2O_3 dans lequel des atomes d'oxygène ont été remplacés au hasard par des groupes $=CHCH_3$ et $—CH_2CH_2—$. Parmi les produits formés en quantités mineures on retrouve le peroxyde d'éthyle, l'éther éthylique, l'acide acétique et probablement l'éthylène. La réaction est fortement inhibée par la diphénylamine et on croit que la réaction se produit par un mécanisme en chaîne de nature radicalique.

Canadian Journal of Chemistry, 49, 1747 (1971)

Introduction

The autoxidation of organometallic alkyls was originally thought to proceed by a nucleophilic rearrangement mechanism to yield first a peroxide, then an alkoxide (for a summary, see ref. 1), but more recent evidence (2–5) suggests that a radical chain mechanism is favored.

The autoxidation of triethylbismuth has been investigated once previously (6) and though products suggestive of a radical chain reaction were found, no attempt was made to substantiate this point. This paper reports the results of a short investigation intended to determine whether or not the reaction is in fact a radical chain and if possible to suggest a mechanism for it.

Results and Discussion

In all cases, when the alkyl was introduced into the solvent and stirring commenced, a period of 1 to 3 min followed in which there was no apparent reaction. Immediately following this period a yellow precipitate suddenly appeared, accompanied by a rapid uptake of oxygen. The yellow compound then faded slowly until after 2 h it was entirely white. The maximum oxygen uptake of 1.5 ± 0.2 mol per mol of alkyl occurred about 5 min after injection of the alkyl; subsequently the contained gas volume increased slightly, due to evolution of gas in the reaction. Under identical conditions but with the addition of 0.1 mol% of diphenylamine, a known radical inhibitor, the oxygen uptake and solid deposition were extremely slow, with solid continuing to deposit on allowing the solution to stand for several weeks.

Results of analysis of the solid product from various reaction times are shown in Table 1. Traces of titratable peroxide were found in the product isolated after the reaction had proceeded for 5 min, but not in the product of any longer reaction period. Gas–liquid chromatography, though not absolutely reliable as an identification method, showed that ethanol, and to a lesser extent acetaldehyde, were probably the major products, together with smaller amounts of diethyl ether, diethyl peroxide, and acetic acid. All were tentatively identified by comparison with the retention times and volumes of authentic samples on two different columns.

TABLE 1. Analyses of solid autoxidation products of triethylbismuth

Reaction time (min)	Analysis				
	C,%	H,%	Bi (± 4%)	C:H	Bi:C (± 0.05)
5	2.90	0.55	81.41	1:2.29	1:0.62
30	3.28	0.57	85.94	1:2.09	1:0.67
60	3.67	0.60	88.18	1:1.96	1:0.73
120	3.60	0.59	84.37	1:1.97	1:0.74

The only gaseous product appeared to be a small amount of an unsaturated hydrocarbon.

In the earlier investigation of this reaction (6), the only ethyl containing solid product at 25 °C was EtOBiO, with Bi:C = 1:2 and C:H = 2.50, where the corresponding ratios obtained in this work are approximately 1:0.7 and 1:2.0, respectively (with the exception of the product of 5 min reaction), suggesting that intact ethyl groups are not generally present in the product. Mixture of sufficient Bi_2O_3 with EtOBiO would depress the Bi:C ratio to the observed figure but would not affect the C:H ratio.

Since inhibition of the reaction by diphenylamine indicates that a radical reaction does occur, and as traces of peroxide and a compound with a higher C:H ratio than 1:2 are found in a sample of the solid reaction product isolated after the reaction had proceeded for 5 min it is thought that a short-lived peroxide $Et_2BiOOEt$ is probably formed initially. Fission of the Et_3Bi into radicals, attachment of oxygen to form peroxy-radicals and abstraction by them of an ethyl group from another Et_3Bi molecule would achieve this. Homolytic fission of the peroxide to produce EtO· and Et_2BiO· radicals is likely, with the radicals then abstracting either hydrogen or ethyl groups from further Et_3Bi molecules to produce ethanol and further radicals to continue the chain. Chain termination reactions involving EtO· and Et· radicals can account for the formation of diethyl peroxide, diethyl ether, and possibly acetaldehyde, though the latter may arise directly from the peroxide.

$$Et_2BiOOEt \rightarrow Et_2BiOH + MeCHO$$

A similar scheme has been proposed in the gas-phase autoxidation of triethylindium (3); there seems little reason why this should not occur in solution provided that the solvent is not involved.

As the micro-analyses indicate few intact ethyl groups in the final product (C:H $\approx$ 1:2.0) it is suggested that this product is a compound similar to Bi_2O_3 but with some of its oxygen atoms replaced by $-CH_2CH_2-$ or $\rangle CH-CH_3$ groups and that this product eventually arises from $Et_2BiCH_2\dot{C}H_2$ or $Et_2Bi\dot{C}HCH_3$ radicals produced by hydrogen abstraction from an Et_3Bi molecule.[2] Since each Et_3Bi molecule reacts with 1.5 oxygen molecules the overall scheme might be represented by

$$2Et_3Bi + 3O_2 \rightarrow Bi_2O_{3/2}(C_2H_4)_{3/2} + 3EtOH + \tfrac{3}{2}CH_3CHO$$

also accounting for the fact that ethanol and acetaldehyde are the major liquid products.

Anal. Calcd. for $Bi_2O_{3/2}(C_2H_4)_{3/2}$: C, 7.44; H, 1.25; O, 4.96; Bi, 86.35; C:H = 1:2.0, and Bi:C = 1:1.5.

It is likely though that Bi_2O_3 is also a product (*cf.* ref. 6), and a mixture of Bi_2O_3 and the proposed product in, for example, a 1:1 ratio would give a solid of composition C, 3.79; H, 0.64; O, 7.58; Bi, 87.99; C:H = 1:2.0, and Bi:C = 1:0.75. These figures are reasonably close to those found in the microanalysis and suggest that such a scheme as proposed may occur.

To elucidate this mechanism further requires considerably more evidence of both kinetic and spectroscopic nature. This paper represents only an effort to suggest a reasonable mechanism based on a small amount of experimental evidence.

Experimental

Preparations

Triethylbismuth was prepared from ethylmagnesium bromide and bismuth trichloride as described by Gilman and Nelson (7). A yield of 22% was obtained. The method of transfer of the alkyl into sealed glass capsules, and other aspects of its handling in an oxygen-free atmosphere have been described by Abraham and Davies (10, and other papers in this series) for other inflammable alkyls.

Diethyl peroxide was prepared as described by Baeyer and Villiger (9). The fraction boiling at 55–75° was collected and purified as described. Gas–liquid chromatography showed two peaks, one of which corresponded to that obtained from pure diethyl ether; the other was assumed to be diethyl peroxide.

Analyses

The original preparation was found to contain 70 ± 4% triethylbismuth, the remainder being a solid believed to be Bi_2O_3. To remove the impurities before use, a capsule was broken under cyclohexane in a small nitrogen-filled vessel fitted with a self-sealing cap. The im-

[2]A referee has suggested that the acetic acid formed in the oxidation may be incorporated in the solid and that this possibility, together with the two outlined above, could probably be distinguished by n.m.r. Unfortunately in the author's present circumstances it is not possible to obtain further samples of the product in order to clarify this point.

purities were allowed to settle and an aliquot of the alkyl in cyclohexane withdrawn and introduced into the reaction vessel as described later. A similar aliquot was allowed to oxidize in air, the bismuth determined, and from this figure was found the amount of alkyl used and its purity (98 ± 4%). In all cases, including product analyses, the bismuth determination was made by the EDTA titration method of Cheng (8).

Peroxidic oxygen was measured by titration of the iodine liberated by the oxidation product from a solution of sodium iodide in isopropanol (11).

Liquid products were examined on a "Pye Panchromatograph" gas–liquid chromatography unit operating at ambient temperature. Columns of silicone oil (5 ft × 5 mm) and dinonyl phthalate (5 ft × 5 mm and 7 ft × 5 mm) were used with nitrogen as the carrier gas. Compounds were identified by comparison with retention times of standards, the result from the silicone oil and one of the DNP columns having to agree before an identification was confirmed.

Gases were examined with an Orsat's gas analysis apparatus, using acid mercuric sulfate and acid chromous chloride solutions as absorbents for unsaturated hydrocarbons and oxygen, respectively.

Autoxidations

The general method was as described by Abraham and Davies (10) except that the flask and swan-neck adaptor was replaced by a water-jacketed reaction vessel carrying a side arm with a self-sealing rubber cap. Aliquots of the alkyl in cyclohexane were injected through this after being withdrawn from the smaller vessel described earlier.

All oxidations were carried out at 25 °C using B.D.H. "Special for Spectroscopy" Grade cyclohexane as solvent. When diphenylamine was used as an inhibitor the required amount was dissolved in the solvent prior to introduction of the alkyl.

The interest and advice of Dr. J. E. Packer in this work is gratefully acknowledged. Microanalyses were performed by the Microanalytical Service of the University of Otago.

Cobalt(II) Complexes of Isothiazole

R. RIVEST AND A. WEISZ
Département de Chimie, Université de Montréal, Montréal, Québec

Received August 25, 1970

The preparation and spectral properties are reported for complexes of CoX_2 (X = Cl, Br, I) and $Co(ClO_4)_2$ with isothiazole (L). The following complexes have been prepared: CoL_2X_2, CoL_4X_2, and $CoL_6(ClO_4)_2$. In the solid state, CoL_2X_2 (X = Br, Cl) are octahedral and polymeric, CoL_4X_2 (X = Br, Cl) are octahedral, CoL_2I_2 is tetrahedral, $[CoL_6](ClO_4)_2$ is octahedral. Except for $[CoL_6](ClO_4)_2$ which remains octahedral, all the other complexes give solutions in which Co(II) has a tetrahedral environment. In all the complexes, the ligand L is N-bonded to cobalt(II).

Ce mémoire décrit la préparation et les propriétés spectrales des complexes de CoX_2 (X = Cl, Br, I) et de $Co(ClO_4)_2$ avec le ligand isothiazole (L). Les complexes suivants ont été préparés: CoL_2X_2, CoL_4X_2 et $[CoL_6](ClO_4)_2$. A l'état solide, CoL_2X_2 (X = Br, Cl) sont octaédriques et polymériques, CoL_4X_2 (X = Br, Cl) sont octaédriques, CoL_2I_2 est tétraédrique et $[CoL_6](ClO_4)_2$ est octaédrique. A l'exception de $[CoL_6](ClO_4)_2$ qui reste octaédrique en solution, tous les autres complexes donnent des solutions dans lesquelles Co(II) a un environnement tétraédrique. Dans tous les complexes, le ligand L est lié au cobalt par l'azote.

Canadian Journal of Chemistry, 49, 1750 (1971)

Introduction

Thiazole in which the two donor atoms nitrogen and sulfur are separated by $—CH_2—$, has been reported to form N-bonded complexes with $CoCl_2$ (1). It was thought interesting to see if isothiazole (L) in which nitrogen and sulfur are neighboring atoms would have the same ligand properties. This was extended to other cobalt(II) salts to see if the anion has some influence on the type of complexes formed.

Experimental

Materials and Manipulations

Cobalt(II) halides and hexaquacobalt(II) perchlorate were obtained from Alfa Inorganics, isothiazole from Raylo Chemicals Ltd. and used as such.

For spectral work and conductivity measurements, Fisher spectro-analyzed nitromethane was used without further purification. All manipulations were performed in a dry box flushed with dry nitrogen. Unless otherwise stated all compounds were dried *in vacuo*, for 15 min at room temperature.

Preparation of the Complexes

CoL_2X_2 (X = Cl, Br, or I)

Anhydrous cobalt(II) halide (10 mmol) was dissolved in the minimum volume of hot absolute ethanol and added to an ethanolic solution of isothiazole (20 mmol). The chloride and bromide complexes precipitated on standing overnight, were filtered off and washed with ethanol and *n*-hexane. For the iodo-complex, 75% of the ethanol was evaporated and then *n*-hexane was added. After standing for a few days small green crystals were formed. These were filtered off and washed with *n*-hexane. These preparations can equally be performed in acetone.

CoL_4X_2 (X = Cl, Br)

Isothiazole (90 mmol) was added to a suspension of anhydrous cobalt(II) halide (3 mmol) in *n*-hexane. After standing overnight the products were filtered off, washed with *n*-hexane, and dried by suction under dry nitrogen for 10 min only. Drying under dry nitrogen and for a shorter length of time was necessary since preliminary experiments had shown that part of the ligand was lost if the drying was done under vacuum for 15 min.

CoL_4I_2

Isothiazole (90 mmol) was added to a suspension of anhydrous cobalt(II) iodide (3 mmol) in *n*-hexane. After standing for a week, the compound was filtered off and washed with *n*-hexane containing isothiazole to avoid exposure to dry nitrogen; only a very short drying time was therefore possible. If the yellow green iodo-complex is exposed to dry nitrogen, the color instantaneously turns to dark green indicating a partial decomposition. Then, it was not possible to prepare small samples for complete analysis on a micro-scale but by using a large sample, we could determine the iodine content. The storage of the iodo-complex is only possible in sealed containers.

$[CoL_6](ClO_4)_2$

To a solution of 15 mmol of $[Co(H_2O)_6](ClO_4)_2$ in 10 ml acetone and 25 ml dimethoxy propane (for dehydration) (2) an excess of isothiazole (263 mmol) was added; pink crystals immediately separated, which were washed once with acetone and twice with *n*-hexane.

Analysis

C, H, N, S, Co, and halogen analysis were made by Galbraith Lab. Inc., Knoxville, Tennessee. Only the iodide determination of CoL_4I_2 was carried out via titration with 0.1 *N* silver nitrate solution in the presence of K_2CrO_4 as indicator. The analytical results are included in Table 1.

Physical Measurements

Infrared spectra were recorded as Nujol mulls between polyethylene sheets or NaCl plates using Perkin–Elmer 621. Electronic spectra were obtained on a Cary 14 spectrophotometer between 25 and 5 kK for solutions. For solids, the same spectrometer was fitted with a reflectance attachment using $MgCO_3$ as reference and covered the range 25 to 12.5 kK. Magnetic measurements were made at room temperature on a Gouy balance. As a calibrant $Hg[Co(CNS)_4]$ (3) was used. The diamagnetic corrections were estimated by the method outlined by Figgis and Lewis (4). The electrolytic conductance measurements were made with a Radiometer direct-reading conductivity meter type CDM, 2d, No. 47477 and the Radiometer conductivity cell type CDC 104.

Result and Discussion

Electronic Spectra

The diffuse reflectance spectra of CoL_2X_2 complexes (Table 2) (X = Cl, Br) are similar to those of the previously prepared Co(II) complexes of pyridine (5, 6), thiazole (1), and 3-Br-pyridine (7) which are all showing a polymeric structure (8). We are therefore suggesting the same band assignment and the same structure for the CoL_2X_2 complexes.

The reflectance spectra of both CoL_4Cl_2 and CoL_4Br_2 are very similar to the respective CoL_2X_2 spectra, the only difference being for CoL_4Cl_2 a little shifting of the higher frequencies and the appearance of a shoulder at 16.5 kK, and for CoL_4Br_2 a broadening of the band at 15.34 kK. This is suggesting that in the solid state these complexes are octahedral.

The CoL_2X_2 and the CoL_4X_2 complexes dissolve in nitromethane to give blue solutions well known for tetrahedral cobalt(II) complexes (9, 10).

The behavior of CoL_2I_2 is quite different. Its reflectance spectrum with an intense band between 14.5 and 16.0 kK suggests a tetrahedral stereochemistry. The reflectance spectrum of CoL_4I_2 shows no difference with the spectrum CoL_2I_2. It is worth mentioning that, after recording, the sample of CoL_4I_2 shows the same green color as the complex CoL_2I_2 thus indicating that during the recording, a decomposition into CoL_2I_2 and the ligand occurs. Both iodo-complexes give green solutions in nitromethane having identical spectra which are also identical to their reflectance spectra and very similar to the spectrum of $Co(pyridine)_2I_2$ (9). This and the high molecular extinction coefficient indicates a tetrahedral stereochemistry.

For $CoL_6(ClO_4)_2$ there are no differences between the reflectance spectrum and the solution spectrum in nitromethane as solvent. The band at 20.2 kK can be assigned to $^4T_1(F) \rightarrow {}^4A_2$, at 18.75 kK to $^4T_1(F) \rightarrow {}^4T_1(P)$ and at 9.17 kK to $^4T_1(F) \rightarrow {}^4T_2$ for an octahedral environment. Nitromethane is the only suitable solvent since the more polar solvents react with the complex

and the non polar organic solvents give solutions too dilute to permit spectral measurements.

Magnetic and Conductance Studies

The magnetic susceptibility data (Table 1) of the complexes fall, with the exception of the iodide complexes within the normal range for octahedral complexes of cobalt(II) (4.8–5.2 B.M.) (11). The magnetic moment of CoL_2I_2 is in the range usually found for tetrahedral species (4.4–4.8 B.M.) (11). This definitely supports the tetrahedral stereochemistry of this complex as found by spectral studies. The moment of CoL_4I_2 (4.9 B.M.) is in the range of octahedral complexes. This may indicate that the size of the sample is such that the decomposition into $CoL_2I_2 + 2L$ is less important here than it is for the samples used to measure the reflectance spectrum.

The spectral studies have indicated that the dissolution of the halogeno-complexes changes their structure, all the solutions containing the tetrahedral blue Co(II) species. The conductance measurements on these complexes indicate that they are non-electrolytes. The perchlorate complex has a conductance value of 172 cm^2 mho/mol which indicates that it is a 1:2 electrolyte.

Infrared Spectra

The infrared spectra covering the range 600–200 cm^{-1} are given in Table 3. The spectrum of the complexes for the whole range 4000–200 cm^{-1} was recorded but for the region above 600 cm^{-1} they were essentially the same as the one of the pure ligand reported recently (12), except for an increase in ring vibrations and for the splitting of these vibrations on coordination. The far i.r. spectra of all complexes are all similar and consist of poorly resolved bands in the 200–260 cm^{-1} region. Since essentially the same bands are observed in this region for the perchlorate and all the halogeno-complexes, it is assumed that one of these bands is due to the Co—L stretching vibration. Exactly the same results were found by Clark and Williams (13) who investigated the violet $Co(pyridine)_2Cl_2$. In addition Goldstein and Unsworth (14) reported that in the case of the violet $Co(pyridine)_2Cl_2$ the ν(M—X) frequencies are below 200 cm^{-1} even for chlorine, and that the bands above 200 cm^{-1} are more clearly attributable to ν(M—N).

The similarity of the electronic and i.r. spectra to those of similar complexes with N-coordinated heterocyclic ligands *e.g.* pyridine (9), halogenopyridines (8), suggests that coordination is probably through nitrogen rather than through sulfur. Thiazole, benzothiazole, 2-methyl and 2-chlorobenzothiazole, 2-aminobenzothiazole (15–19) have all been reported to form N-coordinated complexes with cobalt(II).

Nuclear Magnetic Resonance Evidence Concerning the Effect of Remote Polar Substituents upon Conformational Equilibrium in Substituted Ethanes

G. K. HAMER, W. F. REYNOLDS, AND D. J. WOOD
Department of Chemistry, University of Toronto, Toronto 5, Ontario

Received November 12, 1970

The vicinal coupling constants of 1-(4-X-phenyl)-1,2-dibromoethanes vary with substituent. The coupling constants correlate with parameters which measure the polarity of the C—X bond. It is concluded that the observed changes in coupling constants with substituent are due to electrostatic interactions between the C—X and C_2—Br bonds. Two different types of electrostatic calculations confirm that this interaction should stabilize the rotamers in which the phenyl and C_2—Br groups are in a *gauche* orientation when the C—X group has polarity $C^{\delta+}$—$X^{\delta-}$.

Les constantes de couplage vicinales des (X-4 phényl)-1 dibromo-1,2 éthanes varient avec le substituant X. Les constantes de couplage varient linéairement avec les paramètres qui mesurent la polarité des liens C—X. On en conclue que les changements observés dans les constantes de couplage en fonction du substituant sont dus à des intéractions électrostatiques entre les liens C—X et C_2—Br. Deux types de calculs électrostatiques ont permis de confirmer que cette intéraction devrait stabiliser les rotamères dans lesquels les groupes phényle et C_2—Br prennent une orientation *gauche* si la polarité du groupe C—X est $C^{\delta+}$—$X^{\delta-}$.

Canadian Journal of Chemistry, 49, 1755 (1971)

Introduction

It is well established that electrostatic interactions between polar groups can affect conformational equilibria in both substituted ethanes and cyclohexane derivatives (1–5). However, it is often difficult to separate electrostatic or dipolar interactions from steric interactions. We have determined the n.m.r. spectra of a series of eight compounds of the type 1-(4-X-phenyl)-1,2-dibromoethane where X is a substituent. These compounds are useful for determining the importance of electrostatic interactions since (*1*) a substituent in the 4 position should not alter the steric interaction of the phenyl group with other substituents and (*2*) the position of the remote dipole is well defined and is independent of rotation about the C–phenyl bond. In this note we present evidence that electrostatic interactions cause predictable changes in conformational equilibrium for the above-mentioned compounds.

Experimental

1-(4-X-phenyl)-1,2-dibromoethanes were prepared by the bromination of the corresponding 4-substituted styrenes in methylene chloride. Products were recrystallized from methanol–water and purities were checked by n.m.r. spectroscopy.

Spectra were recorded on a Varian HA-100 operating in frequency sweep mode at a probe temperature of 30°. Procedures used were identical to those previously described (6).

Results and Discussion

The ABC spectra of the substituted ethyl groups were analyzed by the exact method (7). Results are given in Table 1. Some of the data were taken from a previous publication (6). In the cases where the r.m.s. error between measured and calculated line positions exceeded 0.03 Hz these data have been redetermined. It is difficult to estimate the accuracy of the coupling constants since they do not correspond to first order splittings. We believe that a reasonable error limit is 0.05 Hz. The greatest uncertainties occur for compounds with relatively non-polar substituents since in these systems, one of the AB quartets in each ABC system is nearly collapsed to a singlet, reducing the number of measurable lines.

It is obvious from the data presented in Table 1 that there is a variation of the vicinal coupling constants J_{AC} and J_{BC} which is well in excess of

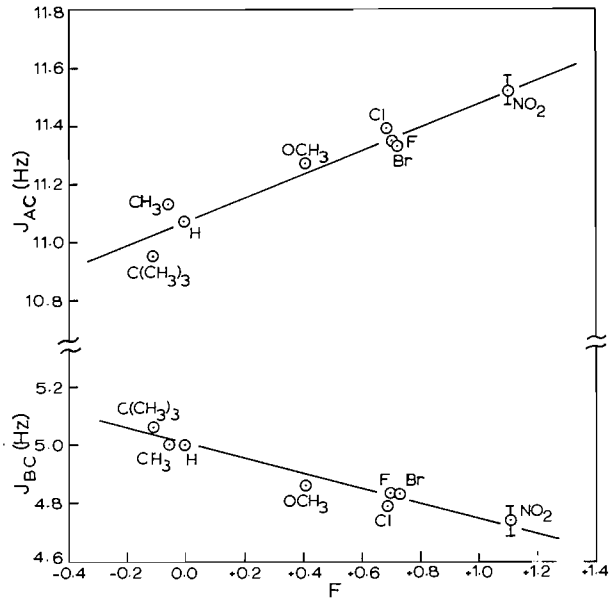

FIG. 1. Plot of vicinal coupling constants for 1-(4-X-phenyl)-1,2-dibromoethane derivatives *vs.* substituent parameter F. Estimated uncertainties in coupling constants are included for nitro derivative.

the experimental error in measuring the coupling constants. It is unlikely that this variation is due to changes in coupling constants of the individual rotational isomers (rotamers) with substituent. The *cis* and *trans* coupling constants of the corresponding 4-substituted styrenes are constant within experimental error (8). Similarly, the vicinal coupling constants of 4-X-phenylhexachloro[2.2.1]heptene derivatives (these compounds roughly correspond to our compounds frozen in an eclipsed conformation) do not vary with substituent (9). The vicinal coupling constants for the parent compound and the nitro derivative have been shown to be nearly concentration independent (6). Consequently, it is highly improbable that the observed variation in coupling constants is due to concentration effects. We believe that the observed changes in coupling constants are due to changes in rotamer populations.[1]

[1]The variation of J_{AB} with substituent may also reflect conformational changes. However, the observed variation may, in part, reflect substituent effects upon individual coupling constants since the corresponding geminal coupling constant in 4-substituted styrenes varies markedly with substituent. It is difficult to separate the two possible effects but they probably both contribute to the variation in J_{AB}.

Changes in rotamer populations with substituent cannot reflect steric interactions since H and *t*-butyl derivatives have similar coupling constants. We believe that they reflect electrostatic interactions between the remote dipolar substituent and the C_2—Br bond (interactions between the substituent and the C_1—Br bond should be essentially equal in all rotamers). In an attempt to confirm this, we have plotted J_{AC} and J_{BC} *vs.* the substituent parameter F (see Fig. 1). Parameter F is a pure field effect substituent parameter derived by Swain and Lupton (the companion parameter R is a measure of resonance interactions) (10). Since F measures the field effect of a substituent, it should be proportional to the polarity of the C—X bond. Therefore, the good correlation of F with J_{AC} (correlation coefficient, $r = 0.966$) and J_{BC} ($r = 0.976$) strongly suggests that the variation of J_{AC} and J_{BC} with substituent has an electrostatic origin. A good correlation also exists between coupling constants and the bond dipole moments (11) of the substituents ($r = 0.949$, 0.943).[2] There is no correlation between coupling constants and R ($r = 0.083$, 0.013).

The three possible rotamers for 1-phenyl-1,2-dibromoethane derivatives are shown in Fig. 2. It is known that the order of energy levels for the parent compound is $E_1 < E_2 \ll E_3$ (6, 12). J_{AC} is a *trans* coupling constant in rotamer **1** while J_{BC} is a *gauche* coupling constant, confirming the assignment $J_{AC} > J_{BC}$ given in Table 1. Since J_{AC} increases and J_{BC} decreases when H is replaced by an electron-withdrawing substituent, the population of rotamer **1** must increase when the latter group has polarity $C^{\delta+}$—$X^{\delta-}$, *i.e.* the interaction between C_2—Br and $C^{\delta+}$—$X^{\delta-}$ groups in rotamer **1** must be relatively stabilizing. We originally rejected the present explanation on the naive grounds that this interaction should destabilize rotamer **1** relative to rotamer **2** (6). While this would be true if X were bonded directly to C-1, it is not true when it is bonded to a more remote carbon. This can be shown in two ways. The C—X and C_2—Br dipoles can be represented as separated charges calculated from the group dipole moments. For example, consider the 4-bromo derivative. The distance between the remote polar group and C-2 is independent of rotation angle. Therefore, electrostatic interactions involving C-2 are equal in all rotamers and need not be considered in a calculation of relative energies. The distances of the two ends of the remote polar group from bromine for *gauche* (rotamer **1**) and *trans* (rotamer **2**) conformations are shown in Fig. 3 (assuming normal bond lengths (13) and tetrahedral bond angles). Assuming a dipole moment of 2.03 D for each group,[3] the calculated energy of interaction is -0.35×10^{-13} ergs/molecule or -0.50 kcal/mol for rotamer **2** and -0.55×10^{-13} ergs/molecule or -0.79 kcal/mol for rotamer **1**. Therefore, rotamer **1** is predicted to be stabilized relative to rotamer **2** by 0.29 kcal/mol due to a remote C—Br bond at the 4 position of the phenyl group. A similar approach has been used by Wood *et al.* (4) to account for the stability of 1,4 dipolar cyclohexane derivatives.

Alternately one could calculate the energy of interaction between the groups as an interaction between two point dipoles acting half way along the bonds, following the method of Allinger and Allinger (3). In this case the predicted relative stabilization is 0.27 kcal/mol, in very good agree-

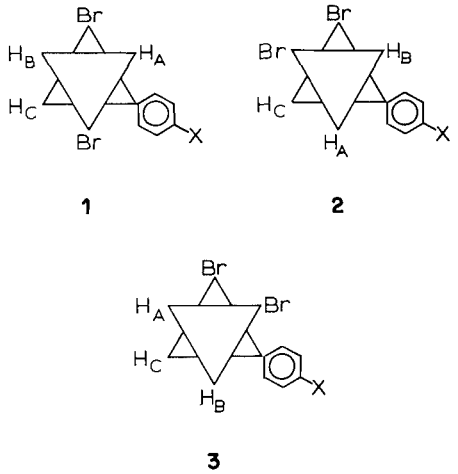

FIG. 2. Possible staggered rotamers for 1-(4-X-phenyl)-1,2-dibromoethane derivatives (looking along C_2—C_1 bond).

[2]The F value was chosen for the primary correlation due to the variety of bond dipole moments quoted in the literature.

[3]The actual numbers would be slightly altered if one used bond dipole moments in place of group dipole moments or assumed different Br–alkyl and Br–aryl moments. The predicted stabilization of rotamer **1** would be slightly less if one assumed an angle of 65–70° between phenyl and bromine instead of 60°. However, none of these changes would alter the basic conclusion. Similarly, calculated energies are positive if interactions involving C-2 are included but rotamer **2** is destabilized relative to rotamer **1** by 0.29 kcal/mol.

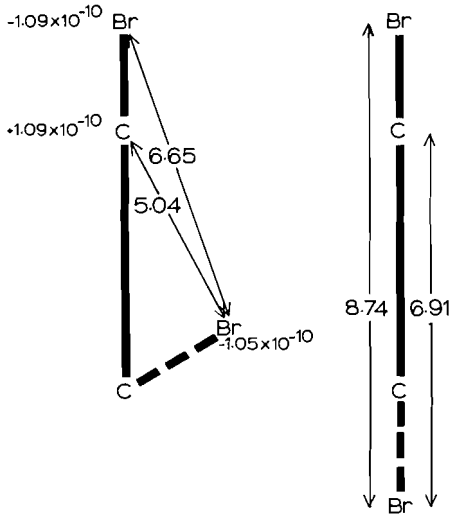

FIG. 3. Distances (Å) of remote polar group from bromine attached to C-2 in *gauche* and *trans* orientations and separated charges (e.s.u.) for polar groups based upon a C—Br dipole moment of 2.03 D and Br–alkyl and Br–aryl bond lengths of 1.94 and 1.86 Å respectively (looking along C_1—C_2 bond).

ment with the previous calculation. If one assigns an effective dielectric constant of 2.0 for the molecular cavity (3), all calculated interactions will be halved. Replacement of a $C^{\delta+}$—$X^{\delta-}$ group by one of polarity $C^{\delta-}$—$X^{\delta+}$ leads to a relative destabilization of rotamer **1**.

Rotamer **3** should also be stabilized relative to rotamer **2** by a $C^{\delta+}$—$X^{\delta-}$ group. However, since the former is by far the least stable rotamer (6, 12), its fractional population should remain negligibly small and the main effect of a remote dipolar group will be to change the relative populations of rotamers **1** and **2**. Precise solution rotamer energy differences and coupling constants for the individual rotamers of the parent compound are unknown. Consequently, it is impossible to precisely determine the expected variation of J_{AC} and J_{BC} with substituent. However, our calculations do show that the variation is in the correct direction, and a variation of 0.2 to 0.4 Hz for a change in energy difference of 0.1 to 0.3 kcal/mol does not seem unreasonable. Furthermore, the variation of J_{AC} and J_{BC} with substituent is generally less in dimethylsulfoxide than in carbon tetrachloride (6). This would be expected since the polar solvent should solvate the remote dipole, reducing its effect. These observations, along with the good correlation of J_{AC} and J_{BC} with parameters which measure the polarity of the C—X bond suggest to us that there is a small but predictable variation of conformational equilibrium in 1-(4-X-phenyl)-1,2-dibromoethanes due to electrostatic interactions involving the remote polar substituent.

Recently we reported the synthesis of benzo-[6,7]cyclohepta-3,6-dien-1-one-3-carboxylic acid (**1**) (1). We would now like to report some transformations of **1** directed at the synthesis of potentially biologically active compounds.

Reduction of **1** gave benzocycloheptan-1-one-3-carboxylic acid **2** (> 95%) which was converted to the methyl ester **3** (87%). Esterification of **1** went with enol ether formation to give methyl 1-methoxybenzo[6,7]-5-*H*-cycloheptatriene-3-carboxylate **4** (70%).

Treatment of **2** with phosphorous pentachloride gave **5** (unstable to distillation) which was readily converted to the amide **6** (45%). An excess of phosphorous pentachloride converted **2** into the trichloride 7 which gave **8** on distillation (50%). Treatment of either **7** or **8** with an excess of benzylamine gave **9** (85%).

The acid chloride **5** was converted to its azide (2) and thence to the urethane **10** through the isocyanate. Urea **11** was also isolated. The overall conversion to **10** from **2** was 57%.

Reduction of **10** with sodium borohydride gave alcohol **12** (97%) which on treatment with sodium hydride gave 9-oxa-7-azabenzo[2,3]bicyclo[4.3.1]-decan-8-one (**13**) (77%). On this basis the *cis* configuration is assigned to **12** since formation of cyclic urethane **13** from the diaxial conformer (3) would be expected to be facile whereas the *trans* isomer would cyclize only with great difficulty, if at all.

Reduction of **13** with lithium aluminum hydride gave *cis*-aminoalcohol **14**. Treatment of **10** with phenyl magnesium bromide followed by acidic work-up gave the olefin **15** rather than the desired alcohol.

Treatment of **10** with benzyl magnesium chloride gave **16** (46%) which on treatment with sodium hydride gave the cyclic urethane **17**

(37%). The addition of methyl iodide to the sodium hydride reaction mixture gave *N*-methyl urethane **18** (80%). Reduction of **18** with lithium aluminum hydride gave *cis*-aminoalcohol **19** (96%). All attempts to esterify this alcohol have failed.

Summary

We have prepared a number of compounds (see Table 1) for biological evaluation as medicinal agents. None of the reported compounds exhibited significant activity although compound **15** did show marginal activity in the test for reversal of reserpine induced ptosis[1] (75 mg/kg in mice) and compound **19** showed slight C.N.S. stimulation (150 mg/kg in mice).

Experimental

The i.r. spectra were recorded on a Unicam SP-200G grating i.r. spectrometer. The n.m.r. spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points are uncorrected and were determined on a Gallenkamp m.p. apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, Illinois.

Benzocycloheptan-1-one-3-carboxylic Acid (2)

Benzocyclohept-3-en-1-one-3-carboxylic acid (**1**) (20.2 g, 0.10 mol) was hydrogenated over prehydrogenated platinum oxide in methanol to give 17.5 g (87%) of **2**; m.p. 132–134°. An additional 2.0 g (9.8%) of **2** was recovered from the mother liquors.

Methyl Benzocycloheptan-1-one-3-carboxylate (3)

Compound **2** (2.04 g, 0.01 mol) was esterified in methanol containing hydrogen chloride to give 1.75 g (82%) of **3** after distillation; b.p. 130–134°/0.1 mm.

Methyl 1-Methoxybenzo[6,7]-5-H-cycloheptatriene-3-carboxylate (4)

Esterification of compound **1** (2.02 g, 0.1 mol) gave 2.06 g of an oil. On distillation 1.60 g (70%) of the enol ester **4** was obtained; b.p. 138–140°/0.1 mm. The n.m.r. spectrum (CCl_4): 2.40 τ (m, 1H), 2.90 (m, 3H), 3.35 (t, J = 7.1 Hz, 1H), 3.87 (s, 1H), 6.18 (s, 3H), 6.34 (s, 3H), 6.98 (d, J = 7.1 Hz, 2H).[2]

N-Methylbenzocycloheptan-1-one-3-carboxamide (6)

A solution of 3.06 (0.015 mol) of **2** and 3.12 g (0.015 mol) phosphorous pentachloride in 50 ml of phosphorous oxychloride – ether (1:1) mixture was refluxed for 30 min. The solution was evaporated at reduced pressure to yield **5** as an oil.

Treatment of the crude acid chloride with an excess of methylamine in ether gave 1.5 g (45%) crystalline amide **6**, m.p. 141–142 °C after one recrystallization from benzene.

1-Chlorobenzocyclohept-1-en-3-carboxoyl Chloride (8)

A solution of 1.02 g (0.005 mol) **2** and 3.12 g (0.015 mol) phosphorous pentachloride in 50 ml phosphorous oxychloride was refluxed for 20 min and let stand for 18 h. The solvent was evaporated at reduced pressure and the residue distilled (gas evolution was observed on

[1]The general screening procedure used has been described by Bergmann and Goldschmidt (4).

[2]For the n.m.r. spectra of a number of similar benzocycloheptatrienes see ref. 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

heating the oil); b.p. 160–170°/0.3 mm, to give 0.60 g (50%) of **8**. The n.m.r. spectrum (CCl_4) 2.2–3.0 τ (m, 4H), 3.57 (d, J = 6 Hz, 1H), 6.5–8.0 (m, 5H).

N-Benzyl-1-chlorobenzocyclohept-1-en-3-carboxamide (9)

Treatment of crude trichloride **7** (prepared from 2.04 g, 0.01 mol **2** as above) with an excess of benzylamine in ether gave an oil which on trituration with ether and filtration yielded 1.75 g (56.5%) of **9**, m.p. 168–169 °C after recrystallization from methanol–water. An additional 0.9 g (29%) of amide was recovered from the mother liquors of trituration.

N-Carboethoxy-3-aminobenzocycloheptan-1-one (10)

The acid chloride **5** prepared as previously described from 2.41 g (0.12 mol) of **2** was added over a period of 20 min to a solution of 1.6 g sodium azide in 8 ml of a 1:1 mixture of dioxane–water precooled to 0–5 °C in an ice bath. The slurry was maintained at this temperature for 2 h, poured into 40 ml of cold water, and extracted with three 20 ml portions of chloroform. The extracts were dried over anhydrous $MgSO_4$ and concentrated below 15 °C at reduced pressure. The i.r. spectrum of the residual oil showed bands at 2135, 1700, and 1670 cm^{-1}.

The azide was then taken up in 20 ml of toluene and warmed gently until gas evolution commenced (~40 °C) after which the solution was brought to reflux for 20 min and evaporated to give 2.5 g of an oil the i.r. spectrum of which had bands at 2255 and 1672 cm^{-1}.

The isocyanate was taken up in 50 ml of benzene. To this solution, 5 ml of absolute ethanol was added and the solution then refluxed 18 h. Evaporation of the solvent gave 2.40 g of a brown oil which was chromatographed on 80 g of Florisil (60–100 mesh, Fisher Scientific) with benzene. The oil which was eluted crystallized on standing. Trituration with 5 ml of ether and filtration gave 1.40 g of white needles, m.p. 86–87.5 °C. The compound could not be recrystallized as the compound partially decomposed and darkened on heating.

In addition to **10** another compound was obtained from a large scale (40 g) experiment in < 2% yield which was identified as the urea **11**, m.p. 189–190 °C after recrystallization from ethanol–water.

N-Carboethoxy-1-hydroxy-3-aminobenzocycloheptane (12)

Reduction of **10** (1.25 g, 0.005 mol) with $NaBH_4$ (0.5 g) in ethanol at 0 °C for 30 min gave 1.20 g of a white solid, m.p. 184–187 °C (raised to 191–192 °C on recrystallization from methanol). The compound was homogeneous by t.l.c. on both silica gel and alumina plates using a number of solvent systems.

9-Oxa-7-azabenzo[2,3]bicyclo[4.3.1]decan-8-one (13)

To 0.25 g of NaH (55% mineral oil dispersion washed free of oil using hexane) suspended in 50 ml of dry THF was added 1.21 g (0.00485 mol) of **12**. A vigorous gas evolution ensued. The solution was refluxed 10 min and let stand 18 h. To the solution was added 10 ml of 10% HCl followed by 200 ml water. The solution was extracted with ether, the extracts dried over anhydrous $MgSO_4$, and concentrated to give an oily solid 1.05 g (~ 100%). Trituration with 3 ml of ether and filtration gave 0.75 g (77%) of pure crystalline **13**, m.p. 184–185 °C.

N-Methyl-1-hydroxy-3-aminobenzocycloheptane (14)

To a solution of 0.8 g $LiAlH_4$ in 50 ml of THF was added 1.02 g (0.005 mol) of **13** in 10 ml THF. The solution was refluxed 3 h after which time 3 ml of water was added to the cooled solution. The solution was filtered and the filtrate evaporated. The resultant oil was taken up in 25 ml of ether and dry HCl gas bubbled in. The salt was then filtered and recrystallized from methanol–ethyl acetate to give 0.62 g of **14** as its hydrochloride, m.p. 196–197 °C.

N-Carboethoxy-1-phenyl-3-aminobenzocyclohept-1-ene (15)

To a solution of 1.235 g (0.005 mol) of **10** in 100 ml of ether was added (at 0 °C) 5 ml of a 2.14 M solution of phenyl lithium in benzene–ether (7:3). The solution was stirred for 10 min and then 25 ml of 10% HCl was added. The layers were separated, the ethereal extract dried over anhydrous $MgSO_4$, and concentrated to give an oil. The oil was chromatographed on alumina (Fluka, neutral activity grade 1) with benzene followed by ether–ethanol (95:5). An oil (1.15 g) was collected in the later fractions from the column. On standing, the oil crystallized, m.p. 114–115 °C.

N-Carboethoxy-1-benzyl-1-hydroxy-3-aminobenzocycloheptane (16)

To a solution of 0.052 mol benzylmagnesium chloride in 50 ml ether was added 4.22 g (0.017 mol) of **10**. After 1 h at reflux the reaction was worked-up by addition of 30 ml of 10% H_2SO_4 and extraction into ether. An oil was obtained which was chromatographed on florisil with benzene to remove toluene and bibenzyl. The column was flushed with ether to give 2.65 g of a pale yellow gum (46%), which could not be induced to crystallize nor could it be distilled.

1-Benzyl-9-oxa-7-azabenzo[2,3]bicyclo[4.3.1]decan-8-one (17)

Treatment of 0.90 g (0.00265 mol) of **16** with an excess of NaH in THF as before gave 0.51 g of an oily solid. Trituration with ether and filtration gave 0.29 g (37%) pure **17**, m.p. 227–228°.

1-Benzyl-7-methyl-9-oxa-7-azabenzo[2,3]bicyclo-[4.3.1]decan-8-one (18)

To a suspension of 2.0 g NaH (55% mineral oil dispersion) in 50 ml of THF was added 4.4 g (0.013 mol) of **16**. The solution was refluxed 10 min and 5 ml (large excess) of methyl iodide added. Reflux was continued for 1 h. The reaction was worked-up as described for compound **13** to give 4.8 g of an oil. Trituration with 10 ml of ether and filtration gave 2.2 g (55%) of pure **18**, m.p. 167–168° after recrystallization from methanol. An additional 1.0 g (25%) was obtained by column chromatography of the residue on Florisil (60–100 mesh) using benzene then ether as eluent.

1-Benzyl-1-hydroxy-3-dimethylaminobenzocycloheptane (19)

To 1.0 g of $LiAlH_4$ in 20 ml of dry THF was added 2.0 g (0.0065 mol) of **18**. The solution was refluxed for 3.5 h, cooled to 0 °C, and the excess hydride decomposed with 3.5 ml of 40% aqueous potassium hydroxide. The granular precipitate was filtered and the filter cake

For personal use only.

washed thoroughly with ether. The filtrate was evaporated to yield 1.85 g (96%) of a pale yellow oil. This oil was taken up in 50 ml of ether and dry HCl bubbled in to give the hydrochloride salt, m.p. 229–230° recrystallized from methanol – ethyl acetate.

On the Isolation of (+)3-Thujone

V. HACH, R. W. LOCKHART, ELIZABETH C. MCDONALD, AND D. M. CARTLIDGE
MacMillan Bloedel Research Limited, Vancouver, British Columbia

Received September 18, 1970

Conditions necessary for the formation of the (+)3-thujone bisulfite adduct **1***a* and its utilization for the isolation of pure (+)-thujone have been established.

On a déterminé les conditions nécessaires pour former le complexe bisulfitique de la (+)-thujone-3 (**1***a*) et pour son utilisation afin d'isoler cette cétone à l'état pur.

Canadian Journal of Chemistry, 49, 1762 (1971)

In our work on western red cedar [Thuja Plicata Donn] leaf oil we have been concerned with the isolation of (+)3-thujone (**1**)[1] and particularly with its separation from (−)3-isothujone (**2**). In regard to the larger amounts of **1** desired, fractional spinning band column distillation of the two ketones which differ in their b.p. by about 1°, proved tedious and time consuming. The same applied to large scale preparative g.l.c. Therefore we became interested in the use of $NaHSO_3$ for the separation of the two ketones.

Bruylants (1) observed that (+)3-thujone (**1**) formed an adduct **1***a* with $NaHSO_3$. Subsequent work has shown that (−)3-isothujone (**2**) does not form a $NaHSO_3$ adduct. Formation of the adduct **1***a* has been used repeatedly for the isolation of (+)3-thujone from various oils (tansy, cedar leaf, artemisia) and for its separation from (−)3-isothujone (3–7). Recently Eastman and Winn (8*a*, *b*) studied in detail the formation and decomposition of **1***a* and described the difficulties they met. However, none of the work recorded has dealt with the quantitative aspects of the (+)3-thujone bisulfite adduct formation. The implication has been that this method is generally applicable for the complete separation of (+)3-thujone from its isomer **2** and from a natural oil.

We now wish to report quantitative studies showing that this method has severe limitations with regard to the yield of adduct **1***a* and the necessary concentration of (+)3-thujone in the starting mixture.

In our work we used western red cedar leaf oil obtained by steam distillation of freshly harvested leaves. This oil contained 70–80% (−)3-isothujone and 5–10% (+)3-thujone. However, using either the conditions of Eastman and Winn (8*a*, *b*) or varying these conditions, we failed to obtain the bisulfite adduct **1***a* of (+)3-thujone from this oil. Subsequently, we utilized the known fact, (2, 7, 9, 10) that the base-catalyzed epimerization of either of the two ketones gives a mixture of (+)3-thujone and (−)3-isothujone in a ratio of 65:35 respectively, to enhance the (+)3-thujone content in our oil to about 55%. From this oil we then obtained the bisulfite adduct using the above mentioned conditions.

This result prompted us to investigate in detail the limits of the bisulfite adduct **1***a* formation using mixtures containing varying proportions of ketones **1** and **2** and cedar leaf oil samples containing varying amounts of **1**. Our results can be summarized as follows. Pure (+)3-thujone forms

[1]We have adopted the nomenclature proposal of H. C. Brown, see ref. 2.

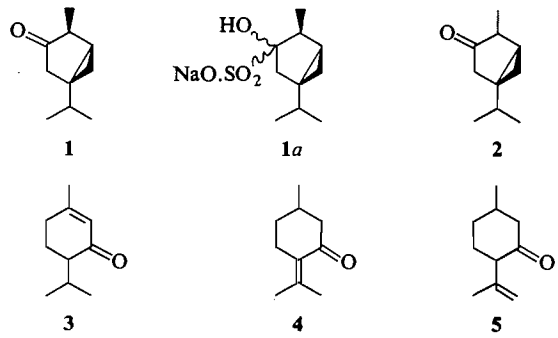
the bisulfite adduct **1***a* quantitatively. The adduct does not form when the content of (+)3-thujone (**1**) is lower than 35% in a mixture from which it is to be separated. A mixture of 70% (−)3-isothujone and 30% (+)3-thujone does not give a bisulfite adduct. The same applies *e.g.* to a mixture containing 70% fenchone and 30% (+)3-thujone (**1**). Fenchone itself does not form a bisulfite adduct. Cedar leaf oil containing less than 35% of ketone **1** does not give any adduct. For practical preparative purposes a (+)3-thujone content of 55% or more in the starting material is necessary to achieve a reasonable yield of the adduct. However, the complete utilization of all (+)3-thujone present in a mixture is apparently not possible. From our extensive experimental series we conclude that a yield of about 25–40% of the (+)3-thujone available in the mixture is attainable with a starting concentration of 55–60% of this ketone.

The reasons why (+)3-thujone (**1**) forms the adduct and ketone **2** does not, still remain obscure. The hypothesis put forward by Eastman and Winn (8*a*, *b*) and based on the steric interference of the SO_3Na and CH_3 groups is not convincing because the authors assumed a wrong configuration of the CH_3 group and the conformation of the bicyclohexane skeleton in ketones **1** and **2** is yet to be proven (13). We inspected Fisher–Hirshfelder molecular models constructed with a flat five-membered ring and observed that the SO_3Na and CH_3 groups could possibly be accommodated even in the *cis*-position. That steric hindrance by an alkyl group is not an important factor in the bisulfite adduct formation of terpenic ketones is shown in the case of piperitone (**3**), pulegone (**4**), and isopulegone (**5**). Whereas ketones **3** and **4** form adducts, isopulegone does not (11). Apparently the CO group in **4** and **5** is rendered more active by conjugation. It is known (12) that conjugated ketones add two molecules of $NaHSO_3$. We prepared the bisulfite adducts of piperitone and pulegone. Due to their instability we were unable to reach completely satisfactory analysis. However, it appeared that two molecules of $NaHSO_3$ were indeed added. Therefore, we hypothesize, that the bisulfite adduct **1***a* formation from (+)3-thujone (**1**) as compared to the unreactivity of (−)3-isothujone (**2**) may be governed by electronic factors such as the hydrogen bonding between a suitably placed OH group and the cyclopropane ring (13) in addition to any steric factors that might be contemplated.



1 **1***a* **2**

3 **4** **5**

Experimental

All determinations of the isomeric thujones were carried out by isothermal g.l.c. at 120°, column 30 ft × 3/8 in., 25% Carbowax 20M on 40–60 mesh Chromosorb A, helium as carrier gas 150 ml/min. Elemental analyses by Galbraith Laboratories, Knoxville, Tennessee. Water in samples of adduct **1***a* was determined by xylene distillation.

Bisulfite Adduct of (+)3-Thujone (1a)

A mixture of 2 g of (+)3-thujone (99%+), 5 ml of a *fresh saturated $NaHSO_3$ solution*, 0.6 g $NaHCO_3$ and 0.8 ml of (95%) ethanol was shaken overnight at room temperature. The separated solid was filtered off and air dried giving 3.54 g (93%) of the bisulfite adduct. Extraction of the filtrate with ether yielded 0.03 g of an oily residue confirming the completion of the reaction.

Anal. Calcd. for $C_{10}H_{17}NaO_4S \cdot 2H_2O$: C, 41.09; H, 7.24; Na, 7.86; O, 32.84; S, 10.96. Found: C, 40.71; H, 7.67; Na, 7.85; O, 32.43; S, 11.04.

The bisulfite adduct was decomposed by heating in water under reflux for 1 h. After an exhaustive (6 times) ether extraction 1.65 g (83%) of pure (+)3-thujone was recovered.

The same amounts of reagents and identical reaction conditions were applied to: (*a*) 2 g of a mixture containing 30% (+)3-thujone and 70% (−)3-isothujone and (*b*) 2 g of a mixture containing 70% (−) fenchone and 30% (+)3-thujone. In both cases there was no bisulfite adduct formation.

Preparation of (+)3-Thujone from Cedar Leaf Oil

The cedar leaf oil used in this experiment contained 10.3% (+)3-thujone and 79.1% (−)3-isothujone. In order to enhance the (+)3-thujone content the (−)3-isothujone-(+)3-thujone equilibration was carried out by stirring the cedar leaf oil (700 g) with a 5% NaOH solution in 95% ethanol (475 ml) for 30 min. The content of (+)3-thujone and (−)3-thujone then was respectively 56.8 and 26.6%. The $NaHSO_3$ solution used to form the bisulfite adduct **1***a* was prepared by dissolving 570 g $NaHSO_3$ in 875 ml H_2O. The freshly prepared $NaHSO_3$–$NaHCO_3$ solution was added to the solution of the "isomerized" cedar leaf oil and the two phase system was stirred vigorously for 16 h by an efficient paddle

stirrer. The separated solid was collected on a glass fritt, pressed to remove excess H_2O and oil, and washed thoroughly with ether (2 × 100 ml). The air dried solid weighed 409 g. We found that in large scale preparations of this type, varying amounts of $NaHSO_3$ (10–40% of the collected solid) separated with the bisulfite adduct. Thus the weight of the collected solid cannot be used to calculate the yield of the adduct.

The adduct was decomposed by heating with 10% aqueous H_2SO_4 (1200 ml) to a gentle reflux for 3 h. The (+)3-thujone was isolated by separating the oil from the aqueous phase and exhaustively extracting the aqueous phase with ether (7 × 200 ml). The ether extracts and the separated oil were combined, washed with 5% Na_2CO_3 solution, H_2O, dried with Na_2SO_4, and evaporated. The weight of crude (+)3-thujone was 111.2 g. Distillation of the crude ketone gave 91.1 g (22.9% based on **1** available in the isomerized oil) of pure (99.9%+) (+)3-thujone, b.p. 40.9° (0.5 mm) uncorrected; $[\alpha]_D^{25}$ +78.8° (neat).

Preparation of β-Cyclocitral

R. N. GEDYE, PARKASH C. ARORA, AND K. DECK
Department of Chemistry, Laurentian University, Sudbury, Ontario

Received December 10, 1970

An improved method for the preparation of pure β-cyclocitral by cyclization of citral anil with 95% sulfuric acid is reported. By avoidance of steam distillation of the reaction product, the formation of the by-products *p*-cymene and 1-acetyl-4,4-dimethyl-1-cyclohexene was prevented. The formation of this ketone by treatment of α- or β-cyclocitral anil with dilute sulfuric acid followed by steam distillation supports the mechanism proposed by Henbest *et al.*

On rapporte une méthode améliorée de préparation de β-cyclocitral pur basée sur la cyclisation de l'anil de citral en présence d'acide sulfurique à 95%. En évitant de faire un entraînement à la vapeur des produits de la réaction, on élimine la formation des produits secondaires *p*-cymène et acétyl-1 diméthyl-4,4 cyclohexène-1. La formation de cette cétone lors du traitement de l'anil de l'α ou du β-cyclocitral par de l'acide sulfurique dilué suivi par un entraînement à la vapeur d'eau corrobore le mécanisme proposé par Henbest *et al.*

Canadian Journal of Chemistry, 49, 1764 (1971)

Introduction

β-Cyclocitral has been used as starting material in the synthesis of vitamin A and related compounds (1–4). The synthesis involves essentially the addition of two isoprene units to β-cyclocitral using two successive Reformatsky reactions with methyl 4-bromo-3-methylbut-2-enoate. One important disadvantage of this method is the lack of availability of pure β-cyclocitral.

β-Cyclocitral is most conveniently prepared by the cyclization of citral anil (**1**) with sulfuric acid at low temperatures (5–7). The accepted method consists of the reaction of citral anil (**1**) in ether with a large excess of 95% sulfuric acid at −20° followed by steam distillation of the product. Henbest *et al.* (6) have shown that under these conditions a mixture of three isomers is formed: α-cyclocitral (**2**), β-cyclocitral (**3**), and a ketone **4**

stirrer. The separated solid was collected on a glass fritt, pressed to remove excess H_2O and oil, and washed thoroughly with ether (2 × 100 ml). The air dried solid weighed 409 g. We found that in large scale preparations of this type, varying amounts of $NaHSO_3$ (10–40% of the collected solid) separated with the bisulfite adduct. Canadian Journal of Chemistry, 49, 1764 (1971)

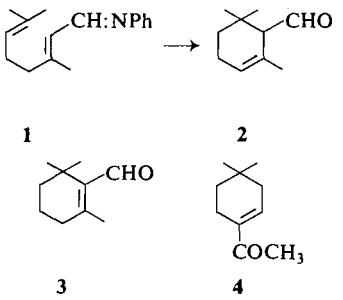
Introduction

β-Cyclocitral has been used as starting material in the synthesis of vitamin A and related compounds (1–4). The synthesis involves essentially the addition of two isoprene units to β-cyclocitral using two successive Reformatsky reactions with methyl 4-bromo-3-methylbut-2-enoate. One important disadvantage of this method is the lack of availability of pure β-cyclocitral.

β-Cyclocitral is most conveniently prepared by the cyclization of citral anil (**1**) with sulfuric acid at low temperatures (5–7). The accepted method consists of the reaction of citral anil (**1**) in ether with a large excess of 95% sulfuric acid at −20° followed by steam distillation of the product. Henbest *et al.* (6) have shown that under these conditions a mixture of three isomers is formed: α-cyclocitral (**2**), β-cyclocitral (**3**), and a ketone **4**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



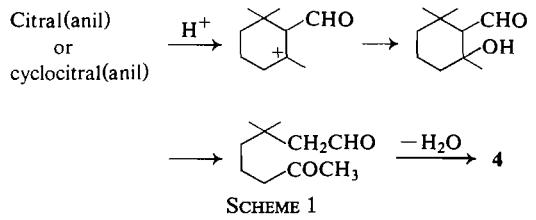
which was shown to be 1-acetyl-4,4-dimethyl-1-cyclohexene.

While α- and β-cyclocitral may be separated by fractional distillation, **3** and **4** have almost identical boiling points. The latter two compounds can be separated by conversion into semicarbazones followed by steam distillation in the presence of phthalic anhydride. Our investigations have indicated, however, that the recovery of pure β-cyclocitral by this method is only fair.

The present study has resulted in an improved method for the formation of pure β-cyclocitral from citral anil. According to Henbest *et al.* (6) the ketone **4** is probably formed during the steam distillation of the diluted product from the reaction of citral anil with sulfuric acid. By avoiding the use of steam distillation in the work-up procedure, we were able to obtain a mixture of α- and β-cyclocitral only from the cyclization in the ratio, 3 parts of α-cyclocitral to 1 part of the β-isomer. It was shown (using g.l.c.) that α-cyclocitral was rapidly converted to a mixture of approximately 8 parts of β-cyclocitral to 1 part of α-cyclocitral, when treated with methanolic KOH. It was also shown the formation of *p*-cymene, formed in about 10% yield, by the method of Henbest *et al.*, was avoided when steam distillation was not used.

It was observed that considerable quantities of black polymeric material were formed during the reaction of citral anil and sulfuric acid even at low temperature (−20°). The extent of polymer formation was reduced by conducting the reaction under nitrogen, with a resulting increase in the total yield of the α- and β-cyclocitrals from about 50% in air to 60% when nitrogen was used. It was also observed that, when conducted under nitrogen, the product was almost pure α-cyclocitral.

Henbest *et al.* (6) suggested the mechanism shown in Scheme 1 to explain the formation of



SCHEME 1

the ketone **4** from citral anil, with hydration occurring at the steam distillation stage.

Our observation that the ketone was not formed when steam distillation was not used, would add support to this mechanism. Further support was offered by the observation that considerable amounts of ketone were formed when pure β-cyclocitral anil was refluxed with dilute sulfuric acid and then steam distilled. Under similar conditions α-cyclocitral anil also gave some ketone. A partial isomerization of α-cyclocitral to β-cyclocitral occurred during the steam distillation of the former in the presence of H_2SO_4. This is to be expected, since loss of a proton from the carbonium ion would result in the formation of a mixture of α- and β-cyclocitral.

Experimental

All melting points are uncorrected. The v.p.c. analysis was carried out using commercial (Varian Aerograph) 10 ft × 1/4 in. stainless steel columns containing the appropriate packing. Fractional distillations were carried out on an annular spinning band column, boiling points being uncorrected.

β-*Cyclocitral*

(*a*) Citral anil (from 76 g citral) in 75 ml ether was added dropwise to 95% sulfuric acid (500 g) at −20° during 30 min in a nitrogen atmosphere, and stirred for a further 45 min at −15°. The product was added to ice (1.5 kg) and extracted several times with ether. Distillation of the extracts gave a colorless liquid (43 g, 57%), b.p. 83–90°/13 mm. Gas chromatography on FFAP and Carbowax 20M showed only two peaks (area ratio 15:1) with relative retention times of 1 to 2 on FFAP and 1.7 to 3.0 on Carbowax 20M. Treatment of a sample with semicarbazide hydrochloride and sodium acetate in 50% aqueous ethanol gave α-cyclocitral semicarbazone, m.p. 202–203°; the other isomer formed in the cyclization was shown to be β-cyclocitral (when nitrogen was not used the cyclization yielded a mixture of 3 parts α- to 1 part β-cyclocitral in 48% yield, a larger amount of dark brown polymer being evident).

The crude α-cyclocitral (30 g) was treated with potassium hydroxide (10 g) in methanol (200 ml) at 0 °C for a few min. The mixture was diluted with water (500 ml), saturated with sodium chloride, and extracted with ether. Distillation of the extracts yielded a colorless liquid (21.6 g, 72%), b.p. 88–94°/12 mm which was shown by

TABLE 1. Physical data of fractions obtained from the cyclization of citral anil

Fraction	Boiling point (8 mm °C)	Weight (g)	n_D^{18}	λ_{max} (mμ)	Semicarbazone m.p. (°C)	% α	% β
1	60–62	1.5	1.4700	235	199–201	95	0
2	62–69	1.0	1.4831	—	—	40	45
3	69–73	1.0	1.4948	—	163–165	8	90
4	73–74	14.0	1.4944	275	165–167	0	99

gas chromatography to contain approximately 8 parts β-cyclocitral to 1 part of the α-isomer.

Fractional distillation of the product using the annular spinning band column gave the fractions listed in Table 1.

Gas chromatography on the FFAP column indicated the product ratios given in Table 1. No ketone semicarbazone was isolated from any of these fractions. The overall yield of pure β-cyclocitral was 25%.

(*b*) Citral anil was cyclized by the method of Henbest *et al.* (6). In agreement with the results of Henbest *et al.*, the products were *p*-cymene, α-cyclocitral, β-cyclocitral, and the ketone, 1-acetyl-4,4-dimethyl-1-cyclohexene, in the approximate ratio 2:6:10:1. The product of the steam distillation was analyzed using gas chromatography on the FFAP column. The ketone and β-cyclocitral were partially separated at 130° using FFAP. The identity of the products was confirmed by the melting points of their semicarbazones and their u.v. spectra.

Isomerization of α- and β-Cyclocitral to 1-Acetyl-4,4-dimethyl-1-cyclohexene

β-Cyclocitral (20 g) was refluxed with 50% sulfuric acid (200 ml) for 3 h and the product steam distilled. The distillate was extracted with ether and the ether evaporated. The residue was shown by gas chromatography on the FFAP column to consist of 60% ketone, 35% β-cyclocitral together with a small amount of α-cyclocitral and other unidentified products.

A similar reaction with α-cyclocitral and with α-cyclocitral anil was shown to give mainly β-cyclocitral together with smaller amounts of the ketone and some unchanged α-cyclocitral.

hydrocarbons (2, 3) and, although a few examples of skeletal rearrangement giving rise to the tropylium ion have been reported in which a contributing carbon was not directly bonded to a phenyl substituent in the parent molecule, the relative abundance of the *m/e* 91 ion in these cases is generally low. The presence of the tropylium ion in the mass spectra of alkylphenylthioethers (4), phenylvinylsulfide (5), and alkylphenylphosphonates and related compounds (6) has been observed. Recent reports (7, 8) on the presence of an intense *m/e* 91 ion in the mass spectra of ethylene glycol phenylboronate (**1**) have prompted us to present our findings in support of the identity and origin of the *m/e* 91 ion in the spectra of this (**1**) (Fig. 1) and other cyclic phenylboronates.

The constitution of the *m/e* 91 ion is inferred from the presence of an ion at *m/e* 65 (attributed to either the cyclopentadienyl cation or more probably an acyclic isomer (9, 10), a metastable peak centered at *m/e* 46.4 corresponding to the transformation $C_7H_7^+ \rightarrow C_5H_5^+$ and the occurrence of the base peak two mass units higher at *m/e* 93 in the mass spectra of ethylene glycol-d_4 phenylboronate (**2**), Fig. 2.

The tropylium ion arises from the parent ion of **1** (**2**) by either a one-step process, *m/e* 148 (152) → *m/e* 91 (93) for which a metastable ion (m*) appears at 55.9 (56.9) or by a two-step process in which CH_2O is lost from the parent ion, giving *m/e* 118 (120) followed by the elimination of a BO radial. An intense metastable peak appears at *m/e* 70.2 (72.1) in support of the latter transformation.

We propose to explain the transformation by the following scheme (Scheme 1) in which the parent ion (*a*) undergoes α-cleavage and the resulting stabilized oxycarbonium ion (*b*), by a cationic site mechanism (11, 12) gives the common intermediate (*c*). Further transformations of (*c*) by a process of one electron shifts give the tropylium ion directly or in two steps, $c \rightarrow d \rightarrow C_7H_7^+$.

Alternately, (*b*) could rearrange by two electron shifts through a four-membered spiran transition state (*f*), analogous to that arbitrarily proposed for the migration of dimethylsilyl groups in both the trimethylsilyl benzoates (*g*) (13) and benzyltrimethylsilyl ethers (*h*) (14).

To further delineate the origin of the tropylium rearrangement ion, the mass spectra of both phenyl-1,3,2-dioxaborinane (**3**) and phenyl-5,5-dideutero-1,3,2-dioxaborinane (**4**) were examined, Figs. 3 and 4, respectively.

By far the most intense ions in the spectra of **3** (**4**) correspond to the parent ion, *m/e* 162 (164) and *m/e* 104, C_6H_5BO, corresponding to the loss of trimethyleneoxide. Although a metastable peak appears at *m/e* 66.8 in **3**, the corresponding metastable ion at *m/e* 65.9 in the spectra of **4** could not be confirmed, and leaves in doubt the

possible direct elimination of trimethylene oxide from the parent ion. Further, the expulsion of CH_2O from **3** and **4** generates a fragmentation sequence leading to the phenyl cation, and intense metastable ions are observed at *m/e* 107.4 (109.6), 82 (80.7), and 56.9 (56.9) in support of each reaction in this sequence (Scheme 2).

The tropylium ion occurs at *m/e* 91 in the mass

spectra of both **3** and **4** and is derived from the parent ion, *m/e* 162 (164) directly, m* 51.15 (50.5). By analogy to the transition state *c* proposed for **1** and **2**, **3**, and **4** would generate *cc* (Scheme 3) which on further rearrangement would be expected to give the tropylium ion directly or by the loss of C_2H_4O and BO in a two step process. The absence of a metastable ion corresponding to M-44 (118) $\rightarrow C_7H_7^+$ in the spectra of **3** and **4** is consistent with a one-step process. The low ion abundance of the *m/e* 118 fragment ion does not permit the confirmation of the expected two-step reaction *i.e.* the loss of C_2H_4O from (*cc*), leading to $C_7H_7^+$. The nearly complete absence of

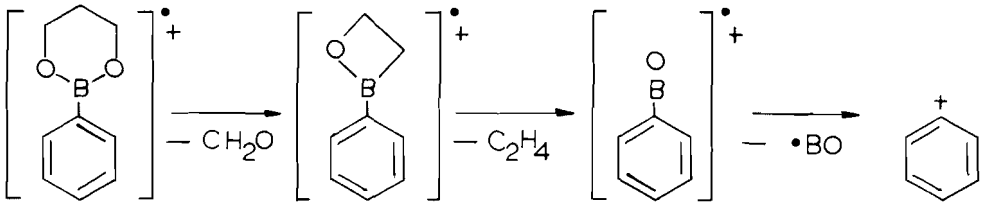
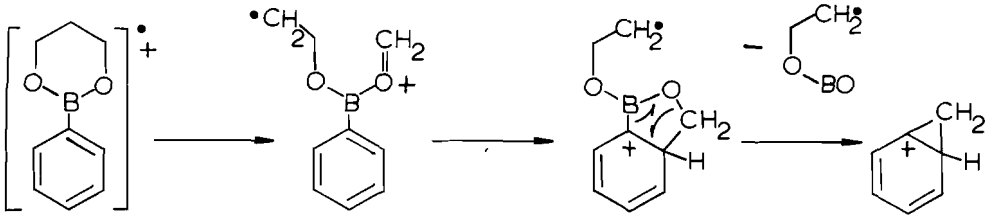


SCHEME 2



SCHEME 3

deuterium labelling of the tropylium ion in the mass spectra of **4** adds support to the proposed intermediate (*cc*), and rules out the possibility of the expulsion of a neutral BO_2 fragment and recombination of the hydrocarbon and aromatic portions.

Experimental

The mass spectra were obtained on a nuclide 12-90-G mass spectrometer at 70 eV potential and 100 μA trap current. The source was maintained at 150 °C and the compounds were introduced as neat liquids on an unheated direct insertion probe. Individual ion intensities were corrected by reference to the total ion current

The cyclic esters were prepared from the appropriate diols by standard procedures (15). Ethylene glycol-d_4 was a commercial sample, Merck, Sharp and Dohme Canada Ltd., while 2,2-dideuteropropane-1,3-diol was prepared by several times exchanging diethylmalonate with D_2O followed by $NaBH_4$ reduction in D_2O. The isotope purity of **4** was determined to be better than 95% from the integrated n.m.r. signal obtained at 100 MHz.

Proton Magnetic Resonance Investigation of Some Weak Interactions Between Naphthalene and Alkyl Iodides in Carbon Tetrachloride[1]

R. SAHAI AND S. H. LIN
Department of Chemistry, Arizona State University, Tempe, Arizona 85281

Received November 27, 1970

A p.m.r. investigation of the interactions between naphthalene and alkyl iodides has been reported. The equilibria, the heats and the entropy changes for the complexation, and the chemical shifts of the acceptor protons in the pure complex have been determined. A crude dipole model for these interactions has been suggested.

On rapporte les résultats obtenus lors d'une étude par r.m.n. des intéractions entre le naphtalène et les iodures d'alkyle. On a pu déterminer la position d'équilibre, les changements d'enthalpie et d'entropie pour la complexation et les déplacements chimiques des protons accepteurs du complexe pur. On croit que ces intéractions peuvent être expliquées en utilisant un modèle dipolaire simple.

Canadian Journal of Chemistry, 49, 1771 (1971)

Theoretical and experimental results (1–5), carried out recently in this laboratory, on the mechanisms for the quenching of the phosphorescence of aromatic hydrocarbons in the presence of heavy atoms (3–5) or paramagnetic species (1, 2), led us to suggest that a complex (exciplex) (4, 5) is formed between lumiphor (the excited molecule) and quencher containing heavy atoms. It seemed then desirable to investigate the equilibria in the formation of charge-transfer complexes between alkyl iodides and naphthalene, quantitatively, since only limited or no information was available about these equilibria and related thermodynamic quantities. The present communication reports a p.m.r. investigation of these complexes. The equilibrium constants, the heats and the entropy changes for the formation of these weak complexes in carbon tetrachloride have been determined over the temperature range -10 to $+50$ °C.

All chemicals used in this study were AR grade. Naphthalene was obtained from Matheson, Coleman & Bell and was recrystallized from alcohol. Methyl iodide (Mallinckrodt Chemical Works), ethyl iodide, and carbon tetrachloride (Baker analyzed reagent) were checked before use and indicated no detectable impurities in these materials. Solutions were prepared by dissolving varying amounts of naphthalene (0.2 to 2.0 M) and a constant amount of methyl iodide (0.01 M) or ethyl iodide (0.08 M) in carbon tetrachloride. All solutions were freshly prepared on the day of measurement. The n.m.r. spectra were taken on a Varian Associates A-60 spectrometer operating at 60 MHz. Line positions of the proton resonance of the acceptor molecule were measured using an internal cyclohexane (0.008 M) resonance reference. Chemical shifts were reproducible to better than 0.3 Hz, the uncertainty being determined by the line width. Measurements were made at -10, $+10$, $+30$, and $+50$°, the temperatures of the probe. All shifts in the signal, caused by additions of electron donor to the system, were to higher field values.

Because n.m.r. spectroscopy is extremely sensitive to small changes in the electronic environment of a magnetic nucleus, a study of the appropriate n.m.r. parameters has recently become a useful method of determining equilibrium constants for charge-transfer complexes (6–8). The method of Foster and Fyfe (7) was used for the determination of K. For a series of solutions in which the concentration of donor is much higher than that of acceptor [D] $\gg$ [A], the difference in chemical shift δ of a particular proton absorption in the acceptor moiety was measured relative to an internal reference of cyclohexane. If δ_0 is the chemical shift of the same proton absorption in the absence of donor species, then for a series of solutions,

$$[1] \qquad \Delta/[D] + \Delta K = \Delta_0 K$$

where $\Delta = \delta - \delta_0$ and Δ_0 is the chemical shift of the particular proton of the acceptor moiety of the pure complex relative to the shift in the acceptor alone. From eq. 1, a plot of $\Delta/[D]$

against Δ gave a straight line with slope $-K$. The typical plots are shown in Figs. 1 and 2. The Δ_0 value was measured from the intercept. The values of K and Δ_0 at various temperatures were computed by using a standard least squares curve fit programme. The results are summarized in Table 1. Concentrations have been expressed in moles of donor or acceptor per litre of solution, so that values of K have obviously the dimensions of the reciprocal of this concentration.

The plot of $\ln K$ against $1/T$ gave a good straight line (Fig. 3). The heat of formation, ΔH, and the entropy change, ΔS, for the complexation were

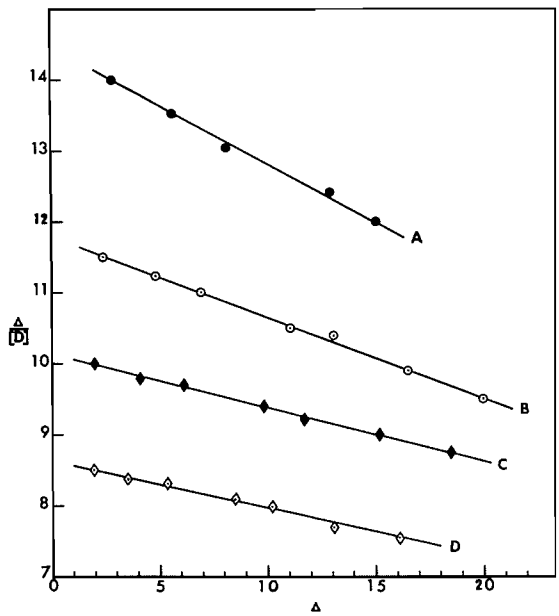

FIG. 1. Plots of Δ/[D] against Δ for complexes of methyl iodide with naphthalene at: (A) −10, (B) +10, (C) +30, and (D) +50°; all in carbon tetrachloride.

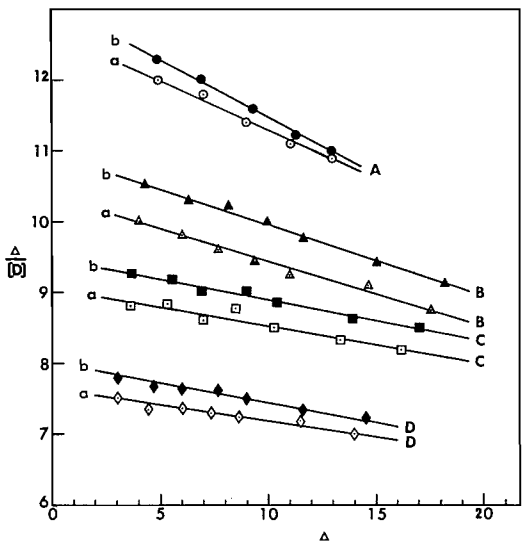

FIG. 2. Plots of Δ/[D] against Δ for complexes of naphthalene with ethyl iodide with respect to: (*a*) methyl protons, (*b*) methylene protons at: (A) −10, (B) +10, (C) +30, and (D) +50°; all in carbon tetrachloride.

obtained from the slope of the straight line and its intersection with ordinate, respectively. These values are given in Table 2.

The methyl and methylene proton resonance of alkyl iodides were observed in the absence of donor species, to vary only within 3 Hz in the temperature range investigated here, with respect to cyclohexane as internal reference. It is apparent from Table 1 that the K values for complexes of alkyl iodides with naphthalene are of the same order of magnitude having a slightly higher value for methyl iodide than for ethyl iodide, and are temperature dependent. The individual maximum proton shifts Δ_{max}, Δ_0, and equilibrium constants for CH_3 and CH_2 groups in ethyl iodide

are listed in Table 1. From Table 1 we can see that the equilibrium constants and the observed shifts are small, and, hence, the errors must be relatively large (9). The standard deviation of K in this investigation is in the range of 5–10%. Thus the differences in K given in Table 1 are within the experimental errors, and we cannot draw any conclusion as to whether there is only 1:1 complex, or more 1:1 complexes or an even more complex situation taking place. The n.m.r. study of the formation of a set of isomeric dimers from a given donor molecule and a given acceptor molecule has been discussed by Kuntz and Johnston (10).

If the crude dipole model of the interaction with naphthalene is valid then we would expect that the measured shifts Δ should be directly proportional to the dipole moment μ of the alkyl iodides and inversely to its molecular volume (V). The molecular volume comes in because after rotational averaging this will determine the mean distance of approach of acceptor to the donor molecule. So we expect larger shift and hence larger equilibrium constant for methyl iodide than ethyl iodide because methyl iodide has comparatively larger μ/V value (0.026) than for ethyl iodide (0.024). These expectations are supported experimentally by the present investigation. This suggests that in these cases the interaction has probably a dipole type of origin in accordance with the observation of Schneider (11) for directed solute–solvent interactions in benzene solutions. Present investigation is further supported by the recent observed charge-transfer band (λ_{max} = 340 mμ) for the intermolecular interaction between naphthalene and ethyl bromide at 77 °K in cyclohexane by Bolotnikova and Sichkar (12).

Comparing the observed and estimated K values for the interaction of alkyl iodides with naphthalene in ground electronic state (0.04–0.16 l mol^{-1}) and excited electronic state (13) (0.50–0.80 l mol^{-1}), respectively, it is apparent that these values are found to be comparatively greater for excited state than for ground state and are within the expectation limit.

In conslusion, this investigation seems to provide further substantial support on the proposed charge-transfer mechanism of quenching by heavy atoms (4, 5).

The authors wish to thank Mr. G. L. Loper for some helpful discussions.

Nuphar Alkaloids: 3-Epinupharamine

T. P. FORREST AND S. RAY
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

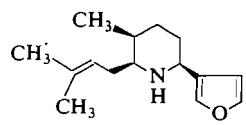
Received December 17, 1970

The structure of a new alkaloid isolated from *Nuphar variegatum* is shown to be that of 3-epinupharamine (**4**).

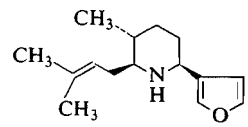
On a établi que la structure d'un nouvel alcaloïde isolé du *Nuphar variegatum* est celle de la 3-epinupharamine (**4**).

Canadian Journal of Chemistry, 49, 1774 (1971)

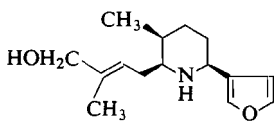
The genus *Nuphar* has been the source of several quinolizidine alkaloids as well as some piperidine alkaloids of similar structure in which the second ring of the quinolizidine nucleus remains open. The major alkaloid of the North American yellow water lily, *Nuphar variegatum* Engelm., has been shown to be nuphenine (**1**) (1), a piperidine alkaloid differing in relative configuration from the alkaloids (*e.g.* anhydronupharamine (**2**) (2)) isolated from the yellow water lilies of Japanese origin, *Nuphar japonicium* (3). Another piperidine alkaloid, 3-epinuphamine (**3**) (4) having the same stereochemistry as nuphenine has recently been found in *Nuphar variegatum*. We now wish to report the isolation of a third such alkaloid 3-epinupharamine (**4**) from the same source.



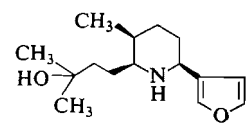
1



2



3



4

The structure of 3-epinupharamine (picrolonate m.p. 83–85 °C, *N*-acetate m.p. 107–109 °C) was proved by analysis of its various spectra and by its synthesis from the known alkaloid nuphenine (**1**). The molecular formula was determined to be $C_{15}H_{25}NO_2$ by mass spectrometry. Evidence for the presence of the hydroxyl group was obtained from the i.r. spectrum, 3575 (sharp) and 3150 cm^{-1} (broad) and the n.m.r. spectrum (in $CDCl_3$) (τ 7.35, 2H, OH and NH). The furan ring was indicated by the i.r. bands at 1500, 1170, and 875 cm^{-1} and by peaks in the n.m.r. spectrum at τ 2.63 (2α-H's) and 3.57 (1β-H). The ring methyl group was observed as a doublet at τ 9.03 (J = 6.6 Hz) and the gem-dimethyl groups as singlets τ 8.83 and 8.75. The magnetic nonequivalence of these gem-dimethyl groups, separated by two methylene groups from the nearest chiral center, is apparently accentuated by hydrogen bonding of the hydroxyl group with the nitrogen. The methyl groups appear as a single peak when the spectrum is determined in dimethyl sulfoxide. One proton α to the nitrogen (position 6) was seen as a doublet of doublets (J = 3 and 10 Hz) centered at τ 6.39 and the other proton α to the nitrogen (position 2) as a triplet (J = 7 Hz)

The methyl groups appear as a single peak when the spectrum is determined in dimethyl sulfoxide. One proton α to the nitrogen (position 6) was seen as a doublet of doublets (J = 3 and 10 Hz) centered at τ 6.39 and the other proton α to the nitrogen (position 2) as a triplet (J = 7 Hz)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

further split into doublets (J = 2.5 Hz) centered at τ 7.21. The presence of the 3-methyl-3-hydroxybutyl side chain on position 2 was substantiated by the appearance of the base peak in the mass spectrum at *m/e* 164 (M—$C_4H_{11}O$). The presence of only two α protons on the piperidine ring and the coupling of the 2-proton to only one 3-proton established the substitution pattern shown (**4**).

This assignment of the structure and stereochemistry was verified by the conversion of nuphenine (**1**) into a compound identical in all respects with the naturally occurring **4**. The isolation of **4** by extraction conditions which would not hydrate a double bond indicated that this compound is indeed a natural product and not formed by acid catalyzed hydration of nuphenine. It is of interest to note that no quinolizidine alkaloids having the relative configuration of nuphenine have been reported, whereas the quinolizidine alkaloids are the major alkaloids of the other stereochemical series.

Experimental

All n.m.r. data were recorded on a Varian A-60 spectrometer in deuterochloroform with tetramethylsilane as internal standard. Optical rotation was measured on a Perkin–Elmer model 141 polarimeter and u.v. spectra on a Coleman-Hitachi 124 double beam spectrometer. The i.r. spectra were determined on a Perkin–Elmer 237B grating spectrometer. The melting points are uncorrected.

Isolation of Alkaloids

Air dried powdered rhizomes (1.15 kg) of *Nuphar variegatum* were continuously extracted with petroleum ether (40–60 °C) for 3 days, then air dried, soaked overnight with 10% Na_2CO_3, and filtered under suction. The residue was then extracted with chloroform at room temperature (over an extended period). Evaporation of the chloroform *in vacuo* gave a viscous residue (47 g). This was dissolved again in chloroform, filtered, and the filtrate repeatedly washed with 5% HCl solution until the aqueous phase showed no cloudiness with Mayers reagent. The combined washings were made basic (*ca.* p*H* 8) with Na_2CO_3 and the bases (25.3 g) obtained by chloroform extraction.

Isolation of 3-Epinupharamine (4)

A quantity of crude bases (12.7 g) was chromatographed on Silicar CC7 (Malinckrodt) by gradient elution using benzene and methanol. Fractions were collected in 100ml portions and were monitored by t.l.c. 3-Epinupharamine (0.5 g) was obtained from the fraction eluted with benzene–methanol (9:1 v/v) and purified by repeated chromatography on preparative alumina plates.

3-Epinupharamine was also obtained by column chromatography of the crude chloroform extract of the rhizomes (without separation of the bases) on neutral alumina and then repeated preparative t.l.c. on alumina plates.

Pale yellow oil: $[\alpha]_D^{23°} = -24.8$ (1.45 MeOH); λ_{max}(MeOH) 274 nm (440) and λ_{max}(CCl_4) 263 nm (400); i.r. (CCl_4), 3575, 3150, 2794 (weak), 2710 (weak), 1500, 1450, 1381, 1170, 1155, 1065, 1025, 875 cm^{-1}; n.m.r. ($CDCl_3$) τ 2.63 (2H, α-furan), 3.57 (1H, β-furan), 8.78 and 8.83 (6H, gem-CH_3), 9.03 (3H, C_3—CH_3), 6.4 (1H, C_6—H), 7.22 (1H, C_2—H), 7.35 (2H, OH and NH), 8.1–8.7 (9H); mass spectrum: major peaks at *m/e* 251.1884 (M^+), 236, 164 (base peak), 107, and 94.

3-Epinupharamine Picrolonate

3-Epinupharamine (170 mg) was dissolved in a small quantity of methanol and picrolonic acid (180 mg) dissolved in a small amount of methanol was added to it. The mixture was kept at 50° for 1/2 h and then the solvent was evaporated producing a semi-solid mass which was crystallized from methanol–acetone, m.p. 83–85 °C.

N-Acetyl-3-epinupharamine

3-Epinupharamine (140 mg) was dissolved in a mixture of freshly distilled pyridine and acetic anhydride (2 ml, 1:1) and left overnight at room temperature. The solvents were removed *in vacuo*, the residue dissolved in chloroform and washed successively with cold 5% $NaHCO_3$, 5% HCl, and finally with distilled water. The chloroform was removed *in vacuo* and the residue crystallized from acetone, m.p. 107–109 °C; i.r. (KBr pellet) 3450, 1615, 1500, 1415, 1375, 1360, 1310, 1260, 1130, 1020, 870, 745 cm^{-1}; n.m.r. ($CDCl_3$, room temperature, showing the presence of both amide conformations) τ 9.03 (d, 3H, C_3—CH_3, J = 6.5 Hz), 8.73 (s, 3H, gem-CH_3), 8.68 (s, 3H, gem-CH_3), 7.8 (s, 3H, *N*-acetyl CH_3), 7.68 (s, 1H, OH), 6.27 (br, 1H, C_2—H), 4.05 (br, 0.7H, C_6—H), 3.56 (br, 0.3H, C_6H), 3.5 (m, 1H, furan βH), 2.6 (m, 2H, furan αH).

Conversion of Nuphenine to 3-Epinupharamine

Nuphenine (0.45 g) was dissolved in 25 ml of 5% HCl and maintained at room temperature for 2 weeks. The solution was made basic with solid Na_2CO_3, extracted with chloroform, the chloroform extract dried over $MgSO_4$, and the solvent removed *in vacuo* to give crude 3-epinupharamine. The crude product was purified on preparative scale alumina plates to yield 0.38 g of pure 3-epinupharamine. The i.r. and n.m.r. spectra were superimposable with those of natural 3-epinupharamine.

L'isomérisation des acétates énoliques en série décalinique

H. FAVRE, F. HUET, ET L. VARFALVY
Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 9 juin 1970[1]

Le réactif d'acétylation énolique préconisé par Edwards et Rao (anhydride acétique et acide perchlorique dans l'acétate d'éthyle) est tout à fait adapté à la préparation d'acétates d'énols et à leur mise en équilibre en série décalinique *cis* et *trans*.

The reagent (acetic anhydride and perchloric acid in ethylacetate) proposed by Edwards and Rao for the enolacetylation of ketones is particularly well suited to the preparation of the enolacetates of *cis* and *trans* 2-decalones, and to the study of their equilibrium.

L'acétylation énolique constitue un moyen d'étudier la direction de l'énolisation de cétones substituées dissymétriquement. Elle a été mise en œuvre dans les séries stéroïdiques A/B *trans* (1–4) et *cis* (5, 6), cyclohexanique (7), et décalinique (8, 9). D'une manière générale, on utilise l'acétate d'isopropényle et l'acide sulfurique (1), réactif I, pour obtenir une commande cinétique et l'anhydride acétique et l'acide perchlorique 70% dans le tétrachlorure de carbone (10) ou dans le mélange tétrachlorure de carbone–benzène (5–9), réactif II, pour la commande thermodynamique; une étude récente (11) confirme les premières observations (7) sur l'action de ces réactifs, mais une généralisation ne semble pas encore possible; en effet, en séries décalinique et stéroïdique (5, 8, 11), le réactif I ne provoque aucune isomérisation des acétates formés, alors qu'il le fait en série aliphatique (12). Le réactif II, selon (11), présente la caractéristique d'une commande cinétique initiale, suivie d'une mise à l'équilibre; nous avons remarqué que ce réactif présente toutefois le désavantage marqué de conduire en série décalinique *cis* à de forts pourcentages de produits secondaires, et en série décalinique *trans*, à l'hydrolyse des acétates d'énols plutôt qu'à leur mise en équilibre. On a rapporté que l'anhydride acétique en présence d'acide *p*-toluène sulfonique anhydre (13) ou d'acide bromhydrique dans le benzène (14) sont de bons agents d'isomérisation des acétates énoliques. De notre côté, nous avons trouvé que le réactif préconisé par Edwards et Rao (15), anhydride acétique, acide perchlorique 70% dans l'acétate d'éthyle, est particulièrement intéressant: (*a*) il ne donne aucune réaction secondaire; les résultats sont facilement reproductibles, (*b*) la réaction est juste assez lente pour permettre de faire les observations suivantes: en série *cis* (*a*) (cétones **1** et **2**), la réaction débute par une commande cinétique et aboutit à un équilibre des acétates d'énols; en série *cis* (*e*) (cétone **3**) il n'y a pas de différence entre les résultats des commandes cinétiques et thermodynamique. En série *trans* (cétone **4**), il y a d'abord acétylation, avec commande cinétique, puis isomérisation et lent retour à la décalone de départ; au bout de 162 h, la réaction s'arrête à toutes fins pratiques; la mise en équilibre de chaque acétate énolique pur indique qu'il y a d'abord hydrolyse en décalone, puis isomérisation des acétates d'énols. Les résultats apparaissent au tableau 1.

La structure Δ^1 correspond, en r.m.n. aux acétates qui donnent un singulet en série *cis* (*a*) (5, 15) et un doublet (J = 4.8 Hz) en série *cis* (*e*): ceci est conforme (16) au fait qu'en série *cis* (*a*) (**5***a* et **6***a*) les protons 1 et 9 forment un angle de 90° et qu'en série *cis* (*e*) (**7***a*) cet angle est de 35° environ (mesuré sur un modèle de Dreiding). Le signal du proton vinylique en position 3 est un multiplet (5, 15).

Les structures découlant des spectres de r.m.n. nous obligent à reviser les pourcentages obtenus par méthode chimique et décrits précédemment (8, 9) pour les décalones **1** et **2**. Nos nouveaux résultats confirment l'absence de différences appréciables dans la direction de l'énolisation de décalones *cis* (*a*) et *cis* (*e*). Ils indiquent aussi que le groupe *gem* diméthyles n'a que peu d'influence sur cette direction en série *cis* (*a*), par rapport au groupe *tert*-butyle.

Partie expérimentale

1. Cétones

Les décalones *cis* **1** et **3** (préparées selon (17)) sont absolument pures et exemptes d'isomère *trans*, après

[1]Revision reçu le 21 décembre 1970.

*La pureté est définie par rapport aux deux isomères Δ^1 et Δ^2.
†On indique 5.07 (s) et 5.22 (doublet de triplets) (13).

analyse en c.p.g. sur: (*a*) 5% QFI (FS 1265) sur Chromosorb G 80/100, A.W. DMCS, 3.6 m, 3 mm, 170–220°, 5–40 ml N_2/min; (*b*) 4% Carbowax 20M sur Chromosorb G 80/100, A.W. DMCS, 2.4 m, 3 mm, 130–200°, 5–40 ml N_2/min; (*c*) 20% Polyester Succinique de Craig sur Chromosorb P 80/100, 4.8 m, 6 mm, 180–200°, 30–60 ml N_2/min.

La cétone *cis* **2** qui résulte de la synthèse décrite précédemment (9) contient deux autres composés, décelés par c.p.g. (colonne *b* plus haut), représentant d'une part 3.2% d'isomère *trans* et d'autre part 8.7% d'un composé non identifié. La cétone pure **2**, homogène en c.p.g., cristallise lentement du mélange brut, abandonné pendant plusieurs semaines à 15–18°; elle fond à 32–33°.[2] Nous avons obtenu la cétone **4** pure par c.p.g. préparative à partir d'un mélange commercial des décalones-2 *trans* et *cis*, dans les conditions suivantes: 20% Carbowax 20M TPA sur Chromosorb P 80/100, A.W., 3.0 m, 6 mm de diamètre, 186°, 70 ml He/min.

2. Acétates énoliques

(2.1) Les mélanges d'acétates énoliques se séparent en c.p.g. analytique:

(*a*) Acétates **5***a* et *b*: sur 5% QFI (FS 1265) sur Chromosorb G 80/100, A.W. DMCS, 3.9 m, 3 mm, 176°, 20 ml N_2/min. Temps de rétention: Δ^1, 7.9 min; Δ^2, 9.2 min.

(*b*) Acétates **6***a* et *b*: sur 5% QFI (FS 1265) sur Chromosorb G 80/100, A.W. DMCS, 3.9 m, 3 mm, 176°, 18 ml N_2/min; temps de rétention: Δ^1, 10.0 min.; Δ^2, 12.2 min.

(*c*) Acétates **7***a* et *b*: sur 4% Carbowax 20M sur Chromosorb G 80/100, A.W. DMCS, 2.4 m, 3 mm, 180°, 42 ml N_2/min; temps de rétention: Δ^1, 8.5 min.; Δ^2, 9.3 min.

(*d*) Acétates **8***a* et *b*: sur 3% Carbowax 20M TPA, sur Chromosorb G 80/100, A.W., DMCS, 3.6 m, 4 mm de diamètre, 170°, 25 ml N_2/min; temps de rétention: Δ^1, 6.0 min.; Δ^2, 6.6 min.

(2.2) La séparation des acétates énoliques, préparés selon les méthodes décrites en (8, 9), se fait en c.p.g. préparative, dans les conditions suivantes, et les résultats figurent au tableau 2.

(*a*) Acétates **5***a* et *b*: sur 5% QFI (FS 1265) sur Chromosorb G 80/100, A.W. DMCS, 6 m, 9 mm, 185°, 60 ml N_2/min.

(*b*) Acétates **6***a* et *b*: sur 15% QFI (FS 1265) sur Chromosorb G 80/100, A.W. DMCS, 6 m, 6 mm, 198°, 60 ml He/min.

(*c*) Acétates **7***a* et *b*: sur 25% Carbowax 20M sur Chromosorb P 60/80, A.W. DMCS, 3 m, 6 mm, 175°, 47 ml He/min.

(*d*) Acétates **8***a* et *b*: sur 20% Carbowax 20M TPA sur Chromosorb P 80/100, A.W. 6 m, 6 mm de diamètre, 182°, 70 ml He/min.

Note: Les acétates énoliques correspondants aux trois décalones **1–4** peuvent très bien être séparés en c.p.g. analytique sur les phases stationnaires suivantes: QFI (FS 1265), Carbowax 20M, Carbowax 20M TPA ou sur Polyester Succinique de Craig en utilisant des taux d'imprégnation faibles (3–5%) et en c.p.g. préparative en utilisant des taux d'imprégnation plus élevés (20–25%).

La position des décalones est variable (il reste toujours quelques % de décalone lors de la formation des acétates énoliques dans les conditions thermodynamiques, voir tableau 1) suivant la phase stationnaire employée. Notamment dans le cas de la phase stationnaire Polyester succinique de Craig, la décalone se trouve masquée par l'un des deux acétates ce qui exclut l'emploi de cette phase stationnaire pour fins de c.p.g. analytique ou préparative dans les cas où il reste une certaine quantité de décalone. D'autre part sur Carbowax 20M nous avons constaté une certaine décomposition thermique des acétates énoliques, en c.p.g. préparative seulement. La phase stationnaire QFI (FS 1265) ne représente par contre aucun inconvénient en c.p.g. préparative.

3. Acétylation énolique et mise à l'équilibre

Le réactif utilisé a la composition suivante: 10^{-2} *M* $HClO_4$, 70% 1 *M* Ac_2O dans l'acétate d'éthyle (18). Un essai typique se déroule comme suit: 2.5 mmol de cétone (ou d'acétate énolique dans le cas d'une isomérisation) sont ajoutées à 24.8 ml de réactif; on laisse la solution,

[2]Pour une synthèse récente (voir 18).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

sous agitation, à la température ambiante pour une durée pré-déterminée.

Le mélange réactionnel est par la suite lavé par une solution saturée de bicarbonate de sodium, par une solution saturée de sel, séché sur sulfate de sodium; puis l'acétate d'éthyle est évaporé sous vide. Les résultats sont rapportes au tableau 1, tels qu'obtenus par analyse par c.p.g. dans les conditions décrites à la section 2.1.

Les rendements sont en général de l'ordre de 90–95%, on ne note aucune formation de produits secondaires.

Un réactif vieux de plusieurs semaines perd de sa force d'acétylation (au bout de 360 min, le rapport **6***a*/**6***b* est 39–61 avec 6.8% de cétone **2**) et de sa force d'isomérisation (au bout de 600 min l'isomère **6***a*, pur à 99.9% s'isomèrise pour donner un mélange **6***a*/**6***b* de 93/7).

CNDO/2 Electron Densities and Proton Chemical Shifts

John F. Sebastian and John R. Grunwell
Department of Chemistry, Miami University, Oxford, Ohio 45056

Received October 30, 1970

An approximate linear dependence of the proton shifts on the CNDO/2[1] calculated electron densities on hydrogen for $C_5H_5^-$, C_6H_6, $C_7H_7^+$, $C_5H_5NH^+$, and $C_6H_5CH_2^-$ has been found. The significance and limitations of the correlation are discussed.

On a trouvé une relation linéaire approchée entre les déplacements chimiques des protons et les densités électroniques calculées d'après la méthode CNDO/2[1] pour les hydrogènes du $C_5H_5^-$, C_6H_6, $C_7H_7^+$, $C_5H_5NH^+$ et $C_6H_5CH_2^-$. On discute de la signification et des limitations de cette corrélation.

Canadian Journal of Chemistry, 49, 1779 (1971)

Linear correlations of ^1H and ^{13}C chemical shifts with carbon charge densities have been established previously (1–4). We wish to report an approximate linear correlation of the hydrogen electron densities with the ^1H chemical shifts for $C_5H_5^-$, C_6H_6, $C_7H_7^+$, $C_5H_5NH^+$ (*para*-hydrogen), and $C_6H_5CH_2^-$ (*para*-hydrogen). All densities were calculated using the CNDO/2 method (5) and, except for pyridine and pyridinium ion, standard geometries were used. The geometries of pyridine and pyridinium ion were taken from a microwave study and X-ray diffraction analysis, respectively (see Table 1 for shift values and densities taken from the literature). The shifts for $C_5H_5^-$ and $C_7H_7^+$ have been corrected for the effect of ring size on the ring current (3).

CNDO/2 Electron Densities and Proton Chemical Shifts

John F. Sebastian and John R. Grunwell
Department of Chemistry, Miami University, Oxford, Ohio 45056

Received October 30, 1970

An approximate linear dependence of the proton shifts on the CNDO/2[1] calculated electron densities on hydrogen for $C_5H_5^-$, C_6H_6, $C_7H_7^+$, $C_5H_5NH^+$, and $C_6H_5CH_2^-$ has been found. The significance and limitations of the correlation are discussed.

On a trouvé une relation linéaire approchée entre les déplacements chimiques des protons et les densités électroniques calculées d'après la méthode CNDO/2[1] pour les hydrogènes du $C_5H_5^-$, C_6H_6, $C_7H_7^+$, $C_5H_5NH^+$ et $C_6H_5CH_2^-$. On discute de la signification et des limitations de cette corrélation.

Canadian Journal of Chemistry, 49, 1779 (1971)

Linear correlations of ^1H and ^{13}C chemical shifts with carbon charge densities have been established previously (1–4). We wish to report an approximate linear correlation of the hydrogen electron densities with the ^1H chemical shifts for $C_5H_5^-$, C_6H_6, $C_7H_7^+$, $C_5H_5NH^+$ (*para*-hydrogen), and $C_6H_5CH_2^-$ (*para*-hydrogen). All densities were calculated using the CNDO/2 method (5) and, except for pyridine and pyridinium ion, standard geometries were used. The geometries of pyridine and pyridinium ion were taken from a microwave study and X-ray diffraction analysis, respectively (see Table 1 for shift values and densities taken from the literature). The shifts for $C_5H_5^-$ and $C_7H_7^+$ have been corrected for the effect of ring size on the ring current (3).

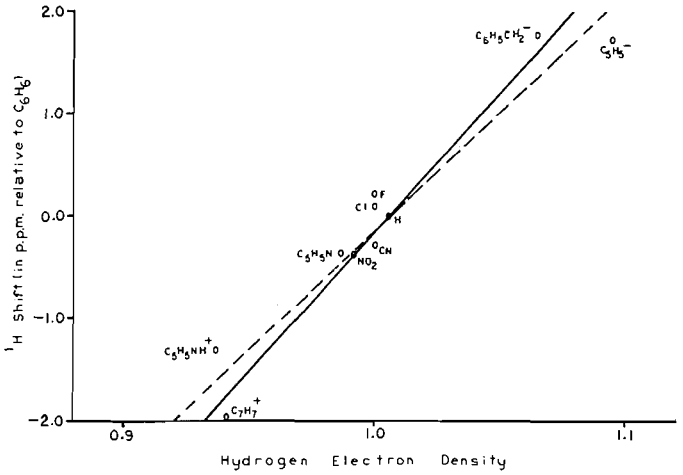

FIG. 1. Correlation of *para*-^{1}H shifts (relative to benzene) of monosubstituted benzenes pyridine, C_6H_6, and aromatic ions and the hydrogen electron densities as calculated by the CNDO/2 method. The solid line was chosen to have a slope of 26.6 p.p.m./*e* and to pass through the point for benzene. The slope of the best line (least squares; dashed line) is 23.4 p.p.m./*e*.

TABLE 1. Summary of chemical shifts and hydrogen electron densities

Compound	Chemical shift*	Hydrogen electron density
$C_7H_7^+$	−1.98	0.941
$C_5H_5NH^+$	−1.30†	0.937†
C_5H_5N	−0.37†	0.987†
$C_6H_5NO_2$	−0.38‡	0.992
C_6H_5CN	−0.28‡	1.001
C_6H_6	0.00	1.006
C_6H_5Cl	0.09‡	1.001
C_6H_5F	0.22§	1.001
$C_6H_5CH_2^-$	1.77§	1.065‖
$C_5H_5^-$	1.73	1.095

‖Reference 16.

A plot of hydrogen electron densities *vs.* ^{1}H chemical shifts is shown in Fig. 1. The solid line drawn through the points was chosen to have a slope of 26.6 p.p.m./*e* and to pass through the point for benzene. This value of the slope is the best estimate for the shielding of a proton in the hydrogen molecule (6). The local diamagnetic shielding in a hydrogen atom has been calculated to be 17.8 p.p.m./*e* (7). The best straight line (least squares, dashed line in Fig. 1) for all points has a slope of 23.4 p.p.m./*e*. The similarity of the two slopes and the observed approximate linear correlation suggest that large differences in the chemical shift (*cf.* aromatic ions of opposite charge type, Table 1) are dominated by changes in the hydrogen electron densities. The deviation from the line of the points may be due to non-linear electric field effects (8, 9), overestimation of charge dipole sigma polarization (10) or other factors. The view presented here suggests that the shift difference between the *para*-hydrogen (γ-H) of pyridine and the corresponding proton of pyridinium ion is largely due to a change in hydrogen 1s electron density. This view differs from that reported earlier (11) and supports the conclusions of Yonezawa and co-workers (12).

Shift data (13) and the calculated hydrogen electron densities for the *para*-hydrogens of some neutral monosubstituted benzene derivatives and pyridine are included in Fig. 1. The *ortho*- and *meta*-hydrogens are not plotted since they may be subject to substituent field effects (14). The deviation of the points is a result of the small values for the charges and chemical shifts (relative to benzene) as compared to the corresponding values for the aromatic ions. The scatter may reflect the intervention of long range shielding effects, to which proton shifts are quite sensitive, and deviations from the standard geometries assumed in the calculations.

Normally, the order of proton shifts in a molecule having two or more chemically distinct protons cannot be predicted correctly by hydrogen charge density considerations alone.

The *para*-hydrogen charge density (−0.001)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

calculated for chlorobenzene and plotted in Fig. 1 is obtained by excluding d-orbitals from the basis set. Including d-orbitals insignificantly changes the hydrogen charge density to +0.001. However, the total charge density on the *para*-carbon atom *is* dependent on inclusion of d-orbitals in the basis set (−0.002 without d-orbitals, +0.014 with). A plot of *para*-^{13}C shifts (14) *vs.* *para*-carbon charge densities (CNDO/2 method) for the neutral monosubstituted benzene derivatives, $C_5H_5^-$, and $C_7H_7^+$ yields a straight line (slope = 280 p.p.m./*e*). The charge density which gave the best fit to the line for the *para*-carbon atom in chlorobenzene was calculated by excluding d-orbitals from the basis set.

One of us (J.F.S.) thanks the Miami University Research Committee for a Summer Faculty Research Fellowship. We are indebted to Mr. Wally Danison and Mr. Art Fiser for getting the CNDO/2 program operational. Finally we wish to express our appreciation to the Miami University Computer Center for the generous amount of computer time.

Electron Spin Resonance Detection of Electrochemical Intermediates Formed During Oxygen Evolution[1]

C. L. GARDNER AND E. J. CASEY

Defence Research Board, Defence Research Establishment Ottawa, Ottawa 4, Canada

Received January 7, 1971

Electron spin resonance detection has been made of ozonide ion (O_3^-) and another unidentified species (X) formed during anodic oxygen evolution in concentrated KOH solutions at low temperature. The relative amounts observed depend on the metal used for the anode. New insight into the mechanism of oxygen evolution results.

Nous avons détecté, par la r.p.e., des ions (O_3^-) ozonides et aussi une autre espèce inconnue qui est engendrée pendant l'émission de l'oxygène par une anode dans une solution concentrée de KOH à basse température. Les quantités relatives observées dépendent du métal utilisé pour l'anode. Une meilleure compréhension du mécanisme de l'émission de l'oxygène est ainsi obtenue.

Canadian Journal of Chemistry, 49, 1782 (1971)

In the course of a recent study of the anodic oxidation of metals in concentrated potassium hydroxide at low temperatures, we have been able to detect several paramagnetic intermediates including the ozonide ion (O_3^-) and an unidentified species, "X". Controlled potential measurements have demonstrated that the O_3^- is formed only during oxygen evolution. In addition, as shown in Table 1, the intermediates observed depend on the metal used.

Anodic oxidations of the various metals were carried out in 45% KOH and at high current densities ($\sim$ 90 mA/cm^2) at -40 °C. The experimental technique necessary to observe the species X involved plunging a cooled, open-ended 4 mm silica tube into the anolyte and transferring this tube as rapidly as possible into liquid nitrogen. The O_3^- is sufficiently long-lived at -40 °C that it could be observed by flowing the anolyte down into a low temperature aqueous cell where the species could then be observed either in solution and the decay kinetics studied or else frozen and the polycrystalline spectrum studied. The electron spin resonance (e.s.r.) spectrum formed during the anodic oxidation of a silver foil electrode is shown in Fig. 1. The spectrum is characterized by

TABLE 1. Species detected by e.s.r. during the anodic process

Anode material	Species detected*
Silver	O_3^-(s); X(w)
Cadmium	O_3^-(s); X(w)
Lead	O_3^-(w); X(w)
Nickel	X(w)
Platinum	X(w)
Copper	CuO_2^{2-}(s); X(w)

*w = weak; s = strong e.s.r. signal.

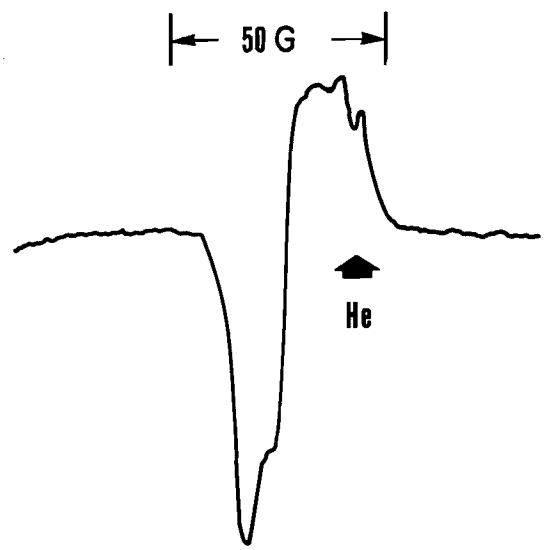

FIG. 1. Electron spin resonance spectrum of O_3^- formed in the anolyte during the anodic oxidation of silver at -40 °C in 45% KOH, then frozen at 77 °K.

TABLE 2. Principal g-values for O_3^-

Matrix	g_{xx}	g_{yy}	g_{zz}
$KClO_4$ (ref. 3)	2.0174	2.0113	2.0025
$KClO_4$ (ref. 4)	2.018	2.011	2.0034
NaO_3 (ref. 1)	2.015	2.015	2.003
This work	2.0181	2.0112	2.0019

a non-axial g-tensor (Table 2). Identification of the species as O_3^- can be made by comparison with the results of other workers on alkali ozonides (1, 2), γ-irradiation of $KClO_4$ (3, 4) and the u.v.-irradiation of alkaline glasses containing H_2O_2 (2). Parameters from some of these systems are included in Table 2.

The e.s.r. spectrum due to the species X consists of a narrow line (linewidth $\simeq$ 2 G) with $g = 2.002$. This species causes the small inflection at He in Fig. 1. In other spectra, this line can be much more pronounced. The absence of hyperfine interactions or g-shifts indicates that this spectrum is due to a species with an essentially "free" electron. In our opinion the most likely identity is either a solvated electron (5) or else it is due to conduction electrons (6) in small metal or metal oxide particles ejected into solution during the oxidation. Additional work is in progress in order that a more positive identification can be made.

The mechanism of oxygen evolution in alkaline solution is generally considered (7) to involve discharge of adsorbed hydroxyl ions as the first step

[1] $$OH^- \rightarrow OH\cdot + e^-$$

Other steps involving adsorbed species, such as those given in reactions 2–4, could follow

[2] $$OH\cdot + OH^- \rightarrow H_2O + O^-$$

[3] $$O^- \rightarrow O\cdot + e^-$$

[4] $$O\cdot + O\cdot \rightarrow O_2$$

The O_3^- formed in our system could arise from reaction

[5] $$O^- + O_2 \rightarrow O_3^-$$

or alternatively by dissociation of HO_3 to O_3^- in strong base following reaction 6

[6] $$OH\cdot + O_2 \rightarrow HO_3$$

Addition of a small amount of methanol to the solution in the electrolysis cell almost completely eliminated the e.s.r. signal due to O_3^-. Since it is known (8) that the formation of O_3^- during the radiolysis of alkaline solutions can be suppressed by the addition of a hydroxyl radical scavenger such as methanol, this observation provides strong evidence that hydroxyl radicals are a precursor to the *anodic* formation of O_3^- as well.

It is interesting to speculate on the observation that the species detected depends on the metal used (Table 1). This result must indicate that the mechanism of oxygen evolution differs amongst the metals. In particular, there appears to be a fundamental difference in the oxygen evolution mechanism between active metals such as silver and cadmium, and the passive metals such as nickel and platinum. One could argue that if the $OH\cdot$ is weakly bound it can leave the surface and form O_3^- by reaction 5 or 6 (Ag or Cd), but if the $OH\cdot$ is strongly bound no O_3^- is produced (Ni or Pt). Lead appears to be intermediate.

Some preliminary results of the anodic oxidation of cadmium at higher temperatures (−10 °C) and lower KOH concentrations (30%) have indicated that O_2^-, rather than O_3^-, is the major product detected by e.s.r. under these conditions.

This work is part of a continuing study of battery electrode mechanisms at low temperature. More complete results including kinetic results and effects of pH on these species will be included in a future publication.

Sur la formation de composés bicycliques lors de réactions de Friedel–Crafts

N. DUFORT, B. JODOIN, ET J. LAFONTAINE

Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 29 décembre 1970

Le méthyl-1 cyclohexène est condensé avec le chlorure de propionyle, de butyryle, et de benzoyle en présence de différents acides de Lewis. Les isomères *exo* et *endo* acyl-1 méthyl-6 bicyclo[3.1.0]hexane se forment avec des pourcentages variables dépendant du catalyseur utilisé. La condensation avec le chlorure de benzoyle en plus de conduire à des composés bicycliques donne également le benzoyl-3 méthyl-2 cyclohexanol. La condensation du chlorure d'acétyle sur le pentaméthyl-1,3,3,5,5 cyclohexène en présence de chlorure stannique ne donne pas de composés bicycliques.

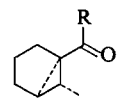
The acylation of 1-methylcyclohexene with propionyl, butyryl, and benzoyl chloride in the presence of different Lewis acids is reported. The *exo* and *endo* 1-acyl-6-methyl bicyclo[3.1.0]hexane isomers are formed with variable percentages depending upon the catalyst used. An unexpected compound, 3-benzoyl-2-methylcyclohexanol, was isolated from the reaction of 1-methylcyclohexene with benzoyl chloride. The acylation of 1,3,3,5,5-pentamethylcyclohexene with acetyl chloride – stannic chloride gave no bicyclic compounds.

Canadian Journal of Chemistry, 49, 1785 (1971)

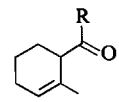
Lors d'une publication antérieure (1), nous rapportions la formation de l'*endo* et de l'*exo* acétyl-1 méthyl-6 bicyclo[3.1.0]hexane lors d'une réaction de Friedel–Crafts. Nous avons poussé plus loin cette étude, en particulier l'effet de la grosseur de l'agent acylant et la nature du catalyseur sur la formation de composés bicycliques et nous en rapportons les résultats dans la présente publication.

Le méthyl-1 cyclohexène est condensé avec le chlorure de propionyle, le chlorure de butyryle, et le chlorure de benzoyle en présence de différents acides de Lewis: $AlCl_3$, $SnCl_4$, $ZnCl_2$, et BF_3. Le mélange réactionnel est ensuite traité par une solution méthanolique d'hydroxyde de sodium. Les résultats obtenus sont rapportés dans le tableau 1. Tous les composés indiqués au tableau 1 sont isolés à l'état pur par c.p.g. préparative sauf le composé **3***a* à cause du fait qu'il ne se forme qu'en très petite quantité et qu'il est alors impossible de le séparer de ses isomères.

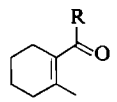
Les cétones α,β et β,γ éthyléniques formées sont identifiées comme on l'indique dans la partie expérimentale par leurs spectres i.r., u.v., et de r.m.n. Le spectre de masse ou l'analyse élémentaire des nouveaux composés vient confirmer leur structure. Les spectres i.r. des composés **1***a* et *d* montrent une bande à 1685 cm^{-1}. Dans l'u.v., ces composés présentent respectivement un maximum à 213 et 211 mμ. Le spectre r.m.n. des composés **1***a* et *d* n'indique aucun proton éthylénique. De plus, ces composés résistent à l'ozone mais s'isomérisent en présence d'acide oxalique pour conduire à un mélange formé de 34% de



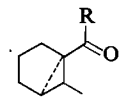
1*a* R = C_2H_5
2*a* R = C_3H_7
3*a* R = C_6H_5



1*b* R = C_2H_5
2*b* R = C_3H_7
3*b* R = C_6H_5



1*c* R = C_2H_5
2*c* R = C_3H_7
3*c* R = C_6H_5



1*d* R = C_2H_5
2*d* R = C_3H_7
3*d* R = C_6H_5

TABLEAU 1. Composés obtenus lors des différentes condensations

Réactifs	Catalyseurs	Produits	Pourcentage des produits formés a:b:c:d
Chlorure de propionyle	$AlCl_3$	**1**	10:47:23:20*
	$SnCl_4$		5:12:33:50
	$ZnCl_2$		0:23:68:9
	BF_3		0:60:40:0
Chlorure de butyryle	$AlCl_3$	**2**	2:49:39:10*
	$SnCl_4$		3:13:36:48
	$ZnCl_2$		1:21:64:14
	BF_3		0:64:36:0
Chlorure de benzoyle	$AlCl_3$	**3**	0:30:55:15*
	$SnCl_4$		2:9:41:48
	$ZnCl_2$		0:46:24:30
	BF_3		0:90:10:0

*L'analyse par c.p.g. des produits de la condensation en utilisant $AlCl_3$ comme catalyseur indique la présence d'une petite quantité d'un produit dont le pic sort avant celui qui représente l'isomère *exo*. Ce produit n'a pas été identifié et est exclu du calcul du pourcentage des différents isomères.

composé **1***b* et de 66% de composé **1***c* ce qui permet de conclure que ces composés comportent un anneau cyclopropanique conjugué avec le groupe carbonyle. Il s'agirait donc de l'*exo* propionyl-1 méthyl-6 bicyclo[3.1.0]hexane (**1***a*) et de l'*endo* propionyl-1 méthyl-6 bicyclo[3.1.0]hexane (**1***d*).

Pour confirmer ces structures, on a fait la synthèse de l'isomère *exo* selon le cheminement indiqué sur le schéma 1. Le composé **1***b* est d'abord transformé sous forme d'acétal **4** et ensuite soumis à l'hydroboration selon la méthode de Brown et Subba Rao (2) pour conduire au composé **5** dans lequel les groupes méthyle et hydroxyle sont nécessairement *trans* l'un par rapport à l'autre. Après hydrolyse et tosylation du composé **5**, on obtient le composé **7** qui traité par NaOH alcoolique conduit à la formation d'un seul composé bicyclique; l'*exo* propionyl-1 méthyl-6 bicyclo[3. 1.0]hexane. Ce composé se superpose parfaitement en c.p.g. avec le composé **1***a* obtenu à 5% lors de la condensation ce qui confirme la structure proposée. Les composés **2***a* et *d* présentent respectivement une bande à 1685 et 1680 cm^{-1} dans l'i.r. et une absorption à 215 et 212 mμ dans l'u.v. Ces composés qui ne présentent pas de proton éthylénique dans leur spectre r.m.n., résistent à l'ozone; mais ils s'isomérisent pour donner 34% de composé **2***b* et 66% de composé **2***c*. En se basant sur les différentes données spectrales, les composés **2***a* et *d* ont été identifiés comme étant respectivement l'*exo* et l'*endo* butyryl-1 méthyl-6 bicyclo[3.1.0]hexane.

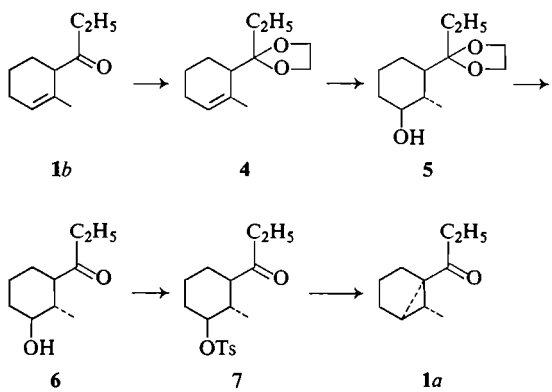


SCHÉMA 1

De plus, l'analyse par c.p.g. de ces composés et des composés analogues de la série propionyle sur trois colonnes différentes comme l'indique le tableau 2 vient confirmer les structures proposées puisque l'ordre d'élution des différents isomères est toujours le même quelle que soit la colonne utilisée; il n'y a que le temps de rétention qui varie.

Le composé **3***a* n'a pas pu être isolé à cause de sa formation en très petite quantité (2%). Le composé **3***d* absorbe à 1660 cm^{-1} dans i.r. et à 241 mμ dans u.v. Le spectre r.m.n. qui présente un doublet à 1.20 p.p.m. pour le méthyle sur le cyclohexane et aucun proton éthylénique est tout à fait conforme à la structure proposée en l'occurence l'*endo* benzoyl-1 méthyl-6 bicyclo[3.1.0]-hexane.

Si lors de la condensation du chlorure de benzoyle avec le méthyl-1 cyclohexène, le mélange

réactionnel obtenu après déshydrochloruration est laissé quelques heures à la température de la pièce, il cristallise un produit avec un rendement de 12.5%. Ce composé fond à 116–117 °C après recristallisation dans un mélange éther – éther de pétrole. Ce composé présente une bande carbonyle à 1665 cm^{-1} et une bande hydroxyle à 3450 cm^{-1} dans i.r. Le spectre r.m.n. indique également la présence d'un groupe hydroxyle puisqu'un massif à 3.26 p.p.m. (1H) disparaît par échange avec de l'eau deutérée. Il apparaît deux multiplets à 7.60 et 7.95 p.p.m. pour les protons du groupe phényle et un doublet à 0.85 p.p.m. pouvant correspondre à un méthyle sur le cyclohexane.

En se basant sur les données spectrales et l'analyse élémentaire, ce composé a été identifié comme étant le benzoyl-3 méthyl-2 cyclohexanol (**8**). Ce composé indique à l'analyse par c.p.g. la présence d'un seul produit dont le temps d'élution est le même que pour le composé **3***b*. Une injection mixte des deux composés conduit à la présence d'un seul pic. Il se produit donc une déshydratation. D'ailleurs par c.p.g. préparative, on a pu isoler le composé **3***b* à partir du composé **8**.

Afin de vérifier si ce produit se forme lors de la condensation ou lors de la déshydrochloruration, le chlorure de benzoyle a été condensé au méthyl-1 cyclohexène en présence de chlorure stannique et le mélange réactionnel après extraction fut laissé à la température de la pièce sans traitement par une base forte. Après quelques heures, le composé **8** commença à cristalliser. Le composé **8** pourrait s'expliquer par un mécanisme analogue à celui qui a été proposé par Ahmad *et al.* (3) pour la formation de l'acétyl-10β *trans* décalol-2β

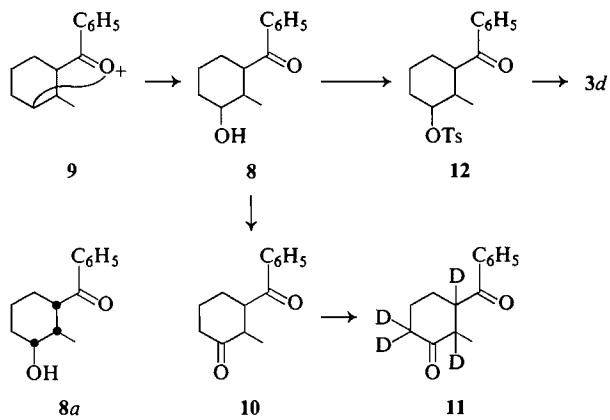

SCHÉMA 2

(schéma 2). L'ion carbonium serait stabilisé par le doublet de l'oxygène pour donner l'intermédiaire **9** qui traité par de l'eau donnerait le composé **8**. Afin de prouver avec certitude la position du groupe hydroxyle qui pouvait occuper la position 3 ou 4 comme dans le cas des cétones chlorées (4), l'alcool est oxydé par l'anhydride chromique dans la pyridine (5) en dicétone **10** qui traitée par de l'eau deutérée donne la dicétone **11**. Comme dans le spectre r.m.n., le méthyle sur le cyclohexane passe d'un doublet à un singulet en traitant la dicétone par de l'eau deutérée, la présence du groupe hydroxyle en position-3 est confirmée.

Comme l'alcool **8** est un composé analogue au composé **6**, il devenait intéressant de le tosyler et de le déshydrotosyler pour savoir s'il y aurait formation de l'*exo* benzoyl-1 méthyl-6 bicyclo[3.1.0]-hexane (**3***a*) comme lors de la synthèse décrite précédemment. Quand le tosylate **12** est traité par une solution méthanolique d'hydroxyde de so-

For personal use only.

dium à 20%, l'analyse par c.p.g. indique la présence d'un seul pic qui se superpose parfaitement avec celui de l'isomère *endo* **3***d*.

A la lumière de ces résultats, on peut donc déduire que les groupes méthyle et hydroxyle doivent être dans une configuration *cis* puisqu'une configuration *trans* de ces deux substituants conduirait exclusivement à l'isomère *exo* tel que prouvé lors de la synthèse de l'*exo* méthyl-6 propionyl-1 bicyclo[3.1.0]hexane (**1***a*). De plus, si la formation du composé **8** se fait par l'intermédiaire **9**, le cétoalcool **8** devrait être représenté par la structure **8***a*. On a également fait la condensation du chlorure d'acétyle sur le pentaméthyl-1,3,3,5,5 cyclohexène en présence de chlorure stannique suivi d'un traitement par l'hydroxyde de sodium alcoolique afin d'étudier l'influence des *gem*-diméthyles en position-3,5 sur la formation de composés cyclopropaniques. Cette condensation donne à l'analyse par c.p.g. l'acétyl-1 pentaméthyl-1,3,3,5,5 cyclohexène (**14**) et l'acétyl-1 pentaméthyl-2,4,4,6,6 cyclohexène (**15**) dans une proportion de 1 à 10 et il n'apparaît pas de pic pouvant correspondre à des composés cyclopropaniques. De plus, le mélange réactionnel ozoné indique à l'analyse par c.p.g. la disparition des pics correspondants aux composés **14** et **15** et le chromatogramme ne présente aucun pic qui pourrait être attribué à des composés bicycliques.

Il est intéressant de noter que l'isomération de ce mélange même pendant quatorze jours en présence d'acide oxalique ne permet pas d'augmenter le pourcentage du composé **15**. Comme il était alors impossible d'obtenir le composé **15** à l'état pur par c.p.g. préparative à cause de son faible pourcentage et des temps de rétention trop voisins, il est synthétisé comme l'indique le schéma 3.

L'hydroboration du composé **13** conduit au *trans* pentaméthyl-2,2,4,4,6 cyclohexanol (**16**) qui

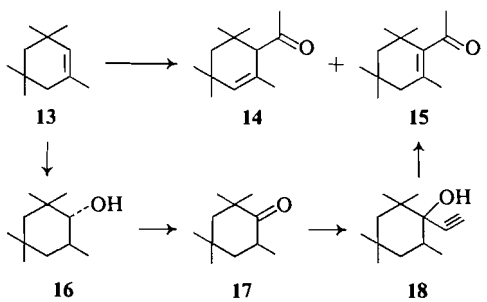

SCHÉMA 3

traité par l'anhydride chromique dans la pyridine (5) donne la pentaméthyl-2,2,4,4,6 cyclohexanone (**17**). Cette cétone traitée par l'acétylure de lithium selon la méthode de Beumel et Harris (6) donne l'éthynyl-1 pentaméthyl-2,2,4,4,6 cyclohexanol (**18**) qui chauffé à reflux en présence d'acide formique donne la cétone conjuguée (**15**).

Ce travail permet de déduire que les chlorures d'acide condensés avec le méthyl-1 cyclohexène conduisent généralement à la formation de composés bicycliques avec des pourcentages variables dépendant du catalyseur utilisé. Le chlorure stannique s'avère de beaucoup le meilleur catalyseur pour la formation de ces composés bicycliques tandis qu'avec le trifluorure de bore, on en retrouve aucune trace.

Enfin, la condensation du chlorure d'acétyle sur le pentaméthyl-1,3,3,5,5 cyclohexène a montré que les groupes *gem*-diméthyles créaient trop d'interactions pour conduire à la formation de composés bicycliques.

Partie expérimentale

Les points de fusion ont été déterminés à l'aide d'un appareil de marque "Büchi" et ne sont pas corrigés. Les spectres i.r. ont été déterminés en solution dans le tétrachlorure de carbone à l'aide d'un spectrophotomètre Beckmann modèle IR-8 à double faisceau.

Les spectres u.v. ont été déterminés en solution dans l'éthanol 95% à l'aide d'un appareil "Bausch & Lomb Spectronic 505". Les spectres de r.m.n. ont été déterminés avec un appareil "Jeol type C 60 H" pour des solutions dans le tétrachlorure de carbone et utilisant le tétraméthylsilane comme référence interne. Les spectres de masse ont été déterminés à l'aide d'un appareil "Hitachi–Perkin" modèle RMU-6D. Les analyses par c.p.g. ont été effectuées à l'aide d'un appareil F et M modèle 810. Les longueurs des colonnes et les adsorbants utilisés sont rapportés dans le tableau 2. Les séparations préparatives ont été effectuées à l'aide d'un appareil "Prep/Partitioner" de Fisher modèle 24 en utilisant des colonnes renfermant 15% de Polyester de Craig supporté par du chromosorb P ou à l'aide d'un appareil "Varian Aerograph" modèle 90 P en utilisant des colonnes renfermant 25% de carbowax 20M TPA supporté sur du chromosorb P. Les analyses élémentaires ont été effectuées par "Schwarzkopf Micro-analytical Laboratory" de New York et par Dr. C. Daesslé "Organic Microanalyses" de Montréal.

Condensation du méthyl-1 cyclohexène avec le chlorure de propionyle en présence de $SnCl_4$

Le méthyl-1 cyclohexène (18 g), en solution dans 54 ml de CS_2 est condensé avec 15 g de chlorure de propionyle en présence de 49 g de $SnCl_4$ selon le procédé décrit par Turner et Voitle (7). Les résultats de l'analyse par c.p.g. sont rapportés dans le tableau 1. Le mélange cétonique (5

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

g) est ozoné selon le procédé décrit par Dufort et Lafontaine (1). Les composés **1***a* et *d* sont ensuite séparés par c.p.g. préparative. Le composé **1***a* distille à 203° à 755 mm; spectre u.v.: λ_{max} 213 mμ (ε 2960); spectre i.r.: bande carbonyle à 1685 cm^{-1}; spectre r.m.n.: multiplet à 0.96 p.p.m. (6H) méthyle de la chaine et méthyle sur le cycle; pas de proton éthylénique.

Anal. Calc. pour $C_{10}H_{16}O$: C, 78.94; H, 10.53. Trouvé: C, 78.57; H, 10.73.

La semicarbazone cristallisée dans le méthanol fond à 207–208°.

Anal. Calc. pour $C_{11}H_{19}N_3O$: C, 63.15; H, 9.09; N, 20.09. Trouvé: C, 63.14; H, 9.33; N, 20.14.

Le composé **1***d* a un point d'ébullition de 221° à 755 mm; spectre u.v.; λ_{max} 211 mμ (ε 4530); spectre i.r.: bande carbonyle à 1685 cm^{-1}; spectre r.m.n.: multiplet à 0.94 p.p.m. (6H) méthyle de la chaine et méthyle sur le cycle; pas de proton éthylénique.

Anal. Calc. pour $C_{10}H_{16}O$: C, 78.94; H, 10.53. Trouvé: C, 78.79; H, 10.48.

La semicarbazone cristallisée dans le méthanol fond à 203–204°.

Anal. Calc. pour $C_{11}H_{19}N_3O$: C, 63.15; H, 9.09; N, 20.09. Trouvé: C, 63.05; H, 9.03; N, 20.11.

Le mélange cétonique (5 g) est traité par 13 g d'acide oxalique en solution dans 65 ml d'eau comme décrit par Dufort et Lafontaine (1). Le composé **1***b* distille à 213–214° à 750 mm; spectre i.r.: bande carbonyle à 1705 cm^{-1}; spectre r.m.n.: triplet à 0.96 (3H, J = 6 Hz) méthyle de la chaine; singulet émergeant d'un massif à 1.53 (3H) méthyle sur le cycle; multiplet à 5.50 p.p.m. (1H) hydrogène éthylénique.

Anal. Calc. pour $C_{10}H_{16}O$: C, 78.94; H, 10.53. Trouvé: C, 78.84; H, 10.37.

La semicarbazone cristallisée dans le méthanol fond à 174–175°.

Anal. Calc. pour $C_{11}H_{19}N_3O$: C, 63.15; H, 9.09; N, 20.09. Trouvé: C, 62.89; H, 9.20; N, 20.06.

Le composé **1***c* distille à 218–219° à 750 mm; spectre u.v.: λ_{max} 248 mμ (ε 4330); spectre i.r.: bande carbonyle à 1680 cm^{-1}; spectre r.m.n.: triplet à 0.96 (3H, J = 6 Hz) méthyle de la chaine; singulet à 1.75 p.p.m. (3H) méthyle sur la double liaison.

Anal. Calc. pour $C_{10}H_{16}O$: C, 78.94; H, 10.53. Trouvé: C, 78.95; H, 10.45.

La semicarbazone cristallisée dans le méthanol fond à 201–202°.

Anal. Calc. pour $C_{11}H_{19}N_3O$: C, 63.15; H, 9.09; N, 20.09. Trouvé: C, 63.12; H, 9.20; N, 20.36.

Préparation de l'acétal **4**

Le composé **1***b* (30 g) est transformé en acétal comme décrit par Dufort et Lafontaine (1) sauf que le mélange d'alcool et d'acétal obtenu est séparé sur une colonne de "Florisil" au lieu d'alumine. On recueille 21 g du composé **4** qui distille à 122–124° à 17 mm; spectre i.r.: bandes à 1145, 1070, et 1045 cm^{-1}; pas de bande à 1705 cm^{-1}; spectre r.m.n.: triplet à 0.80 (3H, J = 6 Hz) méthyle de la chaine propionyle; singulet émergeant d'un massif à 1.70 (3H) méthyle sur la double liaison, singulet à 3.84 (4H) hydrogènes du groupe acétal, et multiplet à 5.45 p.p.m. (1H) hydrogène sur la double liaison.

Anal. Calc. pour $C_{12}H_{20}O_2$: C, 73.43; H, 10.27. Trouvé: C, 73.56; H, 10.28.

Hydroboration de l'acétal **4**

L'acétal **4** (10 g) est soumis à l'hydroboration selon le procédé décrit par Brown et Subba Rao (2); on recueille 9.4 g de composé **5** qui est directement soumis à l'hydrolyse; spectre i.r.: bandes à 3450, 1145, 1070, et 1045 cm^{-1}.

Hydrolyse de l'acétal **5**

Le composé **5** (5 g), en solution dans 110 ml d'éthanol, est chauffé à reflux durant 2½ h et agité à la température de la pièce durant 16 h. Après extraction et évaporation des solvants, on recueille 2.9 g de cétoalcool **6** qui distille 158° à 0.8 mm; spectre i.r.: bande hydroxyle à 3450 et bande carbonyle à 1710 cm^{-1}.

Tosylation du cétoalcool **6**

Le cétoalcool **6** (2.9 g) est tosylé comme décrit par Dufort et Lafontaine (1). Après évaporation des solvants, on obtient un résidu huileux jaune de 2.7 g qui dissous dans l'éther de pétrole, cristallise lentement. Après quatre cristallisations dans un mélange éther – éther de pétrole, on obtient des cristaux qui fondent à 72–73°; spectre i.r.: bandes à 1710, 1600, 1175, 1100 cm^{-1}; spectre r.m.n.: doublet à 0.66 (3H, J = 6 Hz) méthyle du cycle, triplet à 0.96 (3H, J = 8 Hz) méthyle de la chaine propionyle, singulet à 2.45 (3H) méthyle du toluène, multiplet à 4.15 p.p.m. (1H) hydrogène attaché au carbone qui porte le tosylate.

Anal. Calc. pour $C_{17}H_{24}O_4S$: C, 62.95; H, 7.46; S, 9.86. Trouvé: C, 62.90; H, 7.59; S, 9.93.

Déshydrotosylation du cétotosylate **7**

A une solution formée de 60 mg de NaOH dans 0.3 ml de méthanol sont ajoutés 70 mg de cétotosylate **7**. Après une agitation de 20 h à la température de la pièce et extraction de la façon habituelle et évaporation du solvant, le résidu analysé par c.p.g. sur une colonne de Polyester de Craig 15% et une colonne de QF1 3% indique la présence d'un seul composé. Une injection mixte sur les deux colonnes de ce composé et du composé **1***a* formé à 5% lors de la condensation montre que ces deux composés sont identiques. D'ailleurs les donnés spectrales du produit déshydrotosylé correspondent à celles du composé **1***a* obtenu par la réaction de Friedel–Crafts.

Condensation du méthyl-1 cyclohexène avec le chlorure de butyryle en présence de $SnCl_4$

Le méthyl-1 cyclohexène (24 g), en solution dans 64 ml de CS_2 est condensé avec 36 g de chlorure de butyryle en présence de 67 g de $SnCl_4$ selon le procédé décrit par Turner et Voitle (7). Les résultats de l'analyse par c.p.g. sont rapportés dans le tableau 1. L'ozonolyse de 5 g du mélange cétonique suivie d'une séparation par c.p.g. préparative permet d'isoler les composés **2***a* et *d*. Le composé **2***a* distille à 67–68° à 0.1 mm; spectre i.r.: bande carbonyle à 1685 cm^{-1}; spectre u.v.: λ_{max} 215 mμ (ε 7500); spectre r.m.n.: multiplet à 0.96 p.p.m. (6H) méthyle de la chaine et celui du cycle; pas d'hydrogène éthylénique. Le composé **2***d* distille à 68–69° à 0.1 mm; spectre u.v.: λ_{max} 212 mμ (ε 3500); spectre i.r.: bande carbonyle à 1680 cm^{-1}; spectre r.m.n.: multiplet à 1.00

p.p.m. (6H) méthyle de la chaine et celui du cycle; pas d'hydrogène éthylénique.

Anal. Calc. pour $C_{11}H_{18}O$: C, 79.46; H, 10.91. Trouvé: C, 79.17; H, 10.94.

La semicarbazone cristallisée dans le méthanol fond à 178–179°.

Anal. Calc. pour $C_{12}H_{21}N_3O$: C, 64.54; H, 9.48; N, 18.82. Trouvé: C, 64.55; H, 9.72; N, 19.08.

L'isomérisation de 5 g du mélange cétonique par 13 g d'acide oxalique en solution dans 65 ml d'eau donne 34% de composé **2***b* et 66% de composé **2***c*. Ces deux composés sont séparés par c.p.g. préparative. Le composé **2***b* distille à 52–53° à 0.3 mm; spectre i.r.: bande carbonyle à 1710 cm^{-1}; spectre r.m.n.: triplet à 0.92 (3H, $J = 6$ Hz) méthyle de la chaine butyryle, singulet émergeant d'un massif à 1.58 (3H) méthyle sur la double liaison, multiplet à 5.58 p.p.m. (1H) hydrogène sur la double liaison.

Anal. Calc. pour $C_{11}H_{18}O$: C, 79.46; H, 10.91. Trouvé: C, 79.30; H, 10.91.

La semicarbazone cristallisée dans le méthanol fond à 160°.

Anal. Calc. pour $C_{12}H_{21}N_3O$: C, 64.54; H, 9.48; N, 18.82. Trouvé: C, 64.33; H, 9.21; N, 18.72.

Le composé **2***c* distille à 54–55° à 0.3 mm: spectre i.r.: bande carbonyle à 1685 cm^{-1}; spectre u.v.: λ_{max} 247 mμ (ε 4080); spectre r.m.n.: triplet à 0.93 (3H, $J = 6$ Hz) méthyle de la chaine butyryle, singulet émergeant d'un massif à 1.80 p.p.m. (3H) méthyle sur la double liaison.

Anal. Calc. pour $C_{11}H_{18}O$: C, 79.46; H, 10.91. Trouvé: C, 79.36; H, 10.71.

La semicarbazone cristallisée dans le méthanol fond à 187°.

Anal. Calc. pour $C_{12}H_{21}N_3O$: C, 64.54; H, 9.48; N, 18.82. Trouvé: C, 64.32; H, 9.61; N, 18.99.

Condensation du méthyl-1 cyclohexène avec le chlorure d'acide benzoïque en présence de $SnCl_4$

Le méthyl-1 cyclohexène (18 g) en solution dans 54 ml de CS_2 est condensé avec 26.5 g de chlorure d'acide benzoïque en présence de 49 g de $SnCl_4$ selon le procédé décrit par Turner et Voitle (7). Les résultats de l'analyse par c.p.g. sont rapportés dans le tableau 1. Les produits sont obtenus à l'état pur par c.p.g. préparative. Le composé **3***b* distille à 102–103° à 0.1 mm; spectre i.r.: bande carbonyle à 1680 cm^{-1}; spectre r.m.n.: singulet à 1.62 (3H) méthyle sur la double liaison, massif à 3.90 (1H) hydrogène en α du carbonyle, massif à 5.75 (1H) hydrogène sur la double liaison, multiplets à 7.50 et 8.00 p.p.m. (5H) hydrogènes du noyau aromatique.

Anal. Calc. pour $C_{14}H_{16}O$: C, 83.96; H, 8.05. Trouvé: C, 83.95; H, 8.09.

Le composé **3***c* distille à 102–103° à 0.1 mm; spectre i.r.: bande carbonyle à 1650 cm^{-1}; spectre r.m.n.: singulet à 1.50 (3H) méthyle sur la double liaison, multiplets à 7.50 et 7.86 p.p.m. (5H) hydrogènes du noyau aromatique.

Anal. Calc. pour $C_{14}H_{16}O$: C, 83.96; H, 8.05. Trouvé: C, 83.82; H, 8.01.

Le composé **3***d* distille à 102–104° à 0.2 mm; spectre i.r.: bande carbonyle à 1660 cm^{-1}; spectre u.v.: λ_{max} 241 mμ (ε 10 350); spectre r.m.n.: doublet à 1.20 (3H, $J = 6$ Hz) méthyle sur le cycle, multiplets à 7.46 et 7.65 p.p.m. (5H) hydrogènes du noyau aromatique.

Anal. Calc. pour $C_{14}H_{16}O$: C, 83.96; H, 8.05. Trouvé: C, 84.27; H, 8.22.

La semicarbazone cristallisée dans le méthanol fond à 186°.

Anal. Calc. pour $C_{15}H_{19}N_3O$: C, 70.01; H, 7.44; N, 16.33. Trouvé: C, 69.86; H, 7.23; N, 16.62.

De 28 g de produit brut non déshydrochloré, il cristallise 5 g de composé **8** qui recristallisé dans un mélange éther – éther de pétrole fond à 116–117°; spectre i.r.: bande carbonyle à 1665 et bande hydroxyle à 3450 cm^{-1}; spectre r.m.n.: doublet à 0.85 (3H, $J = 7$ Hz) méthyle du cycle, massif à 3.26 (1H) hydrogène de l'hydroxyle, disparition de ce massif par échange avec D_2O, multiplets à 3.64 et 3.90 (2H) hydrogène carbinolique et hydrogène qui est en α de la cétone, multiplets à 7.60 et 7.95 p.p.m. (5H) hydrogènes sur le noyau aromatique.

Anal. Calc. pour $C_{14}H_{18}O_2$: C, 77.06; H, 8.25. Trouvé: C, 77.16; H, 8.20.

*Oxydation chromique du cétoalcool **8***

Le cétoalcool **8** (0.77 g) est oxydé par le complexe anhydride chromique – pyridine selon la méthode de Poos *et al.* (5). On obtient 0.6 g de composé **10** qui fond à 90° après recristallisation dans un mélange éther – éther de pétrole. Spectre i.r.: bandes carbonyles à 1710 et 1670 cm^{-1}; spectre r.m.n.: doublet à 1.00 (3H, $J = 7$ Hz) méthyle sur le cycle, massif dans la région de 2 (7H) protons cyclohexaniques, multiplet à 4.12 (1H) hydrogène en α du groupe benzoyle, multiplets à 7.50 et 7.90 p.p.m. (5H) hydrogènes sur le noyau aromatique. Le spectre de masse indique un ion moléculaire à *m/e* 216.

*Echange de protons de la dicétone **10** en présence d'eau deutérée*

La dicétone **10** (100 mg) et 5 ml de D_2O sont portés à reflux avec 0.5 g de K_2CO_3 durant 72 h. Après extraction de la manière habituelle et évaporation des solvants, le spectre r.m.n. indique la disparition du multiplet à 4.12 p.p.m. et la diminution du massif dans la région de 2.00 p.p.m. Le doublet à 1.00 p.p.m. est maintenant transformé en singulet.

*Tosylation du cétoalcool **8***

Le cétoalcool **8** (5.1 g) est tosylé selon le procédé expérimental décrit précédemment. Après recristallisation dans un mélange éther – éther de pétrole, on recueille 3.6 g de tosylate **12** qui fond à 100°.

Anal. Calc. pour $C_{20}H_{24}O_4S$: C, 68.29; H, 5.69; S, 8.70. Trouvé: C, 68.11; H, 5.44; S, 8.97.

*Déshydrotosylation du composé **12***

Le cétotosylate **12** (3.5 g) est déshydrotosylé selon le procédé décrit précédemment. On obtient 2 g de produit qui indique à l'analyse par c.p.g. la présence d'un seul composé identifié comme étant l'*endo* benzoyl-1 méthyl-6 bicyclo[3.1.0]hexane (**3***d*). D'ailleurs une injection mixte de ce composé et du composé formé à 48% lors de la condensation, montre qu'ils sont parfaitement identiques.

Condensation du méthyl-1 cyclohexène avec le chlorure d'acide en présence de $AlCl_3$

A un mélange de 0.11 mol de $AlCl_3$ dissous dans 30 ml de CS_2 et de 0.1 mol de méthyl-1 cyclohexène refroidi à 0°, on ajoute lentement 0.1 mol de chlorure d'acide. Après une agitation de 1 h à la température de la pièce, le mélange est extrait de la manière habituelle. Après évaporation des solvants, le résidu est traité par une solution

méthanolique de NaOH à 20% pendant une nuit. Après extraction et évaporation des solvants, le résidu est analysé par c.p.g. et les résultats sont rapportés dans le tableau 1.

Condensation du méthyl-1 cyclohexène avec le chlorure d'acide en présence de $ZnCl_2$

A un mélange de 0.1 mol de $ZnCl_2$ en solution dans 30 ml de CS_2 et de 0.1 mol de méthyl-1 cyclohexène, on ajoute lentement 0.1 mol de chlorure d'acide en maintenant la température du milieu réactionnel à 0°. Après une agitation de 20 h à la température de la pièce, le mélange est extrait de la manière habituelle. Le résidu est traité par une solution méthanolique de NaOH à 20% pendant une nuit. Les résultats de l'analyse par c.p.g. sont rapportés dans le tableau 1.

Condensation du méthyl-1 cyclohexène avec le chlorure d'acide en présence de fluorure de bore

A un mélange de 0.1 mol de méthyl-1 cyclohexène et de 0.1 mol de chlorure d'acide refroidi à 0°, on ajoute lentement 0.12 mol de fluorure de bore éthéré. Après une agitation de 20 h à la température de la pièce, le mélange est extrait de la manière habituelle puis traité par une solution méthanolique de NaOH à 20%. Les résultats de l'analyse par c.p.g. sont rapportés dans le tableau 1.

Condensation du pentaméthyl-1,3,3,5,5 cyclohexène avec le chlorure d'acétyle en présence de chlorure stannique

A un mélange de 5 g du composé **13** et de 3.3 g de chlorure d'acétyle refroidi à 0°, on ajoute lentement 3.9 ml de $SnCl_4$. La solution est agitée pendant 5 min puis extraite de la manière habituelle. Le résidu obtenu est déshydrochloré par une solution méthanolique d'hydroxyde de sodium à 20% puis extrait de la manière habituelle. Le résidu analysé par c.p.g. indique la présence des composés **14** et **15** dans une proportion de 1 à 10. L'ozonolyse de 500 mg du résidu indique à l'analyse par c.p.g. la disparition de ces deux composés: on ne décèle pas la présence de composés cyclopropaniques. Le composé **14** est obtenu à l'état pur par c.p.g. préparative. Il distille à 100–101° à 12 mm (rapporté 92–93° à 11 mm (8)); spectre i.r.: bande carbonyle à 1710 cm^{-1}; spectre r.m.n.: singulet à 0.90 (3H), à 1.02 (3H) et à 1.05 (6H) *gem*-diméthyles sur le cycle; doublet à 1.62 (3H, $J = 2$ Hz) méthyle sur la double liaison; singulet à 2.10 (3H) méthyle en α du carbonyle; multiplet à 5.22 p.p.m. (1H) hydrogène sur la double liaison.

Hydroboration du pentaméthyl-1,3,3,5,5 cyclohexène

Le composé **13** (24 g) en solution dans 44 ml de tétrahydrofuranne est soumis à l'hydroboration selon le procédé décrit précédemment. Il se forme 16 g de *trans* pentaméthyl-2,2,4,4,6 cyclohexanol (**16**) qui distille à 65° à 1.5 mm. Cet alcool cristallise lentement à la température de la pièce et fond à 34°. Spectre i.r.: bande hydroxyle à 3450 cm^{-1}; spectre r.m.n.: multiplet à 0.95 (15H) méthyles sur le cycle, singulet à 2.52 (1H) hydrogène de l'hydroxyle, doublet à 2.74 p.p.m. (1H, $J = 9$ Hz) hydrogène carbinolique. Le spectre de masse indique un ion moléculaire à *m/e* 170.

Oxydation du trans pentaméthyl-2,2,4,4,6 cyclohexanol

L'alcool (5.2 g) est oxydé en suivant le même procédé expérimental que pour l'oxydation de l'alcool **8**. On recueille 5 g de cétone **17** qui distille à 43° à 1.5 mm; spectre i.r.: bande carbonyle à 1710 cm^{-1}; spectre r.m.n.: singulets à 0.90, 0.98, et 1.00 (12H) *gem*-diméthyles sur le cycle; doublet à 1.25 p.p.m. (3H, $J = 2.3$ Hz) méthyle en α du carbonyle; multiplet à 2.70 p.p.m. (1H) hydrogène en α de la cétone.

Anal. Calc. pour $C_{11}H_{20}O$: C, 78.51; H, 11.98. Trouvé: C, 78.54; H, 12.14.

La semicarbazone cristallisée dans le méthanol fond à 191–192°.

Anal. Calc. pour $C_{12}H_{23}N_3O$: C, 63.96; H, 10.29; N, 18.65. Trouvé: C, 64.20; H, 10.34; N, 18.64.

Préparation de l'acétyl-1 pentaméthyl-2,4,4,6,6 cyclohexène

La cétone **17** (2.6 g) est traité par 1.9 g d'acétylure de lithium selon le procédé de Beumel et Harris (6). On obtient un résidu de 2.7 g qui distille à 55–60° à 0.1 mm. Le spectre i.r. présente une bande hydroxyle à 3500 cm^{-1}; 1 g de cet alcool est ensuite chauffé à reflux pendant 2 h avec 16 ml d'acide formique 98%. Après neutralisation de l'acide et extraction de la manière habituelle, on recueille 0.9 g de produit qui distille à 45–47° à 0.07 mm. L'analyse par c.p.g. indique la présence d'un seul pic représentant le composé **15**. Spectre i.r.: bande carbonyle à 1685 cm^{-1}; spectre r.m.n.: singulets vers 1.00 (12H) *gem*-diméthyles sur le cycle, singulet à 1.35 (2H) hydrogènes entre les groupes *gem*-diméthyles, singulet à 1.60 (3H) méthyle sur la double liaison, singulet à 1.75 (2H) hydrogènes allyliques, singulet à 2.20 p.p.m. (3H) méthyle en α du carbonyle.

Anal. Calc. pour $C_{13}H_{22}O$: C, 80.35; H, 11.41. Trouvé: C, 80.47; H, 11.43.

Reactions of 1-Phenyl-1,2,3-triazolyllithium Compounds; Formation of Ketenimines, Alkynylamines, and Heterocycles from the Ambident (*N*-Phenyl)phenylketenimine Anion

R. RAAP

R & L Molecular Research Ltd., 8045 Argyll Road, Edmonton 82, Alberta

Received November 2, 1970

At room temperature 1,4-diphenyl-1,2,3-triazolyllithium rapidly undergoes fragmentation to nitrogen and lithium (*N*-phenyl)phenylketenimine anion **8***c*, $(C_6H_5{\equiv}C{-\!\!-}NC_6H_5)^{\ominus}Li^{\oplus}$. Some of the reactions of this ambident anion have been studied. Reaction of **8***c* with methyl iodide results in *C*-methylation to a mixture of (*N*-phenyl)methylphenylketenimine and 3-methyl-1,3-diphenyl-4-(2′-phenylethylene)-2-phenyliminoazetidine. A six-membered heterocyclic compound, 6-anilino-1,3,5-triphenyluracil, results from the reaction between **8***c* and phenyl isocyanate. With dimethyl sulfate and methyl chloroformate *N*-alkylation and *N*-acylation takes place predominantly, forming *N*-methyl-*N*-phenyl-2-phenylethynylamine and *N*-carbomethoxy-*N*-phenyl-2-phenylethynylamine respectively. Reaction of **8***c* with methanol and ethanethiol gives an iminoester and an iminothioester respectively.

1-Phenyl-1,2,3-triazolyllithium and 4-methyl-1-phenyl-1,2,3-triazolyllithium undergo fragmentation at somewhat higher temperatures.

Le sel de lithium du diphényl-1,4 triazolyl-1,2,3 se fragmente rapidement à la température de la pièce pour donner de l'azote et le sel de lithium de l'anion **8***c*, $(C_6H_5{-}C{\equiv}C{-\!\!-}N{-}C_6H_5)^{\ominus}Li^{\oplus}$. On a étudié quelques unes des réactions de cet anion ambivalent. La réaction de **8***c* avec l'iodure de méthyle conduit à une *C*-méthylation fournissant un mélange de (*N*-phényl) méthylphénylcitinimine et de méthyl-3 diphényl-1,3 (phényléthylène-2)-4 phénylimino-2 azètidine. Un composé hétérocyclique à six chaînons, l'amino-6 triphényl-1,3,5 uracile, se forme par réaction entre **8***c* et l'izocyanate de phényle. Avec le sulfate de méthyle et le chloroformate de méthyle des réactions de *N*-alkylation et de *N*-acylation se produisent de façon prépondérante et conduisent respectivement à la formation du *N*-méthyl *N*-phényl phényl-2 éthynylamine et de *N*-carbométhoxy *N*-phényl phényl-2 éthynylamine et de carbométhoxy *N*-phényl phényl-2 éthynylamine. Les réactions de **8***c* avec le méthanol et l'éthanethiol fournissent respectivement une iminoester et une iminothioester.

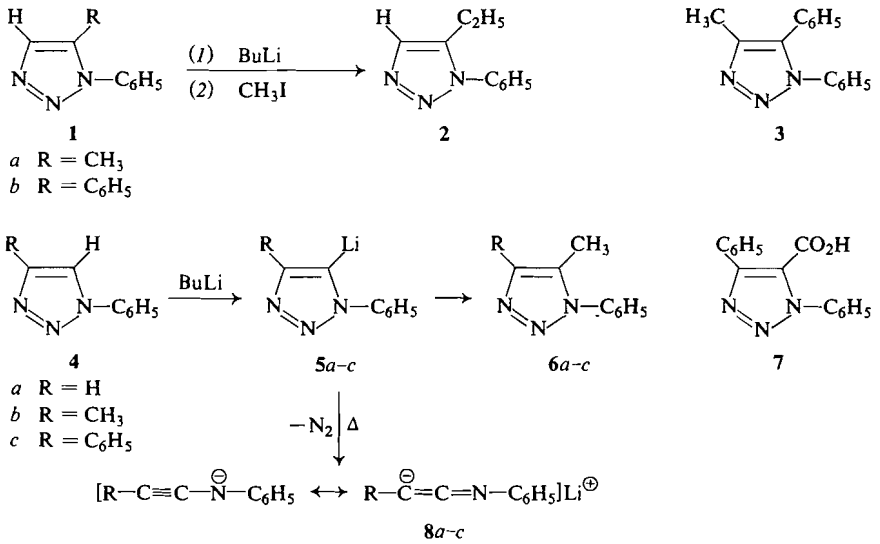
Par ailleurs la fragmentation des sels de lithium des phényl-1 triazolyl-1,2,3 et méthyl-4 phényl-1 triazolyl-1,2,3 s'effectuent à des températures un peu plus hautes.

Canadian Journal of Chemistry, 49, 1792 (1971)

Lithiation of five-membered heteroaromatics has in several instances provided a useful method for the introduction of ring substituents (1). Certain ring systems however undergo fragmentation with elimination of nitrogen under the influence of base, resulting in alkynylthiolates from 1,2,3-thiadiazoles (2, 3), diphenylacetylene from 4,5-diphenyl-1,2,3-thiadiazole (4), carbodiimides from 1,4-disubstituted tetrazolium salts (5), and phenylcyanamide from the reaction between 5-chloro-1-phenyltetrazole and magnesium or *n*-butyllithium (6). In the following we report our results on the lithiation of some 1-phenyl-1,2,3-triazoles. This investigation was of interest not only for the syntheses of substituted 1,2,3-triazoles, but also for the possible interesting products resulting from a fragmentation of the triazole ring.

In tetrahydrofuran (THF) the triazoles **1** and **4** were all readily lithiated with *n*-butyllithium at -20 to $-60°$ (Scheme 1). Ring lithiation takes place preferentially at the 5-position as was indicated by the products **2**, **3**, **6**, and **7** obtained by methylation or carboxylation. Whereas the reaction product of **1***a* with *n*-butyllithium upon reaction with methyl iodide provided **2** as the only isolable product, **4***a* and *b* under these conditions gave high yields of the 5-methyl-1,2,3-triazoles **5***a* and *b*. Solutions of **5***a* and *b* were stable at room temperature but decomposed with gas evolution when heated at 40–50°. A solution of **5***c* readily decomposed at 20° to a yellow to green solution of the ambident *N*-phenylketenimine anion **8***c*, displaying strong absorption at 2140 cm^{-1} in the i.r. The various reactions performed with **8***c* are outlined in Scheme 2.

Reaction of **8***c* with methyl iodide resulted exclusively in *C*-methylation and the formation



1
a R = CH_3
b R = C_6H_5

2 3 4 5*a–c* 6*a–c* 7

a R = H
b R = CH_3

8*a–c*

SCHEME 1

of two products, one being the expected (*N*-phenyl)methylphenylketenimine[1] (**9**). The structure of **9** was indicated by the n.m.r. and i.r. spectra, the latter showing strong absorption at 2000 cm^{-1} in agreement with reported ketenimine absorption (8), and was further proven by conversion to *N*,2-diphenylpropionamide (**10**) with dilute acid and to the imino ester **11** by reaction with methanol in the presence of a catalytic amount of sodium methoxide. The empirical formula $C_{30}H_{26}N_2$ of the second product, a pale yellow solid melting at 114–115°, indicated a dimer of **9**. The n.m.r. spectrum showed the presence of four phenyl groups and two different *C*-methyl groups; the i.r. spectrum contained bands at 1730 and 1655 cm^{-1}. The compound hydrolyzed slowly upon heating in a mixture of THF and 3 *N* hydrochloric acid to aniline and a highly viscous compound, $C_{24}H_{21}NO$. The n.m.r. spectrum of this latter compound showed the presence of three phenyl groups and two *C*-methyl groups; the i.r. spectrum contained strong bands at 1780 and 1680 cm^{-1}, the former band indicating the presence of a β-lactam carbonyl group (9). These observations point to 3-methyl-1,3-diphenyl-4-(2′-phenylethylene)-2-phenyliminoazetidine (**12**) as being the other alkylation product, hydrolysis of which should lead to 3-methyl-1,3-diphenyl-4-(2′-phenylethylene)-2-azetidinone (**13**). The formation of **12** can be explained by attack of **8***c* on the initially formed ketenimine **9** followed by methylation of the intermediate **14** with methyl iodide (Scheme 3). In agreement with this it was found that although the relative amounts of **9** and **12** were little affected by the reaction temperature and the mode of addition of the methyl iodide, it strongly depended on the amount of methyl iodide used. The yields of isolated **9** when a 10, 25, and 100% excess of methyl iodide was employed were 17, 28, and 45% respectively, the yields of isolated **12** being 46, 36, and 19% respectively.

In an attempt to extend the synthesis of azetidine derivatives to compounds derived from the anion **15** (Scheme 3), the reaction between equivalent amounts of **8***c* and phenyl isocyanate was investigated. However no indication for the formation of **15** was obtained and the only product isolated, after treatment of the reaction mixture with water, was 6-anilino-1,3,5-triphenyluracil (**16**; 37%). The structural assignment of **16** is based on the elemental analyses, the n.m.r. and i.r. spectra, and on its hydrolysis to 1,3,5-triphenylbarbituric acid (**17**) in a boiling mixture of 6 *N* hydrochloric acid and acetic acid. Apparently the first addition product of **8***c* to phenyl isocyanate, rather than cyclizing to **15**,

[1]The photochemical decomposition of 1-phenyl-1,2,3-triazoles has been reported and also results in the formation of ketenimines, *e.g.* from **4***c* an 80% yield of diphenylketenimine was obtained (7).

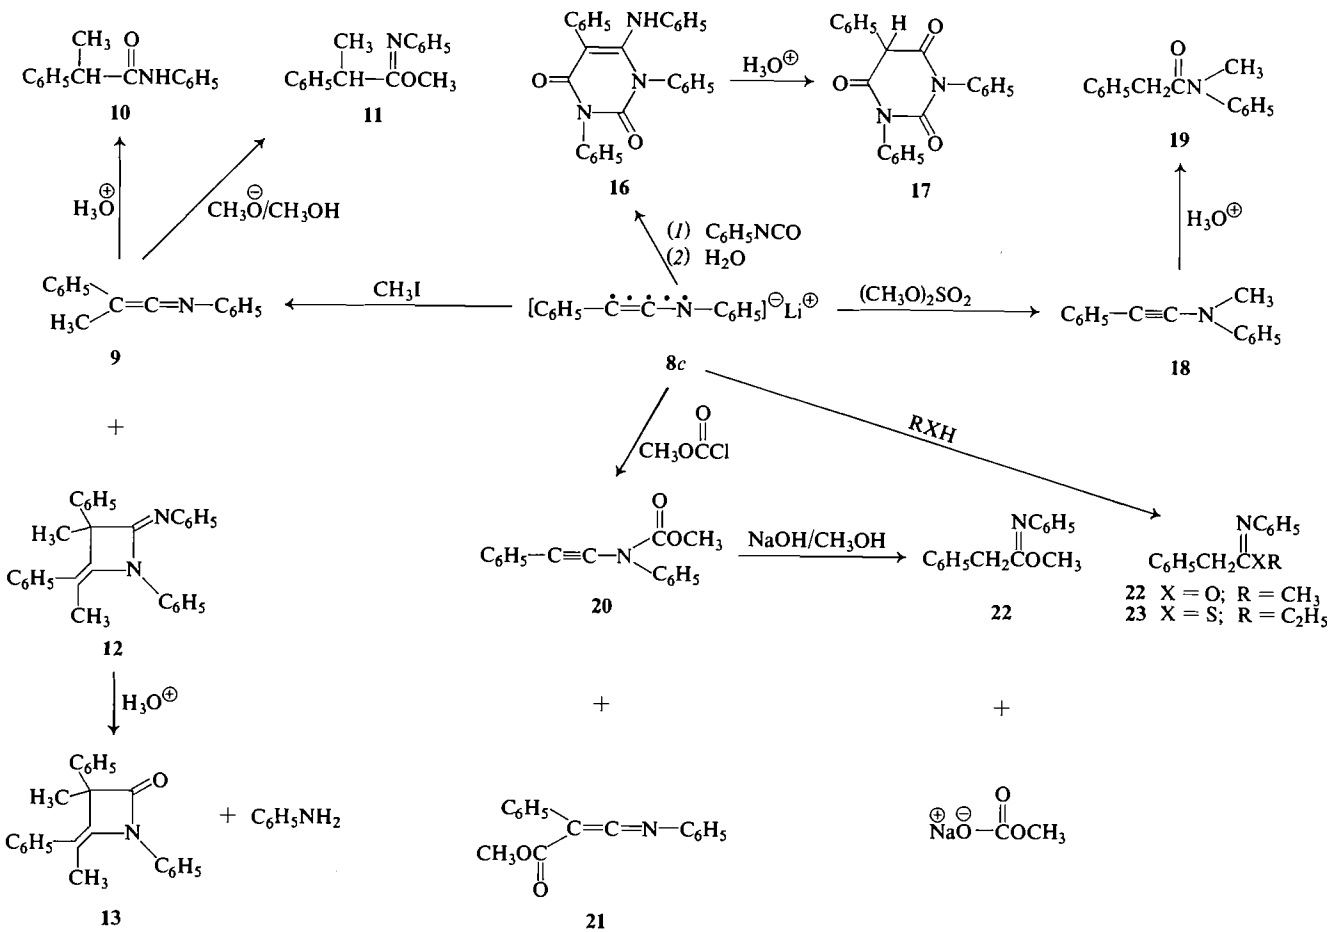
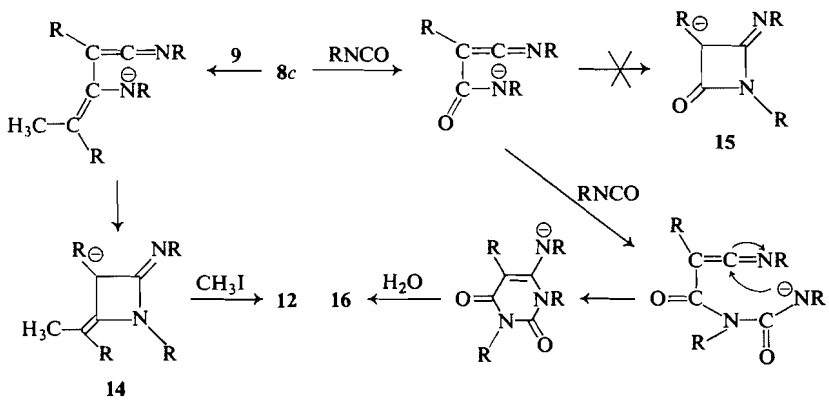


SCHEME 2



(R = C_6H_5)

SCHEME 3

reacts with a second molecule of phenyl isocyanate followed by cyclization to a uracil derivative.

The methylation of **8***c* took a different course with dimethyl sulfate, for *N*-methyl-*N*-phenyl-2-phenylethynylamine (**18**; 42%) was the only product isolated. Only trace amounts of **9** and **12** were detectable in the n.m.r. and i.r. spectra of the crude reaction product. The product showed strong i.r. absorption at 2230 cm^{-1} in agreement with reported absorptions of alkynylamines (10). Compound **18**, m.p. 47–48°, was further characterized by hydrolysis with dilute acid to (*N*-methyl-*N*-phenyl)phenylacetamide (**19**).

Acylation of **8***c* with methyl chloroformate gave *N*-carbomethoxy-*N*-phenyl-2-phenylethynylamine (**20**; 40%) as the main product. The formation of a small amount of the ketenimine **21** was evident from the n.m.r. and i.r. spectra of the crude product, but attempts to isolate this material by chromatography or distillation were unsuccessful. Compound **20** represents a new type of alkynylamine. Whereas **18** undergoes an exothermic reaction with dilute acid, **20** was recovered unchanged from a mixture of THF and 1 *N* sulfuric acid when left at room temperature for 1 h. With methanolic sodium hydroxide **20** underwent a rapid reaction resulting in the formation of sodium methylcarbonate and methyl (*N*-phenyl)phenylacetimidate (**22**), the latter material being identical with that obtained from the reaction between methyl phenylthionacetate and aniline (11).

The iminoester **22** was also obtained when methanol was added to the THF solution of **8***c* (45%). An 80% yield of the iminothioester **23** was obtained from the reaction between **8***c* and ethanethiol, indicating that ethanethiolate is a more efficient reactant for the intermediate ketenimine.

The fragmentation of **5***a* to **8***a* produced a dianion as the alkylation of both **8***a* and *b* with dimethyl sulfate gave the same product, *N*-methyl-*N*-phenyl-1-propynylamine (**24**), in yields of 21 and 31% respectively. The addition of methanol to a solution of **8***a* provided a 47% yield of the iminoester **25** and a 37% recovery of **4***a* (Scheme 4).

Experimental

All melting points and boiling points are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer Model 137 "Infracord" spectrophotometer. The n.m.r. spectra were measured using a Varian Associates Model A-60 spectrometer with tetramethylsilane as a reference. Microanalyses were performed by Dr. F. B. Strauss, Microanalytical Laboratory, Oxford, England.

Substitution Reactions with 1-Phenyl-1,2,3-triazolyllithium Compounds

To a stirred solution (or suspension) of 0.040 mol of either 1-phenyl-1,2,3-triazole (12), 4-methyl-1-phenyl-1,2,3-triazole (13), 5-methyl-1-phenyl-1,2,3-triazole (12), 1,4-diphenyl-1,2,3-triazole (14), or 1,5-diphenyl-1,2,3-triazole (14) in 80 ml of anhydrous THF was added dropwise in 15 min, 26 ml of 1.6 *M* *n*-butyllithium in *n*-hexane at −20 to −60° (depending on the solubility of the triazole) in a nitrogen atmosphere. When the addition was completed the mixture was stirred and cooled for an additional 0.5–1 h whereafter a solution of methyl iodide (8.5 g, 0.060 mol) in 15 ml of THF was added in one portion. The reaction mixtures were worked up by standard procedures. The following compounds were thus prepared:

5-Ethyl-1-phenyl-1,2,3-triazole (2) (42%), m.p. 79–81°; reported m.p. 79–80° (15). The identity was confirmed by the n.m.r. spectrum and the elemental analyses. The n.m.r. spectrum of the crude product indicated that little (if any) 4,5-dimethyl-1-phenyl-1,2,3-triazole was present.

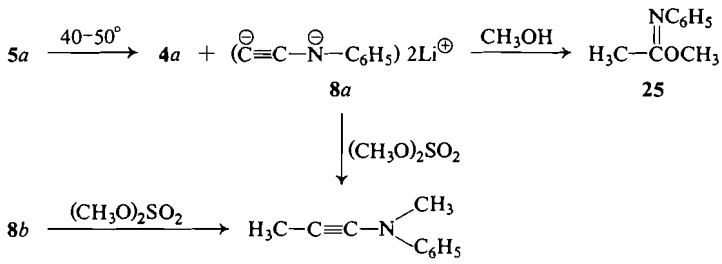

SCHEME 4

1,5-Diphenyl-4-methyl-1,2,3-triazole (3) (99%), m.p. 122–124°; n.m.r. ($CDCl_3$): τ 2.5–3.0 (m, 10H) and 7.58 (s, 3H).

Anal. Calcd. for $C_{15}H_{13}N_3$: C, 76.57; H, 5.57; N, 17.86. Found: C, 76.63; H, 5.70; N, 17.67.

5-Methyl-1-phenyl-1,2,3-triazole (6a) (94%), m.p. 63–65°; reported m.p. 64° (12). The material was identical with an authentic sample.

4,5-Dimethyl-1-phenyl-1,2,3-triazole (6b) (81%), m.p. 87–88°; reported m.p. 98° (16). The structure was confirmed by the n.m.r. spectrum and elemental analyses.

1,4-Diphenyl-5-methyl-1,2,3-triazole (6c) (78%), m.p. 156–159° (C_6H_6 – *n*-C_6H_{14}); n.m.r. ($CDCl_3$): τ 2.1–2.8 (m, 5H), 2.52 (s, 5H) and 7.59 (s, 3H).

Anal. Calcd. for $C_{15}H_{13}N_3$: C, 76.57; H, 5.57; N, 17.86. Found: C, 76.56; H, 5.46; N, 17.72.

1,4-Diphenyl-1,2,3-triazole-5-carboxylic Acid (7)

This compound was prepared in 62% yield by pouring the 1,4-diphenyl-1,2,3-triazolyllithium solution on solid carbon dioxide, followed by acidification of an aqueous solution of the salt; m.p. 169–170° (dec.); reported m.p. 177.5° (17). The structure was confirmed by an elemental analysis.

Lithium (N-Phenyl)phenylketenimine Anion (8c)

To a stirred suspension of 1,4-diphenyl-1,2,3-triazole (8.8 g, 0.040 mol) in 80 ml of anhydrous THF was added dropwise in 10–15 min 26 ml of 1.6 *M* *n*-butyllithium in *n*-hexane at −20 to −40° in a nitrogen atmosphere. The mixture was cooled for an additional 15 min (a white precipitate had formed) and was then allowed to warm up. At approximately 10° gas evolution became noticeable. At room temperature the gas evolution became rapid and was complete within one hour to give a yellow to green solution, the i.r. spectrum of which contained a very intense absorption at 2140 cm^{-1}.

Reaction of 8c with Methyl Iodide

The above prepared solution of **8c** was cooled to −60° and a solution of methyl iodide (11.4 g, 0.080 mol) in 20 ml of THF was added in one portion. After the mixture had reached room temperature the solvent was removed, the residue was dissolved in 75 ml of ether and this solution was washed with two 25 ml portions of water. The ether solution was dried and the solvent removed giving 8.1 g of liquid residue, the n.m.r. spectrum of which indicated that it consisted only of the ketenimine **9** (61%) and the dimer **12** (39%). A solution of the residue in 50 ml of *n*-hexane was cooled to give 1.6 g (19%) of crystalline **12**, m.p. 109–111°. The material could be recrystallized from methanol to pale yellow crystals, m.p. 114–115°; ν_{max} (Nujol) 1730, 1655, and 1590 cm^{-1}; n.m.r. ($CDCl_3$): τ 2.6–3.7 (multiplet, 20H), 8.16 (s, 3H), and 8.31 (s, 3H).

Anal. Calcd. for $C_{30}H_{26}N_2$ (mol. wt. 414.5): C, 86.92; H, 6.32; N, 6.76. Found (409 (Rast)): C, 86.92; H, 6.26; N, 7.18.

The hexane filtrate was concentrated and the residue distilled *in vacuo* to give 3.7 g (45%) of **9** as a yellow liquid, b.p. 128–129° (0.5 mm), which crystallized upon cooling and could be recrystallized from a small amount of methanol to long yellow needles, m.p. 35–37°; ν_{max} (Nujol) 2000 cm^{-1}; n.m.r. ($CDCl_3$): τ 2.6–2.9 (m, 10H) and 7.92 (s, 3H).

Anal. Calcd. for $C_{15}H_{13}N$: C, 86.92; H, 6.32; N, 6.76. Found: C, 86.96; H, 6.45; N, 7.00.

The crude reaction product could also be distilled directly, in which case the dimer **12** could be isolated by recrystallization of the distillation residue from methanol.

N,2-Diphenylpropionamide (10)

A mixture of (*N*-phenyl)methylphenylketenimine (0.35 g, 0.0017 mol), 1 *N* aqueous sulfuric acid (10 ml), and THF (10 ml) was briefly heated at 50°. The product isolated was recrystallized from benzene – *n*-hexane to give 0.31 g (82%) of white crystals, m.p. 135–136°; reported m.p. 133–134° (18). The n.m.r. and i.r. spectra and the elemental analyses were also in agreement with the assigned structure.

Methyl N,2-Diphenylpropionimidate (11)

A mixture of ketenimine **9** (1.24 g, 0.006 mol), sodium methoxide (0.10 g), and methanol (25 ml) was left at room temperature for 1 h, by which time the yellow color had disappeared. From the reaction mixture was isolated 1.3 g (77%) of pale yellow product, b.p. 110–112° (0.1 mm); ν_{max} (neat) 1655 cm^{-1}; n.m.r. (CCl_4): τ 2.87 (s, 5H), 2.5–3.5 (m, 5H), 6.20 (q, 1H), 6.25 (s, 3H), and 8.59 (d, 3H).

Anal. Calcd. for $C_{16}H_{17}NO$: C, 80.32; H, 7.16; N, 5.85. Found: C, 80.18; H, 7.09; N, 6.10.

Hydrolysis of 12

A mixture of **12** (1.0 g), THF (30 ml), and 3 *N* hydrochloric acid (30 ml) was heated under reflux for 5 h. The mixture was cooled and extracted with two 50 ml portions of ether. The aqueous solution was made alkaline and extracted with ether to give 0.25 g of a liquid residue,

the i.r. spectrum of which was superimposable with that of aniline. The ether solution was dried, the solvent removed, and the residue distilled *in vacuo* to give 0.52 g (63%) of a very viscous liquid, distilling at approximately 190° (0.1 mm) with slight decomposition. An analytical sample was obtained by chromatography on silica gel and elution with benzene; ν_{max} (neat) 1780 and 1680 cm^{-1}; n.m.r. ($CDCl_3$): τ 2.3–3.3 (m, 15H), 8.01 (s, 3H), and 8.06 (s, 3H).

Anal. Calcd. for $C_{24}H_{21}NO$ (**13**): C, 84.93; H, 6.24; N, 4.13. Found: C, 84.82; H, 6.43; N, 3.99.

*6-Anilino-1,3,5-triphenyluracil (**16**)*

A solution of phenyl isocyanate (2.4 g, 0.020 mol) in 10 ml of THF was added in one portion to a stirred solution of **8***c* in THF, prepared from 4.4 g (0.020 mol) of 1,4-diphenyl-1,2,3-triazole, at −60°. The cooling bath was removed and when the temperature of the reaction mixture had reached −20°, 20 ml of water was added followed by some ethyl acetate. The organic layer was washed with water, dried, and concentrated. The residue was treated with 40 ml of ether and cooled, resulting in the formation of a white solid precipitate (2.0 g). A small amount of starting material **4***c* could be removed by treating this solid with cold methylene chloride which dissolved **16** but not **4***c*. The product thus obtained amounted to 1.6 g (37%), m.p. 230–234°. The m.p. could be raised to 242–243° by recrystallization from a 1:4 mixture of chloroform and carbon tetrachloride; ν_{max} ($CHCl_3$) 3400, 1700, and 1640 cm^{-1}; n.m.r. ($CDCl_3$): complex phenyl absorption at τ 2.5–3.6 and a singlet at 4.37 with an integrated area ratio of approximately 20:1.

Anal. Calcd. for $C_{28}H_{21}N_3O_2$ (mol. wt. 431.5): C, 77.93; H, 4.91; N, 9.74. Found (432 (osmometric)): C, 77.47; H, 4.96; N, 9.61.

*1,3,5-Triphenylbarbituric Acid (**17**)*

A mixture of **16** (1.0 g, 2.3 mmol), acetic acid (30 ml), and 6 *N* hydrochloric acid (15 ml) was heated under reflux for 1.5 h, then diluted with 15 ml of water and cooled. The solid precipitate was collected by filtration, washed with water, dried, and recrystallized from ethyl acetate – *n*-hexane to give 0.5 g (63%) of fine white needles, m.p. 262–263°; reported m.p. 261–262° (19). The i.r. spectrum (in $CHCl_3$) contained no absorption at 3100–3600 cm^{-1}, but showed a strong carbonyl band at 1690 cm with a shoulder at 1710 cm^{-1}; the n.m.r. spectrum (in DMSO-d_6) contained singlets at τ 2.55 and 4.62 (broad) with an integrated area ratio of approximately 15:1.

Anal. Calcd. for $C_{22}H_{16}N_2O_3$ (mol. wt. 356): C, 74.14; H, 4.53; N, 7.86. Found (380 (Rast)): C, 73.95; H, 4.55; N, 7.96.

*N-Methyl-N-phenyl-2-phenylethynylamine (**18**)*

To the previously described solution of **8***c* (prepared from 0.040 mol of **4***c*) in THF, cooled at −60°, was added in one portion a solution of dimethyl sulfate (5.05 g, 0.040 mol) in 20 ml of THF. The mixture was worked-up as before to give 7.5 g of crude reaction product which upon distillation *in vacuo* provided 3.5 g (42%) of pale yellow liquid, b.p. 134–136° (0.1 mm), which crystallized from *n*-hexane to colorless crystals, m.p. 47–48°; ν_{max} (Nujol) 2230 and 1595 cm^{-1}; n.m.r. ($CDCl_3$): τ 2.5–3.2 (m, 10H) and 6.73 (s, 3H).

Anal. Calcd. for $C_{15}H_{13}N$: C, 86.92; H, 6.32; N, 6.76. Found: C, 86.67; H, 6.46; N, 6.86.

Treatment of a solution of the product in THF with 1 *N* aqueous sulfuric acid resulted in an exothermic reaction to give a quantitative amount of (*N*-methyl-*N*-phenyl)phenylacetamide, identical with an authentic sample prepared from phenylacetyl chloride and *N*-methylaniline.

*N-Carbomethoxy-N-phenyl-2-phenylethynylamine (**20**)*

To a solution of **8***c* in THF, prepared from 4.42 g (0.020 mol) of 1,4-diphenyl-1,2,3-triazole, was added, at −60°, a solution of methyl chloroformate (2.3 g, 0.024 mol) in 10 ml of THF in one portion. After the usual work-up, 5.4 g of crude product was obtained. The i.r. spectrum contained bands at 2250 and 2020 cm^{-1} of approximately equal intensity and a strong band at 1740 cm^{-1} with a shoulder at 1710 cm^{-1}, indicating the presence of both **20** and **21**. The amount of the ketenimine was small as was also indicated by the n.m.r. spectrum. The crude product was extracted with *n*-hexane (5 × 50 ml) to remove some hexane-insoluble resinous material. The residue (3.3 g) obtained by removal of the hexane was chromatographed on silica gel in an attempt to separate **20** and **21**. Although no separation was effected, the material eluted with a 1:4 mixture of ether and benzene contained only a trace of the ketenimine as most of this compound had decomposed on the column. The eluted product (2.8 g) was distilled *in vacuo* to give 2.0 g (40%) of pale yellow viscous liquid, b.p. 150–152° (0.1 mm); ν_{max} (neat) 2250 and 1740 cm^{-1}; n.m.r. (CCl_4): τ 2.3–3.0 (multiplet, 10H) and 6.16 (s, 3H).

Anal. Calcd. for $C_{16}H_{13}NO_2$: C, 76.49; H, 5.21; N, 5.58. Found: C, 76.22; H, 5.38; N, 5.75.

*Methyl (N-Phenyl)phenylacetimidate (**22**)*

*(a) From **8c***

Methanol (10 ml) was added in one portion to a solution of **8***c*, prepared from 2.21 g (0.010 mol) of 1,4-diphenyl-1,2,3-triazole, in THF at −60°. The reaction mixture was worked-up in the usual manner to give 1.0 g (45%) of yellow oil, b.p. 114–115° (0.5 mm), the i.r. spectrum of which was superimposable with that of the product obtained from aniline and methyl phenylthionacetate (11).

*(b) From **20***

Methanolic sodium hydroxide (1.3 ml of 3 *N*) was added to a solution of **20** (0.64 g, 0.0025 mol) in 3 ml of methanol. After 15 min at room temperature the mixture was diluted with ether and cooled. A white solid (0.09 g) precipitated, the i.r. spectrum of which was identical with that of sodium methylcarbonate. The ether solution was washed with water and dried. Removal of the solvent gave 0.53 g (95%) of liquid residue, identical with the material obtained under method *a*. Distillation *in vacuo* gave 0.38 g of colorless liquid, b.p. 110–112° (0.3 mm).

*Ethyl (N-Phenyl)phenylthioacetimidate (**23**)*

A solution of ethanethiol (3.1 g, 0.050 mol) in 10 ml of THF was added in one portion to a solution of **8***c*, prepared from 4.42 g (0.020 mol) of 1,4-diphenyl-1,2,3-triazole, in THF at −60°, followed by the usual work-up. After distillation there was obtained 4.1 g (80%) of yellow oil, b.p. 125–127° (0.05 mm); ν_{max} (neat) 1610 and

1595 cm^{-1}; n.m.r. (CCl_4): τ 2.5–3.5 (multiplet, 10H), 6.38 (s, 2H), 7.06 (q, 2H), and 8.75 (t, 3H).

Anal. Calcd. for $C_{16}H_{17}NS$: C, 75.25; H, 6.71; N, 5.49; S, 12.56. Found: C, 75.47; H, 6.83; N, 5.43; S, 12.28.

Methyl N-Phenylacetimidate (25)

To a stirred solution of 1-phenyl-1,2,3-triazole (4.35 g, 0.030 mol) in 45 ml of THF was added, in 15 min, 19 ml of a 1.6 *M* solution of *n*-butyllithium in *n*-hexane, at −60° in a nitrogen atmosphere. The reaction mixture was heated at 40–45° for 30 min when the gas evolution was complete. The darkly colored mixture was cooled to −60° and 10 ml of methanol was added. After work-up there was obtained 4.0 g of crude product, from which 1.6 g (37%) of starting material, m.p. 55–56°, was recovered by the addition of *n*-hexane. The remaining material was distilled *in vacuo* to give 1.3 g (47%, based on unrecovered starting material) of product, b.p. 64–65° (3 mm); reported b.p. 81–82° (12 mm) (20). The n.m.r. and i.r. spectra and the elemental analyses were in agreement with the assigned structure.

N-Methyl-N-phenyl-1-propynylamine (24)

A solution of **5***b*, prepared from 4-methyl-1-phenyl-1,2,3-triazole (3.20 g, 0.020 mol) in the usual manner, in THF was heated at 40–50° for 2 h in a nitrogen atmosphere. The darkly colored solution was cooled to −60° and a solution of dimethyl sulfate (2.52 g, 0.020 mol) in 10 ml of THF was added in one portion. From the reaction mixture was isolated 0.9 g (31%) of product, b.p. 60–62° (0.2 mm); ν_{max} (neat) 2250 and 1595 cm^{-1}; n.m.r. ($CDCl_3$): τ 2.5–3.3 (m, 5H), 6.83 (s, 3H), and 8.00 (s, 3H). Reported b.p. 96° (6 mm) (21). The material was readily hydrolyzed with dilute acid to *N*-methyl-*N*-phenylpropionamide, m.p. 57–58°; reported m.p. 58° (21).

Compound **24** was also obtained, in 21% yield, when the reaction was repeated with 1-phenyl-1,2,3-triazole.

The author thanks Professor R. U. Lemieux for his interest and encouragement, Dr. R. G. Micetich for many enlightening discussions, and Mr. P. K. Wolfert for his capable technical assistance.

Proton Magnetic Resonance of the Methyl Derivatives of 2-Fluoropyridine. Sigma and Pi Electron Contributions to Spin–Spin Coupling Constants

J. B. ROWBOTHAM, R. WASYLISHEN AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received January 26, 1971

The p.m.r. spectra of the methyl derivatives of 2-fluoropyridine are analyzed. The signs and magnitudes of the long-range spin–spin coupling constants between the methyl protons and the ring protons and between the methyl protons and fluorine are consistent with a model in which the nitrogen atom polarizes the sigma electron system but leaves the pi electron contribution to the coupling constants relatively unchanged. There are dramatic changes in the ring proton – fluorine couplings while the couplings involving the methyl protons vary little from those in the corresponding toluene derivatives. Thus the coupling over six bonds between fluorine and methyl protons is 1.25 ± 0.03 Hz in 2-fluoro-5-methyl pyridine compared to 1.15 ± 0.02 Hz in *p*-fluorotoluene.

On a analysé les spectres r.m.n. des fluoro-2 pyridines méthylées. Les signes et les valeurs des constantes de couplage à longue distance entre les protons des groupes méthyles et d'une part ceux du noyau et d'autre part les atomes de fluor sont en accord avec un modèle dans lequel on fait l'hypothèse que l'azote polarise le système électronique sigma tout en laissant la contribution des électrons pi aux constantes de couplage relativement intacte. On note des changements dramatiques dans les couplages entre les protons du cycle et le fluor; toutefois les couplages impliquant les protons des groupes méthyles ne varient pratiquement pas par rapport à ce qui est observé dans les toluènes correspondants. Par exemple le couplage reparti sur six liaisons entre le fluor et les protons du groupe méthyle est de 1.25 ± 0.03 Hz dans la fluoro-2 méthyl-5 pyridine alors qu'une valeur de 1.15 ± 0.02 Hz est observée dans le *p*-fluorotoluène.

Canadian Journal of Chemistry, 49, 1799 (1971)

Introduction

The full analysis of the p.m.r. spectrum of 2-fluoro-3-methylpyridine (**1**) has been described (1). The signs and magnitudes of the long-range spin–spin coupling constants, $J_{o,m,p}^{H,CH_3}$ and J_o^{F,CH_3}, between methyl protons and the ring protons or fluorine in **1** are consistent with the assumption (2, 3) that the nitrogen atom primarily polarizes the nearby σ bonds in the molecule, leaving the π electron contribution to the coupling constants relatively unaffected. Because it is a coupling over four bonds only, J_o^{F,CH_3} may contain a sizeable σ electron contribution (4), *i.e.*, $J_o^{F,CH_3} = 1.4_5$ Hz in **1** but is nearer 2 Hz in *o*-fluorotoluene (5) and its derivatives (6). In this paper the spectral parameters of the isomers of **1**, *viz.*, **2**, **3**, and **4**, are reported and discussed in spirit of the σ–π model. A knowledge of the contents of ref. 1 is assumed throughout.

Experimental

(1) Preparation of 2, 3, and 4

These compounds were prepared from the amines by the Schiemann reaction (7, 8) via the diazonium fluoroborates. Colorless **2**, 2.6 g, was collected under vacuum between 30–32 °C. Compound **3**, 22.6 g, was collected as a pale yellow liquid, b.p. 153 °C; lit. 155–156 °C at 752 mm (7). Compound **4**, 0.6 g, was obtained on distillation from the CCl_4 extract and probably contained some CCl_4. All compounds gave p.m.r. spectra consistent with their structure and with no detectable proton-containing impurities in the spectral region of interest.

4

(2) Proton Resonance Measurements

Solutions of **2**, **3**, and **4** (20 mol %) in CS_2 containing trace amounts of trifluoroacetic acid (TFA) and internal tetramethylsilane (TMS) as locking material, were degassed. As described for **1** (1) the amount of TFA was sufficient to cause rapid relaxation of ^{14}N, leading to sharp peaks for proton 6, but insufficient to cause changes in the spectral parameters. However, addition of even

very small amounts of TFA to the solution of **2** in CS_2 caused a separation into two layers. The final spectra of **2** were, therefore, taken on solutions containing no TFA, leading to relative large uncertainties in the peak positions of H-6. Addition of as much as 8 mol % of TFA to a more dilute solution of **3** caused significant changes in $J_o^{H,F}$ and $J_m^{H,F}$. An 18 mol % solution of **3** in benzene-d_6 yielded coupling parameters insignificantly different from those in CS_2 solution. In particular, the long-range coupling constants all lay within 0.02 Hz of their values in CS_2 solution.

The proton spectra were recorded at a sweep width of 50 Hz at sweep speeds of 2500 or 5000 s on a DA60I spectrometer. Calibrations were done by reading sweep and manual oscillator frequencies at 5 Hz intervals or less. Double and triple resonance experiments were carried out to find the relative signs of the coupling constants, as described for **1** (1).

Results and Discussion

(1) Spectral Analyses

The analytical techniques followed those for **1** (1), except that the computer program LAOCN 3 (9) was used to optimize the parameters. Therefore, the spectra obtained in the single ($ABCX_3R$) and in the multiple resonance experiments are not reproduced here. Their quality is not inferior to those displayed for **1** (1). Note, however, that the necessary absence of TFA in the sample of **2** led to broad peaks for H-6 resulting in larger errors in some of the parameters involving this proton.

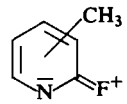
The final parameters in CS_2 solution are given in Table 1. As many as 177 peaks per compound were assigned in iterating to these numbers. The r.m.s. errors in the fits varied between 0.009 and 0.033 (for **2**). The probable errors in the parameters ranged from 0.002 to 0.009 Hz and the worst assignment was 0.095 Hz (for some of the broad peaks in **2**). Calcomp plots of the spectra using the parameters in Table 1 agreed very well with the experimental spectra, in particular with the methyl proton resonances in a manner demonstrated for *p*-fluorotoluene (10*a*).

In a separate experiment on **4**, a recalibration of the spectrum at 0.01 Hz/s and its analysis using the program LAME (10*a*) gave the results listed in the last column of Table 1. In this analysis the r.m.s. error was 0.0088, the maximum standard deviation in the parameters was 0.005 Hz (otherwise between 0.001 and 0.003 Hz), and in the correlation matrix of dimension 14, there were two elements with a magnitude above 0.2 and none with a magnitude greater than 0.3. Over 250 transitions were assigned and the biggest deviation between observed and calculated transitions was 0.033 Hz (normally below 0.02 Hz).

(2) The Methyl Proton–Ring Proton Coupling Constants

To within experimental error, J_p^{H,CH_3} in **1** and **4** is the same as in toluene (11). By the methyl group replacement technique (12, 13), Macdonald and Reynolds (4) have shown that J_p^{H,CH_3} in toluene derivatives arises from a π electron mechanism. Consequently the nitrogen atom does not significantly alter the π electron contribution to this coupling constant or to J_p^{HF} in **1** and **4**.

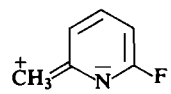
In ref. 1 evidence is adduced that the J_o^{H,CH_3} value of -0.85 Hz in **1** is consistent with a contribution from the resonance structure **5**. This



5

structure increases the mobile bond order between C-3 and -4 and between C-5 and -6 relative to that between C-4 and -5. Because the negative π electron contribution to J_o^{H,CH_3} is expected to increase as the bond order of the intervening C···C bond increases (14), structure **5** implies a larger magnitude of $J_o^{H_3,CH_3}$ in **2** and of $J_o^{H_5,CH_3}$ in **3** than of $J_o^{H_5,CH_3}$ in **2** and of $J_o^{H_4,CH_3}$ in **3**. Indeed, the former are larger in magnitude than the latter by up to 0.2 Hz (see Table 1).

However, $J_o^{H_5,CH_3} = -0.58$ Hz in **4**, rather smaller than predicted by structure **5**. There are two possible reasons. The first invokes structure **6**,



6

supported by ^{14}N quadrupole resonance studies (15), which decreases the mobile bond order[1] between C-5 and -6. The second possible reason lies in an indicated negative σ electron contribution (4) to J_o^{H,CH_3}, suggesting a decrease in the

[1]A referee points out that the larger and unequal values of J_o^{H,CH_3} in **2** can be taken as evidence against a resonance form for **2** analogous to **6**. He points out that in this connection the methyl derivatives of 3- and 4-fluoropyridine should be examined. We have synthesized a number of these compounds and are studying their proton resonance spectra.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

magnitude of this contribution in **4** and caused by polarization of the σ core by the nitrogen atom. Qualitatively, it is simply that the electronegative nitrogen atom reduces the σ electron density near the bonded C-6 atom thereby reducing the σ contribution to J_o^{H,CH_3} in **4**.

Because there is very likely a positive σ contribution to J_m^{H,CH_3} (perhaps as large as 0.2 Hz (1, 4)), the second reason above implies a decrease in this contribution to J_m^{H,CH_3} in both **4** and **2** because C-6 is involved in the coupling path. In fact, J_m^{H,CH_3} is 0.1 Hz smaller in **4** and **2** than in **1** and **3**. In the latter two compounds J_m^{H,CH_3} has the same magnitude as in toluene (11). Other workers (2) have noted that polarization of the σ core in pyridine does not appreciably extend beyond the ortho carbon atoms.

(3) The Methyl Proton – Fluorine Coupling

In **3**, $J_p^{F,CH_3} = 1.25$ Hz, only 0.10 Hz larger than in *p*-fluorotoluene (10*a*). Since it is unlikely that other than a π mechanism is important for this coupling in the latter, the present result strongly suggests that the heteroatom does not appreciably affect the π contribution to J_p^{F,CH_3} in **3**. A similar, less strong, conclusion was reached for J_o^{F,CH_3} in **1** (1).

In 4-amino-5-bromo-3-fluorotoluene $J_m^{F,CH_3} = -0.4_3$ Hz (6), little different in magnitude from the value originally estimated for this coupling in *m*-fluorotoluene (5). The values of J_m^{F,CH_3} in **2** and **4** suggest that, again, the presence of the heteroatom has little effect on the π contribution to this coupling. By the methyl group replacement criterion, the effect of the nitrogen atom on J_m^{F,H_6} occurs predominantly through the σ electron system. For, $J_m^{H,F} = 5.6$ Hz in fluorobenzene (16) but is −1 Hz in **1**; yet J_m^{F,CH_3} remains constant to within 0.2 or 0.3 Hz even when a nitrogen atom replaces the carbon atom in the "coupling path".

(4) The Ring Proton and Ring Proton – Fluorine Couplings

The magnitudes of all these couplings are consistent with an alternating electronegativity effect of the substituents (2, 17) as discussed for **1** (1) and for *p*-fluorotoluene (10*a*); an effect acting primarily through the σ electron system, as suggested originally by Castellano and Kostelnik (2), and now also supported by the couplings with methyl protons reported here.

The additivity of substituent effects on coupling constants between protons in benzene derivatives (1, 18, 19) can be extended to the present pyridine derivatives. Using the coupling constants reported for pyridine dissolved in CCl_4 (20), for benzene (18, 21), fluorobenzene (16), and toluene (11), the predicted and observed values for **1**, **2**, and **3** agree to at least 0.2 Hz for $J_o^{H,H}$ and $J_m^{H,H}$ and to better than 0.1 Hz for $J_p^{H,H}$. In other words, the substituent effects of CH_3 and F on benzene are substantially the same as in pyridine in this regard. The deviations of the predicted from the calculated values are generally in the direction expected if the substituent effects of F (22) and CH_3 are somewhat less than in the monosubstituted benzenes themselves, *i.e.*, as if a saturation effect were occurring; as already noted for trisubstituted benzenes (23). These deviations become as large as 0.4 Hz for $J_o^{H,H}$ in **4** where both substituents are attempting to polarize the σ core at C-2 and -6 when it is already markedly polarized by the heteroatom, in agreement with the idea of a saturation effect.

In **3**, partial protonation of the nitrogen atom by addition of TFA (see Experimental) causes an algebraic increase of 1 Hz in $J_o^{H,F}$, an increase of 0.2 Hz in $J_m^{H_6,F}$, and a decrease of 0.2 Hz in $J_m^{H_4,F}$ of the values in Table 1. These changes are in order if the proton acts as an electronegative substituent polarizing the σ system (2). On this basis the long-range couplings involving methyl protons, particularly J_p^{F,CH_3}, should remain unchanged, as observed experimentally.

Conclusions

A model in which σ and π electron contributions to ring proton and ring proton – fluorine spin–spin coupling constants are distinguished can be extended to pyridine derivatives. In this model the nitrogen atom polarizes the σ electron system but does not strongly alter the π electron contribution to the coupling constants. The most dramatic effects are observed for $J_{o,m,p}^{H,F}$. Thus in fluorobenzene $J_o^{H,F} = 8.9$, $J_m^{H,F} = 5.6$, $J_p^{H,F} = 0.2$ Hz (16). In 2-fluoropyridine $J_o^{H,F} = -2.8$, $J_m^{H_6,F} = -1.0$, and $J_p^{H,F} = 2$ Hz (24). Yet $J_{o,m,p}^{F,CH_3}$ in **1**, **2**, **3**, and **4** are almost the same as in the fluorotoluenes and are a measure of the π electron contributions to the corresponding ring proton and ring proton – fluorine couplings.

This work was supported by the National Research Council of Canada. We are grateful to Mr. L. Olynyk for the synthesis of 2-fluoro-5-methylpyridine.

A Glucan from *Tremella mesenterica* NRRL-Y6158[1]

C. G. FRASER[2] AND H. J. JENNINGS
Biochemistry Laboratory, National Research Council of Canada, Ottawa 7, Canada

Received July 30, 1970[3]

A dextrorotatory glucan has been isolated in good yields from the culture medium of *Tremella mesenterica* NRRL-Y6158. The glucan consumed 1.32 mol of periodate and released 0.33 mol of formic acid per mol anhydroglucose and reduction and hydrolysis of the periodate-oxidized glucan yielded glycerol and erythritol in the ratio 1.0:1.9. Partial hydrolysis of the glucan released maltose, isomaltose, panose, isomaltotriose and *O*-α-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 6)-D-glucose. The fully methylated glucan was composed of 2,3,4,6-tetra-*O*-methyl glucose (0.5%), 2,3,4-tri-*O*-methyl glucose (31.4%), and 2,3,6-tri-*O*-methyl glucose (67.6%).

These results indicate that the glucan was a linear molecule composed of approximately 200 α-D-glucopyranose units linked 1 → 6 and 1 → 4 in the ratio 2:1. Structurally the glucan resembles to varying extents the neutral glucans obtained from the yeast-like fungi of the *Pullularia* species.

L'extraction d'un milieu de culture de *Tremella mesenterica* NRRL-Y6158 a permis d'isoler avec de bons rendements, un glucan dextrorotatoire. Le composé réagit avec 1.32 mol de périodate et fournit 0.33 mol d'acide formique par mole d'anhydroglucose; la réduction et l'hydrolyse du glucan oxydé au périodate conduit à la formation de glycérol et d'érythritol dans le rapport de 1.0 à 1.9. L'hydrolyse partielle du glucan fournit du maltose, de l'isomaltose, du panose, de l'isomaltotriose, et du *O*-α-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 6)-D-glucose. Le glucan méthylé complètement est composé de tétra-*O*-méthyl-2,3,4,6 glucose (0.5%), de tri-*O*-méthyl-2,3,4 glucose (31.4%), et de tri-*O*-méthyl-2,3,6 glucose (67.6%).

Ces résultats indiquent que le glucan est une molécule linéaire composée d'environ 200 unités d'α-D-glucopyranose liées 1 → 6 et 1 → 4 dans un rapport de 2 à 1. Au point de vue structural, ce glucan ressemble aux glucans neutres obtenus à partir de champignons ressemblant à des levures de l'espèce *Pullularia*.

Canadian Journal of Chemistry, 49, 1804 (1971)

In our structural studies on the extracellular polysaccharides of *Tremella mesenterica* NRRL-Y6158 (1), it was found in one preliminary growth experiment that a glucan and not an acidic xylomannan was the predominant polysaccharide in the culture medium. This preponderance of the glucan was probably a direct result of the prolongation of the growth period (to 17 days) which we attempted in an effort to increase the very poor yields of the acidic xylomannan that were obtained with shorter growth periods (7–9 days). Prolongation of the growth period produced the glucan in very high yield, although traces of the acidic xylomannan were still detectable by the presence of xylose, mannose, and glucuronic acid in the hydrolysate of the crude glucan. The yeast *Cryptococcus laurentii* also produces a glucan in addition to an acidic xylomannan (2), and in view of the possible phylogenetic relationship between these two species (3, 4), a structural study of this glucan from *T. mesenterica* was undertaken.

T. mesenterica was grown for 17 days in a glucose medium and following removal of the suspended cells the polysaccharide was obtained by ethanol precipitation of the concentrated supernatant. This polysaccharide was separated into two fractions by precipitation of the acidic xylomannan with 5% cetyltrimethylammonium bromide (5). The material not precipitated by the detergent was isolated by filtration and ethanol precipitation and the product, after washing, contained no ash, and no acetyl or methoxyl groups. This polysaccharide gave glucose only on hydrolysis, gave a single symmetrical peak on moving boundary electrophoresis, and sedimented as a single component on ultracentrifugal analysis.

The presence of α-D-glucoside linkages was shown by the change in the specific rotation of the glucan (+185°) to +51° on hydrolysis, and by an absorption at 845 cm^{-1} in the i.r. (6). The glucan gave no coloration with iodine, and was unattacked by α-, and β-amylases, and consisted

For personal use only.

of about 200 glucopyranose units. This was determined by the estimation of the percentage of end-group (2,3,4,6-tetra-*O*-methyl glucose) released in the methanolysis of the methylated glucan and therefore must be regarded as a minimum value.

The glucan consumed 1.32 mol of periodate with production of 0.33 mol of formic acid per mol anhydroglucose and the periodate-oxidized glucan, after reduction and hydrolysis, yielded glycerol and erythritol; the ratio of glycerol to erythritol was estimated to be 1.0:1.9 by g.l.c. of the derived acetates.

These results attest to the presence of $1 \rightarrow 6$- and $1 \rightarrow 4$-α-D-glucopyranose linkages in the ratio of 1:1.9, and this result was in fairly good agreement with the results obtained from methylation studies. The permethylated glucan which was obtained in good yield was methanolyzed and the components, methyl 2,3,4,6-tetra-*O*-methyl glucoside (0.5%), 2,3,4-tri-*O*-methyl glucoside (31.4%), and 2,3,6-tri-*O*-methyl glucoside (67.6%) were identified by comparison with authentic samples and the quantitative data were obtained by estimation of the areas under the peaks. The ratio of $1 \rightarrow 6$- to $1 \rightarrow 4$-α-D-glucopyranose linkages in this case was calculated as 1:2.1. This value did not change when the duration of methanolysis was both shortened and lengthened indicating that complete methanolysis had been achieved and that no preferential degradation of one of the components had occurred. One unidentified component (0.5%), which may be 1,6-anhydro-2,3,4-tri-*O*-methyl glucose, a known artefact from this type of system (7), was present. The methylated glucan was hydrolyzed and examined by chromatography and the 2,3,4,6-tetra-, 2,3,4-tri-, and 2,3,6-tri-*O*-methyl derivatives of glucose were identified by comparison with authentic samples.

Partial hydrolysis of the glucan with oxalic acid gave a mixture of disaccharides and trisaccharides which were chromatographically indistinguishable from maltose, isomaltose, panose, isomaltotriose, and *O*-α-D-glucopyranosyl-$(1 \rightarrow 4)$-*O*-α-D-glucopyranosyl-$(1 \rightarrow 6)$-D-glucose.

The above evidence indicates that the extracellular glucan from *T. mesenterica* is essentially a linear glucan consisting of approximately 200 α-D-glucopyranose units linked $1 \rightarrow 4$ and $1 \rightarrow 6$ in the ratio of about 2:1. In these respects the glucan closely resembles the one obtained from *Pullularia fermentans* (8) and also exhibits structural similarities to the extracellular glucans (pullulans) obtained from different growths of the yeast-like fungus *Pullularia* pullulans (9–15). Although the $1 \rightarrow 4$- and $1 \rightarrow 6$-α-D-glucopyranose linkages are the main structural features of all these glucans (pullulans) nevertheless they do exhibit variations in overall structure. Wallenfels and coworkers isolated a linear glucan composed of 300 α-D-glucopyranose units linked $1 \rightarrow 4$ and $1 \rightarrow 6$ in the ratio 3:2 (9, 10). Bouveng *et al.* reported a linear glucan having 250 α-D-glucopyranose units linked $1 \rightarrow 4$ and $1 \rightarrow 6$ in the ratio 2:1; however, they did suggest the presence of a small amount of $1 \rightarrow 3$ linkages (1–2%) as a small amount of glucose remained after periodate oxidation of the glucan (11). Unequivocal evidence for the presence of $1 \rightarrow 3$ linkages (6%) in a pullulan was obtained by Sowa *et al.* and they obtained a ratio of $1 \rightarrow 4$ to $1 \rightarrow 6$ linkages of 2.2:1 (14). The ratio of $1 \rightarrow 4$ to $1 \rightarrow 6$ linkages in the latter two preparations of pullulan are very similar to that obtained in the glucan from *T. mesenterica* except that no evidence for $1 \rightarrow 3$ linkages in the glucan from *T. mesenterica* could be found. This appears to be the first reported isolation and study of a glucan with $1 \rightarrow 4$ and $1 \rightarrow 6$ glucosidic linkages from a yeast other than those from the *Pullularia* species, although there is some preliminary evidence to suggest that the glucan from *C. laurentii* may also contain these linkages (2). One major structural difference between the extracellular glucans of *T. mesenterica* and *C. laurentii* is that there is definite evidence for the presence of $1 \rightarrow 3$ linkages in the latter (2, 16), whereas none were detected in the former.

Experimental

Paper chromatography was performed on Whatman No. 1 paper, and t.l.c. on Silica Gel G (Merck, Darmstadt) layers. The irrigants used (v/v) were (*A*) ethyl acetate : pyridine : water, 72:20:23; (*B*) ethyl acetate : acetic acid : formic acid : water, 18:3:1:4; (*C*) benzene : ethanol : water : acetic acid, 200:47:15:1; (*D*) chloroform : methanol, 92:8; (*E*) ethyl acetate : pyridine : water, 8:2:1; (*F*) butan-2-one : water, 10:1; (*G*) butan-1-ol : ethanol : water, 4:1:5; (*H*) butan-1-ol : pyridine : 0.1 *N* hydrochloric acid, 5:3:2; (*I*) butan-1-ol : pyridine : benzene : water, 5:3:1:3. Sugars were detected on chromatograms by *p*-anisidine hydrochloride (17), alkaline silver nitrate (18), or by ethanolic sulfuric acid. A Tiselius-type Spinco model H apparatus was used for moving boundary electrophoresis in 0.05 *M* borate buffer. A Beckman

model E analytical ultracentrifuge was used for sedimentation analysis of 0.3% polysaccharide solutions. An F and M model 500 chromatograph was used for g.l.c. Evaporations were carried out under reduced pressure below 40°. Specific rotations are equilibrium values and were measured on a Perkin–Elmer 141 polarimeter.

Preparation of the Crude Glucan

T. mesenterica NRRL-Y6158, kindly provided by the United States Department of Agriculture, Peoria, Illinois, was grown with aeration in a 12 l baffled flask in an identical glucose medium (8 l) to that previously described for the growth of *C. laurentii* (2). The culture was continuously shaken on a rotary shaker, and was maintained at 25°. A starter culture was prepared by inoculation of the same medium (2 × 250 ml) from a slant of the organism; growth was allowed to occur for 4 days in continuously swirled Erlenmeyer flasks before transfer to the aerated medium was effected. Growth was allowed to continue for a further 17 days during which time the medium became viscous and then began to lose its viscous nature toward the end of the growth period. The culture was then centrifuged on a Sharples ultracentrifuge to remove suspended yeast cells. The supernatant was dialyzed against tap-water for 5 days, and was then concentrated to a viscous solution. The solution was poured into ethanol (5 vol) with stirring, and the fibrous white precipitate recovered, washed successively with ethanol, acetone, and ether, and air-dried to yield 80 g of the polysaccharide (a yield of 27% based on the initial glucose).

A sample of the polysaccharide was hydrolyzed with sulfuric acid in a sealed tube at 100° for 7 h. Chromatographic examination (irrigants *B* and *G*) of the neutralized (barium carbonate) hydrolyzate showed that glucose was the major component together with traces of mannose, xylose, and glucuronic acid.

Isolation of the Glucan

A sample (75 g) of the crude glucan was dispersed in water (1 l), the solution clarified by centrifugation, and 5% cetyltrimethylammonium bromide added until no further precipitation occurred. The mixture was filtered through celite, and the filtrate concentrated to 1 l and poured into ethanol (10 l). The precipitate was washed with ethanol (7 l), dissolved in water (1 l), filtered through celite, and the filtrate poured into ethanol (6 l). The precipitate was dissolved in water (1 l) and freeze-dried to yield 42.5 g of polysaccharide, hereafter referred to as the glucan.

Properties of the Glucan

The glucan gave a single symmetrical peak on moving boundary electrophoresis, and sedimented as a single component on ultracentrifugal analysis. The glucan had $[\alpha]_D^{26}$ +185° (*c*, 0.42 in water) which after hydrolysis (8 h, 100°) changed to $[\alpha]_D^{26}$ +51.4° (*c*, 0.67 in *N* sulfuric acid). Chromatographic examination (irrigants *A*, *B*, *E*, *F*, and *G*) of the neutralized (barium carbonate) hydrolyzate showed glucose alone. The glucan gave no coloration with iodine, and was unattacked by α- or β-amylases. The i.r. spectrum (KBr disc) showed an absorption at 845 cm^{-1}.

Periodate Oxidation

Preliminary experiments showed that the glucan consumed 1.32 mol of periodate and released 0.33 mol of formic acid per mol anhydroglucose.

A sample (1.6 g) of the glucan was dissolved in water (20 ml), 0.05 *M* sodium metaperiodate (500 ml) added, and the solution kept at 4° in the dark for 19 days. Excess periodate was destroyed by the addition of ethylene glycol (10 ml), the solution dialyzed, and sodium borohydride (5 g) added. After 24 h excess borohydride was destroyed by addition of glacial acetic acid, the solution dialyzed, and the resultant polyalcohol (1.2 g) isolated by freeze-drying. A sample (140 mg) of the polyalcohol was hydrolyzed by *N* sulfuric acid at 100° for 12 h. Paper chromatography (irrigant *A*) of the neutralized hydrolyzate showed the presence of two components that were identical to glycerol and erythritol. The hydrolyzate was acetylated with acetic anhydride and sodium acetate, and the product examined by g.l.c. on a column (4′ × 3 mm) of 3% ECNSS-M on Gas-Chrom Q (100–120 mesh) at 185° (19).

Two components were detected having retention times corresponding to those of authentic samples of glycerol triacetate and erythritol tetraacetate. The ratio of glycerol triacetate to erythritol tetraacetate was 1.0:1.9, as determined from the relative areas under the peaks.

Methylation Analysis

A sample of the glucan (300 mg) was dissolved in dry dimethyl sulfoxide (20 ml) and was treated with dimethylsulfinyl cation and methyl iodide by the Hakomori procedure (20). The reaction mixture was poured into water (100 ml) and the resultant solution was dialyzed against water for 24 h. A clear dialyzate was obtained which was then lyophylized to yield the methylated product (300 mg) having a small hydroxyl absorption in its spectrum and OCH_3, 38.0%. Further methylation of the glucan with silver oxide and methyl iodide by the Purdie procedure (21) yielded the permethylated glucan (285 mg, 80%) which showed no hydroxyl absorption in its i.r. spectrum and had $[\alpha]_D^{26}$ +212° (*c*, 0.1 in chloroform) and OCH_3, 43.0%.

A sample of the methylated glucan was heated at 100° with methanolic hydrogen chloride (3%) in a sealed tube for 7 h. After neutralization with silver carbonate the mixture was examined by g.l.c. on a column (8′ × 3 mm) of 15% diethylene glycol succinate on Gas-Chrom S (60–80 mesh) at 170°. The methyl glycosides of 2,3,4,6-tetra-*O*-methyl glucose (0.5%), 2,3,4-tri-*O*-methyl glucose (31.4%), and 2,3,6-tri-*O*-methyl glucose (67.6%) were detected and identified by comparison of their retention times with authentic samples of these methylated derivatives, and their quantitative estimation was carried out by mensuration of the peak areas. Thus the ratio of 2,3,4- to 2,3,6-tri-*O*-methyl glucopyranosides was 1:2.1. To ensure the accuracy of this ratio further methanolyses of the methylated glucan were carried out as above except for varying the time of methanolysis. At both shorter (4 h) and longer (12 h) periods of time the ratio of 2,3,4- to 2,3,6-tri-*O*-methyl glucopyranosides was found to be 1:2.1 in each case.

A small sample of the methylated glucan was hydrolyzed by the formic acid–sulfuric acid method (11) and the neutralized hydrolyzate was examined by paper

chromatography (irrigants *C*, *F*, and *G*) and t.l.c. (irrigants *C* and *D*). The 2,3,4,6-tetra- and 2,3,4-tri- and 2,3,6-tri-*O*-methyl derivatives of glucose were detected and identified by comparison with authentic samples.

Partial Hydrolysis

A sample (160 mg) of the glucan was heated at 100° with 0.1 *M* oxalic acid for 6 h (sealed tube). Chromatographic examination of the neutralized (barium carbonate) hydrolysate (irrigants *E* and *I*) revealed the presence of glucose, maltose, isomaltose, panose, isomaltotriose, and the trisaccharide *O*-α-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 6)-D-glucose.

The authors wish to thank Mrs. A. Martin for technical assistance and Mr. A. E. Castagne for the microanalyses.

Received January 15, 1971

An investigation has been made of the relative importance of the possible pathways [2*a*]–[2*d*]

[2*a*] $O(^1D_2) + N_2O \rightarrow N_2 + O_2$

[2*b*] $O(^1D_2) + N_2O \rightarrow 2NO$

[2*c*] $O(^1D_2) + N_2O \rightarrow N + NO_2$

[2*d*] $O(^1D_2) + N_2O \rightarrow O(^3P) + N_2O$

for the reaction in the gas phase at room temperature between the excited oxygen atom $O(^1D_2)$ and N_2O, using the photolysis of NO_2, O_3, and N_2O as sources of the excited atom. Measurement of the yields of N_2 and NO from the photolysis at 2288 Å of mixtures of NO_2 and N_2O has led to a value of 1.01 ± 0.06 for k_{2a}/k_{2b}, the ratio of the rate constants for [2*a*] and [2*b*], in excellent agreement with the value of 0.99 ± 0.06 obtained from determination of the yields of N_2 and NO_2 arising from the flash photolysis of O_3–N_2O mixtures. The isotopic composition of the N_2 produced in the photolysis of $^{15}NO_2$–N_2O mixtures indicated that $k_{2c}/k_{2a} < 5 \times 10^{-3}$. Furthermore, the value of $k_{2a}/(k_{2b} + k_{2d}) = 1.08 \pm 0.19$, obtained from a study of the effect of CO_2 and Xe additions on the yield of N_2 from the photolysis of N_2O at 2288 Å, suggests that deactivation [2*d*] does not make an important contribution to the total rate constant for destruction of $O(^1D_2)$.

On rapporte les résultats obtenus lors d'une étude entreprise afin de déterminer l'importance relative des diverses réactions possibles [2*a*]–[2*d*]

[2*a*] $O(^1D_2) + N_2O \rightarrow N_2 + O_2$

[2*b*] $O(^1D_2) + N_2O \rightarrow 2NO$

[2*c*] $O(^1D_2) + N_2O \rightarrow N + NO_2$

[2*d*] $O(^1D_2) + N_2O \rightarrow O(^3P) + N_2O$

pour la réaction en phase gazeuse et à température de la pièce, entre l'atome d'oxygène excité $O(^1D_2)$ et le N_2O; on a utilisé la photolyse de N_2O, O_3 et NO_2 comme source d'atome excité. En mesurant les rendements de N_2 et NO obtenus lors de la photolyse, à 2288 Å de mélanges de NO_2 et N_2O, on a pu établir que le rapport des constantes de vitesse pour les réactions [2*a*] et [2*b*], k_{2a}/k_{2b}, est égal à 1.01 ± 0.06; cette valeur est en excellent accord avec celle, 0.99 ± 0.06, obtenue en déterminant les rendements de N_2 et NO_2 obtenus lors de la photolyse éclair de mélanges de O_3 et N_2O. En se basant sur la composition isotopique de N_2 produit lors de la photolyse de mélanges de $^{15}NO_2$–NO_2, on peut déduire que $k_{2c}/k_{2a} < 5 \times 10^{-3}$. Par ailleurs en étudiant l'effet que produit l'addition de CO_2 et de Xe sur le rendement de N_2 lors de la photolyse de N_2O à 2288 Å, on peut établir que $k_{2a}/(k_{2b} + k_{2d}) = 1.08 \pm 0.19$; ce résultat suggère que la contribution de la réaction de désactivation, [2*d*], à la constante de vitesse totale de la destruction de $O(^1D_2)$ est négligeable.

Canadian Journal of Chemistry, 49, 1808 (1971)

Introduction

In the course of our investigations of the chemistry of $O(^1D_2)$ atoms, we have become aware of serious disagreements in the literature concerning the nature and relative rates of the secondary reactions in the photolysis of N_2O. This paper describes work designed to clarify this situation.

The photolysis of N_2O in the wavelength region 1850–2300 Å is believed (1) to yield electronically excited oxygen atoms which are principally, if not entirely in the $^1D_2$ state

[1*a*] $N_2O + h\nu \rightarrow N_2 + O^*$

Recent observations (1, 2) suggest that [1*a*] is the only important primary process in that wavelength region so that the subsequent course of the photodecomposition is controlled entirely by the reaction of O^* with N_2O.

The electronically excited atom $O(^1D_2)$ reacts rapidly with N_2O at room temperature (3–5), in contrast to the behavior of the ground-state $O(^3P)$ atom (6, 7). The rate of N_2 formation from the reaction

[2*a*] $$O(^1D_2) + N_2O \rightarrow N_2 + O_2$$

is a most convenient measure of the stationary concentration of the excited atoms which may be used to determine primary quantum yields of $O(^1D_2)$ production in the photolysis of gaseous oxides and the relative rates of reaction of $O(^1D_2)$ with other gases. Unfortunately there is evidence from quantum yield measurements (8–13) for the photolysis of N_2O that [2*a*] is not the exclusive pathway for reaction and that [2*b*]

[2*b*] $$O(^1D_2) + N_2O \rightarrow 2NO$$

is important. In addition, the spin-forbidden processes

[2*c*] $$O(^1D_2) + N_2O \rightarrow N + NO_2$$

[2*d*] $$O(^1D_2) + N_2O \rightarrow O(^3P) + N_2O$$

may conceivably contribute to the rate constant for the total reaction of $O(^1D_2)$ with N_2O. This investigation was undertaken to establish the relative rates of [2*a*]–[2*d*].

In principle, if [1*a*] is the sole primary process, one can derive information on the relative rates of the secondary processes from measurements of the quantum yields of the products of N_2O photolysis. Data so obtained are, however, subject to considerable experimental error, quite apart from any systematic error incurred through the assumption of unit efficiency for [1*a*]. In this investigation we have avoided uncertainties associated with the primary process in N_2O photolysis by using NO_2 and O_3 as sources of $O(^1D_2)$. From measurements of the yields of products specific to the individual steps [2*a*]–[2*c*], we have obtained their relative rate constants with greater precision than was possible from a study of N_2O photolysis alone. The results of a separate investigation of the effect of added inert gases on the yield of N_2 in N_2O photolysis have confirmed our value for k_{2a}/k_{2b} and have indicated that [2*d*] is unimportant.

Experimental

NO_2 Photolysis

Mixtures of NO_2 and N_2O were photolyzed in a 10 cm long cylindrical cell having plane quartz windows 5 cm in diameter. After an exposure, the contents of the cell were shared with the glass sample loop ($\simeq$ 20 cc volume) of a gas chromatographic analysis train. This aliquot was subjected to several freeze–thaw cycles (at least 3 were required) in which the sample loop was alternately cooled to −196 °C and warmed to room temperature. As experiments with an irradiated sample of pure NO_2 showed, this procedure removed O_2 and NO from the mixture according to $2NO + O_2 = 2NO_2$. Separation of the components of the sample was subsequently effected with three columns in series: NO_2 was removed by adsorption on a 1 ft column of 60/80 mesh silanized glass beads at −78 °C; the remaining components were eluted from an 18 ft column of 80/100 mesh Porapak Q held at room temperature, in the order (N_2, O_2), NO, N_2O and were passed through a thermistor detector; separation and detection of N_2 and O_2 were achieved with a 6 ft column of 60/80 mesh Molecular Sieve 5A at room temperature and a second thermistor element. Calibrations for NO and O_2 relative to N_2 were obtained by measuring peak heights for known mixtures of NO and N_2 or O_2 and N_2. The NO/N_2 calibration mixtures were diluted with sufficient pure NO_2 to simulate approximately an actual reaction mixture since it was found that NO_2 caused a slight broadening of the NO peaks.

Ozone Photolysis

Mixtures of pure, dry ozone and nitrous oxide contained in an all-vycor (7910 glass), cylindrical cell (20 cm long, 17 mm i.d.) having parallel, plane end-windows were subjected to a 3500 J light pulse of $\sim$ 20 μs duration to half peak height. A surrounding flash lamp of annular design (5, 14) was used Two methods of product analysis were used. Products noncondensible at −196 °C (N_2 and O_2) were collected by conventional vacuum techniques and were analyzed by gas chromatography (5). In addition, the nitrogen dioxide concentration in the cell was monitored continuously throughout an experiment with a home-made, double-beam photometer: A parallel beam of light from a 100 W P.E.K. lamp No. 110 was filtered by Corning filters 0–52 and 7–51, giving light in the wavelength region 3400–4200 Å (and a somewhat weaker emission at $\lambda > 6900$ Å), and was split by a partially silvered vycor plate placed at 45° to the beam. The deflected reference beam was focussed onto an RCA 935 phototube; the other (analyzing) beam traversed the length of the reaction cell before being focussed onto a second 935 phototube. The phototubes, two 18 kΩ resistors, and a dry cell formed a simple bridge circuit whose output voltage, which was proportional to the difference between the photocurrents, was recorded during an experiment by an oscilloscope with a polaroid camera attachment. Measurements of the output immediately before and several minutes after a flash and of the output of the reference phototube alone were superimposed on the photograph for each run (Fig. 1). From these readings it was possible to determine the optical density of the reaction cell contents and hence the NO_2 concentration as a function of time. A calibration plot of optical density *vs.* P_{NO_2} was linear for the range of pressures (0.05–0.35 Torr) investigated, and gave an extinction coefficient for NO_2 which agreed well with the established value (15) for the wavelength region used.

In a few experiments the ozone concentration was followed during a photolysis by monitoring light absorption in the region 2900–3000 Å. A monochromator was used to isolate the wavelength region required from the P.E.K. lamp.

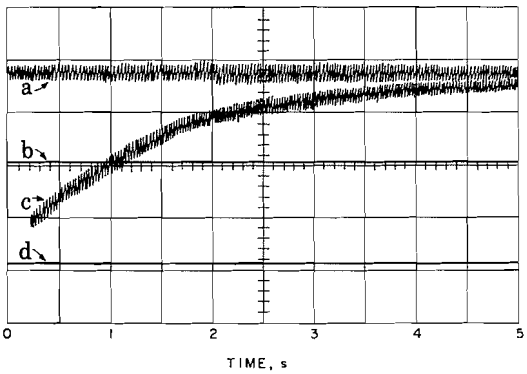

FIG. 1. Oscilloscope traces of the double-beam photometer output in run No. 231 (see Table 2). Curves (*a*) and (*c*) represent the differential output, *i.e.* the difference between the outputs of the reference and the analyzing phototubes, on an ordinate scale of 5 mV per large division. Curve (*a*) is the superimposed trace obtained before and several minutes after the flash; (*c*) is the trace obtained immediately after flash photolysis; (*d*) gives the output of the reference phototube alone on a scale of 0.2 V per large division; and (*b*) is the origin of the ordinate axis.

N_2O Photolysis

Light from a Philips 93107 Cadmium lamp was filtered by a 5 cm path length of NO at 100 Torr and was split into two beams of approximately equal intensity by a partially silvered quartz plate. The light beams were incident upon the plane end-windows of two identical, cylindrical quartz cells each of $\simeq$ 250 ml volume. Prior to an exposure both cells were filled with precisely the same pressure of N_2O ($\simeq$ 50 Torr). One of the vessels served as a reference cell; to the other (the reaction vessel) was added a measured pressure of CO_2 or Xe. After an irradiation period of from 24 to 96 h the noncondensible products at -196 °C of each cell were pumped through three liquid N_2 traps with diffusion and Toepler pumps and were collected in a gas burette. The contents of the first cold trap were distilled into the second and then into the third trap to ensure complete degassing. (When using Xe as an additive the final cold trap was held at -210 °C.) The products were analyzed by gas chromatography using a 20 ft column of Molecular Sieve 13X at room temperature for separation and a thermistor for detection.

The preparation and purification of the materials used in these experiments have been described elsewhere (4, 5). Reactant gases, and in the case of the NO_2 photolyses product gases also, were manipulated in mercury-free vacuum systems.

Results

NO_2 Photolysis

Table 1 summarizes the conditions employed in the photolysis of mixtures of NO_2 and N_2O and gives the values of k_{2a}/k_{2b} derived from the measurements of nitrogen and *excess* nitric oxide yields. The expression

$$[3] \quad [\text{excess NO}]/[N_2] = 3k_{2b}/k_{2a} - 1$$

used to calculate the rate constant ratio results from a consideration of the reaction mechanism consisting of [2*a*], [2*b*], and [2*d*] (for the moment we ignore reaction [2*c*]) and the reactions responsible (4) for the photodecomposition of NO_2

$$NO_2 + h\nu \rightarrow \begin{cases} NO + O^* \\ NO + O \end{cases}$$

$$O^* \text{ (or O)} + NO_2 \rightarrow NO + O_2$$

Contributions to excess NO formation, defined according to

$$[\text{excess NO}] = [NO] - 2[O_2]$$

arise solely from those $O(^1D_2)$ atoms (O*) which react with N_2O. Ground-state O atoms and those O* atoms which react with the NO_2 make no contribution to the excess yield of NO since they simply effect the overall change: $2NO_2 = 2NO + O_2$. Thus, the rate of formation of excess NO is given by

$$[4] \quad [2k_{2b} - 2k_{2a} + (k_{2b} + k_{2a})][O^*][N_2O]$$

where the first two terms represent the rate of formation of NO and twice the rate of O_2 formation, respectively, in reaction 2, and the third term represents a rate of formation of NO in the primary process equivalent to the rate of production of the O* which ultimately react chemically with N_2O. Equation 3 follows immediately from [4] and the expression for the rate of N_2 production, $k_{2a}[O^*][N_2O]$.

The simple mechanism which we have adopted predicts that the yield of excess NO relative to the yield of N_2 should be independent of the pressures of NO_2 and N_2O and of the yield of O*. Our values of k_{2a}/k_{2b} (Table 1) derived from [3] for the photolysis at 2288 Å were certainly constant (within 10%) within the range of reactant concentration ratios studied and did not differ significantly from the values obtained at 2420 Å. (At 2288 Å, the primary quantum yield of $O(^1D_2)$ in the photolysis of NO_2 is in the region 0.3–0.4 (4, 16), and at 2420 Å it is probably (16) close to 0.2.) Although this in itself was an indication that the assumed mechanism was essentially correct, we carried out additional experiments to make certain that [2*a*] was the sole source of N_2 in the system. Since approximately 10% decomposition of the NO_2 was permitted in most runs, the secondary photolysis of NO by light at 2265 and

2144 Å from the Cd lamp was considered a real possibility. The removal of the extraneous light by chemical filters did not, however, lead to a significant change in the measured rate constant ratio (Table 1). A few experiments were also conducted at 150 °C to eliminate light absorption by N_2O_4 and N_2O_3 which was significant (16) in the runs at room temperature. There was, however, no noticeable effect on the value of k_{2a}/k_{2b}. Calculations based on a primary quantum yield of 0.35 for O* from NO_2 and a value for the ratio of extinction coefficients of N_2O and NO_2 at 2288 Å of 4×10^{-4} (16) showed that at the highest ratio of P_{N_2O}/P_{NO_2} used in our experiments at that wavelength the direct photolysis of N_2O would have increased the observed rate constant ratio by only 4%. At 2420 Å, it was demonstrated experimentally that at most only 1% of the N_2 produced in the photolysis of the NO_2–N_2O mixtures employed arose from the direct photolysis of N_2O.

The scatter in the relative rate constant values obtained by this method is largely a reflection of the uncertainty associated with the gas chromatographic analysis for NO. Repeated analyses made with a mixture of NO and N_2 diluted with sufficient NO_2 to simulate an actual reaction mixture indicated that the product ratio [NO]/[N_2] could not be determined with greater accuracy than ±5%. Small, but varying extents of decomposition of NO_2 on the glass beads precolumn, resulting in NO formation, and varying degrees of adsorption of NO on the same column were believed responsible for the irreproducibility. All reaction mixtures were analyzed both before and (several times) after photolysis. Reactant chromatograms were examined closely for the presence of traces of NO, N_2, or O_2; product chromatograms were checked to ensure that the removal of O_2 by reaction with NO was complete. Duplicate analyses of product mixtures made up to 24 h after the initial analyses indicated no changes in composition and therefore no contributions to the formation or destruction of the products from thermal reactions. In a few experiments (indicated by a superscript *d* in Table 1) sufficient pure O_2 (< 3% of [NO_2]) was added initially to the reactants to ensure the complete oxidation of the excess NO produced in the photolysis. Calculations of k_{2a}/k_{2b} were then based on analysis for the O_2 and N_2 contents of the reactant and product mixtures, and the values so obtained were in good agreement with those based on the measurement of NO and N_2 yields.

An estimate of the importance of reaction [2*c*] was made from measurements of the isotopic composition of the N_2 arising from the photolysis of mixtures of $^{15}NO_2$ (95.3% $^{15}NO_2$) and natural N_2O at 2288 Å. Since N atoms reacted only with

the NO_2 under the conditions used, the yield of $^{29}N_2$ from

$$^{15}N + NO_2 \rightarrow {}^{29}N_2 + O_2 \text{ (or } 2O)$$

which accounts for approximately 23% of N atoms destroyed in reaction with NO_2 (17), was a measure of the N atom yield. $^{29}N_2$ contents of 0.88 and 0.84% were obtained for the photolysis of a 15:1 N_2O:$^{15}NO_2$ mixture at 23 and 150 °C, respectively, compared to a natural abundance of 0.76% determined with the same mass spectrometer. These results show that k_{2c}/k_{2a} is no larger than 5×10^{-3}.

Ozone Photolysis

The results (5) of a recent study of the flash photolysis of mixtures of ozone and nitrous oxide under conditions similar to those employed here are consistent with the assumption that the only reactions leading to significant decomposition of N_2O are [2*a*] and [2*b*]. In the presence of O_3 the NO produced in [2*b*] is oxidized to N_2O_5 through the intermediate formation of NO_2 and NO_3 (18, 19).

[5] $$NO + O_3 \rightarrow NO_2 + O_2$$

[6] $$NO_2 + O_3 \rightarrow NO_3 + O_2$$

[7] $$NO_3 + NO_2(+ M) \rightarrow N_2O_5(+ M)$$

In principle the rate constant ratio k_{2a}/k_{2b} can be obtained simply by measurement of the ratio of the yields of N_2 and N_2O_5, but trial experiments showed that the observed yields of N_2O_5 were irreproducible owing to erratic and irrecoverable losses probably at the reaction cell walls. We chose instead to use the yield of NO_2, determined by absorption photometry at short delays after the photolyzing flash, as a measure of k_{2b}. (Measurement of the NO yield at very short delays would, of course, have been preferable, but was unfortunately not possible with the equipment at our disposal.) The lifetimes of NO and NO_2 with respect to destruction in [5] and [6] at 1 Torr O_3, the pressure used throughout this study, were estimated from available rate constants (19, 20) to be $\sim 10^{-3}$ and ~ 1 s, respectively, so that extrapolation to zero time of our measurements for $[NO_2]$ in the time interval 0.2–5 s was expected to give a reliable value for the initial yield of NO. (An electronic disturbance prevented the direct measurement of $[NO_2]$ at times less than 0.2 s and necessitated the extrapolation procedure.) A typical oscilloscope trace of light absorption in the reaction cell is shown in Fig. 1 and the corresponding semilogarithmic plot used for extrapolation to zero time is given in Fig. 2.

In most experiments total pressures of 400 Torr or more were used in order to minimize the temperature rise in the reaction vessel due to the flash. N_2O pressures were always sufficiently large to ensure that practically all $O(^1D_2)$ atoms reacted with N_2O, rather than with O_3, and where necessary, the required total pressure was reached by adding SF_6, a very inefficient (1, 4, 5) deactivator of the excited atoms. The yields of N_2 and of NO_2 at zero time obtained in such high-pressure experiments are summarized in Table 2. The mean value of k_{2a}/k_{2b} deduced from those data is in excellent agreement with the value derived from the study of the photolysis of mixtures of NO_2 and N_2O (Table 1).

At high total pressures, the kinetics of decay of $[NO_2]$ were those expected for a reaction controlled by step [6] when $[O_3]$ is in appreciable excess of $[NO_2]$. Plots of $\log_{10}[NO_2]$ against time (Fig. 2) were linear during the first 70% of the reaction and estimates of k_6 (Table 2) were obtained from the slopes and from ozone con-

centrations calculated from an expression

$$[8] \qquad \Delta[O_3] = -8[N_2]$$

relating the decrease in O_3 concentration to the yield of N_2. This relationship, which assumed (5) that [6] was preceded by [2*a*], [2*b*] (with $k_{2a} = k_{2b}$, as found in this study), [5], and

$$O_3 + h\nu \rightarrow O_2(^1\Delta_g) + O(^1D_2)$$
$$O_2(^1\Delta_g) + O_3 \rightarrow 2O_2 + O(^3P)$$
$$O(^3P) + O_3 \rightarrow 2O_2$$

was shown to be approximately correct in independent experiments (Table 3) in which the ozone concentration was monitored. (The value of 9 obtained for $-\Delta[O_3]/[N_2]$ upon completion of all reaction in those experiments corresponds to a value of 8 at the commencement of [6].) Our mean k_6 value so derived is smaller by a factor of approximately 2 than the most recent value in the literature (20) and is six times smaller than an earlier value (21). While the agreement is only fair, we feel that it provides some justification for our assumptions regarding the fate of NO produced in the flash photolysis of O_3–N_2O mixtures, and certainly validates our extrapolation procedure for the determination of $[NO_2]$ at zero time. By contrast, the light absorption traces obtained in experiments at ~ 100 Torr pressure ($N_2O \simeq 100$ Torr, $O_3 \simeq 1$ Torr) clearly indicated that the simple mechanism formulated above was not applicable at low pressures. NO_2 apparently disappeared at a much slower rate in these experiments and semi-logarithmic plots, although linear, suggested a value for k_6 some 5–6 times smaller than that obtained in the high-pressure runs. Furthermore, the apparent yield of NO_2 and the loss of O_3 relative to the yield of N_2 were significantly larger: an average value $k_{2a}/k_{2b} = 0.87 \pm 0.04$ was obtained from five experiments at $O_3 = 1$ Torr, $N_2O = 100$ Torr, and a value $-\Delta[O_3]/[N_2] \simeq 12$ from experiments under the same conditions. We have chosen to dismiss the value of k_{2a}/k_{2b} obtained at low pressures because of our imperfect understanding of the kinetics and because of a strong suspicion that NO_3 may have contributed

[a]See footnotes to Table 2.

significantly to light absorption in the low-pressure experiments. The rapidity of [7] would normally ensure a very low, stationary concentration of NO_3, but at the temperatures reached in a flash photolysis at 100 Torr (calculated adiabatic temperature rise ~ 50 °C) the reverse of [7] would probably have been important, resulting in a higher NO_3 concentration, a slower removal of NO_3 by

[9] $$2NO_3 \rightarrow 2NO_2 + O_2$$

[10] $$NO_3 + NO_2 \rightarrow NO + O_2 + NO_2$$

(18) and a slower decay of NO_2. If the effective extinction coefficient of NO_3 were higher than that for NO_2, a distinct possibility (22, 23) for the light source used here, the measured yield of NO_2 would then be too high. The greater extent of O_3 decomposition relative to N_2 formation which was noted in the low-pressure runs is consistent with a partial contribution to NO_3 removal from [9] and [10] at low pressures. Confirmation of this explanation of the observations at low pressures must await the results of more detailed studies; meanwhile we accept only the values of k_{2a}/k_{2b} obtained at high pressures where there are apparently no complications.

Following a recent suggestion of Heicklen (24) that the rate constant ratio k_{2a}/k_{2b} is markedly dependent on the translational energy of the $O(^1D_2)$ atom, we examined in one experiment (Table 4) the effect of added helium on the ratio. Compared to the values obtained in control experiments the ratio for the run with added He was somewhat smaller, although the change was barely significant and in any case in the opposite direction to that predicted by Heicklen (24). Our technique for the recovery of product N_2 unfortunately precluded the addition of larger pressures of He, so that we were unable to establish with certainty that the small effect observed was genuine. However, a comparison of the results (Tables 2 and 4) obtained with and without inert gas additions indicated that if excess translational energy is possessed by the $O(^1D_2)$ atom generated in O_3 photolysis, it has little or no effect on the rate constant ratio k_{2a}/k_{2b}. Thus, on the basis of the theory of collisions between hard-sphere molecules and the assumption of a reaction probability of 1 in 3 collisions between $O(^1D_2)$ and N_2O (4, 25), we calculate that the $O(^1D_2)$ atoms which reacted with N_2O in runs 228, 238, and 239 possessed, on average, the fractions 0.56, 0.13, and 0.09, respectively, of the original excess translational energy which the atom acquired in the photodissociation process. (For reaction at every collision between O* and N_2O the corresponding fractions would be 1.0, 0.34, and 0.25.) In spite of this considerable spread of possible excess energy content of O* the observed values of the rate constant ratio did not deviate significantly from the mean.

N_2O Photolysis

Figure 3 illustrates the observed effect of Xe and CO_2 additions on the yield of N_2 from the photolysis of N_2O at 2288 Å. Relative quantum yields $\Phi_{N_2}/\Phi_{N_2}{}^0$ (that is the ratio of the quantum yield of N_2 in the presence to that in the absence of inert gas) were derived from measurements of the N_2 produced in the reaction cell and in the

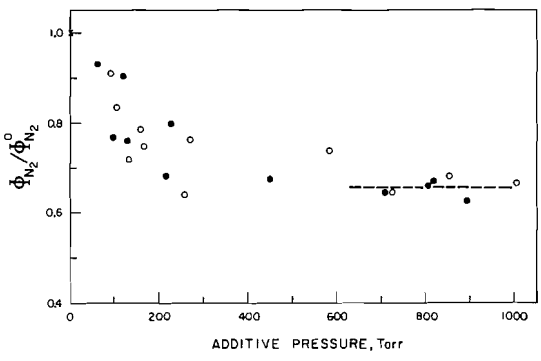

FIG. 3. The effect of Xe (○) and CO_2 (●) additions on the quantum yield of N_2 relative to the quantum yield in the absence of additives for the photolysis of 51 Torr of N_2O at 2288 Å and 23 °C. The dashed line is the average of the relative quantum yield values obtained at additive pressures > 600 Torr.

reference cell. The use of a nitric oxide filter ensured that only the Cd resonance line at 2288 Å was absorbed by N_2O and also prevented secondary photolysis of product nitric oxide. At 2288 Å [1*a*] is unquestionably (1, 2) the only primary photolytic process of importance and the excited oxygen atoms are exclusively in the $^1D_2$ state. Quenching of the $O(^1D_2)$ atoms limits the production of N_2 to the primary process at high Xe or CO_2 pressures (1, 4, 5), since ground-state O atoms do not react with N_2O at room temperature (6, 7). In the limit of complete quenching of the excited atoms we may write

$$\Phi_{N_2}{}^0/\Phi_{N_2}{}^\infty = 1 + k_{2a}/(k_{2a} + k_{2b} + k_{2d})$$

Using this expression and our value (Fig. 3) of the limiting relative quantum yield at high additive pressure, we obtain $k_{2a}/(k_{2b} + k_{2d}) = 1.08 \pm 0.19$ (standard deviation). In view of the appreciable scatter in our data we regard this value as only a crude estimate of the rate constant ratio. It does, however, confirm the values obtained using O_3 and NO_2 as sources of $O(^1D_2)$, and furthermore suggests that k_{2a} is small relative to k_{2b}.

In order to convince ourselves that the primary production of $O(^3P)$ atoms in the photolysis of N_2O at 2288 Å was unimportant, we analyzed the products of the photolysis of a mixture containing 92.6 mol% neopentane, 0.6% butene-1, and 6.8% nitrous oxide. The observed product ratios, [neopentanol]/[N_2] = 0.67 and [1,2-butylene oxide]/[N_2] = 0.013, were identical within experimental error to those obtained in similar experiments at 2139 Å (1), indicating that the total yield of $O(^3P)$, including a possible contribution from quenching of $O(^1D_2)$, was at most only 3% of the primary yield of excited oxygen atoms.

Discussion

Of the possible pathways [2*a*]–[2*d*] for the reaction between $O(^1D_2)$ and N_2O we have shown that at room temperature [2*c*] makes an insignificant contribution to the reaction and that [2*d*] is probably unimportant also. Evidence adduced by Young, Black, and Slanger (3) and by Greenberg and Heicklen (26) supports the assumption that physical deactivation of $O(^1D_2)$, [2*d*], is of negligible importance compared to chemical quenching, [2*a*] and [2*b*]. Our two values for the rate constant ratio k_{2a}/k_{2b} (Tables 1 and 2) obtained by completely independent methods are in excellent agreement and have a mean of 1.00 with a standard deviation of 0.04. This value differs markedly from that of the recent and only previous determination (26), but falls well within the range of the estimates (Table 5) of the ratio which one can derive from absolute product quantum yields reported for the photolysis of N_2O and the assumptions

$$[11] \quad \phi_{O(^1D_2)} = 1.0 \qquad k_{2c} = k_{2d} = 0$$

For the same assumptions, our value for k_{2a}/k_{2b} suggests a nitrogen quantum yield for the photolysis of N_2O of 1.50 ± 0.01, in good agreement with the results of recent determinations at 2139 Å (26) and at 1849 Å (11). Provided the assumptions [11] are exact, absolute quantum yields evidently can be predicted in this manner with greater precision than can be achieved in a direct measurement.

Greenberg and Heicklen (26) have reported a value for k_{2a}/k_{2b} at room temperature of 0.59 ± 0.01 based upon their value of 0.059 ± 0.007 for the quantum yield of O_2 from the photolysis of N_2O at 2139 Å, the postulates [11] and the assumption that the product oxygen which they measured was that remaining after the product NO had been completely consumed according to the stoichiometry $4NO + O_2 = 2N_2O_3$. For an assumed stoichiometry $2NO + O_2 = 2NO_2$, which is usually adopted and which applied in our experiments with mixtures of NO_2 and N_2O (see above), their measured quantum yield of O_2 corresponds to a ratio $k_{2a}/k_{2b} = 1.12 \pm 0.01$ in somewhat better accord with our result and with their value (Table 5) based on a measurement of the quantum yield of N_2. The good agreement between the values which we obtained by three independent methods supports our adoption of a 2:1 stoichiometry for the reaction between NO and O_2 in the determinations using NO_2 as a source of $O(^1D_2)$. Additional support for our value of unity for k_{2a}/k_{2b} comes from the coincidence of predicted and measured values of $-\Delta[O_3]/[N_2]$ for the flash photolysis of O_3–N_2O mixtures. The mechanism outlined above for the flash photolysis predicts values for $-\Delta[O_3]/[N_2]$ of 11.5 when $k_{2a}/k_{2b} = 0.59$ and of 8, the observed value, when $k_{2a}/k_{2b} = 1.0$.

We have found no evidence in this investigation for an effect of excess translational energy of the $O(^1D_2)$ atom on the ratio k_{2a}/k_{2b}. The

TABLE 5. Values of k_{2a}/k_{2b} derived from quantum yield data for the photolysis of N_2O and the assumptions [11]

Quantum yields	Wavelength (Å)	Calculated k_{2a}/k_{2b}	Reference number
$\Phi_{-N_2O} = 2.0$ $\Phi_{NO} = 1.0$, $\Phi_{O_2} = 0.5$	1849	1.0	11
$\Phi_{N_2} = 1.44 \pm 0.08$	1900	$0.79^{+0.29}_{-0.23}$	9
$\Phi_{NO} = 0.82$	1900	1.44	9
$\Phi_{-N_2O}/\Phi_{N_2} = 1.24 \pm 0.07$	1849	$1.56^{+0.77}_{-0.48}$	10
$\Phi_{-N_2O}/\Phi_{O_2} = 3.47 \pm 0.20$	1849	1.36 ± 0.20	10
$\Phi_{N_2} = 1.51 \pm 0.11$	2139	$1.04^{+0.59}_{-0.37}$	26
$\Phi_{O_2}{}^a = 0.059 \pm 0.007$	2139	0.59 ± 0.01^b 1.12 ± 0.01^c	26

[a]Measured after NO had been completely consumed.
[b]Assumed stoichiometry for NO removal: $4NO + O_2 = 2N_2O_3$.
[c]Assumed stoichiometry for NO removal: $2NO + O_2 = 2NO_2$.

same value within experimental error was found for all three sources of $O(^1D_2)$ in spite of the considerable variation in the excess energy available for translational excitation of the atom in the three cases

$$NO_2 \xrightarrow{2420\ Å} NO + O(^1D_2) \qquad \text{0.1 kcal/g-atom max. available}$$

$$NO_2 \xrightarrow{2288\ Å} NO + O(^1D_2) \qquad \text{4.5 kcal/g-atom max. available}$$

$$O_3 \xrightarrow{\sim 2500\ Å} O_2(^1\Delta_g) + O(^1D_2) \qquad \text{14.4 kcal/g-atom max. available}$$

$$N_2O \xrightarrow{2288\ Å} N_2 + O(^1D_2) \qquad \text{25.6 kcal/g-atom max. available}$$

Furthermore, the value obtained with O_3 as the source was not altered by additions of inert moderators.

We note that values close to unity have also been reported (27–30) for the ratio of the rate constants of the reactions [2*a*] and [2*b*] when the oxygen atom is in the ground state (although not all workers agreed on this value (31)). The energy barriers for the two pathways are identical, or nearly so (27, 28, 32), for the reactions with $O(^3P)$ and evidently (4, 25) are both very small in the case of reaction with $O(^1D_2)$. If the transition complexes involved differ little in the two cases, the proximity of the k_{2a}/k_{2b} values for ground- and excited-state oxygen atoms is understandable.

The Effect of α-Substituents on Benzylic Spin–Spin Coupling Constants. Derivatives of 2,6-Dichlorotoluene

A. F. JANZEN[1] AND T. SCHAEFER

Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received November 9, 1970

Spin–spin coupling constants between methylene protons and ring protons over six and five bonds, $J_{m,p}^{H,CH_2}$, are reported for α-substituted derivatives of 2,6-dichlorotoluene. Potential energy calculations suggest that the C—X bond of the CH_2X group lies perpendicular to the plane of the ring. The six-bond coupling is dominated by a π electron mechanism and depends on the conformation of CH_2X with respect to the aromatic plane and on the electronegativity of the substituent, X. The five-bond coupling is independent of X and it is suggested that the decrease in the π electron contribution to this coupling caused by the increasing electronegativity of X, is compensated by a corresponding increase in the sigma electron contribution.

On rapporte les constantes de couplage, $J_{m,p}^{H,CH_2}$, qui se font par l'intermédiaire de cinq ou six liens entre les protons méthylèniques et les protons du noyau de dichloro-2,6 toluènes substitués en α. Des calculs d'énergie potentielle permettent de suggérer que le lien C—X du groupe CH_2X est perpendiculaire au plan du noyau aromatique. Le couplage qui se fait par l'intermédiaire de six liens est dû à un mécanisme dominé par les électrons π et dépend de la conformation du groupe CH_2X par rapport au plan du noyau aromatique et de l'électronégativité du substituant X. Le couplage qui se fait par l'intermédiaire de cinq liaisons est indépendant de X; on croit que la diminution de la contribution des électrons π à ce couplage due à une augmentation de l'électronégativité de X-est compensée par une augmentation correspondante de la contribution des électrons sigma.

Canadian Journal of Chemistry, 49, 1818 (1971)

Introduction

In toluene derivatives long-range proton–proton spin–spin coupling constants between methyl protons and ring protons over four, five, and six bonds, $J_{o,m,p}^{H,CH_3}$, are known for numerous ring substitution patterns (1, 2). J_p^{H,CH_3} and J_m^{H,CH_3} are insensitive to ring substitution (1) whereas J_o^{H,CH_3} may vary by about 10% of its value in toluene, apparently in a manner related to the mobile bond order of the intervening C—C bond in the aromatic ring (3, 4). J_p^{H,CH_3} has its origin in a π electron mechanism (1) but there exist appreciable σ electron contributions to $J_{o,m}^{H,CH_3}$.

Relatively little is known about the behavior of the analogous couplings when the methyl group is replaced by a CH_2X moiety. In this paper we report on the effect of a series of α-substituents on $^5J_m^{H,CH_2}$ and $^6J_p^{H,CH_2}$ in α-derivatives of 2,6-dichlorotoluene. The presence of the ring substituents, while denying information on $^4J_o^{H,CH_2}$, stabilizes one conformation of the CH_2X group with respect to the plane of the ring and thereby facilitates the isolation of other factors influencing the long-range couplings.

[1]Holder of an NRCC scholarship 1969–1970.

Experimental

The compounds were obtained from the usual commercial sources and were used without further purification. 2,6-Dichloroethylbenzene was prepared by hydrogenation of 2,6-dichlorostyrene. 2,6-Dichlorostyrene (3 ml) was dissolved in about 20 ml of distilled methanol containing one drop of concentrated hydrochloric acid. An amount of 50 mg of a palladium-on-charcoal catalyst was used. Air was swept out of the reaction vessel by repeatedly lowering the pressure in the vessel and then admitting hydrogen gas. The reaction vessel was left on a shaker overnight. The solvent was distilled off. Chloroform (10 ml) was added and distilled off and this procedure was repeated. Infrared and nuclear magnetic resonance (n.m.r.) spectra of the resulting compound were consistent with the structure of 2,6-dichloroethylbenzene and no impurity peaks were observed.

Samples were prepared as degassed 10 mol% solution in benzene-d_6 containing internal tetramethylsilane as a locking signal. Proton magnetic resonance spectra were recorded in the sweep frequency mode at a sweep rate of 0.02 Hz/s over a sweep width of 1 Hz/cm on a DA60IL spectrometer. Peak positions were repeatedly calibrated by reading sweep and manual oscillator frequencies at intervals of a few Hz, using period averaging techniques.

The temperature dependence of the long-range coupling constants in 2,6-dichlorobenzylbromide dissolved in toluene-d_8 was measured between −20 and 80 °C. Temperature calibrations depended on the standard methanol and glycol samples from Varian Associates. Temperatures are accurate to at least ±2 °C.

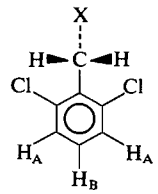
Results and Discussion

(1) Spectral Analysis

Rapid rotation of the CH_2X group in **1** ensures that the spin system can be designated as A_2BX_2. The properties of such a spectrum are well-known (5).



1

$J_{BX} = {}^6J_p^{H,CH_2}$ is easily obtained directly from the splittings of the transitions between antisymmetric states of the spin system. The extraction of $J_{AX} = {}^5J_m^{H,CH_2}$ is only a little more complex. When X = CH_3, no coupling between the methyl protons and ring protons is observable. When X = F the system corresponds to the case A_2BX_2R and has been previously analyzed (6).

The signs of $^5J_m^{H,CH_2}$ and of $^6J_p^{H,CH_2}$ were determined relative to $J_o^{H,H}$ for 2,6-dichlorotoluene and 2,6-dichlorobenzylfluoride by double resonance techniques, as described previously (6). The magnitudes of $^6J_p^{H,CH_2}$ in these two compounds bracket the magnitudes of this coupling in the other compounds (see Table 1) and therefore there is little doubt that the coupling is negative in all compounds. $^5J_m^{H,CH_2}$ does not vary appreciably as X changes in **1** and is no doubt positive for all X.

The coupling constants are given in Table 1. The spectra were taken in benzene-d_6 because the well-known aromatic solvent induced shifts (7) result in a relatively large internal shift for the ring protons, facilitating the extraction of precise values of the small long-range coupling constants from A_2BX_2 spectra.[2] Consequently the chemical shifts do not primarily reflect the electronic nature of the α-substituent and are not given here (the interested reader may write for a copy).

(2) The Six-bond Coupling, J_p^{H,CH_2}

(a) Conformational Dependence

The benzylic coupling over six bonds is transmitted by a π electron mechanism and for toluene one may write (4, 8)

$$[1] \qquad {}^6J_p^{H,CH_3} = B\cos^2\theta$$

where θ is the dihedral angle between the p_π orbital and the plane containing the methyl C—H bond and the carbon atom bearing the p_π orbital. The barrier to rotation of the methyl group in toluene is only 0.014 kcal/mol in the gas phase (9) and hence $\cos^2\theta = \frac{1}{2}$ while $J_p^{H,CH_3} = -0.62$ Hz (2). Consequently $B = -1.3_4$ Hz. In 2,6-dichlorotoluene, $J_p^{H,CH_3} = -0.63 \pm 0.02$ Hz, suggesting relatively rapid and almost free rotation of the methyl group. Furthermore, J_p^{H,CH_3} is constant to within experimental error in 3,5-dichlorotoluene (10), 2,3,5,6-tetrachlorotoluene (11), 2,6-dinitrotoluene (12), and 2,6-dichloro-3-ethyl-5-hydroxytoluene (13). Therefore it is assumed in the following that the ring chlorine atoms act on J_p^{H,CH_2} primarily via steric interactions in **1**.

[2]In many experiments on similar compounds dissolved in solvents ranging in polarity from cyclohexane to acetone we have never found a solvent dependence of the long-range couplings.

Introduction of one α-substituent into 2,6-dichlorotoluene changes the small 6-fold barrier into a 2-fold barrier, expected to be considerably larger. The preferred conformation is as in **2**, with each C—H bond lying at 30° to the plane of the ring. If the rotational barrier is high enough, say $5kT$, the motion of the methylene rotor may be treated as simple harmonic, provided the angular amplitude is small enough (14). The angular displacement from **2** (or **1**) is given classically (14) by

$$[2] \qquad \theta(t) = \theta_0 + \phi \sin x,\ x = 2\pi t/\tau$$

where $\theta_0 = 60°$ in **2**, ϕ is the maximum amplitude of the motion, and τ is the period of the oscillation.

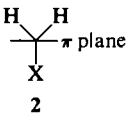
The frequency of oscillation is clearly much larger than J_p^{H,CH_2}. In this approximation one has

$$[3] \qquad J_p^{H,CH_2} = -1.34 \langle \cos^2 \theta(t) \rangle$$

where

$$[4] \qquad \langle \cos^2 \theta(t) \rangle = \langle \cos^2 (60° + \phi \sin x) \rangle$$

For $\theta \leqslant 20°$ one finds, to within 10%, $J_p^{H,CH_2} = \frac{1}{4} \times 1.34 = -0.33$ Hz, *i.e.*, $J_p^{H,CH_2} = \frac{1}{2} J_p^{H,CH_3}$ in toluene. In other words, for small amplitudes of oscillation about the equilibrium conformation **2** of an α-X-2,6-dichlorotoluene, $J_p^{H,CH_2} \approx 0.3$ Hz if X does not affect the magnitude of B in eq. 1.



2

(b) Effect of the Electronegativity of X

It is clear from Table 1 that J_p^{H,CH_2} depends on the substituent, X. If this π electron coupling is dependent on hyperconjugation (15) then it is reasonable that an electron-withdrawing X will polarize the C—H bonds in CH_2X and thereby decrease their hyperconjugative overlap with the p_π orbital of the aromatic ring. In Fig. 1 a plot of J_p^{H,CH_2} *vs.* the electronegativity, E_x, of the substituent, X, is shown. In terms of the model an electronegative substituent decreases the magnitude of B in eq. 1. The plot extrapolates back to X = H giving $J_p^{H,CH_3} = -0.32$ Hz, half the observed value in 2,6-dichlorotoluene, as predicted by the model.

The point for X = CN probably deviates significantly from the least squares line in Fig. 1. A possible explanation calls on the hyperconjugation between CN and CH_3 in methylcyanide, as described by CNDO/2 calculations (16). In 2,6-dichlorobenzylcyanide there then exists an extended hyperconjugated system, encompassing the orbitals of the cyano and methylene groups and the aromatic ring, leading to the enhanced magnitude of J_p^{H,CH_2}.

(c) Amplitude of Oscillation, φ

The present model of a conformationally dependent π electron mechanism for J_p^{H,CH_2}, as modified by the polarization of the C—H bonds by the electronegative α-substituent, is in apparent agreement with the data in Table 1. The agreement depends on the assumed small amplitude of oscillation of the CH_2X group about the minimum energy depicted by **2**.

Rate studies on α,α-dichloro-2,4,6-tribromotoluene yield a barrier of about 16 kcal/mol to the rotation of the dichloromethyl group about the sp^2–sp^3 carbon–carbon bond (17). Calculations (18, 19) based on van der Waals and on modified Buckingham potentials verify that steric interaction of the C—Cl and C—Br bonds where in an eclipsed position gives rise to the barrier. In Fig. 2 is shown a potential energy curve for 2,6-dichlorobenzylbromide. It is based on calculations[3] using van der Waals function (19). The height of the barrier, A, is 22 kcal/mol when tetrahedral bond angles at the α-carbon and 120° bond angles for the ring moiety are assumed. It drops to 15 kcal/mol when all bonds are bent by less than 2°: the bonds at the α-carbon towards the extension of the sp^2–sp^3 bond axis and the ring C—Cl bonds in the plane of the ring away from this axis. Therefore the curve represents the barrier reasonably well in the region of high potential energy where the C—Br bond eclipses the C—Cl bond on the benzene ring.

In Fig. 2 the angle of rotation of 90° corresponds to the conformation **2** of minimum energy. If $A = 16$ kcal, then at an oscillation amplitude $\phi = 20°$ about this position, the potential energy has increased by about 0.4 kcal, somewhat more than the $\frac{1}{2} RT$ needed by the rotor to reach this amplitude of oscillation. Within the limitations of the assumption of simple harmonic oscillation, the potential energy curve supports the model used above for J_p^{H,CH_2}.

[3]We are grateful to Mr. Brian Barber for these computations.

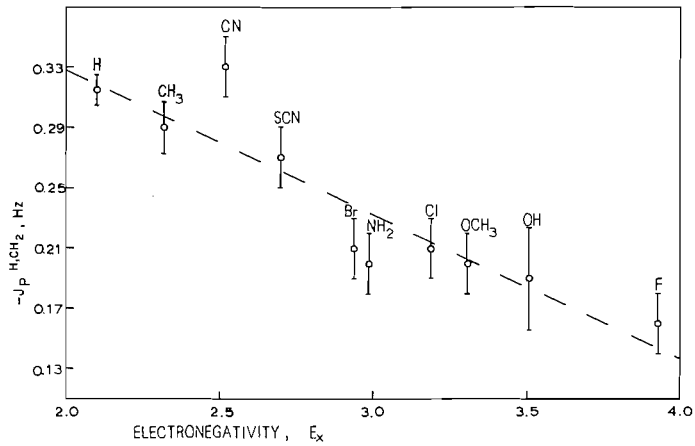


FIG. 1. The coupling constant over six bonds, J_p^{H,CH_2}, in some α-substituted 2,6-dichlorotoluene derivatives, is plotted *vs.* the electronegativity, E_x, of the α-substituent. Parameters are taken from Table 1. The correlation coefficient $r = 0.915$ for the least squares line. If the cyano group, CN, is omitted from the correlation, then $r = 0.954$. Note that $\frac{1}{2}J_p^{H,CH_3}$ is entered for 2,6-dichlorotoluene itself as discussed in the text.

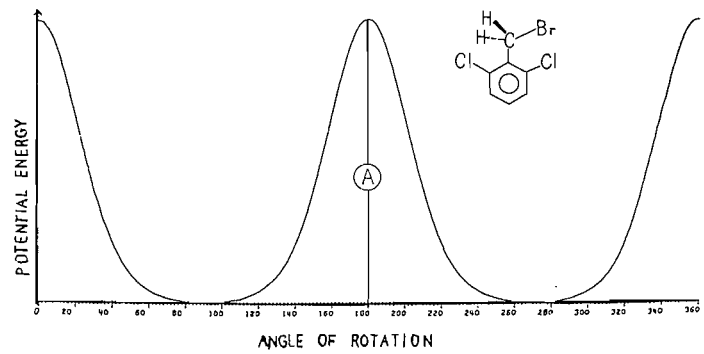

FIG. 2. The potential energy curve for rotation of the bromomethyl group about the sp^2–sp^3 carbon–carbon bond in 2,6-dichlorobenzylbromide as given by a van der Waals potential function. The angle of rotation is 0° when the C—Br bond eclipses a C—Cl bond, *i.e.*, when the former lies in the plane of the aromatic ring. The minimum energy occurs for conformation **1** in the text, where the C—Br bond lies 90° out of the plane of the ring. The barrier, *A*, is about 16 kcal/mol, as discussed in the text.

The fact that J_p^{H,CH_2} in 2,6-dichlorobenzylbromide does not vary between −20 and 80 °C is also in agreement with this picture because φ will remain within the limit of about 20°.

However, a similar calculation for 2,6-dichlorobenzylfluoride yields a barrier *A* of only 3 kcal/mol and, apart from the consideration that such a small barrier may invalidate the classical assumptions, the potential energy curve now apparently allows φ to attain values as large as 50° (although there occur subsidiary maxima at $\phi = \pm 20°$ which, if rather larger, would restrict φ to the smaller value). Since a classical oscillator spends most time near the limits of the motion, one might have expected J_p^{H,CH_2} in the fluoride to be much larger than observed. Yet it has the smallest magnitude in Table 1. Quantum effects on the oscillation will decrease $|J_p^{H,CH_2}|$ insofar as the ground state oscillator then exists most probably in the equilibrium position.

(3) The Five-bond Coupling, J_m^{H,CH_2}

The average value of J_m^{H,CH_2} is 0.35 ± 0.025 Hz, suggesting little, if any, effect of the α-substituent. Coupling between methyl protons in *m*-xylene derivatives (1) implies a π electron contribution of up to 0.25 Hz to J_m^{H,CH_3}. Because the π contribution to J_p^{H,CH_2} decreases as E_x of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the α-substituent increases, one may infer a proportional decrease in the π contribution to J_m^{H,CH_2} in the compounds of Table 1. On this assumption, a compensating increase in the σ electron contribution to J_m^{H,CH_2} occurs and therefore the observed values do not vary appreciably with the α-substituent.

There are known five-bond couplings which increase on α-substitution by a more electronegative substituent. Thus $^5J_p^{H,H} = 0.65$ Hz in benzene (20) and is 0.98 Hz in pyridine (21). Although $J_p^{H,H}$ in benzene is apparently dominated by a π electron mechanism (1), perturbation of the σ core by the substituent may, of course, give rise to a nonzero σ electron contribution to this five-bond coupling.

Just as for J_p^{H,CH_3}, ring substitution does not markedly alter J_m^{H,CH_3}. Thus $J_m^{H,CH_3} = 0.36$ Hz in toluene (2), 0.36 ± 0.02 Hz in 2,3,4,6-tetrachlorotoluene (11), 0.41 ± 0.02 Hz in 2,3,6-trichloro-4-nitrotoluene (12), 0.40 ± 0.02 Hz in 2,4,6-trimethoxytoluene (12), 0.36 ± 0.02 Hz in 2,4,6-tribromobenzylbromide (12), and 0.40 ± 0.02 Hz in 2,6-dinitro-4-*t*-butyltoluene (12).

We are grateful to the National Research Council of Canada for financial assistance.

On the Theory of Linear Electro-Optical Rotation.[1] II. The Three-Photon Effect

HENDRIK F. HAMEKA
Department of Chemistry, University of Pennsylvania, Philadelphia, Pa., 19104

Received August 28, 1970

We present a theoretical description of an effect that we call three-photon electro-optical rotation. We consider a high-intensity beam of polarized monochromatic light, which interacts with an assembly of identical molecules. We calculate the probability of the absorption of two photons from this beam of light and the simultaneous reemission of a third photon, which has the same direction of propagation as the incident light and a direction of polarization that is perpendicular to the incident light. The energy of the emitted photon is the sum of the energies of the absorbed photons. We found that the effect is observable in the presence of a homogeneous electric field F, directed along the direction of polarization of the emitted beam of light. The effect is proportional to F and to the molecular dipole moment and it is inversely proportional to the absolute temperature T.

Nous présentons une description théorique d'un effet que nous appelons la rotation électro-optique impliquant trois photons. Nous considérons un faisceau de lumière monochromatique polarisée d'intensité élevée qui intéragit avec un ensemble de molécules identiques. Nous calculons la probabilité de l'absorption de deux photons de ce faisceau de lumière et la réémission simultanée d'un troisième photon, qui a la même direction de propagation que la lumière incidente et une direction de polarisation qui est perpendiculaire à la lumière incidente. L'énergie du photon émis est la somme des énergies des photons absorbés. Nous avons trouvé que l'effet est observable en la présence d'un champ électrique F homogène, dirigé selon la direction de polarisation du faisceau de lumière émise. L'effet est proportionnel à F et au moment dipolaire moléculaire et il est inversément proportionnel à la température absolue T.

Canadian Journal of Chemistry, 49, 1823 (1971)

Introduction

Conventional optical rotation is a two-photon process because it involves the absorption and simultaneous reemission of a photon by a molecule. The two photons have the same energies and directions of propagation, they differ in their directions of polarization, which are perpendicular to one another. If the molecule is placed in an electric or a magnetic field we speak of electro-optical rotation or magneto-optical rotation, respectively. Both these effects are also two-photon processes.

In the first paper of this series (1) we considered the two-photon electro-optical rotation and specifically the effect that is linear in the electric field. It follows easily from symmetry considerations that this effect is zero unless the electric field F is parallel to the beam of light. Hence we considered the case where F is parallel and our calculations showed that the effect is zero also in that case.

In the present paper we wish to consider higher-order effects in electro-optical rotation, in particular three-photon processes. These processes involve the absorption of two photons k_λ and k_μ by a molecule and the simultaneous reemission of a third photon $k_{\nu'}$. Since we treat the effect as photon scattering by a single molecule our approach is valid only for an assembly of noninteracting molecules, that is, a gas or a liquid.

In our theoretical approach we look upon the effect as some form of optical rotation because we are considering situations where all three protons have the same directions of propagation and where the direction of polarization of the emitted photons is different from the direction of polarization of the incident photons. It should be noted though that the same effect has already been studied from a different view point. Here it is considered as some form of second harmonic generation and since the polarizations of the photons are relatively of minor importance in this approach it is known as electric-field induced second harmonic generation.

If two beams of high-intensity light of frequency ω_1 and ω_2 pass through a medium, they can combine under certain conditions to produce a new beam of light with frequency $\omega_1 + \omega_2$. This is known as second-harmonic generation (2, 3). It was discovered a few years ago that in the presence of an electric field sum frequency

[1]Research supported by the National Science Foundation.

generation can occur if the two incident beams of light coincide. Here we have the situation where a high intensity beam of light of frequency ω produces light of frequency 2ω in the presence of an electric field. The effect is known as electric-field induced optical second harmonic generation; it was first measured in solids by Terhune *et al.* (4) and it was measured in gases and liquids by Mayer (5).

The theoretical description of electric-field induced second harmonic generation in gases was derived by Kielich (6). This derivation is essentially based on the classical Maxwell equations which are solved in higher order. In this way the theoretical results are expressed in terms of higher order electric susceptibilities, which must then be related to molecular quantities. This approach has been used also to derive the theory of conventional optical rotation.

In our theoretical derivation the effect is treated by considering the scattering of photons by individual molecules where we used the quantized radiation field. We have previously used this approach to derive the theory of ordinary optical rotation (7) and we found that this description is mathematically simpler than the theories that were derived from the classical Maxwell equations. Also, we feel that a second theoretical derivation of electric-field induced second harmonic generation or three-photon electro-optical rotation will add to our understanding of the effect.

It is easily seen from symmetry considerations what the most favorable direction of the electric field is. We will consider the experimental situation where the incident beam of light is propagating along the Z direction and polarized along the X direction. The effluent photons propagate also along the Z direction and they are polarized along the Y direction. Consequently, the photons k_λ and k_μ are X polarized and the photon $k_{\nu'}$ is Y polarized. We will show that the probability for this scattering process is non-zero only in first order if the exterior field is directed along the Y axis. We will first derive the general theory for the above described three-photon effect in the absence of exterior fields. In the subsequent section we then calculate the effect of an electric field. Finally, we should point out that we have already calculated this situation if the exterior field is a magnetic field (8) but in that case there was reason to believe that the effect is too small to be observable.

Three-Photon Effect

We wish to calculate the probability for the absorption of two photons k_λ and k_μ and the simultaneous reemission of a photon $k_{\nu'}$ by a molecule. We make use of the Heitler–Ma perturbation method (9) and we use the notation that we introduced previously (10). The molecular eigenvalues and eigenfunctions are denoted by E_n and ψ_n, respectively, and the initial state of the radiation field is denoted by 0. Furthermore, we denote photons that are polarized in the X direction by k_λ, k_μ, etc., photons that are polarized in the Y direction are denoted by primes, such as $k_{\nu'}$, $k_{\alpha'}$, etc. Consequently, the initial state is (0,0) and the final state is $(\bar{\lambda},\bar{\mu},\nu',0)$. Here we use a bar to indicate that a photon is removed from the reference state 0 of the radiation field. Additional states that occur in our calculation are $(\bar{\lambda},\nu',n)$, $(\bar{\lambda},\bar{\mu},n)$, $(\bar{\lambda},n)$ etc. Obviously the state 0 is the molecular ground state.

It has been shown (9, 10) that the probability of a radiative process from an initial state (0,0) to a final state α may be derived from a quantity $U(\alpha;E)$, which is determined from the equations

$$[1] \qquad U(\alpha;E) = H(\alpha;0,0) + \sum_{\beta \neq (0,0)} H(\alpha;\beta)U(\beta;E)\zeta(E - E_\beta)$$

where ζ is the Dirac ζ function. In our situation the above equation becomes

$$[2] \quad U(\bar{\lambda}\bar{\mu},\nu',0;E) = \sum_{n \neq 0} [H(\bar{\lambda}\bar{\mu},\nu',0;\bar{\lambda},\nu',n)U(\bar{\lambda},\nu',n;E)\zeta(E - E_{\lambda\nu' n}) + H(\bar{\lambda}\bar{\mu},\nu',0;\bar{\mu},\nu',n)U(\bar{\mu},\nu',n;E)\zeta(E - E_{\mu\nu' n}) + H(\bar{\lambda}\bar{\mu},\nu',\bar{\lambda}\bar{\mu},n)U(\bar{\lambda}\bar{\mu},n;E)\zeta(E - E_{\lambda\mu n})]$$

The functions U on the right hand side of eq. 2 may be further expressed by using eq. 1,

$$[3]\quad U(\bar{\lambda},\nu',n;E) = \sum_{m\neq 0}[H(\bar{\lambda},\nu',n;\bar{\lambda},m)U(\bar{\lambda},m;E)\zeta(E - E_{\lambda m}) + H(\bar{\lambda},\nu',n;\nu',m)U(\nu',m;E)\zeta(E_\nu - E_{\nu' m})], \text{ etc.}$$

Finally, we observe that

$$[4]\quad \begin{aligned} U(\bar{\lambda},m;E) &= H(\bar{\lambda},m;0,0)\\ U(\bar{\mu},m;E) &= H(\bar{\mu},m;0,0)\\ U(\nu',m;F) &= H(\nu',m;0,0)\end{aligned}$$

Substitution of eqs. 3 and 4 into eq. 2 gives

$$\begin{aligned}[5]\quad U(\bar{\lambda}\bar{\mu},\nu',0,E) = \sum_{n\neq 0}\sum_{m\neq 0\neq n}\Big(&H(\bar{\lambda}\bar{\mu},\nu',0;\bar{\lambda},\nu',n)H(\bar{\lambda},\nu',n;\bar{\lambda},m)H(\bar{\lambda},m;0,0)\zeta(E - E_{\lambda\nu' n})\zeta(E - E_{\lambda m})\\ &+ H(\bar{\lambda}\bar{\mu},\nu',0;\bar{\lambda},\nu',n)H(\bar{\lambda},\nu',n;\nu',m)H(\nu',m;0,0)\zeta(E - E_{\lambda\nu' n})\zeta(E - E_{\nu' m})\\ &+ H(\bar{\lambda}\bar{\mu},\nu',0;\bar{\mu},\nu',n)H(\bar{\mu},\nu',n;\bar{\mu},m)H(\bar{\mu},m;0,0)\zeta(E - E_{\mu\nu' m})\zeta(E - E_{\mu m})\\ &+ H(\bar{\lambda}\bar{\mu},\nu',0;\bar{\mu},\nu',n)H(\bar{\mu},\nu',n;\nu',m)H(\nu' m;0,0)\zeta(E - E_{\mu\nu' n})\zeta(E - E_{\nu' m})\\ &+ H(\bar{\lambda}\bar{\mu},\nu',0;\bar{\lambda}\bar{\mu},n)H(\bar{\lambda}\bar{\mu},n;\bar{\lambda},m)H(\bar{\lambda},m;0,0)\zeta(E - E_{\lambda\mu n})\zeta(E - E_{\lambda m})\\ &+ H(\bar{\lambda}\bar{\mu},\nu',0;\bar{\lambda}\bar{\mu},n)H(\bar{\lambda}\bar{\mu},n;\bar{\mu},m)H(\bar{\mu},m;0,0)\zeta(E - E_{\lambda\mu n})\zeta(E - E_{\mu m})\Big)\end{aligned}$$

The matrix elements in eq. 5 should be taken with respect to the interaction Hamiltonian

$$[6]\quad H_{\text{int}} = (e\hbar/mi)(4\pi)^{\frac{1}{2}}\textstyle\sum_j\sum_\lambda[q_\lambda \exp(ik_\lambda\cdot r_j/\hbar c) + q_\lambda^* \exp(-ik_\lambda\cdot r_j/\hbar c)](e_\lambda\cdot\nabla_j)$$

In order to transform eq. 5 further we may take the exponentials in eq. 6 equal to unity. Furthermore, we make use of the relation

$$[7]\quad \langle\psi_n|(\partial/\partial x_j)|\psi_m\rangle = -(m/e\hbar^2)(E_n - E_m)\langle\psi_n|ex_j|\psi_m\rangle$$

This enables us to transform eq. 5 to

$$\begin{aligned}[8]\quad U(\bar{\lambda}\bar{\mu},\nu',0;E_{\lambda\mu 0'0}) = -i(8\pi^3/k_\lambda k_\mu k_{\nu'})^{\frac{1}{2}}(n_\lambda n_\mu)^{\frac{1}{2}}(n_{\nu'}+1)^{\frac{1}{2}}\sum_{n\neq 0}\sum_{m\neq n\neq 0}(E_0 - E_n)(E_n - E_m)(E_m - E_0)\\ [P_{0,n;x}P_{n,m;y}P_{m,0;x}\zeta(-k_\mu + E_0 - E_n)\zeta(-k_\mu + k_{\nu'} + E_0 - E_m)\\ + P_{0,n;x}P_{n,m;x}P_{m,0;y}\zeta(-k_\mu + E_0 - E_n)\zeta(-k_\lambda - k_\mu + E_0 - E_m)\\ + P_{0,n;x}P_{n,m;y}P_{m,0;x}\zeta(-k_\lambda + E_0 - E_n)\zeta(-k_\lambda + k_{\nu'} + E_0 - E_m)\\ + P_{0,n;x}P_{n,m;x}P_{m,0;y}\zeta(-k_\lambda + E_0 - E_n)\zeta(-k_\lambda - k_\mu + E_0 - E_m)\\ + P_{0,n;y}P_{n,m;x}P_{m,0;x}\zeta(k_{\nu'} + E_0 - E_n)\zeta(-k_\mu + k_{\nu'} + E_0 - E_m)\\ + P_{0,n;y}P_{n,m;x}P_{m,0;x}\zeta(k_{\nu'} + E_0 - E_n)\zeta(-k_\lambda + k_{\nu'} + E_0 - E_m)]\end{aligned}$$

where

$$[9]\quad P_{k,l} = \langle\psi_k|\textstyle\sum_j er_j|\psi_l\rangle$$

We wish to consider the specific situation where the radiation field, that is its state 0, consists of an almost monochromatic beam of photons, which are polarized in the X direction and propagating in the Z direction. The energies of these photons are all very close to an energy k_0 so that we may substitute

$$[10]\quad k_\lambda \simeq k_\mu \simeq k_0$$

In addition, we need consider only those values of U for which the energy is preserved (10) so that

$$[11]\quad k_{\nu'} \simeq 2k_0$$

Since we are not concerned with resonance situations we may replace in eq. 9 the function $\zeta(x)$ by $(1/x)$. We find then that for an assembly of N non-interacting randomly oriented molecules eq. 9 becomes

$$[12]\quad U(\bar{\lambda}\bar{\mu},\nu',0;E_{\lambda\mu\nu'0}) = 2iN(4\pi^3/k_0{}^3)^{\frac{1}{2}}(n_\lambda n_\mu)^{\frac{1}{2}}\sum_{n\neq 0}\sum_{m\neq n\neq 0}(E_n - E_0)(E_m - E_0)(E_n - E_m)$$
$$\times G_{op}[(-k_0 + E_0 - E_n)^{-1}(k_0 + E_0 - E_m)^{-1}P_{0,n;x}P_{m,0;x}P_{n,m;y}$$
$$+ (-k_0 + E_0 - E_n)^{-1}(-2k_0 + E_0 - E_m)^{-1}P_{0,n;x}P_{m,0;y}P_{n,m;x}$$
$$+ (2k_0 + E_0 - E_n)^{-1}(k_0 + E_0 - E_m)^{-1}P_{0,n;y}P_{m,0;x}P_{n,m;x}]$$

Finally, this may be transformed to

$$[13]\quad U(\bar{\lambda}\bar{\mu},\nu',0;E_{\lambda\mu\nu'0}) = 2iN(4\pi^3 n_\lambda n_\mu/k_0)^{\frac{1}{2}}G_{op}\Big[\sum_{n\neq 0}\sum_{m\neq n}(A_{n,m}P_{0,n;x}P_{m,0;x}P_{n,m;y} + B_{n,m}P_{n,m;x}P_{m,0;x}P_{0,n;y})\Big]$$

with

$$[14]\quad A_{n,m} = (E_n - E_0)(E_m - E_0)(E_n - E_m)^2[(E_n - E_0)^2 - k_0{}^2]^{-1}[(E_m - E_0)^2 - k_0{}^2]^{-1}$$
$$B_{n,m} = (E_n - E_0)(E_m - E_0)(E_n - E_m)[2(E_n - E_0) + 4(E_m - E_0)][(E_n - E_0)^2 - 4k_0{}^2]^{-1}$$
$$\times [(E_m - E_0)^2 - k_\lambda{}^2]^{-1}$$

It is easily verified that eq. 13 yields zero in the absence of exterior fields because

$$[15]\quad G_{op}(a_x b_x c_y) = 0$$

However, we will show in the following section that eq. 13 yields in principle a non-zero result if we place our sample in a homogeneous electric field that has a suitable direction.

Electro-Optical Rotation

The probability $U(\bar{\lambda}\bar{\mu}\nu',0;E_{\lambda\mu\nu'0})$ of the three-photon process in the presence of a homogeneous electric field $\boldsymbol{F}$ may be derived from eq. 14 if we take E_n and ψ_n as the eigenvalues and eigenfunctions of the molecule in the presence of $\boldsymbol{F}$ and if we consider the Maxwell distribution of the molecular orientations with respect to $\boldsymbol{F}$.

The Hamiltonian H in the presence of $\boldsymbol{F}$ may be written as

$$[16]\quad H = H_0 - e\textstyle\sum_j r_j\cdot\boldsymbol{F} = H_0 - \boldsymbol{\mu}\cdot\boldsymbol{F}$$

We take E_n and ψ_n as the eigenvalues and eigenfunctions of the operator H and we denote the eigenvalues and eigenfunctions of H_0 by ε_n and ϕ_n. The relations between these two sets of eigenvalues and eigenfunctions are

$$[17]\quad E_n = \varepsilon_n - \boldsymbol{\mu}_{n,n}\cdot\boldsymbol{F}$$
$$\psi_n = \phi_n + \sum_{m\neq n}(\varepsilon_m - \varepsilon_n)^{-1}\phi_m(\boldsymbol{\mu}_{m,n}\cdot\boldsymbol{F})$$

with

$$[18]\quad \boldsymbol{\mu}_{m,n} = \langle\phi_m|\boldsymbol{\mu}|\phi_n\rangle$$

Equation 17 is accurate up to effects that are linear in $\boldsymbol{F}$, which is sufficient for our purpose. It is easily seen now that the three-photon electro-optical rotation is given by

$$[19]\quad U(\bar{\lambda}\bar{\mu},\nu',0;E_{\lambda\mu\nu'0}) = 2iN(4\pi^3 n_\lambda n_\mu/k_0)^{\frac{1}{2}}\Big[G_{op}\sum_{n\neq 0}\sum_{m\neq n}(A_{n,m}P_{0,n;x}P_{m,0;x}P_{n,m;y} + B_{n,m}P_{n,m;x}P_{m,0;x}P_{0,n;y})\exp(\boldsymbol{\mu}_{0,0}\cdot\boldsymbol{F}/kT)\Big][G_{op}\exp(\boldsymbol{\mu}_{0,0}\cdot\boldsymbol{F}/kT)]^{-1}$$

This expression should be transformed further by expressing the vectors $\boldsymbol{P}$ in terms of the vectors $\boldsymbol{\mu}$ and by expressing the energies E in terms of ε and μ. After these substitutions we should evaluate the effects of the operator G_{op}.

We derived previously (1) that for products of four vectors we have

[20] $$G_{op}(a_x b_x c_x d_x) = (1/15)[(\boldsymbol{a}\cdot\boldsymbol{b})(\boldsymbol{c}\cdot\boldsymbol{d}) + (\boldsymbol{a}\cdot\boldsymbol{c})(\boldsymbol{b}\cdot\boldsymbol{d}) + (\boldsymbol{a}\cdot\boldsymbol{d})(\boldsymbol{b}\cdot\boldsymbol{c})]$$

$$G_{op}(a_x b_x c_y d_y) = (1/30)[4(\boldsymbol{a}\cdot\boldsymbol{b})(\boldsymbol{c}\cdot\boldsymbol{d}) - (\boldsymbol{a}\cdot\boldsymbol{c})(\boldsymbol{b}\cdot\boldsymbol{d}) - (\boldsymbol{a}\cdot\boldsymbol{d})(\boldsymbol{b}\cdot\boldsymbol{c})] \text{ and cycl.}$$

All other products of four vector components are zero.

Equation 19 is now evaluated by expanding all its terms as power series in $\boldsymbol{F}$ and by limiting ourselves to the linear terms. It follows from eq. 20 that we obtain a non-zero result only if we take $\boldsymbol{F}$ along the Y direction. In that case $U(\bar{\lambda}\bar{\mu}\nu',0;E_{\lambda\mu\nu'0})$ may be written as a sum of three terms,

[21] $$U(\bar{\lambda}\bar{\mu},\nu',0;E_{\lambda\mu\nu},0) = U_1 + U_2 + U_3$$

Here U_1 results from expanding the Boltzmann exponentials, U_2 from expanding the energies in $A_{n,m}$ and $B_{n,m}$, and U_3 from expanding the eigenfunctions in the vectors $\boldsymbol{P}_{n,m}$.

Let us first consider U_1, which may be written as

[22] $$U_1 = (2iNF/kT)(4\pi^3 n_\lambda n_\mu/k_0)^{\frac{1}{2}}\Big[G_{op}\sum_{n\neq 0}\sum_{m\neq n}(A_{n,m}{}^0\mu_{0,n;x}\mu_{m,0;x}\mu_{n,m;y}\mu_{0,0;y} + B_{n,m}{}^0\mu_{n,m;x}\mu_{m,0;x}\mu_{0,n;y}\mu_{0,0;y})\Big]$$

Here $A_{n,m}{}^0$ and $B_{n,m}{}^0$ are derived from eq. 14 by replacing everywhere the energies E by ε. It follows from eq. 20 that eq. 22 is reduced to

[23] $$U_1 = (iNF/15kT)(4\pi^3 n_\lambda n_\mu/k_0)^{\frac{1}{2}}\Big[G_{op}\sum_{n\neq 0}\sum_{m\neq n}(A_{n,m}{}^0\{4(\boldsymbol{\mu}_{n,m}\cdot\boldsymbol{\mu}_{m,0})(\boldsymbol{\mu}_{0,n}\cdot\boldsymbol{\mu}_{0,0}) - (\boldsymbol{\mu}_{0,n}\cdot\boldsymbol{\mu}_{n,m})(\boldsymbol{\mu}_{m,0}\cdot\boldsymbol{\mu}_{0,0}) - (\boldsymbol{\mu}_{0,n}\cdot\boldsymbol{\mu}_{0,0})(\boldsymbol{\mu}_{m,0}\cdot\boldsymbol{\mu}_{n,m})$$
$$+ B_{n,m}{}^0\{4(\boldsymbol{\mu}_{n,m}\cdot\boldsymbol{\mu}_{m,0})(\boldsymbol{\mu}_{0,n}\cdot\boldsymbol{\mu}_{0,0}) - (\boldsymbol{\mu}_{n,m}\cdot\boldsymbol{\mu}_{0,n})(\boldsymbol{\mu}_{m,0}\cdot\boldsymbol{\mu}_{0,0}) - (\boldsymbol{\mu}_{n,m}\cdot\boldsymbol{\mu}_{0,0})(\boldsymbol{\mu}_{m,0}\cdot\boldsymbol{\mu}_{0,n})\}\Big]$$

or

[24] $$U_1 = (iNF/15kT)(4\pi^3 n_\lambda n_\mu/k_0)^{\frac{1}{2}}\sum_{n\neq 0}\sum_{m\neq 0\neq n}[(4A_{n,m}{}^0 - B_{n,m}{}^0)(\boldsymbol{\mu}_{0,n}\cdot\boldsymbol{\mu}_{m,0})(\boldsymbol{\mu}_{n,m}\cdot\boldsymbol{\mu}_{0,0}) + (4B_{n,m}{}^0 - A_{n,m}{}^0)(\boldsymbol{\mu}_{0,n}\cdot\boldsymbol{\mu}_{0,0})(\boldsymbol{\mu}_{n,m}\cdot\boldsymbol{\mu}_{m,0}) - (A_{n,m}{}^0 + B_{n,m}{}^0)(\boldsymbol{\mu}_{0,n}\cdot\boldsymbol{\mu}_{n,m})(\boldsymbol{\mu}_{m,0}\cdot\boldsymbol{\mu}_{0,0})]$$
$$= (iNF/15kT)(4\pi^3 n_\lambda n_\mu/k_0)^{\frac{1}{2}}\sum_{n\neq 0}\sum_{m\neq 0\neq \pm n}[(4A_{n,m}{}^0 - B_{n,m}{}^0)(\boldsymbol{\mu}_{0,n}\cdot\boldsymbol{\mu}_{m,0})(\boldsymbol{\mu}_{n,m}\cdot\boldsymbol{\mu}_{0,0}) + (4B_{n,m}{}^0 - A_{n,m}{}^0 - A_{m,n}{}^0 - B_{m,n}{}^0)(\boldsymbol{\mu}_{0,n}\cdot\boldsymbol{\mu}_{0,0})(\boldsymbol{\mu}_{n,m}\cdot\boldsymbol{\mu}_{m,0})]$$

Here it has been assumed that the eigenfunctions ϕ_n are all real.

Let us now proceed to the calculation of U_2. It follows easily from eqs. 17 and 19 that it is given by

[25] $$U_2 = -2iNF(4\pi^3 n_\lambda n_\mu/k_0)^{\frac{1}{2}}G_{op}\sum_{n\neq 0}[(\partial A_{n,m}{}^0/\partial\varepsilon_0)\mu_{0,n;x}\mu_{m,0;x}\mu_{n,m;y}\mu_{0,0;y} + (\partial A_{n,m}{}^0/\partial\varepsilon_n)\mu_{0,n;x}\mu_{m,0;x}\mu_{n,m;y}\mu_{n,n;y} + (\partial A_{n,m}{}^0/\partial\varepsilon_m)\mu_{0,n;x}\mu_{m,0;x}\mu_{n,m;y}\mu_{m,m;y}$$
$$+ (\partial B_{n,m}{}^0/\partial\varepsilon_0)\mu_{n,m;x}\mu_{m,0;x}\mu_{0,n;y}\mu_{0,0;y} + (\partial B_{n,m}{}^0/\partial\varepsilon_n)\mu_{n,m;x}\mu_{m,0;x}\mu_{0,n;y}\mu_{n,n;y} + (\partial B_{n,m}{}^0/\partial\varepsilon_m)\mu_{n,m;x}\mu_{m,0;x}\mu_{0,n;y}\mu_{m,m;y}]$$

This may be transformed further by calculating the various derivatives and by making use of eq. 20 and it should lead to a rather involved and unwieldy expression. However, even at this point it may be seen already that U_2 should be much smaller than U_1, the order of magnitude of their ratio is given by

[26] $$(U_2/U_1) \simeq (kT/\Delta\varepsilon)$$

Here $\Delta\varepsilon$ is the order of magnitude of the energy differences $(\varepsilon_n - \varepsilon_0)$, $(\varepsilon_m - \varepsilon_0)$ or $(\varepsilon_n - \varepsilon_m)$ which we roughly take as 1 eV. At room temperature the ratio of eq. 26 should be about 2% and it follows that U_2 is generally much smaller than U_1. We feel that it is somewhat pointless to transform eq. 25 any further because the result is too complicated to be of much help to us and in general we may expect it to be negligible compared to eq. 25.

Similar arguments apply to the calculation of U_3. It may be derived from eq. 13 by substituting

[27] $$\boldsymbol{P}_{k,l} = \boldsymbol{\mu}_{k,} + \sum_{j\neq k} (\varepsilon_j - \varepsilon_k)^{-1} F \mu_{j,k;y} \mu_{j,e} + \sum_{j\neq l} (\varepsilon_j - \varepsilon)^{-1} F \mu_{j,k;y} \boldsymbol{\mu}_{k,j}$$

and by collecting the terms that are linear in $\boldsymbol{F}$. Again, this leads to an unwieldy expression that is not going to be of much help towards understanding the effect. However, it is easily seen that the ratio (U_3/U_1) is again given by eq. 26. We feel that it is both convenient and justifiable to neglect U_2 and U_3 with respect to U_1, so that the probability of three-photon electro-optical rotation is given by eq. 24.

Discussion

Our considerations agree with Kielich's work (6) in the conclusion that in general the term U_1 is much larger than the others. It should be relatively easy to verify this conclusion because this term is temperature dependent and Kielich refers to it as the temperature effect. Unfortunately, Mayer (5) does not mention any temperature dependence and we presume that all of Mayer's measurements were performed at room temperature.

It seems that the theoretical expressions that we derived for U_1 are too complicated to make their numerical evaluation feasible. However, they are suitable for order of magnitude estimates and they can be used to derive some general features of the effect.

The order of magnitude of the effect may be estimated by making a comparison with the conventional Kerr effect. We consider U_1 and the corresponding expression $U_{1,k}$ for the conventional Kerr effect. It is easily seen then that

[28] $$\frac{U_1}{U_{1,k}} = \left(\frac{\boldsymbol{F}_{\text{rad}}}{\Delta\varepsilon}\right)\cdot\left(\frac{kT}{\boldsymbol{F}}\right) = \left(\frac{\boldsymbol{F}_{\text{rad}}}{\boldsymbol{F}}\right)\cdot\left(\frac{kT}{\Delta\varepsilon}\right)$$

Here $\boldsymbol{F}_{\text{rad}}$ is the electric field vector of the radiation field, $\boldsymbol{F}$ is the applied electric field and $\Delta\varepsilon$ is the energy difference that we introduced in eq. 26. The second term of eq. 28 is about 1% and the first term varies between 1 and 20 in Mayer's experiment, so that the ratio of eq. 28 is of the order of 0.1. We expect therefore that the effect is large enough to be measured if a laser is used. Since the effect has already been measured by Mayer this prediction is not of much practical use.

Kielich's result is expressed in terms of higher order electric susceptibilities whereas our result has a more detailed form and it is expressed in terms of matrix elements of the molecular eigenfunctions. Both expressions have their advantages and disadvantages but our result is more suitable for considering the intensity distribution of the incoming and outgoing radiation. Let the incoming radiation be described by

[29] $$I(k_\lambda) = \frac{I_0}{(k_\lambda - k_0)^2 + h^2\Gamma^2}$$

All its photons are polarized in the X direction. The outgoing radiation is the sum of $I(k_\lambda)$ of eq. 29 and of a much weaker line which is polarized in the Y direction and which has an intensity distribution

[30] $$I'(k_{\nu'}) = \frac{I_0^2 U_1^2}{(k_{\nu'} - 2k_0)^2 + h^2\gamma^2}$$

It follows that the term "optical rotation" is not entirely accurate for describing our effect because we do not predict a continuous rotation of the plane of polarization of the light. Instead we find that the effluent light is rotated by 90° and that its intensity is a continuous function of the optical activity of the sample. Of course, the frequency of the reemitted light is double the frequency of the incident light, which is quite different from any of the conventional optical activity effects.

Finally, let us determine the type of molecule for which the effect should be the largest. It follows from eq. 24 that U_1 is proportional to $\mu_{0,0}$ so that it is desirable that the molecule has a large electric dipole moment in its ground state. Obviously, the effect is zero if the molecule has a

center of symmetry, or even if the molecule has two symmetry planes or a symmetry axis. It is desirable that the molecule has a low lying state of appropriate symmetry. Also, U_1 is proportional to $(1/T)$ and the intensity of the emitted light is proportional to $(1/T)^2$ so that it is desirable to perform the experiment at low temperatures. We leave it to the reader to decide which molecules best satisfy the above conditions.

Aqueous Nonelectrolyte Solutions. Part IX. Enthalpies of Mixing of Water and Deuterium Oxide with Ethylene Oxide[1]

D. N. GLEW AND HARRY WATTS

Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received September 30, 1970

Calorimetric enthalpies of mixing have been measured over the whole composition range for the water – ethylene oxide system at 10.75 and 20.00 °C and for the deuterium oxide – ethylene oxide system at 13.45 and 20.00 °C. Less extensive measurements have been made for dilute ethylene oxide solutions in water at 0.6 °C and in deuterium oxide at 4.1 and 7.3 °C. The experimental S-shaped, enthalpy of mixing – composition curves are interpreted in terms of solution hydrogen bonding changes, with particular reference to the hydrogen bonding of water. At low ethylene oxide mole fractions the deuterium oxide systems are more exothermal and at high ethylene oxide mole fractions more endothermal than the corresponding water systems. A good correlation is found between the enthalpy of mixing and the water proton magnetic resonance chemical shift for solutions with greater than 0.55 mol fraction of ethylene oxide.

Des mesures calorimétriques d'enthalpies de mélange ont été effectuées sur tout le domaine de concentration pour les systèmes eau-oxyde d'éthylène à 10.75 et à 20.00 °C et oxyde de deutérium-oxyde d'éthylène à 13.45 et à 20.00 °C. Quelques mesures ont été faites pour des solutions diluées d'oxyde d'éthylène dans l'eau à 0.6 °C et dans l'oxyde de deutérium à 4.1 et à 7.3 °C. Les courbes expérimentales en forme de S de l'enthalpie de mélange en fonction de la concentration sont interprétées en termes de changements de ponts hydrogène dans la solution impliquant tout particulièrement les ponts hydrogène de l'eau. Les systèmes oxyde d'éthylène-oxyde de deutérium sont plus exothermiques que les systèmes oxyde d'éthylène-eau correspondants aux faibles fractions molaires d'oxyde d'éthylène et plus endothermiques aux fractions molaires élevées. Il existe une bonne corrélation entre l'enthalpie de mélange et le déplacement chimique en résonance magnétique nucléaire de l'eau pour les solutions dont la fraction molaire d'oxyde d'éthylène est supérieure à 0.55.

Canadian Journal of Chemistry, 49, 1830 (1971)

Introduction

As part of our study of the properties of solid and liquid aqueous nonelectrolyte solutions (1, 2), measurements in a new mixing calorimeter (3) are reported for the enthalpies of mixing of ethylene oxide (EO) with water and with deuterium oxide. The only earlier calorimetric study of the mixing of H_2O–EO is by Berthelot (4) in 1882, who reported two measurements at 13 °C giving a molar enthalpy of mixing $\Delta_m h = -39.0$ J at EO mole fraction $x_2 = 0.0062$.

The mixing of EO with both H_2O and D_2O has been measured to give a greater insight to the nature of the aqueous dissolution process. Benjamin and Benson (5) measured the enthalpy of mixing for CH_3OH with H_2O and for CH_3OD with D_2O, but the small differences between the enthalpies of mixing for these systems are related not only to the differences between H_2O and D_2O but also to the differences between CH_3OH and CH_3OD. The present investigation with EO is believed to be the first reported for the enthalpies of mixing of both H_2O and D_2O with the same substance.

The behavior observed for the enthalpy of mixing in simple, non-polar, hydrocarbon systems has been interpreted and quantitatively represented using the lattice theory of liquids and the principle of congruence (6, 7). For more polar systems, in which the liquids being mixed are subject to specific molecular interactions, the model of the ideal mixture of associated species has reasonably accounted for the enthalpy of mixing of hydrogen bonded (H-bonded) aniline with toluene, but does not adequately represent the mixing of aniline with cyclohexane (8, 9). The lattice theory of liquids has been partially successful in accounting for the enthalpy of mixing of some H-bonded systems containing alcohols (10). However, for the polar, strongly associated, H-bonded, aqueous systems with EO (1), propylene oxide, acetone, tetrahydrofuran, 1,4-dioxane, and *t*-butyl alcohol (2), and with alcohols (11), there is no solution theory yet developed which permits the *ab initio* calculation of the enthalpy of mixing behavior. This arises

[1]Contribution No. 188.

both from the lack of a quantitative theory of water (12) and from the lack of physically realistic models representing aqueous nonelectrolyte solutions (13, 14). In this paper we provide a semi-quantitative explanation for the S-shaped enthalpy of mixing curves for aqueous EO in terms of solution H-bonding changes (1, 2).

Experimental

Materials

Ethylene oxide was selected from the production of Dow Chemical of Canada, Limited; analysis for aldehydes, water, and nonvolatiles showed that the total of these impurities was less than 80 p.p.m.

Deuterium oxide was obtained from Atomic Energy of Canada, Limited; analysis 99.72 mol% D_2O, 0.28 mol% H_2O.

Water was triply distilled and had a specific conductivity 3.5×10^{-7} ohm^{-1} at room temperature of about 25 °C.

Apparatus and Procedure

The calorimeter has been described previously (3). A small modification in the filling procedure was required owing to the low boiling point of EO. The section of the filling system used for handling EO was packed with ice and the calorimeter was cooled to 10 °C. When the required amount of EO had been introduced into the calorimeter, the opening of the expansion chamber was closed with a plug (Fig. 1, ref. 3) and the calorimeter allowed to warm up to room temperature for weighing.

Previously only the conduct of endothermal mixing experiments was described. Exothermal mixings were encountered in the present systems. Standard calorimetric technique was used in which the temperature rise due to the mixing was compared with a subsequent nearly equal temperature rise due to known electrical energy dissipation in the heater. Allowance was made for the thermal effect of stirring and for heat losses as before.

Results

Measurements were made over the complete composition range for H_2O–EO at 10.75 and 20.00 °C, and for D_2O–EO at 13.45 and 20.00 °C. Tables 1, 2, 4, and 5 record the weight of H_2O or D_2O and of EO taken in each experiment, together with the temperature of the experiment and the heat change observed. The last two columns give the mole fraction of water, x_1, and the enthalpy change per mol of mixture formed, $\Delta_m h$, corrected to the reference temperature of the table.

At lower temperatures clathrate hydrate formation (15, 16) prevented study over the complete composition range so that measurements were made over restricted ranges for the H_2O–EO system at 0.6 °C and for D_2O–EO at 4.1 and 7.3 °C. These less extensive measurements are reported in Tables 3 and 6, which give $\Delta_m h$ values at the experimental temperatures. All measurements were made at a total pressure of 3 atm since many were above the normal boiling point of EO at 10.5 °C.

The experimental results for each system have been fitted by the method of least squares to the equation

$$[1] \quad \Delta_m h\ (\text{J/mol}) = x_1(1-x_1)\sum_{k=0}^{k=m} B_k(1-2x_1)^k$$

with the water mole fraction x_1. To obtain an adequate fit of the measurements over the whole composition range, at least ten terms of the equation are required to minimize the residual variance. Values for the regression coefficients B_k are given in Table 7, together with the assessed standard errors for a single determination, $\sigma(\Delta_m h)$.[2] When the exothermal and endothermal results are fitted separately the number of terms is reduced to six, the value of $\sigma(\Delta_m h)$ remains about the same in the exothermal region but is significantly reduced to about 2 J/mol in the endothermal region. This properly reflects the greater calorimetric accuracy of the endothermal measurements, for which the calorimeter is maintained nearly isothermally by heater compensation. Smoothed values for $\Delta_m h$ calculated from [1] at regular mole fraction intervals are given in Table 8.[2] In Fig. 1 we show a typical S-shaped curve for the H_2O–EO system at 10.75 °C. The root mean squared deviation for this data from the smoothed curve is 4 J/mol.

At low EO concentrations $\Delta_m h$ values in D_2O lie below those for H_2O but at high EO concentrations they lie above. We have observed the same behavior in the $\Delta_m h$ values for tetrahydrofuran with D_2O and H_2O (36).

Discussion

The Nature of Liquid Water

Before we can discuss the nature of aqueous nonelectrolyte solutions we must consider the nature of pure liquid water. Numerous models for water have been proposed, but no single one of them has been able to account satisfactorily for most of the properties of water. Since this has been adequately discussed elsewhere recently (12) we propose only to focus attention on a few relevant points. Liquid water is unique in its capability of forming a three-dimensional network of H-bonds. Each water molecule can form up to a maximum of four H-bonds, but whether or not liquid water is in fact fully H-bonded at temperatures not far above its freezing point has been the subject of much investigation and speculation. Falk and Ford (17) have pointed out that estimates of the number of broken H-bonds in water vary from 0 to over 70%. We believe that the answer to the question "What proportion of H-bonds are broken in pure water?" must depend on the type and time scale of the experiment that purports to answer this question. Let us consider the Pople model for water (18). In terms of this model no H-bonds are broken on melting ice but rather they are subject to considerable distortion. The bending of H-bonds causes weakening, so that in liquid water there is a range of energies associated with a H-bond. However, as Pople points out, each water molecule must be continually breaking its H-bonds and reforming them with different neighbors. If this were not so then water would not be a liquid. When one accepts the fact that H-bonds are being broken and remade, the crucial factor then becomes the time for which the H-bond is broken before reforming. Any experiment designed to detect broken bonds, that is to detect unbonded O—H groups, will only reveal broken bonds if the time scale of measurement is shorter than the time for which the bond is broken. For example, if one seeks evidence from the vibrational spectrum for the existence of unbonded O—H groups as distinct from those H-bonded O—H---O, the unbonded species must exist for at least one vibration to give rise to a quantized band of characteristic frequency.

Broken H-bonds appear to be fairly definitely indicated in the Raman spectrum of water (19–21) but detectable with difficulty in the infrared (22). This implies that the lifetime of an unbonded O—H group is at least greater than 10^{-14} s, and possibly 10 to 100 times longer than this depending on temperature. The importance of the time scale in considering H-bonding interactions seems to have been largely ignored until recently when Eisenberg and Kauzmann gave it detailed consideration (12).

In the present work considering the longer time periods for proton magnetic resonance and thermodynamic property measurements, we are interested in the ability of water molecules to form three-dimensional, H-bonded networks in which most water molecules form four, tetrahedrally oriented, H-bonds with four near neighbors. Here the formation and rupture of individual H-bonds is very rapid compared with the measurement time so that we observe the average over many formations and ruptures of all H-bonds. Since there is much evidence indicating the persistence of tetrahedral co-ordination in water at lower temperatures (12, 18, 23, 24) and since energy is absorbed in breaking H-bonds, it appears that most water molecules form four H-bonds with neighbors, and of those not forming four bonds the majority form three H-bonds with near neighbors, with progressively decreasing fractions forming two, one, and zero H-bonds to neighbors.

Let us now consider the effect on water of the addition of a nonelectrolyte. If the added solute is non-polar, such as argon, nitrogen, and methane, the solubility is very low. Eley (25) formulated a theory for the solubility of inert gases in water, in which the solute gas molecules were accommodated interstitially between the H-bonded water molecules. This theory permitted quantitative calculation of some of the aqueous solute properties. More recently, several authors have considered that the interstices between the water molecules in solution resemble the cages of clathrate hydrates (1, 2, 26–28). We believe that there has been much misinterpretation of this model, largely due to ignoring the importance of the time scale. It is not realistic to talk of clathrates in solution as though an ordered shell of water around the solute molecule had a permanent existence. It must be considered that any ordered shell is continually breaking and re-forming with different molecules, and the reality of such a shell as an entity relates to the time of its existence, compared with the time taken for a water molecule to move from a position of nearest neighbor to that of next nearest neighbor of a given solute molecule. One must also be wary of attributing to the H-bonds between water within this shell of nearest neighbors values of bond lengths and angles that conform rigidly to those found in a clathrate hydrate. We believe that an ordered shell of nearest-neighbor water molecules around a solute can be readily accounted for in terms of the Pople model for water. We visualize the solute as a template around which water molecules can be placed and so reduce the distortion of their H-bonds below that in pure liquid water (1, 2, 28, 29). Thus the bonds being less distorted have a greater stability, consequently the initial dissolution of a gaseous nonelectrolyte in water at low temperature is invariably exothermal.

If the solute added to water is polar, or is able to form H-bonds with water, then eventually, when sufficient solute has been added, a complete disruption of the H-bonded network of liquid water must occur. This will be discussed more fully later in this paper. We point out here, however, that any breaking of water H-bonds must be step-wise. It is common experience that breaking of bonds is step-wise in any process, such as the ionization of hydrogen sulfide or ortho-phosphoric acid, and there is no reason to expect that the breaking of the four-fold H-bonding of water should be supernatural.

Interpretation of the Enthalpy of Mixing of Water and Ethylene Oxide

The S-shaped composition dependence for $\Delta_m h$ observed in these systems and shown in Fig. 1 is typical of many aqueous nonelectrolyte systems (30–32, 38). A composition dependence curve of this shape is indicative of complex interactions between the species being mixed. When mixtures of two nonelectrolytes are considered the interpretation of such S-shaped curves may be straightforward, as, for example, in Barker and Smith's (10) application of the lattice theory of liquids to the ethanol–chloroform system, for which the calculated $\Delta_m h$ composition curve was in reasonable agreement with the experimental curve. In that system H-bonding occurs between ethanol molecules and between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ethanol and chloroform molecules. However, Barker and Smith had no success in the application of the theory to aqueous nonelectrolyte systems. We have attempted to apply their theory to the systems in this paper without success.

Water-rich Region (100–80% Water)

Consider the progressive addition of EO to water at lower temperatures. As pointed out earlier, there is probably a small concentration of unbonded O—H groups in pure water, so that H-bond formation may initially occur between these O—H groups and the oxygen atoms of the EO. However, bonding of these originally unbonded O—H groups disturbs the water–water H-bond equilibrium and causes more water to dissociate. In the absence of other effects the enthalpy change on adding EO to water would seem to be predictable by simple equilibrium constant theory, given values for the equilibrium constants and enthalpy changes for each of the relevant reactions. It is known that H-bonds between water molecules are stronger than those between water and ethers (2, 33, 34). At this point we must be clear about our meaning of the word strong. If we mean that the enthalpy of formation of a water–water H-bond is larger than that of a water–EO H-bond, then we cannot mean also that the equilibrium constant K_H for water–water H-bond formation is larger than K_E for water–EO H-bond formation, except in a limited temperature range (35). Accordingly, calculations have been made with K_H both larger and smaller than K_E, and for similar variations of ΔH_H and ΔH_E, the corresponding enthalpy changes for H-bond formation. We have found it impossible even to obtain the correct sign variation of $\Delta_m h$ with composition. The shortcoming of this calculation appears to lie in our use of concentrations rather than activities of the equilibrium species, but we are unaware of any method for determining the activities of the various H-bonded species.

The exothermal mixing of dilute nonelectrolytes with water can be described in qualitative terms as follows. On adding a small amount of EO to water some H-bonds are formed between unbonded O—H groups of water and EO. Other things being equal, some water–water H-bonds will dissociate. However, on adding EO to water we have changed the nature of the medium and we may in fact not dissociate any water–water H-bonds, or we may even form more or stronger water–water H-bonds (1, 2). This could arise if the activities of all species, both H-bonded and unbonded, were strongly composition dependent in this region. We know that the overall activity of EO and water does vary remarkably in this region (1, 2), but we can get no information on the individual H-bonded species.

As pointed out earlier, the reorientation of the H-bonded network around the solute species to give water H-bond angles nearer to the regular tetrahedral angles could occur and result in stronger and/or more H-bonds between water molecules (1, 2, 28, 29). The increase in strength or number of water–water H-bonds would readily account for the initial negative $\Delta_m h$ values found in this region. There is obviously a limit to the extent that reorientation effects are important although they are probably mainly responsible for the large negative excess entropies associated with this water-rich region. At higher EO levels the competition of the EO oxygen atoms forming H-bonds with the water protons will lead to the breakdown of the three-dimensionally H-bonded water network. Since the EO–water H-bond has a smaller enthalpy of formation than the water–water H-bond that it replaces, this breakdown of the water network will be accompanied by increases of enthalpy, which give rise to the enthalpy minima observed.

The concentration variation of $\Delta_m h$ for the D_2O–EO and H_2O–EO systems is closely similar so that our analysis above applies equally to the deuterium oxide system. The smoothed data given in Table 8[2] show that up to EO mole fraction 0.11 the $\Delta_m h$ values are negative and of greater magnitude with D_2O than with H_2O, implying greater strengthening of the three-dimensionally bonded network in the D_2O solutions, and/or stronger EO bonds with D_2O.

Intermediate Region (80–20% Water)

Once the minimum in enthalpy has been passed, $\Delta_m h$ changes almost linearly with composition while the EO mole fraction x_2 increases from 0.2 to 0.6. Since EO forms only one H-bond with water (1), we invisage this linear composition dependence as arising from the replacement of water–water H-bonds by EO–water H–bonds, so that at mole fraction 0.5, half of the EO is H-bonded to water, and the water molecules on the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

average make three water–water H-bonds. This linear concentration dependence of the enthalpy of mixing of nonelectrolytes with water in this intermediate region is not confined to EO solutions, for example we have observed it with aqueous tetrahydrofuran (36), while others have shown it with aqueous dioxane (31) and acetone (37). Most recently Morcom and Smith (38) have furnished similar S-shaped enthalpy of mixing curves for other cyclic ethers with water.

A linear composition dependence of $\Delta_m h$ is also observed in the D_2O–EO system and the smoothed values given in Table 8 show that the $\Delta_m h$ values increase more rapidly for the D_2O solutions. This implies that the enthalpy difference between a D_2O bond with D_2O and a D_2O bond with EO is of greater magnitude than the corresponding difference for the H_2O–EO system. Thus the breakdown of the stronger bonds in the D_2O system leads to the larger endothermal enthalpies in this composition region.

Correlation of Enthalpy of Mixing with Water Proton Magnetic Resonance Chemical Shift

In aqueous EO solutions containing more than 0.5 mole fraction EO the large excess of unbonded basic oxygen atoms, that is unbonded oxide atoms or unbonded water lone pairs, reduces the fraction of unbonded water O—H groups to negligibly low levels. In this case we can say that all water protons are H-bonded either to EO oxygen atoms or to water lone pairs, so that the proton magnetic resonance (p.m.r.) chemical shift gives a direct measure of the water H-bonding to these two species. In this region we find that the enthalpy of mixing can be accurately related to the p.m.r. chemical shift.

In our earlier work (1) the water protons chemical shift ν at water mole fraction x_1 was interpreted as the resulting average for a fraction f_1 of water protons forming H-bonds with water lone pairs, and a fraction $(1 - f_1)$ forming H-bonds with EO. The extrapolated chemical shifts, $\nu_1 = 132.9$ Hz in pure water and $\nu_2 = -12.6$ Hz in pure EO, were taken as characteristic of water protons completely bonded to water lone pairs and to EO, respectively, so that the observed solution shift was given by the relation

$$[2] \qquad \nu = f_1\nu_1 + (1 - f_1)\nu_2$$

Thus, f_1, the fraction of water protons H-bonded to water lone pairs, was evaluated from each ν over the range of x_1. For ideal averaging f_1 would be identical with x_1, but for every solution measured f_1 was found to be greater than x_1, indicating that the water protons invariably formed more than the ideal fraction of H-bonds with water lone pairs and fewer than the ideal fraction with EO. This was to be expected since water H-bonds with water are on the average stronger, using p.m.r. chemical shift as criterion, than those to EO.

We define the standard molar enthalpy of pure liquid water as $H_{11}{}^0$ and the molar enthalpy for water in EO solution as, (*i*) H_{11} when H-bonded to two water lone pairs, (*ii*) H_{12} when H-bonded to two EO molecules, and (*iii*) $(H_{11} + H_{12})/2$ when H-bonded to one water and one EO molecule. For the molar enthalpy of mixing $\Delta_m h$ we obtain

$$[3] \quad \Delta_m h = x_1 f_1(H_{11} - H_{11}{}^0) + x_1(1 - f_1)(H_{12} - H_{11}{}^0)$$

where it is assumed that the enthalpy change arises predominantly from the change of H-bonding of the water, and that the enthalpy changes from other non-H-bonded interactions are included within the H-bonding terms. As the EO mole fraction $x_2 = (1 - x_1)$ tends to zero, so H_{11} should tend to $H_{11}{}^0$, so that the composition dependence of $H_{11} - H_{11}{}^0$ was taken as the simplest linear function

$$[4] \qquad H_{11} - H_{11}{}^0 = b_{11}(1 - x_1)$$

where the constant b_{11} is the molar enthalpy difference for water H-bonded to water between infinite dilution in EO and pure water. The composition dependence of $H_{12} - H_{11}{}^0$ was taken as the linear function

$$[5] \qquad H_{12} - H_{11}{}^0 = a_{12} + b_{12}(1 - x_1)$$

where a_{12} and b_{12} are constants and $(a_{12} + b_{12})$ is the molar enthalpy difference between water at infinite dilution H-bonded to EO and water H-bonded to water in the pure liquid. Substitution of [4] and [5] into [3] gives the three-parameter equation

$$[6] \quad \Delta_m h = x_1(1 - x_1)f_1 b_{11} + x_1(1 - f_1)a_{12} + x_1(1 - x_1)(1 - f_1)b_{12}$$

relating $\Delta_m h$ to x_1 and to the p.m.r. chemical shift through f_1.

			$\sigma(\Delta_m h)$ =	4.4

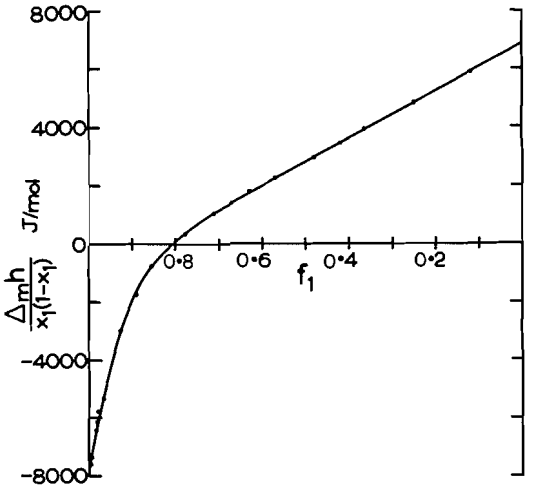

FIG. 2. Correlation of enthalpy of mixing with water proton magnetic resonance chemical shift for the H_2O–EO system at 10.75 °C. Enthalpy of mixing function $\Delta_m h/x_1(1 - x_1)$ variation with the fraction of water protons H-bonded to water, f_1, showing the linear region with $0.7 > f_1 > 0$.

For the systems H_2O–EO at 10.75 and 20.00 °C and D_2O–EO at 13.45 and 20.00 °C at EO mole fractions larger than 0.53, the endothermal $\Delta_m h$ values were fitted by [6] using the method of least squares, assuming constant enthalpy errors and error-free x_1 and f_1. The f_1 values were interpolated from the p.m.r. chemical shifts for the H_2O–EO system at 0 °C (1). The representation of the experimental $\Delta_m h$ by [6] showed that the value of a_{12} was not significantly different from zero. The least squares fits of the data were then redetermined using the two-parameter equation

$$[7]\quad \Delta_m h = x_1(1 - x_1)f_1 b_{11} + x_1(1 - x_1)(1 - f_1)b_{12}$$

Results for this curve-fitting are presented[2] in Tables 9–12, which include x_1, f_1, the experimental $\Delta_m h$(obs.) corrected to the tabulated temperature, the calculated $\Delta_m h$(calcd.) derived from [7], their difference $\delta(\Delta_m h)$, and $\sigma(\Delta_m h)$ the standard error on a single enthalpy determination assessed from the fit of [7].

A plot is shown in Fig. 2 of $\Delta_m h/x_1(1 - x_1)$ against f_1 for the H_2O–EO system at 10.75 °C, where the linear section obeying [7] is seen in the region $0 < f_1 < 0.7$, corresponding with $0 < x_1 < 0.46$. This corresponds with the region in which we previously suggested (1) that water formed one-dimensional H-bonded chains, which at higher water concentrations were further cross-linked to give two-dimensional H-bonded surfaces. At higher water mole fractions the experimental $\Delta_m h/x_1(1 - x_1)$ values become progressively more exothermal than predicted by [7]. In this region water forms three-dimensional H-bonded networks within which EO is included, causing orientation of the network around the solute as discussed earlier.

Tables 9–12[2] show the very good representations of $\Delta_m h$(obs.) by the two-parameter eq. 7, from which the $\sigma(\Delta_m h)$ values of between 2.8 and 4.4 J/mol are realistic estimates of the errors of measurement on $\Delta_m h$. In Table 12 the $\Delta_m h$ values shown in parentheses were not used to determine the least-squares fit of [7] because of their unreasonably large $\delta(\Delta_m h)$ values, which are also shown in parentheses: neglecting these two possibly erroneous measurements yields a reasonable $\sigma(\Delta_m h)$ value of 3.8 J/mol.

Rearrangement of eq. 7 gives

$$[8]\quad \Delta_m h/x_1(1 - x_1) = b_{12} + f_1(b_{11} - b_{12})$$

which defines b_{12} as the intercept when f_1 is zero and b_{11} as the intercept when f_1 is unity. The very

TABLE 13. Regression coefficients for eq. 7

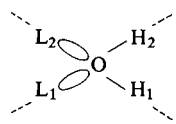
System	Temperature (°C)	b_{11} (J/mol)	b_{12} (J/mol)
H_2O–C_2H_4O	10.75	−1282 ± 30	6881 ± 43
H_2O–C_2H_4O	20.00	−1107 ± 24	7140 ± 30
D_2O–C_2H_4O	13.45	−1148 ± 24	7323 ± 35
D_2O–C_2H_4O	20.00	−1054 ± 40	7518 ± 49

good fits of eq. 7 to the $\Delta_m h$ measurements, or the corresponding linearity of the plots of $\Delta_m h/x_1(1 - x_1)$ against f_1, suggests that the f_1 values for the systems H_2O–EO at 10.75 and 20.00 °C and D_2O–EO at 13.45 and 20.00 °C are directly proportional to those f_1 values derived from the proton chemical shifts of H_2O–EO at 0 °C. Since the b_{12} values are the intercepts at $f_1 = 0$, these values are unaffected by the fact that f_1 is determined from the chemical shifts measured at 0 °C. This is not the case for the b_{11} values, which may change in magnitude but probably not in sign if correct f_1 values replace those at 0 °C.

Table 13 presents the best b_{11} and b_{12} parameters and their standard errors, obtained from [7] for the measurements in Tables 9–12. The b_{12} values show that the molar transfer of pure water or deuterium oxide to infinite dilution in EO is attended by an enthalpy increase of about 7000 J/mol, which values become larger at higher temperature. This means that the two water H-bonds with EO are each some 3500 J/mol weaker, using enthalpy as a criterion, than the two water H-bonds to water in pure water. Further, the increase of the b_{12} values with temperature shows that the water H-bonds with EO weaken more rapidly at higher temperature than do those in liquid water.

The b_{12} values for the D_2O–EO system are significantly larger than those for H_2O–EO at the same temperature, the differences with standard errors are 366 ± 52 J/mol at 13.45 °C and 378 ± 58 at 20.00 °C: these differences at each temperature are the same within experimental error. On the assumption that EO bonds to D_2O at infinite dilution are not weaker than EO bonds to H_2O, we find that D-bonds in liquid D_2O are on a minimum estimate some 186 ± 55 J/mol stronger than H-bonds in liquid H_2O in the range 10–20 °C.

The negative b_{11} values of about −1100 J/mol for solutions with $0 < x_1 < 0.46$ indicate that water H-bonds to water in these EO solutions are on the average some 550 J/mol stronger, lower in enthalpy, than water H-bonds in pure water. The temperature coefficients of b_{11} show that this difference is reduced at higher temperatures. These negative values for b_{11} are consistent with the interpretation of the p.m.r. chemical shifts in terms of strongly bonded, unbranched water chains in solutions with $x_1 < 0.2$, as suggested earlier (1). This means that the water H-bonds to water along these one-dimensional chains are stronger, of lower enthalpy, than those in the three-dimensionally cross-linked water. We believe that the weaker water–water H-bonds in liquid water arise from the mutual repulsions between the pairs of like bonds at the four-coordinated water molecules, that is, from the mutual repulsions of the first bond with proton H_1 by the second bond with proton H_2, and



similarly from the mutual repulsions of the first bond with lone pair L_1 by the second bond with lone pair L_2. Whereas, for the one-dimensional water chains there is no second bond to L_2 and a weaker second bond to H_2 by EO, both of which lead to stronger bonds for lone pair L_1 and for proton H_1 with water along the chains. Similarly even stronger bonds are formed along the well-known alcohol polymer chains which have only the mutually enhancing bonding to H_1 and L_1 (34).

The b_{11} values for the D_2O–EO system are larger than for H_2O–EO by 83 ± 37 J/mol at 13.45 °C and by 53 ± 47 at 20.00 °C: both differences are just significant, arising by chance alone at the 4.5 and 30.8% probability levels, respectively. The differences at 13.45 and 20.00 °C are the same within experimental error.

We note a recent correlation between the water activity coefficient and p.m.r. chemical shift in the systems H_2O–1,4-dioxane and H_2O–acetone (39, 40).

Cycloaddition Reactions of Silyldiazoalkanes

A. G. Brook and Peter F. Jones
Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received November 23, 1970

The products of cycloaddition of silyldiazoalkanes with representative alkenes are described, together with their photolysis products. The photolysis of silyldiazoalkanes yields silylcarbenes which undergo typical reactions.

On décrit les produits obtenus lors de la cycloaddition de silyldiazoalcanes avec des alcènes représentatives; on a aussi déterminé la nature de leurs produits de photolyse. Par ailleurs la photolyse des silyldiazoalcanes fournit des silylcarbènes qui donnent des réactions typiques.

Canadian Journal of Chemistry, 49, 1841 (1971)

A variety of silyl- and germyldiazoalkanes is available from the decomposition of the lithium salts of acylmetalloid tosylhydrazones (1) and a preliminary account of the reactions of silylaryldiazoalkanes with acids has been presented (2). The results are reported here of 1,3-cycloaddition reactions of representative silyldiazoalkanes with suitable alkenes, and of their conversions to carbenes.

The reaction of 1-triphenylsilyl-1-diazoethane (**1**) with methyl vinyl ketone led to the initial formation of a 1-pyrazoline, **2** (eq. 1). However, on attempted purification of **2**, partial isomerization occurred to the corresponding 2-pyrazoline, **3**. Complete rearrangement to the conjugated isomer was effected by the use of pyridine as catalyst. Similar results have been reported by Seyferth *et al.* for the reactions of trimethylsilyldiazomethane with acrylonitrile (3). Reaction of **1** with methyl acrylate (R = CO_2Me) also gave a 1-pyrazoline, **4**, which did not isomerize spontaneously. The geometries described for these and other cases to follow have not been unequivocally established, but because of the great bulk of the triphenylsilyl group, it appears probable that the methyl and R groups will be in a *cisoid* relationship. No evidence was noted for mixtures of stereoisomers in any case.

The identity of the two 1-pyrazoline adducts was clearly established from their n.m.r. spectra. The signal from the single proton at C-3, the X component of an ABX system, was found as a doublet of doublets in both compounds, while the complex AB signal due to the non-equivalent methylene hydrogens at C-4 was extremely broad, extending in both cases over 1 p.p.m. Such large chemical shift differences for geminal protons are characteristic of 1-pyrazolines, whose C-4 methylene protons experience unequal anisotropic effects from the π electrons in the azo linkage due to the puckered pyrazoline ring but to speculate on possible conformations or geometries based on differential shielding effects is unwise in the presence of the very bulky anisotropic triphenylsilyl group (4). Both reactions showed the expected direction of addition, involving bond formation between the nucleophilic α-diazo carbon atom and the electrophilic β-carbon atom of the α,β-unsaturated compound (5).

Attention was next turned to more highly substituted alkenes. Although diethyl fumarate was more reactive than diethyl maleate toward **1**, both reacted very sluggishly giving complex mixtures of products and hence the reactions of **1** with the isomeric pair of esters were found to be of no synthetic utility. However **1** reacted readily with maleic anhydride (**5**, R = H) to give the 1-pyrazoline, **6**, in good yield, and with citraconic anhydride, (**5**, R = Me) to give the 1-pyrazoline adduct, **7** (eq. 2). In the latter case reaction occurred more slowly than with maleic anhydride (several days instead of a matter of hours), and the direc-

[1] Ph_3SiCN_2Me (**1**) +  →  → 
2 R = COMe
4 R = CO_2Me

3 R = COMe

[2] 
[3] 
tion of addition occurred to give the less sterically hindered of the two possible products. The direction of addition of diazoalkanes to alkenes is known to be highly subject to steric factors and the mode of addition expected from electronic effects is frequently reversed under such circumstances (5). The structure of **7** was demonstrated by comparison of its n.m.r. spectrum, which contained a one proton singlet at δ 3.25 p.p.m. assigned to the hydrogen at C-4, with that of the corresponding maleic anhydride adduct, **5**, which showed two doublets, J = 10 Hz, at δ 4.88 and 3.62 p.p.m. The low field doublet is due to the hydrogen at C-3, which is deshielded by both the adjacent carbonyl and azo groups (4). The stereochemistry of **5** and **7** has not been rigorously established but a *cis* ring juncture with the bulky triphenylsilyl group *trans* to the anhydride ring appears from models to be the only reasonable geometry.

In all of the cases studied, it was possible to isolate the 1-pyrazoline adduct although all the compounds prepared, with the exception of the adduct **7** from citraconic anhydride, contain a hydrogen atom at C-3 activated by an adjacent electron-withdrawing substituent and are therefore capable of isomerizing to the corresponding conjugated 2-pyrazolines. It is not uncommon in diazo cycloadditions for the conjugated 2-isomers to be obtained (5) directly and reports of stable 1-pyrazolines of this type are rare (6).

The u.v. spectra of the silyl-1-pyrazolines were examined and the position of this long wavelength n-π* transition of the azo group was found to occur, like other 1-pyrazoline (4, 7, 8), in the region of 320–330 mm. These results indicate little interaction between the silyl group and the distant azo linkage, in contrast to the marked spectral changes that occur when silyl groups are attached directly to an azo group (9).

The reactions of two aryldiazomethanes, phenyltriphenylsilyldiazomethane (**9**) and its trimethylsilyl analogue, **10**, with methyl vinyl ketone have also been studied (eq. 3). The triphenylsilyl compound, **9**, exhibited low reactivity, complete reaction to give the 2-pyrazoline, **11**, requiring in excess of 1 month at room temperature. Since the corresponding reaction of **1** with methyl vinyl ketone was complete in a matter of hours it can be seen that replacement of a methyl by a phenyl group at the α-diazo carbon atom causes a large decrease in the reactivity of the silyldiazoalkane. This result is probably due both to stabilization of the diazo compound by mesomeric delocalization into the aromatic ring (10), and to steric effects. The sluggish reactivity of the triarylsilylaryldiazoalkanes towards methyl vinyl ketone, a fairly good dipolarophile, suggests that as a class they possess limited synthetic utility as dipolar cycloaddition reagents under mild conditions.

Phenyltrimethylsilyldiazomethane (**10**) was found to be much more reactive, since reaction with methyl vinyl ketone was complete over 16 h. The 2-pyrazoline, **12**, was the reaction product. Since the two silyldiazoalkanes appear to show similar ground state stabilities (1), the difference in their dipolar cycloaddition reactivity must be due largely to steric factors. The triphenylsilyl group should have a far larger spatial bulk than a trimethylsilyl group. Again, the direction of addition of both silylaryldiazoalkanes to methyl vinyl ketone was that expected on electronic grounds (5).

Since the photolysis of 1-pyrazolines is an ex-

cellent method for the synthesis of cyclopropanes (7, 11–13), the photolyses of the stable silyl-1-pyrazolines obtained from **1** were examined as possible routes to silylcyclopropanes. Both **5** and **7**, the adducts from maleic and citraconic anhydrides, gave the corresponding cyclopropanes, **13** and **14**, in good yields as the sole isolated product in each case (eq. 4). No evidence was observed for isomeric products. However, the adduct **4** from methyl acrylate gave a mixture of 2-triphenylsilylpropene (13%) and the cyclopropane **15** (35%) (eq. 5) which, like **13** and **14**, is presumed to have *cis* carbonyl and methyl groups to minimize steric crowding. As has been found with other 1-pyrazolines (7), the silylalkene probably arose by elimination of diazoacetic ester, through reversal of the cycloaddition reactions by an alternative pathway (eq. 6).

Finally, a limited investigation of the conversion of silyldiazoalkanes to silylcarbenes was made, mainly using photochemical methods. 1-Triphenylsilyl-1-diazoethane was slowly converted to vinyltriphenylsilane in reflexing toluene in moderate yield. It smoothly underwent the same transformation when irradiated in ether at room temperature (eq. 7). Similarly, diazoalkane **16** gave a mixture of the isomeric triphenylsilylstyrenes **17**, with the *trans* product (54% yield) predominating over the *cis* compound (21%) as anticipated (eq. 8). Photolysis of phenyltriphenylsilyldiazomethane in methanol gave α-methoxylbenzyltriphenylsilane **18**, as expected from carbene insertion into an O—H bond, and thermolysis of the same compound in dimethylsulfoxide, a reagent known to be capable of oxidizing carbenes (14), gave benzoyltriphenylsilane **19** (see Scheme 1).

From the results described, it is evident that the silyldiazoalkanes undergo cycloaddition reac-

tions typical of diazoalkenes, although they are generally more stable and less reactive than their carbon analogs. The behavior of the silylcarbenes derived from their photolysis is unexceptional, although studies in progress on cyclopropane formation have been found to be very unclean reactions.

Experimental

Diethyl ether was dried over sodium metal and was distilled immediately prior to use. Photolyses of 1-pyrazolines were carried out in Pyrex glassware irradiated by a Hanovia high-pressure mercury arc. The n.m.r. spectra were measured on Varian A60, A56/60, or T60 spectrometers, using TMS as an internal standard. The i.r. spectra were taken on a Perkin–Elmer Model 237B with polystyrene calibration. The u.v. spectra were run on a Unicam SP800 spectrometer and were calibrated by means of a Holmium filter. Mass spectra were recorded using an AEI MS-902 instrument. Melting points were taken on a Fisher–Johns hot stage and are uncorrected. Microanalyses were performed by A. B. Gygli, Toronto, Ontario.

The Reaction of 1-Triphenylsilyl-1-diazoethane with Methyl Vinyl Ketone

To a solution of 1.0 g (0.00318 mol) of 1-triphenylsilyl-1-diazoethane in 50 ml of anhydrous ether was added an excess, 2 ml, of methyl vinyl ketone. The reaction flask was stoppered and allowed to stand in the dark at room temperature. After 2 h the mixture had decolorized and the solvent was evaporated to give a thick oil, whose spectra indicated the exclusive formation of a 1-pyrazoline. The i.r. spectrum (CCl_4 solution) showed a strong carbonyl band at 5.80 μ (non-conjugated ketone), with strong Si—Ph bands at 7.0 and 9.0 μ. There was no NH stretching band in the region of 3 μ. The n.m.r. spectrum confirmed the structure of the adduct as 3-acetyl-5-methyl-5-triphenylsilyl-1-pyrazoline by signals at δ ($CDCl_3$), 7.8–7.2 (multiplet, 15H, Si*Ph*), 4.47(1H, doublet of doublets, $J_{AX} = 9$, $J_{BX} = 11$ Hz, C*H*COMe), 2.43(3H, s, CO*Me*), 2.20–1.25(2H, multiplet, ring CH_2), 1.66(3H, singlet superimposed on above multiplet, SiC*Me*) p.p.m.

The oil was crystallized from benzene–hexane to give 1.1 g (90%) of adduct, m.p. 50–65°. However, an i.r. spectrum showed by the appearance of a conjugated carbonyl band at 5.98 μ the formation of some of the isomeric 2-pyrazoline. In a previous experiment, it had also been found that the 1-pyrazoline was slowly converted to the conjugated 2-isomer on repeated recrystallization from methanol. It was therefore decided to isolate the reaction product as the 2-isomer. Isomerization was carried out by adding 5 drops of pyridine to a methanol solution of the above product and allowing the reaction mixture to stand for 24 h. A white solid obtained on evaporation gave, on recrystallization from benzene–pentane, 0.47 g (39%) of 3-acetyl-5-methyl-5-triphenylsilyl-2-pyrazoline, m.p. 184–186°. The analytical sample had m.p. 185–186°.

Anal. Calcd. for $C_{24}H_{24}N_2OSi$: C, 74.98; H, 6.29; N, 7.29. Found: C, 74.44; H, 6.28; N, 7.26.

The n.m.r. spectrum: δ($CDCl_3$), 7.7–7.3(multiplet, 15H, Si*Ph*), 6.0(broad s, 1H, N*H*), 3.04(AB q, J_{AB} = 17 Hz, 2H, ring CH_2), 2.36(s, 3H, CO*Me*), 1.20(s, 3H, SiC*Me*) p.p.m. The i.r. spectrum: λ_{max}(CCl_4), 2.93(w), 3.23(w), 3.36(w), 5.98(s), 6.73(w), 7.00(m), 7.18(m), 7.48(w), 8.00(w), 8.42(w), 9.00(s), 9.25(w), 10.65(w), 11.50(w), 14.35(s) μ.

The Reaction of 1-Triphenylsilyl-1-diazoethane with Methyl Acrylate

To a solution of 1.50 g (0.00478 mol) of 1-triphenylsilyl-1-diazoethane in 50 ml of anhydrous ether was added an excess, ~2 ml, of methyl acrylate. The reaction flask was stoppered and allowed to sit in the dark. After 4 h the mixture had decolorized and the solvent was evaporated to give a clear glass. Crystallization from dichloromethane–hexane gave 1.53 g (80%) of 3-carbomethoxy-5-methyl-5-triphenylsilyl-1-pyrazoline, m.p. 130–133°. Several recrystallizations from dichloromethane–hexane gave the analytical sample, m.p. 135–137°.

Anal. Calcd. for $C_{24}H_{24}N_2O_2Si$: C, 71.97; H, 6.04; N, 7.00. Found: C, 71.90; H, 6.13; N, 6.90.

The Reactions of 1-Triphenylsilyl-1-diazoethane with Dimethyl Fumarate and Dimethyl Maleate

(*a*) A solution of 0.63 g (0.022 mol) of the diazoalkane and 0.29 g (0.002 mol) of dimethyl fumarate in 50 ml of anhydrous ether was allowed to stand in the dark at room temperature. The mixture had decolorized after 16 days. Evaporation gave an oil which on crystallization from dichloromethane–hexane gave a partially solid oil. An n.m.r. spectrum indicated that an extremely complex mixture of products had been formed and no further purification was attempted.

(*b*) A similar complex mixture was obtained from a reaction with dimethyl maleate, using identical quantities to the above. In this case decolorization occurred only after 44 days.

The Reaction of 1-Triphenylsilyl-1-diazoethane with Maleic Anhydride

To a solution of 1.50 g (0.00478 mol) of 1-triphenylsilyl-1-diazoethane in 50 ml of anhydrous ether was added 0.45 g (0.00460 mol) of maleic anhydride. The mixture decolorized after standing in the dark for 15 min, with the formation of a white crystalline precipitate. Evaporation of the solvent gave a white solid, which was recrystallized from dichloromethane–hexane to give 1.64 g (86%) of 5-methyl-5-triphenylsilyl-1-pyrazoline-3,4-dicarboxylic acid anhydride, m.p. 152–154° (dec.).

Anal. Calcd. for $C_{24}H_{20}N_2O_3Si$: C, 69.90; H, 4.89; N, 6.79. Found: C, 70.18; H, 5.14; N, 6.76.

The n.m.r. spectrum: δ($CDCl_3$), 7.7–7.2(multiplet, 15H, aromatic), 4.88(d, J = 10 Hz, 1H, N=N—C*H*CO),

The Reaction of 1-Triphenylsilyl-1-diazoethane with Citraconic Anhydride

To a solution of 0.56 g (0.0050 mol) of citraconic anhydride in 50 ml of anhydrous ether was added 1.50 g (0.00478 mol) of 1-triphenylsilyl-1-diazoethane. The reaction flask was stoppered and allowed to stand in the dark. After 4 days the mixture had decolorized and white crystals had precipitated. These were filtered off and washed with anhydrous pentane to give 1.85 g (91%) of 3,5-dimethyl-5-triphenylsilyl-1-pyrazoline-3,4-dicarboxylic acid anhydride, m.p. 165–167° (dec.). Recrystallization from dichloromethane–hexane raised the m.p. to 167–168° (dec.).

Anal. Calcd. for $C_{25}H_{22}N_2O_3Si$: C, 70.39; H, 5.20; N, 6.57. Found: C, 70.32; H, 5.34; N, 6.57.

The n.m.r. spectrum: δ($CDCl_4$), 7.8–7.1(multiplet, 15H, aromatic), 3.25(s, 1H, CMeC*H*CO), 1.76(s, 3H, SiC*Me*), 0.87(s, 3H, N=N–C*Me*CO) p.p.m. The i.r. spectrum: λ_{max}(CCl_4), 3.25(w, 5.35(m), 5.58(s), 7.00(m), 8.28(m), 9.00(m), 9.88(m), 10.84(m), 14.34(m) μ. The u.v. spectrum: λ_{max}(C_6H_{12}), 330(257), 273(1110), 266(1325), 260(1470), 255(s, 1580), 249(s, 1920), 225(s, 11 700), 206(18 600) mμ.

The Reaction of Phenyltriphenylsilyldiazomethane with Methyl Vinyl Ketone

To a solution of 0.30 g (0.0008 mol) of phenyltriphenylsilyldiazomethane in 50 ml of anhydrous ether was added excess, ~2 ml, of methyl vinyl ketone. The reaction flask was stoppered and was allowed to sit in the dark at room temperature. After 35 days the mixture had decolorized. Following evaporation and crystallization from hexane–benzene there was obtained 0.24 g (66%) of impure 3-acetyl-5-triphenylsilyl-5-phenyl-2-pyrazoline, m.p. 153–163°. The impurity, present to the extent of ~10%, appeared from the n.m.r. spectrum to be 3(5)-acetyl-5(3)-phenylpyrazole, as found in a later experiment with the analogous trimethylsilyldiazo compound. Several recrystallizations from hexane–benzene and hexane–dichloromethane failed to remove this impurity. Finally, recrystallization from methanol gave 0.06 g (17%) of pure 2-pyrazoline, m.p. 170–175° (dec.).

Anal. Calcd. for $C_{29}H_{26}N_2OSi$: C, 78.00; H, 5.87; N, 6.28. Found: C, 78.02; H, 5.86; N, 6.04.

The n.m.r. spectrum: δ($CDCl_3$), 7.6–6.7(multiplet, 15H, aromatic), 3.56(AB q, J_{AB} = 17 Hz, 2H, ring CH_2), 2.34(s, 3H, CO*Me*) p.p.m. The i.r. spectrum: λ_{max}(CCl_4), 2.90(w), 3.25(m), 5.98(s), 6.90(w), 7.00(m), 7.17(m), 7.47(w), 8.03(w), 8.40(w), 9.02(s), 9.66(m), 10.02(w), 10.22(w), 10.58(w), 14.32(s), 14.82(m) μ.

The Reaction of Phenyltrimethylsilyldiazomethane with Methyl Vinyl Ketone

To a solution of 4.10 g of impure diazoalkane, estimated by n.m.r. spectroscopy to contain 3.0 g (0.0158 mol) of phenyltrimethylsilyldiazomethane, in 100 ml of anhydrous ether was added an excess, 4.0 ml, of methyl vinyl ketone. The reaction flask was stoppered and the mixture was allowed to stand overnight in the dark. After 16 h a colorless solution was obtained which on shaking deposited white crystals. These were filtered off to give 3.32 g (81%) of 3-acetyl-5-trimethylsilyl-5-phenyl-2-pyrazoline, m.p. 140–150°. The i.r. spectrum of a solution in chloroform showed the appropriate bands at 2.49 (NH) and 6.02 μ (conjugated ketone), while the n.m.r. spectrum ($CDCl_3$) had signals at δ 7.5–7.0(multiplet, 5H, aromatic), 3.33(s, 2H, ring CH_2), 2.40(s, 3H, CO*Me*), and 0.03(s, 9H, Si*Me*) p.p.m. (external TMS). The n.m.r. spectrum also showed the presence of ~5% of an impurity, later shown to be 3(5)-acetyl-5(3)-phenylpyrazole. The pyrazoline could not be obtained pure, therefore no elemental analyses were attempted. However, the mass spectrum of the initial crude pyrazoline showed a molecular ion at *m/e* 260 (calculated for $C_{14}H_{20}N_2OSi$, 260).

Attempted purification by recrystallization from benzene–pentane led to extensive decomposition, as shown in the n.m.r. spectrum of the products by the removal of the Si*Me* signal and the increase in the signals due to the pyrazole. A 0.3 g sample of the initial crude pyrazoline was dissolved in benzene and the solution was allowed to stand at room temperature for a nominal period of 10 days. The solvent was evaporated to give 0.20 g (93%) of 3(5)-acetyl-5(3)-phenylpyrazole, m.p. 152–154° (lit. (15) 154°). The pyrazole (chloroform solution) showed bands in the i.r. spectrum at 2.90 (NH) and 5.94 μ (conjugated ketone). The n.m.r. spectrum showed signals at δ($CDCl_3$), 7.9–7.2(multiplet, 5H, aromatic), 7.05(singlet, 1H, vinylic H), and 2.61(singlet, 3H, CO*Me*) p.p.m. The molecular formula was confirmed using high-resolution mass spectrometry by the appearance of a molecular ion at 186.0789 (calcd. for $C_{11}H_{10}N_2O$, 186.07931).

Photolyses of 5-Silyl-1-pyrazolines

The Photolysis of 3-Carbomethoxy-5-methyl-5-triphenylsilyl-1-pyrazoline

A solution of 1.23 g (0.00308 mol) of the pyrazoline in 75 ml of anhydrous ether was photolyzed. After 24 h, reaction, as shown by n.m.r. spectroscopy, appeared to be complete. The solvent was evaporated to give a clear glass which was chromatographed on silica gel. Elution with carbon tetrachloride gave a solid which, in recrystallization from methanol, yielded 0.12 g (13%) of 2-triphenylsilylpropene, m.p. 101–102°. A mixed m.p. with an authentic sample (16) was undepressed. Further elution with 1:1 carbon tetrachloride – benzene gave a series of clear oils. Spectral examination indicated a mixture of the desired cyclopropane together with unsaturated esters. Crystallization from methanol gave 0.4 g (35%) of 1-triphenylsilyl-1-methyl-2-carbomethoxycyclopropane, m.p. 90–93°. Several recrystallizations from methanol gave the analytical sample, m.p. 98–99°.

Anal. Calcd. for $C_{24}H_{24}O_2Si$: C, 77.39; H, 6.49. Found: C, 77.21; H, 6.42.

The n.m.r. spectrum: δ($CDCl_3$), 7.7–7.2(multiplet, 15H, Si*Ph*), 3.68(s, 3H, CO_2*Me*),1.59(doublet of doublets, 1H, J_{AX} + J_{AB} = 13 Hz, C*H*CO), 1.4–0.8(multiplet, 2H, cyclopropyl CH_2), 1.31(singlet superimposed on above multiplet, 3H, SiC*Me*) p.p.m. The i.r. spectrum: λ_{max} (CCl_4), 3.25(m), 3.30(m), 3.40(m), 3.50(w), 5.75(s), 6.73(w), 6.94(m), 7.00(m), 7.22(m), 7.50(w), 7.63(w), 8.05(w), 8.28(m), 8.38(m), 8.52(s), 9.00(s), 9.28(w),

9.42(w), 9.70(w), 10.02(w), 10.60(w), 11.51(m), 14.32(s), 14.64(w) μ.

The methanol filtrate was evaporated to give a trace of an oil, whose n.m.r. spectrum showed it was a complex mixture of unsaturated esters. The oil was not examined further.

The Photolysis of 3,5-Dimethyl-5-triphenylsilyl-1-pyrazoline-3,4-dicarboxylic Acid Anhydride

A solution of 1.37 g (0.00333 mol) of the pyrazoline in an anhydrous solvent mixture of 50 ml of ether and 60 ml of dichloromethane was photolyzed. The course of the reaction was monitored by examination of the n.m.r. spectra of aliquots removed at various intervals. After 6 h, ~66% of the starting material was present, being reduced to ~33% after 18 h. After 30 h, ~10% of the pyrazoline remained, while reaction appeared to be complete after 38 h. Evaporation of the reaction mixture gave an aerated solid which, on recrystallization from dichloromethane–hexane, gave 0.85 g (67%) of 1,2-dimethyl-1-triphenylsilylcyclopropane-2,3-dicarboxylic acid anhydride, m.p. 195–197°. The n.m.r. spectrum of the crude reaction mixture had indicated that this cyclopropane was the sole reaction product. The analytical sample, from dichloromethane–hexane, had m.p. 196–198°.

Anal. Calcd. for $C_{25}H_{22}O_3Si$: C, 75.34; H, 5.56. Found: C, 75.30; H, 5.76.

The n.m.r. spectrum: δ($CDCl_3$), 7.8–7.3(multiplet, 15H, aromatic), 2.94(s, 1H, C*H*CO), 1.40(s, 3H, SiC*Me*), 1.35(s, 3H, *Me*CCO) p.p.m. The i.r. spectrum: λ_{max} (CCl_4), 3.25(w), 5.40(m), 5.62(s), 7.00(m), 7.90(m), 8.32(m), 9.00(m), 10.00(m), 10.22(w), 10.45(w), 10.98(s), 14.23(s) μ.

The Photolysis of 5-Methyl-5-triphenylsilyl-1-pyrazoline-3,4-dicarboxylic Acid Anhydride

A solution of 1.05 g(0.00246 mol) of the pyrazoline in an anhydrous solvent mixture of 50 ml of ether and 50 ml of dichloromethane was photolyzed. The course of the reaction was monitored by examination of the n.m.r. spectra of aliquots removed at various intervals. After 5 h, ~70% of the starting pyrazoline was present, being reduced to ~50% after 11 h. After 23 h, ~15% of the pyrazoline remained, while reaction appeared to be complete after 35 h. Evaporation of the reaction mixture gave a cream colored solid which was recrystallized from dichloromethane–hexane to give 0.70 g (72%) of 1-methyl-1-triphenylsilylcyclopropane-2,3-dicarboxylic acid anhydride, m.p. 165–175°. The n.m.r. spectrum of the crude reaction mixture indicated that this cyclopropane was the sole reaction product. The analytical sample, from dichloromethane–hexane, had m.p. 175–180°. A sharply melting sample could not be obtained despite repeated recrystallization.

Anal. Calcd. for $C_{24}H_{20}O_3Si$: C, 74.99, H, 5.24. Found: C, 75.04, H, 5.29.

The n.m.r. spectrum: δ($CDCl_3$), 7.8–7.2(multiplet, 15H, aromatic), 2.66(s, 2H, C*H*CO), 1.48(s, 3H, SiC*Me*) p.p.m. The i.r. spectrum: λ_{max}(CCl_4), 3.25(m), 5.39(s), 5.61(s), 6.75(w), 7.00(m), 7.25(w), 7.50(w), 7.60(w), 8.10(m), 8.40(w), 8.60(w), 9.02(s), 10.20(w), 10.49(m), 11.00(s), 11.60(m), 14.40(s), 14.80(m), 15.25(m) μ.

Attempted Cycloaddition of 1-Triphenylsilyl-1-diazoethane with Diphenylacetylene

A mixture of 0.60 g (0.00191 mol) of 1-triphenylsilyl-1-diazoethane and 0.34 g (0.00192 mol) of diphenylacetylene was dissolved in 50 ml of anhydrous ether to give a yellow solution. No fading of the color was observed after the mixture had stood in the dark for 48 h at room temperature, or after 16 h refluxing in ether or 48 h reflux in benzene. The benzene solvent was evaporated and replaced with 50 ml of anhydrous toluene and after heating under reflux for 48 h, the mixture had decolorized. Evaporation gave a thick, colorless oil. An n.m.r. spectrum indicated vinyltriphenylsilane to be the sole product derived from the diazoalkane since no C—*Me* singlets were present. The oil was chromatographed on silica gel. Elution with 60–70° petrol gave a total of 0.20 g (59%) of recovered diphenylacetylene, m.p. 55–60°. Recrystallization from ethanol raised the m.p. to 61–65°. A mixed m.p. with diphenylacetylene was undepressed. Further elution with carbon tetrachloride gave a total of 0.20 g (37%) of vinyltriphenylsilane, m.p. 63–66°. A mixed m.p. with an authentic sample (17) was undepressed.

The Photolysis of 1-Triphenylsilyl-1-diazoethane in Ether

A yellow solution of 0.90 g (0.00286 mol) of 1-triphenylsilyl-1-diazoethane in 75 ml of anhydrous ether was photolyzed under nitrogen using a long wavelength "Blak-Ray" lamp. The solution had decolorized after a total of 6 h of illumination. Evaporation gave an oil, which was chromatographed on silica gel. Elution with carbon tetrachloride gave a total of 0.45 g (55%) of vinyltriphenylsilane, m.p. 65–68° on recrystallization from ethanol. A mixed m.p. with an authentic sample was undepressed.

The Photolysis of 1-Triphenylsilyl-2-phenyl-1-diazoethane in Ether

A yellow solution of 0.26 g (0.00067 mol) of 1-triphenylsilyl-2-phenyl-1-diazoethane in 50 ml of anhydrous ether was photolyzed under nitrogen using a long wavelength "Blak-Ray" lamp. The solution had decolorized after 4 h. Evaporation gave an oil, whose n.m.r. spectrum showed the presence of the alkene protons due to *cis*- and *trans*-β-triphenylsilylstyrene. No signals due to α-triphenylsilylstyrene could be observed. Crystallization from hexane gave 0.13 g (54%) of *trans*-β-triphenylsilylstyrene, m.p. 141–144°. Further recrystallization from methanol raised the m.p. to 148–150°. A mixed m.p. with an authentic (18) sample was undepressed.

Evaporation of the initial mother liquor gave an oil. Crystallization from methanol gave 0.05 g (21%) of *cis*-β-triphenylsilylstyrene, m.p. 90–94°. A mixed m.p. with an authentic sample (19) was undepressed.

The Pyrolysis of Phenyltriphenylsilyldiazomethane in Dimethyl Sulfoxide

A 0.10 g (0.000266 mol) sample of phenyltriphenylsilyldiazomethane was heated in 5 ml of dimethyl sulfoxide for 10 min at 150°. The mixture was poured into ether and was washed several times with water. The organic layer was dried over magnesium sulfate and the solvent was evaporated to give a yellow oil, whose i.r. spectrum showed the complete removal of the strong diazo band. Crystallization from ethanol gave 0.025 g (27%) of benzoyltriphenylsilane, m.p. 102–104°.

When a similar pyrolysis had been carried out on a 0.50 g (0.00133 mol) sample of the diazoalkane in 10 ml of dimethyl sulfoxide for 10 min at 130°, the diazoalkane

was recovered intact. No trace of benzoyltriphenylsilane could be detected in the i.r. spectrum.

The Photolysis of Phenyltriphenylsilyldiazomethane in Methanol

A solution of 0.50 g (0.00133 mol) of the diazoalkane in 50 ml of methanol and 15 ml of benzene (to effect solution) was photolyzed under nitrogen using a long wavelength "Blak-Ray" lamp. The solution decolorized after 1 h. Evaporation gave a solid, whose n.m.r. spectrum indicated the formation of α-methoxybenzyltriphenylsilane and triphenylmethoxysilane in the ratio of 75:25. The mixture was chromatographed on silica gel. Elution with carbon tetrachloride followed by benzene gave a series of solids which on combination and recrystallization from ethanol gave 0.19 g (37%) of α-methoxybenzyltriphenylsilane, m.p. 146–148°. A mixed m.p. with an authentic sample (20) was undepressed. Continued elution with chloroform gave 0.08 g (21%) of triphenylsilanol, the hydrolysis product of triphenylmethoxysilane, m.p. 150–153°.

Dehydrogenation of 7,12-Dihydropleiadene Compounds with High Potential Quinones

J. W. LOWN AND A. S. K. AIDOO
Department of Chemistry, University of Alberta, Edmonton, Alberta

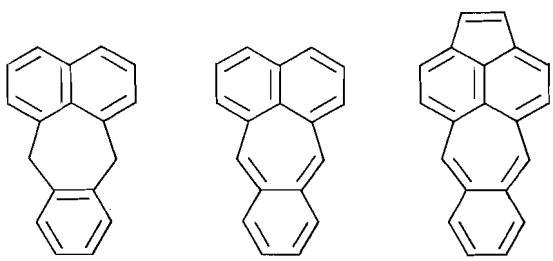
Received December 7, 1970

Dehydrogenation with high potential quinones has been extended to dihydro derivatives of non-aromatic hydrocarbons using 7,12-dihydropleiadenes as models. Reaction of 7-phenyl-7,12-dihydropleiadene with high potential quinones resulted in dehydrogenative cyclization whereas preparative scale and rate studies in 9-aryl-9,10-dihydroanthracenes gave no evidence of aryl participation during quinone dehydrogenation due to geometrical restrictions on this system.

Utilisant les dihydro-7,12 pléiadènes comme modèles, on a étendu aux dérivés dihydrogénés des hydrocarbures non aromatiques la méthode de déshydrogénation faisant appel aux quinones à haut potentiel. La réaction du phényl-7 dihydro-7,12 pléiadène avec de telles quinones provoque une cyclisation déshydrogénante; par ailleurs des études tant préparatives que cinétiques sur des aryl-9 dihydro-9,10 anthracènes n'ont fourni aucune preuve que les restrictions géométriques imposées à ce système provoquent une participation du groupe aromatique au cours de ces déshydrogénations.

Canadian Journal of Chemistry, 49, 1848 (1971)

Dehydrogenation of hydroaromatic compounds with high potential quinones is an important reaction widely used in synthetic schemes and in the oxidation of natural products (1). A substantial part of the driving force for the two-step ionic mechanism, proceeding by initial hydride transfer to the quinone is thought to be provided by the net resonance energy gain in both the quinone (acceptor) and the hydroaromatic compound (donor) which is thereby aromatized (2). In previous publications (3, 4) we demonstrated that aralkyl groups may react further with quinones often with surprising ease (*e.g.* 9,10-dimethylanthracene and 7,12-dimethylbenzanthracene) giving rise to cyclic and acyclic quinol ethers some of which are plausibly interpreted as arising via the intermediacy of para-quinodimethane intermediates. We report studies of the reaction of high potential quinones on derivatives of 7,12-dihydropleiadene (**1**), the parent compound of which, pleiadene (**2**) is expected not to exhibit substantial resonance stabilization (5, 6). Compounds **1** had the added interest of containing a potential ortho-quinodimethane moiety which could be expected to result from quinone dehydrogenation. The results on these systems extend the range of quinone dehydrogenation, limited to hydroaromatic donors hitherto, and also one compound proved ideal for testing predictions of cyclodehydrogenation.



1 **2** **3**

7,12-Dihydropleiadene as Donors

Pleiadene has been generated in solution by Cava and Schlessinger by the elimination of sulfur dioxide from 7,12-dihydropleiadene-7,12-sulfone (**4**) both thermally and photochemically (see eq. 1) and by dehalogenation of 7,12-dibromo-7,12-dihydropleiadene with zinc or copper bronze at moderate temperatures (7). Pleiadene, in contrast to acepleiadylene (**3**) cannot be regarded as a peripherally conjugated system, and consequently exhibits a greater degree of ortho-quinodimethane character than **3** and dimerized readily to **5** in solution or could be trapped with *N*-phenylmaleimide in a Diels–Alder reaction to form **6**, however, only at higher temperatures.

Reaction of **1** (8) with 2 equiv of tetrachloro-

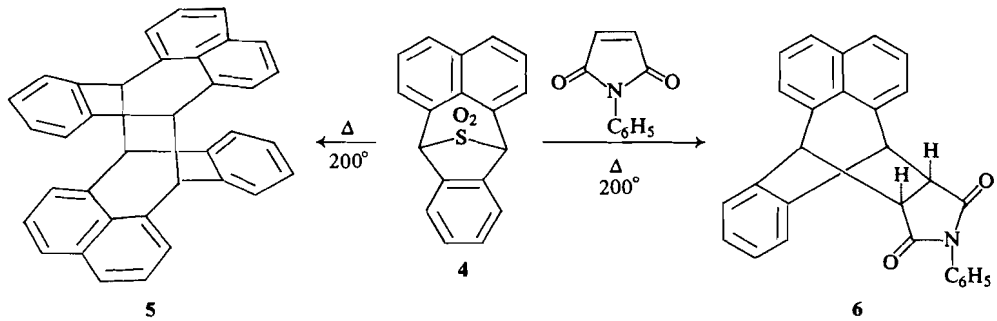
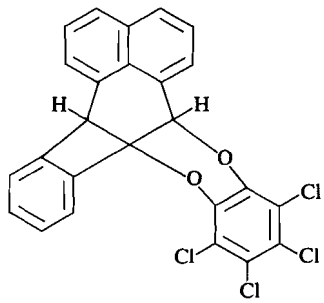
[1]



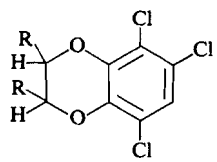
5 4 6

1,2-benzoquinone (TOQ) in refluxing chlorobenzene readily gave compound **7**. Examination

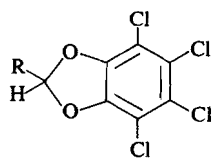


7

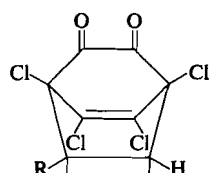
of the products of the reaction of quinones with alkenes by Horner and Merz (9) and in our own work with arenes (3, 4) have shown that products may be formed of types **8**, **9**, and **10** from ortho



8



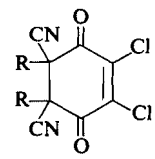
9



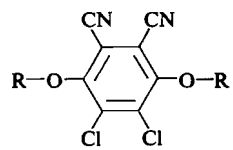
10

quinones (*e.g.* TOQ) and of types **11** and **12** from para quinones such as 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ).

Compounds of types **8** and **9** are white or pale



11

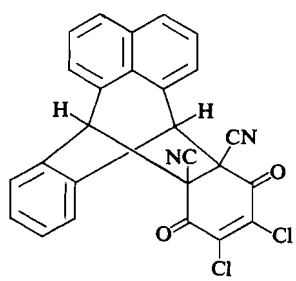


12

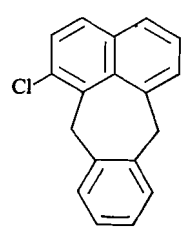
yellow solids the i.r. spectra of which exhibit strong and characteristic ether bands in the region 1420–1450 cm^{-1} due to tetrachlorobenzodioxan and tetrachlorobenzodioxole moieties (10). Adducts of type **10** are formed when TOQ acts as a diene and are characteristically bright yellow and exhibit strong α-diketone i.r. bands near 1680 cm^{-1}. In adducts of type **11** DDQ acts as a dienophile at the more reactive (nitrile substituted) double bond, an assumption which has recently been justified by X-ray analysis of a DDQ adduct of 1,3,5,5-tetramethylcyclohexa-1,3-diene (11).

Compound **7**, $C_{24}H_{12}Cl_4O_2$ showed a benzodioxan absorption at 1454 cm^{-1} but no hydroxyl or ketone absorption.

In contrast **1** reacted with DDQ to give compound **13**, $C_{26}H_{12}N_2Cl_2O_2$ in 47% yield, the formation of which can plausibly be interpreted by initial dehydrogenation of **1** to **2** followed by Diels–Alder addition to the nitrile substituted bond of DDQ. Compound **13** showed i.r. bands



13



14

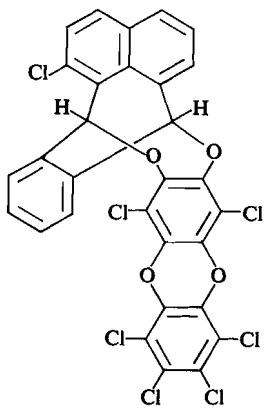
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

at 1705 (C=O) and 2250 cm^{-1} (C≡N) and the n.m.r. spectrum showed, besides aryl protons, a singlet at 5.05 δ (2H) demonstrating the equivalence of the 7- and 12-protons and therefore the symmetry of the molecule. (The signals of the corresponding protons in **7** are shifted by the adjacent oxygens into the aromatic region.)

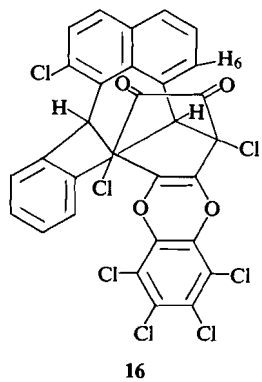
Evidently 7,12-dihydropleiadene, lacking the driving force available to hydroaromatic donors, is still dehydrogenated readily by the two different quinones.

Cava and Schlessinger have convincingly demonstrated that Diels–Alder addition products of **2**, *e.g.* **6**, have the *exo* configuration illustrated (7). Accordingly we have assigned the *exo* configuration to **13** and tentatively assigned the conformation of **7** as *exo* as shown.

In contrast to the formation of **7** reaction of 1-chloro-7,12-dihydropleiadene (**14**) with TOQ gave rise to two isomeric products to which structures **15** and **16** were assigned the com-



15

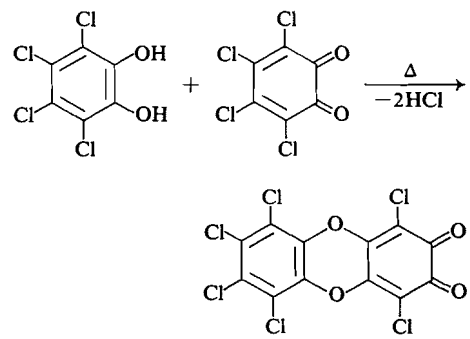


16

position which corresponded to $C_{30}H_{10}Cl_4O_4$, *i.e.* 1:2 pleiadene:quinone −2HCl. Compound **15** showed two strong ether bands in the i.r. at 1420 (=C—O—C) and 1445–1453 cm^{-1} (=C—O—C=) and no C=O bands, the 7- and 12-protons as in the case of **7** appeared in the aromatic region in the n.m.r. The isomer **16** was a bright yellow solid the i.r. spectrum of which showed bands due to both tetrachlorobenzodioxan (1445 cm^{-1}) and α-diketone (1680 cm^{-1}). The n.m.r. spectrum showed, in addition to aryl protons, two singlets at 5.26 and 6.31 δ (1H each) unambiguously assigned to the 7- and 12-pleiadene bridge protons since the corresponding adduct prepared from 1-chloro-7,7,12,12-tetradeuteropleiadene lacked these signals. In addition a doublet at 6.26 δ (J = 10.6 Hz), unaffected by the deuteration, was shown to be an aromatic proton by double irradiation experiments. It is tentatively assigned to the C-6 proton, adjacent to a carbonyl group in the proposed structure **16**.

Compound **14** is far less reactive than **1** because the electron-withdrawing 1-chloro substituent in **14** so deactivates the potential hydride ion at the benzylic positions, that higher reaction temperatures and longer reaction times are required for dehydrogenation. A similar sensitivity to electron-withdrawing substituents reflected in the Hammett ρ value of −2.5 has been observed in the dihydronaphthalene series (12). Under these forcing conditions TOQ undergoes a preceding reaction with the corresponding quinol to form **17** (see eq. 2).

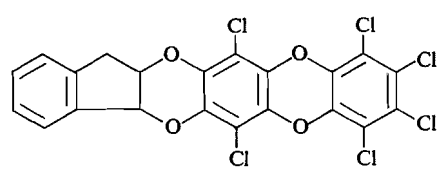
[2]



17

Compound **17** prepared independently (13) was allowed to react with **14** and gave rise to both compounds **15** and **16**.

In view of the reactions discussed above, the formation of **15** and **16** can be envisaged as involving similar reaction paths to those implied in the formation of **7** and **13** respectively, *i.e.* via an acyclic quinol ether to form **15** and by addition to 1-chloropleiadene to form **16**.



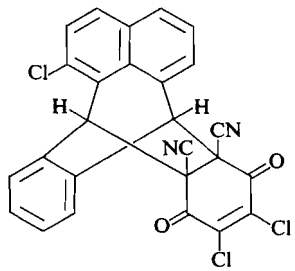
18

Indane, which like **14** requires forcing conditions to react with TOQ, similarly affords com-

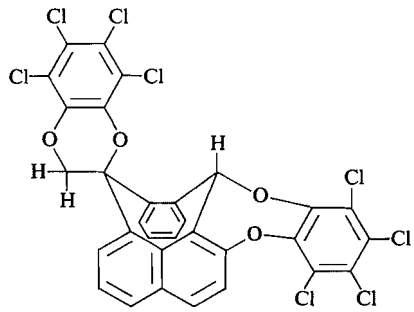
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

pound **18** (14). Compound **14** reacted with DDQ to give adduct **19**, $C_{26}H_{11}Cl_3N_2O_2$ similar to **13**.

Substitution of an alkyl group at the 7-position of 1-chloro-7,12-dihydropleiadene has a pronounced effect on the course of reaction with

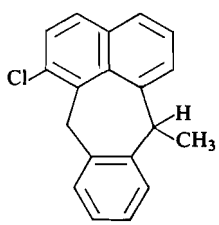


19

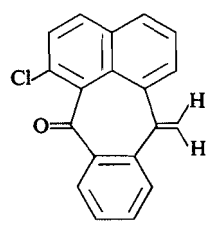


20

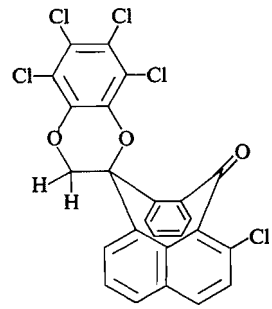
TOQ. The major product obtained from the 7-methyl derivative **21** was a pale yellow solid, $C_{31}H_{12}Cl_8O_4$, corresponding to the addition of 2 mol of TOQ and the elimination of H_2 and HCl. The product shows two distinct tetrachloroquinol ether bands at 1420 and 1445 cm^{-1} and is formulated as **20**. Supporting evidence for dehydrogenation into the methyl group of **21** to form the methylene compound followed by addition of TOQ to form the cyclic quinol ether is provided by reaction of **22** to form adduct **23**, $C_{25}H_{11}Cl_5O_3$, which shows a strong quinol ether absorption at 1423 cm^{-1}. In addition the methyl-



21

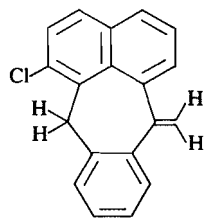


22

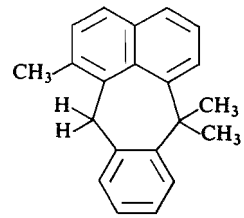


23

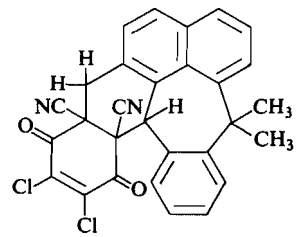
ene compound **24** forms **20** by reaction with 2 mol of TOQ. Reaction of the second quinone molecule results in substitution of the 1-chlorine by the quinone oxygen to form the cyclic ether.



24

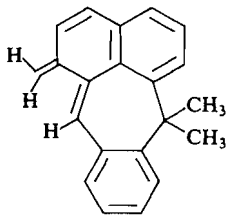


25

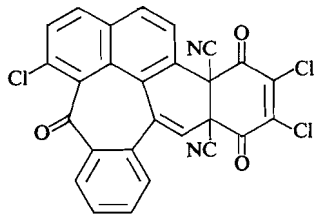


26

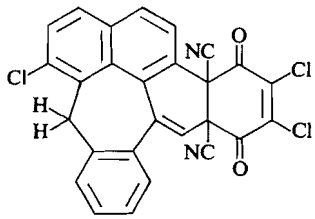
Reaction of 1,7,7-trimethyl-7,12-dihydropleiadene (**25**) with DDQ gave compound **26** $C_{29}H_{18}N_2Cl_2O_2$. The i.r. spectrum was typical of a Diels–Alder adduct of DDQ to the nitrile substituted double bond such as **13** and **19** and the n.m.r. spectrum showed the 7-methyl groups intact at 1.6 and 1.9, an AB quartet (J = 16 Hz) at 3.85 and 4.20 due to the methylene protons, and the methine singlet at 5.20 δ. Formation of **26** presumably involves Diels–Alder addition of DDQ to the reactive intermediate **27** which contains an ortho quinodimethane moiety and would resemble **2** in its reactivity towards dienophiles. Product **26** resembles those obtained from **22** and **24** with DDQ which gave **28** $C_{27}H_9Cl_3O_2N_2$, and **29**, $C_{27}H_{11}Cl_3N_2O_2$, respectively. In



27



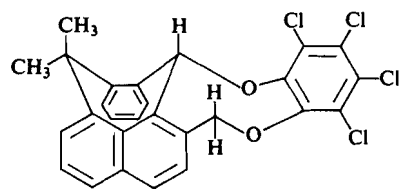
28



29

the case of **28** and **29** however the initial Diels–Alder addition products undergo further dehydrogenation to aromatize the naphthalene moiety. A corresponding subsequent dehydrogenation does not take place in the case of **26** since this would result in formation of a high energy ortho-quinodimethane structure. Compound **29** shows an AB quartet in the n.m.r. spectrum due to the C-12 methylene proton at 4.4 δ J = 16 Hz.

Compound **25** reacted with TOQ in refluxing benzene to give a white solid $C_{27}H_{18}Cl_4O_2$, the n.m.r. spectrum of which like **26** showed the 7-methyl groups unaffected at 1.8 and 2.05 δ and an AB quartet (2H) centered at 5.95 and 6.56 δ (J = 16 Hz) corresponding in chemical shift to a methylene bonded to oxygen. Since the i.r. spectrum showed a strong quinol ether absorption at 1405 cm^{-1} and no hydroxyl absorption this compound is formulated as **30**.



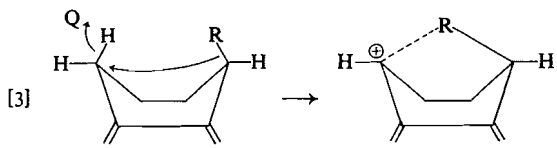
30

Thus the 1-methyl group in **25** shows a reactivity towards quinones comparable with that of methylnaphthalenes and 9-methylanthracene which also form quinol ethers under comparable conditions (3, 4).

Quinone Dehydrogenation of 9-Aryl-9,10-dihydroanthracenes and 7-Aryl-7,12-dihydropleiadenes

(i) Anthracene Models

The general quinone dehydrogenation reaction involves in the rate-determining initial step a hydride transfer from the donor (an arene or hydroaromatic compound) to the acceptor (quinone) with the concomitant generation of an electron deficient carbon (1, 2). It follows that in model compounds with a suitable geometry some degree of participation by a neighboring group could be anticipated (see eq. 3) and in the limit dehydrogenative cyclization could result.



[3]

31

As a first approach we have examined the dehydrogenation with some high potential quinones of some 9-aryl-9,10-dihydroanthracenes since their geometry is reasonably well defined (15). 9,10-Dihydroanthracene, and its 9-phenyl, 9-*p*-tolyl, and 9-*p*-anisyl derivatives reacted with TOQ (in benzene at moderate temperatures) to give the corresponding anthracenes quantitatively. The rates of these reactions could be followed conveniently by a spectrokinetic procedure (16) by observing the rate of disappearance of the red quinone. Individual reactions obeyed the second order rate law strictly and the rate data obtained are summarized in Table 1.

9-Phenyl, 9-*p*-tolyl, and 9-*p*-anisyl-9,10-dihydroanthracenes have reaction rates with TOQ very close to that of 9,10-dihydroanthracene when allowance is made for the statistical factor of 2. 9,10-Dihydroanthracenes adopt a quasi-boat conformation of the central ring and a 9-aryl substituent adopts the quasi-axial position preferentially so as to minimize interactions with the flanking benzene rings. Inspection of models suggests that the quasi-axial hydrogen atom at the 10-position is correctly disposed with respect to the aromatic rings of the anthracene structure to provide maximum stabilization of the incipient carbonium ion, in contrast to the quasi-equational hydrogen atom which is unfavorably oriented. We therefore make the reasonable

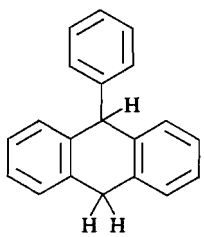
TABLE 1. Kinetic data for reaction of 9-aryl-9,10-dihydroanthracenes with tetrachloro-1,2-benzoquinone in 1,2-dichlorobenzene

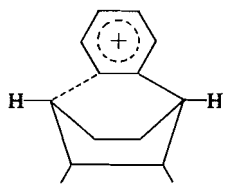
Donor	Second order rate constant (80°)	Arrhenius parameters	
		E (kcal mol^{-1})	$\text{Log}_{10} B$
9,10-Dihydroanthracene	$3.10 \pm 0.20 \times 10^{-1}$	12.06 ± 0.17	6.95
9,10-Dihydro-9-phenylanthracene	$1.37 \pm 0.04 \times 10^{-1}$	14.55 ± 0.58	8.15
9,10-Dihydro-9-*p*-tolylanthracene	$1.56 \pm 0.05 \times 10^{-1}$	13.48 ± 0.47	7.45
9,10-Dihydro-9-*p*-anisylanthracene	$1.75 \pm 0.12 \times 10^{-1}$	13.43 ± 0.23	7.65

assumption that the quasi-axial hydrogen atoms are potential hydride ions in the anthracene series.

In view of the known sensitivity of the quinone dehydrogenation reaction to substituent electronic effects in the dihydronaphthalene series (Hammett $\rho = -2.5$) (12) one would have anticipated a greater spread in the relative reactivities as reflected in the reaction rates, had hydride abstraction occurred at the 9-position.



32



33

It is apparent therefore that hydride abstraction occurs at the 10-position in this series of hydroaromatic donors (a conclusion which is borne out by experiments in the dihydropleiadene series described below) and we may also conclude that the axial 9-substituent does not participate in the removal of the hydride ion by bridging to the cationic center as in **33**.

We infer from the rate data that the geometry of the quasi-boat in the anthracene series is such that the 9-aryl substituent is not in a suitable position for this kind of interaction.

(ii) Pleiadene Models

The experience of the quinone dehydrogenation of the pleiadene system outlined in preceding sections and an examination of molecular models suggested that the geometry of this system in contrast to the anthracene case might be suitable to allow attack of a 7-arylsubstituent at the cationic center generated at the 12-position by hydride abstraction leading to dehydrogenative cyclization as illustrated in eq. 4. 7-Phenyl-7,12-dihydropleiadene (**34**) reacted with TOQ in benzene to give the bridged hydrocarbon **36** as the sole product. Evidently aryl attack as represented by **35** is so effective with this molecular geometry as to prevent loss of the 7-proton from the carbonium ion with formation of a 7-phenylpleiadene.

Recently Lansbury and coworkers (17) have prepared a similar compound **38** in an attempted dehydration of the alcohol **37** and this reaction must proceed by a similar mechanism once the cationic center has been generated at position 12 (see eq. 5).

7-Phenyl-7,12-dihydropleiadene (**34**) also reacted with DDQ to give pure **36**. Compound **36** is completely unreactive towards further reaction with either TOQ or DDQ, a result which is in accordance with the observed lack of reactivity of the bridgehead hydrogens in trypticene **39**. This may be attributed to the inability of an incipient carbonium ion generated from **36** or **39** to attain coplanarity with the aryl rings despite the additional flexibility allowed in **36** by the

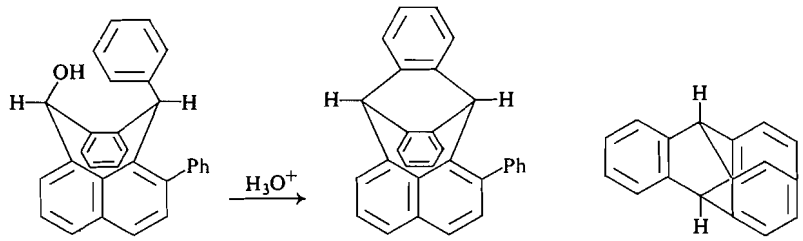
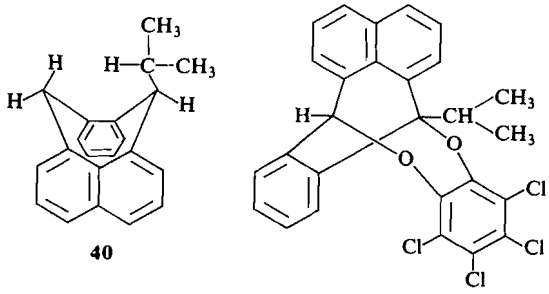
[5]



37 38 39

introduction of another fused aromatic ring compared with **39**.

Reaction of 7-isopropyl-7,12-dihydropleiadene (**40**) with TOQ gave compound **41**, similar in structure to **7** and **15**. The n.m.r. spectrum of **41**



40 41

shows bands characteristic of an intact isopropyl group and also reveals an absence of absorption characteristic of the 7,12-protons in **40**. A strong quinol ether absorption at 1455 cm^{-1} and the absence of carbonyl absorption support structure **41**.

The results obtained with the 9,10-dihydro-9-arylanthracenes lead one to expect the 12-axial proton in **40** to be the potential hydride ion in the first step of the reaction since Lansbury has shown the isopropyl group in **40** adopts a pseudo-axial conformation. Had 1,5-hydride shift occurred from the isopropyl group in **40** such as occurs in the dehydration of **42** studied by Lansbury (see eq. 6 (17)), one would have expected a final product of addition of TOQ to the isopropenyl or isopropylidene group such as **23** to have resulted. We conclude that, unlike the rapid dehydrogenative cyclization in **34** to form **36**, **41** results from collapse of the quinol anion to the initially formed carbonium ion which prevents a 1,5-transannular hydride shift, and that a second dehydrogenation step involving participation by the quinol hydroxyl results in the formation of **41**.

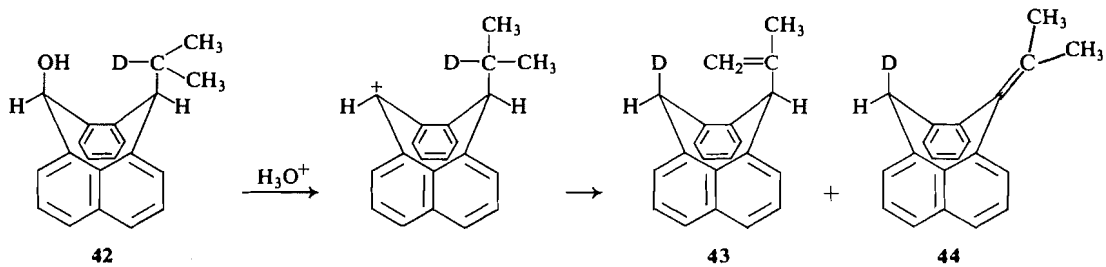
Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15 000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for t.l.c. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalysis Ltd., Montreal, Quebec and by Mrs. D. Mahlow of this Department. Values for carbon microanalysis of some adducts were unacceptable owing to difficulties in combustion of high molecular weight compounds. In such cases an accurate peak measurement by mass spectrometry was performed.

1-Chloro-7,12-dihydropleiadene

1-Chloro-7,12-dihydropleiadene was prepared from 1-chloro-7,12-dihydropleiadene-7,12-dione by the method of Cava and Schlessinger (7). The crude product was

[6]



42 43 44

purified by chromatography on alumina using hexane as eluent. Crystallization from hexane gave white needles, m.p. 116–119° (lit. 117–119° (7)).

7,12-Dihydropleiadene

7,12-Dihydropleiadene was prepared from 1-chloro-7,12-dihydropleiadene by a modification of the method of Cava and Schlessinger (7). A mixture of 25 g (0.095 mol) of 1-chloro-7,12-dihydropleiadene, 5 g of 10% palladium-on-charcoal, 100 ml of 85% hydrazine hydrate, and 1000 ml of 95% ethanol was refluxed for 1 h. The filtered solution was concentrated to *ca.* 100 ml, acidified with 2 *N* hydrochloric acid, and the solid product collected, washed repeatedly with water, and dried. Recrystallization from hexane gave 20 g (91.8% yield) of 7,12-dihydropleiadene, m.p. 115–117° (lit. 113–114° (7), 116° (8)).

Reaction of 7,12-Dihydropleiadene with Tetrachloro-1,2-benzoquinone

A solution of 4 g (0.017 mol) of 7,12-dihydropleiadene in 50 ml of dry chlorobenzene was added to a solution of 10 g (0.041 mol) of tetrachloro-1,2-benzoquinone in 250 ml of chlorobenzene and the mixture heated under reflux for 72 h. The solvent was removed *in vacuo*, the residue taken up in benzene and subjected to chromatography on BDH alumina using (1:1) benzene:hexane as eluent. The main fraction consisted of a buff-white solid recrystallized from benzene, m.p. 266–268°, 4.3 g (52.4% yield) of 7.

Anal. Calcd. for $C_{24}H_{12}Cl_4O_2$ (mol. wt. 471.9593): C, 60.78; H, 2.56; Cl, 29.90. Found (471.9594 (mass spectrum)): C, 61.26; H, 2.51; Cl, 29.05.

The i.r. spectrum $\nu_{max}(CHCl_3)$: 1454 cm^{-1} (C—O—C); n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 7.1–8.2 (m, aryl, C-7 and -12 protons).

Reaction of 7,12-Dihydropleiadene with 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone

A solution of 5 g (0.022 mol) of 7,12-dihydropleiadene in dry chlorobenzene was added to a solution of 10 g (0.044 mol) of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in 350 ml of chlorobenzene and the mixture refluxed for 30 min during which time a brown solid separated. Refluxing was continued for a further 1½ h, the mixture cooled, and the solid collected and washed with benzene. The filtrate was concentrated *in vacuo*, benzene added whereupon a yellow solid separated which was collected and washed with benzene yielding **13** 4.7 g (47.1% yield) m.p. > 300°.

Anal. Calcd. for $C_{26}H_{12}N_2Cl_2O_2$ (mol. wt. 454.0276): N, 6.16; Cl, 15.42. Found (454.0275 (mass spectrum)): N, 6.08; Cl, 15.31.

The i.r. spectrum ν_{max}(Nujol mull): 1705 (C=O), 2250 cm^{-1} (C≡N); n.m.r. spectrum $\delta_{TMS}((CD_3)_2SO)$: 5.05 (2H, s, C-7 and -12 protons), 7.1–8.2 (m, 10H, aromatic protons).

Reaction of 1-Chloro-7,12-dihydropleiadene with Tetrachloro-1,2-benzoquinone

A solution of 3.01 g (9 mmol) of 1-chloro-7,12-dihydropleiadene in 100 ml of dry *o*-dichlorobenzene was added to a solution of 8.36 g (0.0336 mol) of tetrachloro-1,2-benzoquinone in 300 ml of *o*-dichlorobenzene and the mixture refluxed for 48 h. The solvent was removed *in vacuo* (0.05 mm) and the residual solid taken up in benzene and subjected to chromatography on acid washed alumina. Elution with benzene gave **16**, 1 g, (13% yield) m.p. 280–281°.

Anal. Calcd. for $C_{30}H_{11}Cl_7O_4$: C, 52.94; H, 1.62; Cl, 36.03. Found: C, 53.05; H, 2.05; Cl, 36.48.

Mass Spectrum Calcd. for $C_{30}H_{10}{}^{35}Cl_6{}^{37}ClO_4$ (M^+-1): 680.8369. Found: 680.8372.

The i.r. spectrum $\nu_{max}(CHCl_3)$(Nujol): 1680 (C=O) 1454 cm^{-1} (—C—O—C); n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 5.26 and 6.31 (1H each, s, C-7 and -12 pleiadene bridge protons), these signals disappear in the analogous compound obtained from 1-chloro-7,7,12,12-tetradeuteropleiadene, 6.26 (1H, d, J = 10.6 Hz ortho coupling, C-6(?) aromatic proton. Irradiation at 7.45 causes collapse of the 6.26 signal to a singlet, 7.0–8.0 (8H, m, aromatic protons).

Further elution with chloroform gave **15** 1.2 g (20% yield), m.p. > 300°.

Anal. Calcd. for $C_{30}H_{11}Cl_7O_4$: Cl, 36.03. Found: Cl, 35.62.

The i.r. spectrum $\nu_{max}(CHCl_3)$: 1420 (—C—O—C—), 1445–1453 cm^{-1} (—C=C—O—C); n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 6.7–8.2 (m, aromatic, C-7 and -12 bridge protons).

Reaction of 1-Chloro-7,12-dihydropleiadene with Hexachloro-ortho-quinopyrocatechin Ether

A solution of 0.61 g (25 mmol) of 1-chloro-7,12-dihydropleiadene in 50 ml of dry chlorobenzene was added to a solution of 2.09 g (50 mmol) of hexachloro-ortho-quinopyrocatechin ether (13) in 300 ml of warm chlorobenzene and the mixture refluxed for 72 h. The solvent was removed *in vacuo* and the residue dissolved in benzene and subjected to chromatography on BDH alumina using benzene as eluant to give a bright yellow solid, m.p. > 300°, 0.5 g (29.4% yield).

Mol. Wt. Calcd. for $C_{30}H_{11}Cl_7O_4$: 679.8480. Found (mass spectrum): 679.8470.

The i.r. spectrum $\nu_{max}(CHCl_3)$: 1672 (—CO—CO—) 1452 cm^{-1} (C=C—O—C=C). This compound proved to be identical with adduct **16** obtained above.

Further elution with chloroform gave a violet compound 0.43 g (25.3% yield) the i.r. spectrum of which in $CHCl_3$ showed bands at 1453 and 1422 cm^{-1} (—C—O—C) and which proved to be identical with adduct **15** obtained above.

1-Chloro-7,7,12,12-tetradeutero-7,12-dihydropleiadene

Aluminum chloride (2.7 g, 0.02 mol) and 0.84 g (0.02 mol) of lithium aluminum hydride were added to ether at 0°. To this mixture was added with stirring 2.54 g (8 mmol) of 1-chloro-7,12-dihydropleiadene-7,12-dione and the mixture stirred for 45 min, decomposed with ice, the ether layer washed with water and dried (Na_2SO_4), and the ether removed *in vacuo* to give a slightly yellow solid. The latter was chromatographed on BDH alumina to give 2 g of 1-chloro-7,7,12,12-tetradeutero-7,12-dihydropleiadene, m.p. 119–121°.

Mol. Wt. Calcd. for $C_{18}H_9D_4Cl$: 268.0876. Found (mass spectrum): 268.0879.

Reaction of 1-Chloro-7,7,12,12-tetradeutero-7,12-dihydropleiadene with Tetrachloro-1,2-benzoquinone

A solution of 0.5 g (1.86 mmol) of 1-chloro-7,7,12,12-tetradeutero-7,12-dihydropleiadene in 25 ml of *o*-dichlorobenzene was added to a solution of 1.05 g (4.26 mmol) of tetrachloro-1,2-benzoquinone in 50 ml of

For personal use only.

o-dichlorobenzene and the mixture refluxed for 48 h. The solvent was removed *in vacuo* and the residue subjected to chromatography using benzene as eluant to give 0.3 g (29.4% yield) of D-**16** m.p. 280–281°.

Mol. Wt. Calcd. for $C_{30}H_9D_2O_4{}^{35}Cl_6{}^{37}Cl$: 683.8581. Found (mass spectrum): 683.8576.

The i.r. spectrum ν_{max}(Nujol): 1660 (C=O), 1445 cm^{-1} (—C—O—C=C—O).

Reaction of 1-Chloro-7,12-dihydropleiadene with 2,3-Dichloro-5,6-dichloro-1,4-benzoquinone

A solution of 4 g (15 mmol) of 1-chloro-7,12-dihydropleiadene in 75 ml of dry chlorobenzene was added to a solution of 10 g (0.044 mol) of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in 350 ml of chlorobenzene and the mixture heated under reflux for 2 h. The insoluble quinol which separated from the reaction mixture was collected and the filtrate concentrated *in vacuo*. The residual solid was taken up in chloroform and subjected to chromatography on silica gel with benzene:chloroform (2:1) as eluent giving **19** as bright yellow crystals in m.p. 270°, 3.8 g (51.2% yield).

Anal. Calcd. for $C_{26}H_{11}Cl_3N_2O_2$ (mol. wt. 487.9886): C, 63.95; H, 2.25; Cl, 21.52; N, 5.73. Found: 487.9888 (mass spectrum): C, 63.35; H, 2.39; Cl, 21.39; N, 5.64.

The i.r. spectrum ν_{max}(Nujol mull): 2246 (C≡N), 1700, 1715(sh) cm^{-1} (C=O); n.m.r. spectrum δ_{TMS}-($(CD_3)_2SO$): 5.15 (1H, s, C-7 proton), 5.64 (1H, s, C-12 proton), 7.2–8.2 (9H, m, aromatic protons).

Reaction of 1-Chloro-7-methyl-7,12-dihydropleiadene with Tetrachloro-1,2-benzoquinone

A solution of 0.556 g (2 mmol) of 1-chloro-7-methyl-7,12-dihydropleiadene in dry chlorobenzene was added to a solution of 0.976 g (4 mmol) of the quinone in 150 ml of dichlorobenzene and the mixture refluxed for 10 h. The solvent was removed *in vacuo* and the residual solid purified by chromatography on BDH alumina using hexane:benzene (2:1) as eluent to give 0.13 g (8.9% yield) of **20**, m.p. 286–289.

Anal. Calcd. for $C_{31}H_{12}Cl_8O_4$ (mol. wt. 727.8248): C, 51.10; H, 1.65; Cl, 38.47. Found (727.8237 (mass spectrum)): C, 51.71; H, 1.65; Cl, 37.03.

The i.r. spectrum $\nu_{max}(CHCl_3)$: 1445, 1420 cm^{-1} (—C—O—C).

1-Chloro-7-methylene-7,12-dihydropleiadene and 1-Chloro-7-methyl-7,12-dihydropleiadene

A stirred suspension of 10 g (0.036 mol) of 1-chloro-7-pleiadenone in 200 ml anhydrous ether was treated dropwise with a solution of methyllithium in ether added through a serum cap until a pink coloration persisted. The mixture was stirred for 2 h, then poured on to ice, and acidified with dilute hydrochloric acid. The ether layer was separated, washed with water and dried ($NaSO_4$). The ether was removed *in vacuo*, the residual solid dissolved in hexane and purified by chromatography on BDH alumina giving 1-chloro-7-methylene-7,12-dihydropleiadene (**24**) 6 g (60.4% yield). The latter (5.52 g) was dissolved in 250 ml of 95% ethanol and hydrogenated over 1.5 g of 5% palladium-on-charcoal at atmospheric pressure giving 5.5 g (99% yield) of 1-chloro-7-methyl-7,12-dihydropleiadene (**21**), m.p. 95°.

Anal. Calcd. for $C_{19}H_{15}Cl$ (mol. wt. 292.0655): Cl, 12.59. Found (292.0653 (mass spectrum)): Cl, 12.40.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 1.80 (3H, d, CH_3), 4.6–4.97 (3H, m, C-7 and -12 protons), 7.05–7.70 (9H, m, aromatic protons).

1-Chloro-7,12-epoxy-7,12-dihydro-7-methylpleiaden-12-ol

1-Chloro-7,12-dihydropleiadene-7,12-dione (10 g, 34 mmol) was added during 20 min to a stirred solution of methyl magnesium iodide (prepared from 15 g of methyl iodide, 3 g of magnesium, and 200 ml of anhydrous ether). After completed addition, stirring was continued for 8 h and worked-up in the usual way with saturated aqueous ammonium chloride giving 6.2 g (59% yield) of 1-chloro-7,12-epoxy-7,12-dihydro-12-methylpleiaden-7-ol as a white solid m.p. 205–207°.

Anal. Calcd. for $C_{19}H_{13}ClO_2$: C, 74.03; H, 4.22; Cl, 11.36. Found: C, 74.00; H, 4.28; Cl, 11.47.

The i.r. spectrum $\nu_{max}(CHCl_3)$ 3560, 3360 cm^{-1} (OH), 1450 cm^{-1} (—C—O—C); n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 2.2 (3H, s, CH_3), 4.95 (1H, s, OH), 7.0–8.0 (9H, m, aromatic protons).

1-Chloro-7-methylene-7,12-dihydropleiaden-12-one

1-Chloro-7,12-epoxy-12-methyl-7,12-dihydropleiaden-12-ol (6.2 g, 2 mmol) was dissolved in 100 ml of benzene, a catalytic quantity of *p*-toluenesulfonic acid added, and the mixture refluxed for 8 h, allowed to cool, and washed successively with 10% aqueous sodium hydrogen carbonate and water. The benzene layer was removed and dried ($MgSO_4$). Removal of the solvents *in vacuo* gave 1-chloro-7-methylene-7,12-dihydropleiaden-12-one (**22**), m.p. 169–171°, 5.3 g (91.4% yield).

Anal. Calcd. for $C_{19}H_{11}ClO$: C, 78.61; H, 3.79; Cl, 12.07. Found: C, 78.64; H, 3.79; Cl, 12.01.

The i.r. spectrum $\nu_{max}(CHCl_3)$ 1685 cm^{-1} (C=O); n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 5.65, 5.45 (2H, pair of doublets, J = 1.5 Hz, methylene protons), 7.25–7.85 (9H, m, aromatic protons).

Reaction of 1-Chloro-7-methylene-7,12-dihydropleiaden-12-one with Tetrachloro-1,2-benzoquinone

A solution of 1.45 g (5 mmol) of 1-chloro-7-methylene-7,12-dihydropleiaden-12-one in 75 ml of dry dichlorobenzene was added to a solution of 2.44 g (0.01 mol) of tetrachloro-1,2-benzoquinone in 125 ml of dichlorobenzene and the mixture refluxed for 24 h. The solvent was removed *in vacuo* and the residue triturated with benzene and recrystallized from benzene to give 1.3 g, m.p. 292–293° of **23**. The mother liquor was subjected to chromatography on BDH alumina to give an additional 0.5 g of **23** making a total yield of 67%.

Anal. Calcd. for $C_{25}H_{11}Cl_5O_3$ (mol. wt. 533.9153): C, 56.16; H, 2.07; Cl, 32.77. Found (533.9150 (mass spectrum)): C, 56.24; H, 2.07; Cl, 32.69.

The i.r. spectrum $\nu_{max}(CHCl_3)$, 1685 (C=O), 1423 cm^{-1} (—C—O—C—).

Reaction of 1-Chloro-7-methylene-7,12-dihydropleiadene with 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone

A solution of 0.552 g (2 mmol) of 1-chloro-7-methylene-7,12-dihydropleiadene in 25 ml of benzene was added to a solution of 0.904 g (4 mmol) of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in 200 ml of benzene and the mixture refluxed for 10 h, cooled, and filtered. Concentration of the filtrate gave a brick-red solid purified by recrystallization from benzene to give **29**, 0.68 g (68% yield), m.p. 242–245° (dec.).

Anal. Calcd. for $C_{27}H_{11}Cl_3N_2O_2$ (mol. wt. 499.9888): C, 64.80; H, 2.20; Cl, 21.00. Found (499.9886 (mass spectrum)): C, 64.79; H, 2.37; Cl, 20.95.

The i.r. spectrum ν_{max}(Nujol mull): 1718 (C=O); 2250 cm^{-1} (CN), n.m.r. spectrum $\delta_{TMS}((CD_3)_3SO)$: quartet centered at 4.4 (2H, C-12 bridge protons J_{AB} = 15 Hz broad lines), 6.1, 6.47 (1H, singlets, vinyl proton), 6.95–8.5 (8H, aromatic protons).

1,7,7-Trimethyl-7,12-dihydropleiadene

To a stirred solution of 6.5 g of methyl-2-[2′-methyl-1′naphthylmethyl]benzoate in ether (prepared by treating the acid with methanol in the presence of a catalytic quantity of sulfuric acid), was added excess of a solution of methyllithium in ether. The mixture was poured on to ice, acidified with 2 *N* hydrochloric acid, and the ether layer separated and dried ($MgSO_4$). Evaporation of the solvent gave 1-[2′-(1′′-hydroxy-1′′-methylethyl)tolyl]-2-methylnaphthalene as a yellow oil. The oil was dissolved in 100 ml of formic acid containing a catalytic amount of *p*-toluenesulfonic acid and the mixture heated on the steam bath for 3 h. The solution was diluted with water extracted with ether, and the ether layer separated and washed with 10% sodium hydrogen carbonate solution then water and dried ($MgSO_4$). Evaporation of the solvent gave a yellow oil, chromatography of which on alumina gave 1-(2-isopropenyltolyl)-2-methylnaphthalene as a white crystalline solid identified by its n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 2.25 (3H, s, isopropenyl protons), 2.40 (3H, s, aryl methyl protons), 4.50 (2H, s, bridge methylene protons), 5.15, 5.40 (2H, m, isopropenyl vinylic protons), 6.40–8.0 (9H, m, aromatic protons). The latter was dissolved in 50 ml of anhydrous ether, treated with 25 ml of boron trifluoride-etherate in ether (48%) and the mixture stirred for 2 h. The reaction mixture was decomposed with ice, the ether layer removed, washed with water, and dried ($MgSO_4$). Evaporation of the solvent gave a brown solid purified by chromatography on BDH alumina to give 2.5 g (40% yield overall from the ester) of 1,7,7-trimethyl-7,12-dihydropleiadene (**25**), m.p. 165–166°.

Anal. Calcd. for $C_{21}H_{20}$: C, 92.64; H, 7.36. Found: C, 92.62; H, 6.7.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 1.74 (6H, s, C-7 methyl groups), 2.73 (3H, s, C, methyl group), 4.18 (2H, s, C-12 methylene protons), 7.00–8.00 (9H, m, aromatic protons). This compound has previously been reported but no experimental details were given (18).

Reaction of 1,7,7-Trimethyl-7,12-dihydropleiadene with 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone

A solution of 0.34 g (1.25 mmol) of 1,7,7-trimethyl-7,12-dihydropleiadene in 25 ml of benzene was added to 0.565 (2.5 mmol) of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in 150 ml of benzene and the mixture refluxed for 30 min during which time the hydroquinone separated as a brown solid. The solution was refluxed for a further 1½ h, cooled, and filtered. Concentration of the filtrate to *ca.* 50 ml deposited bright orange-red crystals of **26** purified by recrystallization from benzene 0.531 g (85.6% yield), m.p. 209–212°.

Anal. Calcd. for $C_{29}H_{18}N_2Cl_2O_2$ (mol. wt. 496.0746): C, 70.17; H, 3.63; Cl, 14.11. Found (496.0753 (mass spectrum)): C, 70.33; H, 3.41; Cl, 14.03.

The i.r. spectrum $\nu_{max}(CHCl_3)$: 1718 (C=O), 2225 cm^{-1} (C≡N); n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 1.6 (3H, s, C-7 equatorial CH_3), 1.9 (3H, s, C-7 axial CH_3), AB quartet centered at 3.85 and 4.20 (2H, q, J_{AB} = 16 Hz, C-12 CH_2), 5.20 (1H, s, C-12 methine proton), 7.20–8.30 (9H, m, aromatic protons).

Reaction of 1-Chloro-7-methylene-7,12-dihydropleiaden-12-one with 2,3-Dichloro-5,6-dicyano-1,4-benzoquinones

A solution of 1.37 g (5 mmol) of 1-chloro-7-methylene-7,12-dihydropleiadene in 100 ml of chlorobenzene was added to a solution of 2.230 g (10 mmol) of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in 150 ml of chlorobenzene and the mixture heated under reflux for 6 h. The filtered solution was concentrated to a small volume to give **28** as a yellow ocher solid, m.p. 225–228°, 1.77 g (67.3% yield).

Anal. Calcd. for $C_{27}H_9Cl_3O_3N_2$: Cl, 20.43; N, 5.45. Found: Cl, 21.65; N, 5.50.

The i.r. spectrum ν_{max}(Nujol mull): 1736, 1705 (C=O of quinone) 1680 cm^{-1} (C=O at C-12), n.m.r. spectrum $\delta_{TMS}((CD_3)_2SO)$: 6.45, 6.7 (1H, s, vinyl proton) 6.95–8.4 (8H, m, aromatic protons).

The appearance of two singlets for the vinyl protons is tentatively attributed to the presence of stereoisomeric adducts, resulting from the two possible modes of addition of DDQ to the diene system.

Reaction of 1,7,7-Trimethyl-7,12-dihydropleiadene with Tetrachloro-1,2-benzoquinone

A solution of 0.34 g (1.25 mmol) of 1,7,7-trimethyl-7,12-dihydropleiadene in 25 ml of dry benzene was added to a solution of 0.61 g (2.5 mmol) of tetrachloro-1,2-benzoquinone in 125 ml of benzene and the mixture heated under reflux for 48 h, cooled, and concentrated to *ca.* 25 ml yielding a gray solid which on crystallization from benzene gave **30**, m.p. 197–199°, 0.263 g (41% yield).

Anal. Calcd. for $C_{27}H_{18}Cl_4O_2$: C, 63.02; H, 3.50; Cl, 27.24. Found: C, 63.48; H, 3.45; Cl, 27.12.

The i.r. spectrum $\nu_{max}(CHCl_3)$: 1405 cm^{-1} (C—O—C); n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 1.8 (3H, s, C-7 equatorial CH_3), 2.05 (3H, s, C-7 axial CH_3), 5.95, 6.56 (AB quartet, J_{AB} = 16 Hz, C-19 CH_2 protons), 7.2–8.3 (9H, m, aromatic protons).

Synthesis of 9-Arylanthracenes and 9,10-Dihydro-9-arylanthracenes

The general method is described for 9-*p*-tolylanthracene and 9,10-dihydro-9-*p*-tolylanthracene.

(a) 9-p-Tolylanthracene

Anthrone (10 g, 0.0515 mol) was extracted with ether during 12 h into a refluxing solution of *p*-tolyl magnesium bromide (prepared from 26 g, 0.152 mol of *p*-bromotoluene, 3.7 g, 0.154 mol of magnesium turnings, and 100 ml of ether). The solution was cooled and hydrolyzed with aqueous ammonium chloride. The mixture was extracted with ether and the extract washed with (*a*) 2 *N* sodium hydroxide solution, (*b*) 2 *N* hydrochloric acid, (*c*) aqueous sodium hydrogen carbonate solution, and dried ($MgSO_4$). The filtered solution was concentrated to 75 ml and refluxed for 1 h, the solvent removed, and the residual oil heated at 100°/0.5 mm for 12 h. Recrystallization of the yellow solid residue from ethanol and chromatography on grade 1 alumina (BDH) in benzene afforded pure *p*-tolyl-

anthracene in pale yellow needles, 4.0 g (29% yield), m.p. 145–147°.

(b) 9,10-Dihydro-9-p-tolylanthracene

Sodium (10 g) was added in small portions to a refluxing solution of 2 g (7.47 mmol) of 9-*p*-tolylanthracene in 150 ml of ethanol, until the solution no longer fluoresced in u.v. light. The solution was diluted with 600 ml of water and the resulting precipitate collected. Recrystallization from ethanol afforded 9,10-dihydro-9-*p*-tolylanthracene in colorless plates, m.p. 104–106°, 1.4 g (69% yield). The properties of other 9-arylanthracenes together with their 9,10-dihydro derivatives prepared by this method are summarized in Tables 2 and 3.

Preparative Scale Dehydrogenations

The general method is exemplified for 9,10-dihydro-9-*p*-tolylanthracene.

A mixture of 0.242 g (0.9 mmol) of 9,10-dihydro-9-*p*-tolylanthracene and 0.271 g (1.1 mmol) of tetrachloro-1,2-benzoquinone in 7 ml of benzene was heated under reflux for 8 h. The resulting mixture was passed down a column of grade 1 alumina and the column eluted with benzene. The evaporated eluent (0.23 g) had λ_{max} 255, 364, 384 mμ (log ε, 5.19; 4.01; 4.10). Pure 9-*p*-tolylanthracene has λ_{max} 256, 364, 384 mμ (log ε, 5.15, 4.01, 4.10). The product therefore contained 9-*p*-tolylanthracene (99.5%) and the overall yield of the latter was 94.5%.

Similarly 9,10-dihydro-9-phenylanthracene afforded 9-phenylanthracene (95% yield) and 9,10-dihydro-9-*p*-anisylanthracene afforded 9-*p*-anisylanthracene (92.5% yield).

Dehydrogenation Reaction Rate Studies

Materials

Pure 1,2-dichlorobenzene was dried over sodium and then distilled and had b.p. 177–178° at 750 mm. Commercial samples of tetrachloro-1,2-benzoquinone were purified by sublimation *in vacuo*.

Reaction Rates

The rates were determined by following spectrophotometrically the disappearance of the red quinone. The E_0 values were determined by graphical extrapolation. The experimental method used and detailed treatment of the rate data have been described previously (16). Values for the second order rate constants for reaction of the dihydroanthracenes with the quinone at 80° together with the Arrhenius parameters are summarized in Table 1.

A representative kinetic run at one temperature is recorded in Table 4. A summary of the rate constants for all the runs at different temperatures is given in Table 5. Unless otherwise stated the initial concentration of both the acceptor and the donor were 0.0100 *M* and 1,2-dichlorobenzene was the solvent.

Control Reaction Between Triptycene and Tetrachloro-1,2-benzoquinone

Reaction between 187 mg of triptycene and 429 mg of tetrachloro-1,2-benzoquinone in 5 ml of refluxing benzene for 8 days resulted in the recovery of unchanged triptycene, m.p. 250–252° in 81% yield, which set an approximate upper limit for any reaction as $k = 2 \times 10^{-6}$ l mol^{-1} s^{-1}.

†The units are l mol^{-1} s^{-1}.

7-Phenyl-7,12-dihydropleiadene

7-Phenyl-7,12-dihydropleiadene **34** was prepared from 1-(β-benzhydryl)naphthylcarbinol by the method of Lansbury in 80% yield, m.p. 180–181° (lit. m.p. 179–179.5) (19).

Reaction of 7-Phenyl-7,12-dihydropleiadene with 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone

A solution of 1.53 g (5 mmol) of 7-phenyl-7,12-dihydropleiadene in 25 ml of benzene was added to a solution of 2.26 g (0.01 mol) of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone in 150 ml of benzene and the mixture refluxed for 8 h, then concentrated to about 20 ml and chromatographed on BDH alumina using hexane:benzene (3:1) as eluent. Crystallization of the resulting solid in benzene gave 0.81 g (53.3% yield) of **36**, m.p. 271–273°.

Anal. Calcd. for $C_{24}H_{16}$: C, 94.73; H, 5.27. Found: C, 94.67; H, 5.45.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 5.16 (2H, s, C-7 and -12 protons); 6.95–7.67 (14H, m, aromatic protons).

Reaction of 7-Phenyl-7,12-dihydropleiadene with Tetrachloro-1,2-benzoquinone

A solution of 1.53 g (5 mmol) of 7-phenyl-7,12-dihydropleiadene in 50 ml of dry benzene was added to a solution of 3.66 g (15 mmol) of tetrachloro-1,2-benzoquinone in 125 ml of benzene and the mixture refluxed for 72 h. The solution was concentrated *in vacuo* to a small volume and chromatographed on BDH alumina using hexane:benzene as eluant. Recrystallization of the main fraction from benzene gave 1.22 g of **36**, (80.3% yield) m.p. 272°.

Anal. Calcd. for $C_{24}H_{16}$: C, 94.73; H, 5.27. Found: C, 94.53; H, 5.66.

This material was identical in every respect with that obtained in the preceding experiment.

7-Isopropyl-7,12-dihydropleiadene

7,12-Dihydropleiadene (6.9 g, 0.03 mol) was dissolved in 150 ml of anhydrous ether in a pressure bottle under an atmosphere of nitrogen and 14 ml of 2.25 *M* *n*-butyllithium in hexane added to it gradually with stirring. The bottle was securely stoppered and the complex stirred magnetically for 2 h. After cooling the mixture to −20°, 2.6 g (0.033 mol) of isopropylchloride in 10 ml of anhydrous ether was added from a syringe with stirring and under nitrogen. The bottle was stoppered again and the contents stirred at room temperature for 8 h. The complex was decomposed with ice and the ether layer dried (Na_2SO_4) and the solvent removed to give a thick yellow oil. This oil was treated with a hot methanolic solution of 2,4,7-trinitro-9-fluorenone when only the unreacted starting material formed a complex, which was removed by filtration. The solvent was removed from the filtrate and the residual oil extracted subjected to chromatography on BDH alumina using hexane as eluent to give **40** as a yellow oil. The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.8–1.05 (6H, m, $CH(CH_3)_2$), 2.55 (1H, m, $CH(CH_3)_2$), 3.6 (1H, d, J_{AB} = 10.5 Hz, C-7 bridge proton), 3.84, 5.14 (2H, q, $J_{A'B'}$ = 16 Hz, C-12 bridge protons), 7.0–7.83 (10H, m, aromatic protons) (20).

Reaction of 7-Isopropyl-7,12-dihydropleiadene with Tetrachloro-1,2-benzoquinone

A solution of 1.7 g (6.25 mmol) of 7-isopropyl-7,12-dihydropleiadene in 75 ml of dry chlorobenzene was added to a solution of 3.20 g (0.0120 mol) of tetrachloro-1,2-benzoquinone in 125 ml of chlorobenzene and the mixture refluxed for 72 h. The solvent was removed *in vacuo* and the residue dissolved in benzene and subjected to chromatography on BDH alumina using 1:1 hexane:benzene as eluent to give 1.56 g **41**, m.p. 160–165°.

Anal. Calcd. for $C_{27}H_{18}Cl_4O_2$ (mol. wt. 514.0063): Cl, 27.24. Found (514.0050 (mass spectrum)): Cl, 27.44.

The i.r. spectrum $\nu_{max}(CHCl_3)$: 1455, 1425 cm^{-1} (—C—O—C—); n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 0.5–1.5 (6H, m, $CH(CH_3)_2$), 1.87 (1H, m, J = 5 Hz, $CH(CH_3)_2$), 7.0–8.2 (8H, m, aromatic protons).

Quinodimethane Analogs in the Pleiadene and Acepleiadene Systems

J. W. LOWN AND A. S. K. AIDOO
Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received January 6, 1971

5,10-Dimethylene-5,10-dihydroacepleiadene and 7,12-dimethylene-7,12-dihydropleiadene have been synthesized. Their facile hydration to bridged epoxide structures suggests a non-planar boat structure in which they react as dienes. Evidence is presented for the base-catalyzed tautomerization of the former to the 18π peripheral aromatic 5,10-dimethylacepleiadylene. The isoelectronic diketone and methylene ketones in the acepleiadene series similarly tautomerize with potassium *t*-butoxide in dimethyl sulfoxide giving rise to stable radical anions.

On a synthétisé le diméthylène-5,10 dihydro-5,10 acépléiadène et le diméthylène-7,12 dihydro-7,12 pléiadène. Le fait que ces composés s'hydratent facilement pour conduire à des composés ayant une structure époxyde permet de croire qu'ils réagissent comme diènes dans une conformation bateau non-planaire. Des données sont présentées qui permettent de conclure que le premier de ces composés se tautomérise en milieu basique pour donner le diméthyl-5,10 acépléiadylène qui est aromatique et qui possède 18 électrons π périphériques. De la même manière les composés isoélectroniques, dicétone et méthylène-cétone de la série acépléiadène, se tautomérisent, en présence de *t*-butylate de potassium dans le DMSO, pour fournir des radicaux anions stables.

Canadian Journal of Chemistry, 49, 1861 (1971)

The possible intermediacy of 9,10-anthraquinodimethane (**1**) in the quinone dehydrogenation of 9,10-dimethylanthracene (1) and the generation of pleiadenes containing an ortho-quinodimethane moiety from 7,10-dihydropleiadenes by the same method (2) suggested that analogs of **1** could be prepared in the pleiadene **2** and acepleiadene **3** series.

The synthesis of **2** and **3** could be used to test theoretical predictions of their properties of either (*i*) pseudoaromaticity in which case they would possess non-planar structures and react as dienes or (*ii*) aromaticity like **1** and exhibit high free valence reactivity of the exocyclic methylene groups requiring planar structures. Also the possible tautomerization of **3** to the 18π peripheral aromatic compound **4** could be studied.

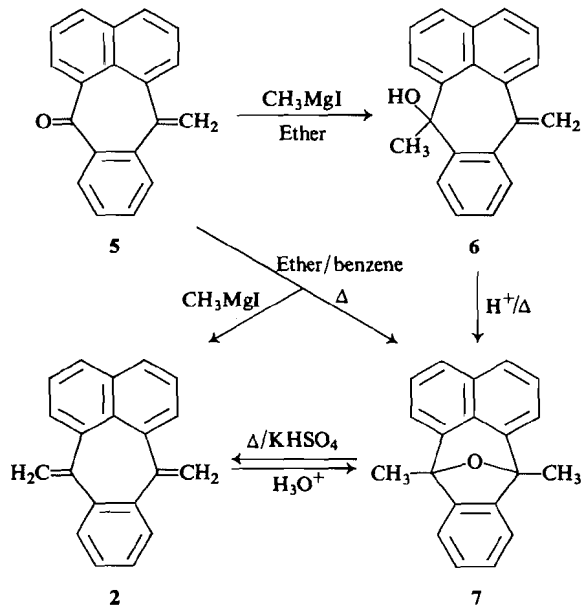
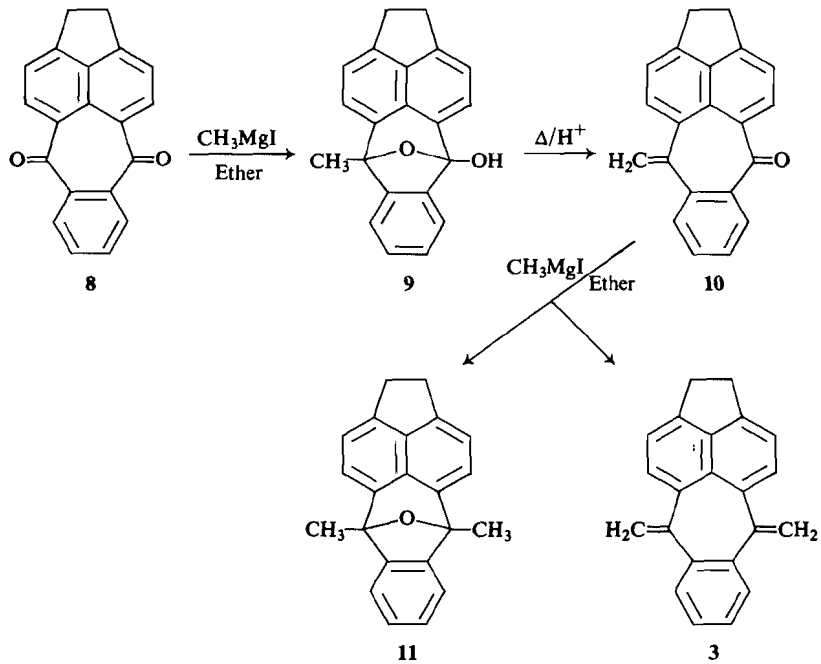
Synthesis of 7,12-Dimethylene-7,12-dihydropleiadene and 5,12-Dimethylene-5,10-dihydroacepleiadene

Reaction of 7-methylene-7,12-dihydropleiaden-12-one (**5**) with methylmagnesium iodide in ether at room temperature gave only 7-hydroxy-7-methyl-12-methylene-7,2-dihydro pleiadene (**6**). This reaction has been reported recently not to proceed under these conditions (3). In contrast when **5** was added to methylmagnesium iodide in ether/benzene and the mixture refluxed, a mixture of 7,12-dimethyl-7,12-epoxy-7,12-dihydropleiadene (**7**) and 7,12-dimethylene-7,12-dihydropleiadene (**2**) were obtained (see Scheme 1). Compound **6** was converted quantitatively into **7** upon brief heating with acid, whilst **7** in turn could be dehydrated to **2** in fair yield by heating with potassium hydrogen sulfate. The preparation of **2** has been reported recently employing a similar route (3). 5,12-Dihydroacepleiadene-5,12-dione (**8**) (4), was added to methyl magnesium iodide in ether to give 5-methyl-5,12-epoxy-5,12-dihydropleiaden-12-ol (**9**) (compare **6** above) which was readily dehydrated by treat-



SCHEME 1



SCHEME 2

ment with *p*-toluenesulfonic acid in benzene to give 5-methylene-5,12-dihydropleiaden-12-one (**10**).

Treatment of **10** with methylmagnesium iodide in ether gave a mixture of **11** and the required compound **3** which were separated by chromatography on a silicic acid column (see Scheme 2).

SCHEME 3

Properties of 7,12-Dimethylene-7,12-dihydropleiadene and 5,10-Dimethylene-5,10-dihydroacepleiadene

Compound **2** is quite hygroscopic and a solution of **2** in benzene gradually absorbed atmospheric moisture and was converted into **7**, a reaction which could be easily monitored by n.m.r. spectroscopy. The appearance of a sharp singlet (6H) at 2.13 δ indicated the formation of **7** while the diminution of the vinyl absorption at 5.22 and 5.49 δ signaled the disappearance of **2**. This conversion becomes very rapid when a solution of **2** is refluxed in the presence of acid catalysts. Compound **3** is similarly readily converted into the ether **11**. This ready formation of **7** from both **6** and **2** and the marked stability of **7** and of **11** made dehydration of the latter difficult.

The facile ring closure observed in the formation of **7** and **11** is attributed to the geometry of the seven-membered rings and to the known conformational preference of the hydroxyl group for an axial position and of the methyl group for the equatorial position in pleiadene systems (5) (see Scheme 3).

Another example of such transannular participation attributed to the ideal geometry of the pleiadene system and conformational preference of substituents at the bridge positions is in the quinone dehydrogenative cyclization of 7-phenyl-7,12-dihydropleiadene (2).

The stability of **2** and **3** compared with **1** leads to the conclusion that these hydrocarbons lack coplanarity in the seven-membered ring and react as dienes.

When a 2.5×10^{-2} *M* solution of potassium *t*-butoxide in dimethylsulfoxide was added to a 10^{-2} *M* solution of **3** in the same solvent a deep greenish-blue color was obtained which showed absorption maxima at 248, 326, 354, 498, and 625 mμ in the visible and u.v. regions, characteristic of the acepleiadylene moiety (4). This is attributed to base-catalyzed tautomerization of **3** to the aromatic 5,10-dimethylacepleiadylene (**12**). Cava and Schlessinger similarly obtained a blue solution of acepleiadylene by treatment of 5,10-dihydroxy-5,10-dihydroacepleiadene with hydrogen bromide. Compound **12**, like acepleiadylene, is stable only in solution, and upon attempted work-up yielded only polymers. Acepleiadylene upon attempted isolation gives a mixture of polymers and dimer (4).

Generation of Radical Anions from Acepleiadene Derivatives

The facile tautomerization in solution of **3** to **12** suggested examination of the properties of the diketone **8** which is isoelectronic with **3**. This led to the generation of stable radical anions.

Treatment of a 1×10^{-2} *M* solution of the diketone **8** in dimethylsulfoxide with a 2.5×10^{-2} *M* solution of potassium *t*-butoxide solu-

tion at ambient temperature gave a deep blue solution containing a paramagnetic species **14** as evidenced by a strong e.p.r. signal which persisted for 72 h.

Russell and coworkers (10) have generated many semidione anions by treatment of diones with potassium *t*-butoxide or the enolate anion of propiophenone in dimethylsulfoxide solution. The e.p.r. spectrum showed extensive hyperfine coupling with a spectrum width of 11.0 Oe (see Fig. 1). The blue solution in dimethylsulfoxide showed absorption in the u.v. and visible region at 342, 362(sh), 552 and 688 mμ, characteristic of an acepleiadylene structure (4) (compare absorption spectrum of 12).

The identical e.p.r. spectrum was obtained when a 1×10^{-2} *M* solution of 5,10-dihydroacepleiadylene-5,10-dione (**15**) in dimethylsulfoxide was treated with 2×10^{-2} *M* potassium *t*-butoxide in dimethylsulfoxide (see Scheme 4).

Compound **15** was prepared as illustrated in Scheme 5. 5,10-Dihydroacepleiadene-5,10-dione was treated with 2 mol equiv of *N*-bromosuccinimide to give the dibromide **16** which was then dehalogenated by refluxing an acetone solution of **16** with potassium iodide.

Dauben *et al.* have suggested that a similar mechanism to that outlined in Scheme 4 is operative in the conversion of certain cyclic 1,4-diketones by shaking an alkaline alcoholic solution in air, via the dianion thence to the radical anion to an enedione (6).

Further support for the structure of the radical anion **14** is provided by the reduction of the diketone **15** with potassium in dimethoxyethane. The e.p.r. spectrum obtained had the same gross features as that obtained in dimethyl sulfoxide but differed in details as expected for radicals generated under two quite different conditions. The distribution of spin density in an aromatic radical anion is affected by the polarity of the solvent (7). The spin density variation with solvents is assumed, to a first approximation, to be affected only by localized complexes between solvent and polar substituents in the radical anion (7*b*). The identity of the radical anion species obtained under both oxidizing and reducing conditions from **8** and **15** respectively precludes the possibility of oxidation at the 1 and

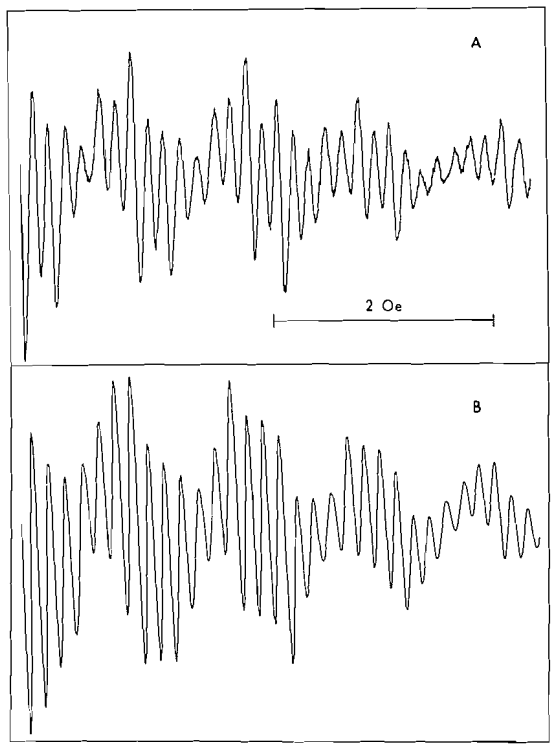

FIG. 1. (A) Experimental partial e.p.r. spectrum of 7,12-acepleiadylene semidione anion obtained from 1×10^{-2} *M* solution of 5,12-dihydroacepleiadene-5,12-dione with 2.5×10^{-2} *M* potassium *t*-butoxide in dimethylsulfoxide solution at room temperature. (B) Simulated partial e.p.r. spectrum using Lorentzian lines with a peak to peak width of 0.100 Oe (see Experimental for values of hyperfine coupling constants).

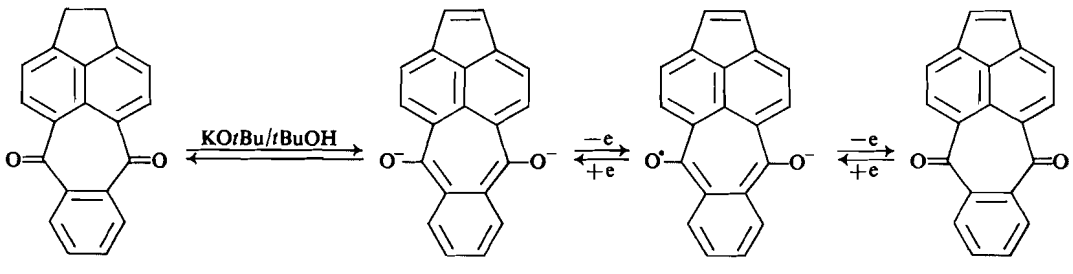
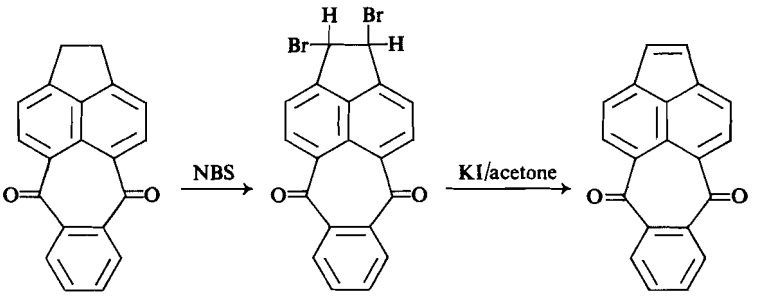


8 **13** **14** **15**

SCHEME 4

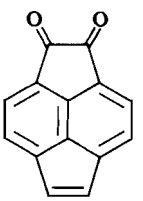


8 16 15

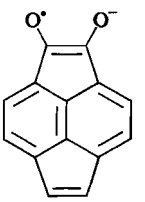
SCHEME 5

2 positions of **8** upon treatment with potassium *t*-butoxide.

Trost and coworkers found differences in the e.p.r. spectra of the related pyracyclosemiquinone anion **18** generated from 1,2-diketopyracene **17** by (*i*) potassium *t*-butoxide reduction in dimethylsulfoxide and (*ii*) irradiation of a 1,2-dimethoxyethane solution in the presence of sodium hydroxide or potassium hydroxide (8).



17



18

Values for the hyperfine coupling constants in the radical anion **14** were derived by obtaining the closest fit of a simulated spectrum, using Lorentzian lines with a peak to peak width of 0.100 Oe, with the experimental spectrum (see Fig. 1 and Experimental). Experiments are in hand to make the assignments of the coupling constants in **14** and analogous radical anions involving the syntheses of specifically deuterated compounds.

One of the most stable paramagnetic species is the super-oxide anion $O^{\cdot}—O^{-}$. The phenylogues of this species, the semi-quinones, are well known and have been explored exhaustively (9) while the vinylogues, the semidiones, have been examined by Russell and his coworkers (10). The 7,12-acepleiadylene semidione anion **14** represents an extension of this series, and evidently owes its stability to the aromaticity of the acepleiadylene moiety which possesses an 18 π-electron periphery since 7,12-pleiadenedione could not be induced to form a radical anion under similar conditions. The radical anion **14** appears to be much more stable than the parent hydrocarbon acepleiadylene which retains its blue color in solution for only 40 min (4).

The successful isomerization of the diene **3** to the acepleiadylene **12** and the generation of the radical anion **14** from the diketone **8** suggested examination of derivatives of **8** such as **10** under similar conditions. Accordingly a 1×10^{-3} *M* solution of 5-methylene-5,10-dihydroacepleiaden-10-one (**10**) in dimethyl sulfoxide was treated with potassium *t*-butoxide to give a stable paramagnetic species which gave a strong e.p.r. spectrum, which is attributed to the radical anion **19**. 5-Benzylidene-5,10-dihydroacepleiaden-12-one (**20**) was also observed to give a strong e.p.r. spectrum on treatment with potassium *t*-butoxide in dimethylsulfoxide which is ascribed to the radical anion **21**. Compound **20** was prepared by a similar sequence of reactions as was employed to synthesize **10**, *i.e.* by reaction of **8** with benzylmagnesium chloride in ether and acid-catalyzed dehydration of the resulting alcohol to give **20**.

Radical anions of the type **19** and **21** are a logical extension of species **14** and are analogs of benzophenone ketyl.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference.

10 R = H **19** R = H; spectrum width, 15.53 Oe
20 R = Ph **21** R = Ph; spectrum width, 15.75 Oe

Absorption spectra were recorded in 'spectro'-grade solvents on a Beckman DB recording spectrophotometer. Mass spectra were determined on an Associated Electrical Industries MS-9 double focussing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15000. First derivative e.p.r. spectra were measured on a Varian V-2503 spectrometer fitted with a V-4532 dual cavity, operating at a nominal frequency of 9.5 GHz. The microwave power incident on the cavity was attenuated to 10 db below maximum. Hyperfine couplings were measured by comparison with a peroxylamine disulfonate solution in the audio cavity. The triplet spacing of the standard was taken to be 13.0 Oe. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin layer chromatography. Microanalyses were carried out by Mrs. D. Mahlow of this department.

7,12-Dihydropleiadene

7,12-Dihydropleiadene was prepared from 1-chloro-7,12-dihydropleiadene by a modification of the method of Cava and Schlessinger (11). A mixture of 25 g (0.095 mol) of 1-chloro-7,12-dihydropleiadene, 5 g of 10% palladium-on-charcoal, 100 ml of 85% hydrazine hydrate, and 1000 ml of 95% ethanol was refluxed for 1 h. The filtered solution was concentrated to *ca.* 100 ml, acidified with 2 *N* hydrochloric acid, and the solid product collected, washed repeatedly with water, and dried. Recrystallization from hexane gave 20 g (91.8% yield) of 7,12-dihydropleiadene, m.p. 115–117° (lit. (11), 116°).

7,12-Dihydropleiadene-7,12-dione

7,12-Dihydropleiadene-7,12-dione was prepared in 93% yield from 7,12-dihydropleiadene by the method of Cava and Schlessinger (11), m.p. 166–168° (lit. 168° (11)).

7,12-Epoxy-7-hydroxy-12-methyl-7,12-dihydropleiadene

7,12-Dihydropleiadene-7,12-dione (20 g, 77 mmol) was added during 30 min to a stirred solution of methyl magnesium iodide (prepared from 6 g of magnesium and 30 g of methyl iodide in 200 ml of anhydrous ether). After addition was completed, stirring was continued for 12 h. The complex was decomposed with cold saturated ammonium chloride solution, the ether layer washed with water, dried (Na_2SO_4), and concentrated to give 19.6 g (92.3% yield) of the ether, m.p. 186–188° (lit. (3) 184–186°).

Anal. Calcd. for $C_{19}H_{14}O_2$ (mol. wt. 274.0994): C, 83.21; H, 5.11. Found (274.0996 (mass spectrum)): C, 82.96; H, 5.08.

7-Methylene-7,12-dihydropleiaden-12-one

A catalytic amount of *p*-toluenesulfonic acid was added to a solution of 13.7 g (0.05 mol) of 7,12-epoxy-7-methyl-7,12-dihydropleiadene-7-ol in 400 ml benzene and the mixture refluxed for 8 h. After cooling, the solution was washed successively with water, 10% sodium bicarbonate, and water; dried and concentrated to give 10 g (85% yield) of **5**, m.p. 155–157° (lit. (3) 154–156°).

Anal. Calcd. for $C_{19}H_{12}O$ (mol. wt. 256.0888): C, 89.06; H, 4.69. Found (256.0888 (mass spectrum)): C, 89.09; H, 4.77.

7-Hydroxy-7-methyl-7,12-dihydropleiaden-12-ene

7-Methylene-7,12-dihydropleiaden-12-one (0.5 g, 19.5 mmol) was added to a Grignard reagent (0.5 and 3 g iodomethane in 30 ml of anhydrous ether) and stirred for 30 min. The mixture was then refluxed gently for another 30 min, stirring continued overnight, cooled, and the complex decomposed with ice and saturated solution of ammonium chloride. The ether layer was washed with water, dried ($MgSO_4$), and solvent removed to yield a gum which was triturated with hexane to give 0.41 g (77.3% yield) of **6** as a crystalline solid, m.p. 114–116°.

Anal. Calcd. for $C_{20}H_{16}O$ (mol. wt. 272.1201): C, 88.24; H, 5.88. Found (272.1200 (mass spectrum)): C, 88.08; H, 5.90.

The i.r. spectrum ν_{max} ($CHCl_3$): 3690, 3610, 3580 cm^{-1} (O—H); n.m.r. spectrum δ_{TMS} ($CDCl_3$): 1.97 (3H, singlet, C-7 methyl protons); 5.6, 5.2 (2H, pair of doublets J_{AB} = 1.5 Hz, C-12 methylene protons); 7.3–8 (11H, multiplet, aromatic ring protons and O—*H*).

7-12-Dimethylene-7,12-dihydropleiadene and 7,12-Dimethyl-7,12-epoxy-7,12-dihydropleiadene

7-Methylene-7,12-dihydropleiaden-12-one (1 g, 0.004 mol) was added with stirring over 30 min to a Grignard reagent, prepared from 1 g of magnesium and 6 g of iodomethane in 30 ml of anhydrous ether. Dry benzene (30 ml) was then added to the mixture and refluxed with stirring overnight, cooled, and decomposed with ice and ammonium chloride solution. The organic layer was washed with water, dried, and solvent removed *in vacuo* to yield a gum. This gum was dissolved in benzene and subjected to chromatography on B.D.H. silica gel using hexane as eluant to give 26 mg (25% yield) of **2**, m.p. 91–93° (lit. (3) 88–90°). The i.r. spectrum ν_{max} (CCl_4): 1625 cm^{-1} (C=C); n.m.r. spectrum δ_{TMS} (CCl_4): 5.22,

5.49 (4H, a pair of doublets, J = 2 Hz, CH_2); 7.0–7.8 (10H, multiplet, aromatic protons).

Further elution with benzene gave 0.65 g (60% yield) of **7**, m.p. 152–153°.

Anal. Calcd. for $C_{20}H_{16}O$ (mol. wt. 272.1201): C, 88.24; H, 5.88. Found (272.1200 (mass spectrum)): C, 88.13; H, 5.69.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 2.13 (6H, singlet, methyl protons); 7.0–7.75 (8H, multiplet, aromatic protons).

Dehydration of 7,12-Dimethyl-7,12-epoxy-7,12-dihydropleiadene

A mixture of 1.4 g (5 mmol) of **7**, and 0.5 g of potassium hydrogen sulfate was heated in an oil bath at 140° for 15 min. The mixture was cooled and extracted with hexane, and the hexane solution subjected to chromatography on silicic acid (p*H* 7) to give 1.1 g (85% yield) of **2**.

5-Methylene-5,10-dihydroacepleiaden-12-one

A suspension of 2.84 g (0.01 mol) of 5,10-dihydropleiadene-5,10-dione (4) in 50 ml of dry benzene was added to a Grignard reagent prepared from 4.3 g of magnesium and 22.5 g of iodomethane in 150 ml of anhydrous ether. The mixture was stirred for 30 min; 70 ml of ether was distilled off and replaced by 50 ml of dry benzene. The reaction mixture was then refluxed overnight, cooled, decomposed with ice, and saturated ammonium chloride solution, the organic layer dried ($MgSO_4$), and solvent removed *in vacuo* to give a light yellow solid, **9**. The i.r. spectrum ν_{max} ($CHCl_3$): 3605, 3576 cm^{-1} (O—H); n.m.r. δ_{TMS} ($CDCl_3$): 2.1 (3H, singlet methyl protons); 3.26 (4H, C-1 and -2 protons).

Compound **9** without further purification was dissolved in benzene and a small amount of *p*-toluenesulfonic acid added to the solution. The mixture was refluxed for 4 h, cooled, washed with water, sodium bicarbonate solution, and water; the benzene solution dried, concentrated, and the residue subjected to chromatography on B.D.H. alumina using benzene as eluant to give 1.5 g (88.2%) of **10** as a brilliant yellow solid, m.p. 202–205°.

Anal. Calcd. for $C_{21}H_{14}O$ (mol. wt. 282.1045): C, 89.37; H, 4.96. Found (282.1040 (mass spectrum)): C, 88.94; H, 4.95.

The i.r. spectrum ν_{max} ($CHCl_3$): 1648 cm^{-1} (C=O); n.m.r. spectrum δ_{TMS} ($CDCl_3$): 3.41 (4H, singlet, C-1 and -2 protons); 5.42, 5.50 (2H, pair of doublets, J = 1.5 Hz, $=CH_2$); 7.2–8.4 (8H, aromatic protons).

Reaction of 5-Methylene-5,10-dihydroacepleiaden-12-one with Methylmagnesium Iodide

A methylmagnesium iodide solution was prepared from 2.4 g of magnesium and 14.5 g of iodomethane, in 100 ml of anhydrous ether; and 2.0 g (0.007 *M*) of 5-methylene-5,10-dihydroacepleiaden-12-one was added to it a little at a time, with stirring. Stirring was continued for 8 h, the complex decomposed with ice and ammonium chloride, the ether layer dried (Na_2SO_4) and solvent removed to give a light yellow oil. This oil was dissolved in benzene and subjected to chromatography on silicic acid (p*H* 7), using hexane as eluant to give 0.5 g (25.3% yield) of **3** as a light yellow oil, which solidified on standing, m.p. 85–87°.

Anal. Calcd. for $C_{22}H_{16}$ (mol. wt. 280.1252): C, 94.28; H, 5.72. Found (280.1253 (mass spectrum)): C, 94.30; H, 5.78.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 3.27 (4H, singlet, C-1 and -2 protons); 5.3, 5.56 (4H, a pair of doublets, J = 1.5 Hz, $=CH_2$); 7.05–7.65 (8H, multiplet, aromatic ring protons).

Further elution with benzene gave 0.7 g (33.6% yield) of **11**, m.p. 222–224°.

Anal. Calcd. for $C_{22}H_{18}O$ (mol. wt. 298.1357): C, 88.59; H, 6.04. Found (298.1355): C, 88.46; H, 6.12.

The n.m.r. spectrum δ_{TMS} ($CDCl_3$): 2.15 (6H, singlet, methyl protons); 3.23 (4H, singlet, C-1 and -2 bridge protons); 7.05–7.43 (8H, multiplet, aromatic protons).

1,2-Dibromo-5,10-dihydroacepleiadene-5,10-dione

N-Bromosuccinimide (5.34 g, 0.030 mol) was added to a refluxing solution of 4.26 g (0.015 mol) 5,10-dihydroacepleiadene-5,10-dione and benzoyl peroxide in carbon tetrachloride, over a period of 10 min and refluxing was continued for an additional 1½ h. The succinimide was removed, and the mother liquor concentrated and cooled to give a dull yellow solid. This was further crystallized from carbon tetrachloride to give 6.5 g (98% yield) of **16**, m.p. 200°.

Anal. Calcd. for $C_{20}H_{10}Br_2O_2$ (mol. wt. 439.9047): C, 54.30; H, 2.26; Br, 36.20. Found (439.9046 (mass spectrum)): C, 54.40; H, 2.27; Br, 36.41.

The i.r. spectrum ν_{max} ($CHCl_3$) 1650 cm^{-1} (C=O); n.m.r. spectrum δ_{TMS} ($CDCl_3$): 5.95 (2H, singlet, C-1 and -2 protons); 7.5–8.1 (8H multiplet, aromatic protons).

5,10-Dihydroacepleiadylene-5,10-dione

1,2-Dibromo-5,10-dihydroacepleiadene-5,10-dione (3.08 g 0.07 mol) was dissolved in 300 ml of acetone, and 15 g of potassium iodide was added to the solution under nitrogen. The reaction mixture was refluxed for 3 h, cooled, poured into sodium thiosulfate solution, and extracted with chloroform. The chloroform layer was dried (Na_2SO_4) and solvent concentrated to give a red solid, which was recrystallized from methanol to give brick red flakes of **15**, 1.4 g (71% yield), m.p. 196–198°.

Anal. Calcd. for $C_{20}H_{10}O_2$ (mol. wt. 282.0681): C, 85.11; H, 3.55. Found (282.0678 (mass spectrum)): C, 84.87; H, 3.53.

The i.r. spectrum ν_{max} ($CHCl_3$): 1660 cm^{-1} (C=O); n.m.r. spectrum: δ_{TMS} ($CDCl_3$): 7.05 (2H, singlet, C-1 and -2 protons); 7.55–8.40 (8H, multiplet, aromatic protons).

5-Benzylidene-5,10-dihydroacepleiaden-12-one

5,10-Dihydroacepleiadene-5,10-dione, 2.84 g (0.001 mol), was added a little at a time to a Grignard reagent prepared from 2 g of magnesium and 13 g of benzyl-chloride in 200 ml of ether. Ether was distilled off (100 ml) and replaced by 100 ml of dry benzene and the mixture refluxed for 8 h. The complex was then decomposed with ice and saturated solution of ammonium chloride. The organic layer was dried (Na_2SO_4) and the solvent was removed *in vacuo* to give the hydroxyketone as a brilliant yellow solid. The i.r. spectrum ν_{max} ($CHCl_3$): 3530 (O—H) 1653 cm^{-1} (C=O); n.m.r. spectrum δ_{TMS} ($CDCl_3$): 3.5 (4H, singlet, C-1 and -2 protons); 5.13 (2H, singlet, $—CH_2—$Ph); 7.25–8.2 (13H, multiplet, aromatic protons).

This yellow solid, without further purification was dissolved in benzene, *p*-toluenesulfonic acid was added, and the solution was refluxed for 3 h. The reaction mixture was worked-up as for **10** to give 1.4 g (37.2%

yield) of 5-benzylidene-5,10-dihydroacepleiaden-12-one (**20**), m.p. 182–184°.

Anal. Calcd. for $C_{27}H_{18}O$: C, 90.48; H, 5.25. Found: C, 90.51; H, 5.24.

The i.r. spectrum ν_{max} ($CHCl_3$): 1645 cm^{-1} (C=O); n.m.r. spectrum δ_{TMS} ($CDCl_3$) 3.6 (4H, singlet, C-1 and -2 protons); 6.7 (1H, singlet, $=\!\!<^{Ph}_{H}$); 6.87–8.4 (13H, multiplet, aromatic protons).

Electron Spin Resonance Determinations

(a) Generation of Radical Anions in Dimethylsulfoxide

The dimethylsulfoxide used was dried with sodium sulfate, distilled, and kept standing on molecular sieve.

The radical anions were generated according to the method of Russell *et al.* (12). Solutions of the diketones in dimethylsulfoxide were placed in one leg of an inverted U-cell; the potassium *t*-butoxide in dimethylsulfoxide was placed in the other leg, and both solutions simultaneously deoxygenated by streams of prepurified nitrogen. After about 15–20 min of deoxygenation, the solutions were mixed by inverting the cell and the final solution was shaken into the sample cell, and the e.p.r. spectrum recorded. Fremy's salt in saturated sodium carbonate was used as a calibration standard.

(b) Generation of Radical Anion by Reduction of 5,10-Dihydroacepleiadylene-5,10-dione with Potassium in 1,2-Dimethoxyethane

The dimethoxyethane used was dried over sodium and distilled. It was kept standing on freshly-cut sodium.

The apparatus used is sketched in Fig. 2. About 6 mg of **15** was placed in the sample tube and the apparatus set up as shown in the diagram. Small pieces of freshly cut potassium were placed in bulb A, and the cell sealed off at D. The complete apparatus was evacuated and some potassium distilled into the bulb B. The cell was then sealed off at E. Dimethoxyethane was then distilled into the sample tube C, to dissolve the sample. The cell was then sealed off at F, allowed to cool, and inverted to allow the solution to come into contact with the potassium for about 2 min. After about 15 min, the solution went blue, indicating the formation of the radical anion, and the e.p.r. spectrum was recorded as for section *a*.

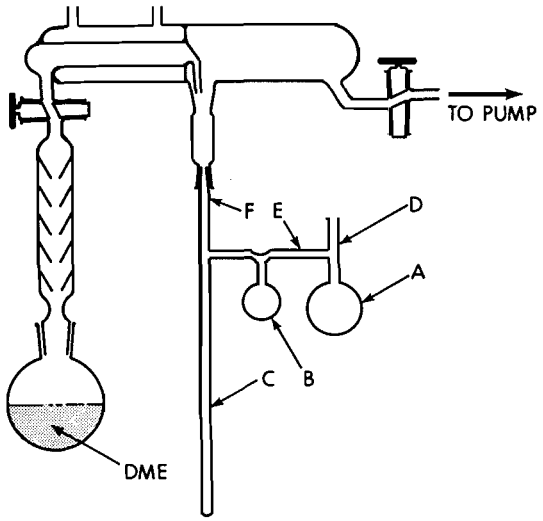

FIG. 2. Diagram of apparatus used in generation of acepleiadylene-5,10-semidione anion from 5,10-dihydroacepleiadylene-5,10-dione by reduction with potassium metal in 1,2-dimethoxyethane.

The hyperfine coupling constants for species **14** determined by the best fit of the simulated spectrum with that of the experimental spectrum were 2.50, 2.05, 1.11, 0.30, and 0.15 Oe.

This research was supported by a National Research Council of Canada grant to J. W. Lown. We thank Mr. R. Swindlehurst, Dr. A. Hogg, and Mr. G. Bigam for the n.m.r., mass, and e.p.r. spectra respectively. We also thank Dr. R. E. D. McClung for helpful discussions on the interpretation of the e.p.r. spectra.

Electron Spin Resonance Studies of the Radiolysis of Aliphatic Amines at 77 °K[1]

P. WARDMAN[2] AND D. R. SMITH[3]

Physical Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received January 13, 1971

Several frozen aliphatic amines have been γ-irradiated at 77 °K and the electron spin resonance (e.s.r.) spectra of the trapped radicals obtained at 77 °K and on warming. Radiolysis of methyl, ethyl and isopropyl amines produces predominantly alkylamino (RĊNH) radicals. The proton hyperfine (h.f.) couplings of RĊNH radicals are 10–30% larger than those in the corresponding isoelectronic alkyl radicals and the parallel component of the ^{14}N coupling is about 35 G. Restricted rotation of alkyl groups occurs at 77 °K in some cases. On warming from 77 °K, the RĊNH radicals generally abstract from the solvent or isomerize to produce radicals of the aminoalkyl type (*e.g.* $R\dot{C}HNH_2$). The alkyl proton h.f. splittings of these latter radicals are 20–40% lower than in the corresponding alkyl radicals, and the observed ^{14}N coupling was $A_{14_{N,\parallel}} = 12 \pm 3$ G in $\dot{C}H_2NR_2$ and $A_{14_{N,iso}} \simeq 4$ G in $(CH_3)_2\dot{C}NH_2$ and $CH_3\dot{C}HNH_2$. The amino proton couplings in the aminoalkyl radicals were not resolved. Irradiated dimethylamine produces both $(CH_3)_2\dot{N}$ and $\dot{C}H_2N(CH_3)$ radicals, but $(CH_3)_2\dot{N}$ disappears on warming. Only $\dot{C}H_2N(CH_3)_2$ was observed after irradiation of $(CH_3)_3N$ at 77 °K. Solid methoxyamine (giving CH_3ONH) and *tert*-butylamine were also studied.

Plusieurs amines aliphatiques à l'état solide ont été irradiées à 77 °K par des rayons-γ et les spectres de résonance paramagnétique électronique (R.p.e.) ont été obtenus à 77 °K et à des températures plus élevées. La radiolyse des méthyl, éthyl et isopropyl amines produit en prépondérance les radicaux alkylamino (RNH). Lesécarts hyperfins (e.h.) du proton des radicaux RNH sont de 10–30% plus grand que ceux des radicaux alkyles isoélectriques correspondant et le composant parallèle du couplage de ^{14}N est d'environ 35 G. En réchauffant l'échantillon qui est à 77 °K les radicaux RNH généralement abstraient du solvant ou s'isomérisent pour produire des radicaux du type amino-alkyle (*e.g.* $R\dot{C}HNH_2$). Les écarts hyperfins des protons des groupements alkyles sont 20–40% plus bas que les radicaux alkyles correspondants et le couplage ^{14}N observé était $A_{14_{N,\parallel}} = 12 \pm 3$ G pour $\dot{C}H_2NR_2$ et $A_{14_{N,iso}} \simeq 4$ G pour $(CH_3)_2\dot{C}NH_2$ et $CH_3\dot{C}HNH_2$. Le couplage du proton sur l'azote dans les radicaux aminoalkyles n'était pas résolu. L'irradiation de la diméthylamine produit les deux radicaux $(CH_3)_2\dot{N}$ et $\dot{C}H_2N(CH_3)$, mais $(CH_3)_2\dot{N}$ disparait lorsqu'on élève la température. Seulement le radical $\dot{C}H_2N(CH_3)_2$ fut observé après irradiation de $(CH_3)_3N$ à 77 °K. La méthoxyamine (donnant CH_3ONH) et la *tert*-butylamine ont aussi été étudiées.

Canadian Journal of Chemistry, 49, 1869 (1971)

Introduction

Little is known about the radiolysis of solid aliphatic amines. Pukhal'skaya *et al.* (1, 2) γ-irradiated several methyl and ethyl amines at 77 °K and, for example, ascribed the e.s.r. spectrum of the radicals trapped in solid CH_3NH_2 to the aminomethyl radical, $\dot{C}H_2NH_2$. Their spectra were poorly resolved and no hyperfine (h.f.) splittings were derived. Hadley and Volman (3) found quite different e.s.r. spectra after ultraviolet photolysis of frozen CH_3NH_2 and suggested that in this case only $CH_3\dot{N}H$ was produced. The relative strengths of the C—H and N—H bonds in alkyl amines are not known, but in the gas phase, both $\dot{C}H_2NH_2$ and $CH_3\dot{N}H$ are produced (to about equal extents (4)) from methylamine in the ion–molecule reaction [1]

$$[1a] \quad CH_3NH_2^+ + CH_3NH_2 \rightarrow CH_3NH_3^+ + \dot{C}H_2NH_2$$

$$[1b] \quad \rightarrow CH_3NH_3^+ + CH_3\dot{N}H$$

In an attempt to provide further information about the radicals produced by radiolysis of amines, we have irradiated several of the lower aliphatic amines at 77 °K.

Experimental

Materials

Matheson CH_3NH_2, $(CH_3)_2NH$, $(CH_3)_3N$, and $C_2H_5NH_2$, Baker Analyzed Reagent grade $(C_2H_5)_2NH$, Eastman n-$C_3H_7NH_2$ and $(CH_3)_2CHNH_2$ and Fisher Certified grade n-$C_4H_9NH_2$ were distilled *in vacuo* and

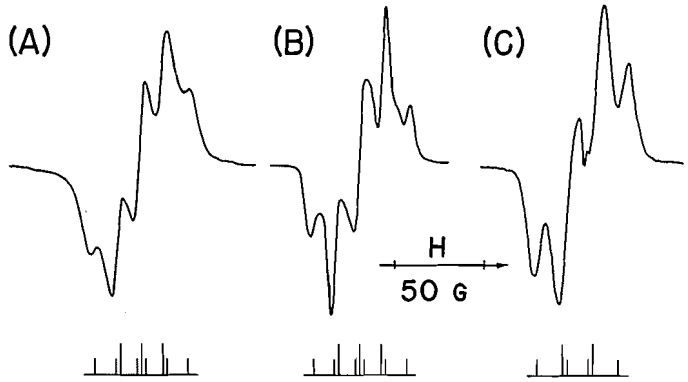

FIG. 1. First derivative e.s.r. spectra of γ-irradiated glassy methylamine at 77 °K: (*A*), CH_3NH_2; (*B*), CH_3ND_2; (*C*), $CH_3{}^{15}NH_2$.

stored over a Na mirror. Eastman $(CH_3)_3CNH_2$ was fractionated using a 1 m column of stainless steel gauze rings and stored over Na *in vacuo*. Eastman CH_3ONH_2. HCl was added to NaOH in aqueous solution, CH_3ONH_2 separated by fractionation as above (b.p. 48.5–49.5 °C) and stored over CaO *in vacuo*. Isotopes Inc. supplied $CH_3{}^{15}NH_2$.HCl and $(CH_3)_2{}^{15}NH$.HCl (96% ^{15}N), which were added to KOH in aqueous solution and separated by distillation *in vacuo* through two traps at 193 °K to a bulb at 77 °K. CH_3OND_2, $(CH_3)_2CHND_2$, and $(CH_3)_3CND_2$ were prepared by refluxing the protiated amine with at least five times its volume of D_2O (A.E.C.L. high grade material), separating the amine by fractionation and repeating the process a further three times before storage *in vacuo* over CaO. CD_3NH_2, CD_3ND_2, CH_3ND_2, $(CD_3)_2NH$, $(CD_3)_3N$, $C_2H_5ND_2$, and $CH_3CD_2NH_2$ were supplied sodium-dried by Merck, Sharp and Dohme.

Sample Preparation, Irradiation, and e.s.r. Spectroscopy

Amines deuterated in the amino group were handled on a mercury- and grease-free vacuum system that had been exposed to repeated lots of D_2O at 200 °C for several days, then flushed several times with ND_3 and finally with the amine in use. All samples were degassed on grease-free vacuum lines and distilled *in vacuo* into 3 mm i.d. Spectrosil tubes before ^{60}Co γ-irradiation at 77 °K. Doses between 0.1 and 0.5 Mrads were used. A Varian V-4502 X-band e.s.r. spectrometer was used with Fieldial, TE_{104} cavity and X–Y recorder. Samples were warmed from 77 °K by a stream of cold N_2 gas. Temperatures quoted are accurate to ±3 °K.

Results

Methylamine forms a glass rather than a polycrystalline solid if 10% H_2O is added before freezing to 77 °K: somewhat different spectra were obtained for these two types of solid. In some cases the effects of isotopic substitution were quite unexpected: we present fuller consideration of these effects, and of the hyperfine coupling parameters derived, in the Discussion section. Unless shown as ^{15}N, the nitrogen isotope is ^{14}N. Support for some of our assignments, including better resolved spectra in some cases, is to be found in our studies of the radiolysis of amines adsorbed on silica gel (see accompanying paper).

(i) Glassy Methylamine (+10% H_2O)

Glassy methylamine is deep blue after γ-irradiation at 77 °K but illumination with $\lambda > 640$ nm removes the color and the associated e.s.r. singlet spectrum of the trapped electron (1). We are concerned here only with the radical remaining after photobleaching. *In all cases, the spectra presented are those obtained after photobleaching.* In Fig. 1(*A*) we show the spectrum from CH_3NH_2 at 77 °K which is similar to that obtained by Pukhal'skaya *et al.* (1) but with superior resolution. Glassy CH_3ND_2 (10% D_2O) gave a similar spectrum (Fig. 1(*B*)), with slightly better resolution, showing that the amino proton h.f. coupling is too small to be resolved in our experiments. (A very weak 14.3 G quartet from CH_3ND_2 was just detectable on 2nd derivative presentation, which may be a very small amount of another radical.) The quintet spectra in Figs. 1(*A*) and (*B*) have $A_{av} = 13.0 \pm 0.5$ G. Glassy $CH_3{}^{15}NH_2$ gave a quartet spectrum, Fig. 1(*C*), with $A_{av} = 15.5 \pm 0.5$ G.

If the radical is the same in glassy CH_3NH_2, CH_3ND_2, and $CH_3{}^{15}NH_2$ and contains one interacting N atom, then the difference in the separation of the outermost lines in the spectra for the ^{15}N and ^{14}N isotopes will equal $(2A_{^{14}N} - A_{^{15}N}) = 0.58A_{^{14}N}$. Thus $A_{^{14}N} = 12 \pm 3$ G. The

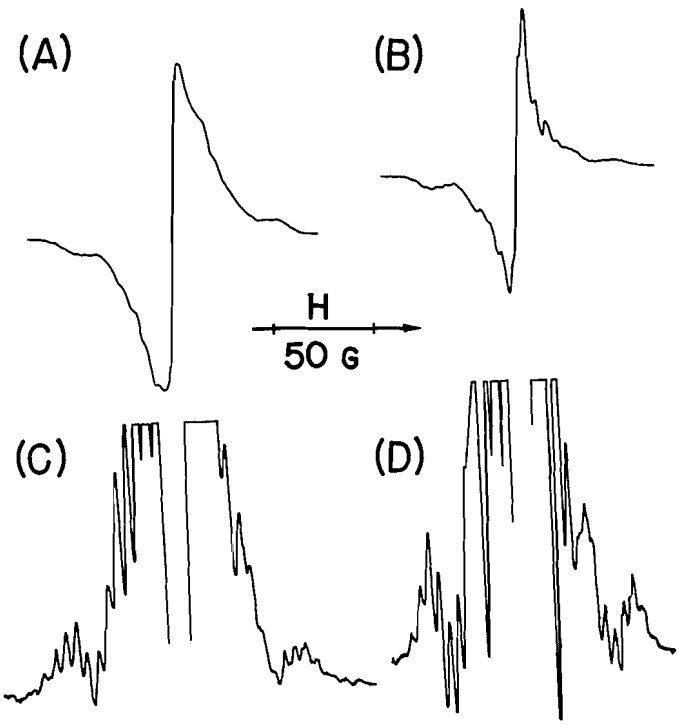

FIG. 2. Electron spin resonance spectra of γ-irradiated glassy methylamine at 77 °K: (*A*), CD_3NH_2 and (*B*), CD_3ND_2 (first derivative); (*C*), CD_3NH_2 and (*D*), CD_3ND_2 (2nd derivative).

spectra in Fig. 1 may then be assigned to $\dot{C}H_2NH_2$ with $A_H^{CH_2} = 14.5 \pm 3$, $A_{^{14}N} = 12 \pm 3$ ($A_{^{15}N} = 17 \pm 4$), and $A_H^{NH_2} \leq 5$ G, the "stick" spectra being for this assignment.

On this basis we expect to obtain spectra from CD_3NH_2 and CD_3ND_2 which are basically ~12 G ^{14}N triplets with the 2.2 G methylene *D* splitting unresolved. The spectra observed were quite different from those expected and are shown in Fig. 2. (Second derivative presentation gives the line positions as minima.) Both amines gave similar triplet spectra with the outer lines considerably broadened, and similar to the spectrum observed for $CD_3\dot{N}H$ by Hadley and Volman (3). Superimposed on the major triplet splitting are 5 ± 1 G deuterium splittings, very characteristic of the ~34 G methyl proton splitting of $CH_3\dot{N}H$. For this radical, these authors assigned $A_H^{CH_3} \simeq A_H^{NH} \simeq A_{^{14}N} = 32$ G. The observed ^{14}N coupling is the parallel component (see Discussion). For CD_3NH_2 we observed about 26 lines over 135 G, and for CD_3ND_2 about 25 lines over 117 G. This broadening (we expect ~ 136 and 110 G total separation, respectively, if the ^{14}N perpendicular component is neglected) was also observed by Hadley and Volman (3). Apparently the broadening of the $M_I(^{14}N) = \pm 1$ lines masks the amino proton splitting in $CD_3\dot{N}H$. By analogy with NH_2 (32) we might expect $A_{^{14}N,\parallel} \simeq 37$ G, $A_{^{14}N,\perp} \simeq 1$ G, $A_{H,\parallel}^{NH} \simeq 31$ G, and $A_{H,\perp}^{NH} \simeq 25$ G. The perpendicular features, especially if they are broad, would further inhibit resolution of the amino proton splitting in this case.

(ii) Polycrystalline (Anhydrous) Methylamine

Polycrystalline CH_3NH_2 and $CH_3{}^{15}NH_2$ gave the asymmetrical and poorly resolved spectra shown in Fig. 3(*A*) and (*B*). There are 7 major lines ($A_{av} \simeq 30$ G) for CH_3NH_2 and 6 major lines ($A_{av} \simeq 33$ G) for $CH_3{}^{15}NH_2$. We have not completely analyzed these spectra, but it is noteworthy that both spectra show 33 G h.f. splittings (therefore probably due to H) and that the difference in separation of outermost lines of the spectra of the two N isotopes gives $A_{^{14}N} \simeq 33$ G. On warming CH_3NH_2 to 100 °K for 15 min, the two outer pairs of lines disappeared leaving an ill-resolved singlet (and a small amount of $CH_2{=}\dot{N}$ (5) detectable). In Fig. 3(*C*) we show the spectrum of γ-irradiated CH_3NH_2 after

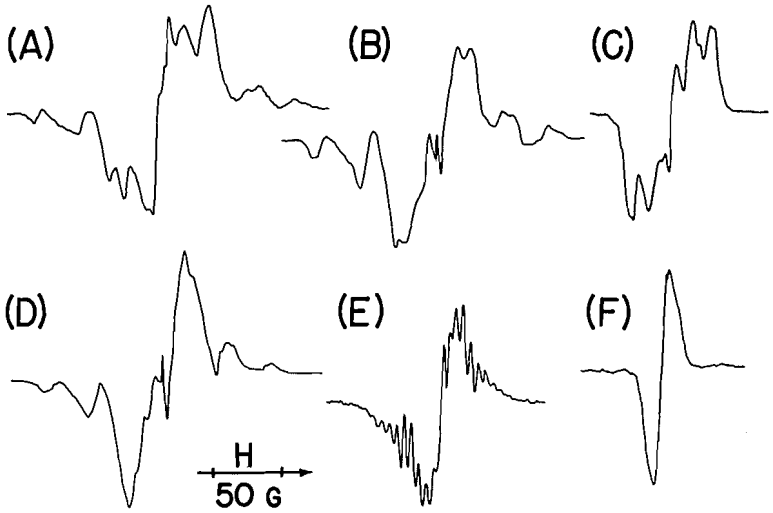

FIG. 3. First derivative e.s.r. spectra of γ-irradiated polycrystalline methylamine: (*A*), CH_3NH_2 at 77 °K; (*B*), $CH_3{}^{15}NH_2$ at 77 °K; (*C*), CH_3NH_2 after warming to 165 °K for 15 min and re-cooling to 77 °K; (*D*) CH_3ND_2 at 77 °K; (*E*), CD_3NH_2 after 10 min at 125 °K; (*F*), CD_3ND_2 after warming to 150 °K for 15 min and re-cooling to 77 °K.

warming to 165 °K for 15 min and then re-cooling to 77 °K. The resultant quintet structure has $A_{av} \simeq 13$ G, and the shape and width of the spectrum was similar at 165 and 77 °K. Thus although polycrystalline CH_3NH_2 and $CH_3{}^{15}NH_2$ gave ill-resolved spectra, the spectra at 77 °K were ascribable to $CH_3\dot{N}H$ and those after warming to 165 °K and re-cooling, to $\dot{C}H_2NH_2$ (the formation of $\dot{C}H_2NH_2$ from $CH_3\dot{N}H$ being non-reversible). The spectra of $CH_3\dot{N}H$ were not as well resolved as those of Hadley and Volman (3), and we note that in all cases, u.v. photolysis after γ-irradiation not only produced the $CH_2{=}\dot{N}$ radical (1) but also increased the resolution of the $CH_3\dot{N}H$ spectrum.

The major features of the e.s.r. spectrum of the radical(s) in irradiated polycrystalline CH_3ND_2 at 77 °K are seen in Fig. 3(*D*) to be six lines with $A_{av} \simeq 30$ G, *i.e.* near to that expected for $CH_3\dot{N}D$. CD_3NH_2 gave at 77 °K a spectrum similar to that found for the glass (Fig. 2(*A*)) but with a better defined ~35 G triplet. Optimum resolution for $CD_3\dot{N}H$ was after 10 min at 125 °K (Fig. 3(*E*)) but above 140 °K the outer lines almost disappeared (irreversibly), leaving a singlet spectrum with no resolved structure and peak-to-peak first derivative linewidth $\Delta H_{ms} \simeq 20$ G. This is compatible with $\dot{C}D_2NH_2$. Behavior identical to CD_3NH_2 was found for CD_3ND_2 and in Fig. 3(*F*) we show the spectrum observed for CD_3ND_2 after warming to 150 °K for 15 min and re-cooling to 77 °K. The singlet has $\Delta H_{ms} \simeq 11$ G, illustrating the linewidth contribution of the amino proton coupling in $\dot{C}D_2NH_2$. With both CD_3NH_2 and CD_3ND_2 the linewidth of this singlet did not change between ~150 and 77 °K.

(iii) Polycrystalline Ethylamine

The resolution of the spectrum obtained from $C_2H_5NH_2$ after irradiation at 77 °K was improved considerably (without change in line positions) by warming to 120 °K for 20 min. In Fig. 4(*A*) and (*B*) we show spectra for $C_2H_5NH_2$ which although still slightly asymmetric, may readily be analyzed into a 45 G doublet, a 36 G triplet, and a 25 G triplet. We assign this pattern to $CH_3CH_2\dot{N}H$ with $A_{^{14}N,\parallel} = 36$ G, $A_H{}^{NH} = 25$ G, and two inequivalent methylene protons $A_{H_1}{}^{CH_2} = 45$ G, $A_{H_2}{}^{CH_2} = 25$ G. The "stick" diagram shows that 16 of the 18 lines are resolved. The alternative assignment from these line positions of $A_{^{14}N} = 25$ G, $A_H{}^{NH} = 36$ G, $A_{H_1}{}^{CH_2} = 45$ G, and $A_{H_2}{}^{CH_2} = 36$ G is excluded by comparison with similar radicals (see Discussion).

With $CH_3CD_2\dot{N}H_2$, no overall change in the spectrum was observed on heating to 170 °K for 10 min and in Fig. 4(*C*) we see that ~5 G *D* hyperfine splittings are resolved. The width and overall shape of the spectrum are compatible with $CH_3CD_2\dot{N}H$ and the couplings derived above, but because of poor resolution we cannot confirm this assignment.

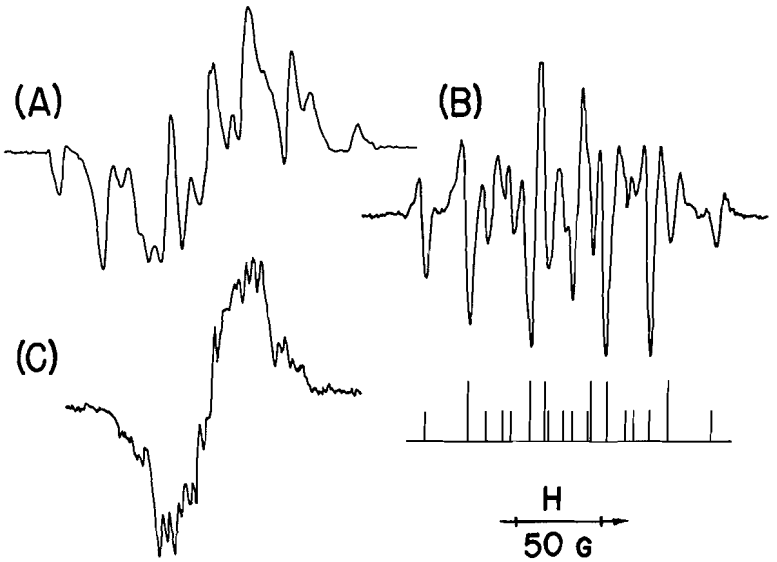

FIG. 4. Electron spin resonance spectra of γ-irradiated polycrystalline ethylamine: (*A*), $C_2H_5NH_2$ after 20 min at 120 °K (first derivative) and (*B*), (2nd derivative); (*C*), $CH_3CD_2NH_2$ after 10 min at 170 °K.

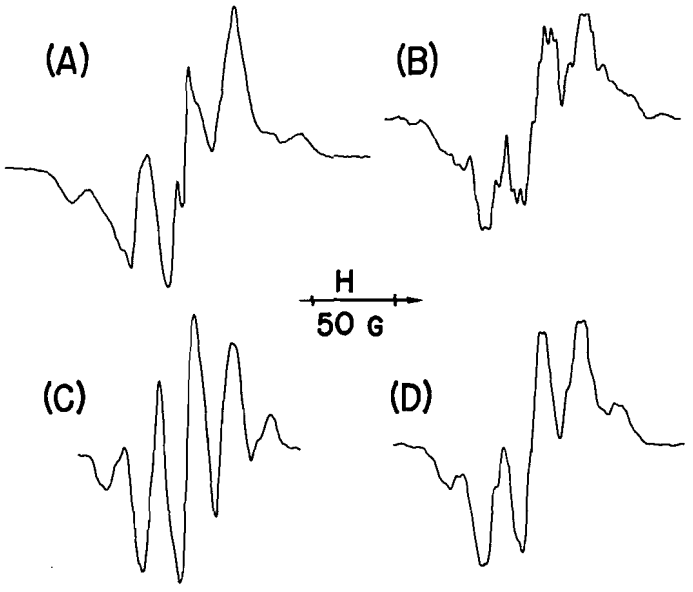

FIG. 5. First derivative e.s.r. spectra of γ-irradiated polycrystalline ethylamine: (*A*), $C_2H_5ND_2$ at 77 °K; (*B*), $C_2H_5NH_2$ after 30 min at 155 °K; (*C*), $C_2H_5ND_2$ after 10 min at 170 °K; (*D*), $C_2H_5ND_2$ after warming to 170 °K for 15 min and re-cooling to 77 °K.

Irradiated polycrystalline $C_2H_5ND_2$ gave at 77 °K a spectrum (Fig. 5(*A*)) quite unlike that of $C_2H_5NH_2$, suggesting that if a similar radical was formed in both cases, the radical was $C_2H_5\dot{N}D$ rather than $\dot{C}H_2CH_2ND_2$ or $CH_3\text{-}\dot{C}HND_2$. Both these latter alternatives would have small amino proton h.f. splitting (see Discussion). Although the spectrum computed for $C_2H_5\dot{N}D$ is somewhat different from that observed at 77 °K, the separation of the outermost lines of the spectrum was ~135 G, which is similar to that expected for this assignment and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

much larger than that thought reasonable for the two alternatives mentioned above. It may be that $CH_3\dot{C}HND_2$ is already present at 77 °K as a minor radical in addition to $CH_3CH_2\dot{N}D$ (see below), and this prevents exact analysis of the spectrum.

Although the radical in irradiated CH_3CD_2-NH_2 did not appear to change on warming to 170 °K for 20 min, when irradiated $C_2H_5ND_2$ or $C_2H_5NH_2$ was warmed to 150–155 °K for 20 min, major changes in the spectra occurred. These changes were non-reversible on re-cooling to 77 °K and it was clear that a new radical had been formed on warming, which had the same e.s.r. spectra for both $C_2H_5ND_2$ and $C_2H_5NH_2$. Figures 5(*B*), (*C*), and (*D*) show the spectra for $C_2H_5NH_2$ and $C_2H_5ND_2$, respectively. The deuterated amine showed considerably better resolution as a 1:4:6:4:1 quintet ($A_{av} = 22 \pm 1$ G) with little further splitting observable after 10 min at 170 °K (Fig. 5(*C*)), but on re-cooling to 77 °K (Fig. 5(*D*)), the spectrum resembled that of $C_2H_5NH_2$ after 30 min at 155 °K (Fig. 5(*B*)). The second derivative spectra for both $C_2H_5ND_2$, re-cooled to 77 °K after warming to 150 °K (corresponding to Fig. 5(*D*)), and for $C_2H_5NH_2$ at 155 °K (Fig. 5(*B*)), showed the 22 ± 1 G quintet but with a 5 or 6 G quartet splitting superimposed. These features are not characteristic of $\dot{C}H_2CH_2NH_2$, the isotropic h.f. parameters of which are known (6). This radical would be expected to have two inequivalent β protons in solids at low temperatures similar to those observed in (isoelectronic) $\dot{C}H_2CH_2CH_3$ (7). We consider the radical to be $CH_3\dot{C}HNH_2$ ($CH_3\dot{C}HND_2$), although the 22 G average coupling seems rather larger than that thought likely for this radical even if the alkyl protons are nearly equivalent. The α and β proton couplings for the $CH_3\dot{C}HNH_2$ radical are 15.3 and 20.2 G, respectively (8). However, although the h.f. splittings for the α and β protons in the CH_3-$\dot{C}HOH$ radical are 15.4 and 22 G, respectively, in solution at 25 °C (9), this radical in the solid phase at 100 °K shows 5 lines ($A_{av} = 22$ G) of binomial intensity distribution (for a review, see ref. 10). The minor 5–6 G quartet splitting observed in $C_2H_5NH_2$ at 155 °K may result both from the isotropic ^{14}N splitting and the amino proton coupling, both about this magnitude in $CH_3\dot{C}HNH_2$ (see Discussion). Without superior resolution we cannot be sure it is definitely a quartet splitting.

(iv) Polycrystalline Isopropylamine

After irradiation at 77 °K, $(CH_3)_2CHNH_2$ gave the spectrum shown in Fig. 6(*A*). The major feature is a quintet, $A_{av} \simeq 33$ G with the central line showing clear evidence of a poorly resolved doublet splitting. A different spectrum (Fig. 6(*B*)) with a quartet structure predominating, was obtained with $(CH_3)_2CHND_2$, which was warmed to 104 °K for 20 min to increase the resolution without major overall change in the spectrum. The line envelopes are compatible with $(CH_3)_2$-$CH\dot{N}H$ ($(CH_3)_2CH\dot{N}D$), with $A_H^{CH} \simeq 40$ G, $A_H^{NH} \simeq 25$ G ($A_D^{ND} \simeq 4$ G), and $A_{^{14}N,\parallel} \simeq 35$ G.

Major (and similar) changes in the spectra of irradiated $(CH_3)_2CHNH_2$ and $(CH_3)_2CHND_2$ occurred on warming to ~140 °K or higher. Figure 6(*C*) and (*D*) are for $(CH_3)_2CHND_2$ after 30 min at 176 °K. The septet has approximate binomial intensity distribution with a major splitting of 18.0 ± 0.5 G and a minor triplet splitting of 4.5 ± 0.3 G. An almost identical spectrum was observed for $(CH_3)_2\dot{C}NH_2$ at 170 °K, an 18.5 ± 0.8 G binomial septet but with a minor 7 ± 1 G doublet splitting. Katayama and Gordy (11) showed that a poorly resolved triplet may appear as a doublet with second derivative presentation. This would explain the apparent 7 G doublet in the less well resolved, protiated amine instead of the expected 4.5 G triplet, although an amino proton coupling (~5 G (8)) may also contribute to the minor splitting. The amino proton coupling must also be small since deuteration has little effect on the spectrum. This observation plus the low nitrogen coupling indicates that these spectra are due to $(CH_3)_2\dot{C}NH_2(D_2)$ (8).

When either the protiated or deuterated amine was warmed to 170 °K for ~20 min to isolate the $(CH_3)_2\dot{C}NH_2(D_2)$ radical, and then re-cooled to 77 °K, the spectrum changed from the 18 G septet to a markedly different ~36 G triplet. Spectra from $(CH_3)_2CHND_2$ are shown in Fig. 6(*E*) and (*F*). The second derivative may be fitted to a 36 ± 2 G triplet with a 12 ± 1 G splitting superimposed. This change in the spectrum of the $(CH_3)_2\dot{C}NH_2$ radical with temperature is ascribed to restricted rotation of the methyl groups at 77 °K. A similar effect is known for $(CH_3)_2\dot{C}OH$ (12) and other radicals (13), and it may be that two of the 6 protons give the 36 G triplet, the other 4 giving much smaller (~12 G) splittings. The apparent quartet splitting may result from incomplete resolution, and from the

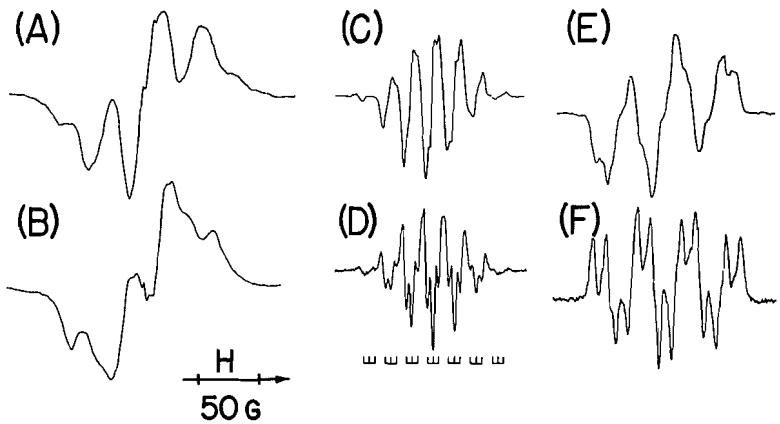

FIG. 6. Electron spin resonance spectra of γ-irradiated polycrystalline isopropylamine: (*A*), $(CH_3)_2CHNH_2$ at 77 °K; (*B*), $(CH_3)_2CHND_2$ after 20 min at 104 °K; (*C*) and (*D*), $(CH_3)_2CHND_2$ after 30 min at 175 °K (first and 2nd derivative); (*E*) and (*F*), $(CH_3)_2CHND_2$ after warming to 175 °K for 30 min and re-cooling to 77 °K (first and 2nd derivative).

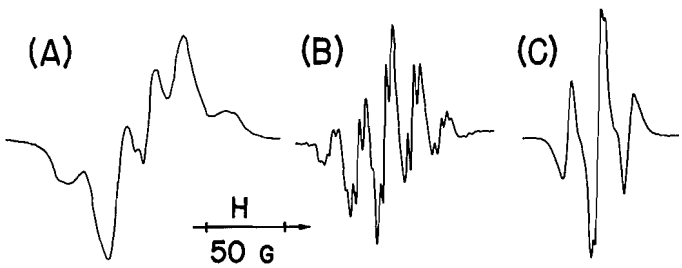

FIG. 7. First derivative e.s.r. spectra of γ-irradiated polycrystalline *tert*-butylamine: (*A*), $(CH_3)_3CNH_2$ at 77 °K; (*B*), $(CH_3)_3CNH_2$ after 30 min at 179 °K; (*C*), $(CH_3)_3CND_2$ after 20 min at 184 °K.

^{14}N splitting (which may be increased to $A_{^{14}N} \simeq$ 10–15 G at the lower temperature). At elevated temperatures the 18 G splitting represents the average value for the 6 methyl protons which are now equivalent due to rapid rotation. These data are consistent with $B_1 = 3.7$ G and $B_2 = 32.8$ G in the equation

$$A = B_1 + B_2 \cos^2 \theta$$

When rotation is restricted at 77 °K, θ (see standard texts for definition) approximately equals 0° for one proton in each methyl group and 60° for the other 4 protons. This value of B_2 is low compared to the normal value of about 50 G, presumably due to spin density delocalization onto the nitrogen, similar to the $\dot{C}H_2NH_2$ radical.

(v) Polycrystalline tert-Butylamine

The spectrum of γ-irradiated $(CH_3)_3CNH_2$ was five lines which were neither equally spaced nor of binomial intensities at 77 °K (Fig. 7(*A*)), but warming to 179 °K for 30 min resolved the spectrum into an approximately binomial quintet ($A = 18 \pm 1$ G) with a minor splitting (probably a quintet) $A = 4.0 \pm 0.5$ G, Fig. 7(*B*). This change was reversible on re-cooling to 77 °K. Irradiated $(CH_3)_3CND_2$ gave a 20 ± 1 G triplet spectrum with the outer lines considerably broadened. Figure 7(*C*) shows the spectrum after 20 min at 184 °K, when a minor 4 ± 1 G triplet splitting of the central line was evident. There was no change in the shape of this spectrum to 99% of the radical decay at 190 °K, nor on re-cooling to 77 °K.

These results are considered in the Discussion section.

(vi) Polycrystalline Di- and Tri-methylamines

Pukhal'skaya (1) suggested that $\dot{C}H_2NR_2$ radicals were formed by radiolysis of these amines, although their spectra were inadequate for analysis. If our assignment for $\dot{C}H_2NH_2$ in glassy CH_3NH_2 is correct, then we might expect

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

similar spectra from $\dot{C}H_2NHCH_3$ or $\dot{C}H_2N(CH_3)_2$.

Irradiated $(CH_3)_2NH$ showed at 77 °K a central broad singlet ($\Delta H_{ms} \simeq 40$ G) with lines from $(CH_3)_2\dot{N}$ radicals superimposed, as observed by Pukhal'skaya (1) and confirmed by our observation of a ~30 G ^{14}N triplet (parallel component) and 4.0 G *D* splitting (at least 30 lines over 124 G) with $(CD_3)_2NH$. On warming irradiated $(CH_3)_2NH$ to 125 °K for 10 min, the $(CH_3)_2\dot{N}$ radicals disappeared, leaving only a singlet which on further warming for 20 min at 155 °K was seen to be a quintet, $A_{av} = 15 \pm 1$ G, similar to that observed in glassy CH_3NH_2 and in the case of $(CH_3)_2NH$ thought to be the $\dot{C}H_2NHCH_3$ radical, with $A_H^{CH_2} \simeq A_{^{14}N} \simeq 15$ G.

The spectrum of irradiated $(CH_3)_3N$ at 77 °K was a broad singlet ($\Delta H_{ms} \sim 40$ G) but after 20 min at 143 °K a quintet ($A_{av} = 14 \pm 1$ G) was resolved (Fig. 8(*A*)). Radiolysis of $(CD_3)_3N$ at 77 °K gave a 13.5 G triplet with two small satellite lines (separation 80 G), the latter probably arising from a small amount of another radical. At 140 °K a further ~ 4 G splitting was observed, but after 10 min at 156 °K (Fig. 8(*B*)) a 2 G splitting was clearly resolved on the central line. These spectra are compatible with $\dot{C}H_2N(CH_3)_2$ or $\dot{C}D_2N(CD_3)_2$ with $A_{^{14}N} = 13.5 \pm 1.0$, $A_H^{CH_2} = 14.5 \pm 1.0$ ($A_D^{CD_2} \simeq 2$), and $A_H^{CH_3} \simeq 0$ G, an assignment supported by the isolation of $(CH_3)_2NCH_2CH_2N(CH_3)_2$ from irradiated liquid $(CH_3)_3N$ (14).

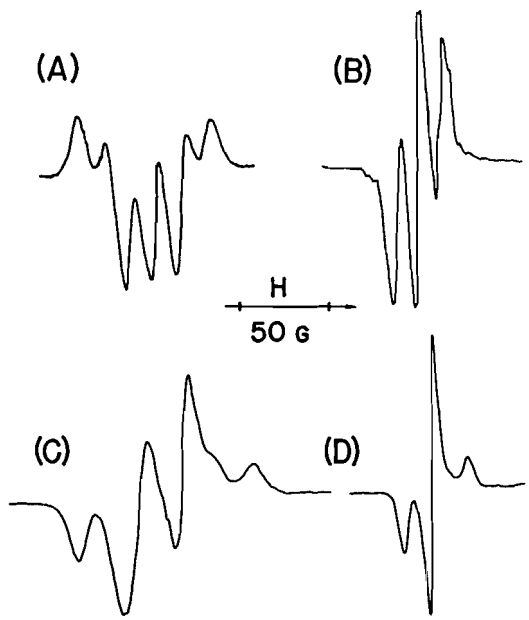

FIG. 8. Electron spin resonance spectra of γ-irradiated polycrystalline trimethylamine or methoxyamine: (*A*), $(CH_3)_3N$ after 20 min at 143 °K (2nd derivative); (*B*), $(CD_3)_3N$ after 10 min at 156 °K (first derivative); (*C*), CH_3ONH_2 and (*D*), CH_3OND_2 at 77 °K (first derivative).

(vii) Glassy (Anhydrous) Methoxyamine

We irradiated methoxyamine because the radicals produced by C—H and N—H bond breakage should have readily distinguishable e.s.r. spectra and because the N—H bond strength is ~ 4 kcal mol^{-1} lower than in methylamine (15) and is therefore probably lower than the H—CH_2ONH_2 bond strength.

Both CH_3ONH_2 and CH_3OND_2 were pale yellow after irradiation at 77 °K. The yellow color and minor lines in the e.s.r. spectra from both amines were removed by illumination with (visible) light from a quartz–iodine (tungsten) lamp at 77 °K. The minor signal removed by illumination was a 14 ± 2 G triplet for CH_3OND_2 but only a central line was removed in CH_3ONH_2. In the latter case the major spectrum would mask the outer lines of such a triplet. This minor species is probably $\dot{C}H_2ONH_2$ ($\dot{C}H_2OND_2$). The signal remaining after illumination was a quartet for CH_3ONH_2 (Fig. 8(*C*)) and a 30–35 G triplet for CH_3OND_2 (Fig. 8(*D*)). These spectra are assigned to $CH_3O\dot{N}H$ ($CH_3O\dot{N}D$) with $A_{^{14}N,\parallel} \simeq 30$ G, $A_H^{NH} \simeq 25$ G, and $A_H^{CH_3} \simeq 0$.

(viii) g-Values

All our spectra had $g = 2.003 \pm 0.001$, which is within the range found for $\dot{C}H_2NR_2$ or $R\dot{N}R'$ radicals in the literature.

Discussion

(i) Formation of the Radicals

The most likely routes for the formation of the majority of the radicals observed in glassy or polycrystalline solid amines are ion–molecule reactions such as [1]. In glassy CH_3NH_2 or CH_3ND_2, only $\dot{C}H_2NH_2$ ($\dot{C}H_2ND_2$) was observed, but in glassy CD_3NH_2 or CD_3ND_2, the predominant radical observed at 77 °K was $CD_3\dot{N}H$ ($CD_3\dot{N}D$). This sensitivity to selective deuteration may result from a close similarity in C—H and N—H bond strengths. Deuteration of the methyl group may change the crystal

structure (16) (see below). On the other hand some of the effect may not be genuine. There may be mixtures of aminoalkyl and alkylamine radicals in all cases. The predominance of the spectrum of one over the other in a particular case may arise partly from an isotopic effect on the relative yield and also from linewidth effects.

In all the polycrystalline methylamines, the $CH_3\dot{N}H$ radical was observed at 77 °K but was transformed into $\dot{C}H_2NH_2$ on warming, suggesting that $D(H—CH_2NH) < D(CH_3NH—H)$. This conclusion was also reached by Smithies and Whitworth (17) (who observed ethylenediamine as a major product of radical combination in irradiated liquid methylamine, but found no dimethyl hydrazine), and contrasts with the selectivity of methyl radical attack on amines (18). The transformation of $RCH_2\dot{N}H$ to $R\dot{C}HNH_2$ radicals was also observed on warming $C_2H_5NH_2$, $C_2H_5ND_2$, $(CH_3)_2CHNH_2$, and $(CH_3)_2CHND_2$. The effect of deuteration of the alkyl group on this transformation of $RCH_2\dot{N}H$ radicals was seen by the absence of such reaction of $CH_3CD_2\dot{N}H$ after 10 min at 170 °K, and by the fact that the reaction was occurring at 100 °K in polycrystalline CH_3NH_2, but required warming to about 140 °K in CD_3NH_2. A similar thermal reaction has been reported for dimethylamine (1).

The absence of spectra attributable to $\dot{C}H_2CH_2NH_2$ in irradiated $C_2H_5NH_2$ results from the almost negligible reactivity of the methyl protons both in ion–molecule reactions similar to [1] (19), and also in attack by methyl radicals (18). In contrast, reaction of the Ti^{3+}/H_2O_2 system with $C_2H_5NH_2$ *in acid solution* produces the $\dot{C}H_2CH_2NH_2$ radical (6).

The differences between glassy and polycrystalline CH_3NH_2 and CH_3ND_2 are not thought to originate directly from the 10% water added to the glass, since the ionization potential of water is much higher than that of CH_3NH_2. It seems likely to reflect an importance of the structure of the solid on the ion–molecule reaction. A hydrogen-bonded collision complex with the amino groups adjacent may be preferentially formed in the polycrystalline solid, resulting in preferential formation of $R\dot{N}H$ radicals. This may not be the case in the glassy mixture with 10% water since this water will disrupt the hydrogen bonding between amino groups to a significant extent.

Effects of phase modifications and deuteration have been observed in other systems (20). The radicals observed in irradiated glycine depend on the crystal structure and on deuteration (21).

(ii) The e.s.r. Parameters of the Radicals

By using extensive isotopic labelling, we have been able to make reasonable spectral assignments without reference to published hyperfine parameters for similar radicals prepared by other methods. However, since this work was completed, high resolution spectra of some amines have been reported. Wood and Lloyd (8) obtained isotropic spectra for some radicals of the type $R\dot{C}HNR'_2$ in an adamantane matrix and Neta and Fessenden (22) observed $\dot{C}H_2NR_2$ and other radicals in aqueous solutions of amines. Danen and Kensler (23) have reported parameters for $R_2\dot{N}$ radicals in cyclopropane solution. In Table 1 we summarize our data for amine radicals trapped in solid amines to facilitate comparison with these new high resolution data. The radicals for which h.f. parameters have recently been reported are $(CH_3)_2\dot{N}$ (23); $\dot{C}H_2NH_2$ (22),

*From ^{15}N data.

$\dot{C}H_2NHCH_3$, and $\dot{C}H_2N(CH_3)_2$ (8, 22); and $CH_3\dot{C}HNH_2$ and $(CH_3)_2\dot{C}NH_2$ (8). Our results are in substantial agreement with these recent reports and in addition permit clarification of earlier anomalies such as the assignment of the ~32 G ^{14}N splitting in $R\dot{N}H$ radicals to an isotropic coupling (3).

The 30–35 G ^{14}N coupling we observed for $R\dot{N}H$ (R = CH_3, C_2H_5, $(CH_3)_2CH$, CH_3O) and $R_2\dot{N}$ (R = CH_3) radicals is much larger than the 14.8 G isotropic ^{14}N splitting of $(CH_3)_2\dot{N}$ (23) or the 10.4 G ^{14}N isotropic coupling for $\dot{N}H_2$ in an argon matrix (24). The ^{14}N coupling for $\dot{N}H_2$ varies with the radical environment (25), possibly because of differing bond angles (26). However, a matrix effect is unlikely to raise the isotropic coupling for $R\dot{N}H$ or $R_2\dot{N}$ to 30–35 G and we assign our observed splitting to the parallel component of the ^{14}N interaction. This interpretation is supported by the published isotropic and anisotropic ^{14}N h.f. splittings of the related radicals shown in Table 2, and by calculation of the anisotropic couplings expected for these radicals.

We may estimate the anisotropic h.f. interaction for ^{14}N in $R_2\dot{N}$ and $R\dot{N}H$ type radicals if the isotropic splittings and the spin density in the ^{14}N 2p orbital ($\rho_{2p}{}^N$) are known. The axially symmetric h.f. tensor for the interaction with the electron in the ^{14}N 2p orbital will have magnitudes $A_{^{14}N,\parallel} = A + 2B$ and $A_{^{14}N,\perp} = A - B$, using Morton's nomenclature (34).[4] A is the isotropic ^{14}N splitting and B the anisotropic parameter associated with p character. The latter is estimated from the relation $B = \rho_{2p}{}^N.B_0{}^N$ where $B_0{}^N$ = 17.1 G (34). For $(CH_3)_2\dot{N}$ (23), electron density in proton 1s orbitals is $6 \times A_{CH_3}{}^H/A_0{}^H = 0.324$ and in the ^{14}N 2s orbital is $A_{^{14}N,iso}/A_0{}^N = 0.027$, leaving 0.649 in the ^{14}N 2p orbital. Hence B = 11.1 G and $A_{^{14}N,\parallel} = 37.0$, $A_{^{14}N,\perp} = 3.7$ G, very similar to observed values for $\dot{N}H_2$ (32). Thus this treatment, although simple, gives values for $A_{^{14}N,\parallel}$ which are similar to those listed in Table 1, *i.e.* 30–35 G for $R\dot{N}R'$ radicals. Since we observe a ^{14}N coupling in $\dot{C}H_2NH_2$ in the solid of 12 ± 3 G and the isotropic ^{14}N coupling is 5.0 G (22), the observed splitting in the solid must be the largest component of the ^{14}N anisotropic hyperfine tensor and the other two principal values must be close to zero. (That the ^{14}N coupling for $\dot{C}H_2NR_2$ in solid amines is considerably larger than the ~5 G isotropic value (22) is without doubt the cause of the marked differences between $CH_3{}^{14}NH_2$ and $CH_3{}^{15}NH_2$. We assign $A_H{}^{CH_2}$ = 14.5 ± 3 G, which is close to the isotropic value (22) and there are no satellite lines characteristic of methylene proton anisotropy. The total width of the spectrum therefore requires an ~11 G ^{14}N coupling. The larger ^{14}N coupling is also particularly apparent in $\dot{C}D_2N(CD_3)_2$, shown in Fig. 8(*B*)). Surprisingly, both $CH_3\dot{C}HNH_2$ and $(CH_3)_2\dot{C}NH_2$ show ^{14}N h.f. couplings in the solid which are close to the isotropic values (8) and the limit of our resolution, and are certainly not the 10–15 G anisotropic components found for $\dot{C}H_2NR_2$. This effect is probably not one of temperature, since $\dot{C}H_2NH_2$ shows a similar ^{14}N coupling at ~165 and 77 °K.

The low (4–5 G) amino proton h.f. couplings in $R\dot{C}HNH_2$ radicals (8, 22) confirm our observations that we are generally not resolving these splittings in the solid amines. The inequivalence

[4]The terms parallel and perpendicular refer to the direction of the applied external field with respect to the nitrogen 2p orbital containing the odd electron.

of methylene protons in $CH_3CH_2\dot{N}H$ in solid ethylamine is similar to the effects of restricted rotation in the isoelectronic alkyl radicals in solids (7). The increase in methyl proton coupling from 24.7 G in $(CH_3)_2\dot{C}$ (35) to 27.4 G in $(CH_3)_2\dot{N}$ (23) is in accord with the ~32 G methyl proton coupling in $CH_3\dot{N}H$.

We are unable to positively interpret our results from irradiated *tert*-butylamine. Smith and Swan (14) found products which may result from both $(CH_3)_3C\dot{N}H$ and $\dot{C}H_2C(CH_3)_2NH_2$ formation after irradiating liquid $(CH_3)_3CNH_2$. Either radical would give a triplet from $(CH_3)_3CND_2$ but neither would give a quintet for $(CH_3)_3CNH_2$. A possible assignment is the parent ion $(CH_3)_3C\overset{+}{N}H_2$ with $A_{^{14}N} \simeq A_H^{NH_2} \simeq 18$ G. Such a ^{14}N coupling, if isotropic, is similar to that in NH_3^+ (33, 36) and $\overset{+}{N}(CH_3)_3$ (29) (see Table 2). Although it would be surprising if this ion were stable at 190 °K in the solid, an identical radical was produced by γ-irradiation of *tert*-butylamine adsorbed on silica gel and in the latter case the parent ion is a not unreasonable assignment (see accompanying paper).

Conclusions

The radiolysis of aliphatic amines at 77 °K results in radicals formed by hydrogen atom loss from the amino or alkyl groups. The $R\dot{N}H$ radicals disappear on warming to give $R\dot{C}HNH_2$ radicals. (Neta and Fessenden (22) invoke such a reaction to explain some of their observations.) The relative proportion of these two types of radicals is considerably influenced by selective deuteration of the alkyl or amino groups, and (in the case of CH_3NH_2) also depends on whether the solid is glassy or polycrystalline. Some difficulties are anisotropy of $A_{^{14}N}$, the broadening of the $M_I(^{14}N) = \pm 1$ lines and the restricted rotation of alkyl groups in the solid amines at low temperatures.

Electron Spin Resonance Studies of the Radiolysis of Aliphatic Amines Adsorbed on Silica Gel[1]

P. WARDMAN[2] AND D. R. SMITH[3]

Physical Chemistry Branch, Atomic Energy of Canada Limited, Chalk River Nuclear Laboratories, Chalk River, Ontario

Received January 13, 1971

Several aliphatic amines have been adsorbed in sub-monolayer amounts on silica gel and γ-irradiated at 77 °K. The electron spin resonance (e.s.r.) spectra of the radicals trapped on the surface at 77 °K were similar, in most cases, to the spectra obtained after irradiating the corresponding polycrystalline solid amine at 77 °K. Methyl-, ethyl-, *n*-propyl, and *n*-butylamines all gave $R\dot{N}H$ radicals, and dimethylamine gave $(CH_3)_2\dot{N}$ radicals. The radical cation ($(CH_3)_3\dot{\overset{+}{N}}$) was observed in the case of trimethylamine. Adsorbed methoxy-amine and *t*-butyl amine have also been studied and the cation-radical of the latter tentatively identified. The results are discussed in terms of reaction of the adsorbed amine with a surface active site.

Plusieurs amines aliphatiques ont été absorbées sur le gel de silice pour donner des mono-couches et irradiées par des rayons-γ à 77 °K. Les spectres de résonance paramagnétique électronique (r.p.e.) des radicaux piégés à 77 °K sur la surface de l'absorbant sont semblables, dans la plupart des cas, aux spectres obtenus en irradiant la même amine à l'état polycristalline à 77 °K. Les méthyl-, éthyl-, *n*-propyl et *n*-butyl amines donnent tous les radicaux $R\dot{N}H$, et la diméthyl-amine donne les radicaux $(CH_3)_2\dot{N}$. Le cation radicalaire ($(CH_3)_3\dot{\overset{+}{N}}$) a été observé dans le cas de la triméthyl-amine. Aussi, methoxy-amine et *t*-butyl amine adsorbées ont été etudiées et le cation-radicalaire de ce dernier a été identifié provisoirement. Les résultats sont discutés en termes de réaction des amines absorbées sur un site actif à la surface de l'absorbant.

Canadian Journal of Chemistry, 49, 1880 (1971)

Introduction

Recent work has shown that when suitable scavengers are adsorbed on silica gel and the gel γ-irradiated, reactions with what are apparently migrating positive or negative charged species occur. Thus adsorbed benzene forms the benzene cation (1) and alkyl halides capture electrons dissociatively to produce alkyl radicals (2), both radicals being trapped on the surface.

Amines are adsorbed strongly on silica gel and are expected to have a low reactivity towards migrating electrons, but because of their low ionization potentials should trap positive charge very effectively. The use of silica gel as adsorbent therefore provides us with a means of investigating the radicals derived from ionization of amines. In contrast, we have found quite different radicals, not yet identified, by reaction of negative species (surface trapped electrons) with amines: these latter results are presented elsewhere, in our study of the radiolysis of amines adsorbed on magnesium oxide powder (3, 4).

Experimental

The amines used, procedures for handling deuterated amines and irradiation and electron spin resonance (e.s.r.) spectroscopy have been described in the accompanying paper on irradiated polycrystalline or amorphous amines. Fisher 100–200 mesh (A.S.T.M.) silica gel was degassed with ~ 1 mm depth in a 2 cm diameter silica tube at 450 °C for 16 h at 10^{-5} Torr, cooled to 77 °K and a measured amount of amine distilled in. The tube, terminated by a length of 3 mm i.d. Spectrosil silica, was sealed off and the sample warmed to room temperature for 10 min with gentle shaking. The sample was irradiated at 77 °K in the wide end of the tube and tipped without warming into the Spectrosil end for e.s.r. observations. Amines deuterated in the amino group were adsorbed on silica gel which had been deuterated by first removing the bulk of the adsorbed H_2O by a preliminary degassing at 450 °C for 3 h, then exposing the cooled gel to 5 successive lots of D_2O for several minutes each, finally leaving the gel in contact with D_2O for 8 h before final degassing as above. The B.E.T. surface area of the gel was 635 $m^2 g^{-1}$. This was measured by nitrogen adsorption at 77 °K using an Aminco Sor-bet apparatus and the helium carrier technique. The area of the nitrogen molecule was assumed to be 16 $Å^2$.

Results

No e.s.r. absorption was observed in the sample prior to irradiation. We did not investigate the effects of variation of surface coverage with all the amines, but no qualitative differences were

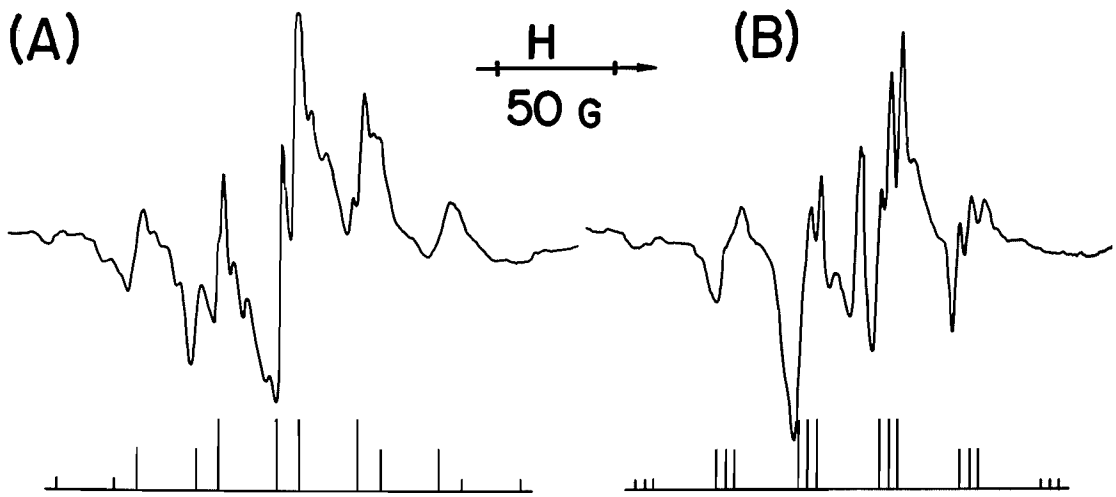

FIG. 1. First derivative e.s.r. spectra of γ-irradiated 10^{-3} mol g^{-1} methylamine on silica gel at 77 °K: (*A*), CH_3NH_2; (*B*) CH_3ND_2.

found for CH_3NH_2 between 2×10^{-4} and 2×10^{-3} mol g^{-1}. Most results were found for a coverage of 10^{-3} mol g^{-1}, which corresponds to $\sim$ 1 molecule/100 Å^2. The radicals disappeared in less than 1 min on warming to 300 °K. Support for our assignments, including better resolved spectra in some cases, is to be found in the accompanying paper.

(i) Methylamine

The spectrum of 10^{-3} mol g^{-1} CH_3NH_2 on silica gel after γ-irradiation at 77 °K is shown in Fig. 1(*A*), which has superior resolution to the similar spectrum observed in irradiated polycrystalline CH_3NH_2 and is assigned to $\dot{C}H_3\overset{+}{N}H$. The high field line of the outermost pair (total separation 200 G) is almost masked by the very broad line in this region which is characteristic of irradiated silica gel without adsorbent. The high field lines of several other spectra were also difficult to detect. The "stick" diagram gives satisfactory agreement with the position of the major lines for our assignment $A_H^{CH_3} = A_{^{14}N,\parallel} =$ 35 G and $A_N^{NH} = 25$ G, but additional splitting is observed. The most likely cause of at least part of this splitting is the perpendicular component of the ^{14}N anisotropic hyperfine tensor, the observed 35 G splitting corresponding to the parallel component (see preceding paper).

We may eliminate $\dot{C}H_2NH_2$ (5) or $\dot{C}H_2\overset{+}{N}H_3$ (6) as alternative assignments because these radicals would give quite different spectra only $\sim$ 64 and $\sim$ 132 G wide, respectively, assuming an $\sim$12 G ^{14}N principal splitting would be observed. The spectrum for $CH_3\overset{+}{N}H_2$ may be predicted by comparison with hyperfine (h.f.) parameters for $\overset{+}{N}H_3$ (7) and $(CH_3)_3\overset{+}{N}$ (8) (see also Table 2 of the preceding paper). For $CH_3\overset{+}{N}H_2$ we predict $A_H^{CH_3} \simeq 31$ G, $A_H^{NH_2} \simeq 26$ G, and $A_{^{14}N,\parallel} \geqslant 35$ G, which would result in a spectrum of 8 major groups of lines ($A_{av} \simeq 30$ G) spread over $\geqslant$215 G. This pattern would not be greatly affected by errors in the value of $A_{^{14}N,\parallel}$, the predicted proton splittings being fairly reliable and dominating the overall features of the spectrum because of broadening of the $M_I(^{14}N) = \pm 1$ lines. In particular, $CH_3\overset{+}{N}H_2$ is not expected to show a strong central line, as was observed and is predicted by our parameters for $CH_3\dot{N}H$.

The spectra from 10^{-3} mol g^{-1} $CH_3{}^{15}NH_2$, CD_3NH_2, and CD_3ND_2 on silica gel after γ-irradiation also resembled those found for the irradiated polycrystalline solid amines. One difference between the silica gel and solid systems (for CH_3NH_2 and $CH_3{}^{15}NH_2$ at least) is an increase in average hyperfine splitting of about 10% in the silica gel system. The difficulties in analyzing the spectra of radicals trapped on surfaces are illustrated by Fig. 1(*B*), which shows the spectrum of $CH_3\dot{N}D$ on silica gel. This shows the six h.f. lines ($A_{av} = 35$ G) but with additional 4–5 G splitting only resolved in the high field lines. Variation in line width is also observed for the $\dot{N}H_2$ radical on silica gel (9), and may be due to slow rotation of the radical on the surface.

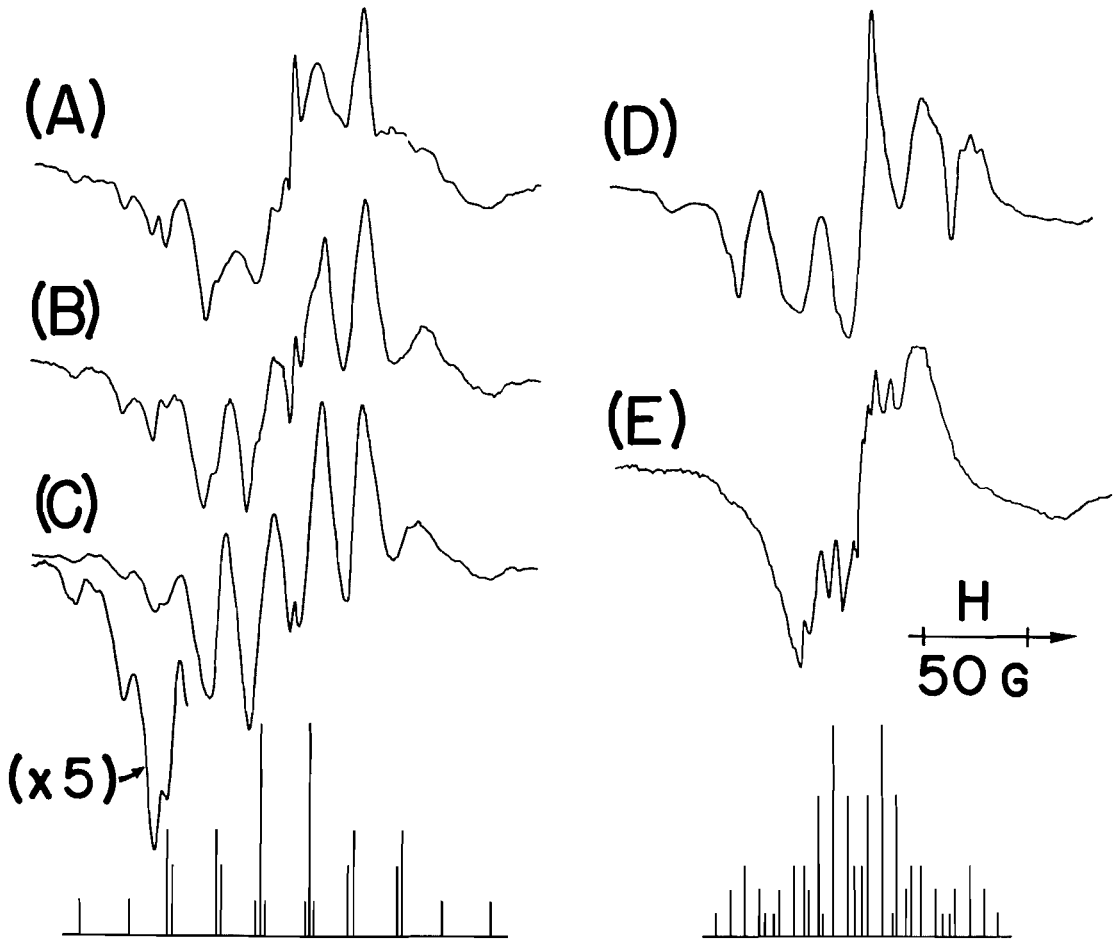

FIG. 2. First derivative e.s.r. spectra of γ-irradiated 10^{-3} mol g^{-1} *n*-alkyl amines on silica gel at 77 °K: (*A*), $C_2H_5NH_2$; (*B*), *n*-$C_3H_7NH_2$; (*C*), *n*-$C_4H_9NH_2$; (*D*), $C_2H_5ND_2$; (*E*), $CH_3CD_2NH_2$.

(ii) Ethyl-, n-Propyl-, and n-Butyl-amines

Poorer resolution of the $C_2H_5\dot{N}H$ radical was observed than in solid $C_2H_5NH_2$, but the results for the irradiation of these higher amines on silica gel support our assignment of $R\dot{N}H$ radicals. Similar spectra were observed for irradiated ethyl-, *n*-propyl-, and *n*-butyl-amines adsorbed on silica gel. In Fig. 2(*A*), (*B*), and (*C*) we see the spectra for γ-irradiated 10^{-3} mol g^{-1} $C_2H_5NH_2$, *n*-$C_3H_7NH_2$, and *n*-$C_4H_9NH_2$, respectively. The spectrum from *n*-butylamine is the best resolved of the three, but it is clear that the number of major lines and the line positions are identical in all three amines. This could only arise if the radicals are of the $R\dot{N}H$ (or $R\dot{N}H_2^+$) type, since neither $R\dot{C}HNH_2$ nor $\dot{C}H_2(CH_2)_nNH_2$ would give similar spectra for all three amines with lines up to 200 G total separation. The spectra from the ethylamines are not identical to those obtained from the γ-irradiated solids at 77 °K (see preceding paper) and in particular the total width from $C_2H_5NH_2$ is about 10% higher in the silica gel system than in the solid. By comparison with CH_3NH_2 and other amines, we might expect a small increase in alkyl proton couplings for $R\dot{N}H$ on silica gel compared to those in the solid phase, and our analysis agrees with this prediction.

In Fig. 2(*C*) the two outermost low-field lines, readily seen on higher gain, are characteristic of $M_I(^{14}N) = \pm 1$ lines that are broadened considerably relative to the $M_I = 0$ line. The separation between these lines is only ~ 23 G, too low for a ^{14}N parallel coupling in $R\dot{N}H$ or $R\dot{N}H_2^+$, suggesting that the 1st and 2nd lines (from low

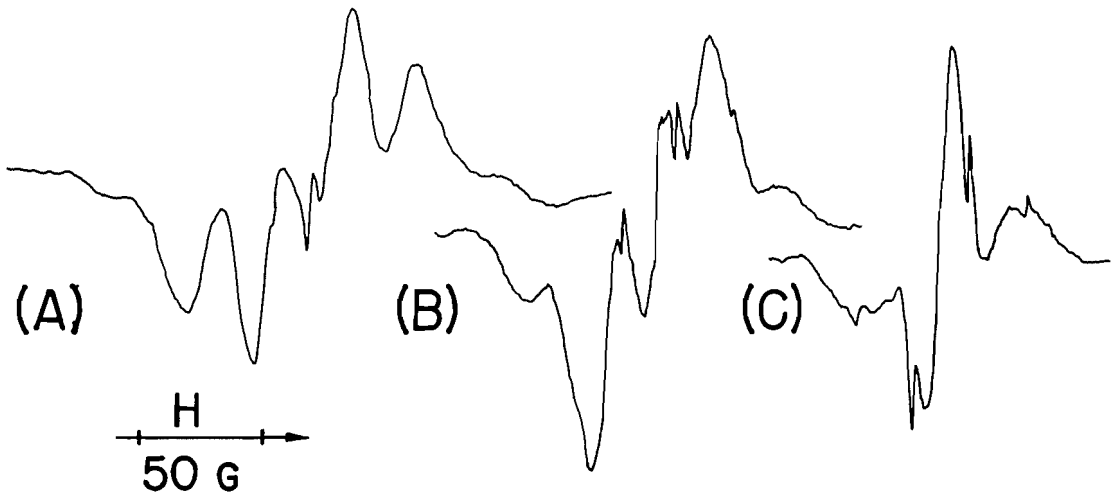

FIG. 3. First derivative e.s.r. spectra of γ-irradiated 10^{-3} mol g^{-1} isopropylamine or *t*-butylamine on silica gel at 77 °K: (*A*), $(CH_3)_2CHNH_2$; (*B*), $(CH_3)_3CNH_2$; (*C*), $(CH_3)_3CND_2$.

field) are both $M_I(^{14}N) = \pm 1$ lines and the 3rd and 4th lines the corresponding $M_I = 0$ lines with $A_{^{14}N,\parallel} = 43$ G. Thus as generally observed the proton couplings dictate the major spectral lines, which form a sextet with total separation of the outermost lines ~115 G and $A_{av} = 23$ G. The total width of the spectrum from $C_2H_5ND_2$ (Fig. 2(*D*)) is ~177 G, suggesting coupling with a single amino proton in $C_2H_5NH_2$ of ~ 25 G, *i.e.* that appropriate for A_H^{NH} in $RCH_2\dot{N}H$. With this coupling the total methylene proton coupling in the $RCH_2\dot{N}H$ radical must be (115–25) ≃ 90 G. The sextet of major lines from the total proton coupling in $RCH_2\dot{N}H$ must then arise from two equivalent methylene protons, $A_H^{CH_2} \simeq 45$ G and a single amino proton, $A_H^{NH} \simeq 25$ G. The "stick" diagram below Fig. 2(*C*) gives a best fit for our analysis for $RCH_2\dot{N}H$ with $A_H^{CH_2} = 45$ G, $A_H^{NH} = 24$ G, and $A_{^{14}N,\parallel} = 43$ G. There is excellent agreement with all three experimental spectra, apart from poor correspondence with line intensities due to line width variation. (Both "stick" spectra in Fig. 2 have been drawn with the $M_I(^{14}N) = \pm 1$ lines only one third the height of the $M_I = 0$ line to approximate this effect.)

The spectrum from $CH_3CD_2NH_2$ on silica gel (Fig. 2(*E*)) supports this analysis, an ~ 7 G deuterium splitting being resolved only on the $M_I(^{14}N) = 0$ line and the total width being that expected. The "stick" diagram is for the couplings above. Surprisingly, although the total width of the spectrum from $C_2H_5ND_2$ (Fig. 2(*D*)) is exactly that expected for $C_2H_5\dot{N}D$, the pattern of 5 major lines ($A_{av} \simeq 25$ G) is quite unlike the ~ 45 G triplet expected from the CH_2 splitting. Poor agreement with the computed spectrum was also obtained with γ-irradiated solid $C_2H_5ND_2$ (see preceding paper). It may be that an isotope effect is being observed in this case, producing a mixture of radicals with a radical other than $C_2H_5\dot{N}D$ dominating the center of the spectrum. The quintet with $A_{av} \simeq 25$ G is not unlike that found for $CH_3\dot{C}HND_2$ (see preceding paper).

Attempts to fit the sextet major spectrum arising from proton h.f. interaction from irradiated RCH_2NH_2 on silica gel to either $RCH_2\dot{N}H$ with inequivalent β protons or to $RCH_2\dot{N}H_2$ failed. In both cases reasonable values of the h.f. parameters failed to produce a sextet with the observed splittings; rather precise degeneracy is necessary to produce the relatively narrow lines seen in Fig. 2(*C*).

(iii) Isopropyl- and tert-Butylamines

The spectrum from irradiated 10^{-3} mol g^{-1} $(CH_3)_2CHNH_2$ on silica gel is shown in Fig. 3(*A*) and is similar to that observed in the irradiated solid at 77 °K but the central doublet (only partially resolved in the solid) is completely resolved on silica gel. The latter spectrum is approximately that expected from $(CH_3)_2CH\dot{N}H$ with the β proton coupling (40 G in the solid) increased to $A_H^{CH} \simeq 50$ G, with $A_H^{NH} \simeq 25$ G and $A_{^{14}N,\parallel} \simeq 35$ G.

The spectrum from irradiated $(CH_3)_3CNH_2$

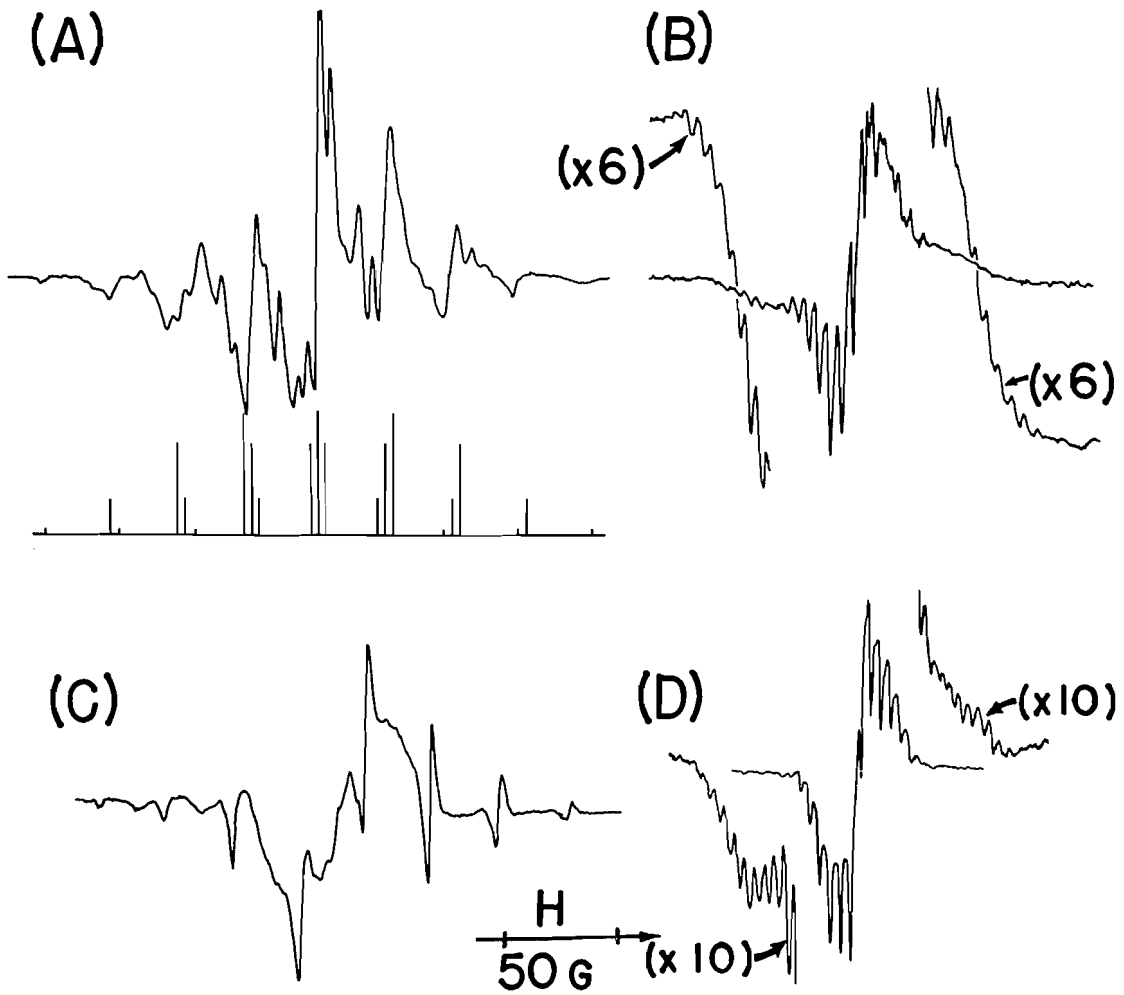

FIG. 4. First derivative e.s.r. spectra of γ-irradiated di- and tri-methylamines on silica gel at 77 °K: (*A*), 2×10^{-4} mol g^{-1} $(CH_3)_2NH$; (*B*), 2×10^{-4} mol g^{-1} $(CD_3)_2NH$; (*C*), 10^{-3} mol^{-1} $(CH_3)_3N$; (*D*), 10^{-3} mol g^{-1} $(CD_3)_3N$.

on silica gel (Fig. 3(*B*)) is seen to be *identical* to that observed from the solid amine after irradiation at 77 °K (see Fig. 7(*A*) of the preceding paper). A *very* small amount of $\dot{C}H_3$ radicals was also observed, the 23 G quartet being readily recognizable in the spectrum from $(CH_3)_3CND_2$ on silica gel (Fig. 3(*C*)). Again, the spectrum from $(CH_3)_3CND_2$ is very similar to that observed in the irradiated solid at 77 °K. We have tentatively attributed these spectra to the parent ion, $(CH_3)_3C\overset{+}{N}H_2$ ($(CH_3)_3C\overset{+}{N}D_2$) with $A_H^{NH_2} \simeq A_{^{14}N,iso} \simeq 18$ G in the solid (see preceding paper). The ^{14}N coupling may not be isotropic at 77 °K and is probably increased over the ~18 G value seen at ~175 °K in the solid. Poor resolution on silica gel prevents precise measurement of the anisotropic coupling.

(iv) Di- and Tri-methylamines

At a coverage of 2×10^{-4} mol g^{-1}, $(CH_3)_2NH$ on silica gel gave a well-resolved $(CH_3)_2\dot{N}$ spectrum after γ-irradiation (Fig. 4(*A*)). The seven major lines from the proton coupling give $A_H^{CH_3} = 29.5 \pm 1$ G and the low-field outermost line of the parallel component of the ^{14}N splitting, readily observed on high gain gives $A_{^{14}N,\parallel} = 33$ G. The "stick" spectrum is for this assignment. The additional splitting observed arises from the imprecise degeneracy of the proton coupling and the ^{14}N parallel coupling and probably also from

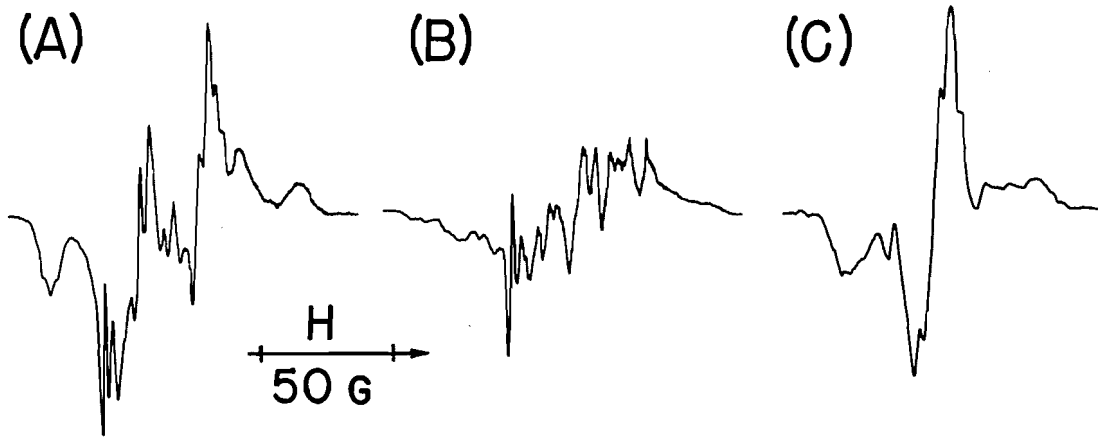

FIG. 5. First derivative e.s.r. spectra of γ-irradiated methoxyamine on silica gel at 77 °K: (*A*), 10^{-3} mol g^{-1} CH_3ONH_2; (*B*), 2×10^{-4} mol g^{-1} CH_3ONH_2; (*C*), 10^{-3} mol g^{-1} CH_3OND_2.

an $\sim$ 5 G ^{14}N perpendicular component. The spectrum from 2×10^{-4} *M* $(CD_3)_2NH$ on silica gel (Fig. 4(*B*)) illustrates clearly the broadening of the $M_I(^{14}N) = \pm 1$ lines also seen in $R\dot{N}H$ radicals. The $\sim$ 4.5 G D-splitting confirms the $\sim$ 30 G H-coupling. The spectrum for 10^{-3} mol g^{-1} $(CH_3)_2{}^{15}NH$ on silica gel, though somewhat asymmetric, was in accord with the results for $(CH_3)_2NH$.

The radical produced by irradiation of 10^{-3} mol g^{-1} $(CH_3)_3N$ on silica gel was not observed in irradiated solid trimethylamine. Figure 4(*C*) shows the spectrum for $(CH_3)_3N$ and Fig. 4(*D*) that for $(CD_3)_3N$. For both amines a central, broader absorption obscured the spectra, but the narrow lines (again of varying width) are ascribed to the $(CH_3)_3\overset{+}{\dot{N}}$ ($(CD_3)_3\overset{+}{\dot{N}}$) radical cation, the isotropic and anisotropic couplings of which are known (8, 11). For $(CH_3)_3\overset{+}{\dot{N}}$ we observed 8 of the 10 isotropic ($M_I(^{14}N) = 0$) lines arising from the proton coupling ($A_H = 29.5 \pm 1.0$ G) but the much weaker anisotropic $M_I(^{14}N) = \pm 1$ lines were too ill-resolved to extract the ^{14}N coupling. The broadening of the $M_I(^{14}N) = \pm 1$ lines is particularly well illustrated in the spectra for $(CD_3)_3\overset{+}{\dot{N}}$. We expect to detect at most only 13 of the 19 deuterium lines for each value of $I_N = 0$, ± 1 and on this basis the total separation should be less than $2A_{^{14}N} + 12A_D$. We observed 31 h.f. lines ($A_D = 4.5$ G) over 134 G, showing $A_{^{14}N,\parallel} >$ 40 G. This is in agreement with the 49 G parallel component of the ^{14}N coupling of $(CH_3)_3\overset{+}{\dot{N}}$ in solid betaine hydrochloride (11) and much larger than the 18 G isotropic ^{14}N splitting (8) of this radical.

(v) Methoxyamine

Quite different spectra were observed for CH_3ONH_2 on silica gel at coverages of 10^{-3} and 2×10^{-4} mol g^{-1}, Fig. 5(*A*) and (*B*), respectively. At the higher coverage, the major species was clearly the $CH_3O\dot{N}H$ radical, which we have observed in solid methoxyamine (preceding paper). We assign $A_H^{NH} \simeq 25$ G, $A_H^{CH_3} \simeq 0$, and $A_{^{14}N,\parallel} \simeq 35$ G. In addition to this major quartet feature, we see further splitting of the central portion of the spectrum. This does not arise from the $CH_3O\dot{N}H$ radical (*e.g.* from the methoxy protons) because at the lower coverage essentially only the spectrum of narrow lines is observed, with very little $CH_3O\dot{N}H$ spectrum underlying. We cannot analyze this latter spectrum because of the possibility of small contributions from $CH_3O\dot{N}H$ and/or $\dot{C}H_2ONH_2$ to an already weak spectrum. It may be due to $\dot{N}H_2$ radicals, as these lines were not observed in the CH_3OND_2/silica gel systems and in fact the marked variation in line shape and approximate positions of the major lines are similar to those found for $\dot{N}H_2$ on silica gel (9). Figure 5(*C*) shows the spectrum of irradiated 10^{-3} mol g^{-1} CH_3OND_2 on silica gel. The $\sim$30 G triplet of the $CH_3O\dot{N}D$ radical has additional lines superimposed, possibly some $\dot{C}H_2OND_2$ or $\dot{N}D_2$ radicals.

(vi) g-Values

Except those for $(CH_3)_3\overset{+}{\dot{N}}$ ($(CD_3)_3\overset{+}{\dot{N}}$), all our spectra had $g = 2.003 \pm 0.001$, which is that

expected for the radicals we have identified. Our measured $g = 2.0046 \pm 0.0006$ for $(CH_3)_3\dot{N}^+$ is in good agreement with published values (8, 11).

Discussion

(i) Formation of the Radicals

The nature of the adsorbed species when ammonia is adsorbed on silica gel has been studied extensively (for reviews see ref. 12), although less is known for monoamines other than ethylamine (13, 14) and for higher amines. Silica gel degassed at 450 °C retains little or no adsorbed bulk H_2O molecules but does retain large numbers of hydroxyl groups, perhaps ~0.5 monolayer (15). Adsorption of amines strongly perturbs these OH groups, the major reaction probably being [1] (13)

[1] $\equiv SiOH + RNH_2 \rightleftharpoons \equiv SiO^-R\dot{N}H_3^+$

resulting in a very high heat of adsorption (~15–20 kcal mol^{-1}).

Production of radicals originating from adsorbed species after irradiation of silica gel systems has been explained in terms of migrating surface electrons (2), energy tranfer (1) or reaction of the adsorbate with hydrogen atoms released from surface hydroxyl groups (16). Although the free amine molecules are expected to be unreactive towards migrating surface electrons, the conjugate acid produced in [1] may have higher reactivity. However, the ammonium ion has low reactivity towards solvated electrons in water (17), and the increased basicity of amines over ammonia is probably insufficient to affect the reactivity markedly. Hydrogen atoms are expected to be unreactive towards amines adsorbed on silica gel, since protonation of the amino group greatly deactivates protons on the α carbon towards abstraction reactions (5). (Amines are not protonated on adsorption on magnesium oxide, but we have been unable to observe radicals produced by bombardment with H atoms of MgO doped with methylamine, using the technique described by Smith and Tench (18). Large yields of radicals were observed by H abstraction from CH_3OH on MgO under the same conditions.[4])

It appears then that the more likely routes for production of radicals by irradiation of amines on silica gel are either by reaction with a migrating surface positive center (surface hole) or by ionization of the amine by direct energy transfer. Doping MgO powder with an adsorbed amine prevents the formation of surface holes (V_s^+ centers) upon γ-irradiation, but no $R\dot{N}H$ or $R\dot{N}H_2^+$ radicals are observed (3, 4). The most appropriate model for the formation of $R\dot{N}H$ or $R\dot{N}H_2^+$ radicals on silica gel may be represented by reactions 2 to 5

[2] $S \dashrightarrow S^*$

[3] $S^* + \equiv SiO^-R\dot{N}H_3^+ \rightarrow S + \equiv SiOR\dot{N}H_3^+ + e^-$

[4] $\equiv SiOR\dot{N}H_3^+ \rightarrow [\equiv SiOH\text{---}R\dot{N}H_2^+]$

[5] $[\equiv SiOH\text{---}R\dot{N}H_2^+] \rightleftharpoons [\equiv SiOH_2^+\text{---}R\dot{N}H]$

Following Kinell *et al.* (1) we denote S as a surface active site formed by migration of energy from the bulk solid to the surface.

Of course, reaction 5 is simply the acid–base dissociation of $R\dot{N}H$ radicals on the surface. The effective pK of this equilibrium will be greatly affected by the stability of the $R\dot{N}H_2^+$ parent ion. Such an ion may form $R\dot{N}H$ either by equilibrium 5 being to the right or by ion–molecule (proton transfer) reactions, [6],

[6] $R\dot{N}H_2^+ + RNH_2 \rightarrow R\dot{N}H_3^+ + R\dot{N}H$

with adjacent amine molecules. Nearest neighbors are ~10 Å away. In the case of trimethylamine (and probably *tert*-butylamine) the radical cation was stabilized on the surface of silica gel. The gas phase ion–molecule reaction analogous to reaction 6 is only slightly slower for trimethylamine than for the mono- and di-methylamines (19). A reasonable explanation of these differences is that the positive charge is more effectively delocalized (by hyperconjugation) in trimethylamine and *tert*-butylamine. The radical cations of these two amines are more stable and hence equilibrium 5 is further to the left than for the other amines studied.

(ii) The e.s.r. Parameters of the Radicals

The β proton splittings observed for $R\dot{N}H$ radicals on the surface of silica gel were ~ 35 G for $CH_3\dot{N}H$, ~ 45 G in $RCH_2\dot{N}H$ (R = CH_3,

[4] D. R. Smith and P. Wardman, unpublished observations.

C_2H_5, n-C_3H_7), ~ 50 G in $(CH_3)_2CH\dot{N}H$, and ~ 30 G in $(CH_3)_2\dot{N}$. The isotropic (solution) spectrum for $(CH_3)_2\dot{N}$ gives a β proton splitting of 27.4 G (20), an increase of 11% over that in the isoelectronic $(CH_3)_2\dot{C}H$ radical (10). We have seen in the preceding paper that β proton couplings in $R\dot{N}H$ radicals are some 10–20% higher than for the corresponding alkyl radicals. The β proton splittings for $R\dot{N}H$ on silica gel are further increased by ~ 10–20% over those in the solid, giving rather high values for proton couplings. The β proton splittings in $R_2\dot{N}$ radicals in solution are markedly affected by conformational factors (20) and we must assume a similar explanation.

It is interesting that Bobrovskii and Kholmogorov (21) observed 5–10% higher methyl proton couplings for the well-resolved $(CH_3)_2\dot{C}OH$ radical on silica gel than those observed in solution or the solid phase for this radical. The β proton splittings for $RCH_2\dot{N}H$ ($R \neq H$) on silica gel show equivalence of the methylene protons whereas inequivalence was inferred from the spectrum of $C_2H_5\dot{N}H$ in solid ethylamine. Evidently there is somewhat more rotational freedom of the alkyl groups in amines on silica gel than in the solid at 77 °K.

Conclusions

Radiolysis of sub-monolayer amounts of aliphatic amines adsorbed on silica gel produced $R\dot{N}H$ radicals from lower monoamines, $R_2\dot{N}$ radicals from dimethylamine and radical-cations from trimethylamine and probably t-butylamine.

The authors wish to thank Dr. F. P. Sargent for helpful criticism of the manuscript.

The Trifluoroacetic Acid Solvent System. Part I. Bases

M. G. Harriss and J. B. Milne
Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received September 28, 1970

Electrical conductivity has been used to study the ionic behavior of several simple solutes in 100% trifluoroacetic acid. Fuoss extrapolations have been used to evaluate the limiting equivalent conductivities and association constants of the ammonium and alkali metal trifluoroacetates. The dependence of ionic mobility upon cation radius is different from that in water and other solvents and suggests that solvation is much less important in 100% trifluoroacetic acid. On the basis of these results, a proton transfer mechanism of conductance for the trifluoroacetate ion appears unlikely.

On a utilisé la conductivité électrique pour étudier le comportement ionique de solutés simples dans l'acide trifluoroacétique à 100%. On a utilisé les extrapolations de Fuoss pour évaluer les conductivités équivalentes limites et les constantes d'association des trifluoroacétates d'ammonium et de métaux alcalins. On note que la dépendance de la mobilité ionique sur le rayon du cation est différente de celle observée dans l'eau ou les autres solvants et ces résultats suggéreraient que la solvatation est moins importante dans l'acide trifluoroacétique à 100%. En se basant sur ces données, on peut déduire qu'il semble peu probable que la mécanisme de la conductivité de l'ion trifluoroacétate implique un transfert de proton.

Canadian Journal of Chemistry, 49, 1888 (1971)

Trifluoroacetic acid is a moderately strong non-oxidizing acid with good solvent properties (1) and a convenient liquid range. It is an attractive reaction medium (2) and, principally because of its acid properties, it has been used as a solvent for the titration of weak bases (3). Before we can fully understand the chemical reactions which take place in this solvent a basic knowledge of the behavior of simple solutes is necessary. For this reason it was considered of interest to begin a basic study of the solvent. Such a study affords, in addition, an opportunity for comparison with acetic acid, which has been extensively studied (4), and contributes to what has been termed "a fertile field . . . for experimental research" (*5a*), that is electrical conductivity in solvents of low dielectric constant ($\varepsilon < 20$).

Electrical conductivity studies on solutions in pure trifluoroacetic acid were first carried out by Simons and Lorentzen (6). Since that time, the dielectric constant for this solvent has been firmly established as 8.20–8.40 at 25 °C (7–10). Bessière (11) has re-treated the results of Simons and Lorentzen for potassium trifluoroacetate by the Shedlovsky method (*5b*) using a dielectric constant of 7.8. From the dissociation constants of potassium trifluoroacetate and perchloric acid, the latter determined by the indicator method of Kolthoff and Bruckenstein (12), Bessière established a scale of dissociation constants for several acids and bases by a potentiometric method. In the present work electrical conductivity has been used to study the behavior of the ammonium and alkali metal trifluoroacetates and water at concentrations where simple ion-pairing is occurring and the concentration of higher ion-aggregates is negligible.

Experimental Section

Materials

Trifluoroacetic acid for conductivity experiments was prepared by a preliminary fractional distillation of acid, with 5% by weight of anhydride added, through a 40 cm column packed with glass helices followed by a double distillation in a one-piece double distillation apparatus. The best grade acid from Matheson, Coleman and Bell was used. A small quantity of trifluoroacetic acid anhydride was added in the first step and the receiving end of the apparatus was flamed out for both steps while dry nitrogen was passed through the apparatus. The acid was distilled directly into the conductivity cell. In both distillation steps the acid boiling at 71.0–72.0 °C was collected. Acid prepared in this way had a specific conductivity (K_{sp}) of 0.041–0.079 μmho cm^{-1}.

Trifluoroacetic acid anhydride was prepared by refluxing the acid over P_2O_5 and then distilling the product (b.p. 38–39 °C).

The trifluoroacetates were prepared from the parent carbonate or hydroxide and sufficient trifluoroacetic acid for neutralization. The salts were recrystallized from water except for the lithium salt which was too soluble in water for recrystallization and could only be obtained by pumping an exactly neutral solution to dryness under vacuum. All of the salts were found to be deliquescent, particularly those of Li and Na.

Procedure

Electrical conductivities were measured with a Beckman RC-18A conductivity bridge. The temperature for all measurements was maintained at 25 ± 0.010 °C by

means of an oil bath. Measurements were made in a glass conductivity cell similar to that described previously (13) with a cell constant of 0.0177 cm^{-1}. To ensure that the acid in the cell remained dry during the course of the additions of the electrolyte solution, a small quantity of anhydride (*ca.* 0.5% by weight) was added to this solution in the weight dropper used for solute additions. The amount necessary was estimated from the concentration of water present in the freshly distilled acid and the amount introduced during each solute addition as determined from the increase in conductivity caused by a dummy addition. All solutions were made up by weight and the solvent density was taken as 1.4775 g/cc (14) for the calculation of molarity. For the concentrations studied, 10^{-4}–10^{-5} m l^{-1}, the density of the solutions will differ little from that of pure acid. Solutions of the solutes were added to the cell, and the cell was shaken and readings taken until steady values were obtained.

The dielectric constant of the solvent was taken as 8.40, the value determined by Harris and O'Konski (9), since these authors took considerable precautions to ensure the purity of their acid. The viscosity used, 0.008565 P at 25 °C, has been interpolated from data given in reference (14). The limiting equivalent conductivity, Λ^0, and association constant, K_a, of electrolytes were determined by the Fuoss method (15) of 1935, using the extended Debye–Hückel expression for the activity coefficient, thereby allowing for ionic volume. The calculation and least mean squares extrapolation were carried out by computer and repeated until a Λ^0 was obtained, self consistent to within 1 part in 10^5. Initially Λ^0 was assumed to be 60 $ohms^{-1}$ cm^2 $equiv.^{-1}$ and the distance of closest approach, "a", was taken as 5×10^{-8} cm. The distance a was then calculated from the association constant by the Fuoss expression (5*c*) and the calculation of Λ^0 and K_a repeated.

Results and Discussion

Solutes, Water, and Trifluoroacetic Acid Anhydride

The results of the conductivity measurements for all solutes are given in Table 2. The results of an experiment in which several additions of anhydride were added to freshly distilled acid and then back titrated with water show that the freshly distilled acid contained some water ($[H_2O] \sim 0.005$ M). The addition of anhydride causes an initial steep decrease in the conductivity followed by a more gradual decrease with further additions. The conductivity curve was retraced upon addition of water. The intersection of the steep section, where excess water is present, and the more gradual section, where excess anhydride is present, fixes the 100% pure trifluoroacetic acid on the concentration scale. The initial steep decrease upon addition of anhydride is due to the presence of water in the freshly distilled acid. The difference in the positions of 100% acid and freshly distilled acid on the concentration scale gives the water concentration in freshly distilled acid.

Comparison of the specific conductivities of water and potassium trifluoroacetate in Table 2 shows that water is a very weak electrolyte. This rather surprising result confirms Simons and Lorentzen's (6) and shows the water molecule is indeed a weak base compared to bulk water since trifluoroacetic acid is a moderately strong acid in water. Water behaves similarly in nitric acid (16). Addition of anhydride to 100% pure trifluoroacetic acid causes the conductivity to decrease slightly. This is to be expected since the introduction of the anhydride molecules, which are less polar than the solvent molecules, would make ionization less favorable and the concentration of the solvent self-dissociation ions would be reduced. Randles *et al.* have also reported on the conductivity of water and anhydride in trifluoroacetic acid (17) but at solute concentrations an order of magnitude greater than ours. The results are essentially in agreement.

Solutes, Ammonium and Alkali Metal Trifluoroacetates

The dielectric constant of trifluoroacetic acid at 25 °C is 8.40 (9) and, consequently, ion association is expected to be important even at low concentrations. Both the Bjerrium and the Fuoss equations (5*c*) predict for an ionophore with a distance of closest approach of 5×10^{-8} cm, an ion-pair association constant of greater than 10^5 m^{-1} l. The limiting equivalent conductivity

*Uncorrected for solvent produced by reaction with anhydride.

and ion-pair association constant of an electrolyte in a solvent of low dielectric constant may be calculated by means of a Fuoss (15) or a Shedlovsky (18) plot. Both methods yield the same Λ^0 and the difference in the association constants is less than 0.1% for a solvent of dielectric constant, 8.4 (19). The Fuoss extrapolation was used in this work with modification to allow for ionic volume in the activity function. The equations used were

$$\Lambda = \gamma(\Lambda^0 - (B_1\Lambda^0 + B_2)\sqrt{c\gamma})$$

$$\frac{1}{K_a} = \frac{cf^2\gamma^2}{1-\gamma}$$

$$\log f = -\frac{A\sqrt{c\gamma}}{1 + Ba\sqrt{c\gamma}}$$

The constants used here are defined as in ref. 20 and γ is the degree of dissociation.

According to Fuoss (5*d*), triple ion formation should become noticeable in electrical conductivity measurements in this solvent at 1.9×10^{-4} $m\,l^{-1}$. This should represent an upper limit for the treatment of data, assuming only a simple ion-pair equilibrium. A lower limit of applicability of the extrapolation would arise where the solvent contains an ion common to the solute. Such an ion may arise from solvent self-dissociation or from some extraneous electrolyte. If the equilibrium giving rise to such an ion were not completely repressed by the solute, the conductivity observed will not be due to solute ions alone and deviations from the Fuoss slope will be observed. Both the upper and lower limits of the extrapolation are expected to appear as negative deviations from the slope since the apparent Λ used in constructing the plot will be too large. Figure 1 shows an extrapolation for potassium trifluoroacetate. An abscissa value of 100 in the figure shows the upper limit for simple ion-pair behavior. However, from the plot it may be seen that the points lie on the straight line up to concentrations three times that of this limit. The inclusion of even higher concentration points in the extrapolation will result in a low Λ^0 and a small association constant. The lowest concentration point is seen to be below the line, indicating an additional contribution to the conductivity as discussed above.[1]

[1]The lowest pure solvent conductivity observed in this work was 0.041 μmho cm^{-1}. In subsequent studies of other electrolytes (Parts II and III, to be published), the first fractions of acid distillate were used to rinse the conductivity cell and then discarded. The pure acid collected after this procedure was carried out had conductivity one tenth of that reported here, which suggests that the residual conductivity was due to electrolyte leached from the apparatus by this strongly acid solvent. If such an electrolyte were solvolyzed to give trifluoroacetate ion in solution, this would be more likely to cause the low concentration deviation in the Fuoss plot than ions arising from solvent self-dissociation.

*Simons and Lorentzen's measurements (1).
†Distance of closest approach according to the Fuoss equation (ref. 5, p. 213).

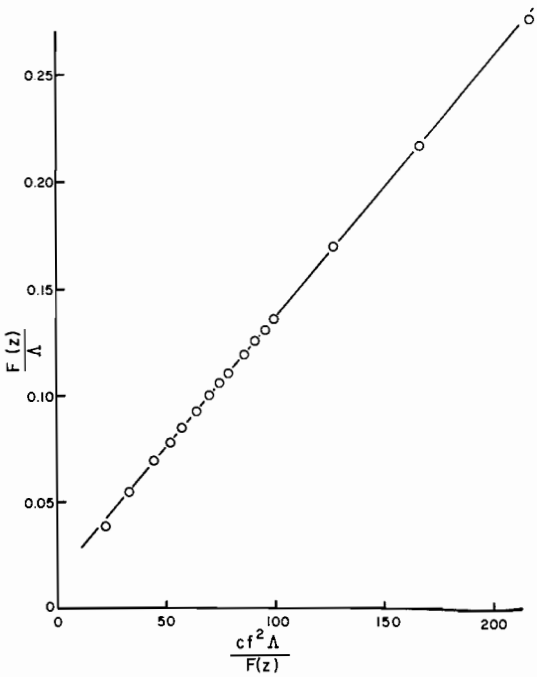

FIG. 1. Fuoss extrapolation of the potassium trifluoroacetate conductivities.

The results of extrapolation of measurements on ammonium and alkali metal trifluoroacetates, strong 1:1 bases in trifluoroacetic acid, are collected in Table 3. These values are arrived at by considering only those measurements below the triple-ion region (1.9×10^{-4} ml^{-1}) and eliminating the lowest concentration measurement (the lowest two in the case of potassium trifluoroacetate), which all lay below the extrapolation line and resulted in a greater Λ^0 and standard error on Λ^0. Included in Table 3 are the % standard error on Λ^0 and the "a" value, calculated from the theoretical Fuoss equation for the association constant. The results of the extrapolation of Simons and Lorentzen's data are given for comparison.

Considering the scatter of Simons and Lorentzen's measurements, reflected in the % standard error, the agreement between results obtained in this work and theirs is excellent. The results from two cesium trifluoroacetate runs are also in good agreement, showing the reproducibility of the experiments.

Bessière has used a Shedlovsky plot to evaluate Simons and Lorentzen's results (11). The association constant for potassium trifluoroacetate is 5×10^4 ml^{-1}, which is nearly an order of magnitude lower than the value reported here. Single hand extrapolations of Simons and Lorentzen's results below the triple-ion formation limit by both the Fuoss and Shedlovsky methods, assuming an initial Λ^0 of 60.0 ohm^{-1} cm^2 equiv.$^{-1}$, give Λ^0 and K_a values within 2% of each other. This order of discrepancy is within the variation which results from the subjective choice of the slope and thus Bessière's low K_a may well be due to the inclusion of some high concentration points above the simple ion-pairing concentration limit. For sodium trifluoroacetate the association constant reported here is 80× that reported by Bessière based on potentiometric measurements. Many of Bessière's measurements were carried out at concentrations where triple ion equilibria predominate and this may account for the discrepancy.

Lithium trifluoroacetate is an electrolyte in trifluoroacetic acid but extrapolation of the results gives a negative intercept. Examination of the association constants in Table 3 with changing alkali metal cation size shows that the association

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

constant for the lithium salt is expected to be very large. The competition between the solvent molecules (solvation) and the anion (ion association) for the cation presumably favors the latter due to low solvation energies. The trifluoroacetate ion concentration coming from the lithium salt appears to be too low to completely repress the equilibria contributing to the initial solvent conductivity and a steep slope, resulting in a negative intercept, arises as discussed above. Triple ions are formed before the solvent self-dissociation is repressed and the Fuoss plots for values of Λ^0, chosen between 50 and 200 ohms^{-1} cm^2 equiv.$^{-1}$, yield smooth curves with no flat portion as for the potassium salt in Fig. 1.

Trifluoroacetic acid is a non-electrolyte in sulfuric acid (21). It is a very weak base and, for this reason, cation solvation is expected to be weak. For solutions of alkali metal halides in solvents where solvation is important, ion association decreases with decreasing cation size since the anion is more readily displaced by solvent molecules (22). It has been argued that the opposite trend is present in solvents such as acetonitrile and nitromethane (24). While the trend is substantiated for quaternary ammonium compounds, Minc and Werblan's work on alkali metal perchlorates in acetonitrile (24, 25) suggests that solvation is important for small cations in this system also. Trifluoroacetic acid is, however, exceptional with a more than 20 fold decrease in K_a from the sodium to cesium trifluoroacetate. However, ammonium trifluoroacetate is less associated than the rubidium salt while, according to its crystal radius, it should lie between potassium and rubidium. There appears, in this case, to be some special stabilization of the ammonium ion in solution, perhaps by hydrogen bonding. The % standard error on Λ^0 for ammonium trifluoroacetate is larger than that for the other salts studied and the conductivity of solutions of this salt was observed to decrease very slowly. We have subsequently shown that bis(trifluoroacetyl)amide may be prepared by refluxing the anhydride with ammonium trifluoroacetate and this reaction occurring at 25 °C will affect the conductivity results for this electrolyte also, although the relative order of Λ^0 and K_a for this base among the others will not be affected.

The limiting equivalent conductivities of the electrolytes studied increase with decreasing cation size with the exception of the ammonium salt, where the ammonium cation in solution is apparently larger than that of rubidium. This suggests a greater degree of solvation as was indicated by the K_a for the ammonium salt. The general trend of change in Λ^0 with changing cation size is different from that generally observed (23, 26, 27). In water, alkali metal cations or any series of alkali metal salts with a common anion exhibit a maximum mobility at rubidium and Λ^0 decreases with decreasing cation radius from rubidium to lithium. The decrease in Λ^0 is attributed to increasing solvation and consequent greater effective size of the diffusing ion. The diffusion of the alkali metal cations in trifluoroacetic acid apparently depends upon ion size and solvation is not of primary importance as was indicated by the variation in K_a discussed above. The large spread of Λ^0 values for the 1:1 trifluoroacetates in the solvent indicates that the cation is making a large contribution to the conductivity and suggests that the anion conducts by diffusion, unlike the corresponding self-dissociation anions in water (20), sulfuric (20), and fluorosulfuric acids (28).

From the individual ionic mobilities listed in ref. 20 and Λ^0 for trifluoroacetic acid in water (14), Λ^0 for the alkali metal trifluoroacetates in water can be calculated. (Λ^0 for potassium trifluoroacetate is 115.5 ohms^{-1} cm^2 equiv.$^{-1}$.) By comparison the values in trifluoroacetic acid are low. These low ionic mobilities in trifluoroacetic acid cannot be accounted for by cation solvation, which appears to be weak in this solvent, and tunnelling of the ions between the much larger solvent molecules and consequent failure of Stoke's Law would lead to higher mobilities. Fuoss has shown that for large ions in some solvents ionic mobility may be retarded by a solvent dipole "relaxation effect" (29). This concept has been given a quantitative basis by Boyd (30) and Zwanzig (31). Application of Zwanzig's expression to the trifluoroacetic acid solvent system gives impossibly small mobilities for the trifluoroacetates. These low mobilities arise from an inordinately large contribution to the ion size from the "relaxation effect" compared to the ionic crystal radius. Moreover, the solvent dipole "relaxation effect" cannot have a predominant influence, since the mobilities are larger for the smaller cation; exactly the opposite trend to that predicted by the theory. Apparently no single concept may be used to account for the mobilities

in trifluoroacetic acid and detailed consideration of these effects at this time would be premature.

Unfortunately a comparison with the mobilities of the alkali metal acetates in acetic acid (32–36) is not possible for several reasons. Hopfgartner (32), Jones and Griswold (33), and Martin (34) worked at temperatures other than 25 °C and, apart from the work reported in refs. 33 and 34 the concentrations studied exceed the limit of simple ion-pair formation in this solvent (0.771×10^{-4} $m\,l^{-1}$). Jones and Griswold subtracted the pure solvent conductivity from their measurements for the acetates studied and evaluated Λ^0 and K_a from a Fuoss extrapolation. This correction for solvent self-dissociation ions is not justified, since the autoprotolysis equilibrium is undoubtedly repressed at the lowest solute concentrations studied and the observed conductivity arises from solute ions alone. Fuoss extrapolation of Jones and Griswold's data with pure solvent conductivity included leads to a negative intercept and the study of the conductivity of $NaOOCCH_3$ and $KOOCCH_3$ at 25 °C would bear further study for this reason.

Sur quelques réactions acide–base dans les solvants fortement basiques anhydres. III. *n*-Butylamine

W. R. HEUMANN ET L. ŠAFAŘÍK[1]

Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 7 decembre 1970

Le césium est le seul métal alcalin à réagir avec la *n*-butylamine, même à chaud. Les *n*-butylamidures de Na et de K ont été préparés par chauffage de l'amine avec les hydrures des deux métaux. Ces amidures forment des poudres cristallines blanches grisâtres, stables sous une atmosphère d'azote pur. La neutralisation par ces amidures, d'une série d'acides monobasiques de différentes forces dans la *n*-butylamine a été étudiée par potentiométrie au moyen d'une électrode indicatrice de platine. Les sauts de potentiel variaient entre 1550 mV pour l'acide chlorhydrique et environ 110 mV pour le diphénylméthane. Ce dernier composé était le moins acide ($pK^{H_2O} = 35$) à réagir avec les bases, tandis que le toluène ($pK^{H_2O} = 37$) ne réagit pas. Le pK^{H_2O} de la *n*-butylamine se situe probablement autour de 37 et 38. Plusieurs acides dibasiques et des mélanges d'acides ont également été neutralisés. Le pouvoir de différenciation du système *n*-butylamine/butylamidure est assez bon, mais la précipitation des sels formés rendait souvent difficiles les mesures potentiométriques. La neutralisation du triphénylméthane donne des solutions fortement colorées en orange rougeâtre. Ceci permettrait d'utiliser ce produit comme indicateur dans des titrages visuels d'acides faibles avec les *n*-butylamidures.

Cesium is the only alkali metal to react with *n*-butylamine, even at higher temperature. The *n*-butylamides of Na and K were prepared by heating the amine with the respective alkali hydrides. The amides were obtained as crystalline greyish white powders, which are stable when kept under pure nitrogen. The neutralization of a series of monobasic acids of various strength in *n*-butylamine by these amides was studied potentiometrically using a platinum indicating electrode. Potential jumps ranging from 1550 mV for hydrochloric acid to about 110 mV for diphenylmethane were obtained. The latter compound was the least acidic ($pK^{H_2O} = 35$) to react with the bases, while toluene ($pK^{H_2O} = 37$) did not react. The pK^{H_2O} value of *n*-butylamine should therefore be about 37 to 38. Several dibasic acids and mixtures of two acids were also neutralized. The power of differentiation of the *n*-butylamine/butylamide system is quite pronounced, but in many cases potentiometric measurements were difficult due to precipitation of the salts formed. The neutralization of triphenylmethane produces an intense reddish orange color, which could be used as an indicator in visual titrations of weak acids with the *n*-butylamides.

Canadian Journal of Chemistry, 49, 1895 (1971)

En 1951, la *n*-butylamine a été introduite dans l'analyse chimique comme solvant fortement basique pour les titrages d'acides très faibles en milieu non-aqueux (1). A en juger par les travaux qui ont été publiés depuis, cette amine semble avoir été acceptée comme une alternative pour l'éthylènediamine dans le domaine des titrages acide–base, bien que les propriétés fondamentales de ce système de solvant soient peu connues. La présente étude a été entreprise dans le but d'étudier quelques aspects fondamentaux du système *n*-butylamine/butylamidure en vue d'une évaluation objective des possibilités d'applications pratiques. Dans ce but, les *n*-butylamidures de sodium C_4H_9NHNa et de potassium ont été préparés. Leurs réactions dans la *n*-butylamine avec une serie d'acides ont été étudiées potentiométriquement, pour établir la gamme des acidités possibles dans ce solvant.

La préparation des n-butylamidures alcalins

Les métaux alcalins

Les alcalins réagissent difficilement avec la *n*-butylamine. Même à la température d'ébullition de l'amine, 78 °C, seul le césium réagit, bien que cette réaction est lente. Il s'est, en effet avéré nécessaire de chauffer ce métal dans l'amine pendant 5 h à ébullition pour qu'un gramme se dissolve dans 100 ml d'amine, en engendrant ainsi une solution d'amidure environ 0.07 *M*. Contrairement à l'ammoniac anhydre liquide, à l'éthylènediamine et à d'autres amines aliphatiques, la réaction du césium avec la *n*-butylamine ne conduit pas à la formation d'une solution bleue foncé d'électrons solvatés, comme stage intermédiaire de la formation de l'amidure. L'alliage

liquide de 78% de potassium et 22% de sodium, qui, en général, est plus réactif que l'un ou l'autre des deux métaux seul, se montre également indifférent envers la *n*-butylamine.

L'amidure ammoniacal de sodium

$NaNH_2$ ne réagit pas avec la *n*-butylamine à la température ambiante. Des essais visant à aider la réaction par un abaissement de la pression pour enlever l'ammoniac formé par la réaction ont échoué en raison de la trop grande volatilité de la *n*-butylamine. Un procédé breveté pour la préparation de *n*-butylamidure de sodium à partir de l'amidure ammoniacal de sodium est la seule mention faite dans la littérature d'un *n*-butylamidure (2). D'après ce procédé, le butylamidure est obtenu en faisant bouillir pendant 63 h une solution de *n*-butylamine dans du toluène, contenant de l'amidure ammoniacal de sodium. L'amidure formé est recueilli par cristallisation du résidu après distillation de l'excès d'amine. Selon nos expériences, cette réaction est accompagnée de la formation d'un produit orange rougeâtre, soluble avec coloration rouge intense dans le pentane, le toluène ou l'éther. Au contact de l'humidité atmosphérique, ces solutions se décolorent et dégagent un précipité blanc de NaOH. Ces observations semblent indiquer que la coloration est due au benzylsodium $C_6H_5CH_2$-Na, produit de la réaction entre l'amidure ammoniacal et le toluène. Etant donné que dans ce procédé le rôle du toluène se limite apparemment à augmenter la température du mélange au-dessus du point d'ébullition de l'amine pure, 78 °C, il a été essayé de remplacer le toluène par le *n*-octane (p.éb. 114 °C). Cependant, le *n*-butylamidure de sodium n'est pas soluble dans les hydrocarbures aliphatiques et précipite lors de sa formation. De ce fait le produit est contaminé par de l'hydroxyde de sodium qui se forme à partir des traces d'eau toujours présentes et, éventuellement, aussi par de l'amidure ammoniacal n'ayant pas réagi.

Les hydrures alcalins

Les hydrures alcalins sous leurs formes commerciales, c'est-à-dire LiH comme poudre cristalline, NaH et KH comme dispersions à 50% dans de l'huile minérale, ne réagissent pas avec la *n*-butylamine à la température ambiante. Ils réagissent, cependant, à des températures plus élevées pour former leurs *n*-butylamidures. L'hydrure de lithium réagit le moins facilement. Une quantité de l'hydrure, suffisante pour former une solution 1.2 *M* de C_4H_9NHLi dans la *n*-butylamine, avait réagi si peu après 8 h d'ébullition de l'amine sous reflux (environ 78 °C), que la concentration de la solution d'amidure formée n'était que de 0.04 *M*. Par ailleurs, dans les mêmes conditions, la réaction de l'hydrure de sodium est considérablement plus vive; elle atteint son maximum de vitesse, qui se manifeste par un dégagement d'hydrogène, sitôt que le milieu atteint la température de l'ébullition et la réaction est complète après 4 h. L'amidure formé reste en solution. L'hydrure de potassium réagit encore plus facilement; sa réaction commence dès que la température dépasse 30 °C et elle est complète en moins de 2 h. C'est à partir des hydrures que les *n*-butylamidures de sodium et de potassium ont été préparés et isolés.

Partie expérimentale

Azote

L'azote pur, utilisé pour purger les récipients les appareils et la boîte à gants, passe par des colonnes contenant des tamis moléculaires "Linde Molecular Sieves 4A" ou "5A" pour éliminer l'eau et le CO_2, ainsi que par un tube de verre "Vycor" contenant du cuivre maintenu à 600 ± 20 °C pour éliminer les traces d'oxygène.

n-Butylamine anhydre

Le produit commercial contenant moins de 2% d'eau est d'abord traité avec de l'oxyde de barium poreux (Barium & Chemicals Inc., Willoughby, Ohio) à raison d'environ 200 g de BaO par litre d'amine. Le mélange est remué de temps à autre pendant 5 à 6 jours ou secoué continuellement durant 25 à 30 h, ce qui réduit la teneur en eau à moins de 500 p.p.m. Le liquide est transféré par décantation moyennant une pression d'azote en système clos dans un appareil à distillation. Celui-ci est muni d'un réfrigérant de reflux et d'un réfrigérant de distillation. Le récipient du distillat a deux tubulures, dont l'une est connectée au réfrigérant et l'autre à un petit barboteur contenant soit une huile de silicone pas trop visqueuse soit un hydrocarbure peu volatil tel que le *n*-dodécane. Cette barrière contre les contaminants atmosphériques est suivie d'un tube d'absorption contenant des "Linde Molecular Sieves 5A". Les deux connections du récipient comprennent des robinets, pour qu'il puisse être déconnecté sans danger de contamination. On ajoute à la *n*-butylamine de l'hydrure de sodium sous forme d'émulsion dans de l'huile à 50% à raison d'environ 1 g de NaH par litre. Le mélange est chauffé à l'ébullition (environ 78 °C) sous reflux pendant 1 à 2 h, avant de distiller sous pression ambiante. Si du *n*-butylamidure de sodium est disponible, 40 à 50 milli-équivalents (4 à 5 g), sous forme d'une solution dans la *n*-butylamine, peuvent être ajoutés par litre d'amine au lieu de NaH. Dans ce cas, le réfrigérant de reflux n'est pas nécessaire et la distillation peut être effectuée tout de suite. La *n*-butylamine préparée

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ainsi ne contient pas plus que 10 p.p.m. d'eau, qui peut être titrée avec une solution étalonnée de *n*-butylamidure de sodium dans la *n*-butylamine suivant la technique décrite plus loin.

n-Butylamidures de sodium et de potassium

Un ballon à 3 tubulures est utilisé. Une tubulure est munie d'un robinet pour l'entrée de l'azote; une autre porte un tube, muni d'un robinet, qui descend jusqu'au fond du ballon, où il se termine par un petit filtre de verre fritté de porosité moyenne ou grossière. La troisième tubulure est surmontée d'un réfrigérant de reflux, dont la sortie est connectée avec un petit barboteur contenant du dodécane ou de l'huile de silicone. Le barboteur communique avec l'extérieur par un tube d'absorption chargé de "Linde Molecular Sieves 5A". Après avoir purgé l'appareil avec de l'azote pur, on charge le ballon à environ deux tiers de *n*-butylamine, qui a été séchée préalablement avec de l'oxyde de Ba et qui contient moins qu'environ 500 p.p.m. d'eau. La quantité voulue de dispersion huileuse de NaH à 50% est ajoutée, en tenant compte de la quantité nécessaire pour réagir avec l'eau. Des solutions allant jusqu'à 2 *M* peuvent être préparées ainsi. On chauffe le mélange à l'ébullition (environ 78 °C) en agitant avec une barre magnétique enrobée de polyéthylène ou de verre. La réaction, qui si manifeste par un courant d'hydrogène dans le barboteur, cesse après environ 4 h. On laisse alors refroidir, en faisant passer en même temps un courant d'azote.

Si la solution de l'amidure est utilisée comme telle, le ballon est transféré dans la boîte à gants et laissé au repos pendant la nuit. La solution est ensuite transférée à l'aide de pression d'azote par le tube muni du filtre de verre poreux, dans une bouteille ou, encore, dans le réservoir d'une burette automatique. Ces solutions peuvent être étalonnées potentiométriquement par le *p*-méthoxyphénol suivant la technique décrite par la suite.

Si la solution est destinée à la préparation de l'amidure solide, elle est transvasée, moyennant une pression d'azote en système clos, par le tube muni du filtre de verre dans un appareil de distillation sous vide. Le ballon de cet appareil, qui a été purgé préalablement avec de l'azote, a deux tubulures, dont une comporte un robinet pour l'entrée de la solution. L'autre tubulure doit être aussi large que possible pour faciliter le transfert sur le filtre de l'amidure solide qui cristallise après l'évaporation du solvant. Elle est connectée au réfrigérant par l'intermédiaire d'un robinet à grand diamètre intérieur. Le récipient du distillat est refroidi avec de la glace ou de la neige carbonique. On applique graduellement le vide, sans chauffage, en agitant avec une barre magnétique. On distille jusqu'à ce que le vide ait baissé à environ 20 mm et la cristallisation ait commencé. Le ballon est ensuite déconnecté et transféré dans la boîte à gants. Le lendemain le contenu est filtré par aspiration sur un filtre de verre de porosité moyenne. Le résidu est lavé avec de l'octane et séché dans un courant d'azote. Une poudre cristalline blanche grisâtre, devant être gardée sous azote pur, est ainsi recueillie.

Le *n-butylamidure de potassium* et ses solutions sont préparés de la même façon, mais la réaction avec l'hydrure de potassium est déjà terminée après 1½ à 2 h.

Les *solubilités des butylamidures* dans la *n*-butylamine furent déterminées comme suit: Le mélange de 5 ml d'amine et d'un excès d'amidure solide fut agité dans un pèse-tare fermé, pendant 5 à 6 h, puis laissé au repos jusqu'au lendemain. Un ml de la solution claire fut dilué à 30 ml avec de la *n*-butylamine et titré potentiométriquement avec une solution étalon 0.3 à 0.4 *M* de *p*-méthoxyphénol.

Acides

La préparation de la plupart des acides purs utilisés dans le présent travail a été décrite dans deux études antérieures (3, 4). L'acide chlorhydrique fut utilisé sous forme du chlorhydrate de *n*-butylammonium; le produit commercial fut purifié par précipitation à partir d'une solution alcoolique, par addition d'éther (5). L'acide carbonique a été utilisé sous forme de carbonate de *n*-butylammonium, obtenu par évaporation spontanée de l'amine pure dans une atmosphère enrichie de CO_2. De la masse cristalline qui en est résultée, les cristaux blancs du carbonate furent isolés par filtration avec aspiration, puis séchés dans une atmosphère d'azote. Ce produit se décompose et se volatilise assez facilement tant par l'action de la chaleur que par l'effet d'une réduction de pression.

Appareillage

L'appareil utilisé pour effectuer et suivre potentiométriquement les réactions de neutralisation, était le *titreur clos* aux électrodes de platine décrit dans un autre mémoire (6). Ce dernier donne aussi la description de la *boîte à gants*, dans laquelle le titreur était placé, et où toutes les autres opérations ont été effectuées à l'exception de celles qui nécessitaient l'application de chaleur. Le contrôle analytique de l'atmosphère de la boîte fut décrit dans le mémoire précédent (4).

Tous les joints rodés étaient secs et garnis de manchons de Teflon. Tous le robinets étaient également en Teflon. Puisque ni les manchons ni les robinets en Teflon sont parfaitement étanches, ils étaient scellés de l'extérieur par de la graisse "Silicone". Les butylamidures attaquent légèrement le Teflon. Dès lors, les robinets qui étaient en contact fréquent, voire même continu avec les solutions des amidures, devaient être remplacés de temps en temps.

Mode opératoire

De même que lors des deux études antérieures sur le système éthylènediamine/amino-2 éthylamidure (3, 4), le comportement des différents acides a été étudié en neutralisant toujours 25 ou 30 ml de solution d'acide 0.065 à 0.066 *N* par une solution étalonnée 0.195 à 0.200 *N* de l'amidure, de sorte qu'aux points d'équivalence les solutions étaient toujours 0.05 *N*.

Résultats et discussion

Les n-butylamidures

Les *n*-butylamidures de sodium et de potassium ont été obtenus sous forme de poudres cristallines blanches grisâtres, stables dans une atmosphère inerte, qui réagissent violemment avec l'eau. Ils ont été identifiés par la détermination de leurs poids moléculaires en titrant conductimétriquement par l'acide chlorhydrique des solutions aqueuses obtenues par décomposition des ami-

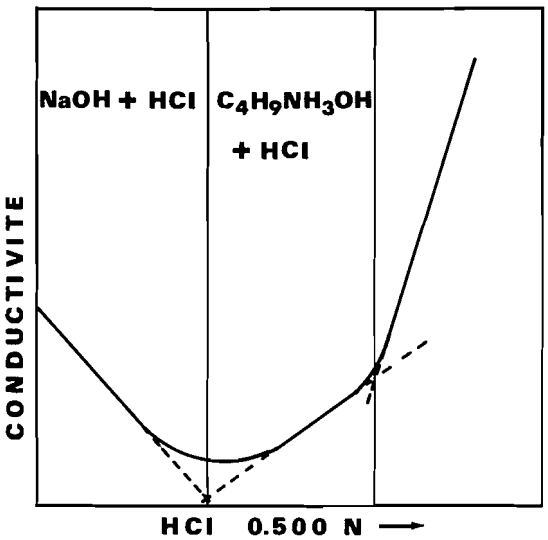

FIG. 1. Titrage conductimétrique du *n*-butylamidure de sodium. Environ 190 mg (2 méquiv) d'amidure dans 100 ml d'eau.

dures avec de l'eau. Une courbe de titrage obtenue à partir de l'amidure de sodium est reproduite dans la Fig. 1. Elle permet la distinction nette entre les hydroxydes de sodium et de *n*-butylammonium. Le poids moléculaire trouvé ainsi dans deux titrages fut 97 au lieu de 95.1. Dans le cas de l'amidure de potassium, la valeur trouvée fut 112 au lieu de 111.2. Comme les poids moléculaires des hydrures NaH et KH, respectivement 24.0 et 40.1, sont beaucoup plus petits que ceux des butylamidures correspondants, la présence, dans ces produits, d'hydrures qui n'auraient pas réagi lors de la préparation des amidures, pouvait être exclue avec certitude.

Les *solutions* de ces deux amidures *dans la n-butylamine* ont une coloration jaune pâle à faible concentration, tandis que les solutions concentrées sont colorées en brun foncé. Contrairement aux amino-2 éthylamidures (4) ni les *n*-butylamidures solides, ni leurs solutions, sont affectées de façon perceptible par des traces d'oxygène moléculaire; ils ne changent pas de couleur; la formation de produits de polymérisation foncés, goudronneux, même après des semaines, n'a pas été observée.

Les *solubilités* des deux *n*-butylamidures *dans la n-butylamine* sont de 4.5 à 5 mol/l de solution pour l'amidure de sodium et 1.5 à 1.6 mol/l pour celui de potassium. La solution saturée de l'amidure de sodium étant assez visqueuse, son analyse exacte est assez difficile.

Réactions acide–base

La Fig. 2 représente les courbes potentiométriques de la neutralisation de plusieurs acides monobasiques par le *n*-butylamidure de sodium. Ces courbes représentent les moyennes de 2 ou 3 expériences. Cependant, la reproductibilité des mesures, ainsi que la régularité des changements des f.e.m. laissaient parfois à désirer, surtout dans la partie des courbes comprise entre le début et l'inflexion autour du point d'équivalence. La raison principale, sinon la seule, était sans doute que, dans la plupart des cas, le sel de sodium formé précipitait de la solution. Avec l'acide chlorhydrique et avec l'eau, les précipités se formaient dès le début de la réaction. Dans le cas de l'eau, ceci s'avérait particulièrement gênant, en raison de la formation d'agglomérations gélatineuses, qui tendaient à boucher la pointe de la burette. La courbe de l'acide benzoïque n'a

pas pu être établie, parce que le précipité volumineux rendait les mesures des f.e.m. trop irrégulières et instables. Le *p*-méthoxyphénol, le triphénylméthane et le diphénylméthane ne formaient pas de précipité. Ces deux hydrocarbures donnent des solutions fortement colorées, ce qui est vraisemblablement dû à la liaison carbone–sodium. La coloration des solutions de triphénylméthane sodique change avec la concentration croissante de jaune–orange jusqu'au rouge foncé brunâtre. Les solutions du diphénylméthane sodique sont colorées en orange foncé. Le diphénylméthane, dont le $pK_a^{H_2O}$ est d'environ 35 (7), était l'acide le plus faible de ceux qui ont réagi avec l'amidure. Le toluène ($pK^{H_2O} = 37$) ne réagit pas, ses solutions dans la *n*-butylamine se comportant comme le solvant seul. Par un raisonnement analogue à celui exposé au sujet de l'acidité de l'éthylènediamine (3), il semble raisonnable de conclure que la valeur du $pK_a^{H_2O}$ de la *n*-butylamine se situe vers 37–38.

La neutralisation de quelques *acides dibasiques* et de *mélanges de deux acides* a également été étudiée. Les trois acides hydroxybenzoïques se comportent comme des acides monobasiques, ils donnent, en effet, une seule inflexion potentiométrique, qui correspond à la somme des deux fonctions acides. Les courbes ressemblent à celles obtenues avec des phénols. Même les deux fonctions de l'acide *o*-hydroxybenzoïque (salicylique) ne se différencient pas malgré la différence numérique considérable entre les deux constantes d'acidité ($pK_2 - pK_1 = 13.4 - 3.0 = 10.4$). Il est à noter, que la même observation a été faite pour les solutions de ces mêmes acides dans l'éthylènediamine (3). D'un autre côté, l'acide carbonique, malgré la différence assez petite entre les deux acidités ($pK_2 - pK_1 = 3.9$) et nonobstant la formation d'un léger précipité pendant la réaction, donne une courbe nette avec deux inflexions, qui est présentée dans la Fig. 3. Quant aux mélanges d'acides, les acides suivants se différencient facilement dans leurs mélanges respectifs avec l'eau : acide chlorhydrique (malgré la formation de précipités), *p*-méthoxyphénol, aminoéthanol, triphénylméthane. Les mélanges de l'eau avec le phénol et l'acide carbonique ne permettent pas d'obtenir des courbes suffisamment nettes à cause de la formation de précipités. Le mélange eau–éthanol ne se différencie pas, d'une part probablement à cause de la petite différence entre leurs forces acides respectives et, d'autre part, parce que ces deux composés polaires peuvent facilement subir une interaction dans un milieu si peu polaire que la *n*-butylamine. Plusieurs exemples de différenciation sont illustrés dans la Fig. 3.

Les neutralisations avec le *n*-butylamidure de potassium donnent des courbes semblables à celles obtenues avec l'amidure sodique. Les forces électromotrices mesurées aux points de demi-neutralisation, ainsi que les sauts de potentiel autour des points d'équivalence, sont à peu près les mêmes avec les deux amidures. Les petites différences ne sont pas assez régulières ou significatives pour permettre une conclusion quant à une différence entre les forces basiques des deux amidures.

La différenciation entre le triphénylméthane et des acides plus forts tels que l'eau ou le *p*-méthoxyphénol, ainsi que l'apparition de la coloration jaune–orange foncé du triphénylméthane sodique, sont très nettes. Ceci devrait permettre l'utilisation du triphénylméthane comme indicateur dans des titrages visuels avec

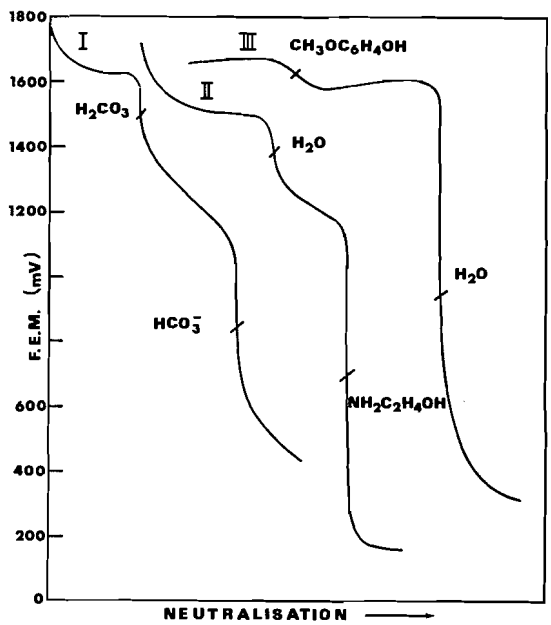

FIG. 3. Courbes de neutralisation de solutions à deux fonctions acides. Courbe *I*, acide carbonique; *II*, mélange d'eau et d'aminoéthanol; *III*, mélange de *p*-méthoxyphénol et d'eau. Les courbes *II* et *III* sont déplacées horizontalement afin de mieux les observer.

les *n*-butylamidures. En effet, des solutions d'eau dans la *n*-butylamine ont été titrées et par la méthode potentiométrique dans le titreur clos et visuellement avec cet indicateur de la manière conventionnelle dans une fiole conique ouverte, sans différence significative entre les résultats.

Dans une étude ultérieure, les résultats du présent mémoire seront comparés avec ceux obtenus avec d'autres systèmes de solvants fortement basiques.

Nous remercions sincèrement le Conseil National de Recherches du Canada de l'aide financière sous forme d'octrois de recherches (W.R.H.), qui a rendu possible ce travail.

The Crystal Structure of $[Rh(f_6fos)_2]^+[cis\text{-}(CO)_2RhCl_2]^-$

F. W. B. Einstein and C. R. S. M. Hampton
Department of Chemistry, Simon Fraser University, Burnaby 413, British Columbia

Received October 19, 1970

The crystal structure of di(1,2-bis(diphenylphosphino)hexafluorocyclopentene) rhodium(I) *cis*-dicarbonyldichlororhodate(I), $[Rh(f_6fos)_2][cis\text{-}Rh(CO)_2Cl_2]$ has been determined from three-dimensional X-ray scintillation counter data. The structure has been refined by full-matrix least-squares techniques to a conventional R factor of 8.8%. The salt crystallizes in the tetragonal space group $I4_1/a$ with eight formula units in a cell of dimensions $a = 17.722(1)$ Å and $c = 36.773(4)$ Å. Each ion is nearly square planar and has a crystallographic two-fold axis passing through the rhodium atom. The two independent Rh—P distances are 2.282(6) and 2.300(6) Å, and the bite of the chelating ditertiary phosphine, f_6fos, is 3.111(8) Å as measured by the intra-ligand P—P distance.

On a déterminé la structure cristalline du di(1,2-bis(diphenylphosphino)hexafluorocyclopentène) rhodium(I) *cis*-dicarbonyldichlororhodate(I), $[Rh(f_6fos)_2][cis\text{-}Rh(CO)_2Cl_2]$, à partir des données tridimensionelles de diffraction des rayons-X, mesurées par un compteur de scintillation. La structure a été affinée par moindrescarrés (matrice complète) jusqu'à un facteur d'accord $R = 8.8\%$. Ce sel cristallise dans le groupe d'espace $I4_1/a$ avec 8 unités dans la maille de dimensions $a = 17.722(1)$ et $c = 36.773(4)$ Å. Chaque ion est presque plan et l'atome de rhodium se trouve sur un axe cristallographique d'ordre 2. Les deux distances indépendantes Rh—P mesurent 2.282(6) et 2.300(6) Å tandis que la distance entre phosphores des ligands f_6fos est de 3.111(8) Å.

Canadian Journal of Chemistry, 49, 1901 (1971)

Introduction

As a part of a program to investigate the reactions of fluorocarbon-bridged tertiary diphosphines and diarsines with transition metals (1–9), the reactions between these ligands and chlorodicarbonyl rhodium dimer were studied. The intention was to prepare simple monocarbonyl complexes of the type LRh(CO)Cl (L is a chelating ditertiary diphosphine), and to study the ability of the ligands to stabilize these complexes with respect to oxidative addition (1). However, instead of simple monocarbonyl complexes, the type of product obtained from reacting 1,2-bis(diphenylphosphino) ethane with $[Rh(CO)_2Cl]_2$, Cullen *et al.* obtained salts containing cations of the type $[RhL_2]^+$ by reacting *cis*-1,2-bis(diphenylphosphino) ethylene with $[Rh(CO)_2Cl]_2$. We describe the crystal structure of one of these salts.

Experimental

Crystals were kindly provided by Dr. W. R. Cullen and their preparation is described elsewhere (1). The sample received was a mixture of crystals which had two different morphologies. The majority were small needles (of the order of 0.1 mm long) and much smaller fraction were approximately octahedral in shape. A crystal of the second type was used for the crystal structure determination. (The two types gave identical X-ray powder patterns.)

Crystal Data

$[Rh(f_6fos)_2][cis\text{-}Rh(CO)_2Cl_2]$ f.w. = 1421

Tetragonal, space group $I4_1/a$ (identified unambiguously from Laue group $4/m$ and systematic absences). $a = b = 17.722(1)$ Å, $c = 36.773(4)$ Å, $V = 11\,815$ Å^3, $1.60 < D_m < 1.63$ g/cc, $F_{(000)} = 5664$ and μ (Mo-Kα) = 8.2 cm^{-1}.

X-Ray Data Collection

Weissenberg photographs of the layers $h0l$–$h4l$ inclusive using Cr-Kα radiation, together with precession photographs of the zones $hk0$ and $h0l$ using Mo-Kα radiation, showed absences for hkl with $h + k + l$ = odd, for 001 with $l = 4n + 2$ and for $hk0$ with h = odd.

All counter data were collected using a crystal mounted with the "b" axis parallel to Φ. The crystal had the shape of a slightly tetragonally distorted octahedron. Distension was in the c direction of the crystal. In the apical directions a, b, and c the dimensions of the crystal were $0.36 \times 0.36 \times 0.28$ mm. However, one c apex was chipped off, and had that apex been complete it is estimated that the dimension in the c direction would have been 0.42 mm. Cell dimensions were determined by least-squares refinement of 13 accurately measured high-angle reflections at 19 °C ($\lambda K\alpha_1 = 0.70926$ Å). The standard errors were estimated from the internal consistency obtained by the least-squares procedure.

Reflection intensities for the unique set of data were measured using a Picker four-circle diffractometer equipped with our own semi-automation. Zirconium filtered Mo-Kα radiation was used in conjunction with a scintillation detector and pulse height analysis. The take-off angle was 1.3° and a symmetrical θ–2θ scan of 1.6° width was used. Background was measured by stationary counts lasting 12 s on either side of the 1.6°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

scans. Any net intensity which was less than two standard deviations (*i.e.*, 2σ where $\sigma = \sqrt{N}$, and N is the sum of counts obtained for the scan plus both background counts) was treated as unobserved, and denoted as $-F_{obs}$ in Table 1. Of the 2934 intensities recorded in the range $0° < 2\theta < 40°$, 1628 were observed. Three measurements for each of two standard reflections were taken at intervals ranging from 1½ to 5 h, and the scale determined from them ranged over ±5% during the data collection. Because of the large size of the unit cell care had to be exercised in order to recognize cases of scans overlapping more than one reflection.

Lorentz and polarization factors were applied and the structure factors calculated in the usual way. No correction for absorption was made since the small size, regular shape, and low absorption coefficient suggested this would be negligible and nearly isotropic.

Structure Solution

From the unsharpened Patterson function (13)[1] it was possible to assign approximate positions on the two-fold axis to two crystallographically distinct rhodium atoms, and also to one other atom which was assumed to be a chlorine atom. One cycle of least-squares (12)[2] refinement varying the scale, together with coordinates and isotropic thermal parameters for four atoms yielded a conventional R factor of 46.2% (a misplaced chlorine atom was incorrectly included). The remainder of the structure was filled in as prominent features of successive difference maps and good chemical sense dictated.

With all non-hydrogen atoms allowed appropriate coordinates and isotropic thermal parameters, the structure was refined to a conventional R value of 11.5%. It was inferred from prominent features of a difference map at this point that the six fluorine atoms were all vibrating anisotropically, and after two further cycles of least-squares, varying anisotropic parameters for these atoms, the R factor dropped to 9.8% (weighted R, 10.1%). A difference map indicated the possibility that the anion was also vibrating anisotropically. After two cycles of least-squares varying the required anisotropic parameters, the R had dropped to 9.4% (weighted R, 9.7%).

Up to this point all reflections had received unit weights. Unobserved reflections were not included in the least-squares refinement at any stage. After introduction of the weighting scheme described below, and further refinement, the R factor dropped to 9.2% (weighted R, 11.1%). The weighting scheme was set up to approximate the condition $w = 1/\sigma_F^2$ where σ_F is the standard deviation of F_{obs}. The weighting function

$$w = \frac{1}{378 - 3.49|F_o| + 0.011|F_o|^2}$$

was chosen to make $w\Delta^2$ constant as a function of $|F_o|$; $\sin\theta/\lambda$, and the Miller indices (11) ($\Delta = |F_o| - |F_c|$). The standard deviation for an observation of unit weight, at the stage where the conventional R was 9.2% was 0.97.

The R factor dropped to its final value of 8.8% (weighted R, 10.5%) after three changes had been made: (*i*) anomalous dispersion corrections (10)[3] were applied to the rhodium scattering factor curve; (*ii*) the cationic rhodium atom and the carbon (C(6)) at the extreme end of the fluorocarbon moiety of the $f_6$fos ligand were allowed anisotropic thermal parameters; (*iii*) the phosphorus scattering factor curve was employed, in the calculations, for phosphorus atoms which had been mistakenly given chlorine scattering power.

In the last cycle of least squares refinement all elements of the full-matrix were varied except for the parameters of atoms (C(16)–C(21)). These parameters were varied in the previous cycle. Final positional and thermal parameters are listed in Table 2.

A final difference Fourier contained no peaks larger than 0.86 e/Å^3, which corresponds to about 29% of the height of the broad peak that was found for the carbonyl group. There was also a peak of 0.75 e/Å^3 remaining 1.49 Å from the cationic carbon atom. This corresponds to the position a fluorine atom would be expected to take for the alternative conformation of the fluorocyclopentenyl ring. This together with the extreme anisotropic motion of the fluorine atoms led us to consider the possibility of disorder involving another conformation for the fluorocyclopentenyl ring. Such a conformation, if it exists, must occur much less frequently in the crystal structure than the one which was selected. No refinement involving two conformations of

[1]This program was originally written by A. Zalkin, University of California.

[2]This program is based on versions of UCILS (Northwestern University and University of California, Irvine, but with additional features, notably as regarding weighting schemes and optional printed summaries.

[3]Both real ($\Delta F'$) and imaginary ($\Delta F''$) corrections were applied.

the ring was carried out since one conformation was predominant. Numerous smaller peaks appeared, many of them in likely hydrogen atom positions.

The function minimized was $\sum w(|F_o| - |F_c|)^2$ and the discrepancy factor R was $\sum(||F_o| - |F_c||)/\sum|F_o|$. The weighted R was $[\sum w(|F_o| - |F_c|)^2/\sum wF_o^2]^{1/2}$.

Scattering factors used for the rhodium atoms were those calculated on the basis of the TFD statistical model; for the other atoms, scattering factors were obtained from self-consistent or variational wave functions (14). Structure factors listed in Table 1 have the modulus of the structure amplitude with the sign of the real component.[4] All calculations are based on a cell with an origin at the center of symmetry. Interatomic distances and bond angles with standard deviations are given in Table 4.

Description and Discussion of the Crystal Structure

The crystal structure of $[Rh(f_6fos)_2][cis\text{-}Rh(CO)_2Cl_2]$ contains $[Rh(f_6fos)_2]^+$ ions and $[cis\text{-}Rh(CO)_2Cl_2]^-$ ions packed together in a body-centered tetragonal lattice (see Fig. 1). Interatomic distances and angles are listed in Table 4.

The asymmetric unit contains half a cation and half an anion. All rhodium atoms are on two-fold special positions so that both cation and anion possess crystallographic two-fold symmetry. The disposition of coordinating atoms about the rhodium in both cation and anion is approximately square planar. The bite of the ligand as measured by the intra-ligand P–P distance is 3.111(8) Å. Cation and anion are so packed together than the terminal atoms of the anion are directed toward the adjacent cation, as illustrated in Fig. 2. These terminal atoms are directed away from the P(3) and P(3)′ atoms and towards the P(4) and P(4)′ atoms. This is accommodated by a twist in the cation such that the P(4) and P(4)′ atoms are depressed relative to the anion. (In Fig. 2, the z-coordinate of P(3) is −0.1410(2), of Rh(1) is −0.1410(1), and of P(4) is −0.1440(2).) Consequently the cation is not superimposable on its mirror image;

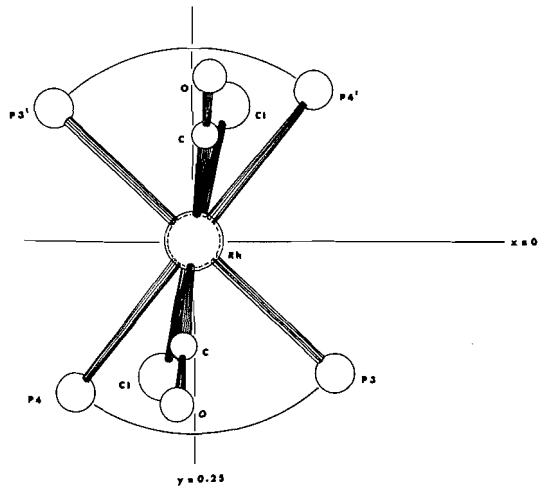

FIG. 2. View down a two-fold axis ($x = 0, y = 0.25$) illustrating the relation between cation and adjacent anion. Only the anion and the cationic rhodium atom (in dashed lines) with its phosphorus atoms are shown; arcs between phosphorus atoms represent the fluorocarbon bridge. The anion is above the cation, with chlorine atoms directed down towards the cation, and carbonyl groups directed upwards.

this means there are two distinct enantiomorphs in the crystal lattice, related to each other by either a center of symmetry or a glide plane operation.

Each half of the cation contains two puckered, five-membered rings (Fig. 3). Carbon atoms C(14) and C(15) are, respectively 0.28(2), and 0.26(2) Å out of the plane of the phosphorus atoms of the same ligand and the rhodium (Rh(1)) atom. The fluorocarbon ring is also significantly puckered. This can be seen by examination of the results in Table 3 for the weighted mean plane through four of the carbon atoms of this ring. C(6), the carbon atom farthest from the cationic rhodium atom, is significantly out of this plane (in fact by 0.10(3) Å). Featured in Fig. 4 are the conformations of the five-membered rings of the cation; the cyclopentenyl ring conformation is shown to be consistent with the orientation of the C—F bonds farthest from the rhodium atom. F(5) is in the axial position, F(7) in the equatorial. Discussion of the C—F bond lengths is precluded by the extreme thermal motion of the fluorine atoms (see Table 2) which may be further aggravated by the fractional presence of the other (flipped) conformation of the cyclopentene ring.

Atom	Distance from plane (in Å)
P(4)	−0.112(6)
P(4)′	−0.112(6)

(3) Plane containing Rh(1) and only the P atoms of one ligand

$0.0355x - 0.0321y - 0.9989z + 5.6055 = 0$

Atom	Distance from plane (in Å)
C(14)	0.28(2)
C(15)	0.26(2)

(4) Mean plane through C(9), C(13), C(14), and C(15) of the fluorocarbon ring

$-0.0999x - 0.0414y - 0.9941z + 5.8798 = 0$

Atom	Distance from plane (in Å)
C(9)	0.01(3)
C(13)	−0.01(3)
C(14)	0.01(2)
C(15)	−0.01(2)
C(6)	−0.10(3)

*The equations are given in Å coordinates. Planes (2) and (4) are weighted mean planes. The weight assigned to an atom is inversely proportional to the sum of the standard deviations for the positional coordinates of the atom.

In the anion the Rh–Cl and Rh–CO(midpoint) distances are identical. This fact coupled with the lower thermal motion of the light atoms, the high correlation coefficients (Table 5), and the unreasonable C—O bond length indicate that while the electron density may be approximately described, a more sophisticated model is needed. Disorder involving the Cl and CO groups could explain all the features mentioned.

Two structural features of the $[Rh(f_6fos)_2]$ cation have implications concerning other compounds containing the $f_6$fos ligand. Firstly, the bite of the ligand (3.111(8) Å) has a bearing on the structure proposed for $f_6$fosFe$(CO)_3$ (7). The nuclear magnetic resonance (n.m.r.) spectrum showed that the original symmetry of the $f_6$fos ligand was preserved in the latter complex. Cullen *et al.* have suggested two possible

B_{23}	B_{12}	0.48

regular arrangements (Fig. 5) and proposed that the true structure is one that is intermediate between these two possibilities.

Assuming that the Fe–P distance in f_6fos-$Fe(CO)_3$ is close to 2.2 Å (it is 2.18 Å in the compound $(\pi\text{-}C_5H_5)Fe(CO)(f_6fos)Sn(CH_3)_3$ where f_6fos is monodentate (15)) and also that the P–P distance is no greater than 3.1 Å in $f_6fosFe(CO)_3$, the angle subtended at the Fe atom by the Fe–P vectors would be 90°. This suggests that structure (**b**) is more likely.

Secondly, the conformations found for the cation suggest that other complexes shown to contain f_6fos (*e.g.*, $f_6fos(CO)_3$ and $f_6fosM(CO)_4$,

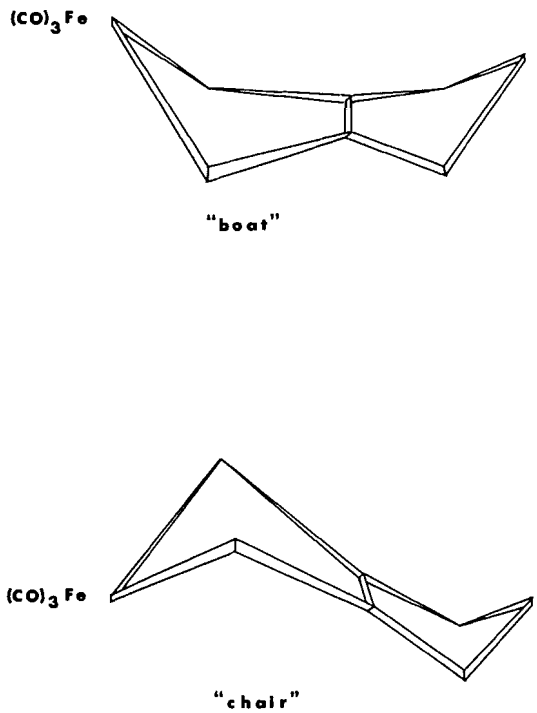

FIG. 6. Two possible isomers of $f_6fosFe(CO)_3$. The pucker of the five-membered rings has been much exaggerated to emphasize the difference between the two conformations.

M = Cr, Mo, W) also may contain puckered, five-membered rings. It is conceivable that two short-lived isomers might appear in solution. They might be loosely described as "boat" and "chair" forms. (See Fig. 6.) The carbonyl stretching (i.r.) spectrum of $f_6fosFe(CO)_3$ shows four bands, one more than the number expected for a compound with C_{2v} symmetry (5). Similarly in $f_6fosM(CO)_4$ complexes four bands are predicted yet five are observed. The evidence here adds credibility to the suggestion of Cullen and co-workers that this extra band could arise from the presence of two distinct isomers in solution which have a long enough lifetime to be detected by i.r. spectroscopy.

We wish to thank the National Research Council of Canada for providing the financial support which made this work possible.

Indole Oxidation: the Dimer of 3-Hydroxy-2,3-dimethylindolenine[1]

VINOD DAVE AND E. W. WARNHOFF
Department of Chemistry, University of Western Ontario, London, Ontario

Received November 3, 1970

Chemical and spectroscopic evidence for the structure **1** of the dimer of 3-hydroxy-2,3-dimethylindolenine is presented. This evidence is based mainly on a comparison of the spectroscopic properties and reactions of both the dimer **1** and its hexadeutero analog **13**. The stereochemistry derived by consideration of n.m.r. shielding is that found by the X-ray analysis of other investigators. The various ways in which this dimer can arise are discussed critically.

Des données chimiques et spectroscopiques permettant d'attribuer la structure **1** au dimère de l'hydroxy-3 diméthyl-2,3 indolénine sont présentées. Les conclusions sont basées principalement sur une comparaison des réactions et des propriétés spectroscopiques du dimère **1** et de son analogue hexadeutéré **13**. La stéréochimie déduite par considération du blindage en r.m.n. est la même que celle trouvée par d'autres chercheurs à l'aide d'une analyse par rayons-X. Les diverses façons par lesquelles ce dimère peut se former sont discutées d'une façon critique.

Canadian Journal of Chemistry, 49, 1911 (1971)

Oxidation and rearrangement play a key role in the chemistry of indoles and indole alkaloids (1–3). The susceptibility of indoles to oxidation is well illustrated by 2,3-dimethylindole which gives rise to a dimeric oxidation product, $C_{20}H_{22}N_2O_2$ (m.p. variously reported as 213 (4), 214 (5), 222 (6), 224 (7), and 225° (8)), under a variety of conditions: simple recrystallization from petroleum ether (7), peroxide-catalyzed oxidation (8), and catalytic oxygenation–reduction (5). In an earlier investigation (5) Kershaw and Taylor suggested an imidazolidine formula **11** for this compound, but further work,[1] the details of which are now presented, definitely established the revised formula **1** as the correct structure of this product. Recently, on the basis of mechanistic considerations and spectroscopic data Berti *et al.* (7), have independently proposed this structure for the dimeric product without, however, providing unambiguous evidence to support it. Still more recently (9), an X-ray crystallographic analysis has been reported which confirms this structure and, moreover, provides the stereochemistry of this molecule.

The unusual feature of the dimer as a chemical structural problem was that spectroscopy was of limited utility, and this limitation obliged the use of supplementary chemical methods. The problem became more interesting during the course of obtaining the structural evidence when an intricate rearrangement sequence was discovered (10). In this paper is presented briefly the chemical proof for the dimer structure together with observations on its chemistry, and in the accompanying paper (10) a description of the acid-catalyzed rearrangements which it undergoes.

Structure

Since the same oxidation product has also been found to arise by dimerization of 3-hydroxy-2,3-dimethylindolenine (**5**) (5), the simplest interpretation[1] of its formation would be addition of the enamine tautomer **6** to the indolenine **5** followed by intramolecular addition of a tertiary hydroxyl group in the resulting imine **7** to yield the dimer **1**, as also suggested by Berti *et al.* (7) (see Scheme 1). This structure is in accord with the two indoline chromophores of the u.v. spectrum and the absence of carbonyl absorption in the i.r. region. As expected of structure **1**, only one nitrogen atom is titratable in the methylcellosolve–water (80:20) system, and the pK_a ~ 3.0 found[2] corresponds to an *N*-alkylaniline (*cf.* *N*-methylaniline pK_a 3.37 in the same solvent); the basicity of the nitrogen atom of the ring-closed carbinolamine ether is weakened by the oxygen atom (expected decrease: 2–3 pK_a units (11)) to the point that it is not titratable in this solvent system. Also in agreement with structure **1**, the n.m.r. spectrum (Fig. 1) consisted of three

[1]Presented in part at the 52nd Annual Conference of the Chemical Institute of Canada, Montreal, Quebec, May 25–29, 1969.

[2]We would like to thank Dr. W. Simon, E. T. H., Zürich, for this determination.

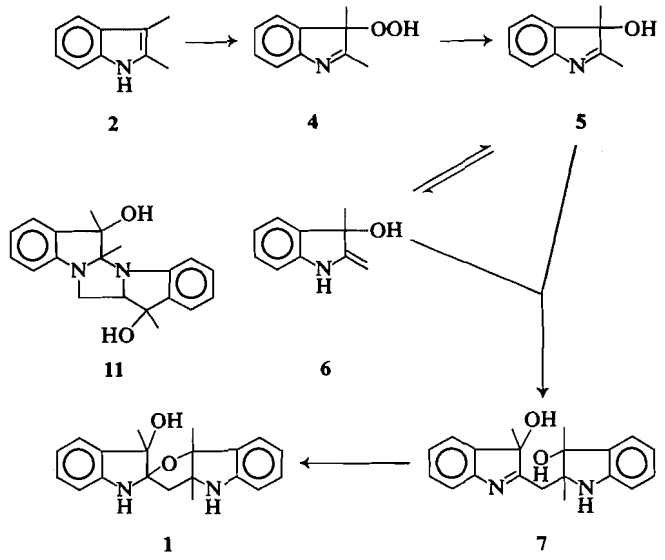

SCHEME 1

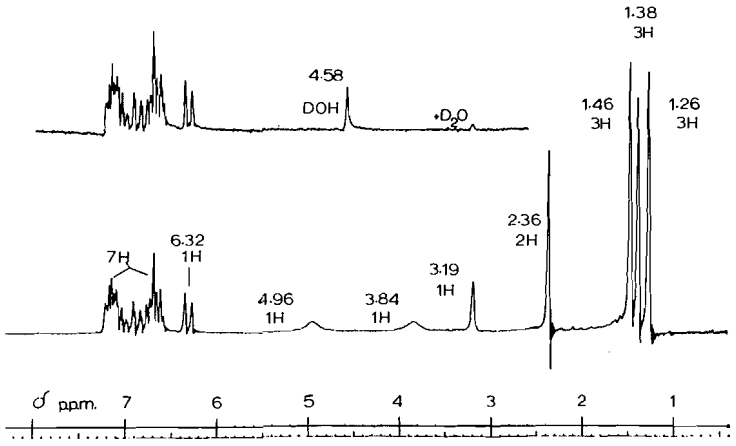

FIG. 1. The n.m.r. spectrum (100 MHz) of the dimer **1** of 3-hydroxy-2,3-dimethylindolenine in $CDCl_3$.

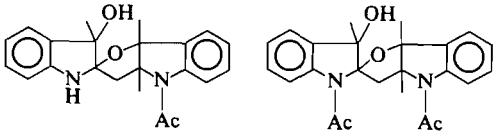
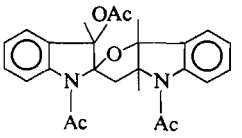
unsplit methyl peaks (δ 1.26, 1.38, and 1.46), a two-proton singlet (δ 2.36), a broad pattern from eight aromatic protons, and three separate broad one-proton peaks exchangeable with deuterium oxide (δ 3.19, 3.84, and 4.96).[3] The nature of these three exchangeable hydrogen atoms was determined by acetylation in mildly basic medium to mono-, di-, and triacetyl derivatives. The first acyl group was introduced onto the more basic indoline nitrogen atom even at room temperature,[4] but acetylation of the other two functions occurs at a convenient rate only at higher temperature. The mono- and diacetates **8** and **9** were both *N*-acyl compounds (i.r.), but the triacetate **10** was an *N,N,O*-triacyl compound (i.r.). Each of the acetates was saponified back to the dimer, and the spectra of

[3]Of course the shape and position of these peaks are solvent, temperature, and p*H* dependent. This fact and the appearance of a DOH peak corresponding to ~1H close to the lowest field peak after addition of D_2O are partly responsible for the original suggestion of the imidazolidine structure **11** (5).

[4]Evidence that the monoacetate is indeed **8** comes from its acid-catalyzed rearrangement described in the succeeding paper (10).



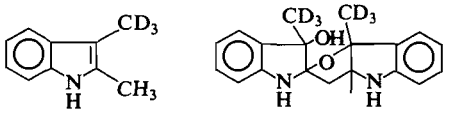
8 9



10

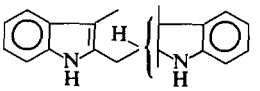
the acetates indicate the carbinolamine ether ring to be still intact.

That the two indolenine moieties were joined through the 2-methyl group of one was determined by preparing the dimer from 2-methyl-3-methyl-d_3-indole. The Fischer indole synthesis with butanone-4,4,4-d_3 (available from methyl iodide-d_3 and ethyl acetoacetate) and phenylhydrazine gave **12** whose n.m.r. spectrum had a single methyl peak at δ 2.28. Catalytic oxygenation–reduction to the 3-hydroxyindolenine and subsequent dimerization furnished the hexadeuterio dimer (later found to be **13**) whose n.m.r. spectrum was lacking only the two methyl peaks at δ 1.38 and 1.46 of the protio analog. The two-proton peak at δ 2.36, which is still present in the n.m.r. spectrum of the hexadeuterio dimer, must originate from the hydrogen atoms of the carbon bridge which joins the two hydroxyindolenines, and therefore this connecting carbon atom must have been a 2-methyl group.



12 13

The question of whether the 2-methyl group of one indolenine unit was linked to the 2- or the 3-position of the other unit was answered by a dissolving metal reduction, a reaction considered unlikely to lead to skeletal rearrangement because of general experience with the method. The action of sodium and *t*-butyl alcohol on **1** gave six products of progressive reduction (**2** and **14–18**) two of which, desoxystereoisomers of partial formula **19**, could be used to decide between the alternative arrangements. In the n.m.r. spectrum of each of these epimeric products one methyl group was a doublet (J = 7 Hz) due to coupling with an adjacent methine hydrogen, but in the n.m.r. spectra of the analogous products from sodium–*t*-butyl alcohol reduction of the hexadeuterio dimer **13** this doublet was absent.[5] Therefore, the methyl group in **19** with an adjacent carbinyl hydrogen atom was the C-3 methyl group of the indolinyl moiety, and the desoxy compounds are the epimers **14** and **15** with the methylene bridge linking the C-2 position of each heterocyclic unit. Attachment of the two hydroxyl groups to this firmly established carbon–nitrogen skeleton in the only way possible gives **7** which would only undergo facile ring closure to **1**, the structure derived from the earlier mentioned mechanistic considerations.



19

Stereochemistry

During the formation of the dimer, the addition of the enamine **6** to the imine **5** should occur mainly from the least hindered side opposite the C-3 methyl group to produce *cis* methyl groups at C-2 and -3 of the indoline, and certainly ring closure (reversible) of the carbinolamine ether ring would be expected only with the *cis* fusion of the two five-membered rings. The X-ray analysis (9) found that these methyl groups were indeed *cis*. The closure of the carbinolamine ether ring could occur in two senses to yield **20** or **21**,[6] and the actual arrangement **20** found by the X-ray determination is the only one in agreement with certain shielding effects in the n.m.r. spectra. One of the eight aromatic protons is so shielded (δ 6.32, $J \sim 7$ Hz) that it is separated from the other seven. From its position and coupling and by analogy with model indolines (12, 13) this proton is one of the two ortho to the nitrogen atom on a benzene ring. In the monoacetate of the dimer **8**, the strongly shielded proton is still present, but in the di- and triacetates **9** and **10**, this proton has been deshielded and moved back among the other seven aromatic hydrogen atoms, a known effect of acetylation on the C-7 proton of an indoline (12, 13). Therefore, this proton must be the one encircled in **20**, and the abnormal

[5]The peak from the indole methyl group was also missing.

[6]Only one of the racemic pair is shown.

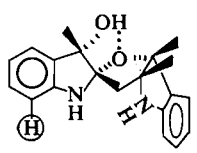
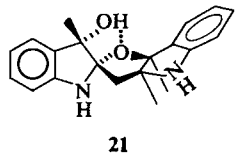
shielding is attributed to the orientation of the other aromatic ring. The acetyl methyl on the basic indoline nitrogen atom is strongly deshielded ($\delta \sim 2.5$–2.6) in all three acetates, but the carbinolamine *N*-acetyl methyl group in the di- and triacetates is abnormally shielded ($\delta \sim 1.9$ instead of ~ 2.2 (12)), the latter observation being in agreement only with the stereochemistry in **20**. Finally, the reaction of the dimer with formaldehyde to produce a homo dimer in which the two nitrogen atoms are linked by a methylene group (10) is only possible with **20**.



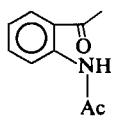
20



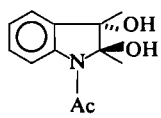
21

Formation in Other Reactions

The basic features of the mechanism leading to dimer from the 3-hydroxyindolenine **5** suggest that dimerization could also occur through the hydroperoxide **4** or a combination of **4** and **5** followed by reduction of any hydroperoxide linkages, and there is no evidence to exclude this possibility. Furthermore, thermal breakdown of the hydroperoxide regenerates some 2,3-dimethylindole which could react with more hydroperoxide to yield the hydroxyindolenine. As might then be expected, dimer is formed to some extent under a variety of conditions not initially involving the hydroxyindolenine: autoxidation of 2,3-dimethylindole in chloroform solution,[7] reaction of the indole and hydroperoxide at room temperature (8), and thermal decomposition of the hydroperoxide in boiling benzene.



22



23

[7]This reaction shows an interesting dependence on agitation (see Experimental). If the solution is allowed to stand without stirring, oxygen absorption is slow. Consequently any hydroperoxide formed has time to react with the indole to yield hydroxyindolenine and finally dimer. However, if the solution is stirred so that oxygen absorption is rapid, most of the indole is converted to hydroperoxide before much reaction of the peroxide with excess indole can occur. In this case the major product is *o*-acetamidoacetophenone (**22**) from the usual decomposition of the hydroperoxide (8).

This last reaction was done according to the conditions of Ghosal and Dutta (6) who obtained a compound,[8] $(C_{10}H_{11}NO)_n$, m.p. 220–222°, which they formulated as the 2,3-epoxide of the indole **2**, but which is undoubtedly the dimer **1** (see Experimental).[9]

However, one reaction reported to lead to the dimer does not do so on re-investigation. Although saponification of *N*-acetyl-2,3-*trans*-dihydroxy-2,3-dimethylindoline (**23**) was reported (5) to yield 2,2-dimethylindoxyl (**25**) and dimer **1**,[10] only 2,2-dimethylindoxyl was formed in our repetition of the experiment. Nevertheless, variation of the ratio of indoxyl **25** to dimer **1** with experimental conditions is to be expected. For the two competing reactions (Scheme 2), the higher the concentration of hydroxide ion or other added base, the greater the proportion of indoxyl formed. On the other hand, the imine $\rightleftharpoons$ enamine tautomerization is fast relative to dimerization and, provided the reaction medium is basic enough to maintain the equilibrium, an increased concentration of base would have little effect on the dimerization rate. Moreover, the dimerization being bimolecular in hydroxyindolenine will be slowed by dilution.

This dimerization reaction should have some degree of generality, and provided that steric factors are not unfavorable, other 3-hydroxyindolenines and indoles should undergo the same reaction.

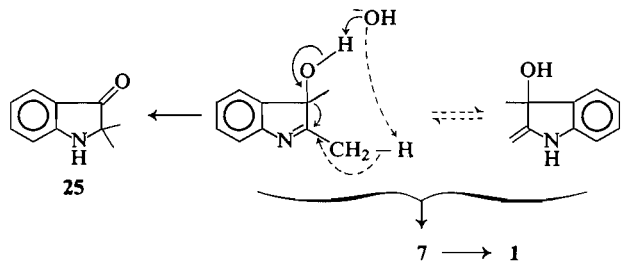
Addendum

The products of the sodium – *t*-butyl alcohol reduction are readily rationalized (Scheme 3). Whether the left hand aromatic ring of **1** or the imine group of **7** accepts electrons, the initial

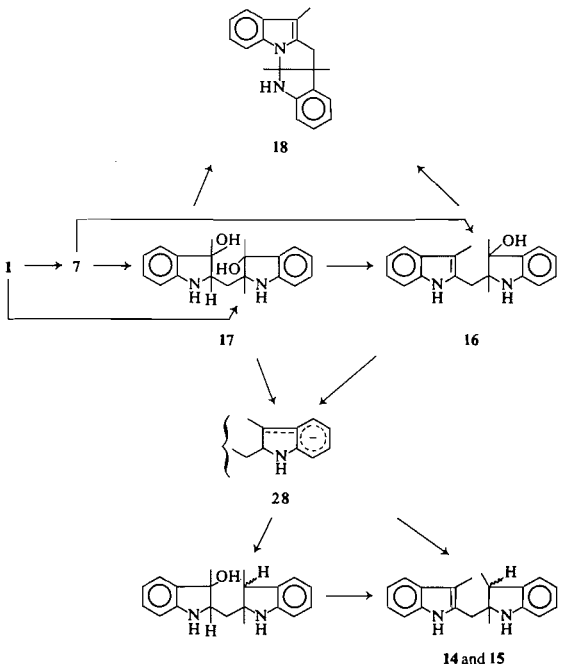
[8]In our hands treatment of the compound (actually dimer **1**) with dilute hydrochloric acid did not give *o*-acetamidoacetophenone (**22**) as reported (6), but only the rearrangement products described in the accompanying paper (10). However, treatment of the hydroperoxide **4** with dilute hydrochloric acid does give *o*-acetamidoacetophenone (see footnote 7).

[9]The difference in products from the benzene and chloroform reactions (see footnote 7) is probably mainly a function of temperature. At higher temperatures the hydroperoxide breaks down to the indole **2** which reacts with additional hydroperoxide to produce dimer via the hydroxyindolenine. In the absence of this thermal regeneration of **2** the favored reaction path of hydroperoxide is formation of *o*-acetamidoacetophenone (see footnote 8).

[10]Dimer was found after recrystallization of chromatogram fractions having the same m.p. as hydroxyindolenine **5**.

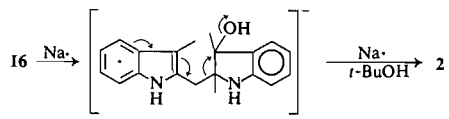


SCHEME 2



SCHEME 3

product could be diol **17**. Elimination of water would then produce the indole **16**, or possibly **7** is hydrogenolyzed directly to **16**. Similar electron addition to the aromatic ring on the right and hydroxyl elimination would remove the other oxygen function. Protonation of the carbanion **28** would occur from both sides of the benzylic carbon atom to produce both epimers **14** and **15**. 2,3-Dimethylindole could arise by reduction of the 3-hydroxyindolenine from retro Mannich scission of dimer (see footnote 12) or else by direct reductive cleavage, *e.g.*



It is not surprising that both **16** and **17** should be extremely sensitive to acid, even the traces of hydrogen chloride present in chloroform, and undergo dehydration with rearrangement to **18**, thus explaining its presence in the reduction product (see the accompanying paper, ref. 10).

Experimental

General

Melting points were determined on a Reichert–Kofler microscope hot stage and are corrected.

The i.r. spectra were recorded on a Beckman IR-10 instrument with chloroform solutions. The n.m.r. spectra were recorded on Varian A-60, T-60 and HA-100 spectrometers with ~ 10–15% (w/v) solutions in deuteriochloroform solution containing tetramethylsilane as internal standard. In the few cases where a different solvent was used, it is specified. Aromatic n.m.r. absorptions are not reported. The u.v. spectra were recorded on a Cary model 14 spectrometer with methanol solutions. Mass spectra were obtained on a Varian M-66 instrument.

Silica gel GF_{254} (Merck, Germany) was used for thin and thick layer (20 g/20 × 20 cm plate) chromatography. Thin layer plates were sprayed with a 5% solution of phosphomolybdic acid in ethanol. On thick layer plates bands were detected under a u.v. lamp. Woelm neutral, Brockman grade IV alumina, or British Drug Houses silica gel was used for column chromatography. Petroleum ether refers to the fraction of b.p. 60–80°.

Organic layers from work-up of reactions were washed with saturated NaCl solution, dried over anhydrous $MgSO_4$, and then evaporated at reduced pressure on the rotary evaporator.

The n.m.r. data are given in Table 1.

2,3-Dimethylindole (2)

This starting material was either purchased from the Aldrich Chemical Co. or was made by the Fischer indole synthesis in which a solution of methyl ethyl ketone (50 g, 0.70 mol), phenylhydrazine hydrochloride (100 g, 0.70 mol), and glacial acetic acid (500 ml) was refluxed for 3 h. The cooled solution was diluted with water, filtered, washed with water, and dried. Percolation of a petroleum ether solution of the crude product through silica gel gave 71 g (70%) of white crystalline solid, m.p. 98–100° (lit. (14) 106°).

2,3-Dimethylindolenyl-3-hydroperoxide (4)

In our hands the procedure of Beer *et al.* (8) gave miserable yields of **4**. The major product obtained was

TABLE 1. The n.m.r. data exclusive of aromatic protons*

Compound	Absorption δ
2,3-Dimethylindole (**2**)	2.20 (s, 3-Me), 2.28 (s, 2-Me) *dilute* $CDCl_3$ (13 mg/0.25 ml) 2.19 (s, 3-Me), 2.28 (s, 2-Me) CD_3COOD
2-Methyl-3-methyl-d_3-indole (**12**)	2.28 (s, 2-Me) dilute $CDCl_3$ (15 mg/0.25 ml) 2.28 (s, 2-Me) CD_3COOD
3-Hydroperoxy-2,3-dimethylindolenine (**4**)	1.40 (s, 3-Me), 2.17 (s, 2-Me) 10.97 (s, OOH)
3-Hydroxy-2,3-dimethylindolenine (**5**)	1.39 (s, 3-Me), 1.89 (s, 2-Me)
2-Hydroxymethyl-3-methylindole (**24**)	2.28 (s, Me), 4.81 (s, CH_2), 1.68 (s, OH), 8.07 (b, NH)
2-Formyl-3-methylindole (**3**)	2.72 (s, Me), 9.03 (b, NH), 10.12 (s, CHO)
2,2-Dimethylindoxyl (**25**)	1.32 (s, diMe), 4.85 (s, NH)
N-Acetyl-2,3-dimethylindole	2.15 (s, Me) 2.50 (s, Me), 2.62 (s, NCOMe)
N-Acetyl-*trans*-2,3-dihydroxy-2,3-dimethylindoline (**23**)	1.72 (s, Me), 1.91 (s, Me), 2.03 (s, Me), 4.40 (OH)
N-Acetyl-*cis*-2,3-dihydroxy-2,3-dimethylindoline (?)	1.45 (s, Me), 1.56 (s, Me), 2.23 (s, NCOMe), 4.28 (OH)
2-Acetamidoacetophenone (**22**)	2.26 (s, Me), 2.70 (s, NCOMe), 11.69 (NH)
Dimer **1**	1.26 (s, 2-Me), 1.38 (s, 3-Me), 1.46 (s, 3-Me), 2.36 (s, CH_2), 3.19 (OH), 3.84 (NH), 4.96 (NH)
Dimer-d_6 **13**	1.26 (s, 2-Me) 2.36 (s, CH_2), 3.20 (OH), 3.84 (NH), 4.95 (NH)
Dimer monoacetate **8**	1.38 (s, Me), 1.52 (s, diMe), 2.54 (s, NCOMe), 3.05 (s, OH), 3.30 and 3.54 (AB of CH_2, J = 14), 3.88 (b, NH)
Dimer diacetate **9**	1.35 (s, Me), 1.51 (s, Me), 1.73 (s, Me), 1.95 (s, NCOMe), 2.55 (s, NCOMe), 4.27 center of AB of CH_2 of which only two strongest lines visible. [OH not apparent in this spectrum]
Dimer triacetate **10**	1.32 (s, Me), 1.73 (s, Me), 1.80 (s, Me), 1.88 (s, COMe), 2.47 (s, COMe), 2.51 (s, COMe), 3.50 and 3.84 (AB of CH_2, J = 16)
Reduction product **16**	1.07 (s, Me), 1.40 (s, Me), 2.27 (s, Me), 3.10 (s, CH_2)
Desoxy indolylindoline **14**	1.06 (s, Me), 1.19 (d, 3H, J = 7), 2.24 (s, Me), 2.94 (s, CH_2), 3.35 (indoline NH), 8.53 (indole NH)
Desoxy indolylindoline **15**	1.30 (s, Me), 1.34 (d, 3H, J = 7), 2.16 (s, Me), 2.58 and 2.88 (AB of CH_2, J = 14)

*Chemical shifts are given in p.p.m. from tetramethylsilane (δ) and coupling constants in Hz; $CDCl_3$ solutions unless otherwise specified; 2-Me and 3-Me signify that the methyl group giving rise to the absorption originated from a 2- or 3- methyl group of 2,3-dimethylindole, respectively; s = singlet, d = doublet, b = broad absorption.

the hydroxyindolenine dimer **1**. However, the hydroperoxide **4** was obtained in good yield by McCapra's procedure.[11] A solution of 2,3-dimethylindole (**2**) (0.50 g), which had been freshly crystallized from aqueous methanol, was dissolved in petroleum ether (50 ml) and cooled to ~ 0°. Oxygen was bubbled in with stirring at ~ 0°, and a white crystalline solid slowly precipitated. At the end of 12 h, t.l.c. showed the absence of **2** and the presence of a single spot more polar than **2**. The solid was filtered, washed once with petroleum ether, and dried to give 0.35 g (57%) of colorless hydroperoxide, m.p. 103–108° (dec.) (lit. (8) 113° (dec.)). The compound was used without further attempted purification. It tends to decompose within a day at room temperature, but it is stable for months in a refrigerator. It also turns brown on the t.l.c. plate.

[11]We would like to thank Dr. F. McCapra, University of Sussex, Brighton, England, for sending us his experimental details before publication.

3-Hydroxy-2,3-dimethylindolenine (5)

The procedure of Beer, Donavanik, and Robertson (8) was used. To a mixture of pure hydroperoxide **4** (200 mg), ether (6 ml) and 2 *N* NaOH (3.5 ml) was added sodium dithionite (0.4 g). The mixture was stirred (magnetic bar) at room temperature for 1.5 h, diluted with ether, and separated. The organic layer was washed with water, dried, and evaporated to leave 170 mg of crystalline solid which t.l.c. showed to be composed of ~ 90% of **5** and ~ 10% of dimer **1**. The n.m.r. spectrum agreed with this analysis. Attempts at further purification by recrystallization only increased the proportion of dimer **1**.

Reactions Leading to Dimer 1

(a) Oxygenation–Hydrogenation of 2,3-Dimethylindole (2) (5)

Platinum oxide (0.40 g) in ethyl acetate (200 ml) was reduced with hydrogen. The apparatus was flushed with nitrogen, and 2,3-dimethylindole (3.00 g) was added to the mixture which was stirred (magnetic bar) and oxy-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

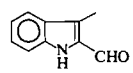
genated for 12 h (oxygen uptake ~ 400 ml). The t.l.c. showed the *complete absence* of 2,3-dimethylindole (**2**). The apparatus was flushed with nitrogen, and the mixture then hydrogenated for 30 min (hydrogen uptake ~ 400 ml). The t.l.c. at this stage revealed the *presence* of 2,3-dimethylindole (**2**) and more polar materials. The catalyst was removed by filtration, and the filtrate was evaporated at reduced pressure to leave 3.10 g of viscous brown liquid which was chromatographed on a column of 90 g of alumina.

(*i*) Petroleum ether eluted 0.70 g (23%) of **2,3-dimethylindole** (**2**), m.p. 98–100°, identical with starting material.

(*ii*) Petroleum ether – benzene (95:5) eluted 0.30 g (8.2%) of ***o*-acetamidoacetophenone** (**22**) which was recrystallized from chloroform – petroleum ether to give colorless needles, m.p. 74–75° (lit. (8) m.p. 77–78°), ν_{max} 3240 (NH), 1690 (ArC=O), and 1650 cm^{-1} ($CH_3C(=O)N$).

(*iii*) Petroleum ether – benzene (85:15) eluted 70 mg (2%) of **2-formyl-3-methylindole** (**3**) which on recrystallization from methanol gave colorless crystals, m.p. 137–139° (lit. (15) m.p. 139–140°), ν_{max} 3640 (NH) and 1650 cm^{-1} (conj. CH=O); *m/e* 159 (molecular ion).

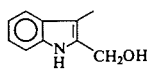


3

(*iv*) Petroleum ether – benzene (60:40) eluted 1.20 g (36%) of crude **dimer 1** which on recrystallization from methanol gave 0.70 g of colorless crystals, m.p. 195–225° (lit. (4–8) m.p. from 213 to 225°),[12] pK_a ~ 3.0 (80% methyl collosolve – 20% water), λ_{max} 245 (16 300) and 297 nm (7600); *m/e* 322 (molecular ion).

Anal. Calcd. for $C_{20}H_{22}N_2O_2$ (322.4): O, 9.92. Found: O, 10.41.

(*v*) Benzene eluted 0.15 g (4.5%) of crude yellowish **2-hydroxymethyl-3-methylindole** (**24**) which was purified by thick layer chromatography (ether–benzene (60:40) used for development) and subsequent recrystallization from chloroform – petroleum ether to give colorless crystals, m.p. 124–126° (lit. (15) m.p. 123–124°), undepressed on admixture with an authentic specimen, m.p. 125–127°, prepared by lithium aluminum hydride reduction of 2-formyl-3-methylindole (**3**), *m/e* 161 (molecular ion).



24

(b) Autoxidation of 2,3-Dimethylindole (2)

A solution of **2** (25 g) in reagent grade chloroform (400 ml) was allowed to stand undisturbed in an open beaker at room temperature for 4 days with chloroform being added occasionally to maintain the original volume. Concentration of the dark brown solution gave an oily solid which was recrystallized once from methanol and twice from chloroform – petroleum ether to yield 11 g (40%) of the dimer **1** identical in all respects with the compound obtained in section *a*.

[12]The wide m.p. range is due to thermal decomposition; see later experimental description.

If the chloroform solution of **2** in an open vessel was *stirred* (magnetic bar), the major product was *o*-acetamidoacetophenone (**22**) with only a minor amount (2–5%) of dimer **1**.

(c) Reaction of 2,3-Dimethylindole (2) and 2,3-Dimethylindolenyl-3-hydroperoxide (4)

A solution of **2** (35 mg) and **4** (35 mg) in chloroform (1 ml) was sealed under nitrogen in a tube and stored in the dark for 3 days. The t.l.c. of the reaction mixture showed the absence of hydroperoxide **4** and the presence of 2,3-dimethylindole (**2**) and dimer **1**. The n.m.r. spectrum of the mixture gave the proportion of **1**:**2** as 80:20.

When the hydroperoxide **4** alone was allowed to stand at room temperature in chloroform solution, *o*-acetamidoacetophenone (**22**) was the major product together with a minor amount of the dimer **1**.

(d) Thermal Decomposition of 2,3-Dimethylindolenyl-3-hydroperoxide (4)

The reaction was conducted according to the directions of Ghosal and Dutta (6). A solution of colorless hydroperoxide **4** (0.20 g, pure by t.l.c.) in reagent grade benzene (25 ml) was refluxed for 40 min, after which time the benzene was evaporated at reduced pressure to leave a brown oily solid. The t.l.c. (benzene–ether, 50:50) showed some remaining **4** and three other spots corresponding to **2**, **3**, and dimer **1**. Chromatography on alumina (6.0 g) yielded: (*i*) 75 mg of 2,3-dimethylindole (**2**) eluted by petroleum ether; (*ii*) 8 mg of 2-formyl-3-methylindole (**3**) eluted by petroleum ether – benzene (70:30); and (*iii*) 24 mg of dimer **1** eluted by petroleum ether – benzene (60:40). Recrystallization of the 24 mg of **1** from methanol gave colorless crystals, m.p. 195–225° (dec.)

(e) Basic Treatment of 3-Hydroxy-2,3-dimethylindolenine (5)

A solution of **5** (50 mg, 90% pure with 10% of dimer **1** as impurity) in 2 *N* aqueous NaOH (4 ml) was refluxed for 3 h. After extraction into ether, the product was washed with water and dried. Evaporation left 49 mg of yellowish solid whose t.l.c. (benzene–ether, 50:50) showed a major spot corresponding to dimer **1** and a minor spot corresponding to 2,2-dimethylindoxyl (**25**). From the n.m.r. spectrum the ratio of **1**:**25** was ~ 90:10.

Acidic Treatment of Hydroperoxyindolenine 4

A solution of the hydroperoxide **4** (100 mg) in 2 *N* HCl (1 ml) was stirred at room temperature for 1.5 h. The brownish black solution was diluted with chloroform, washed with water, dried, and concentrated to leave 38 mg of a dark brown oil. The t.l.c. in benzene–ether (50:50) gave a single significant spot of the same R_f as **22**. The n.m.r. spectrum of the crude product clearly showed it to contain about 85% of *o*-acetamidoacetophenone (**22**). No attempt was made to isolate **22**.

Acetylation of Dimer 1

(a) Monoacetate

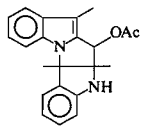
A mixture of dimer **1** (0.50 g), anhydrous sodium acetate (0.10 g), pyridine (5.0 ml), and acetic anhydride (3.0 ml) was stirred (magnetic bar) at room temperature for 11 days. At this point t.l.c. showed the absence of starting material **1**. The reaction mixture was poured into chloroform, washed with water, dried, and concentrated to leave 0.48 g of viscous brown liquid. The t.l.c.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(benzene–ether, 50:50) gave a spot (R_f 0.71) corresponding to *O*-acetate **26** (absent in t.l.c. of the reaction mixture before work-up), a spot (R_f 0.49) corresponding to monoacetate **8**, and two minor spots due to di- and triacetates **9** and **10**. Separation by t.l.c. (benzene–ether, 1:1, used for development) gave 0.20 g (40%) of solid which after several recrystallizations from chloroform – petroleum ether gave 50 mg of *N*-monoacetate **8**, m.p. 175–177°, ν_{max} 3530 (OH), 3380 (NH), and 1650 cm^{-1} (amide C=O); λ_{max} 248 (16 700) and 280 nm (3600); *m/e* 364 (molecular ion).

Anal. Calcd. for $C_{22}H_{24}N_2O_3$ (364.4): C, 72.51; H, 6.64; N, 7.69. Found: C, 72.36; H, 6.61; N, 7.54.

From a less polar band of the t.l.c. separation was isolated 42 mg of yellow oily solid. One recrystallization from petroleum ether gave 30 mg of *O*-acetate **26** identical (m.p., t.l.c., i.r., n.m.r.) with the authentic specimen (10). This compound was an artifact formed at some stage of the work-up procedure. It was not present if the chloroform solution of the crude product was washed with $NaHCO_3$ solution.



26

(b) Di- and Triacetates

To a stirred (magnetic bar) mixture of dimer **1** (0.30 g), anhydrous sodium acetate (0.1 g), and pyridine (2.0 ml) was added acetic anhydride (2.0 ml), and the reaction mixture was heated at 85° for 18 h. Dilution of the cooled reaction mixture with water and extraction with chloroform gave an organic layer which was washed with water, dried, and evaporated to leave 0.32 g of dark brown oil. Separation by t.l.c. (benzene–ether, 25:75, used for development) gave a band (R_f 0.34) from which 32 mg of crystalline ***N,N*-diacetate 9** was extracted. Recrystallization from ether – petroleum ether (b.p. 30–60°) gave colorless granules, m.p. 194–204°, ν_{max} 3535 (OH), and 1655 cm^{-1} (amide C=O); *m/e* 406 (molecular ion).

Anal. Calcd. for $C_{24}H_{26}N_2O_4$ (406.5): C, 70.92; H, 6.45. Found: C, 71.11; H, 6.74.

From a slightly more polar band (R_f 0.44) was extracted 48 mg of the ***N,N,O*-triacetate 10** which on recrystallization from chloroform – petroleum ether gave colorless granules, m.p. 165–188° (wide range due to stereoisomers?), ν_{max} no OH or NH absorption, 1730 (ester C=O) and 1650 cm^{-1} (amide C=O); *m/e* 448 (molecular ion).

Anal. Calcd. for $C_{26}H_{28}N_2O_5$ (448.5): C, 69.63; H, 6.29. Found: C, 69.18; H, 6.32.

Saponification of Dimer Acetates

A solution of the *N,N*-diacetate **9** (90 mg), KOH (2 pellets), and methanol (2 ml) was refluxed for 18 h. Dilution of the reaction mixture with water and extraction with chloroform gave an organic layer which was washed with water, dried, and evaporated at reduced pressure to leave 48 mg of yellowish solid. Two recrystallizations from chloroform – petroleum ether gave colorless crystals of the dimer **1**, m.p. 195–225° (dec.), undepressed on admixture with the authentic sample. The i.r. and n.m.r. spectra of the saponification product were also identical with those of authentic **1**.

The same procedure was used to saponify the *N*-monoacetate **8** and the *N,N,O*-triacetate **10**; in both cases the dimer **1** was the only product recovered.

2-Methyl-3-methyl-d_3-indole (12)

Methyl ethyl ketone-4,4,4-d_3 was prepared by modification of the *Organic Syntheses* procedure (16). To a solution of sodium (0.80 g) in absolute ethanol (17.5 ml) was added ethyl acetoacetate (4.4 g, 0.033 mol). After a 10 min reflux period, methyl iodide-d_3 (5.0 g, 0.034 mol, > 99% D) was added to the refluxing solution during 15 min. The reaction mixture was refluxed for 6 h at the end of which time it was neutral to p*H* paper. After additon of 5% aqueous NaOH (35 ml), the solution was stirred at room temperature for 5 h. Aqueous H_2SO_4 (1:1, 4 ml) was added and the acidic solution was stirred at room temperature for 15 min before refluxing for 2 h. The solution was distilled, and the fraction of b.p. 78–90° was collected. Redistillation from five pellets of NaOH gave the ketone accompanied by some ethyl alcohol. To this mixture of ketone and ethyl alcohol was added glacial acetic acid (20 ml) and phenylhydrazine hydrochloride (3.1 g, 0.021 mol). The resulting solution was refluxed for 3 h, then cooled and diluted with water. The precipitate was filtered, washed with water, dried, and percolated in petroleum ether solution through a column of 50 g of silica gel to give 1.8 g (37%) of colorless crystalline **12**, m.p. 90–96°, *m/e* 148 (molecular ion). The t.l.c. gave a single spot of the same R_f as **2**. The compound was used for subsequent reactions without further purification.

Hexadeuterio Dimer 13

The procedure of Kershaw and Taylor (5), described in section *a* under dimer preparation above, was used with 2-methyl-3-methyl-d_3-indole (590 mg). The dimer-d_6 (110 mg, 17%) obtained had identical m.p. and t.l.c. behavior as the non-deuterated material, *m/e* 328 (molecular ion corresponding to hexadeuteration).

Sodium–t-Butanol Reduction of Dimer 1

To a refluxing solution of the pure (t.l.c. and n.m.r.) dimer (4.50 g, 14.1 mmol) in *t*-butyl alcohol (150 ml) was added freshly cut sodium metal (15 g) during 0.5 h. Reflux was continued for 2.5 h. Methanol was added to the cooled solution to dissolve unreacted sodium. After the sodium had dissolved, water was added and the mixture was thoroughly extracted with ether. The ethereal solution was washed with water, dried, and evaporated to leave 4.38 g of clear brown oil composed of six compounds according to t.l.c. in benzene – petroleum ether (70:30). The crude product was chromatographed on 200 g of neutral alumina.

(*i*) Petroleum ether eluted 30 mg (1.4%) of colorless **2,3-dimethylindole (2)**, R_f 0.85.

(*ii*) Further elution with petroleum ether gave 55 mg (1.3%) of **Berti's desoxy compound 18**, R_f 0.67, which was recrystallized from chloroform – petroleum ether to give colorless crystals, m.p. 185–190°, whose n.m.r. spectrum was identical with that of the authentic synthetic specimen (see ref. 10).

(*iii*) Continued elution with petroleum ether gave a pale

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

yellow oil (660 mg) which was chromatographed again on six thick plates developed with benzene–ether (95:5). Extraction yielded 475 mg (11%) of colorless oil, R_f 0.54, which solidified (single t.l.c. spot). Recrystallization from chloroform – petroleum ether gave 330 mg of colorless crystals of the **indolylindoline 14**, m.p. 106–108°, ν_{max} 3480 and 3410 cm^{-1} (NH); λ_{max} 230 (33 500) and 288 nm (9900).

Anal. Calcd. for $C_{20}H_{22}N_2$ (290.4): C, 82.72; H, 7.64; N, 9.65. Found: C, 83.02; H, 7.68; N, 9.66.

(*iv*) The final petroleum ether eluates left 580 mg (14%) of colorless oily solid which on recrystallization from chloroform – petroleum ether gave 355 mg of colorless crystals of the **indolylindoline** stereoisomer **15**, m.p. 160–170°, R_f 0.44 ν_{max} 3440 and 3390 cm^{-1} (NH); λ_{max} 227 (31 900) and 285 nm (9500).

Anal. Calcd. for $C_{20}H_{22}N_2$ (290.4): C, 82.72; H, 7.64; N, 9.65. Found: C, 82.35; H, 6.92; N, 9.57.

(*v*) Elution with petroleum ether – benzene (60:40) gave 220 mg (5%) of colorless oil which was chromatographed again on four thick plates developed in petroleum ether–benzene (50:50). Extraction yielded 70 mg of colorless oil which solidified. On recrystallization from chloroform – petroleum ether the compound underwent dehydration and rearrangement to Berti's desoxy compound **18**, m.p. 178–183°, n.m.r., and u.v. spectrum identical with that of authentic synthetic **18** (see ref. 10).

(*vi*) Elution with chloroform gave 650 mg of a brown viscous mass which was chromatographed on four thick plates developed with ether–benzene (75:25). Extraction of the band at R_f 0.39 gave 55 mg of colorless solid, m.p. 162–174° (dec.) after recrystallization from methanol – petroleum ether. However, on standing in chloroform solution this product of unknown structure[13] was transformed into Berti's desoxy compound **18** before analysis.

N-Acetyl-2,3-dimethylindole

This compound was made according to a modification of the published procedure (17). A solution of 2,3-dimethylindole (4.0 g), camphor-10-sulfonic acid (40 mg), and acetic anhydride (40 ml) was refluxed for 9 h. The excess anhydride was distilled at reduced pressure, and the residue was percolated in benzene solution through a column of 100 g of silica gel. Evaporation of the eluate left 3.4 g (66%) of colorless crystalline amide which was used without further purification. A sample recrystallized from petroleum ether (b.p. 30–60°) had m.p. 68–70° (lit. (17) m.p. 74°), ν_{max} 1700 cm^{-1} (indole amide C=O); *m/e* 187 (molecular ion).

N-Acetyl-trans (and cis?) -2,3-dihydroxy-2,3-dimethylindoline (23)

The published procedure (18) was modified. To a stirred (magnetic bar) solution of *N*-acetyl-2,3-dimethylindole (2.0 g) in glacial acetic acid (3 ml) cooled in an ice–salt bath was added nitric acid (0.84 g) during 5 min. After being stirred for 1 h at room temperature, the reaction mixture was filtered to remove unreacted starting material. The filtrate was concentrated to one quarter of its volume at room temperature under reduced pressure. The residual viscous brown liquid was diluted with ether and allowed to stand overnight to complete the precipitation of solid. Filtration and washing with ether gave 0.66 g (28%) of yellowish **23** (single t.l.c. spot). Two recrystallizations from methanol gave 0.42 g of colorless crystals, m.p. 130–132° (lit. (18) m.p. 133–134°), ν_{max}(Nujol) 3420, 3300 (OH), and 1635 cm^{-1} (amide C=O); *m/e* 221 (molecular ion). The n.m.r. spectrum indicated the crystalline compound to be a mixture of the *trans* and *cis* stereoisomers. The mother liquors from the two recrystallizations were saved for the basic treatment described below.

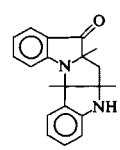
Base Treatment of N-Acetyl-trans-2,3-dihydroxy-2,3-dimethylindoline (23)

The directions of Kershaw and Taylor (5) were followed. A mixture of 130 mg of **23**, m.p. 130–132° (single t.l.c. spot), in 1 *N* aqueous NaOH solution (5 ml) was refluxed. Within a few minutes a greenish-yellow fluorescent color had appeared. At the end of 1 h the reaction mixture was cooled and extracted with benzene. The organic layer was washed with water, dried, and evaporated to leave 85 mg (90%) of yellow **2,2-dimethyl indoxyl (25)**. The n.m.r. spectrum showed the absence of starting material **23** and dimer **1**, and t.l.c. gave a single spot corresponding to **25**. The n.m.r. spectrum of the crude product contained no peaks due to the dimer **1**. Recrystallization from petroleum ether gave yellow needles, m.p. 86–87.5° (lit. (8) m.p. 89–90°), ν_{max} 3420 (NH) and 1710 cm^{-1} (indoxyl C=O).

The mother liquors from the isolation of **23** in the experiment above were treated with refluxing sodium hydroxide as described above for pure **23**. The n.m.r. spectrum and t.l.c. of the crude product did show the presence of 5–10% of the dimer **1**, but no attempt was made to isolate it.

Thermal Decomposition of Dimer 1

Dimer (0.20 g) was heated at ~ 225° in a test tube for 1 h. The t.l.c. of the dark brown residue gave only one significant spot having the same R_f as the dimer. Chromatography on a thick plate developed with benzene–ether (50:50) gave a yellow band at R_f 0.59. Extraction of the band yielded 124 mg (62%) of yellow solid whose n.m.r. spectrum unambiguously showed it to be a mixture of 2,2-dimethylindoxyl (**25**) and the dimeric indoxyl **27** (see accompanying paper, ref. 10). No attempt was made to separate the mixture.



27

We would like to thank the National Research Council of Canada for financial support. We would also like to thank Dr. A. Taylor, NRCC Atlantic Regional Laboratory, Halifax, Nova Scotia, for his very helpful cooperation.

[13]The product had the same t.l.c. R_f as **17**, the $LiAlH_4$ reduction product (7) from **1**, but it was not investigated further.

Complex Rearrangements of the Dimer of 3-Hydroxy-2,3-dimethylindolenine[1]

VINOD DAVE AND E. W. WARNHOFF
Department of Chemistry, University of Western Ontario, London, Ontario

Received November 3, 1970

In the presence of acid the dimer **1** of 3-hydroxy-2,3-dimethylindolenine rearranges to **4**, and then via **6** to **7***a* which is cleaved to 2,3-dimethylindole (**2**) and 2-formyl-3-methylindole (**3**). If peroxides and oxygen are not excluded, two other products, **13** and **30**, are also formed. A rationalization of these reactions is offered which takes into account subtle differences in migratory aptitudes.

Le dimère **1** de l'hydroxy-3 diméthyl-2,3 indolénine se réarrange, en milieu acide, en **4** puis en **7***a* via **6**; **7***a* est scindé dans ces conditions en diméthyl-2,3 indole (**2**) et formyl-2 méthyl-3 indole (**3**). Si des précautions pour exclure les peroxydes et l'oxygène ne sont pas prises, deux autres produits, **13** et **30** sont aussi formés. La rationalisation proposée pour ces réactions fait appel à des différences subtiles dans les aptitudes migratrices des groupes.

Canadian Journal of Chemistry, 49, 1921 (1971)

During the accumulation of evidence for the structure **1** of the dimer ($C_{20}H_{22}N_2O_2$) of 3-hydroxy-2,3-dimethylindolenine presented in the preceding paper (1), the dimer was treated with acid (2). With hot hydrochloric acid in an organic co-solvent or with phosphoric acid the major products were 2,3-dimethylindole (**2**) and 2-formyl-3-methylindole (**3**), as noted by Berti *et al.* (3), with varying amounts of another crystalline compound ($C_{20}H_{20}N_2O_2$, m.p. 217°) formed if oxygen and/or traces of organic peroxides were present (see later).[2] In peroxide-free co-solvent and the absence of oxygen, the yield of equimolar amounts of **2** and **3** was nearly quantitative (t.l.c.). However, with dilute hydrochloric acid at room temperature, t.l.c. (benzene–ether 50:50) revealed intermediates (2). After about 1 h the only product detectable, **A** (R_f 0.34), was more polar than the dimer **1** (R_f 0.62). After longer periods (~3 h) another less polar compound **B** (R_f 0.46) appeared as well as the ultimate products **2** (R_f 0.81) and **3** (R_f 0.71). Compounds **A** and **B** are probably intermediates on the reaction path from the dimer **1** to **2** and **3** because pure **A** was shown to be transformed into **B**, **2** and **3** without any noticeable amount of dimer being reformed. Furthermore **B** was converted into **2** and **3** without any dimer or **A** becoming evident on t.l.c.

The structure of **B** was determined to be **7***a* in the following way. Initially it was a liquid which was purified through the crystalline *O*-acetate **7***b*, m.p. 175°, to obtain crystals, m.p. 169°, whose u.v. absorption contained both indole and indoline chromophores (Fig. 1). The compound was a secondary alcohol (δ_{CHOH} 5.00 → δ_{CHOAc} 6.31) with an indoline NH and three unsplit methyl groups, one of which (δ 2.35) was attached to the indole heterocyclic ring (Fig. 2*b*), thus accounting for all of its non-aromatic hydrogen atoms. Moreover, the n.m.r. spectrum of this alcohol prepared from the hexadeuterio dimer (1) lacked two methyl peaks, one being the indolic methyl. With this information plus the dual requirements that the action of acid on the dimer monoacetate **8** give *N*-acetyl indole and the aldehyde **3** (Scheme 1), and that acid treatment of the alcohol **B** yield **2** and **3**, there were only two reasonable structural possibilities, **7***a* or **15**. These isomers were distinguishable through their desoxy derivatives. Alcohol **B** could be converted by two different routes (Scheme 2) into its desoxy derivative, m.p. 126°, whose formation is, therefore, unlikely to have involved rearrangement. Firstly, sodium – *t*-butyl alcohol hydrogenolysis of alcohol **B** yielded the desoxy compound (either **10***a* or **18**) directly. Secondly, alcohol **B** was oxidized by the chromic acid – pyridine reagent to a pale yellow ketone, subsequently found to be **11**, m.p. 194°, which on mild Wolff–Kishner reduction at 155° gave, as the only product, the same desoxy compound, m.p. 126°. By direct comparison this desoxy derivative was *not* identical with a sample

[1]Presented in part at the 52nd Conference of the Chemical Institute of Canada, Montreal, Quebec, May 25–28, 1969.

[2]A fourth compound was occasionally isolated if peroxides were not excluded, and it is also discussed later.

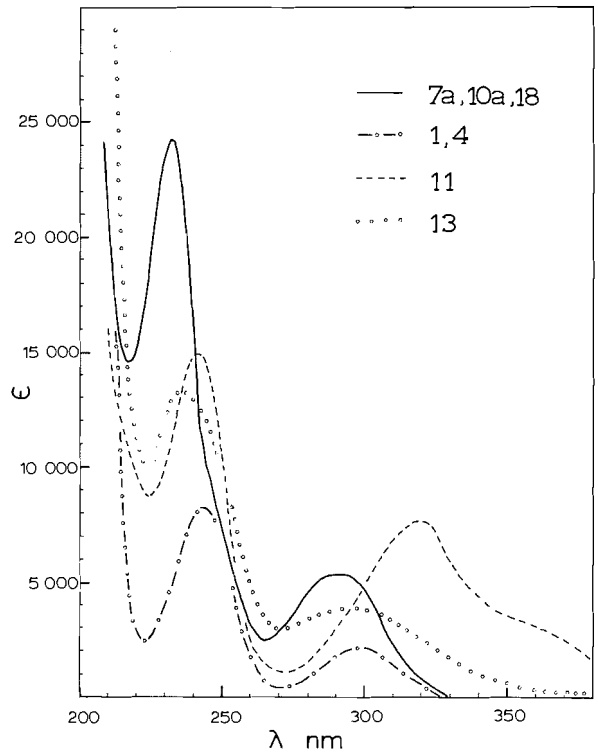

FIG. 1. The u.v. spectra of dimer **1** transformation products.

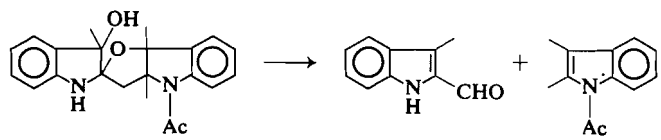

8 **3**

SCHEME 1

of **18**, m.p. 194°, prepared by the unambiguous synthesis of Berti *et al.* (4), which employs the Grignard reagent from 2,3-dimethylindole in a nucleophilic displacement of the pyridinium group of **16** (Scheme 3). (See Fig. 2*d* and *e* for the n.m.r. spectra of the two compounds.)

Although both **10***a* and **18** can exist as *cis* and *trans* racemates, the desoxy compound of m.p. 126° cannot differ from the synthetic compound **18** in stereochemistry alone. The formation of **18** occurs by closure of the central ring in a reversible reaction, amine addition to an imine, and results in the more stable, presumably *cis*, 5/5 ring fusion. If the alcohol precursor of the 126° desoxy compound, which alcohol is also formed by closure of the central ring, had had the structure **15**, it would also have been formed by the same reversible reaction and would necessarily have the same ring configuration as the synthetic desoxy compound **18**. Therefore, the 126° desoxy derivative must possess the other structure **10***a*. This assignment was confirmed by demonstrating that the 126° compound **10***a* did not undergo deuterium exchange under the same conditions that Berti's 194° compound **18** did incorporate deuterium into the methyl group (δ 1.79) adjacent to the potential imine (see **17**).

The initial, more polar compound **A** formed in acid is identical by direct comparison with the boron fluoride isomerization product of the dimer **1** reported by Berti *et al.* (3), whose procedure is the better preparative method. The u.v.

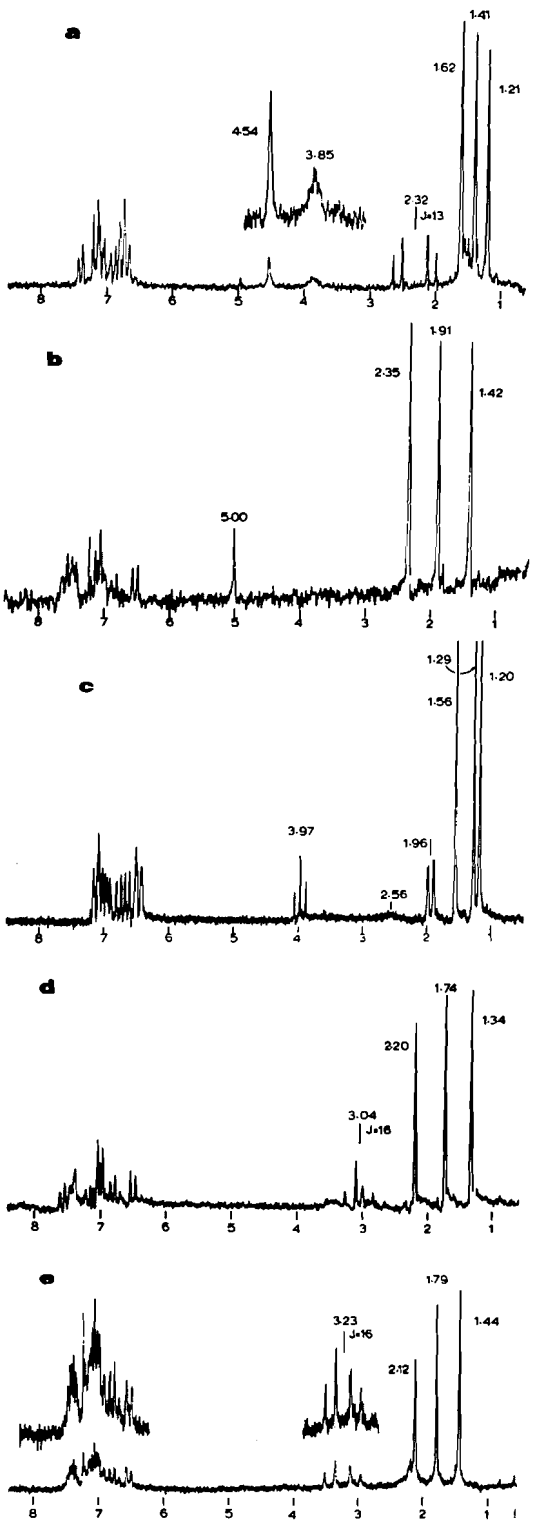

FIG. 2. The n.m.r. spectra ($CDCl_3$, 100 MHz) of diol **4** (*a*), alcohol **7***a* (*b*), sodium borohydride product **9** (*c*), 126° desoxy compound **10***a* (*d*), and Berti's 194° desoxy compound **18** (*e*).

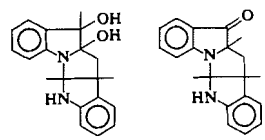
spectrum (Fig. 1) contains two indoline chromophores while the n.m.r. spectrum (Fig. 2*a*) contains three unsplit methyl peaks and a methylene AB pattern. Intermediate **A** shows the properties of a carbinolamine in that it is readily reduced by sodium borohydride with loss of one oxygen atom. This borohydride product **9** (see Fig. 2*c* for the n.m.r. spectrum) is very sensitive to acid and readily loses a molecule of water to generate the 126° desoxy compound **10***a* encountered above. Acetylation of the borohydride product under mildly basic conditions also resulted in dehydration and formation of the *N*-acetyl derivative **10***b* of the 126° desoxy compound. It is unlikely that skeletal rearrangement occurred during the borohydride reduction or the acetylation,[3] and consequently the initial diol must be assigned structure **4** instead of the alternative **19** proposed by Berti *et al.* (3). It follows that the yellow indoxyl that is formed readily from diol **4** on heating or treatment with base must be **14** rather than **20** proposed by the same group (3).[4]



19 **20**

The vicinal relationship of the two hydroxyl groups in **4** was demonstrated by sodium periodate oxidation. Surprisingly, the same crystalline compound, $C_{20}H_{20}N_2O_2$, m.p. 217°, was obtained that was formed during acid treatment of the dimer in the presence of oxygen or peroxides (see above). Previously, the n.m.r. spectrum of this compound from the acid reaction had been very puzzling, but this second method of preparation provided the clue needed to realize that it must indeed be the ketone **13**. The i.r.

[3]However, acetylation of the diol **4**, which cannot be readily dehydrated to an indole, does proceed with rearrangement since the *O*,*N*-diacetate **7***c* of alcohol **B** was obtained.

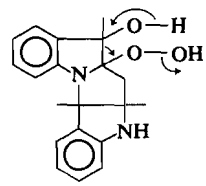
[4]The structure of the indoxyl *N*-nitroso compound prepared by this group (3) must also be re-assigned; structure **14** with N–NO in place of NH would fit the reported n.m.r. effects on the methylene and (one) methyl groups.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

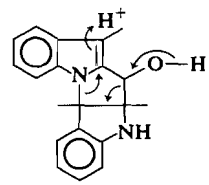
spectrum contained both carbonyl (1680 cm^{-1})[5] and amino (3390 cm^{-1}) absorption. In the u.v. spectrum (Fig. 1) there were indoline and *o*-acylaminobenzoyl chromophores. The non-aromatic region of the n.m.r. spectrum in deuteriochloroform contained two narrow unsplit quaternary methyl signals (δ 1.35 and 1.52), a methylene AB pattern (δ 2.70 and 2.87, J = 17 Hz), an indoline NH (δ 4.18), but instead of a sharp three-proton singlet for the acetyl methyl group there was only a broad three-proton lump centered at δ 2.25. The explanation for this remarkable observation lies in rotation of the acetyl and heterocyclic groups being substantially hindered by their *o*-relationship. At 37° the deuteriochloroform solution is coincidentally near the coalescence point for conformations of the acetyl methyl group which have appreciably different chemical shifts due to varying anisotropic effects, and the absorption for this group is a broad ill-defined pattern. This signal is absent in the spectrum of **13** prepared from the hexadeuterio dimer in which the acetyl methyl is now a CD_3 group. A variable temperature study, the effects of various solvents, and the results of additional chemical experiments all fully confirm this interpretation.[6] Ketone **13** is also formed by periodate oxidation of the desoxyindole **10***a* according to Dolby's procedure (6). This transformation completes a web of reactions inter-relating compounds **4**, **7**, **9**, and **10** and providing assurance that they all have the same C, H, N skeleton.

The origin of the same ketone **13** during the acid-catalyzed rearrangement of the dimer is understandable after the first stage of the reaction sequence. The carbinolamine **4** on loss of hydroxide ion could then undergo addition of any hydroperoxide present (or formed by air oxidation during reaction) to form **21**. Breakdown as indicated would yield the keto pyrrolidone **13** just as Witkop and Patrick (5) have found for the reaction of hydroxyindolenines with peracid. In fact, when precautions were taken to exclude both oxygen and peroxides in the solvent, no **13** was formed in the acid-catalyzed reaction.

The evidence presented above strongly supports the probable sequence of reactions (Scheme 2) for the acid-catalyzed reaction to be rearrangement of the dimer **1** to diol **4**, dehydration of the carbinolamine to the enamine **6** (postulated) via **5**, allylic rearrangement of the enamine to the indole alcohol **7***a* (well precedented by the work of Taylor (7)), and finally cleavage of the alcohol as indicated in **31** to 2,3-dimethylindole (**2**) and 2-formyl-3-methylindole (**3**). This mechanism is



21



31

supported by the fact that rearrangement of the dimer in DCl–D_2O gives alcohol **7***a*-d_1 (see Scheme 4) with the deuterium atom on the carbon atom bearing the hydroxyl group, and this alcohol is further transformed by phosphoric acid into 2-formyl-3-methylindole-d_1 bearing the deuterium atom in the aldehyde function.

Although the overall driving force toward the cleavage products is the reformation of two stable indole systems from the dimer, it must be asked why, with such good grounds for divorce, the partners of this union choose this roundabout route (**1** → **4** → **5** → **6** → **7***a* → **2** + **3**) to sever relations when there is an apparently more direct way (**1** → **22** → **23** → **24** → **2** + **3**, Scheme 5) that does not involve formation of a new N–C bond. Part of the answer is that the carbinolamine ether ring is more reluctant to open and enolize than might be expected, perhaps due to the intramolecular hydrogen bonding of OH and NH groups (8). The dimer was not affected by sodium borohydride in refluxing methanol, although it was reduced to the dihydroderivative **26** by lithium aluminum hydride (3). The dimer slowly incorporates up to two *C*-deuterium atoms in refluxing methanol-*O*-d_1 containing sodium methoxide (~20% deuteration in 12 h, but with no rearrangement to indoxyl detectable by n.m.r.

[5]The carbonyl absorption of *N*-phenylpyrrolidone is at 1684 cm^{-1} and the ketone carbonyl absorption of *o*-acetamidoacetophenone is at 1650 cm^{-1}. The model compound **i** has a single carbonyl peak at *ca.* 1670 cm^{-1} (5).

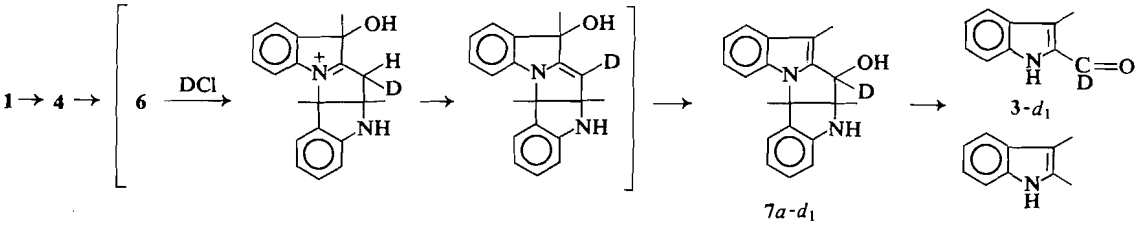
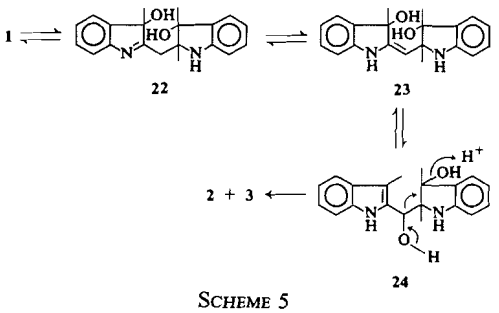


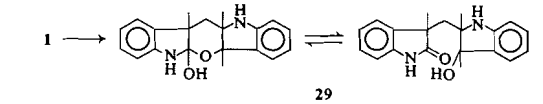
SCHEME 4



SCHEME 5

in this time).[7] In dilute deuteriochloric acid – acetone-d_6 solution when rearrangement was allowed to proceed part way, only 15% of the recovered dimer had incorporated *C*-deuterium atoms after ½ h at room temperature. The observed slow rates of the forward steps leading to **22** and **23** together with the fast back reactions (undetectable equilibrium concentration of **22** and **23** in n.m.r. solutions of **1**) and the slowness of the allylic rearrangement **23** → **24** (*cf.* the slow rate of **4** → **6** → **7***a*), all combine to allow the alternative rupture of one of the benzylic oxygen bonds to become a competitive process.

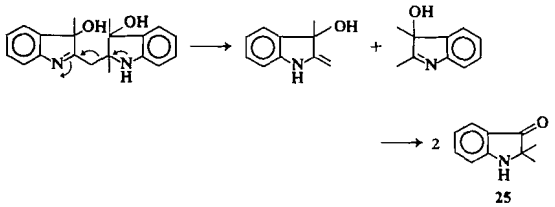
Loss of a protonated hydroxyl group from the dimer should lead by migration of the adjacent *trans*-situated methylene group to **29** (or a transformation product thereof) (Scheme 6), which was not found among the products of the acid treatment. However, in the absence of anchimeric



SCHEME 6

assistance the loss of this hydroxyl group might be slower than scission of the protonated benzylic ether bond because of the additional electronegative substituent in the β-position with respect to the hydroxyl group. Once the benzylic ether bond is broken, the subsequent attachment of nitrogen to form the five-membered ring of **4** is expected,[8] and the remainder of the route to **2** and **3** is thereby fixed. This ring closure takes place *without* migration of the methylene group from the 2- to the 3-position, probably because the migrating efficiency of the methylene group with an adjacent carbinolamine (or imine) function is reduced. Nevertheless, $C_2 \rightarrow C_3$ migration can occur when the methylene group has fewer electronegative groups nearby as in Berti's dihydrodimer **26** from lithium aluminum hydride reduction of **1**. On heating (3) or treatment with acid (see Experimental) this compound undergoes loss of water, rearrangement, and ring closure (**26** → **18**, Scheme 7). The migrating group is either the β-aminomethylene of **26** or, more likely, the methylene of **27** resulting from loss of the first molecule of water because this same indole **27** obtained in the sodium – *t*-butanol reduction of the dimer also undergoes dehydration with migration of the benzylic methylene group (**27** → **28** → **18**) on standing in chloroform solution (1).[9]

[7]However, heating the dimer to its melting point does result in rearrangement to a mixture of indoxyl **14** and the decomposition product 2,2-dimethylindoxyl (**25**) (1). The decomposition is presumably initiated by a retro Mannich reaction:



This behavior probably accounts for the dimer's wide and variable melting point.

[8]Ring formation cannot be a concerted S_N2 displacement of the protonated ether because inversion at the carbon atom undergoing displacement cannot occur so long as the carbinolamine ether is intact.

[9]Several of the compounds in the present work (**9**, **26**, **27**, and the most polar sodium – *t*-butanol reduction product from **1** (1)) were unstable in chloroform solution due to dehydration and rearrangement presumably catalyzed by hydrogen chloride formed either on exposure of these solutions to light or else from reaction of a basic nitrogen atom with the chloroform.

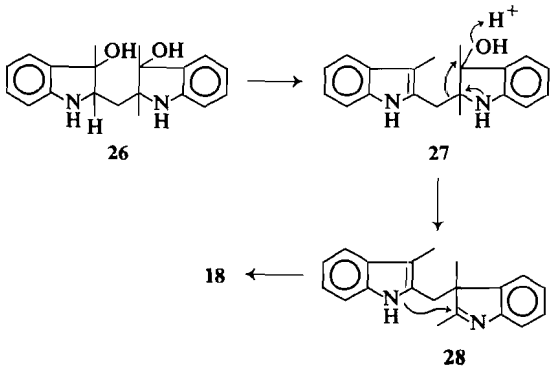
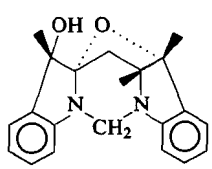


SCHEME 7

The relative stereochemistry of these compound can now be specified. When the dimer rearranges to **4**, only the *cis* stereochemistry of the fused pyrrolidine rings would be expected to result, and the all *cis* orientation of the methyl groups of **1** (8) would therefore become the *trans,trans,cis* arrangement shown in **4** after the required rotation of the right hand indoline moiety of **1**. For the two alcohol stereoisomers **7***a* and **12** which are epimeric only at the hydroxyl-bearing carbon atom, the stereochemistry depicted is assigned because formation of an alcohol by allylic rearrangement of **6** should occur by attack of water at the less hindered side of the carbon atom away from the fold of the molecule, while the hydroxyl group resulting from hydride reduction of ketone **11** should be in the more hindered position because hydride is donated to the less protected side.

The earlier mentioned second artifact found when peroxides were not excluded from the acid treatment of dimer in dioxane co-solvent proved to be **30**, a molecule of 2,3-dimethylindole and one of 2-formyl-3-methylindole joined at the nitrogen atoms by a methylene bridge presumably from formaldehyde or its precursor. Since treatment of these two indoles **2** and **3** with formaldehyde and acid gave no **30**, the two nitrogen atoms must have been joined earlier in the reaction sequence. When dimer **1** was treated with formaldehyde under the conditions for the acid-catalyzed rearrangement, it was changed completely into **30** within 15 min, much faster than the rearrangement sequence. However, under milder conditions (more dilute acid, shorter reaction time) the dimer was converted exclusively into the crystalline homo compound **32**. The formation of this product is not surprising in view of the stereochemistry of the dimer (8, 1). Acid treatment of **32** gave **30** quantitatively. Although the product is basically **2** + **3**, this latter rearrangement cannot take place by the path established for the dimer itself, and presumably occurs by some variation of it. The reaction was not investigated further.



32

Experimental[10]

Cleavage of Dimer 1 by Phosphoric Acid

To a solution of the dimer (200 mg) in warm 95% ethanol (5 ml) was added 85% H_3PO_4 (3.5 ml). The solution, which immediately became a cherry red to dark brown color, was stirred at room temperature for 2.5 h. The reaction mixture was diluted with water and extracted with ether. Evaporation of the water-washed and dried ethereal solution left 193 mg (~100%) of yellowish solid whose t.l.c. (benzene–ether, 1:1) had only two spots corresponding to **2** and **3**. The crude product was chromatographed on alumina (5 g). Petroleum ether eluted 65 mg of colorless crystalline **2,3-dimethylindole** (**2**). Petroleum ether – benzene (1:1) eluted 85 mg of **2-formyl-3-methylindole** (**3**), m.p. 137–140° (lit. (9) m.p. 139–140°) after two recrystallizations from chloroform – petroleum ether; ν_{max} 3550 (NH) and 1650 cm^{-1} (conj. C=O); λ_{max} 241 (4000) and 315 nm (6500).

Preparation of the Diol 4

(a) By the Action of Hydrochloric Acid on Dimer 1

To a stirred solution of the dimer (1.00 g) in acetone (25 ml) was added a solution of 0.1 *N* HCl (2 ml) and acetone (5 ml). After 1 h at room temperature the yellow solution was diluted with water and extracted with ether. The organic layer was dried and concentrated to leave 1.10 g of a pale yellow liquid whose t.l.c. had only two spots corresponding to **4** and **1**. Chromatography on four thick layer plates developed in benzene–ether (50:50) and ether extraction of the band at R_f 0.33 gave 220 mg of pale yellow oil. Further purification of this material on three thick-layer plates gave 85 mg (8.5%) of almost colorless oil which solidified. Recrystallization from ether – petroleum ether (b.p. 30–60°) gave colorless crystals of the **diol 4**, m.p. 115–125° (dec.).

Anal. Calcd. for $C_{20}H_{22}O_2N_2$ (322.4): C, 74.51; H, 6.88; N, 8.69. Found: C, 75.15; H, 7.14; N, 8.54.

The i.r., u.v., and n.m.r. spectra were identical with those of the compound prepared with boron trifluoride in section *b* below.

A yellow band (R_f 0.58) on some of the t.l.c. plates was found to contain the indoxyl **14**, m.p. 190–196° (lit. (3) m.p. 200–210°) after recrystallization from chloroform –

[10]For general experimental methods see the preceding paper (1). The n.m.r. data are given in Table 1.

TABLE 1. The n.m.r. data exclusive of aromatic protons*

Compound	Absorption
Diol **4**	1.21 (s, 2-Me), 1.41 (s, 3-Me), 1.62 (s, 3-Me), 2.08 and 2.56 (AB of CH_2, J = 13), 3.85 (NH), 4.54 (OH)
Diol **4**-d_6	1.21 (s, 2-Me), 2.08 and 2.56 (AB of CH_2, J = 13) [spectrum too weak to see NH and OH]
$NaBH_4$ product **9**	1.20 (s, 2-Me), 1.29 (s, 3-Me), 1.56 (s, 3-Me), 1.96 (center of complex AB of CH_2), 2.56 (b, OH or NH), 3.65 (v.b, NH or OH), 3.97 (center of 1H 3-line pattern, 9Hz spacing)
Alcohol **7***a*	1.42 (s, 2-Me), 1.91 (s, 3-Me), 2.35 (s, indole Me), 5.00 (s, C*H*OH) [OH and NH too broadened to be noticeable]
Alcohol **7***a*-d_6	1.41 (s, 2-Me), 5.00 (s, C*H*OH)
Alcohol **7***a*-d_1	Same as spectrum of alcohol **7***a* except that the 1H peak at δ 5.00 missing
O-Acetate **7***b*	1.31 (s, 2-Me), 1.91 (s, 3-Me), 2.08 (s, OCOMe), 2.27 (s, indole Me), 4.00 (NH), 6.31 (s, C*H*OAc)
N-Acetate **7***d*	1.68 (s, 2-Me), 1.95 (s, 3-Me), 2.31 (s, indole Me), 2.42 (s, NCOMe) [spectrum too weak to locate C*H*OH]
O,*N*-Diacetate **7***c*	1.62 (s, 2-Me), 1.98 (s, 3-Me), 2.10 (s, OCOMe), 2.30 (s, indole Me or NCOMe), 2.35 (s, NCOMe or indole Me), [C*H*OAc indistinguishable among aromatic protons]
Alcohol **12**	1.35 (s, Me), 1.75 (s, Me), 2.33 (s, indole Me), 3.02 (2H, NH + OH), 5.00 (s, C*H*OH)
O-Acetate of **12**	1.47 (s, Me), 1.85 (s, Me), 2.05 (s, OCOMe), 2.23 (s, indole Me), 4.30 (NH), 6.12 (s, C*H*OAc)
Ketone **11**	1.49 (s, Me), 2.01 (s, Me), 2.54 (s, indole Me), 4.70 (NH)
126° Desoxy compound **10***a*	1.34 (s, 2-Me), 1.74 (s, 3-Me), 2.20 (s, indole Me), 2.96 and 3.12 (AB of CH_2, J = 16) [NH not observable]
N-Acetate of 126° compound **10***b*	1.62 (s, 2-Me), 1.75 (s, 3-Me), 2.18 (s, indole Me), 2.31 (s, NCOMe), 3.08 and 4.34 (AB of CH_2, J = 17)
194° Desoxy compound **18**	1.44 (s, 3-Me), 1.79 (s, 2-Me), 2.12 (s, indole Me), 3.06 and 3.42 (AB of CH_2, J = 16) [NH not observable]
Ketone **13**	1.35 (s, Me), 1.52 (s, Me), 2.25 (b.l. COMe), 2.70 and 2.87 (AB of CH_2, J = 17), 4.18 (NH)
Ketone **13**-d_6	1.35 (s, Me), 2.70 and 2.87 (AB of CH_2, J = 17), 4.18 (NH)
Indoxyl **14**	1.17 (s, Me), 1.41 (s, Me), 1.43 (s, Me), 2.02 and 2.16 (AB of CH_2, J = 13), 3.72 (b, NH)
Dihydrodimer **26** (Pyridine solution)	1.28 (s, Me), 1.41 (s, Me), 1.59 (s, Me), 2.16 and 2.74 (AB of CH_2, J = 13), 4.28 (1H, X of ABX, $J \sim 6$, ~ 6)
Homodimer **32**	1.21 (s, 2-Me), 1.50 (s, di-3-Me), 2.10 (s, CH_2), 3.30 (s, OH), 4.10 and 4.59 (AB of NCH_2N, J = 11)
The methylene bis indole **30**	2.13 (s, di Me), 2.61 (s, Me), 6.80 (s, NCH_2N) 10.00 (s, CHO)

*Chemical shifts are given in p.p.m. from tetramethylsilane (δ) and coupling constants in Hz; $CDCl_3$ solutions unless otherwise specified; 2-Me and 3-Me signify that the methyl group giving rise to the absorption originated from a 2- or 3-methyl group of 2,3-dimethylindole, respectively; s = singlet, d = doublet, b = broad absorption, l = lump.

petroleum ether. The i.r. and n.m.r. spectra were identical with those reported (3).

(b) By the Action of Boron Trifluoride on Dimer **1**

The procedure is that of Berti *et al.* (3), slightly modified. A solution of dimer (200 mg) in chloroform (20 ml) was chilled in an ice-salt bath and treated with a mixture of boron trifluoride etherate (0.2 ml) and chloroform (0.2 ml). After 5 min the yellow reaction mixture was diluted with 2 *N* Na_2CO_3 solution and extracted with ether. The pale yellow oil (185 mg) obtained after evaporation of the water-washed and dried organic layer was chromatographed on a thick plate developed with benzene–ether (50:50). Extraction of the band at R_f 0.32 gave 23 mg (11%) of almost colorless solid **4**. Recrystallization from ether – petroleum ether (b.p. 30–60°) gave colorless crystals, m.p. 114–125° (dec.) (lit. (3) m.p. 112–122° (dec.)); ν_{max} 3580, 3360, and 3340 (shoulder) cm^{-1} (NH and OH); λ_{max} 250 (8000) and 298 nm (3400).

(c) By the Action of Boron Trifluoride on Dimer **1**-d_6

The reaction was carried out on 54 mg of **1**-d_6 (1) as described in section *b*. There was obtained 53 mg of diol **4**-d_6 (90% pure by t.l.c.) whose n.m.r. spectrum was lacking the methyl peaks at δ 1.41 and 1.62 of the protio analog.

Borohydride Reduction of Diol **4**

A solution of the diol (35 mg), methanol (6 ml), and $NaBH_4$ (50 mg) was allowed to stand at room temperature for 4 h. The methanol was removed at reduced

For personal use only.

pressure, and the residue was treated with water. Extraction with chloroform yielded 37 mg of colorless oily solid after evaporation of the water-washed and dried solution. The t.l.c. gave a single spot slightly more polar than **4**. Recrystallization from ether – petroleum ether (b.p. 30–60°) gave colorless crystals of **9**, m.p. 128–140°; ν_{max} 3575 (OH) and 3380 cm^{-1} (NH); λ_{max} 247 (8800) and 295 nm (5100).

Anal. Calcd. for $C_{20}H_{22}N_2O$ (306.4): C, 78.40; H, 7.24; N, 9.14. Found: C, 78.77; H, 7.31; N, 9.06.

When a chloroform solution of **9** was allowed to stand in an open vessel at room temperature for 3 days, it was found to have been dehydrated to **10***a*. The n.m.r. spectrum, m.p., mixed m.p., and t.l.c. behavior were identical with that of authentic **10***a*.

Acetylation of Borohydride Product **9**

A mixture of the borohydride reduction product (100 mg), sodium acetate (100 mg), and acetic anhydride (2.0 ml) was heated at 140° (bath temperature) for 12 h. The cooled mixture was added to 5% $NaHCO_3$ solution and extracted with chloroform. The organic layer was washed with water, dried, and evaporated to leave 104 mg (96%) of yellowish solid which was essentially pure (t.l.c.). Recrystallization from chloroform – petroleum ether gave colorless crystals of the **N-acetyl desoxy compound 10***b*, m.p. 273–275°; ν_{max} 1637 cm^{-1} (amide C=O); λ_{max} 232 (18 000), 285 (8900), and 290 nm (4400); *m/e* 330 (molecular ion).

Anal. Calcd. for $C_{22}H_{22}N_2O$ (330.4): C, 79.97; H, 6.71; N, 8.48. Found: C, 79.90; H, 6.31; N, 8.48.

Preparation of the Alcohol 7a

(a) From Dimer and Hydrochloric Acid

To a stirred (magnetic bar) solution of the dimer **1** (100 mg) in *p*-dioxane (2.5 ml Baker Analyzed freshly distilled from $LiAlH_4$) under a nitrogen atmosphere was added at room temperature a solution of 0.1 *N* HCl (0.2 ml) in the same dioxane (0.2 ml). The solution immediately became pale yellow changing successively to dark yellow, pale brown, and finally dark brown. After 5.5 h the reaction mixture was diluted with chloroform, washed once with water, dried, and concentrated at reduced pressure to leave 102 mg of brownish black viscous liquid. Chromatography on a thick plate developed with benzene–ether (75:25) gave a band (R_f 0.66) from which 15 mg of pale yellow oil was isolated. The n.m.r. spectrum of this fraction revealed it to be a mixture of the dimer **1**, 2-formyl-3-methylindole (**3**), and an unknown component. From a band with R_f 0.39 was extracted 51 mg (54%) of pure (t.l.c.) almost colorless liquid **alcohol 7***a*. Attempts to induce crystallization were unsuccessful. However, the crystalline compound was obtained by saponification of the crystalline *O*-acetate (see below) with sodium hydroxide in methanol at room temperature. The oily solid from the saponification was recrystallized from methanol to give colorless crystals of **7***a*, m.p. 162–169°; ν_{max} 3585 (OH) and 3380 cm^{-1} (NH); λ_{max} 232 (25 000) and 297 nm (6300); *m/e* 304 (molecular ion).

Anal. Calcd. for $C_{20}H_{20}N_2O$ (304.4): C, 78.92; H, 6.62; N, 9.20. Found: C, 78.77; H, 7.03; N, 9.09.

The n.m.r. and i.r. spectra as well as the t.l.c. behavior of the crystalline material were identical with those of the liquid alcohol obtained from the reaction with HCl.

Essentially the same results were obtained when acetone was used in place of dioxane as the organic cosolvent. If reagent grade *p*-dioxane was used without purification for the reaction, varying amounts of two other compounds were formed in addition to the alcohol **7***a* when the reaction was conducted under a nitrogen atmosphere. One of these appeared in the least polar t.l.c. band (R_f 0.85) whose extraction yielded a pale yellow solid which was recrystallized from petroleum ether to give very pale yellow clusters of needles of **30**, m.p. 146–147.5°; ν_{max} 1650 cm^{-1} (conj. C=O), NH absorption absent; λ_{max} 230 (25 000) and 315 nm (13 000); *m/e* 316 (molecular ion).

Anal. Calcd. for $C_{21}H_{20}N_2O$ (316.4): C, 79.72; H, 6.37; N, 8.85. Found: C, 79.15; H, 6.40; N, 8.69.

A second artifact, the ketone **13**, is described later.

(b) From Diol **4**

To a stirred (magnetic bar) solution of the diol (~90% pure by t.l.c.) (35 mg) in acetone (1.5 ml) was added a solution of 0.1 *N* HCl (0.2 ml) in acetone (0.5 ml). After 4 h at room temperature during which the color of the solution changed from yellow to pink to brown to almost black, most of the solvent was removed at reduced pressure on the rotary evaporator. A chloroform solution of the residue was washed with water, dried, and evaporated to leave 27 mg of clear amber liquid whose i.r. and n.m.r. spectra as well as t.l.c. behavior were identical with those of **alcohol 7***a* prepared in section *a* above.

(c) From Dimer **1** *and Deuteriochloric Acid*

To a stirred (magnetic bar) solution of the dimer **1** (80 mg) in dioxane (1 ml, freshly distilled from $LiAlH_4$) was added a solution of 0.1 *N* DCl in D_2O (0.25 ml). The solution was kept at room temperature for 3 h, then diluted with chloroform, washed with water, dried, and evaporated. The 72 mg of residual brown oil was chromatographed on a thick plate developed in benzene – petroleum ether (75:25). Extraction of the band at R_f 0.34 gave 18 mg (24%) of the liquid **alcohol 7***a*-d_1 whose n.m.r. spectrum lacked the carbinyl proton (< 5%) present at δ 5.00 in the protio compound. The crystalline acetate, m.p. 173–177° was prepared for mass spectroscopy; *m/e* 347 (molecular ion corresponding to monodeuteration).

Phosphoric Acid Cleavage of Alcohol 7a-d_1

To a stirred (magnetic bar) solution of monodeuterio alcohol **7***a*-d_1 (140 mg) in 95% ethanol (2 ml) was added 85% H_3PO_4 (1 ml), and the reaction mixture was kept at room temperature for 3 h. The solution was diluted with ether, washed twice with water, dried, and concentrated to 118 mg of brown oily solid. The t.l.c. in benzene–ether (50:50) gave only two spots which corresponded to **2** and **3** in about equal amounts. Chromatography on alumina (5 g) gave 20 mg of colorless 2,3-dimethylindole (**2**) from the petroleum ether eluates. Elution with petroleum ether – benzene (50:50) gave 52 mg (70%) of pale yellow solid 2-deuterioformyl-3-methylindole (**3**-d_1). Recrystallization gave colorless plates, m.p. 137–140°; *m/e* 160 (molecular ion corresponding to monodeuteration), whose n.m.r. spectrum lacked the formyl proton.

Elution with chloroform yielded 42 mg of brown oily solid whose t.l.c. behavior and n.m.r. spectrum showed it to be the dimer **1**, presumably formed by air oxidation of the 2,3-dimethylindole.

For personal use only.

*Reaction of Dimer Monoacetate **8** with Acid*

A solution of **8** (200 mg), acetone (4 ml), and HCl (0.8 ml of 0.1 *N* aqueous HCl) was refluxed for 2 h. Evaporation of the acetone and partition of the residue between chloroform and water gave 180 mg of crude product which was chromatographed on two thick plates developed with benzene–ether (88:12). The band at R_f 0.71 yielded 15 mg of colorless crystalline *N*-acetyl-2,3-dimethylindole identical with an authentic specimen. The band at R_f 0.53 yielded 7 mg of colorless crystalline 2-formyl-3-methylindole (**3**) identical with an authentic specimen. More polar products (48 mg) on the base line had a complex n.m.r. spectrum and were not investigated further.

O-Acetate of Alcohol 7a

A solution of the liquid alcohol (55 mg), pyridine (0.5 ml), and acetic anhydride (0.5 ml) was allowed to stand at room temperature for 5 h. After the addition of chloroform, the reaction mixture was washed with water, dried, and concentrated to leave 72 mg of a brown viscous oil. Chromatography on alumina (3 g) gave a white solid on elution with petroleum ether – benzene (80:20). Recrystallization from methanol – petroleum ether gave 23 mg (38%) of colorless crystals of 7*b*, m.p. 172–175°; ν_{max} 3371 (NH), and 1732 cm^{-1} (*O*-acetate C=O); λ_{max} 230 (26 000) and 295 nm (7000); *m/e* 346 (molecular ion).

Anal. Calcd. for $C_{22}H_{22}N_2O_2$ (346.4): C, 76.28; H, 6.40; N, 8.09; O, 9.24. Found: C, 76.81; H, 6.26; N, 8.29; O, 9.22.

N-Acetate of Alcohol 7a

To a solution of the *O,N*-diacetate 7*c* (180 mg) in a mixture of methanol (3 ml) and dioxane (3 ml) was added sodium hydroxide (3 pellets) with stirring at room temperature. Within 15 min solid began to precipitate. After 30 min water was added, and the mass was extracted with chloroform. The organic layer was washed with water, dried, and concentrated to leave 135 mg of pale yellowish solid. Recrystallization from chloroform–methanol gave colorless crystals of pure 7*d*, m.p. 268–280°; ν_{max} (Nujol) 3280 (OH) and 1625 cm^{-1} (amide C=O); *m/e* 346 (molecular ion).

Anal. Calcd. for $C_{22}H_{22}N_2O_2$ (346.4): C, 76.28; H, 6.40; N, 8.09. Found: C, 76.53; H, 6.32; N, 7.89.

O,N-Diacetate of Alcohol 7a

*(a) From Diol **4***

A mixture of the diol (320 mg), pyridine (5 ml), sodium acetate (320 mg), and acetic anhydride (2 ml) was heated at 120° for 17 h. The cooled reaction mixture was added to 5% aqueous $NaHCO_3$ and extracted with chloroform. The organic layer was washed with water, dried, and evaporated to give 327 mg of a brown solid. Recrystallization from chloroform–methanol gave 78 mg of colorless crystals of the *O,N*-diacetate 7*c*, m.p. 245–252° (capillary sealed under vacuum); ν_{max} 1735 (*O*-acetate C=O) and 1650 cm^{-1} (amide C=O); *m/e* 388 (molecular ion).

Anal. Calcd. for $C_{24}H_{24}N_2O_3$ (388.5): C, 74.21; H, 6.23; N, 7.21. Found: C, 74.42; H, 6.33; N, 7.10.

(b) From Alcohol 7a

A mixture of alcohol (70 mg), pyridine (1 ml), sodium acetate (70 mg), and acetic anhydride (0.5 ml) was heated at 120° for 17 h. Work-up as in section *a* gave 68 mg of viscous brown oil which was chromatographed on a thick plate developed with benzene–ether (50:50). The band at R_f 0.60 yielded 31 mg (47%) of colorless solid. On recrystallization from chloroform – petroleum ether there was obtained 18 mg of colorless crystals of 7*c*, m.p. 245–250° (capillary sealed under vacuum), undepressed on admixture with the sample prepared from the diol **4** in section *a*. The two samples had identical i.r., n.m.r., and t.l.c. data.

(c) Saponification

A solution of the *O,N*-diacetate 7*c* (30 mg), NaOH (2 pellets), methanol (2 ml), and dioxane (2 ml) was refluxed for 4 days. After evaporation of solvent and addition of water, the product was extracted with chloroform. The organic solution was washed with water, dried, and evaporated to leave 24 mg of pale yellow oily alcohol 7*a*, whose t.l.c. behavior and n.m.r. spectrum were identical with those of authentic alcohol 7*a*.

*Ketone **11***

(a) From Liquid Alcohol 7a

To a stirred solution of the liquid alcohol 7*a* (200 mg, 0.66 mmol) in pyridine (2 ml) at room temperature was added CrO_3 (200 mg, 2.00 mmol) during 5 min. After the mixture was stirred at room temperature for 24 h, it was partitioned between water and chloroform. The organic layer was washed with water, dried, and evaporated to leave 183 mg of a violet oil which was chromatographed on alumina (3 g). Elution with petroleum ether – benzene (80:20) afforded 48 mg (25%) of yellow solid **ketone 11**. Recrystallization from methanol gave 17 mg of pale yellow crystals, m.p. 192–194°; ν_{max} 3370 (NH) and 1690 cm^{-1} (conj. ketone); λ_{max} 242 (15 000) and 322 nm (8500); *m/e* 302 (molecular ion).

Anal. Calcd. for $C_{20}H_{18}N_2O$ (302.4): C, 79.44; H, 6.00; N, 9.26. Found: C, 78.76; H, 5.81; N, 9.53.

*(b) From $LiAlH_4$ Alcohol **12***

A solution of alcohol **12** (150 mg, 0.49 mmol) in pyridine (3 ml) was oxidized at room temperature by addition of CrO_3 (150 mg, 1.5 mmol) in the same procedure used in section *a* above. There was obtained 12 mg of pale yellow ketone **11**, m.p. 188–194°, identical (i.r., t.l.c., n.m.r., mixed m.p.) with the ketone prepared by oxidation of 7*a*.

*Desoxy Compound **10a***

*(a) By Wolff–Kishner Reduction of Ketone **11***

A mixture of ketone **11** (45 mg), hydrazine hydrate (0.7 ml), and diethylene glycol (1 ml) was heated at 155° (bath temperature) for 2.5 h. Then NaOH (2 pellets) was added, and heating was continued for 1.5 h more. The reaction mixture was partitioned between water and ether. The organic layer was washed with water, dried, and evaporated to leave 40 mg of a colorless oil whose t.l.c. showed a single spot less polar than ketone **11**. Further purification on a thick layer plate gave 36 mg of an oil which crystallized on trituration with petroleum ether. Recrystallization from petroleum ether gave colorless rosettes of **10***a*, m.p. 125–126°, ν_{max} 3470 cm^{-1} (NH); λ_{max} 232 (24 000) and 295 nm (4600); *m/e* 288 (molecular ion).

Anal. Calcd. for $C_{20}H_{20}N_2$ (288.4): C, 83.30; H, 6.99. Found: C, 83.56; H, 7.08.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

When the above reaction was carried out at 220°, the only product isolated was 2,3-dimethylindole (**2**).

(b) By Hydrogenolysis of Alcohol 7a

To a refluxing solution of alcohol **7***a* (160 mg) in *t*-butyl alcohol was added sodium metal (1 g). The mixture was refluxed for 9.5 h and then partitioned between water and ether. The ethereal extract was dried and concentrated to a brown oil (130 mg) which was chromatographed on a thick plate developed in benzene–ether (95:5). The band on the base line yielded 33 mg of recovered liquid alcohol **7***a*. Extraction of the band at R_f 0.55 gave 48 mg (32%) of almost colorless **desoxy compound 10***a*, m.p. 118–122° after recrystallization from ether – petroleum ether (b.p. 30–60°). The mixed m.p. with the specimen from the Wolff–Kishner reduction was 120–123°, undepressed. The i.r., n.m.r. and t.l.c. data were the same for both samples.

(c) By Saponification of the N-acetate 10b

A solution of the *N*-acetyl desoxy compound **10***b* (35 mg) and NaOH (2 pellets) in methanol (2 ml) – dioxane (2 ml) was refluxed for 12 h. After evaporation of the solvents, water was added and organic material was extracted with chloroform. The water-washed and dried organic solution was concentrated to leave 32 mg of a brown oil whose i.r. and n.m.r. spectra as well as t.l.c. behavior were identical with those of the desoxy compound **10***a*.

Deuteration of Desoxy Compounds

(a) Berti's 194° Desoxy Compound 18

A mixture of **18** (30 mg), methanol-*O*-d_1 (1.8 ml), and sodium methoxide (50 mg) protected from atmospheric moisture was refluxed for 10 h. The methanol was evaporated at reduced pressure and the residue was partitioned between chloroform and water to yield 30 mg of recovered **18** which was purified by recrystallization from chloroform – petroleum ether. In the n.m.r. spectrum the methyl peak at δ 1.79 had almost completely disappeared. Deuterium analysis by mass spectroscopy gave 2% d_0, 4% d_1, 15% d_2, 74% d_3, and 5% d_4.

(b) 126° Desoxy Compound 10a

The above reaction was carried out on 30 mg of **10***a* for 10 h. The crude product was recrystallized from ether – petroleum ether (b.p. 30–60°) to yield 18 mg of pure **10***a* whose n.m.r. spectrum showed no diminution of any peak. Deuterium analysis by mass spectroscopy gave 100% d_0, and no d_1 or d_2 species.

Epimeric Alcohol 12

A mixture of ketone **11** (50 mg), dry tetrahydrofuran (2 ml), and lithium aluminum hydride (50 mg) was stirred (magnetic bar) at room temperature for 5 h. Water was added and the reaction mixture was extracted with ether. The organic layer was washed with water, dried, and evaporated to leave 47 mg of colorless liquid epimeric alcohol **12** which crystallized on trituration with petroleum ether. Recrystallization from methanol and from chloroform – petroleum ether gave glistening granules, m.p. 189–193°; ν_{max} 3530 (OH) and 3360 cm^{-1} (NH); *m/e* 304 (molecular ion), whose R_f on t.l.c. was greater than that of alcohol **7***a*.

Anal. Calcd. for $C_{20}H_{20}N_2O$ (304.4): C, 78.92; H, 6.62; N, 9.20. Found: C, 78.39; H, 6.97; N, 9.07.

The ***O*-acetate** was prepared by treatment of **12** with acetic anhydride and pyridine at room temperature. Recrystallization from chloroform gave colorless crystals, m.p. 153–160°; ν_{max} 3395 (NH) and 1728 cm^{-1} (ester C=O); *m/e* 346 (molecular ion).

Anal. Calcd. for $C_{22}H_{22}N_2O_2$ (346.4): C, 76.28; H, 6.40. Found: C, 76.83; H, 6.51.

Preparation of Ketone 13

(a) During Treatment of Dimer 1 with Hydrochloric Acid

Treatment of the dimer with 0.1 *N* HCl in undistilled, unpurified Fisher *p*-dioxane (the n.m.r. spectrum showed only the *p*-dioxane peak) in a stoppered flask gave the liquid alcohol **7***a* (R_f 0.77, ether) in ~30% yield and in addition ~10% of a more polar (R_f 0.19, ether) compound which was separated by chromatography.[11] Recrystallization from chloroform – petroleum ether gave colorless crystals of the **ketone 13**, m.p. 214–217°, ν_{max} 3390 (NH) and 1680 cm^{-1} (Ar—C=O and pyrrolidone C=O); λ_{max} 235 (13 000) and 300 nm (3800); *m/e* 320 (molecular ion). The compound was identical with that prepared in section *b* below.

(b) By Periodate Oxidation of Diol 4

To a solution of the diol **4** (30 mg, 0.094 mmol) in methanol (3 ml) under a nitrogen atmosphere was added with stirring (magnetic bar) a solution of $NaIO_4$ (30 mg, 0.14 mmol) in water (1 ml) and methanol (0.5 ml). Within 5 min a white solid ($NaIO_3$) had precipitated. After 15 min water was added and the mixture was extracted with chloroform. The organic layer was washed with water, dried, and evaporated to leave 30 mg (100%) of an oily solid whose t.l.c. (chloroform–methanol, 87:13) showed the absence of starting material **4** and the presence of a single more polar spot of the same R_f as the ketone from section *a* above. Recrystallization from chloroform – petroleum ether gave colorless crystals of ketone **13**, m.p. 214–216°, undepressed on admixture with the compound from section *a* above. The n.m.r. and i.r. spectra of the two samples were identical.

Anal. Calcd. for $C_{20}H_{20}N_2O_2$ (320.4): C, 74.98; H, 6.29; N, 8.74; O, 9.99. Found: C, 74.51; H, 6.11; N, 8.72; O, 9.96.

(c) By Periodate Oxidation of Desoxy Compound 10a

A modification of Dolby's procedure (6) was used. To a solution of **10***a* (25 mg, 87 μmol) in methanol (2 ml) was added with stirring (magnetic bar) at room temperature a solution of $NaIO_4$ (60 mg, 280 μmol) in water (0.5 ml). Within 15 min solid had begun to precipitate. The mixture was stirred for 12 h, then diluted with water and extracted with chloroform. Evaporation of the washed and dried chloroform solution left 24 mg of light brown oily solid. Recrystallization from chloroform – petroleum ether gave 18 mg of buff colored solid, m.p. 208–217°. Sublimation (190° at 0.1 mm Hg) gave colorless crystalline **13**, m.p. 213–217°, undepressed on admixture with the sample from section *b* above. Their i.r. and n.m.r. spectra and t.l.c. behavior were also identical.

(d) By Periodate Oxidation of Diol 4-d_6

The reaction was carried out with 50 mg of **4**-d_6 and 36 mg of $NaIO_4$ according to the procedure described in section *b* above. The n.m.r. spectrum of the 50 mg of

[11]When oxygen was deliberately bubbled into the reaction mixture, the yield of ketone **13** increased markedly.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

13-d_6 obtained was lacking the methyl peak at δ 1.52 and the three proton lump centered at δ 2.25. Recrystallization from chloroform – petroleum ether gave material of m.p. 214–216° whose t.l.c. behavior was identical with that of **13**; *m/e* 326 (molecular ion corresponding to hexadeuteration).

194° Desoxy Compound ***18***

(*a*) The procedure of Berti *et al.* (3) was used. The pyridinium salt **16** was prepared from 2,3-dimethylindole (1.0 g), *N*-bromosuccinimide (1.23 g), and pyridine (0.6 g). The crude salt obtained was treated with the Grignard reagent prepared from 2,3-dimethylindole (2.0 g). There was obtained 3.1 g of crude product which after two chromatograms and recrystallization from chloroform – petroleum ether yielded 28 mg of **18**, m.p. 178–183° (lit. (4) 186–194°).

(*b*) The low yields of **18** from section *a* and the difficulty of obtaining reproducible yields of **18** by thermal dehydration (3) of the dihydrodimer **26** led to the development of the following procedure.

A solution of **26** (480 mg) from $LiAlH_4$ reduction of **1** (3) in chloroform (35 ml) was refluxed for 36 h. The t.l.c. (benzene:ether, 50:50) showed the absence of starting material and the presence of a less polar product. Evaporation of the chloroform and recrystallization from ether – petroleum ether (b.p. 30–60°) gave 66 mg of colorless crystals of **18**. The residue from evaporation of the mother liquors was chromatographed on four thick plates developed with benzene – petroleum ether (63:37). The bands at R_f 0.36 yielded 70 mg more of **18** which after recrystallization amounted to 31 mg of **18** to bring the total yield of pure material to 97 mg (23%), m.p. 175–188°, identical with the compound prepared by the other two methods.

Deuteration of Dimer ***1***

(a) In Methanol-O-d_1 *with Sodium Methoxide*

A mixture of dimer (100 mg), sodium methoxide (100 mg), and methanol-*O*-d_1 (2 ml) was refluxed for 12 h with exclusion of atmospheric moisture. Evaporation of the methanol and partition between water and chloroform yielded 93 mg of recovered dimer which was recrystallized from methanol – petroleum ether. The 60 mg of **1** obtained was identical in melting point and t.l.c. behavior with starting material. Deuterium analysis by mass spectroscopy gave 78% d_0, 20% d_1, and 2% d_2 species.

(b) In Acetone-d_6 *with DCl*

To a solution of dimer **1** (100 mg) in acetone-d_6 (2 ml) was added a solution of 0.1 *N* DCl in D_2O (0.2 ml). The yellow solution was stirred at room temperature for 0.5 h and was then diluted with chloroform. Extraction with water, drying, and evaporation of chloroform left 105 mg of colorless oil. The t.l.c. showed the presence of **4** and **7***a* in addition to **1**. Separation on a thick plate developed in benzene–ether (75:25) gave 43 mg of recovered dimer which after recrystallization from methanol – petroleum ether was identical in melting point and t.l.c. behavior with **1**. Deuterium analysis by mass spectroscopy gave 85% d_0, 6% d_1, and 9% d_2.

Homodimer ***32***

To a stirred (magnetic bar) mixture of dimer **1** (400 mg), acetone (8 ml), and formaldehyde (1.6 ml of 37% aqueous solution) at room temperature was added a mixture of aqueous HCl (0.8 ml of 0.01 *N*) and acetone (0.5 ml). At the end of 5 min the pale yellow solution was added to ether, washed with water, dried, and concentrated to leave an amber oil. The t.l.c. in benzene–ether (50:50) showed the absence of **1** and the presence of a spot slightly more polar than **1** with considerable tailing. Chromatography on two thick plates developed in benzene–ether (75:25) yielded 280 mg (67%) of colorless crystalline solid from a band at R_f 0.43. Two recrystallizations from methanol – petroleum ether gave pure homodimer of m.p. 155–170° unchanged by further recrystallization; ν_{max} 3505 cm^{-1} (OH); λ_{max} 252 (6700) and 290 nm (1400); *m/e* 334 (molecular ion). This material was pure from its n.m.r. spectrum, and the wide melting point is due to decomposition to **30** during melting as demonstrated by t.l.c.

Anal. Calcd. for $C_{21}H_{22}N_2O_2$ (334.4): C, 75.42; H, 6.63; N, 8.38. Found: C, 75.11; H, 6.39; N, 8.49.

Treatment of the dimer with formaldehyde under the same conditions of concentration and acidity that allowed isolation of **4** gave only **30** and no **32**. Thus, from dimer (100 mg), acetone (2 ml), formaldehyde (0.5 ml of 37% aqueous solution), and aqueous HCl (0.2 ml of 0.1 *N*) after 15 min at room temperature there was obtained 103 mg (97%) of crude **30**. Thick layer chromatography and recrystallization from chloroform – petroleum ether gave 62 mg of pale yellow needles of 30, m.p. 146–147.5°, identical with the compound obtained from treatment of **1** with acid in dioxane.

Rearrangement of Homodimer ***32***

To a stirred (magnetic bar) solution of **32** (100 mg) in acetone (2 ml) at room temperature was added a solution of aqueous HCl (0.2 ml of 0.1 *N*) in a few drops of acetone. After 10 min the pale yellow solution was poured into ether, washed with water, dried, and concentrated to leave 93 mg (98%) of yellow solid. Two recrystallizations from chloroform – petroleum ether gave colorless **30**, m.p. 146–149°, identical with the artifact obtained by the action of acid on dimer **1** in dioxane.

Etude par spectroscopie infrarouge de mélanges binaires de l'eau avec quelques accepteurs de protons dans la région des vibrations de valence OH

ANNE LE NARVOR, EMILIE GENTRIC, ET PIERRE SAUMAGNE

Laboratoire de Spectrochimie Moléculaire, Faculté des Sciences, 29N Brest, France

Reçu le 18 novembre, 1970

Les spectres i.r. de mélanges binaires de l'eau (HDO et H_2O) avec quatre cosolvants non ioniques: acétonitrile, dioxanne, diméthylsulfoxyde, et hexaméthylphosphorotriamide, ont été enregistrés entre 3700 et 3100 cm^{-1}, pour des concentrations en eau variant de 0 à 1 en fraction molaire. L'analyse de la région des bandes de valence OH de l'eau suggère la présence de différents types de complexes par liaison hydrogène et confirme en particulier l'existence de complexes bien définis de type I–II (une molécule d'eau liée à deux molécules de cosolvant) quand $X_{eau} < 0.1$. Dans le domaine de concentration $0.8 < X_{eau} < 1$ l'effet du cosolvant organique sur le spectre de l'eau est négligeable.

The i.r. spectra of binary mixtures of water (HDO and H_2O) and four non-electrolyte cosolvants: acetonitrile, dioxane, dimethylsulfoxide, and hexamethylphosphorotriamide have been recorded from 3700 to 3100 cm^{-1}, the mole fractions of water varying from 0 to 1. The investigation of the OH stretching bands of water suggests the presence of various types of hydrogen bonded complexes and confirms the existence of well-defined I–II complexes (one molecule of water bonded to two molecules of cosolvent) when $X_{water} < 0.1$. In the range $0.8 < X_{water} < 1$ the organic cosolvent has negligible effect on the spectrum of water.

Canadian Journal of Chemistry, 49, 1933 (1971)

Introduction

Les études sur la structure de l'eau liquide et sur les interactions eau-soluté ont fait l'objet de récentes mises au point (1–4).

Le problème de la structure de l'eau liquide n'est pas encore élucidé; la diversité des structures proposées reflète la difficulté de l'interprétation des résultats expérimentaux. On peut cependant classer les différents modèles de structure en deux types principaux. Le premier, ou "modèle discontinu" représente l'eau liquide comme un mélange en équilibre d'"agrégats fluctuants" comportant des molécules diversement liées. Le second modèle ou "modèle continu" décrit l'eau comme un réseau continu de molécules liées, les quatre liaisons hydrogène sur chaque molécule pouvant se courber ou se tordre et présentant une distribution continue d'énergies et de géométries. Les spectres i.r. et Raman de l'eau liquide ont donné lieu à des interprétations différentes s'appuyant sur l'un ou l'autre des modèles.

Il existe peu d'études concernant les solutions concentrées d'eau dans des solvants organiques accepteurs de protons. Très récemment, des mélanges eau–diméthylsulfoxyde ont été étudiés par spectroscopie i.r. pour des concentrations en eau de 1 à 0.8 en fraction molaire (5). En outre, Fratiello et coll. (6), Mavel (7), Holmes *et al.* (8) ont analysé par r.m.n. les spectres de quelques mélanges eau–solvant organique, tandis que la diffusion des neutrons lents par le mélange eau–diméthylsulfoxyde était suivie par Safford *et al.* (9). Enfin Kenttämaa et Lindberg (10) par des mesures thermodynamiques et diélectriques, Cowie et Toporowski (11) par des mesures de viscosité, et tout récemment Jung et Hyne (12) par des déterminations de compressibilité, ont discuté les structures des mélanges eau–diméthylsulfoxyde, tandis que le système eau–dioxanne était étudié par Rizk (13). Mais aucun de ces travaux ne paraît permettre une détermination précise des espèces présentes en solution.

Au contraire, il semble que la structure des solutions diluées d'eau dans les solvants organiques soit mieux connue à la suite des travaux de spectroscopie i.r. de Greinacher *et al.* (14), Saumagne (15–18), Sidorov (19), de Mohr *et al.* (20), et de Yuknevich *et al.* (21).

Dans ce mémoire, nous analyserons systématiquement les spectres de vibration de solutions contenant les molécules HDO et H_2O et les organiques suivants: acétonitrile, dioxanne, diméthylsulfoxyde, et hexaméthylphosphorotriamide.

Partie expérimentale

L'acétonitrile, le dioxanne, et l'hexaméthylphosphorotriamide sont d'origine Prolabo, tandis que le diméthylsulfoxyde provient du Laboratoire du Bois de Boulogne. Ces solvants ont été desséchés par contact prolongé avec

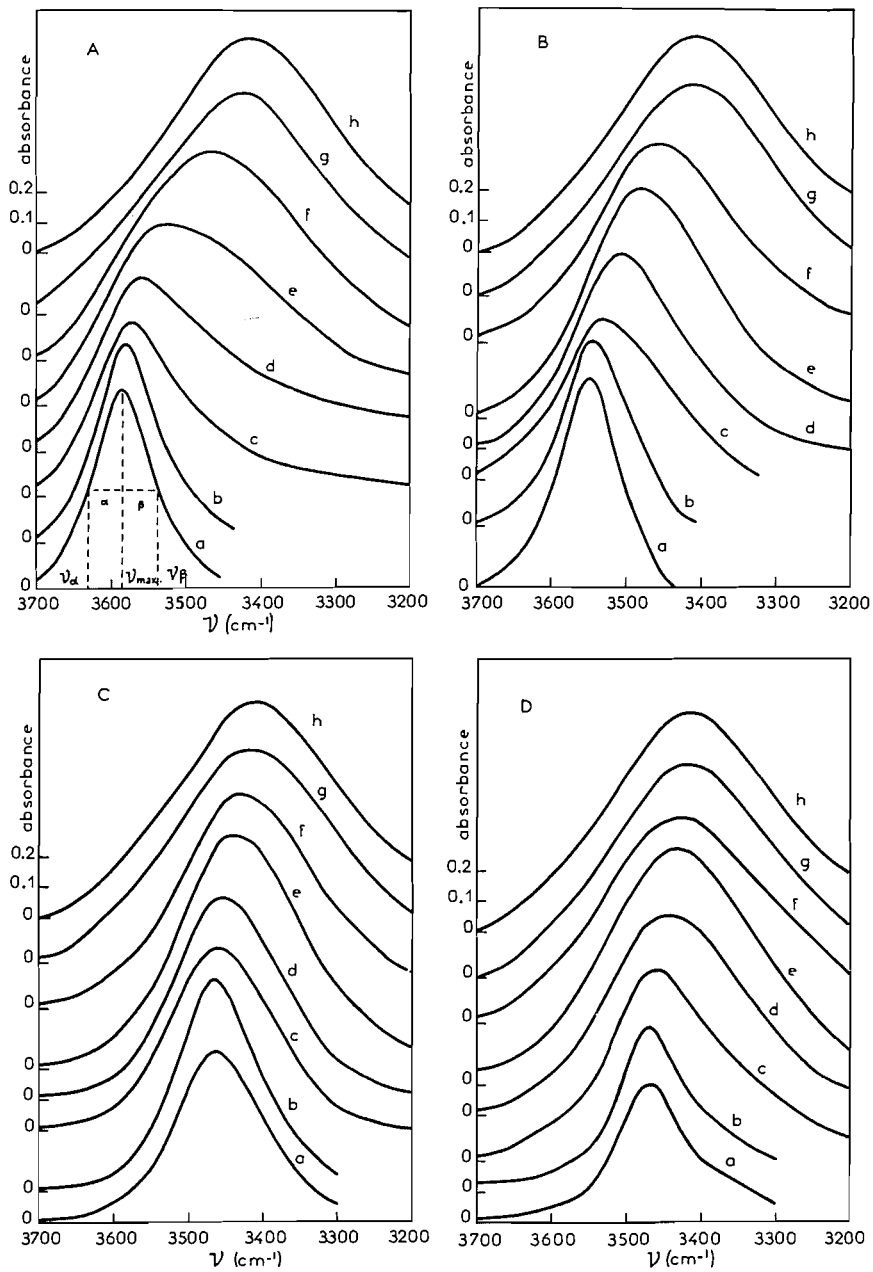

FIG. 1. Spectres de vibration de valence ν(OH) de HDO en mélange binaire avec A, acétonitrile; B, dioxanne; C, diméthylsulfoxyde (DMSO); D, hexaméthylphosphorotriamide (HMPT); concentrations, voir tableau 1. La courbe *h* est celle de HDO.

du tamis moléculaire Linde 4 Å. L'eau résiduelle a été dosée par la méthode de Karl Fisher: on a trouvé moins de 100 p.p.m. pour le diméthylsulfoxyde et moins de 50 p.p.m. pour les autres solvants. Les solvants anhydres ont été conservés et manipulés en boîte sèche. L'eau lourde titre 99.7% en D_2O et provient du Commissariat à l'Energie Atomique. Les solutions à faible teneur en eau ont été préparées en utilisant une micro-seringue Hamilton, et les autres par pesée directe. Les correspondances entre concentrations en mol l^{-1} et fractions molaires en eau pour les divers mélanges sont indiquées dans le tableau 1.

Les solutions jusqu'à 10 *M* en eau ont été étudiées dans une cuve à pas variable RIIC à fenêtres en CaF_2, le

TABLEAU 1. Concentrations en eau des solutions étudiées

Désignation de la courbe	Concentration en mol l^{-1} de l'eau dissoute dans les différents solvants	Fraction molaire en eau: X_{eau}			
		Acétonitrile	Dioxanne	DMSO	HMPT
a	0.05	0.0026	0.0042	0.0035	0.0087
b	0.5	0.026	0.041	0.035	0.081
c	2.5	0.12	0.18	0.16	0.31
d	5	0.22	0.32	0.28	0.49
e	10	0.39	0.51	0.46	0.68
f	20	0.62	0.73	0.69	0.84
g	40	0.88	0.92	0.91	0.99

produit concentration par épaisseur étant maintenu constant. L'eau pure ou les solutions plus concentrées ont été étudiées en film capillaire entre faces de CaF_2. Les spectres ont été enregistrés indifféremment sur un spectromètre Perkin–Elmer 225, équipé d'un réseau à 150 traits par mm travaillant dans le premier ordre, ou Beckman IR 9 muni d'un réseau à 150 traits par mm travaillant dans le second ordre. Quel que soit l'appareil, la précision de lecture sur les fréquences et les demi-largeurs est de $\pm 1\ cm^{-1}$ pour les bandes fines des solutions diluées, et de $\pm 3\ cm^{-1}$ pour les massifs les plus larges. Tous les spectres ont été enregistrés à température ambiante.

Résultats

Sur la fig. 1, nous avons représenté les spectres i.r. obtenus entre 3700 et 3100 cm^{-1} pour des solutions binaires d'eau HDO dans les solvants organiques cités, pour des valeurs de la fraction molaire X en eau totale variant de 1 à 0.005. L'eau HDO résulte de l'équilibre $H_2O + D_2O \rightleftarrows 2\ HDO$, dont la constante vaut 3.80 à 25 °C (22). Dans ce cas, les fractions molaires sont indiquées en eau "totale" ($[H_2O] + [D_2O] + [HDO]$), aux fins de comparaisons ultérieures avec le terme H_2O seul: dans les solutions utilisées, les concentrations à l'équilibre sont: $[H_2O] = 1.04$, $[HDO] = 17.91$, $[D_2O] = 81.04\%$ en volume. On admettra que la dilution par un solvant organique ne modifie pas l'équilibre.

Dans tous les cas, on constate un glissement vers les basses fréquences du maximum d'absorption et un élargissement du massif avec l'augmentation de la concentration en eau. Sur les figs. 2, 3, et 4, nous avons reporté respectivement le déplacement du maximum, la demi-largeur $\Delta\nu 1/2$ et la dissymétrie de la bande ν(OH) de HDO en fonction de la fraction molaire en eau.

Les spectres analogues de solutions d'eau H_2O sont reproduits sur la fig. 5. Bien que ces spectres soient compliqués par la présence de deux bandes de vibration de valence OH, l'allure générale du massif évolue de façon similaire à celle observée dans le cas précédent de l'eau HDO.

les solvants organiques découle de travaux antérieurs (15–21). En effet, les spectres de HDO présentent dans la région des vibrations de valence OH (fig. 1) une bande fine correspondant au vibrateur OH non couplé, dont la position varie en fonction du caractère basique plus ou moins marqué du solvant. Pour la molécule H_2O (fig. 5), nous retrouvons les deux maximums des vibrations symétrique ν_1 et antisymétrique ν_3, dont les nombres d'onde sont également fonction du solvant. Pour ces faibles concentrations en eau, les spectres s'interprètent par l'existence de complexes I–II comprenant une molécule d'eau liée par pont d'hydrogène à deux molécules de solvant (15, 17). Cependant, sur le spectre de l'eau H_2O dissoute dans l'hexaméthylphosphorotriamide (fig. 5D), on relève la présence d'une petite absorption vers 3690 cm^{-1}; on l'attribue à la vibration ν(OH) libre de complexes I–I contenant une molécule d'eau pour une molécule de solvant (16, 21, 23). Un phénomène d'empêchement stérique est vraisemblablement responsable de tels complexes en faible proportion dans le mélange.[1]

Solutions très concentrées en eau

A l'opposé, l'examen des spectres de la fig. 1 ou 5 montre que l'addition de petites quantités de soluté organique à l'eau modifie très peu l'allure générale des spectres tant que la concentration en eau reste supérieure à 0.8 en fraction molaire. Dans ce cas, on remarque que pour les solutions contenant HDO, la position du maximum de la bande ν(OH), sa demi-largeur et sa dissymétrie restent sensiblement inchangées en fonction de la concentration du soluté ou en fonction de sa nature (figs. 2, 3, et 4). Notons cependant que, parmi les quatre solvants étudiés, l'acétonitrile et le dioxanne ont une influence plus

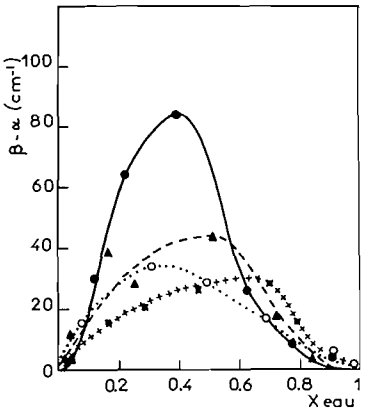

FIG. 4. Evolution de la dissymétrie (β-α) de la bande ν(OH) de HDO en fonction de la fraction molaire en eau. β et α sont respectivement définis par $\beta = \nu_{max} - \nu_\beta$ et $\alpha = \nu_\alpha - \nu_{max}$ (*cf.* fig. 1A, courbe *a*). On appelle ν_α et ν_β les nombres d'onde correspondant aux limites supérieure et inférieure de la largeur de la bande à demi-absorbance. ● acétonitrile; ▲ dioxanne; ✖ DMSO; ○ HMPT.

marquée sur le profil de la bande. En effet, pour une fraction molaire en eau de 0.8 ces composés élèvent d'environ 15 cm^{-1} la fréquence du maximum, en même temps qu'ils provoquent un élargissement égal au plus à 20 cm^{-1}, aux erreurs d'expérience près. Toutefois, ces modifications du spectre restent faibles et nos résultats dans leur ensemble confirment les observations récentes de Brink et Falk (5) sur le mélange eau–diméthylsulfoxyde.

L'absence de modification importante du spectre i.r. de l'eau contenant de petites quantités de soluté organique semble indiquer que les liaisons hydrogène présentes dans le milieu restent, en moyenne, de même force. Par ailleurs, lors d'une étude électrochimique de la solvatation du cation Ag^+ dans les mélanges eau–diméthylsulfoxyde, il a été montré que dans les milieux très riches en eau le rôle du soluté organique est négligeable (26). Dans ces conditions, on pourrait admettre que les molécules organiques sont piégées par l'eau et ne se manifestent pas. Il est donc vraisemblable que la structure de l'eau se conserve jusqu'à une fraction molaire de l'ordre de 0.9 à 0.8 en eau.

Solutions de concentrations intermédiaires

L'interprétation des courbes de variation de la fréquence, de la demi-largeur et de la dissymétrie pour les solutions d'eau HDO de concentrations

[1]Dans les complexes I–I (HOH...A) observés dans les mélanges eau–solvant accepteur de proton à faible concentration dans CCl_4, la symétrie C_{2v} de la molécule H_2O disparaît, tandis qu'elle se conserve dans le complexe I–II (A...HOH...A) correspondant à l'eau dans le solvant basique pur (24, 25). Le premier cas se traduit par une vibration de valence ν(OH) libre dont le nombre d'onde se situe dans la région 3700–3680 cm^{-1} et par une vibration ν(OH) associée dont la position dépend de la basicité du solvant. Par contre, pour une force croissante du pouvoir accepteur de proton du solvant, les fréquences ν_1 et ν_3 sont abaissées de façon parallèle, tandis que la différence $(\nu_3 - \nu_1)$ diminue et que le rapport des intensités $I(\nu_1)/I(\nu_3)$ augmente et tend vers 1.

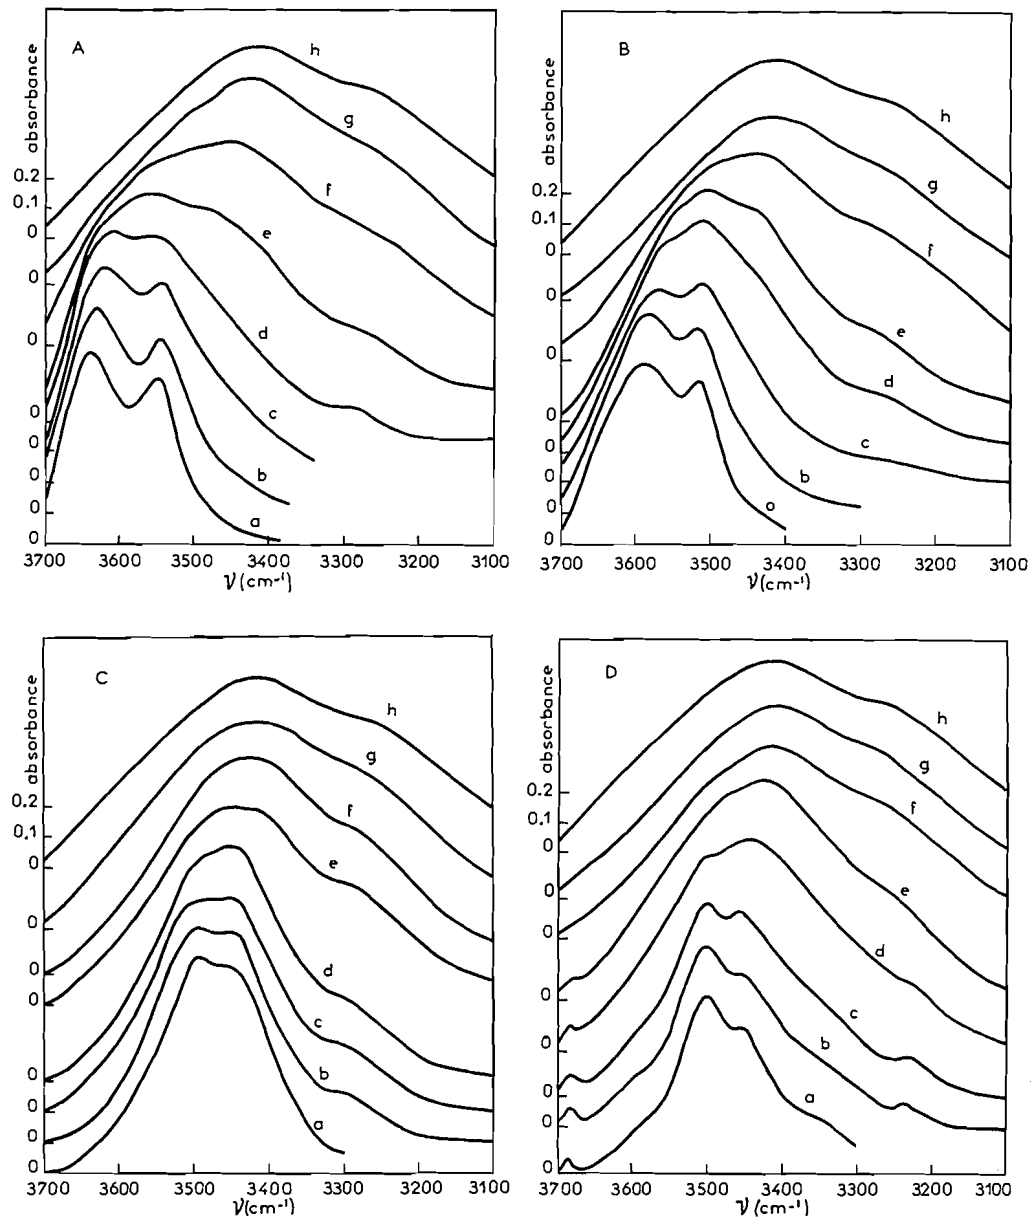

FIG. 5. Spectres de vibration de valence de H_2O en mélange binaire avec A, acétonitrile; B, dioxanne; C, DMSO; D, HMPT. La courbe *h* est celle de H_2O pure.

intermédiaires ($0.1 < X_{eau} < 0.8$) est délicate. La dissymétrie du massif passe par un maximum d'autant plus marqué que le cosolvant est moins basique et que l'écart entre les nombres d'onde du vibrateur OH complexé et autoassocié est grand (fig. 4). Au contraire, dans le même intervalle de concentration, la fréquence du maximum et la demi-largeur du massif varient continûment sans accident (figs. 2, 3).

Dans les études de certaines propriétés physico-chimiques du mélange eau–diméthylsulfoxyde (constante diélectrique et grandeurs thermodynamiques, viscosité, compressibilité isotherme ...), différents auteurs (10–12) ont observé, pour

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

une composition du mélange X_{eau} de l'ordre de 0.6 à 0.7, un extremum qu'ils relient à l'existence préférentielle d'un agrégat contenant une molécule de diméthylsulfoxyde pour deux molécules d'eau. Il ne semble pas que les maximums de dissymétrie observés précédemment puissent valablement être reliés à ces agrégats définis; ces maximums résultent plutôt sans doute d'une composition graphique très variable avec X d'un nombre élevé de bandes, souvent très larges, qui correspondent chacune à un type donné de complexe eau–solvant par liaison hydrogène.

L'interprétation des courbes similaires obtenues pour les solutions de H_2O dans le même intervalle de concentration est encore plus difficile. Par accroissement progressif de la teneur en eau dans les diverses solutions, on constate que les intensités relatives des bandes ν_3 et ν_1 varient, ainsi que leur position, ces bandes tendant à se rapprocher et à se confondre en un même massif. Cette évolution pourrait s'expliquer par un découplage progressif entre les deux vibrateurs OH d'une molécule d'eau, en raison des perturbations importantes auxquelles celle-ci est soumise dans ces solutions. Les vibrations ν_1 et ν_3 ne sont donc plus des vibrations purement symétrique et antisymétrique. Simultanément, dès $X_{eau} > 0.1$, apparaît sur tous les spectres une absorption notable centrée autour de 3420 cm^{-1}. Celle-ci augmente considérablement avec la concentration en eau et devient le maximum principal pour des fractions molaires en eau supérieures en moyenne à 0.5. Cette absorption a été attribuée à de l'eau autoassociée (16).[2]

En outre, sur tous les spectres de solutions de H_2O, lorsque l'absorption propre du solvant le permet, on remarque vers 3250 cm^{-1} une épaule dont l'intensité et la position restent sensiblement constantes dans toute la gamme de concentration étudiée. Ce sous-maximum correspond à l'harmonique de la vibration de déformation $2\nu_2$ (16).

[2]Une interprétation différente des spectres eau–acétonitrile pour des concentrations inférieures à 10 *M* a été donnée par Karetnikov et Golishnikova (27). Ces auteurs observent aux faibles concentrations deux bandes à 3620 et 3650 cm^{-1} qu'ils attribuent à ν_1 et ν_3. Ces deux maximums correspondent, selon nous, à l'acétonitrile lui-même. D'autre part, la bande située à 3540 cm^{-1} serait due d'après ces auteurs à une association eau–eau, ce qui n'est pas en accord avec la disparition progressive de ce massif pour des concentrations en eau supérieures à 10 *M*.

Conclusion

L'effet de concentration nous permet d'apporter quelques précisions concernant le spectre de l'eau H_2O liquide, qui confirment l'interprétation proposée précédemment par l'un de nous (16). Nous pensons que le maximum principal situé vers 3420 cm^{-1} contient les bandes de valence ν_3 et ν_1 des vibrateurs OH partiellement découplés tandis que l'épaule à 3250 cm^{-1} correspond à l'harmonique $2\nu_2$. Cette interprétation est en accord avec celles données récemment par Falk et Ford (28) Schiffer et Hornig (29).

Nous remercions Monsieur J. Lauransan, Maître de Conférences à la Faculté des Sciences de Brest, pour l'intérêt qu'il a porté à ce travail et pour les discussions dont il nous a fait bénéficier.

Conformational Preference and Configurational Equilibria of the Methyl 3-Deoxy-3-nitro-pentopyranosides and their Nitronates[1]

HANS H. BAER AND JAN KOVÁŘ
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received November 27, 1970

The conformations of four methyl 3-deoxy-3-nitropentopyranosides and their sodium nitronates in aqueous solution were examined by n.m.r. spectroscopy, and the results are explained by calculation of free energies of non-bonded interactions. It is shown that protonation of glycoside nitronates is a kinetically controlled process. The β-epimerization of nitronates was investigated, and relative thermodynamic stabilities of epimers were determined and correlated with conformations. The non-bonded interaction between the nitronate grouping and an adjacent, equatorial hydroxyl group ($A^{(1,3)}$ effect) must be associated with a free energy in excess of 2 kcal/mol. The influence of this effect upon conformational and configurational equilibria in glycoside nitronates and upon nitromethylene acidity is emphasized. The compounds were found to differ in their behavior during early stages of the β-epimerization reaction, which was linked to differential nitromethylene acidities. Mechanisms for the reaction are discussed.

On a déterminé en solution aqueuse et par r.m.n., les conformations de quatre méthyl déoxy-3 nitro-3 pentopyranosides et de leurs nitronates de sodium; on explique les résultats obtenus à l'aide de calculs d'énergie libre d'intéractions non liées. On démontre que la protonation des nitronates de glycosides est un processus contrôlé cinétiquement. On a de plus étudié l'épimérisation β des nitronates; on a déterminé les stabilités thermodynamiques relatives des épimères et établi une corrélation avec les conformations. On doit considérer que l'intéraction non liée entre le groupe nitronate et un groupe hydroxyle équatorial voisin (effet $A^{(1,3)}$) amène une contribution de plus de 2 kcal/mol à l'énergie libre. On met en relief l'influence de cet effet sur l'équilibre conformationnel et configurationnel des nitronates de glycosides et sur l'acidité des groupes nitrométhylènes. On a trouvé que, suivant l'acidité des groupes nitrométhylènes, la réactivité des divers composés varie dans les stades préliminaires de la réaction d'épimérisation β. On discute des mécanismes de la réaction.

Canadian Journal of Chemistry, 49, 1940 (1971)

Introduction

The nitromethane cyclization of L′-methoxydiglycolaldehyde (**1**) and its D′ enantiomer (**1***)[2] (1–3), and many further applications of this reaction which have recently been reviewed (4), have provided facile access to a large body of nitrogenous carbohydrates. In the course of these investigations a stereochemical rule has emerged that concerns the liberation of 3-deoxy-3-nitroaldopyranosides (and analogous 4-deoxy-4-nitro-ketopyranose derivatives) from their *aci* salts, in which process a new center of asymmetry is created. The configuration adopted, usually to the exclusion of the epimeric alternative, is that which possesses an equatorial nitro group in the favored chair conformation. Thus, for example, in methyl D-hexopyranosides with their innate preference for the C_1^4 chair, products having the D-*gluco*, D-*manno*, D-*galacto*, and D-*talo* configurations are obtained, whereas corresponding β-1,6-anhydro sugars locked in the C_4^1 conformation give rise to products having the D-*allo*, D-*altro*, D-*gulo*, and D-*ido* configurations (4). One puzzlement of long standing has been the seemingly exceptional behavior of methyl 3-deoxy-3-*aci*-nitro-β-D-*erythro*-pentopyranoside sodium (**2**), the main product in the nitromethane cyclization of **1**, which on acidification gave both 3-epimers, with methyl 3-deoxy-3-nitro-β-D-ribopyranoside (**6**) unexpectedly preponderating strongly over the β-D-*xylo* isomer **7** (2). Methyl 3-deoxy-3-*aci*-nitro-α-L-*threo*-pentopyranoside sodium (**3**) produced the α-L-arabinopyranoside **8**, whereas the β-D-*threo* nitronate **4** gave the β-D-arabinopyranoside **9**; in other words,

[1]Part XIX of a series on the reactions of nitro sugars. For part XVIII see ref. 22.

[2]Occasional reference is made herein to optical antipodes of some of the compounds depicted. They are indicated by starred numbers, and mirror image formulas are dispensed with. The conformational symbols used in this article are explained in ref. 23.

For personal use only.

opposite configurations were engendered at C-3 in these two nitronates (3). The 3-epimers of **8** and **9**, *i.e.* the corresponding *lyxo* derivatives **10** and **11**, were not encountered.

In order to shed light on these stereochemical problems, and also to explore further the factors which govern epimeric product composition in the formation and base-catalyzed epimerization of sugar nitronates, we have now examined by n.m.r. spectroscopy the aforementioned methyl deoxynitropentosides and their sodium salts. For the purpose of this study the β-D-*xylo* isomer **7**, which had previously been shown to exist but had not been isolated, was prepared in crystalline form for the first time, as were also the β-L-*xylo* and β-L-*ribo* enantiomers **7*** and **6***.

Results and Discussion

Conformation of the Glycoside Nitronates

Contrary to earlier assumptions (2), which were based on the tenets of conformational analysis prevailing at a time when the importance of certain non-bonded interactions had not yet been realized and the benefits of n.m.r. spectroscopy were not widely available, we now have found that the β-D-*erythro* nitronate **2** does not prefer the C_1^4 chair conformation (**2***a*). All the coupling constants for the ring protons H-1, -2, and -4 are small (Table 1), indicating absence of vicinal, *trans*-diaxial orientations and therefore ruling out the C_1^4 form which would possess two pairs of protons so oriented. The spectral data are consistent with the inverted, C_4^1 chair conformation (**2***b*), which we believe describes best the molecule in its ground state even though three axial substituents are present.[3]

The α-L-*threo* isomer **3** possesses one pair of vicinal, *trans*-diaxial protons in either chair conformation (**3***a* and *b*). However, the n.m.r. spectrum shows only small couplings in the H-1, -2, and -4 proton signals (Table 1), thus ruling out both chair forms, and it therefore appears that we are dealing with one of the unusual cases where a skew conformation can be postulated for a monocyclic pyranoside. Inspection of models leaves little choice but the S_1^5 form (**3***c*), which is consistent with the spectrum.[4]

The spectrum of the β-D-*threo* isomer **4** also exhibits only small couplings in the H-1, -2, and -4 signals, indicating absence of vicinal *trans*-diaxial protons. While this feature eliminates conformation **4***a* from consideration, it is compatible with the inverted chair **4***b* but also with a skew form, S_1^5 (**4***c*).

Relative Thermodynamic Stabilities of the Glycoside Nitronates

As had earlier been shown (3), mainly by polarimetry and chromatography, the three sodium nitronates **2**, **3**, and **4** spontaneously equilibrate, in aqueous solution, by epimerizing at C-2 and -4. At equilibrium, which is reached at room temperature within several hours, the β-D-*erythro* isomer **2** was found to predominate strongly over the *threo* isomers **3** and **4**. We have now confirmed this by n.m.r. spectroscopy, the chemical shifts and intensities of the methoxyl proton signals affording a convenient means of differentiating components, and of determining their ratios, in mixtures of the isomers. As the equilibration reaction progressed, starting from whichever nitronate, a fourth methoxyl signal appeared, at lowest field. We assign it to the fourth possible stereoisomer, the α-L-*erythro* nitronate **5**, which had hitherto escaped detection. A typical spectrum of an equilibrium mixture is depicted in Fig. 1, and the results of various experiments are recorded in Table 2. The differences in free energy calculated from the equilibrium constants show that **2** is more stable than its stereoisomers by approximately 0.8–1.0 kcal/mol. The differences between the three less stable compounds are slight, but **5** quite consistently appears to have the lowest stability.

[3]The chair may be assumed to be slightly flattened due to the sp^2 hybridization of C-3, which relieves somewhat the *syn*-diaxial hydroxyl interaction strain. The molecule could thus *approach* the half-chair form **2***c* (which would still agree with our n.m.r. data), but there is no reason for assuming a very great departure from the C_4^1 chair.

[4]A referee has suggested that the n.m.r. data of **3** may be interpreted in terms of "a rather strongly distorted chair form". Strong distortion so as to approach the half-chair HC_4^5 would in fact be consistent, and a definitive assignment is not implied. However, the half-chair would suffer from eclipsing of the C-2 and -3 bonds whereas rotation about the $C_{(2)}$–$C_{(3)}$ axis produces **3***c*, in which these bonds are staggered, without very much affecting the positions of the hydroxyl groups relative to the nitronate group. We therefore believe the skew form to be more likely (see also footnote 6) but, in the subsequent discussion, the only point that really matters is the fact that the compound obviously does not assume one of the normal chair forms.

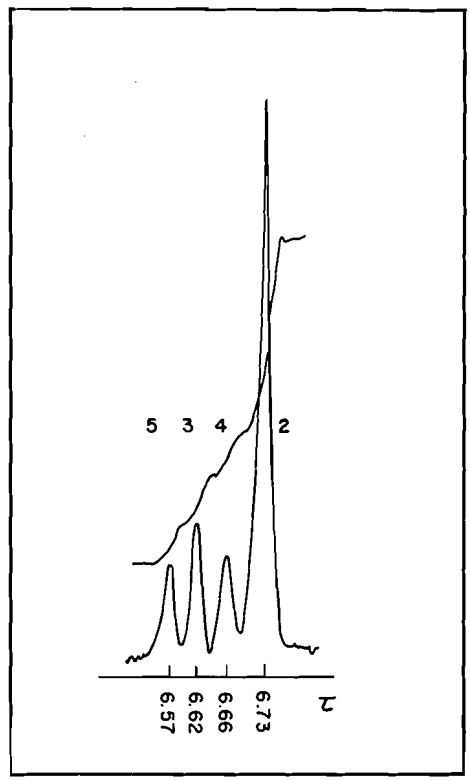

FIG. 1. The n.m.r. spectrum (60 MHz, with 100 Hz sweep width) of the methoxyl signal region of sodium nitronates at epimeric equilibrium in D_2O.

With this information on hand, the conformational preferences displayed by the nitronates may be discussed in terms of free energies of non-bonded interactions. Experimental values recorded for conformational free energies of substituents on six-membered rings show considerable scattering (5*a*, 6), and some arbitrariness is therefore inherent in the choice of certain parameters for calculations. Nevertheless, a reasonable picture has been presented of the conformational preferences in cyclitols, hexopyranosides, and pentopyranosides (5*b*, *c*). We are using the same approach and are adopting recent improvements which have been described in great detail by Angyal (7). Accordingly, we employ the following values (in kcal/mol) for non-bonded interactions: between an axial hydroxyl or methoxyl group and one *syn*-axial hydrogen, 0.45; between two *syn*-axial hydroxyl groups, 1.5; between adjacent, diequatorial hydroxyl (or methoxyl) groups, 0.35; for the anomeric effect of the methoxyl group in aqueous solution, 1.05; increment to the anomeric effect if 2-OH is axial, 0.45 (Δ2 effect). Unknown at the outset was the magnitude of the interaction between the nitronate grouping and an adjacent hydroxyl. When the latter is axial, its dihedral angle with the C=N bond is about 120°, and interaction can be assumed to be negligible; but when it is equatorial, the dihedral angle is close to 0°, and substantial strain will exist. This condition is an example of the more general $A^{(1,3)}$ effect (8), and an energy term (*A*) must be added whenever it occurs. Table 3 contains the calculated, total interaction energies for the two chair forms of each of the four nitronates, and by

	b	1.25+*A*
5 (α-L-*erythro*)	**5***a*	3.35
	b	0.8+2*A*

relating these data with our experimental findings it became possible to derive at least a minimum estimate for the *A* term and to demonstrate the importance of the $A^{(1,3)}$ effect in the stereochemical behavior of nitro glycosides.

From the fact that compound **2** preponderantly exists in the conformation **2***b* one may deduce for **2***a* a relative energy excess of at least 1 kcal/mol, whence $1.4 + 2A \geqq 1.95 + 1$, or $A \geqq 0.8$ kcal/mol. More revealing is the observation that the free energy of **3** is 0.84 kcal/mol higher than that of **2** (Table 2). From this difference an interaction energy of 2.8 kcal/mol is computed for **3**, based on the value 1.95 for **2** in its prevailing form, **2***b*. Hence if **3** existed as an equilibrium mixture of conformers **3***b* and *a*, and the free energy of such a mixture were given[5] by the expression (0.8 + *A*) kcal/mol, *A* would equal 2.0 kcal/mol. However, the n.m.r. spectrum showed that **3** does not in fact occupy the chair forms, and therefore one has to conclude that *A* is even larger, perhaps 2.5 kcal/mol or more, causing the energy of **3***b* to exceed markedly that of the skew form **3***c* into which the molecule seems to escape on account of this strain. For although skew forms are not normally adopted by pyranosides, **3***c* is free from $A^{(1,3)}$ strain, thus offering an attractive choice for a molecule which would be severely hindered in either chair form.[6] A similar calculation for the isomer **4**, using the experimentally determined energy difference *vs.* **2** (0.9 kcal/mol, see Table 2) and assuming an equilibrium of conformers **4***b* and *a* in the ratio 86:14 (calculated from Table 3), would result in an *A* value of 1.70 kcal/mol. However a higher value, demanded by the conformational behavior of **3** as just discussed, should apply here too, on the premise that the $A^{(1,3)}$ effects are equal in the chair conformations of both isomers. Since any higher *A* value will make **4***b* (and *a*) less stable than the compound has actually been found to be, in relation to **2**, one is led to postulate that **4***b*, although allowed by the n.m.r. data, is not the preferred conformation but that a skew form, **4***c*, is adopted to a large extent.

These results can be viewed in yet another way. Considering that the calculated energy difference between the most favored chair forms **3***b* and **4***b* is 0.35 kcal/mol, one would expect the isomers to be present, at the epimeric equilibrium, in a ratio of about 2:1 if indeed the chair conformations prevailed. The ratio actually found is different (close to 1:1), suggesting that other conformations are involved.

Finally, the epimeric equilibrium between **2** and what is presumed to be the α-L-*erythro* isomer **5** (Table 2) corresponds to a free energy difference of 1.04 kcal/mol. The preferred conformation of **5** is not known, but in view of the magnitude of the $A^{(1,3)}$ effect it is safe to say that it should be **5***a* even though all the other steric factors work in favor of **5***b* (see Table 3). The difference in interaction energies calculated for the system **2***b* ⇌ **5***a* (1.4 kcal/mol, Table 3) is somewhat higher than the experimental value,[7] but calculation based on **5***b*, using any *A*- value consistent with the other findings, would give much too high a figure.

In summary, the studies have revealed that the $A^{(1,3)}$ effect is the most powerful factor determining preferred conformations and equilibria of epimerization in glycoside nitronates, the interaction energy associated with it certainly exceeding 2 kcal/mol. The order of thermodynamic stabilities, **2** > **3** > **4** > **5**, is as previously

[5]The difference (0.95 kcal/mol) in interaction energies calculated for **3***b* and *a* (Table 3) corresponds to an equilibrium ratio 83:17 for these conformers. By taking into account the entropy of mixing, one finds 0.8 + *A* as the calculated energy value for an equilibrium mixture **3***b* ⇌ **3***a*.

[6]In cyclohexanone, the energy difference between chair and flexible forms is only about one-half that in cyclohexane, allowing skew forms in substituted cyclohexanones to play a significant role (5*d*). A similar situation should pertain in our nitronates.

[7]Agreement would of course be achievable by taking the anomeric effect to contribute 0.35 kcal/mol less energy. Such arbitrary measure, when applied to the isomers **3** and **4**, would affect the results of the previous calculations somewhat but not significantly, in the direction of a higher *A* value.

suggested but must be interpreted in the light of this interaction. Whether the effect is primarily of steric or dipolar nature remains open.

Conformation of the Free Nitro Glycosides

Methyl 3-deoxy-3-nitro-β-D-ribopyranoside (**6**) and its β-D-*xylo* (**7**), α-L-*arabino* (**8**), and β-D-*arabino* (**9**) isomers were all found to prefer, in aqueous solution, that chair conformation in which the nitro substituent occupies the equatorial position. This is the C_1^4 conformation for the β-D-*xylo* compound (**7***a*), but the C_4^1 conformation for the others (**6***a*, **8***a*, **9***a*). The ring proton resonances leading to these conclusions are listed in Table 4. In agreement herewith, the signals given by the axial methoxyl groups in **6***a* and **9***a* occur at higher field than those of the equatorial methoxyl groups in **7***a* and **8***a*.

These findings remove the basis for regarding the formation of the β-D-riboside **6** from the β-D-*erythro* salt **2** as a peculiar exception to the general rule of equatorial placement of the nitro group, and this rule is now recognized to hold for the acidification of all known 3-deoxy-3-nitro-aldopyranosides and structurally analogous keto-pyranosides and sugar anhydrides. The conformations **7***a*, **8***a*, and **9***a* come as no surprise as they are the same as those preferred by the corresponding, non-nitro parent glycosides, but the case of **6***a* is worthy of special note. β-D-Ribopyranose favors the C_1^4 chair (9), although the inverted chair is populated to a considerable degree (7). Methyl β-D-ribopyranoside had long been assumed to exist in the C_1^4 chair form (10), but recent n.m.r. data indicate that the two chair forms have about equal stability (7), and this is ascribed to a somewhat greater anomeric effect of the methoxyl group compared to that of the hydroxyl group. An analogous situation pertains in β-D-ribopyranose tetraacetate in acetone solution (11). Only further enhancement of the anomeric effect, as experienced by tri-*O*-acetyl-β-D-ribopyranosyl halides in chloroform, causes strong predominance of the C_4^1 form (12). Substitution by a nitro group of the axial hydroxyl on C-3 in methyl β-D-ribopyranoside (in the C_1^4 form) evidently compels chair inversion with similar strength.[8] The conformational free energy of the nitro group in the nitrocyclohexane system has been determined (6) to be 1 kcal/mol, but this value (which refers to a nonaqueous medium) barely exceeds the 0.9 kcal/mol associated here with an axial hydroxyl, in opposition to two axial hydrogens, and would be unable to account for the observed effect.[9] An appreciably higher value must apply in our nitro glycosides in water, which could be due to increased bulk owing to hydration, or to dipolar interaction with the ring oxygen.

Stereochemistry of Acidification of Nitronates

At this point it is interesting to discuss, in the light of the preceding considerations, the stereochemical course of the acidification of the nitronates **2**, **3**, and **4**. Let us compare the relative, thermodynamic stabilities calculated for the two 3-epimeric nitro glycosides that can theoretically arise from each nitronate. The interaction energies for the favored conformers (*i.e.* those having an equatorial nitro group) are listed in Table 5.

[8]The n.m.r. spectra of **6** in D_2O (Table 4) and in $CDCl_3$ exhibited virtually identical splitting patterns, indicating that the predominant conformation (**6***a*) was, within observable limits, no less populated in the former solvent than in the latter. The extra stabilization that **6***a* may be afforded in a nonpolar solvent due to an increased anomeric effect and the possibility of intramolecular hydrogen bonding between the *syn*-axial hydroxyl groups is, therefore, not required for its preponderance.

[9]In fact, by equating the interaction of an axial nitro group and two opposing hydrogen atoms with 1 kcal/mol, one would obtain equal energies for the two chair forms of **6**, assuming that the *gauche*, nitro–hydroxyl interactions are the same.

TABLE 5. Calculated, partial* energies of non-bonded interaction in conformers having an equatorial nitro group

Compound (Configuration)	kcal/mol
6*a* (β-D-*ribo*)	2.4
7*a* (β-D-*xylo*)	1.75
8*a* (α-L-*arabino*)	2.20
10*a* (α-L-*lyxo*)	1.35
9*a* (β-D-*arabino*)	1.70
11*a* (β-D-*lyxo*)	2.65

*Less *gauche* nitro-hydroxyl interactions; see text.

Where applicable in these computations, the anomeric effect was assigned a value of 1.4 kcal/mol (rather than 1.05 kcal/mol as in Table 3), the higher value applying to methanolic solutions (5*e*).[10] The figures do not include the contributions by *gauche* interactions of the nitro group with its neighboring hydroxyls; the energy associated therewith is unknown but may be disregarded as it should be equal in any two 3-epimers and will therefore cancel in their free energy difference. Now it is seen that the β-D-riboside (**6***a*), the major product obtained from **2**, is considerably less stable than the β-D-xyloside (**7***a*) which was obtained as a minor product only. Similarly the α-L-arabinoside (**8***a*), which arose from the salt **3**, is less stable according to these calculations than its 3-epimer, the α-L-lyxoside (**10***a*), which has not been detected as a product. It is therefore concluded that the acidification of **2** and **3** is kinetically controlled. The same is presumably true for the acidification of **4**, although in this case the product, namely the β-D-arabinoside (**9***a*), represents the more stable epimer. Angyal and Luttrell have recently reported (14) that, in the analogous acidification of 2-*aci*-nitrocyclohexan-1,3-diol, kinetic control is not achievable because epimerization at the nitro carbon is too rapid. Obviously this does not apply to the nitro sugars, and as far as **6** and **7** are concerned we have noticed no mutual interconversion of these epimers in aqueous solution, neutral or acidic.

Evidently, the predominant path for protonation of the salt **2** is approach from the less hindered, upper side of the favored conformer **2***b*. Protonation of **2***b* from the opposite side, to give the minor product **7**, is disfavored for one or both of two reasons, namely, hindrance from the hydroxyl groups and resistance of the nitro group against being placed axially. Protonation of the conformer **2***a* should lead to **7** more readily, but since **2***a* can be present only in small proportion, **7** is relegated to the role of a by-product. As for the *threo* salts **3** and **4**, inspection of molecular models of the likely conformations **3***c* and **4***c* suggests that steric impediments to proton approach are not much different on either side, but it reveals that the direction which leads to the respective *arabino* configuration is that which avoids transitional placement of the nitro group in the unfavorable, axial position. One may thus infer, from the observed stereoselectivity in these protonations, that the structure of the transition state resembles the product and not the nitronate; for if it resembled the latter, appreciable selectivity would not be expected.[11]

Mechanism of β-*Epimerization*

To explain epimerizations at carbon atoms adjacent to the nitromethylene group, as well as some other base-catalyzed reactions involving those β-carbons, intermediate α-nitroalkene structures have been postulated, and the role of such intermediates has been substantiated by experimental evidence in several instances (16–20). Accordingly it is thought that $\Delta^{2,3}$- and $\Delta^{3,4}$-unsaturated nitro glycosides are intermediates in the epimerizations **2** ⇌ **3** ⇌ **4** ⇌ **5**. We have been able to isolate a small amount of an unsaturated material by column chromatography of the mixture of **6*** and **7*** that was obtained upon deionization of the β-L-*erythro* nitronate **2*** (see footnote 2). The i.r. spectrum of the syrupy material showed a strong peak at 1528 cm^{-1} indicating a nitroalkene grouping. The n.m.r.

[10]For preparative purposes the liberation of the nitro glycosides from their *aci* salts has been performed in this work and earlier (3, 13) by the action of a cation exchange resin in methanol, which superseded the original procedure (2) of acidification with potassium bisulfate in the dry state.

[11]During this writing there appeared extensive studies by Bordwell and Yee (15), presenting evidence for product-like transition states in the protonation of cycloalkanenitronates.

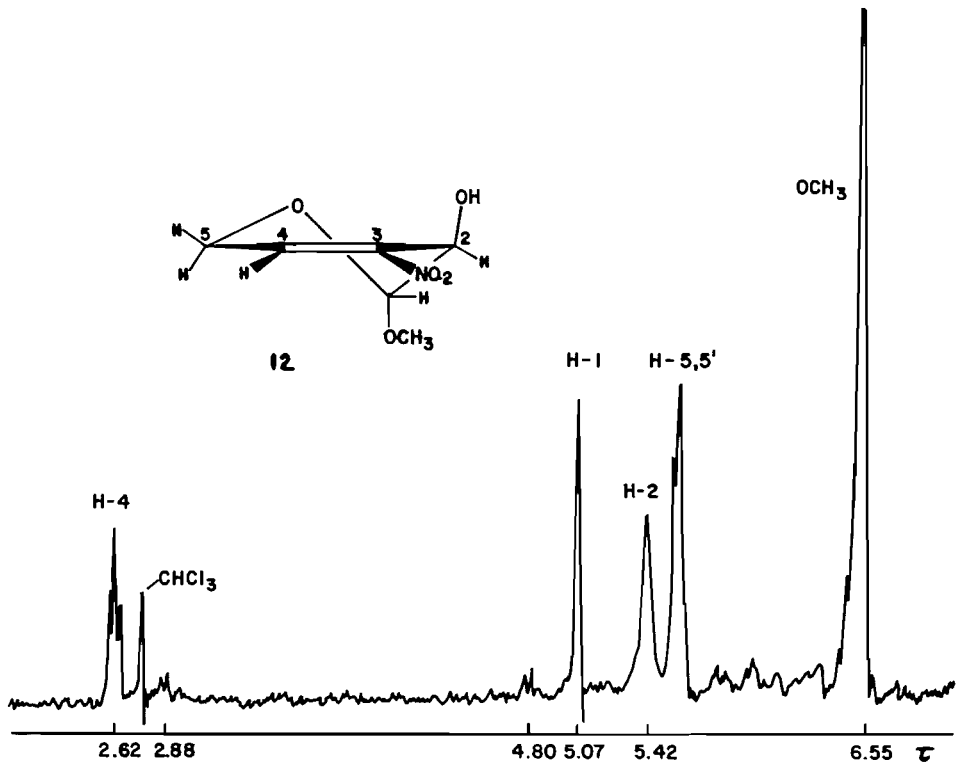

FIG. 2. The n.m.r. spectrum (100 MHz in $CDCl_3$) of nitro olefin **12**.

spectrum (Fig. 2) revealed that the product was not entirely uniform. The major component was characterized by a low-field triplet attributable to an olefinic proton which was coupled with two vicinal protons and must, therefore, be situated on C-4. The two one-proton signals assigned to H-1 and -2, respectively, appeared as singlets due to very small vicinal coupling. The spectrum fits the structure of methyl 3,4-dideoxy-3-nitro-β-L-*glycero*-pent-3-enopyranoside (**12**) in the conformation depicted. The weak doublets observed at τ 4.80 and 2.88 are probably due to the olefinic and anomeric protons of the corresponding, $\Delta^{2,3}$-unsaturated isomer. The minor component amounted to about 15% of the product.

The nitro olefins so obtained arose by acid-catalyzed dehydration of **6*** and(or) **7***, and it does not necessarily follow that they are involved in the epimerizations which occur in weakly basic medium. However, the fact that dehydration can take place under mild conditions, albeit to a limited extent, seems significant. It was shown, moreover, that **12** meets at least one requirement for being an intermediate in the epimerization. When placed in aqueous alkali (1 equiv), the olefin instantly added base to give nitronate, and the addition was found to be faster than the epimeric nitronate equilibration. An n.m.r. spectrum scanned from 1–5 min after the start of the reaction indicated that the olefin had already disappeared, giving mainly **2*** along with some **4*** (the latter presumably originating from the minor component in the olefin). There was only a trace of **3*** at this point, but its proportion increased with time as the proportion of **2*** decreased. These observations may be interpreted in terms of a rapid setting-up of a mobile equilibrium **2*** ⇌ **12** in which **2*** preponderates vastly (so that **12** is not seen in the spectrum), and through which **3*** is formed in a relatively slow reaction.

Whereas the findings just described lend support to the mechanism of reversible dehydration

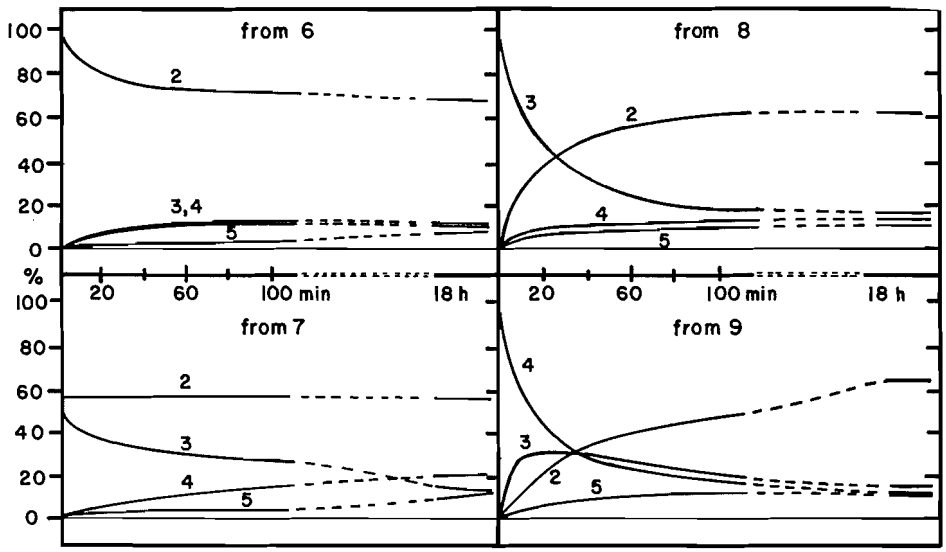

FIG. 3. Time-dependent change in composition of glycoside mixtures during alkaline epimerization.

for the β-epimerization of **2** (and hence, **6**), an unexpected behavior exhibited by the nitro xyloside **7** in alkaline solution requires that a second mechanism be assumed to operate, at least in part, in the epimerization of this compound. Even though the reaction eventually leads to the expected equilibrium mixture of nitronates, it differs in early stages from the alkaline epimerization of the nitro riboside **6**. Upon addition of an equivalent amount of alkali, **6** is rapidly converted into its salt **2**, and no other product is visible in the n.m.r. spectrum for several minutes until the epimeric salts slowly emerge (Fig. 3). Since the salt **2** is common to the 3-epimers **6** and **7**, it might have seemed obvious to expect precisely the same sequence of events to occur with **7**. Contrary to expectations, addition of alkali to **7** produced the salt **2** *and* the salt **3** practically simultaneously (*i.e.*, within the 2 min needed for recording a spectrum), in a ratio of about 1:1. Thereafter followed slow equilibration, with formation of the remaining nitronate epimers and with a final ratio of about 4:1 in respect of **2** and **3** (Fig. 3; compare also Fig. 1). The change in optical rotation during this reaction also was in agreement with an "initial" formation, not of **2** alone but of **2** and **3** in about equal amounts (Fig. 4). Clearly, the large proportion of **3** observed near the start of the reaction must be due to a fast epimerization that occurs in **7**

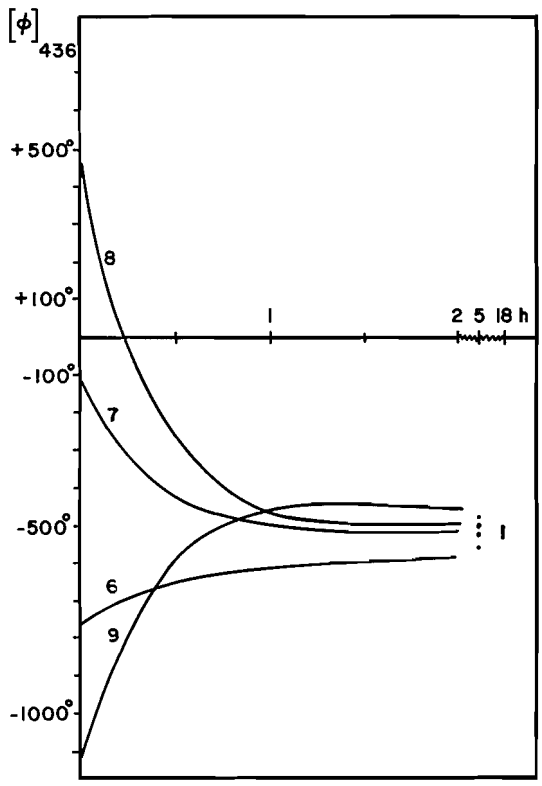

FIG. 4. Change of molecular rotations $[\Phi]_{436}$ of nitro glycosides in alkaline medium.

and does not proceed via **2**. Another phenomenon apparently related herewith was observed in the alkaline epimerization of the β-D-arabinoside **9**. In an early stage of this reaction, too, the nitronate **3** was produced in an amount larger than corresponded to the final equilibrium proportion. Its initial rate of formation was greater than that of **2** concurrently formed, but the rates then reversed, and that part of **3** which constituted a temporary excess over the equilibrium disappeared slowly (Fig. 3). It has thus become understandable that **9**, in the presence of alkali, displays a *complex* "mutarotation", a fact which had been recorded but not commented upon earlier (3). The results suggest that a mechanism other than the reversible dehydration to nitroalkene is involved at least in part of the over-all epimerization. For if only the dehydration mechanism were available, all **3** engendered from **9** (or its salt **4**) would of necessity have to arise via **2** (or via **5**), which evidently is not the case. A clue to an understanding of the epimerizations

came forth when the pK_a values of the nitro glycosides were compared. Table 6 shows p*H* values measured (at zero time) upon half-titration, and while some of these data may be apparent rather than true pK_a values,[12] they nevertheless reflect differential tendencies of nitronate formation. Most conspicuously, the xyloside **7** is a markedly weaker acid than the riboside **6**. This result is in harmony with the conformational free energies of **7***a*, **6***a*, and their common anion **2***b* which, on the basis of the preceding discussions, is expected to arise more readily from the latter than from the former. Now we suggest that **7***a*, having for stereochemical reasons a diminished nitromethylene acidity, is prone to competitive proton abstraction from its hydroxyl groups. Alkoxide formation at position 4 would initiate

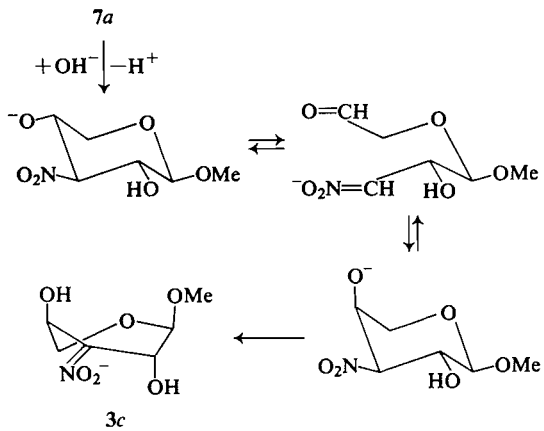
[12]A true value would be expected only if there existed, at the time of measurement, an equilibrium between the given nitro compound and the corresponding *aci* form, unadulterated by the presence of substantial amounts of epimers. This condition seems to be largely fulfilled for **6** and **8**, perhaps less so for **9**, but certainly not for **7**.

ring opening between C-4 and -3 (reverse Henry reaction), and subsequent recyclization would account for the formation of the epimeric nitronate **3** (Scheme 1). A similar if more complicated



SCHEME 1

sequence could be written to explain the formation of **3** from the relatively weak acid **9** without intermediacy of **2** (Scheme 2). Although reversible ring opening was invoked by Grosheintz and Fischer (21) to explain epimerization in deoxynitroinositols, those investigators did not consider alternative pathways via nitroolefins, nor did they advance proof for the mechanism. The nitroolefin route is certainly available as long as the nitromethylene group, rather than a vicinal carbinol group, is the site of base-induced ionization. This condition can ordinarily be presumed to apply.[13] However, when steric factors reduce the nitromethylene acidity, as they do in **7**, the compound approaches in character a *tertiary*-nitro β-carbinol.[14] Such carbinols, in contrast to those having a primary or secondary nitro group, are known to undergo reverse Henry reaction with facility.

In the light of the results presented in this article, many observations regarding epimerizations and relative thermodynamic stabilities in the hexose analogs (4) become understandable. An example is the predominance of the α-D-*talo* configuration after nitronate equilibration followed by acidification. A comprehensive treatment of the hexose series is under way.

[13]The formation of $\Delta^{4,5}$-unsaturated 3-nitronate (18) is compelling evidence for the presence of $\Delta^{3,4}$-olefins in equilibrium with 3-nitronates.

[14]Other instances of steric diminution of nitromethylene acidity have been discovered by W. Rank in this laboratory and will be dealt with elsewhere.

Experimental

Nuclear Magnetic Resonance Spectra

The spectral data of Table 4 and Fig. 2 were measured on a Varian HA 100 instrument, and those of Tables 1 and 2 and of Figs. 1 and 3 were obtained on a Varian T60 instrument. The values for the nitronates **2**, **3**, and **4** in Table 1 were recorded within 2–3 min of adding an equivalent amount of sodium deuteroxide to solutions of the corresponding nitro glycosides **6**, **8**, and **9** in deuterium oxide. The spectra from which the points of Fig. 3 were derived by measuring methoxyl signal intensities were taken in similar fashion. Epimeric nitronate distributions at equilibrium (Table 2) were calculated from spectra that were taken 18–22 h after the start of the reaction; Fig. 1 is representative.

Optical Rotations

Optical rotations refer to aqueous solutions (*c* approximately 0.5 unless specified otherwise) at room temperature. They were determined in 1-dm tubes in a Perkin–Elmer automatic polarimeter, model 141. The specific rotations at various wavelengths of the free nitro glycosides are shown in Table **7**.

The molecular rotation curves of Fig. 4 were obtained from solutions which were made up by adding equal volumes of 0.02 *N* NaOH to 0.01 *M* solutions of the nitro glycosides. Hence the solutions were 0.05 *M* in nitronate (*c* approximately 0.1) and contained 1 equiv of excess NaOH. The wavelength 436 nm was chosen because large absolute rotations and optimal light intensity resulted in more accurate readings than at other wavelengths.

Materials

The sodium nitronates **2** and **2*** and the nitro glycosides **8** and **9** were prepared as previously described (refs. 2 and 3, respectively).

The nitronate **2** (0.62 g) was suspended in a mixture of methanol (36 ml) and nitromethane (4 ml), and the suspension was shaken for 5 min with 6 ml of methanol-washed Amberlite IR-120 (H^+), whereby the salt went in solution. Filtration and evaporation of the filtrate furnished a residue which was crystallized from ethyl acetate – petroleum ether (b.p. 30–60°) to give 0.27 g (48%) of *methyl 3-deoxy-3-nitro*-β-D-*ribopyranoside* (**6**), melting as reported (2) at 90–92°. The amorphous residue (0.31 g) obtained by evaporation of the mother liquor was chromatographed on 15 g of silica gel (Merck, 70–325 mesh) with carbon tetrachloride to which increasing amounts of ethyl acetate were added. At an eluent composition 2:1, a crystalline mixture of glycosides was obtained. Recrystallization from ethyl acetate – petroleum ether gave *methyl 3-deoxy-3-nitro*-β-D-*xylopyranoside* (**7**) as shiny needles, m.p. 186–187°, in a yield of 70 mg (13%).

Anal. Calcd. for $C_6H_{11}O_6N$ (193.2): C, 37.31; H, 5.74; N, 7.25. Found: C, 37.21; H, 5.62; N, 7.12.

An additional 17 mg (3%) of **6**, m.p. 92–94°, was obtained from the mother liquor.

In order to identify the product **7**, a sample (21 mg)

was catalytically hydrogenated in 11 ml of 0.01 *N* hydrochloric acid in the presence of PtO_2 (30 mg), at 28° and ordinary pressure. Hydrogen consumption was 15 ml (required, 13.5 ml) after 2 h. The solution was then passed through a small column containing 0.5 ml of Dowex 1X2 (OH^-) resin, and was evaporated to give 16 mg of spontaneously crystallizing methyl 3-amino-3-deoxy-β-D-xylopyranoside. It melted at 195–197° after recrystallization from ethanol, undepressed upon admixture of a freshly recrystallized, authentic specimen (2).

The enantiomeric nitronate **2*** was deionized as described above for **2**. Work-up including column chromatography gave *methyl 3-deoxy-3-nitro-β-L-ribopyranoside* (**6***) as soft, granular crystals, m.p. 92–93°, and *methyl 3-deoxy-3-nitro-β-L-xylopyranoside* (**7***) as either feather-like crystals or hard prisms. Both kinds of crystals melted at 186–187°. A chromatographic fraction immediately preceding the fraction of **6*** and **7*** furnished a colorless oil which failed to crystallize although it showed a single spot on t.l.c. (CCl_4–EtOAc, 1:1). It had $[\alpha]_D$ +214, $[\alpha]_{578}$ +224, $[\alpha]_{546}$ +255, $[\alpha]_{436}$ +451° (*c*, 0.4 in water); ν_{max} in chloroform, 3200 (OH) and 1528 cm^{-1} (nitroalkene). The n.m.r. spectrum (Fig. 2) was in agreement with the structure of *methyl 3,4-dideoxy-3-nitro-β-L-glycero-pent-3-enopyranoside* (**12**).

Gas–Solid Exchange Reactions: Zinc Vapor and Monocrystalline Zinc Telluride[1]

E. A. Secco and Richard Swee-Chye Yeo

Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received[2] July 28, 1970

The exchange reaction between radioactive zinc vapor and single crystals of zinc telluride was studied in a static system in the temperature range 760–860 °C and $P_{Zn} = 0.10$ atm.

The experimental rate data are consistent with a diffusion process which is interpreted in terms of a simple vacancy mechanism. The diffusion coefficient is given by

$$D = 2.34 \pm 0.37 \exp(-47.1 \pm 5 \text{ kcal}/RT)\ \text{cm}^2\ \text{s}^{-1}$$

Utilisant un système statique entre 760 et 860 °C et à $P_{Zn} = 0.10$ atm on a étudié la réaction d'échange entre de la vapeur de zinc radioactif et des cristaux uniques de tellurure de zinc.

Les résultats expérimentaux sont consistants avec un processus de diffusion qui peut être interprété en termes d'un mécanisme de cavités simples. Le coefficient de diffusion peut être exprimé par l'équation

$$D = 2.34 \pm 0.37 \exp(-47.1 \pm 5 \text{ kcal}/RT)\ \text{cm}^2\ \text{s}^{-1}$$

Canadian Journal of Chemistry, **49**, 1953 (1971)

Introduction

This study is a continuation of a program of research on heterogeneous isotopic exchange reaction involving a metallic vapor and its II–VI solid compound. The program is an attempt to understand the kinetics and mechanism of gas–solid interaction.

Previous studies reporting on the Zn–ZnO (1) and Zn–ZnS (2) systems have shown the exchange rate to be controlled by two processes, an initial first-order rate followed by a diffusion rate. On the other hand, the Zn–ZnSe (3) kinetic data showed the exchange reaction to be diffusion-controlled over the entire range investigated. The fact that ZnSe possesses a zinc blende cubic structure in contrast to the wurtzite hexagonal structure of ZnO and ZnS focussed attention on the crystal structure of the solid compound.

It was considered desirable, therefore, to probe the effect of the structural parameter by including the Zn–ZnTe system in this program; ZnTe is the fourth member in this family of compounds and possesses a cubic structure.

Experimental

The ZnTe single crystals used in this work were obtained from the laboratory of Prof. D. A. Stevenson, Dept. of Materials Science, Stanford University. The ZnTe was grown from Te rich solution, with Zn 6′9[3] and Te 6′9[3], and spectrosil quartz. A given crystal specimen was re-used for successive exchange experiments at the same temperature.

The exchange reaction was assumed to occur on one face, since the specimen geometry approximated a thin plate and the bottom face resting on the bucket floor was not exposed to the zinc vapor. The accessible depth for exchange is thus assumed to be the average thickness of the crystal. The crystal thickness was calculated from the projected area which was measured by an Olympus ECTR microscope.

The exchange runs were carried out in a static system with the use of quartz vessels, and the reaction fraction was determined by the uptake of radioactive zinc, as previously described (4, 5). All exchange experiments were done at a zinc pressure of 0.10 atm at the annealing temperature.

Results

The kinetic data for the Zn–ZnTe exchange reaction, although exhibiting exponential features, could not be fitted to a first-order rate expression. The alternative, that is, that the exchange process is a diffusion-controlled transport mechanism whose rate is a function of depth, was most probable.

The diffusion equation of interest in this case is that in which an infinite sheet of uniform material of thickness h is bathed in an atmosphere containing the diffusant. For the case of the lamina, to which the single crystal specimen is assumed to approximate quite well, the solution to the prob-

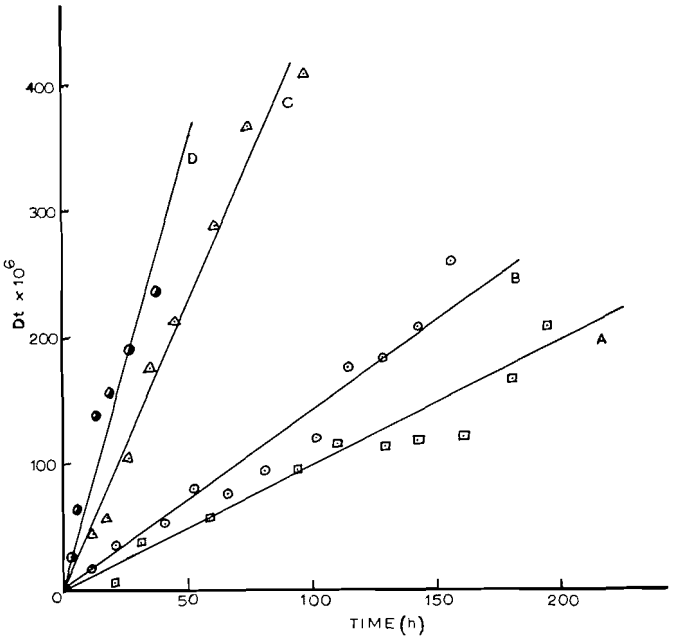

FIG. 1. Plot of Dt *vs.* time. *A*(769 °C); *B*(800 °C); *C*(820 °C); *D*(860 °C).

lem is given by Crank (6) in the form

$$[1]\quad \frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty} \frac{2\beta(\beta+1)}{1+\beta+\beta^2 q_n^2} \times \exp(-Dq_n^2 t/h^2)$$

This gives the total amount of M_t of tracer in the solid lamina at time t as a fraction of the amount M_∞ at equilibrium. β is the ratio of the moles of zinc in the vapor to the moles of zinc in the solid, *i.e.* n^g/n^s; D is the diffusion coefficient and h is the lamina thickness. The q_n's are the non-zero positive roots of

$$[2]\quad \tan q_n + \beta q_n = 0$$

In order to test the applicability of the diffusion equation and evaluate the diffusion coefficients, a theoretical plot is made of (M_t/M_∞) against $x = (Dt/h^2)^{1/2}$ and from this curve a value of x is read from each experimental value of (M_t/M_∞) and mole fraction, $S = n^s/(n^s + n^g)$. Eventually, a plot of $x^2h^2 = Dt$ against the reaction time $t = \sum_{i=1}^{n} t_i$ was made; t_i represents the individual reaction time intervals. If the diffusion equation is obeyed, the resulting graph should be a straight line through the origin, the slope of which is D. Figure 1 shows such plots of Dt as a function of time for ^{65}Zn exchange with ZnTe at different temperatures. The very good fit of the experimental data with the theoretical diffusion expression supports the interpretation that the exchange reaction is governed by a diffusion process at the outset.

The diffusion coefficients at the various temperatures were taken from the slope of the straight line in Fig. 1. The logarithm of the diffusion coefficients *vs.* $1/T$ °K yields a straight line, Fig. 2, corresponding to an activation energy of 47.1 ± 5 kcal. The diffusion equation is given as

$$[3]\quad D = 2.34 \pm 0.37 \exp(-47.1 \pm 5 \text{ kcal}/RT) \text{ cm}^2 \text{ s}^{-1}$$

Discussion

The fact that a single diffusion-controlled rate is observed in the cases of cubic ZnTe and ZnSe whereas two rate processes, first-order followed by diffusion, are observed in the hexagonal structures of ZnO and ZnS confirms the effect of the crystal structure parameter on the gas–solid exchange reaction. The rate-determining processes involved in our gas–solid exchange studies have been analyzed and interpreted (3) in terms of two limiting conditions: (*i*) the solid is relatively permeable and the exchange sites are readily accessible to the gas with a first-order rate pre-

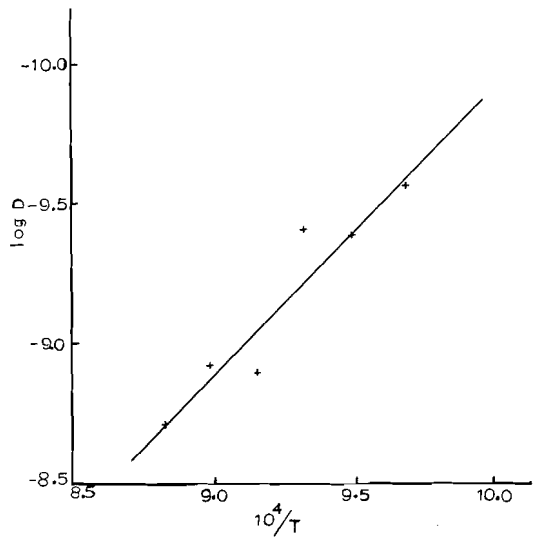

FIG. 2. Plot of log D *vs.* $1/T$ °K.

vailing, and (*ii*) the solid exchange sites are *not* readily accessible to the gas so that diffusion or transport step is rate-controlling. In the case of hexagonal structure conditions (*i*) and (*ii*) are operative in sequence whereas condition (*ii*) only is operative in the cubic structure.

Diffusion Mechanism in Zinc Telluride

Thomas and Sadowski (7) have reported results which are consistent with the vacancy model suggested by Aven and Segall (8); that is, doubly ionized zinc vacancies are the dominant native acceptor defect in undoped ZnTe in contact with zinc vapor. The equilibrium between lattice zinc atoms, Zn_i, zinc vacancies V_{Zn}, holes h, and zinc vapor Zn_g, may be written as

$$[4] \qquad Zn_i \rightarrow V_{Zn}^{2-} + 2h^+ + Zn_g$$

with the equilibrium constant K expressed as

$$[5] \qquad K = [V_{Zn}^{2-}]p^2P_{Zn} = \tfrac{1}{2}p^3P_{Zn}$$

where $[V_{Zn}^{2-}]$ is the concentration of V_{Zn}^{2-}, doubly ionized zinc vacancy, p is the concentration of holes h^+, and P_{Zn} is zinc vapor pressure. Rearranging [5], we have

$$[6] \qquad p = 2[V_{Zn}^{2-}] = (2K/P_{Zn})^{1/3}$$

which is the observed pressure dependence on the hole concentration (7),

$$[7] \quad p(\text{holes/cm}^3) = 3.73 \times 10^{23}P_{Zn}^{-1/3} \text{ (mm Hg) } \exp(-1.31 \text{ eV}/kT)$$

Assuming that zinc diffusion in zinc telluride crystal occurs via the vacancy mechanism, the diffusion coefficient is given by (9)

$$[8] \qquad D = \alpha\lambda^2\Gamma[V_{Zn}^{2-}]$$

where α is the geometry jump factor, that is, the number of possible jump vectors that give the same jump distance λ and still move in a particular direction; in the case of ZnTe, $\alpha = 4$. Γ is the jump frequency which is given as

$$[9] \qquad \Gamma = \nu \exp(-E_m/RT)$$

where ν is the atomic vibration frequency and E_m is the activation energy for mobility or the migration energy. The concentration of V_{Zn}^{2-} can be expressed as

$$[V_{Zn}^{2-}] = \exp(S_v^f/R)\exp(-E_v^f/RT)$$

where E_v^f and S_v^f are the energy and entropy change involved in the formation of the vacancy, respectively.

The zinc vacancy concentration in ZnTe in contact with zinc vapor at $P_{Zn} = 0.10$ atm can be calculated from [7] and [8] to yield

$$[10] \quad [V_{Zn}^{2-}] = 2.23 \exp(-30.2 \text{ kcal}/RT)$$

The diffusion coefficient normally expressed as $D = D_0 \exp(-Q/RT)$ now becomes

$$[11] \quad D = \alpha\lambda^2\nu \exp(S_v^f/R)\exp(-E_m - E_v^f/RT)$$

where

$$D_0 = \alpha\lambda^2\nu \exp(S_v^f/R) \quad \text{and} \quad Q = E_m + E_v^f$$

By assuming ν as the average between $\nu_{760\,°C}$ and $\nu_{860\,°C}$ which is calculated from Debye theory to be 9.639×10^{13} s^{-1} and taking λ as Zn–Zn jump distance in ZnTe to be 4.31×10^{-8} cm, D_0 is computed to be 1.67 cm^2 s^{-1} as compared to the experimental value of 2.34 ± 0.37 cm^2 s^{-1}. The agreement is to be considered excellent in view of the assumptions and the experimental errors involved.

The diffusion equation for self-diffusion of ^{65}Zn in ZnTe reported by Reynolds and Stevenson (10), $D = 14 \exp(-62.0 \text{ kcal}/RT)$ cm^2 s^{-1}, differs from our observed equation. They reported an enhanced self-diffusion of Zn in Al-doped (2×10^{19}/cm^3) ZnTe in the temperature interval 650–830 °C, $D = 10^{-4} \exp(-39.2 \text{ kcal}/RT)$ cm^{-2} s^{-1}, but observed no dependence of D on Zn partial pressure in undoped ZnTe crystals.

Infrared Combination Frequencies in Coordination Complexes containing Nitrate Groups in various Coordination Environments. A Probe for the Metal–Nitrate Interaction

A. B. P. LEVER, E. MANTOVANI, AND B. S. RAMASWAMY
Department of Chemistry, York University, Downsview, Toronto, Ontario

Received November 30, 1970

The number and relative energies of nitrate combination frequencies in the 1700–1800 cm^{-1} region of the infrared spectrum may be used as an aid to distinguish the various coordination modes of the nitrate group. The data also provide an excellent probe for the strength of the metal–nitrate interaction.

Le nombre et les énergies relatives des combinaisons de fréquence des groupes nitrates dans la région de 1700–1800 cm^{-1} du spectre infrarouge peuvent être utilisés dans le but de déterminer les divers modes de coordination du groupe nitrate. Les résultats fournissent un outil excellent pour déterminer la force d'une intéraction métal–nitrate.

Canadian Journal of Chemistry, 49, 1957 (1971)

Introduction

It is well known that in a nitrato complex, the nitrate group may be present as a free ion, or as a coordinated ligand, bound in a unidentate or bidentate or intermediate fashion or may be bridging (1). Moreover, in complexes containing several nitrate groups, more than one coordination mode may be present. Many papers have appeared (2–21) in which attempts have been made to use the infrared spectra and Raman spectra of such complexes as a guide to the coordination mode present. It was initially proposed that the presence of an N=O stretching frequency above 1570 cm^{-1} (10) (or above 1600 cm^{-1} (9)) indicated the presence of a bidentately coordinated nitrate group, but many exceptions to these suggestions soon became apparent (3, 14, 15). Of more fundamental validity was the suggestion that the doubly degenerate asymmetric ν_3 stretching vibration (E' in the D_{3h} symmetry of the free nitrate ion (16)) should split upon coordination (8), since the symmetry of the nitrate species would be reduced to C_{2v}, and moreover that the extent of the splitting is a guide to the coordination mode (3, 7). Unfortunately this criterion is also highly unreliable (15).

Raman studies have been of greater utility in distinguishing monodentate from bidentate coordination since these give rise to different sequences of polarization of the fundamental stretching modes (19). However, for various reasons Raman data are not so routinely available as infrared spectra.

In 1965 Curtis and Curtis (7) concluded, on the basis of a very small amount of data, that bands in the infrared spectra near 1750 cm^{-1}, assigned to combination modes, could be used for structural diagnosis. In particular, an ionic nitrate group gives rise to one relatively strong and very sharp combination frequency, whilst coordinated nitrate groups give two frequencies with the bidentate coordination mode giving a wider separation of these two frequencies than the unidentate coordination mode. The intensities were shown to decrease in the order ionic > unidentate > bidentate. This correlation has rarely been referred to in subsequent studies despite the apparent usefulness of the criteria and the fact that this region of the spectrum is generally free from other absorption.

In this paper we have studied this region in the spectra of a large number of nitrato complexes and report our conclusions. Some typical spectra are shown in Fig. 1.

Experimental

Most of the compounds have been previously reported. They were prepared by the methods outlined in the literature according to the references. The new complexes listed in Table 1 were all prepared by reaction of the stoichiometric amounts of amine and metal nitrate in ethanol, followed by recrystallization from the same solvent where feasible. They were dried in a vacuum desiccator prior to analysis and the recording of spectra.

The nickel analysis employed the dimethylglyoxime complex, whilst the cobalt and copper analyses were by the pyridine thiocyanate method. Nitrate was analyzed as its Nitron salt. Infrared spectra were obtained as Nujol mulls between NaCl plates with a Beckman IR12 instrument. There was no evidence of any exchange of Cl^- for NO_3^- when using NaCl plates, since the nitrates under study were generally of low reactivity.

In order to correctly identify the combination bands the spectra of the complexes were compared with the spectra of corresponding complexes with other anions, in the 1700–1800 cm^{-1} region. Overtones from organic ligands are sometimes seen in this region.

Results and Discussion

Nitrate complexes are known (7, 11, 12) to give rise to combination frequencies near 1750 and near 2400 cm^{-1} and to an overtone (of the symmetric stretching vibration) near 2000 cm^{-1}. The bands near 1750 cm^{-1} are generally clearly defined and often relatively strong (see below), whilst those near 2000 and 2400 cm^{-1} are weaker, and often broad and sometimes very difficult to locate. For these reasons we are concerned here solely with the absorption near 1750 cm^{-1}. In this region the ionic nitrate group exhibits a single band which has been assigned (7, 11, 12) to a combination of the ν_1 symmetric stretch (A_1, in D_{3h}) and the doubly degenerate in-plane bending mode ν_4 (E' in D_{3h}). This combination is allowed by symmetry although of course combination frequencies are generally forbidden for an harmonic oscillator. The fact that it is observed implies some anharmonicity is present. When the nitrate group coordinates to a metal atom (in either a unidentate or bidentate fashion), then its local symmetry is reduced to C_{2v} (or perhaps lower (1)). As a consequence, the doubly degenerate in-plane bending mode splits into two components (A_1 and B_2 in C_{2v}). Combination of both of these modes with the symmetric stretch (A_1 in C_{2v}) is still allowed by symmetry and therefore two combination frequencies may be expected. These are observed and it is highly pertinent to their assignment that their separation

corresponds closely to the splitting of the ν_4 fundamental mode (7).

Whilst coordination of the nitrate group will formally reduce its symmetry to C_{2v}, one may suppose that if the metal nitrate interaction is small the species may still be effectively D_{3h} and give rise to only a small splitting in ν_4 and, therefore, a small splitting in the combination frequency. Thus the separation in the combination frequencies is expected to be a guide to the degree of metal–nitrate interaction. It is expected that for a given metal, bidentate coordination involves a greater distortion from D_{3h} symmetry than unidentate coordination and, therefore, bidentate complexes should show a larger separation of $(\nu_1 + \nu_4)$; Curtis and Curtis (7) showed that this is indeed true.

The above discussion makes the tacit assumption that correlation coupling between one nitrate molecule and another in a polynitrato species (such as the ion $Ce(NO_3)_6^{2-}$) or between one molecule and another (solid state site symmetry phenomena) will not lead (if the nitrate groups within the molecule are equivalent by symmetry) to more than one set of combination bands. Curiously, and somewhat unexpectedly, this assumption does seem to be valid for all the complexes we have investigated to date. Thus even though the ν_1 and the components of the ν_4 fundamental bands in the spectrum of the hexanitratocerate(IV) ion show structure presumably arising through coupling phenomena, only two sharp bands, whose separation is typical of a bidentate coordination, are observed in the combination region near 1750 cm^{-1}. The only indication of any structure in this region is an almost imperceptible shoulder on the lower energy band.

It is worthwhile emphasizing at this point that the data to be discussed in this paper reflect the symmetry of the environment in which the nitrate finds itself and does not necessarily infer a covalent metal–nitrate interaction. If the nitrate group is asymmetrical as a consequence of monodentate or bidentate coordination to a metal ion, then there is clearly some degree of metal–nitrate interaction, and the nitrate electron density is clearly polarized by the metal ion. The polarization, however, may proceed by an ionic or covalent mechanism or mixture thereof.

With this background it is now useful to consider the various series of complexes studied in turn.

Complexes with Bidentate Nitrate Groups

The series $M(R\text{-}Py)_2(NO_3)_2$ (M = Co(II), Ni(II), and Cu(II), see Table 1) all possess bidentate nitrate groups (3, 13) and give rise to two fairly weak combination bands separated (with one exception, see below) by 38–56 cm^{-1}. These data agree well with those found (41–53 cm^{-1}) by Curtis and Curtis (7) for a series of mononitrato tetraammine complexes of nickel(II). The series $(Ph_3AsCH_3)_2\ M^{II}(NO_3)_4$ have varying structures depending upon the nature of M. The cobalt complex (with Ph_4As^+ as cation) was shown to be eight coordinate, with bidentate nitrate groups, by Cotton and Bergman (22). Very recently the manganese and zinc complexes were also shown (23) to be eight coordinate, analogous to the cobalt derivative (in the case of the zinc complex the structure was inferred from a limited amount of X-ray data). All three complexes exhibit a pair of combination frequencies separated by 45–51 cm^{-1}, in agreement with their structure. The nickel and copper complexes have different structures and different i.r. spectra and are referred to below. The complex dinitrato[bis(2-pyridyl)disulfide]copper(II) has been shown to be octahedral with bidentate nitrate groups (24) and exhibits two combination frequencies separated by 47 cm^{-1}. The complex $Cu_2(Py)_5(NO_3)_2$ has recently been shown by X-ray methods (25) to contain both bidentate and bridging nitrate groups. The presence of the bidentate nitrate groups is shown by two well defined bands at 1720 and 1741 cm^{-1} whilst the bridging bands appear only to give rise to weak absorption at higher energies (see below). If the interaction between the metal and the bidentate nitrate group is weakened for some reason, then, following the argument developed above, a decrease in the splitting may be expected. Such decreases are exhibited, for example, by $Rb(UO_2NO_3)_3$ and the salts of $Nd(NO_3)_6^{3-}$ and $Sm(NO_3)_6^{3-}$, presumably as a consequence of the more electropositive character of the lanthanides and actinides, which would form only weak metal oxygen bonds. The rubidium complex has been shown to contain bidentate nitrate groups (26, 27). Although X-ray structural data are not available for the lanthanide derivatives quoted, there are some X-ray data available for lanthanide nitrate complexes (28) and it is fairly safe to infer that the coordination polyhedron around these ions is 12 coordinate.

For personal use only.

A series of lanthanide complexes of the formulae $Ln(NO_3)_3(TBP)_3$ (TBP = tri-*n*-butylphosphate) have been studied by Ferraro *et al.* (20) and are shown by Raman polarization studies (19) to contain bidentate nitrate groups. These exhibit a pair of combination bands near 1750 cm^{-1} separated by 29–54 cm^{-1}. Some uranium and thorium TBP complexes (shown in Table 1) contain bidentate nitrate groups as indicated by Raman studies (20) and give rise to combination band splittings near 45 cm^{-1}. The salt $(NH_4)_2Ce(NO_3)_6$ exhibits a separation of similar amount (*vide supra*) and X-ray evidence (28) indicates that the $[Ce(NO_3)_6]^{2-}$ ion contains bidentate nitrate.

The mono-diamine copper complexes also represent interesting members of this class. Because of the tetragonal distortion expected for d^9 Cu(II) complexes, it is very likely that these complexes have an in-plane CuN_2O_2 chromophore with long axial Cu—O bonds (29), such that the bidentate nitrate group is unsymmetrically bound with two different copper oxygen bond lengths. No X-ray data are available to confirm this supposition but it is significant that the splitting of the combination bands is decreased from the values observed with the cobalt and nickel complexes described above. It is also highly relevant that whilst the complex $Cu(3\text{-}Pic)_2(NO_3)_2$ has a band splitting of 38 cm^{-1} the more highly hindered $Cu(2\text{-}Pic)_2(NO_3)_2$ gives a splitting of only 21 cm^{-1}. In this last case a very recent X-ray structure has indeed revealed (30) the presence of a long and a short copper–oxygen interaction to the same nitrate group. The situation is intermediate between monodentate and bidentate coordination.

Complexes with Monodentate Nitrate Groups

Curtis and Curtis (7) had shown, on the basis of only three nickel compounds, that the splitting of the combination bands for a monodentately bound nitrate group, was of the order of 15–21 cm^{-1}. Our own data (Table 1) for cobalt and nickel complexes suggest a slightly larger range of 16–26 cm^{-1} for a strongly bound monodentate nitrate group. Once again, however, the copper complexes, in which the nitrate groups occupy the axial sites and will only be weakly bound, give rise to much smaller splittings, of the order of 5–11 cm^{-1}. There seems little doubt that *for a given metal* the splitting in complexes with monodentate nitrate complexes is smaller than that exhibited by the bidentate derivatives and that the size of the splitting for a given mode of bonding depends upon the strength of the interaction (*vide infra*).

Complexes with both Monodentate and Bidentate Nitrate Groups

Such complexes may be expected to show four combination bands because a pair of frequencies is generated from each coordination mode. In many cases four such bands are observed, although occasionally two may overlap. There is no simple way of identifying which bands belong to which coordination mode and the splitting values given in Table 1 are somewhat arbitrary in that the pairs are chosen to yield values of Δ consistent with the presence of the two coordination modes. If inter or intramolecular coupling between equivalently bonded nitrate groups can be excluded as a mechanism for introducing band multiplicity in the combination region, then the presence of multiple bands (more than two) in this region can be used as an indicator of the presence of inequivalently bound nitrate groups. As discussed above, such coupling might well be expected to introduce additional structure in the combination region, but our experiments to date indicate that this does not generally occur. Clearly however, care must be taken in deducing information from multiple combination bands, and solution data should be obtained if possible. Rosenthal and Drago (31) had previously proposed that the tris(pyridine) metal nitrates contained both monodentate and bidentate coordination and our results support this supposition. These data also support the structure previously suggested for the complex $Cu(PE)(NO_3)_2$ (24). The tetranitrato anions of nickel and copper have long been known to have structures different from their cobalt and manganese analogs, but the precise structures have remained unknown. The nickel complex is undoubtedly octahedral (6, 32) on the basis of its electronic spectrum. Our data support the previously inferred conclusion (32) that the coordination polyhedron is made up of both monodentate and bidentate nitrate groups, although it is not possible to unequivocally exclude the presence of bridging nitrate groups (see Note added in proof). Similar comments may be made about the structure of the $[Cu(NO_3)_4]^{2-}$ ion; in this case there is a

For personal use only.

similarity between the spectrum of this compound in this region and that of the solid anhydrous $Cu(NO_3)_2$, which may favor a polymeric structure.

Bridging Nitrate Groups

Three kinds of bridging nitrate groups may generally be recognized. The first, through all oxygen atoms, is likely to occur in some simple anhydrous metal nitrates. Such structures may be seen as an extension of simple ionic structures, such as $NaNO_3$, when the alkali metal is replaced by a more covalent metal such as silver. Silver nitrate itself has an "ionic" lattice in which the nitrate ions are asymmetrically situated such that two oxygen atoms are similar to one another but different from the third in their environment (33). A separation of 20 cm^{-1} is observed in the combination bands which probably reflects the asymmetry of the nitrate group and does not necessarily reflect the presence of a covalent metal oxygen interaction. Whether such a lattice may be considered to contain bridging nitrate groups is perhaps debatable and a Raman study to locate silver–oxygen vibrations would be useful in this context. Certainly the combination spectra are not consistent with the presence of symmetric nitrate ions.

Bridging through two oxygen atoms to different metal atoms is exemplified by the α modification of copper nitrate (34). Finally one oxygen atom of the nitrate group may bridge two metal atoms as in the complex $Cu_2(Py)_5(NO_3)_2$ previously described (25).

Consideration of the combination frequencies of these and other bridging nitrate complexes does not, unfortunately, lead to any unequivocal relationships between the spectra and structure, or mode of bridging. Perhaps the only systematic observation is that complexes containing bridging nitrate groups almost invariably exhibit a combination band at a higher frequency (near 1800 cm^{-1}) than those generally observed in non-bridging systems. The presence of such a band may well imply bridging nitrate, but its absence does not convey the converse. The polymeric $Ni(NO_3)_2.2H_2O$ complex (35) absorbs at 1797 cm^{-1}, considerably higher than any other nickel complexes studied so far.

Similarly high energies were observed in some anhydrous metal nitrates reported by Addison and Gatehouse (11). Anhydrous copper nitrate (β form, which apparently has a similar structure to the α form (1)) also shows a band at 1792 cm^{-1} with a shoulder at 1733 cm^{-1}. The obvious relationship of this spectrum to that of the $[Cu(NO_3)_4]^{2-}$ ion suggests the latter might be polymeric. The data do not appear consistent with the recent suggestion (23) that this complex is similar to the $[Au(NO_3)_4]^-$ ion which possesses monodentate nitrate groups (36).

The complex $(Ph_3P)_2Ni(NO_3)_2$ described by Venanzi (37) has been an enigma for some time. Similar complexes with the halides were shown to be tetrahedral but the magnetic and electronic spectroscopic properties of the nitrate were inconsistent with this stereochemistry. The complex exhibits multiple absorption in the region 1700–1800 cm^{-1} but unfortunately so does the free triphenylphosphine ligand. The bands indicated in Table 1 were chosen on the assumption that the bands due to the ligand have not shifted much upon coordination; these were then subtracted from the spectrum. The band at 1798 cm^{-1} is consistent with the presence of a bridging nitrate group (although it is very weak) whilst the bands at 1765 and 1711 cm^{-1} (the latter being the strongest) represent the pair of bands arising from a bidentate nitrate group. The complex is then formulated as being a polymeric octahedral derivative with both bidentate and bridging nitrate groups.

Ionic Nitrate Complexes

Ionic nitrates when present with complex counterions, such as those in Table 1 give rise to a single sharp narrow band near 1750–1800 cm^{-1}. The absorption is strong relative to the absorption shown in this region by other types of nitrate group, and is quite distinctive. Simple salts such as $NaNO_3$ and $Sr(NO_3)_2$ generally exhibit a similar sharp narrow band, but somewhat weaker and at energies varying from 1750 to as high as 1800 cm^{-1} or a little above (38–40). Detailed studies of some anhydrous Group(II) metal nitrates have been reported (39, 40) in which the spectra were analyzed with correlation coupling of the nitrate groups (39, 40) taken into account. Although multiple combination bands are expected they are not generally observed (39) (Schutte finds evidence in some cases of a splitting of the order of 5 cm^{-1} or less (40)). Hydrated

For personal use only.

nitrates, on the other hand, do not always show this absorption. Extensive hydrogen bonding may be responsible.

Conclusion

It is apparent that useful structural information can be derived from consideration of the combination bands exhibited by nitrato complexes in the 1700–1800 cm^{-1} region. Intermolecular or intramolecular correlation coupling of the nitrate groups does not seem to be an interfering factor although it may be responsible for minor shoulders in some of the spectra. The magnitude of the splitting depends on the metal–nitrate interaction and is generally larger for bidentate than for monodentate coordination *for a given metal and oxidation state*. With the fairly restricted range of polarizing cations in this study the separation for the monodentate nitrate group lies in the range 5–26 cm^{-1} whilst for the bidentate complexes it is 20–66 cm^{-1}. It is relevant that the Ce(III) complex $Ce(NO_3)_3(TBP)_3$ gives a separation of 54 cm^{-1} (20) whilst the Ce(IV) complexes $Ce(NO_3)_4(TBP)_2$ (20) and $(NH_4)_2Ce(NO_3)_6$ yield separations of 25 and 41 cm^{-1}, respectively. Clearly polarization alone cannot explain these differences and consideration must be taken of the number of nitrate groups attached to the metal ion and of the nature of any other coordinating ligands. With the very strongly polarizing Au(III) cation, in the complex ion $Au(NO_3)_4^-$ containing monodentate nitrate groups (36), the fundamental ν_4 band is split by as much as 80 cm^{-1} inferring that the combination band should be similarly split.[1] However, this complex does not exhibit combination absorption in the 1750 cm^{-1} region.[1]

Thus in conclusion the multiplicity and separation of the combination bands in the 1750 cm^{-1} region when observed can be used as additional support for structural diagnosis when used in conjunction with Raman studies or with information from the fundamental vibration region of the infrared spectrum. They may also provide information concerning the polarizing power of the cation but further studies with a wider range of cations are needed to confirm whether useful bonding information can be derived.

[1]We are grateful to a referee for providing this information.

NOTE ADDED IN PROOF: The combination frequencies of the $M(NO_3)_4^{2-}$ series (M = Mn, Co, Ni, Zn) in CH_2Cl_2 solution are essentially identical to the solid state spectra except for minor shifts in energy. Evidently the nickel complex is not polymeric.

NOTES

Temperature Dependence of the Diffusion of 1,2-Dichloroethane, 1,1,1-Trichloroethane, Trichloroethylene, and Tetrachloroethylene in Air[1]

HARRY WATTS

Exploratory Research Laboratory, Dow Chemical of Canada Limited, Sarnia, Ontario

Received January 19, 1971

The diffusion coefficients in air of 1,1-dichloroethane, 1,1,1-trichloroethane, trichloroethylene, and tetrachloroethylene have been measured over a temperature range from room temperature to close to their boiling points by a rate of evaporation method.

Utilisant une méthode faisant appel à la vitesse d'évaporation, on a mesuré à différentes températures variant entre celle de la pièce et celle de leur point d'ébullition les coefficients de diffusion dans l'air du dichloro-1,1 éthane, du trichloro-1,1,1 éthane et du tétrachloroéthylène.

Canadian Journal of Chemistry, 49, 1965 (1971)

Introduction

The measurements reported in this paper constitute a continuation of a study of diffusion in air of chlorinated hydrocarbons of industrial importance. Previously, data obtained with some chloromethanes over a wide temperature range were reported (1). Earlier data on diffusion in air of a number of compounds have been collected by Fuller, Schettler, and Giddings (2). Lugg (3) recently published measurements of the diffusion coefficients of 147 compounds in air at 25 °C, while other measurements have been reported by the present author and co-workers (4, 5).

Experimental

The apparatus and procedure for measurements by the rate of evaporation method have been described previously (1). All of the chlorinated hydrocarbons were made by Dow Chemical of Canada, Limited and shown by gas chromatographic analysis to have the following purities: 1,2-dichloroethane 99.89%, 1,1,1-trichloroethane 99.96%, trichloroethylene 99.99%, tetrachloroethylene 99.99%.

Results

Measurements were made from 25 °C up to near the boiling point of each substance except tetrachloroethylene for which the vapor pressure at 25 °C was too low to permit measurements in a reasonable time and the boiling point was above the temperature range for which the present apparatus functioned satisfactorily. Diffusion coefficients were calculated both by assuming that vapor of the diffusing substance behaved as an ideal gas so that its concentration was proportional to its partial pressure and by making appropriate corrections for gas non-ideality using the McGlashan–Potter equation (6) to calculate second virial coefficients as before (1). Auxiliary data used in computing the diffusion coefficients are given in an appendix. All diffusion coefficients were corrected to 1 atm pressure by the usual method (1).

Diffusion coefficients were fitted to the equation

$$[1] \qquad \log D = \log D_0 + \nu \log T$$

where D is the diffusion coefficient, T is the absolute temperature, and D_0 and ν are constants. Values of D_0 and ν for each system are given in Table 1 together with the root mean square deviations of experimental diffusion coefficients from the fitted line which are given only for the data corrected for gas non-ideality; the corresponding deviations when the vapor was assumed ideal differ from these insignificantly.

Discussion

The precision of the results as measured by the root mean square deviations from the least squares fit to eq. 1 is 1–2% and comparable with that obtained in earlier work on the same apparatus. More significant is the difference between

diffusion coefficients calculated assuming the diffusing vapor is an ideal gas and those calculated making corrections for non-ideality. This difference is shown clearly by the smoothed values given in Table 2 and varies from 1 to 6%, depending on the system and temperature. The importance of correction for non-ideality of the vapor is again stressed. Diffusion coefficients so corrected are those that should be compared with theoretical values and with diffusion coefficients determined by other methods that measure the true concentration of diffusing gases. However, it is still desirable to publish diffusion coefficients uncorrected for non-ideality because in certain practical problems they may be required to calculate the amount of vapor diffusing when the partial pressure of it is known.

Diffusion in these systems at 25 °C has been studied by Lugg (3), and his results are quoted in Table 2. Lugg used the rate of evaporation method and did not correct for gas non-ideality, consequently his results must be compared with the uncorrected results of this study. Our results are in excellent agreement with 1,2-dichloroethane and 1,1,1-trichloroethane. However, the agreement between our results for trichloroethylene and tetrachloroethylene is not good. Admittedly the value at 25 °C for tetrachloroethylene in this work is extrapolated from data at higher temperatures, which can account for part of the discrepancy. Lugg does not give an analysis of purity of his materials but simply states that they were the purest available. Hence in view of the analysis of the materials used in this work it is suspected that the discrepancy between our results is due to impurities in his materials and the present results are to be preferred. In view of the close agreement between some of our results given here and elsewhere (1), it is unlikely that the discrepancy is due to differences in our experimental techniques.

Theoretical values of diffusion coefficients were also calculated using the equation (7)

[2]
$$D_{12} = \frac{2.628 \times 10^{-5}[T^3(M_1 + M_2)/2M_1M_2]^{1/2}}{p\sigma_{12}^2\Omega_{12}(T_{12}^*)}$$

where the subscripts 1 and 2 refer to the two components, D_{12} is the first approximation to the binary diffusion coefficient, M the molecular weight, T the absolute temperature, p the pressure in atmospheres, and Ω_{12} (T_{12}^*) is a collision integral at a reduced temperature of $T_{12}^* = kT/\varepsilon_{12}$, and σ_{12} and ε_{12}/k are molecular potential energy parameters characteristic of a 1–2 inter-

For personal use only.

action expressed in units of nm and K, respectively. Values of the collision integral for a Lennard–Jones 6–12 potential function have been tabulated (7). Experimental values of σ_{11} and ε_{11}/k for the pure components were not available so values were estimated from the critical properties by the method of Stiel and Thodos (8). Where experimental values of the critical properties were not available, values were estimated by Lyderson's method and the method of García–Bárcena (8). The Hudson–McCoubrey combining rules (9) were used to calculate σ_{12} and ε_{12}/k from the corresponding values for the pure components. Comparison of the theoretical diffusion coefficients with the experimental values corrected for non-ideality shows agreement almost within experimental error for most systems. Even when some of the data required to use eq. 2 is not available, estimation of data by the best methods available can give values of the diffusion coefficient in accord with experiment.

Synthesis of *N*-Methylamino Acid Derivatives from Amino Acid Derivatives using Sodium Hydride/Methyl Iodide[1]

JOHN R. COGGINS AND N. LEO BENOITON[2]

Department of Biochemistry, University of Ottawa, Ottawa 2, Canada

Received January 8, 1971

Reaction of *N*-acetyl-, *N*-benzoyl-, and *N*-carbobenzoxy derivatives of aliphatic amino acids with sodium hydride/methyl iodide in tetrahydrofuran containing dimethylformamide at 80° gave the corresponding *N*-methylamino acid methyl esters as oils in high yields. Saponification of these gave the *N*-protected-*N*-methylamino acids, and decarbobenzoxylation gave the *N*-methylamino acid methyl ester hydrobomides. The products are essentially optically pure and free of unmethylated amino acid derivative.

On fait réagir, à 80 °C dans le tétrahydrofuranne contenant de la diméthylformamide, les dérivés *N*-acétyle-, *N*-benzoyle-, ou *N*-carbobenzoxyle d'acides aminés avec de l'iodure de méthyle en présence d'hydrure de sodium et l'on obtient, avec d'excellents rendements, les esters méthyliques des dérivés *N*-méthylamino correspondants qui se présentent sous forme d'huile. La saponification de ces esters conduit aux acides aminés portant sur l'azote un groupe méthyle et un groupe protecteur; leur décarbobenzoxylation conduit aux bromhydrates des esters méthyliques des acides aminés *N*-méthylés. Les produits sont essentiellement optiquement purs et exempts de produits non méthylés.

Canadian Journal of Chemistry, 49, 1968 (1971)

The preparation of derivatives of optically active *N*-methylamino acids presents many obstacles. Optically pure *N*-methylamino acids are not readily accessible; no method has been described for establishing their optical purity; *N*-methylamino acids are difficult to determine because they react slowly with ninhydrin; and their derivatives are not easy to make because *N*-methylamino acids are generally less reactive than are amino acids. We report here a new and simple one or two step synthesis of optically pure *N*-methylamino acid derivatives from commercially available starting materials. The method involves the *N*-methylation of *N*-acyl- or *N*-carbobenzoxyamino acids with methyl iodide and sodium hydride.[3] The determination of *N*-methylamino acids and their optical purity has been described elsewhere (3).

Methylation of aromatic amides has been achieved using methyl iodide (4–7) or dimethyl sulfate (8) in the presence of alkali. Alkylation of aliphatic amides (7, 9) and lactams (9) has been similarly achieved. Methylation of sulfonamides (10) has provided a route to *N*-methylamino acids (11). The more recent permethylation of peptides using silver oxide/methyl iodide (12), a reagent previously used for the methylation of a lactam (13), suggested consideration of this reagent for an approach to the synthesis of *N*-methylamino acid derivatives. Sodium hydride, however, was investigated in preference on the basis of the reports of its use for the alkylation of amides (14) and urethanes (15).[4]

N-Carbobenzoxyleucine in tetrahydrofuran (THF) was treated with sodium hydride/methyl iodide under various conditions, and the reaction mixture was analyzed for amino acids with an amino acid analyzer[5] after suitable deprotection. Representative results of these and subsequent experiments with other leucine derivatives appear in Table 1. The best yield (96%) of *N*-methylleucine was obtained using the reactants in an 8:3:1 molar ratio (MeI/NaH/R-Leu) after 24 h at 80 °C

[1]Supported by a grant from the Medical Research Council of Canada. This investigation is dedicated to the memory of our colleague Dr. Jean Leclerc who died on December 31, 1969, at the age of 27.

[2]Associate of the Medical Research Council of Canada.

[3]A preliminary account of this work has been presented (1). Complete details of all aspects of this work are described in the Ph.D. thesis of J.R.C. Sodium hydride/methyl iodide has since been used for the permethylation of peptides for sequencing by mass spectrometry (2).

[4]A synthesis of *N*-methylamino acid derivatives using silver oxide/methyl iodide has since appeared (16).

[5]We have found that α-*C*-methyl- and *N*-methylamino acids can be determined satisfactorily with a Beckman amino acid analyzer if a half-normal eluting buffer flow rate is used. Under these conditions, the ninhydrin color constants are 10–30 times those obtained using the normal flow rate (3).

*Standard conditions: MeI/NaH/R-Leu (8:3:1 mol). NaH added to a solution of R-Leu (1 mmol) and MeI in THF/DMF (10:1). Mixture was placed on an oil bath at 80 °C for 24 h.
†Determined with an amino acid analyzer (3) after deprotection.
‡Reactant ratio: 4:2:1 mol.
§DMF replaced by dimethylsulfoxide as solvent.
‖MeI added after heating R-Leu and NaH for 10 min.
¶Same value obtained in a duplicate experiment.
**MeI added after leaving R-Leu and NaH at room temperature until hydrogen evolution had ceased.
††Low total believed due to difficulty with deprotection.

in the presence of dimethylformamide (DMF), and unexpectedly when the sodium hydride was added to the mixture after the methyl iodide had been added and not before.

In experiments on a preparative scale (Scheme 1), *N*-acetyl-, *N*-benzoyl-, and *N*-carbobenzoxy-amino acids were methylated to give the corresponding *N*-methylamino acid methyl esters whose i.r. curves were characterized by a sharp absorption band at 1735–1740 cm^{-1} (ester carbonyl), and the absence of bands at 3280 and 1520 cm^{-1} (—NH stretch and amide II bands, respectively). The esters were isolated as oils by extraction into ether and were therefore contaminated with the paraffin oil from the sodium hydride dispersion. Saponification of the *N*-acyl-*N*-methylamino acid esters in *N* NaOH/THF gave the *N*-acyl-*N*-methylamino acids in satisfactory yield. Similar treatment of the *N*-carbobenzoxy-*N*-methylamino acid esters gave very low yields of the corresponding acids. Good yields were finally obtained using warm 2 *N* NaOH/methanol. Removal of the carbobenzoxy group from the esters with hydrogen bromide in acetic acid gave the *N*-methylamino acid methyl esters as hydrobromides. After one recrystallization, these esters contained less than 0.1% of the unmethylated amino acid ester. An aliquot of one preparation of L-MeLeu-OMe·HBr was hydrolyzed before the crystallization step, and was shown to contain not more than 1% (the limit of detection) of the D-isomer by the method described elsewhere (3). Similarly, crystalline L-MePhe prepared from the carbobenzoxy derivative, and the hydrolysis product of Ac-L-MeLeu were also shown to be optically pure. However, preparations of Ac-MePhe were found to be partially or completely racemized. It is known that phenylalanine derivatives are more susceptible to base-catalyzed racemization than are most other amino acids (19). The properties of the derivatives prepared are recorded in Table 2. The i.r. curves of all compounds have been recorded.[3]

Experimental

Materials and Methods

Methyl iodide and DMF were obtained from Fisher Scientific Co. The DMF was purified by shaking over KOH pellets, then over CaO, followed by distillation (151–154°/753 mm) (20). The THF was the J. T. Baker product containing butylated hydroxytoluene as stabilizer.

Sodium hydride was a 50% dispersion in oil obtained from BDH Chemicals. The amino acids were purchased from General Biochemicals, Chagrin Falls, Ohio. The *N*-carbobenzoxyamino acids were synthesized by the usual procedure of Bergmann and Zervas (21), with the phenylalanine derivative being purified as described (22). The *N*-benzoyl- and *N*-acetylamino acids were prepared by standard procedures as described for each amino acid in the treatise by Greenstein and Winitz (23). The optical purity of the *N*-acetylamino acids was verified.

The DMF and THF were dried immediately before use by adding sodium hydride dispersion (0.2 g/10 ml solvent) and filtering under suction after shaking for 2 min. Optical rotations were measured with a Perkin–Elmer model 141 polarimeter using a 1 dm tube. Melting points were taken by the capillary method and are uncorrected. All evaporations were carried out under reduced pressure using a rotary evaporator. Compounds melting above 100° were dried for analysis by heating at 65° under vacuum over P_2O_5 for 2 h.

N-Acyl- and N-Carbobenzoxy-N-methylamino Acid Methyl Esters

To a solution of *N*-acyl- or *N*-carbobenzoxyamino acid (0.020 mol) in THF/DMF (10:1; 55 ml)[6] were added methyl iodide (10.0 ml; 0.160 mol) and sodium hydride dispersion (2.88 g; 0.060 mol of NaH) (*caution*) *in that order*. A reflux condenser protected with a drying-tube (Drierite) was mounted on the flask which was then placed in an 80 °C wax-bath for 24 h. The solvent was removed under vacuum, ether (25 ml) was added, and the evaporation was repeated (to remove the methyl iodide). The residue was distributed between ether (100 ml) and water (25 ml). The ether layer was washed with water (25 ml), dried ($MgSO_4$), and evaporated to give two clear immiscible oils[7] (one is the oil from the sodium hydride dispersion). All products gave satisfactory i.r. analyses at this stage.

N-Acyl- and N-Carbobenzoxy-N-methylamino Acids

The suspension of oils described above was saponified by stirring in the presence of 80 ml of *N* NaOH/THF (1:1) for 30 min for the *N*-acyl derivatives and 60 ml of 2 *N* NaOH/methanol (1:2) at 35 °C for 3 h for the *N*-carbobenzoxy derivatives. The THF and methanol were evaporated off, the remaining aqueous solution was washed with ether (2 × 20 ml), cooled (0°), and brought to p*H* 2 with 4 *N* HCl. The product was extracted into ethyl acetate (3 × 40 ml), the combined extracts were dried ($MgSO_4$), and the solvent was removed by evaporation. The residue was crystallized as indicated in Table 2.

[6]This solvent volume was used for 0.01 to 0.03 mol quantities.

[7]The product is sometimes slightly colored due to the presence of iodine. We have recently found that washing with aqueous potassium iodide solution removes the color.

N-Methylamino Acid Methyl Ester Hydrobromides

To an *N*-carbobenzoxy-*N*-methylamino acid methyl ester obtained as described above was added 37% HBr in acetic acid and the mixture was left at room temperature for 2 h. The mixture was evaporated to an oil which was dissolved in water (25 ml). The solution was washed with ether (2 × 10 ml), and then evaporated to dryness. The residue was dried overnight under vacuum over P_2O_5, and crystallized from methanol–ether.

A Possible Relationship Between Oxidation Rates of Alcohols and Their Carbon-13 Chemical Shifts

A. S. PERLIN
Department of Chemistry, McGill University, Montreal, Quebec

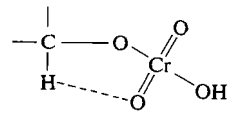
Received November 9, 1970

Variations in the oxidation rates of alicyclic alcohols with chromate and of aldopyranoses with bromine, parallel variations in ^{13}C chemical shifts for the carbinols. Accepting that these shifts closely reflect electron densities, mechanisms for these oxidations are depicted in terms of the minimal change in electron configuration required on passage from the ground to the transition state. A net flow of electrons from H-1 to C-1 is visualized for the chromate reaction, and hence relief of strain is associated in the transition state, as well as in the ground state, with a relatively high electron density on carbon. In the bromine oxidations, a net flow of electrons from C-1 to H-1 is visualized, which thereby allows for a sterically-dependent contribution by the ring oxygen atom to resonance stabilization of the transition state. These patterns are consistent with chromate and bromine oxidation mechanisms that now find wide acceptance.

On a observé un parallèle entre d'une part les variations dans les vitesses d'oxydation chromique d'alcools alicycliques ou les vitesses d'oxydation d'aldopyranoses par le brome et d'autre par les variations des déplacements chimiques du ^{13}C des carbinols. Acceptant que ces déplacements permettent d'évaluer avec précision les densités électroniques au niveau de ces atomes de carbone, on représente les mécanismes de ces oxydations en terme d'un changement minimal de la configuration électronique pour passer de l'état fondamental à l'état de transition. Pour l'oxydation chromique on imagine un déplacement net d'électrons de H-1 à C-1; l'amoindrissement des tensions serait donc associé dans l'état de transition et dans l'état fondamental avec une densité électronique relativement grande au niveau du carbone. Dans les oxydations par le brome, on imagine que ce serait plutôt un déplacement net d'électrons de C-1 vers H-1 qui interviendrait; cette conception permettrait d'envisager que l'oxygène du cycle apporte une contribution, dépendante des facteurs stériques, à la stabilisation par résonance de l'état de transition. Ces propositions sont en accord avec les mécanismes d'oxydations chromiques ou par le brome qui sont le plus couramment acceptés.

Canadian Journal of Chemistry, 49, 1972 (1971)

Differences in the rate of oxidation of alcohols have been examined, perhaps most extensively, with reference to chromate oxidation of alicyclic alcohols and sterols, and bromine oxidation of aldoses. In both series, the observed variations in rate have been ascribed to specific steric factors. It is found, for example, that bromine oxidation of an aldose (which is highly selective in converting the hemiacetal to a lactone) takes place more rapidly when the anomeric hydroxyl group is equatorial than when axial; or that a sugar possessing the β-D-*xylo* or α-L-*arabino* configuration is oxidized at a faster rate than a conformationally less stable epimer of the β-D-*lyxo* or β-D-*ribo* configuration (1, 2). The situation is reversed for chromate oxidation of alicyclic alcohols: in this instance, an axial carbinol is more reactive than its equatorial epimer (3–8), and the greater the number of non-bonding interactions present in the alcohol the faster the oxidation rate (9, 10). Both the bromine and chromate reactions are characterized by a kinetic isotope effect (2, 11) which shows that rupture of the C-1 to hydrogen bond is a rate-determining process.



1

Most mechanisms proposed for chromate oxidation (7, 12, 13) invoke transient formation of an ester **1** and subsequent loss of the hydrogen to the medium as a proton (11, 14) or via a concerted process (5, 15) to an oxygen atom of ester **1** (broken line). It is generally accepted that rate differences between epimeric alcohols reflect variations in relief of strain on going from the ground state to the activated complex (3, 7, 8). Wilcox *et al.* (9) have shown additionally that among alicyclic alcohols and related sterols there is a close relationship between ground state free energy differences and differences in oxidation rate, which has led to the suggestion that transition states for the epimeric alcohols approach each other in energy (9, 10).

In the light of conformational and geometrical influences on the ^{13}C chemical shifts of cyclo-

hexanes (16–19), we have noted recently (20) that the net shielding of ^{13}C nuclei of isomeric cyclohexane derivatives increases additively with an increase in repulsive non-bonding interactions. This applies equally for a number of cyclohexanols for which chromate oxidation rates have been measured (Table 1). As shown in Table 1, an increase in ^{13}C shielding for a given epimeric pair is accompanied by an increase in the oxidation rate. Moreover, differences between epimers are seen to be relatively constant. The sums of the chemical shifts (column 3) permit comparisons to be made of total shielding (20) of ^{13}C nuclei within the group of six isomeric methylcyclohexanols. Hence total shielding decreases in the order *cis*-2 > *cis*-4 > *trans*-3 > *trans*-2 > *trans*-4 > *cis*-3, which also is the general order of decreasing interaction energy and of decreasing oxidation rate. Since the ^{13}C chemical shift appears to be determined principally by electron density at the atom (21–25), the data of Table 1 express the rate *vs.* stability relationship of Wilcox *et al.* (9) in terms of charge density, rather than of non-bonding interaction. That is, with this class of molecules steric and electronic factors appear to be interconvertible, at least qualitatively.

From these and the earlier data, therefore, it is found that the charge density on carbon is increased when a destabilizing interaction is introduced, and we assume (20) that this arrangement of electron densities arises in response to the unfavorable interaction, as part of the energy-minimizing process. If a similar situation were to hold for the transition state, then relief of strain during the chromate oxidation also should be accompanied by a tendency to maintain a relatively high electron density on carbon.[1] Transfer of electrons within the ester **1** from carbon towards the chromium could then be compensated for by a flow of electrons from the hydrogen towards carbon. In this way, a proton would be released on rupture of the C—H bond (8, 12, 13), in contrast with the alternative possibility of abstraction of a hydride ion by the chromate (24). With the more reactive isomers, therefore, the arrangement of electrons in the ground state is closer to that anticipated for the transition state.

Isbell (1) has treated the bromine oxidation of aldoses in terms of a resonance-stabilized transition state resembling anion **2**. The latter is regarded as more easily attainable when the hydroxyl group in the ground state is equatorial rather than axial, because less reorganization would be required of the equatorial isomer.

[1]It may be noted also that chromate oxidations are characterized by negative rho values (14), an indication that these reactions are favored by high electron density at the reaction site.

Another possibility (26) considers the relative ease of a base-catalyzed *trans*-elimination of hydrogen bromide from an intermediate such as **3**. This process can be visualized more readily for the equatorial product than for the axial one because in the latter, suitable orientation of the bromine atom would be relatively hindered by substituents at positions 3 and 5 (26).

Relief of strain can have only a minor bearing on the rate of bromine oxidation of aldoses, because the most reactive anomers are also the most thermodynamically stable ones (1, 2, 26). It is noteworthy, therefore, that ^{13}C chemical shifts and oxidation rates in this series appear to be related inversely, with respect to the chromate reactions just considered: *i.e.*, the rate of bromine oxidation decreases progressively as ^{13}C shielding increases (Table 2). An orderly progression is found also for the proton chemical shifts (Table 2), which emphasizes the differences in polarization of C—H bonds in these molecules[2] (27, 28).

Taking the anomeric forms of D-glucose as examples, the ^{13}C-1 nucleus of the β-isomer is the *less* shielded (by 3.9 p.p.m.) whereas its appended proton is the *more* shielded (by 0.58 p.p.m.), and the oxidation rate for β-D-glucose is 39 times that of the α-anomer (Table 2). If oxidation of these aldoses involves a flow of electrons from C towards H in the rate-determining step then, initially, the C—H bond of the β-anomer is more polarized in this same direction than is the C—H bond of the less reactive α-anomer. That is, a closer relationship between the ground and transition states may be visualized for the β-anomer than for the latter.

Turning to the transition states there is the possibility, suggested by Isbell (1), of resonance

[2]Although only anomeric centers are considered here, these differences apply broadly to the molecules themselves (27).

TABLE 2. The ^{13}C and ^{1}H chemical shifts and rates of bromine oxidation

Aldopyranose	^{13}C-1*	τ H-1†	Relative rates‡
α-L-Arabinose	95.3	5.40	52

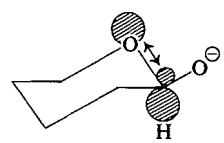
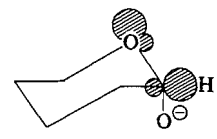
stabilization through involvement of the unshared electrons of the ring oxygen atom and the anomeric C—O bond (which offers a reasonable explanation of the greater reactivity of hemiacetal carbinol groups than of other kinds of carbinols towards bromine (1)). However, such stabilization could be relatively greater for the β-anomer. Thus, as pointed out by Snyder (29), the developing β-transition state appears to allow for more effective overlap between an orbital occupied by unshared electrons of the ring oxygen and an emerging vacant orbital of C-1, than would be permitted in the transition state for the α-anomer (compare **4** and **5**).



4



5

Accordingly, these overall characteristics favor more rapid oxidation of β- than of α-D-glucose, and apply similarly for several of the other anomeric pairs listed (arabinose, xylose, galactose). D-Mannose represents the most extreme departure from this pattern, since the anomers differ little in chemical shift but, nevertheless, the β- is oxidized 15 times more rapidly than the α-anomer. Accordingly, in this instance more facile stabilization of the β-transition state (as above) could be regarded as the overriding rate determinant.

In contrast to the aldopyranoses, *cis*- and *trans*-

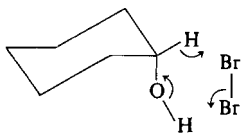
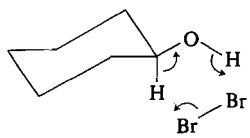
4-*t*-butylcyclohexanol, or 3-α- and -β-cholestanol, are oxidized by bromine at nearly the same rate, their reactions are not base-catalyzed and, of course, are relatively very slow (30). A concerted type of mechanism involving **6** has been proposed (30),[3] simultaneous removal of the hydrogen atoms accounting for the lack of sensitivity to p*H*. Since resonance stabilization of the transition states is not a likely factor here, then there is no need to anticipate, as with the aldoses (above), that the favored direction of electron flow is from carbon towards hydrogen. Taking **6** as a model for the two transition states and noting the difference in electron density of C-1 of the epimers (based on the ^{13}C shifts, Table 1), a net flow of electrons in opposite directions may be visualized: from hydrogen towards carbon in the axial reaction, maintaining the relatively high charge density associated with C-1, and in the reverse direction (**7**) in the equatorial one. The overall tendency is to equalize the difference between the ground and transition states of the epimers, and hence minimize differences between their oxidation rates.



6



7

To summarize, variations in the oxidation rates of alcohols discussed above find close analogies with the manner in which ^{13}C chemical shifts, and hence C-1 electron densities, vary. The fact that chromate oxidation of alicyclic alcohols is more rapid with those epimers characterized by a relatively high charge density on carbon, appears to be compatible with the most widely-accepted view that a proton is abstracted in these oxidations. Thus, rate-determining rupture of the C_1—H bond would involve a minimal change of electronic configuration as the transition state is formed. It is suggested also that relief of strain due to non-bonding interactions may be associated both in the ground and transition states with a relatively high electron density on carbon. Because chemical shift and rate differences are reversed in the bromine oxidation of aldoses, rate-determining release of a hydride ion (1) rather than of a proton appears to be a plausible step. In addition, the incipient development of carbonium ion character on C-1 allows for a sterically dependant resonance stabilization of the transition state.

Many mechanisms that have been proposed for these different reactions are concerted, and involve cyclic transition states. Accordingly, the C—H bond-breaking process has been described here in terms of the direction of flow of electrons rather than of formation of a proton or hydride ion, *per se*. In these concerted routes the net flow in a given direction corresponds to the extent of change in electronic configuration between the ground and transition states. Hence, in the bromine oxidation of cyclohexanol derivatives, in which resonance stabilization becomes unimportant, charge density could be displaced in either direction, whichever is a minimal pathway.

It is not evident that the changes in electron distribution visualized above are related quantitatively to the energy changes that govern the oxidation rates (admittedly, in fact, the relationships that have been drawn may be coincidental). Nevertheless, the rate differences between epimers are not large: in the chromate oxidations the factor is 3–5 and in the bromine oxidation of aldopyranoses, a maximum of 50. Therefore, it is not unreasonable that they could be reflected in relatively small ground state epimeric differences in the polarization of C—H bonds, especially since these polarization differences could well be magnified in the transition states.

The author expresses his gratitude to P. G. Farrel, J. P. Snyder, and H. J. Koch for most helpful discussions.

[3]Other mechanistic possibilities for bromine oxidation of carbinols, involving either hydride (31–33) or proton (34) abstraction, have been described (also see ref. 12, p. 131–132).

Alkaloids of Certain Oriental *Ormosia* Species

STEWART MCLEAN, P. K. LAU, S. K. CHENG, AND D. G. MURRAY
Department of Chemistry, University of Toronto, Toronto, Ontario

Received January 21, 1971

The basic extracts of five oriental *Ormosia* species (*O. sumatrana*, *O. emarginata*, *O. indurata*, *O. semicastrata*, and *O. pachycarpa*) have been examined and *N*-methylcytisine, *N*-methyltetrahydrocytisine, ormosanine, 18-epiormosanine, and *racemic* piptanthine have been isolated and identified. A further alkaloid of formula $C_{20}H_{33}N_3$, which does not appear to have been described previously, has been isolated from *O. semicastrata*.

On a étudié les extraits basiques de cinq espèces orientales d'*Ormosia* (*O. sumatrana*, *O. emarginata*, *O. indurata*, *O. semicastrata*, et *O. pachycarpa*) et l'on a ainsi pu isolé et identifié la présence de *N*-méthylcytisine, *N*-méthyltétrahydrocytisine, ormosanine, 18-epiormosanine, et de piptanthine racémique. Un autre alcaloïde de formule moléculaire $C_{20}H_{33}N_3$ qui ne semble pas avoir été décrit précédemment a aussi été isolé de *O. semicastrata*.

Canadian Journal of Chemistry, 49, 1976 (1971)

The genus *Ormosia* is comprised of about 100 species of woody legumes native to tropical regions of the Americas and South-East Asia (1). The geographical separation of these two areas and the absence of surviving members of the genus elsewhere indicate that genetic isolation of the two divisions could have been complete for 50 million years or more and that a comparison of their phytochemistry is of great potential interest. The alkaloids of occidental species, which have received a considerable amount of attention in recent years (2), fall into two main groups, both of which are substituted quinolizidines. Members of the first group appear to have

The basic extracts of five oriental *Ormosia* species (*O. sumatrana*, *O. emarginata*, *O. indurata*, *O. semicastrata*, and *O. pachycarpa*) have been examined and *N*-methylcytisine, *N*-methyltetrahydrocytisine, ormosanine, 18-epiormosanine, and *racemic* piptanthine have been isolated and identified. A further alkaloid of formula $C_{20}H_{33}N_3$, which does not appear to have been described previously, has been isolated from *O. semicastrata*.

On a étudié les extraits basiques de cinq espèces orientales d'*Ormosia* (*O. sumatrana*, *O. emarginata*, *O. indurata*, *O. semicastrata*, et *O. pachycarpa*) et l'on a ainsi pu isolé et identifié la présence de *N*-méthylcytisine, *N*-méthyltétrahydrocytisine, ormosanine, 18-epiormosanine, et de piptanthine racémique. Un autre alcaloïde de formule moléculaire $C_{20}H_{33}N_3$ qui ne semble pas avoir été décrit précédemment a aussi été isolé de *O. semicastrata*.

Canadian Journal of Chemistry, 49, 1976 (1971)

The genus *Ormosia* is comprised of about 100 species of woody legumes native to tropical regions of the Americas and South-East Asia (1). The geographical separation of these two areas and the absence of surviving members of the genus elsewhere indicate that genetic isolation of the two divisions could have been complete for 50 million years or more and that a comparison of their phytochemistry is of great potential interest. The alkaloids of occidental species, which have received a considerable amount of attention in recent years (2), fall into two main groups, both of which are substituted quinolizidines. Members of the first group appear to have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

structures based on a tetracyclic $C_{15}H_{26}N_2$ parent or to be derived from it, at least nominally, by oxidation; the second group can be related in a similar way to a $C_{20}H_{35}N_3$ pentacyclic parent structure and a notable feature of the group is the occurrence of a diversity of stereoisomers differing in relative or absolute configuration or both. The C_{20} alkaloids ormosanine and panamine, found in American *Ormosia* species, have also been isolated from the stems of *O. emarginata* from Hong Kong (3), but otherwise the alkaloids of oriental species appear to have received little attention.

We have examined the bases isolated from five Asian species of *Ormosia* and found representatives of both main alkaloid groups in them. The seeds of *O. semicastrata* have been studied the most thoroughly and have yielded the most interesting results. Four alkaloids, all members of the C_{20} group, have been isolated from this source and, of these, one has been identified as (±)-ormosanine (**1***a*)[1] and another as (±)-piptanthine (**1***b*); although the occurrence of (−)-piptanthine and the elucidation of its complete structure are well documented (2, 4) and Liu *et al.* have very recently described the total synthesis of the racemic modification (2*d*), this appears to be the first time that the isolation of the *racemic* alkaloid from a natural source has been described. (We report a second case in the sequel.) An interesting feature, and one that initially caused us some difficulty, is that the melting point of the racemic base (220–221°) is substantially different from that of the optically active form (142–143°). Identification was secured by comparison with natural (−)-piptanthine by spectroscopy and behavior on t.l.c., and by direct comparison with (±)-piptanthine derived from (±)-ormosanine (2*c*).

The third alkaloid, m.p. 267° (dec.), also has the formula $C_{20}H_{35}N_3$ and reacts with phosgene to form a urea (referred to as the "homoxy" derivative (2*c*)) bridging the two secondary

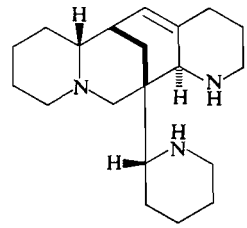
b	β	β	α	α
c	α	β	α	β

(α indicates H below plane at position designated; β, H above plane at position designated)



2

amine groups. This alkaloid has not been previously obtained from a natural source, but it has been shown by direct comparison of the bases and their homoxy derivatives to be identical with 18-epiormosanine (**1***c*) which has been synthesized and characterized by Liu *et al.* (2*d*). The fourth alkaloid, m.p. 263° (dec.), has the formula $C_{20}H_{33}N_3$, shows a doublet (J = 6 Hz) at τ 4.35 characteristic of one vinyl proton in its n.m.r. spectrum, and forms a homoxy derivative under standard conditions. It is not identical with dihydroormojanine (**2**) (2*c*), but is probably stereoisomeric with it, although the possibility that it may differ structurally, particularly with respect to the position of the double bond, has not been ruled out. Further investigation of this alkaloid is being undertaken at the present time.

The seeds of *O. sumatrana* afforded ormosanine (**1***a*) and representatives of the first group of alkaloids, *N*-methylcytisine and *N*-methyltetrahydrocytisine, were obtained from the seeds of *O. emarginata* and *O. indurata*, respectively. In each of the latter cases, t.l.c. provided evidence that the basic extract contained at least one more component, but shortage of material precluded further examination of its constitution.

[1]Despite an indication to the contrary in a review (2*a*), apparently arising from a misreading of the original literature, natural ormosanine has always been obtained as a racemic modification as far as we are aware. It should be noted further that, for purposes of illustration, one enantiomer has been drawn for each alkaloid discussed in this paper; however, no claim regarding the true absolute configuration of the molecules is implied and, in the case of racemic modifications, the description in the text makes the stereochemical situation clear.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The bark of *O. pachycarpa* afforded a single isolable alkaloid which was shown to be identical with the racemic piptanthine described above.

It is clear that the alkaloids obtained so far from Asiatic *Ormosia* species belong to the same structural classes as the alkaloids from American species and the differences which have been established are stereochemical and no greater than the differences that exist between alkaloids previously isolated from American species only.

Experimental

Melting points were determined on a Thomas–Kofler micro hot stage. Spectrometers used were: Perkin–Elmer model 257 infracord (i.r.), Varian A-60 and HA-100 (n.m.r.), and AEI MS902 (mass spectra). Plant identifications were made by the collectors (see Acknowledgements).

Extraction Procedures

Coarsely ground seeds (ground bark in the case of *O. pachycarpa*) were placed in a Soxhlet apparatus and extracted with light petroleum ether and then methanol. Extracts which, after evaporation of the solvent, gave a positive Dragendorff test (5) were partitioned between dilute hydrochloric acid and chloroform. The aqueous solution was made basic and then extracted with an organic solvent.

O. sumatrana Prain

Extraction with ether afforded a basic fraction (*ca.* 1.5%) which deposited crystals from the ether solution. Recrystallization afforded ormosanine, m.p. 178–179°; identity with an authentic sample was confirmed on the basis of m.p. and spectroscopic characteristics. The mother liquor (ether extract) afforded a material which showed two spots on t.l.c., one of which appeared to correspond to ormosanine.

O. emarginata Benth.

Extraction with chloroform afforded a basic fraction (*ca.* 0.5%) which was purified by preparative t.l.c. on silica gel with elution by ether containing a little diethylamine. *N*-Methylcytisine, m.p. 131–134°, identical with an authentic sample was obtained. Analytical t.l.c. indicated that the basic fraction contained at least one more component but this has not yet been characterized.

O. indurata Chen

Extraction with chloroform afforded a basic fraction (*ca.* 3.1%) which was fractionally crystallized from ether. The fraction which, on recrystallization from acetone, afforded crystals, m.p. 210°, was identified as *N*-methyltetrahydrocytisine. The mass spectrum was identical with that described by Schumann *et al.* (6). Catalytic hydrogenation of *N*-methylcytisine over pre-reduced platinum oxide produced material that was spectroscopically indistinguishable from the above material.

O. semicastrata Hance

Extraction with ether afforded a basic fraction (*ca.* 0.3%) consisting of one main component and several smaller components which appeared to be identical to alkaloids obtained in more substantial quantities by continuing the extraction with chloroform. The main component, after recrystallization from ethyl acetate, was identified as (±)-piptanthine, m.p. 220–221°; this formed a homoxy derivative (2*c*), m.p. 164–165°. Identification was made on the basis of comparison with material obtained by Valenta and co-workers (2*c* and *d*). The chloroform extract afforded, on fractional crystallization, ormosanine, an alkaloid, m.p. 267° (dec.), mol. wt. 317.2829 ($C_{20}H_{35}N_3$ requires 317.2831), and an alkaloid, m.p. 263° (dec.), mol. wt. 315.2665 ($C_{20}H_{33}N_3$ requires 315.2674). The $C_{20}H_{35}N_3$ alkaloid formed a homoxy derivative, m.p. 193–194°, and comparison of the free base and its derivative with material supplied by Valenta and co-workers allowed us to identify the alkaloid as 18-epiormosanine. The $C_{20}H_{33}N_3$ alkaloid, i.r. max ($CHCl_3$) 3.30, 6.25 μ; n.m.r. (τ; $CDCl_3$; HA-100) 3.62 (2H; removed by D_2O), 4.35 (1H; doublet, *J*, 6 Hz), 6.34 (1H; removed by D_2O), 6.56, 6.70 (together ≃2H), 6.90 (≃1H), 7.0–8.9 (remainder of protons; complex, 7.20 peak very prominent), formed a homoxy derivative m.p. 178–180°, i.r. max ($CHCl_3$) 3.50, 6.22 μ; n.m.r. (τ; $CDCl_3$; HA-100) 4.45 (1H; doublet, *J*, 6 Hz), 5.2–5.9 (6H; complex), 6.37 (1H; singlet), 6.7–9.2 (remaining protons; complex).

O. Pachycarpa Champ.

Extraction with ether afforded a basic fraction which, although it showed several spots on t.l.c., afforded predominantly (±)-piptanthine (*ca.* 0.14%) (*cf. O. semicastrata* Hance).

We thank the National Research Council of Canada for financial support of this research. Plant material was obtained through the courtesy of Mr. S. Azis, National Biological Institute, Indonesia, Mr. H. C. Tang, Hong Kong Herbarium, and Professor L. B. Thrower, Department of Botany, University of Hong Kong, to whom we express our sincere thanks. Professor J. L. Beal kindly supplied an authentic sample of *N*-methylcytisine. Professor Z. Valenta supplied a number of invaluable reference compounds and spectra, and we are additionally indebted to him for his frequent advice and encouragement.

On the Intermediate in the Reaction of Diethyl Malonate with 1-Fluoro-2,4-dinitrobenzene

K. T. LEFFEK AND P. H. TREMAINE[1]
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received October 28, 1970

No evidence has been found for a stable intermediate during the reaction of 1-fluoro-2,4-dinitrobenzene with diethyl malonate in the presence of triethylamine as has been reported in the literature. The spectral and chemical properties attributed by earlier work to the intermediate have been assigned to the final products of the reaction.

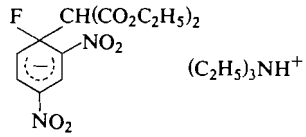
Aucune preuve n'a été trouvée pour la formation d'un intermédiaire stable pendant la réaction du dinitro-2,4-fluoro-1-benzène avec le malonate d'éthyle. Les propriétés spectrales et chimiques qu'attribuait un rapport dans la littérature à un intermédiaire ont été appliquées aux produits finals de la réaction.

Canadian Journal of Chemistry, 49, 1979 (1971)

Introduction

The aromatic nucleophilic displacement of halide from halonitrobenzenes has been thoroughly investigated (1) but little attention has been paid to carbanions as displacing nucleophiles in this reaction.

Baudet reported (2) the observation of an intermediate **1** during the reaction of 1-fluoro-2,4-dinitrobenzene with diethyl malonate in the presence of triethylamine.



1

As part of a study of aromatic nucleophilic substitution by carbanions, we have repeated Baudet's preparation and found that the observed "intermediate" is in fact the anion of diethyl 2,4-dinitrophenylmalonate, the final product **3** of the reaction (eqs. 1 and 2).

Experimental

The u.v. and visible spectra were recorded on a Unicam SP800 spectrophotometer. The i.r. spectra were recorded on a Perkin–Elmer 237B, with frequency calibration at 1601 cm^{-1} from polystyrene film.

The sodium salt of diethyl malonate was prepared by allowing sodium metal to react overnight in an ether solution of excess diethyl malonate. After filtering and washing with ether, the white salt was pumped dry *in vacuo*.

Diethyl 2,4-dinitrophenylmalonate was prepared by the method of Zaheer and Sidhu (3), from the sodium salt of diethyl malonate and 1-chloro-2,4-dinitrobenzene in diethyl ether and recrystallized from ethanol–water (m.p. 48–49 °C; lit. 50 °C).

Diethyl 2,4-dinitrophenylmalonate was also prepared in dimethyl sulfoxide (DMSO) in a similar manner using 1-fluoro-2,4-dinitrobenzene. The product consisted of pale orange leaflets, m.p. 46–47 °C (mixed m.p. with authentic material 47–48 °C).

The electronic spectra of the sodium salt of diethyl 2,4-dinitrophenylmalonate in mixtures of methanol–DMSO (0, 30, 60, 80, and 100% (v/v) methanol) showed respective λ_{max} (log ε) of 520 (4.38), 514 (4.28), 505 (4.21), 490 (4.14), and 480 nm (3.97).

Results and Discussion

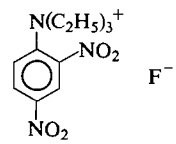
Baudet (2) reported two absorption maxima of the intermediate **1** in solution in DMSO, one weak at 370 and one very strong at 520 nm. The spectrum of the sodium salt of the product **2** was reported in methanol (λ_{max} 475 nm; log ε 3.98), but not in DMSO.

We have found that the reaction of 1-fluoro-2,4-dinitrobenzene with an excess of the sodium salt of diethyl malonate in DMSO produced immediately a stable purple color (λ_{max} 520 nm; log ε 4.38). The only other feature of the spectrum is end-absorption near 275 nm. Acidification and subsequent work-up afforded a 55% yield of diethyl 2,4-dinitrophenylmalonate (**2**).

The addition of an excess of base to diethyl 2,4-dinitrophenylmalonate in DMSO produced immediately a spectrum identical with the one obtained above (λ_{max} 520 nm; log ε 4.38). On addition of methanol, this maximum decreased in wavelength and intensity, and in 100% methanol, the anion appeared orange (see Experimental), as Baudet observed.

The i.r. spectrum of the crude equimolar mixture of 1-fluoro-2,4-dinitrobenzene, diethyl malonate, and triethylamine exhibited an absorption peak at 1676–1680 cm^{-1}, in DMSO or in the absence of solvent (2). The triethylammonium salt of the product **2**, both in Nujol and in DMSO, showed a band at 1677 cm^{-1}. Exposure of any of these samples to air resulted in a rapid disappearance of the red color and of the i.r. band at 1676–1680 cm^{-1}. Both the red color and the i.r. band were restored by treatment of the sample with triethylamine vapor. It is apparent that the changing concentration of the volatile base affects the concentration of the anion **3** (eq. 2).

The reaction of an excess of both diethyl malonate and triethylamine with 1-fluoro-2,4-dinitrobenzene in DMSO gave rise to two absorption maxima, one at 500 and the other at 365 nm. The formation of both peaks was relatively slow at 25 °C (half-life ~100 s), and the relative intensities of the peaks depended on the relative concentrations of diethyl malonate and triethylamine. Triethylamine in the absence of diethyl malonate reacted with 1-fluoro-2,4-dinitrobenzene in DMSO to form a yellow solution (λ_{max} 380 nm). We have observed similar spectra on addition of 1-fluoro-2,4-dinitrobenzene to DMSO solutions of tri-*n*-butylamine (λ_{max} 370 nm) and tribenzylamine (λ_{max} 370 nm). The synthesis of a quaternary pyridinium salt by aromatic nucleophilic substitution of 1-chloro-2,4-dinitrobenzene in pyridine has been reported (4). There is a very early report (5) of the formation of a quaternary salt from triethylamine and *o*-bromonitrobenzene. Although it is most probable that the product of the reaction of triethylamine and 1-fluoro-2,4-dinitrobenzene in DMSO is the quaternary salt **4**, our attempts to isolate it have been unsuccessful. Cavell and Chapman (6) have mentioned the instability of similar quaternary products.



4

Thus, there is no evidence that compound **1** is a stable observable intermediate during the reaction of 1-fluoro-2,4-dinitrobenzene with diethyl malonate and triethylamine. The properties attributed by Baudet (2) to the intermediate **1** are more readily explained as those of a mixture of starting materials, end-product **3** and by-product **4**.

Although the reaction of the sodium salt of diethyl malonate with 1-fluoro-2,4-dinitrobenzene in DMSO is complete in seconds, the slower reaction of diethyl malonate in the presence of triethylamine is probably due to a lower concentration of the attacking nucleophile, the conjugate base of diethyl malonate. Further kinetic work is in progress on the detailed mechanism of this reaction.

The authors are grateful for financial assistance from the National Research Council of Canada.

Studies on the Ethylation of Nucleosides with Triethyloxonium Fluoroborate[1]

F. J.-M. RAJABALEE[2] AND S. HANESSIAN
Department of Chemistry, University of Montreal, Montreal, Quebec

Received January 14, 1971

Alkylation of inosine and adenosine triacetates with triethyloxonium fluoroborate leads to selective *N*-ethylation. Inosine triacetate affords 7-ethylinosine as a major product, while adenosine triacetate is ethylated at the N-6 and -1 positions. Treatment with base affords the 6-ethyl analog by rearrangement.

L'alkylation des triacétates d'inosine et d'adénosine avec le fluoroborate du triéthyloxonium conduit à une *N*-éthylation sélective. Le triacétate d'inosine fournit l'éthyl-7 inosine comme produit majeur alors que l'éthylation de l'adénosine se fait aux positions 1 et 6. Le traitement avec des bases conduit, par réarrangement, aux analogues éthylés en position 6.

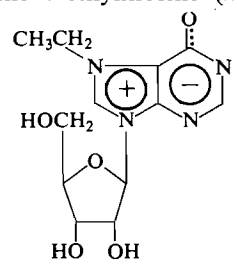
The isolation of various *N*-methylated purine (1, 2) and pyrimidine (3) nucleosides from biological sources in the past few years has prompted an interest in evaluating the methods of alkylation of nucleosides. The available procedures for purine nucleosides (1) in general utilize methyl iodide, dimethyl sulfate and methyl *p*-toluenesulfonate as methylating agents. Diazomethane, methyl iodide, and *N*,*N*-dimethylformamide dimethyl acetal among other reagents, have been used in the case of pyrimidine nucleosides (4). In all these methods, which involve a variety of conditions, the specificity of alkylation as well as the stability of the nucleosidic linkage are some important factors (4).

N-Alkylated nucleosides present various aspects of biological interest such as their potential inhibitory action on deaminating enzymes (5) and their role in t-RNA, ribosomal RNA, and DNA (6). Although the ultimate biological function of the methylated nucleosides in nucleic acids remains obscure, their presence imparts significant biological characteristics to these vital substances. For example, methylation of homologous RNA from lost cells induces complete resistance to subsequent viral infection to the cells (7). On the other hand the action of alkylating agents on nucleic acid components might lead to mutagenesis and a perturbation of the normal base–pair sequences (6).

We report on the ethylation of certain nucleoside *O*-acetates with triethyloxonium fluoroborate (8) in organic solvents. While our work was in progress, a communication (9) was published on the ethylation of certain heterocyclic bases and nucleosides with the same reagent in aqueous buffers. Although our results differ significantly from those of the Japanese workers (9)[3] the two methods could be considered as being complementary to each other.

Reaction of inosine triacetate with a slight excess of triethyloxonium fluoroborate in dichloromethane solution at 0° during 3 h, followed by treatment with aqueous sodium bicarbonate and processing gave a mixture of ethylated inosine triacetates as a syrup (*ca.* 90%). Deacetylation of the product in methanolic ammonia gave crystalline 7-ethylinosine (**1**, 59%) which



1

crystallized from solution. It exhibited a blue fluorescence on paper chromatograms, characteristic of 7-substituted inosines (1). Authentic 7-ethylinosine was prepared by the method of Jones and Robins (1) for the corresponding methyl analog and found to be identical (m.p., mixed m.p., R_f, u.v.) with the deacetylated sample. The mother liquors of deacetylation con-

[1]Reactions of carbohydrates with oxonium salts. II. For Part I, see ref. 20.

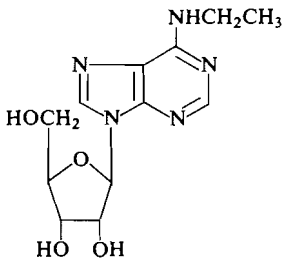
[2]Postdoctoral Fellow, 1969–1970.

[3]Unfortunately, details of the alkylation as well as physical constants of the products and their method of identification were not given in ref. 9. References to known compounds for purposes of comparison were also omitted.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tained, in addition to some 7-ethylinosine, a faster-moving ethylated component which was isolated by column chromatography on Avicel, as a syrup (18%). This product was different from 1-ethylinosine (10) and is tentatively assigned a 3-ethylinosine structure based on spectrophotometric data on the corresponding ethylhypoxanthine obtained by acid hydrolysis, λ_{max} 266 (p*H* 7), 254 (p*H* 2), and 266 mμ (p*H* 12) and comparative data on 1-ethylhypoxanthine (10) and 3-methylhypoxanthine (11). The major product of ethylation of inosine triacetate with triethyloxonium fluoroborate is therefore the 7-ethyl derivative in agreement with the predictions of quantum calculations and electron density considerations (12). The patterns of alkylation of inosine with oxonium salts is the same as in the alkylation with methyl iodide in dimethylsulfoxide (1).

Treatment of adenosine triacetate with triethyloxonium fluoroborate in dichloromethane solution (0°, 2.5 h) followed by processing with aqueous bicarbonate gave a mixture of *N*-ethyladenosine triacetates as a syrup (*ca.* 90%). Deacetylation in methanolic ammonia followed by evaporation gave a crystalline product (40%) which consisted of two components on paper chromatograms. The mother liquors were evaporated to a syrup (38%) which also consisted of the same two components in addition to some adenosine and a third component. Fractional crystallization of the solid portion from small volumes of water gave crystalline 6-ethyladenosine (**2**) (20%). The product was identical (mixed



2

m.p., u.v., R_f) with an authentic sample prepared from ethylamine and 9-(β-D-ribofuranosyl)-6-chloropurine (13). Treatment of a mixture of the three components with aqueous NH_4OH at 90° for 3 h (14) gave only two of the original components from which the 6-ethyl derivative could be obtained crystalline. It follows from this experiment that one of the components (slowest-moving) in the mixture must correspond to 1-ethyladenosine which like other N-1 alkylated adenosines (1, 14, 15) rearranges to the N-6 analog. The minor component in the alkylation could correspond to 3-ethyladenosine (16).

Reaction of adenosine triacetate with triethyloxonium fluoroborate occurs even at −50° but at a much slower rate, to give the N-6 ethylated product selectively. The alkylation procedure was also adapted to the direct preparation of 6-ethyladenosine in 55–60% overall yield without isolation of intermediates, by sequential alkylation, rearrangement and crystallization. It is of interest that methylation of adenosine with methyl *p*-toluenesulfonate in DMF or with methyl iodide in DMAC at room temperature leads to selective N-1 methylation. This result is in agreement with predictions based on electron density considerations of adenine and its simple analogs. Alkylation with trialkyloxonium salts differs from all other methods in the case of adenosine, in that appreciable alkylation occurs on the N-6 nitrogen atom, which is perhaps a reflection of the extreme reactivity of alkyloxonium type reagents.

Uridine triacetate reacted very sluggishly at 0° even in the presence of a large excess of reagent. Thus, with 10 equiv at 0° only a 25–30% conversion to 3-ethyluridine could be realized as evidenced by paper chromatography and u.v. spectral data of the deacetylated mixture. According to the Japanese workers (9), uridine is ethylated nearly quantitatively with 2 mol of the reagent at p*H* 9 in aqueous buffer. Under the same conditions, adenosine, cytidine, and guanosine resist ethylation (9). Furthermore, treatment of an aqueous mixture of adenosine, cytidine, and uridine with the reagent (3 equiv) is reported to effect exclusive ethylation of uridine only (9). We have observed the opposite behavior when a mixture of uridine acetate and adenosine acetate was treated with an equimolar amount or an excess of triethyloxonium fluoroborate in methylene chloride. Preliminary experiments indicate that cytidine tetraacetate and 2-deoxy adenosine diacetate are also ethylated under mild conditions (0°, 2–4 h). These and related results will be reported at a later date.

Experimental

Melting points are uncorrected. The n.m.r. spectra were obtained in deuteriochloroform (unless otherwise stated) at 60 or 100 MHz using tetramethylsilane as internal standard. The i.r. spectra were recorded on a Beckman IR-8 instrument. The u.v. spectra were recorded on a Beckman DK recording spectrophotometer. Paper

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

chromatography was performed on Whatman No. 1 paper using the solvent system methanol–water (7:3) and spots were revealed with u.v. light.

Ethylation of Inosine Triacetate with Triethyloxonium Fluoroborate

To a suspension of inosine triacetate (17, 18) (5 g, 12.7 mmol) in 100 ml of dichloromethane was added triethyloxonium fluoroborate (8) (2.90 g, 15.3 mmol) with stirring at 0°. After a few minutes, the reaction mixture became homogeneous and the solution was stirred at 0° for 3 h. The t.l.c. (chloroform–methanol, 5:1) indicated the virtual absence of starting material. The solution was treated with aqueous sodium bicarbonate, the organic layer was separated, washed, and evaporated to a foam (yield, 5.42 g). An n.m.r. spectrum of this product showed incorporation of the ethyl group. The product was dissolved in 80 ml of methanol previously saturated with ammonia and the solution was left at room temperature for 6–8 h at which time a crystalline product had separated out. After storing at 0° overnight, the solution was filtered, the product was washed with cold methanol and dried; yield 1.345 g, m.p. 153–155° (dec.); a further crop afforded a total quantity of 1.8 g (46%) of product. The mother liquors (1.8 g) showing two spots (R_f 0.69, 0.83) on paper chromatograms, was chromatographed on a column containing Avicel[4] using methanol–water (7:3) as developer. Fractions containing the faster-moving component (R_f 0.83) were combined and evaporated to a syrup (0.7 g, 18%) which failed to crystallize. Fractions containing the slower-moving component (R_f 0.69) were combined and evaporated to give a crystalline product, m.p. 152–154°, yield 0.43 g, identical with the crystalline product obtained above; combined yield 2.3 g (59%); m.p. 159–161°. Recrystallization from methanol–water afforded *7-ethylinosine* (**1**), m.p. 173–174°; λ_{max} 262 (p*H* 7), 252 (p*H* 2), 256 mμ (p*H* 12); R_f 0.69 (blue fluorescence); identical with an authentic sample (22 g),[5] mixed m.p. 168–170°.

Anal. Calcd. for $C_{12}H_{17}N_4O_5$: C, 48.60; H, 5.44; N, 18.88. Found: C, 48.53; H, 5.22; N, 18.91.

The syrup corresponding to the R_f 0.83 component was an *N*-ethylinosine as shown by the presence of an ethyl group in the n.m.r. spectrum. This product was different from 1-ethylinosine (10) and is designated as 3-ethylinosine based on the u.v. spectral properties of the corresponding *N*-ethylhypoxanthine obtained by acid hydrolysis with *N* HCl (2 h at 100°); λ_{max} 266 (p*H* 7), 254 (p*H* 2), and 266 mμ (p*H* 12). These values are in agreement with u.v. data on 3-methylhypoxanthine (11) but not 1-ethylhypoxanthine (10).

Ethylation of Adenosine Triacetate with Triethyloxonium Fluoroborate

Procedure a

A solution containing 4.5 g (11.3 mmol) of adenosine triacetate (18) in 100 ml of dichloromethane was treated with 2.85 g (15 mmol) of triethyloxonium fluoroborate at 0°. After stirring for 2.5 h in the cold, t.l.c. (chloroform–methanol, 5:1) indicated a small amount of starting material and the appearance of a slow-moving elongated spot. The solution was treated with aqueous sodium bicarbonate and the organic phase was processed to a syrup; yield 4.75 g. The n.m.r. spectrum of this product showed the incorporation of an ethyl group in the adenine portion.

The syrup was dissolved in 75 ml of methanol, previously saturated with ammonia, and the solution was left standing at 0° overnight. The solution was evaporated to dryness, the residue was taken up in methanol, and the solution was chilled. Successive crops of crystalline material could be recovered by repeating the procedure; total yield, 1.36 g (40%). On paper chromatograms, this product consisted of two spots with R_f 0.72 and 0.65. Fractional crystallization of this product from small volumes of water gave *6-ethyladenosine* (**2**) (20%), m.p. 186–188° (dec.); λ_{max} 266 (p*H* 7), 261 (p*H* 1), 265 mμ (p*H* 12); R_f 0.72. The product was identical (mixed m.p., u.v., R_f) with an authentic sample prepared from ethylamine and 9-(β-D-ribofuranosyl)-6-chloropurine (13). The n.m.r. spectrum of 6-ethyladenosine in DMSO-d_6 showed the expected patterns, particularly the triplet at τ 2.2 due to the NH proton. This triplet was diagnostic of N-6 ethylation.

The mother liquor from the original crystallization was evaporated to a syrup (1.135, 38%) which showed three spots on paper chromatograms, R_f 0.80, 0.72, and 0.65, in addition to some adenosine, R_f 0.45. The syrup was dissolved in aqueous NH_4OH (10 ml) and the solution was heated at 90° for 2.5 h. Evaporation to a small volume afforded crystalline 6-ethyladenosine (0.5 g, 14%). The final mother liquors contained small amounts of adenosine and the R_f 0.8 component which was not investigated further.

Procedure b

In another experiment the preparation of 6-ethyladenosine was carried out without the isolation of intermediates. A solution containing 0.5 g (1.3 mmol) of adenosine triacetate and 350 mg (1.8 mmol) of triethyloxonium fluoroborate in 15 ml of dichloromethane was stirred at 0° for 2.5 h. The slightly acidic solution was neutralized with a drop of dilute ammonium hydroxide solution and evaporated to dryness. The resulting foam was dissolved in 4 ml of water, containing 0.5 ml of concentrated ammonium hydroxide and the solution was heated at 80–90° with stirring for 2 h, with periodic addition 0.1 ml of base. The solution was evaporated to a crystalline residue which was triturated with methanol and filtered. This product was inorganic and was discarded. The mother liquors were evaporated to give a crystalline residue which was triturated with cold water, filtered and washed well with the same to give 6-ethyladenosine (180 mg, 48%), m.p. 181–184°. The mother liquors were evaporated to dryness and extracted with boiling ethyl acetate to give a syrup consisting of the expected product and minor quantities of adenosine and the R_f 0.8 component.

Ethylation of Adenosine with Ethyl Iodide in N,N-Dimethylacetamide

The same procedure was used as for the methylation of

[4]A product of American Viscose Corporation, Marcus Hook, Pennsylvania.

[5]This product was obtained by ethylation of inosine with ethyl iodide in DMSO as described for the methyl analog (1). A small amount of pure product was recovered for comparison purposes and optimum yields were not pursued.

For personal use only.

adenosine (1). A suspension of adenosine (0.4 g) in 7 ml of DMAC containing 0.5 ml of ethyl iodide was left at room temperature in the dark for 6 days. The slightly colored solution was diluted with a large volume of acetone and ether. The precipitate was allowed to settle and the supernatant was decanted. The residue, consisting of unreacted adenosine and the hydroiodide salt of 1-ethyladenosine was dissolved in 5 ml of water and adjusted to p*H* 8 with aqueous ammonium hydroxide. The solution was diluted with acetone–ether and the precipitate allowed to settle at 5° overnight. Decantation, washing, and drying afforded 0.45 g of a white crystalline solid which consisted of substantial amounts of adenosine (R_f 0.46) and another product (R_f 0.66), presumably 1-ethyladenosine as evidenced by paper chromatography. An n.m.r. spectrum showed the presence of an ethyl group, but the characteristic NH triplet was absent. This product was heated in aqueous ammonia at 90° for 2 h and the solution evaporated to dryness. Trituration of the crystalline residue with water and filtration gave 215 mg (47%) of 6-ethyladenosine, m.p. 182–184°.

Ethylation of Uridine Triacetate with Triethyloxonium Fluoroborate

Uridine triacetate (19) (0.37 g, 1 mmol) was dissolved in 30 ml of dichloromethane and the solution was treated with triethyloxonium fluoroborate (1.9 g, 10 mmol) at 0°. After stirring at 0° overnight, approximately 40% conversion to another component was evidenced by t.l.c. The solution was treated with aqueous sodium bicarbonate and the organic phase was processed as usual to give a syrup which was deacetylated in methanolic ammonia to give another syrup (0.26 g). This product showed the presence of unreacted uridine (R_f 0.62) and 3-ethyluridine (R_f 0.74) on paper chromatograms. The latter was isolated as a syrup (25–30%) by column chromatography on Avicel; λ_{max} 277 (p*H* 1), 268 (p*H* 7), 268 mμ (p*H* 12); n.m.r. data (D_2O): τ 8.6 (center of a triplet, CH_3—CH_2), 2.23 (doublet, H-5), 2.6 (doublet, H-6), etc. The product obtained was identical (R_f, u.v., n.m.r.) with 3-ethyluridine obtained from the reaction of uridine with triethyloxonium fluoroborate (9) in aqueous solution at p*H* 9. Complete ethylation, as claimed by the Japanese workers (9) could not be achieved in our experiments.

Ethylation of a Mixture of Uridine Triacetate and Adenosine Triacetate with Triethyloxonium Fluoroborate

The two nucleosides (0.5 mmol each) were dissolved in 30 ml of dichloromethane and treated at 0° with 0.5 mmol of triethyloxonium fluoroborate. After 6 h at 0°, t.l.c. indicated that only the adenosine triacetate had reacted. The solution was treated with aqueous sodium bicarbonate and the organic phase was processed to give a syrup. Deacetylation with methanolic ammonia followed by paper chromatography indicated traces of 3-ethyluridine and considerable *N*-ethyladenosine formation. In the presence of an excess of reagent (6 mmol/mmol of nucleoside), a preferential reaction with adenosine triacetate was still observed.

Reçu le 11 février, 1971

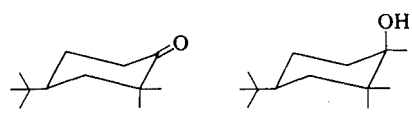
Nous avons poursuivi l'étude de déplacements induits par le tris(dipivalométhanato) praséodyme (III) en r.m.n. Des déplacements vers des champs plus élevés que le tétraméthylsilane ont été observés de même qu'une relation linéaire entre le déplacement chimique induit et l'inverse du cube de la distance métal–hydrogène. Cette relation sert de base à la détermination de la stéréochimie de paires d'épimères et les résultats y sont rapportés pour les *tert*-butyl-4 trimethyl-1,2,2 cyclohexanols *cis* et *trans*.

Shifts induced by tris(dipivalomethanato) praseodymium (III) have been applied to the determination of the stereochemistry of *cis* and *trans* 4-*tert*-butyl 1,2,2-trimethyl cyclohexanols. Observed shifts were at higher field than tetramethylsilane and a linear relationship has been established between the induced shifts and the cube of reciprocal distance metal–hydrogen.

Canadian Journal of Chemistry, 49, 1985 (1971)

La découverte de Hinckley (1) et de Sanders et Williams (2) sur l'utilisation du tris (dipivalométhanato) europium (III), $Eu(dpm)_3$, a été suivie de nombreuses publications sur certaines applications de ce réactif (3–6). Jusqu'à présent, il n'existe que très peu de publications sur le tris (dipivalométhanato) praséodyme (III), $Pr(dpm)_3$, bien que ce réactif est légèrement supérieur à $Eu(dpm)_3$ quant aux déplacements chimiques induits (7–9). A cause de la relation linéaire typique aux déplacements chimiques induits de cette façon, qui relie le déplacement chimique et l'inverse du cube de la distance métal–hydrogène (10), il devenait intéressant d'examiner l'utilisation possible de ces réactifs à la solution de certains problèmes stéréochimiques, un peu à la manière de Yonezawa *et al.* (11) qui ont utilisé des complexes du nickel et du cobalt pour déduire la stéréochimie de méthyl pipéridines.

Au cours de nos travaux sur la stéréochimie des produits dérivés de la *tert*-butyl-4 diméthyl-2,2 cyclohexanone (**1**), les *tert*-butyl-4 triméthyl-1,2,2 cyclohexanols *cis* (**2**) et *trans* (**3**) furent obtenus et caractérisés (12).



1 **2**

3

La stéréochimie des deux alcools tertiaires **2** et **3** étant bien établie, les spectres de r.m.n. furent déterminés en présence de $Pr(dpm)_3$ dans le but de déterminer les différents déplacements paramagnétiques et de voir l'effet de la stéréochimie des deux alcools tertiaires **2** et **3** sur les déplacements observés.

Les meilleurs résultats sont obtenus lorsque 50 mg de **1**, **2**, ou **3** et 50 mg de $Pr(dpm)_3$ sont dissous dans 0.5 ml de tétrachlorure de carbone et que la solution résultante est filtrée pour enlever les quelques particules en suspension. Les résultats sur **1**, **2** et **3** sont compilés dans le tableau 1 pour les différents groupements méthyles.

TABLEAU 1. Déplacement induit par le tris(dipivalométhanato) praséodyme (III) sur la cétone **1** et sur les deux alcools tertiaires **2** et **3**

	$-\Delta\delta$*			
Produit†	$(CH_3)_3C$—	CH_3 1	CH_3 2*a*	CH_3 2*e*
1	1.14	—	5.95	9.35
2	2.07	10.80	5.12	8.02
3	1.35	10.35	8.00	9.10

*$\Delta\delta = \delta_{Pr=100\,mg} - \delta_{Pr=0\,mg}$ exprimé en p.p.m.
†La concentration en produit est 1.28×10^{-4} mol dans 0.5 ml CCl_4.

Les observations suivantes peuvent être facilement notées à partir des valeurs contenues dans le tableau 1. Dans le cas de la cétone **1**, les deux groupements méthyles sont entièrement différents l'un de l'autre et le spectre obtenu le montre clairement. Le méthyle équatorial, qui se trouve dans le plan du carbonyle, est le plus rapproché de l'ion métallique et se trouve à être le plus déplacé. Par contre, le méthyle axial est plus faiblement déplacé vers les champs élevés à cause de son éloignement beaucoup plus considérable.

L'alcool *cis* **2** montre dans le spectre de r.m.n. des groupements méthyles déplacés de 5.12, 8.02, et de 10.80 p.p.m. pour les méthyles 2*a*, 2*e* et 1 respectivement. L'isomère *trans*, **3**, au contraire, montre une différence beaucoup moins marquée pour les deux groupements méthyles axiaux et équatoriaux de la position 2. Dans le cas de l'isomère **2**, la distance entre le méthyle axial et équatorial de la position 2 d'une part et l'ion métallique complexant d'autre part est grandement différente, ce qui n'est pas le cas pour l'alcool **3** où les deux groupes méthyles se trouvent de part et d'autre du plan comportant le groupement hydroxyle. Il est aussi à noter que le méthyle de la position 1 est déplacé de façon à peu près identique, car la distance demeure constante pour les deux isomères.

Il faut aussi remarquer que le groupement *tert*-butyle, facilement identifié dans le spectre, est beaucoup plus déplacé lorsque la fonction hydroxyle est axiale.

Une relation linéaire existe entre le déplacement chimique et l'inverse du cube de la distance oxygène portant le métal et les hydrogènes déplacés. Cette relation linéaire est aussi observée pour les complexes du praséodyme et il devient alors possible de prédire le déplacement chimique de certains hydrogènes dans des molécules cycliques simples. D'autres exemples permettront d'augmenter la précision de ces prédictions, rendant alors possible de préciser certaines conformations.

Ce travail préliminaire montre donc qu'il est facile de déterminer la stéréochimie d'une paire d'épimères par la simple détermination de quelques spectres de r.m.n. Ces déterminations sont d'autant plus aisées qu'il y a toujours une partie de la molécule qui est facilement identifiable et qui servira de base pour une telle détermination. Ce travail démontre aussi que le complexe du praséodyme est aussi utile que celui de l'europium pour des études de ce genre.

Il devient possible, à partir des conclusions de ce travail, de déterminer la stéréochimie d'une série d'alcools alicycliques où des doutes subsistent actuellement au cours d'études faites actuellement dans nos laboratoires.

Les auteurs tiennent à remercier monsieur A. T. Morse du département de production de la compagnie Merck, Sharp & Dohme Canada, Limited pour un don généreux de $Pr(dpm)_3$. Des remerciements vont aussi au Conseil National de Recherches du Canada pour l'aide financière apportée.

The Rates of Some Reactions of Aqueous Hypobromous Acid and Hypobromite Ions

M. W. LISTER AND P. E. MCLEOD

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received October 21, 1970

The reactions of hypobromite ions, or of hypobromous acid, with iodate, nitrite, and formate ions have been investigated, together with the decomposition of hypobromite ions. The p*H* dependence of the rate show that the reactions with formate and nitrite ions are presumably reactions of hypobromous acid. The kinetic parameters for these reactions are reported, and show some similarities to the analogous reactions of hypochlorite ions or hypochlorous acid.

On a étudié la décomposition des ions hypobromites de même que leurs réactions, ou celles de l'acide hypobromeux, avec les ions iodate, nitrite ou formiate. Le fait que les vitesses de ces réactions dépendent du p*H* indique que les réactions des ions nitrites ou formiates se font probablement avec l'acide hypobromeux. On rapporte les paramètres cinétiques de ces réactions et ils sont similaires à ceux des réactions impliquant les ions hypochlorites ou l'acide hypochloreux.

Canadian Journal of Chemistry, **49**, 1987 (1971)

Numerous studies have been made of rates of a series of somewhat similar reactions in order to detect regularities of trends in the rate constants, and hence to throw light on the mechanisms of the reactions. In particular, oxidations by the hydrogen peroxide and related peroxides (1, 2), and by hypochlorous acid or the hypochlorite ion (3, 4) with a series of reducing agents, mostly fairly simple oxidizable anions, have shown somewhat parallel trends. Some empirical relations of the rate constants with other properties of the reagents have been deduced (see also ref. 5). The present paper describes an extension of this work to hypobromous acid and hypobromite ions. In addition some work on the decomposition of aqueous sodium hypobromite is briefly reported. This decomposition has already been studied (6, 7), but it was necessary to extend somewhat the range of conditions used, in order to have rate constants which could be applied to correct for the effects of decomposition in the study of other reactions. The decomposition is itself an oxygen transfer reaction, similar to the others under study.

Experimental

The reactions reported in this paper are those between sodium hypobromite and sodium iodate, nitrite, and formate. As the experimental procedures were fairly similar in each case (this also applies to the decomposition of sodium hypobromite), the experimental aspects will be outlined first.

Sodium hypobromite was prepared in the usual way by adding bromine slowly to cold sodium hydroxide solution. Sodium bromide or sodium nitrate was in general added to adjust ionic strength. Analytical reagent grade samples of these substances, and of the reducing agents, were used throughout.

Runs were carried out by immersing the appropriate mixture in a thermostat held constant to ± 0.02 °C. Samples were removed at known times, rapidly cooled, and analyzed.

Bromine oxyions were mostly estimated spectrophotometrically, but the results were checked (*i*) by titration with arsenious oxide in a bicarbonate solution, which measures hypobromite plus bromite, and (*ii*) by addition of potassium iodide and acid, followed by titration with sodium thiosulfate. Attempts to destroy hypobromite ions by phenol, followed by titration of the residual bromite with arsenious oxide, as recommended by Chapin (8), gave rather erratic results. A similar method of Hashmi and Ayaz (9) using ammonium sulfate to destroy hypobromite also seemed not to be sufficiently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

accurate, a result which agrees with that of Andersen and Madsen (10).

The spectrophotometric analyses involved determining the extinction coefficients of sodium hypobromite and bromite. For the latter a sample of sodium bromite ($NaBrO_2.3H_2O$) was prepared by the method of La Societe d'Etudes Chimique pour l'Industrie et l'Agriculture (Argenteuil, France) (11), which also kindly supplied us with samples of the material. The extinction coefficients found were

	Extinction coefficient (M^{-1} cm^{-1}) at wavelength (mμ)			
Compound	380	355	333	296
NaBrO	56.6	192.2	304.8	113.2
$NaBrO_2$	19.4	53.3	81.4	115.3

Measurements on samples were usually made at two of the above wavelengths, except with sodium nitrite as reducing agent, as this also absorbs appreciably at these wavelengths. For these solutions, measurements were made at 355, 333, and 296 mμ.

Other analyses used were as follows. The concentration of hydroxide ions was found by treating a sample with hydrogen peroxide to destroy hypobromite and bromite, followed by titration with HCl. In the reaction with sodium iodate, sodium periodate precipitates out. It was filtered off, washed, and dried, and analyzed by adding potassium iodide at a pH regulated by excess sodium bicarbonate, followed by titration with arsenious oxide. The analysis agreed with the formula $Na_3H_2IO_6$, which is that to be expected from the phase diagram (12). It was checked that, before precipitation of sodium periodate, the total oxidizing normality did not change, as measured by the iodine liberated by potassium iodide plus acid. In the reaction with sodium formate, analyses for sodium formate were made as follows. Hypobromite ions were destroyed in a sample by adding excess hydrogen peroxide, the excess being then destroyed by boiling; excess standardized potassium permanganate was added, and the excess potassium permanganate remaining after oxidation of the formate was determined by adding potassium iodide and sulfuric acid, and titrating the iodine.

Evaluation of Rate Constants

It was found that the reactions studied followed similar rate laws (with minor differences arising from dependence on hydroxide concentration), and consequently a general method was used to determine the rate constants, which will be outlined here. Firstly, a correction had to be made for the decomposition of sodium hypobromite, and for this reason measurements of the rate of this reaction were made under conditions comparable to those used in the other experiments. It was known from the work of Perlmutter-Hayman and Stein (7) that this was a second order reaction, so the mechanism presumably is

$$2BrO^- \xrightarrow{k_1} BrO_2^- + Br^-$$

$$BrO^- + BrO_2^- \xrightarrow{k_2} BrO_3^- + Br^-$$

k_2 is larger, but not immensely larger, than k_1. If k_2 were immensely larger than k_1, then a plot of $[BrO^-]^{-1}$ against time would give a straight line of slope $3k_1$. For fairly large values of k_2, the limiting slope would be

$$3k_1\left\{\frac{1 + 2R - \sqrt{1 - 8R + 4R^2}}{6R}\right\}$$

where $R = k_1/k_2$. This assumes that the concentration of bromite has adjusted itself so that a plot of $[BrO^-]^{-1}$ against time is linear. A similar equation is given by Perlmutter-Hayman and Stein. If R is small, the slope approximates to $3k_1(1 + R + 4R^2)$, and Perlmutter-Hayman and Stein quote values of R of 0.05 to 0.08 under different conditions. However, if the differential equations corresponding to the reaction mechanism are solved numerically, with the assumption that the bromite concentration is initially zero, it is found that the limiting slope is established somewhat slowly, and that the mean slope over the range from roughly 10 to 40% decomposition is within 2–3% of $3k_1$. Accordingly k_1 was calculated from this.

The rate laws for the reaction of sodium hypobromite with the reducing agents were the same, except for the dependence on hydroxide concentration. The effective rate law was always

$$\frac{dx}{dt} = -kxy - 3k_1x^2 \quad \frac{dy}{dt} = -kxy$$

where $x = [BrO^-]$, and y is the concentration of reducing agent. These equations allow for the simultaneous spontaneous decomposition of sodium hypobromite. As we could not integrate these equations completely, approximate rate constants were calculated for each time interval with the use of average values of the concentrations. The first equation was rearranged to

$$k = \frac{-\Delta[\ln x]/\Delta t - 3k_1\bar{x}}{\bar{y}}$$

where the bar indicates an average value. It was found that the average rate constants, obtained from this equation, did not drift during a run, in some cases up to 80% reaction of the hypobromite ions.

The size of the error introduced by use of the approximate equation was investigated by integrating the above equations numerically with rate constants of approximately the size actually found. The equations were integrated numerically over small intervals, and the concentrations so obtained were then used to generate a second, and better, approximation. It was found that a third repetition of this procedure produced virtually no

further change. These concentrations were then used to give approximate values of k by the method outlined above. The error depends on the ratios k_1/k and x_0/y_0, and the calculated rate constants were low by an amount given in Table 1, in which the initial concentrations are assumed equal. Consequently under the conditions of experiments, the error introduced by use of the approximate equation for k was always well under 2%.

Results

Decomposition of Sodium Hypobromite

The values of k_1 (defined above) obtained are given in Table 2. A few comments may be made on these results. There is a slight upward drift in the rate constant with ionic strength, and also with hydroxide concentration. The ionic strength was adjusted by adding sodium bromide, except in Run 6, when sodium sulfate was used, and this gave a somewhat lower rate constant. The initial sodium hypobromite was between 0.19 and 0.07 M in various runs. From runs under similar conditions the activation energy was calculated to be 19.4 kcal/mol; hence at 60 °C $\Delta H^{\ddagger}$ is 18.8 kcal/mol, and $\Delta S^{\ddagger}$ is -21 cal/deg mol.

Oxidation of Sodium Iodate

The reaction here is

$$NaBrO + NaIO_3 + 2NaOH \rightarrow NaBr + Na_3H_2IO_6$$

The analogous oxidation by sodium hypochlorite has already been investigated (3). The rate constants obtained as described above showed no dependence on hydroxide ion concentration. They are given in Table 3. From the average rate

constant at each temperature, the activation energy is 25.9 kcal/mol; whence $\Delta H^{\ddagger}$ is 25.2 kcal/mol and $\Delta S^{\ddagger}$ is 4 cal/deg mol.

Oxidation of Sodium Nitrite

Here the reaction is

$$NaBrO + NaNO_2 \rightarrow NaBr + NaNO_3$$

and the analogous oxidation by sodium hypochlorite has also been investigated (3). The rate constants, obtained as described above, were inversely proportional to the hydroxide ion concentration. Hence the rate constants, which are given in Table 4, allow for this and are defined by

$$\frac{-d[BrO^-]}{dt} = k'\frac{[BrO^-][NO_2^-]}{[OH^-]} + 3k_1[BrO^-]^2$$

The values for k_1 were taken from the measurements on the decomposition of sodium hypobromite, although they could in theory be obtained directly from the present runs. The apparent activation energy obtained from k' is 11.5 kcal/mol.

Oxidation of Sodium Formate

Here the reaction is

$$NaBrO + NaHCO_2 + NaOH \rightarrow NaBr + Na_2CO_3 + H_2O$$

As with sodium nitrite, the rates fitted the equation

$$\frac{-d[BrO^-]}{dt} = k'\frac{[BrO^-][HCO_2^-]}{[OH^-]} + 3k_1[BrO^-]^2$$

The rate constants, k', are given in Table 5. The main group of runs at 60 °C show a slight increase in the rate constant with hydroxide concentration, and with the ionic strength. The mean values of

$HC_2O_4^-$	HOCl	1.2	14.4	−4.7	HOBr	2.5	14.7	2

the rate constants at an ionic strength of about 1.0 and $[OH^-]$ about 0.1 M are 0.76×10^{-4} (49.7 °C), 1.83×10^{-4} (59.9 °C), and 3.28×10^{-4} (70.4 °C). These do not give a good straight line plot of log k' against $1/T$; the activation energy appears to be about 15 kcal/mol. This may in part be connected with the degree of protonation of hypobromite ions at various temperatures, and will be discussed further.

Discussion

Some of the reactions are dependent on $[OH^-]$, and in similar cases this has usually been interpreted as involving reaction of the acid molecule, in this case HOBr, rather than the ion. The reaction could, of course, be one involving the conjugate acid of the reducing ion. However, if we consider these as reactions of hypobromous acid, the true rate constants can be evaluated from the hydrolysis constants of hypobromite ions. Data are available on the ionization constants of hypobromous acid (13), and these combined with the ionization constants of water make pK_h (where $K_h = [HOBr][OH^-]/[BrO^-]$), 5.52 (15 °C), 5.40 (25 °C), 5.21 (35 °C), and 5.03 (45 °C). These values must be extrapolated for the higher temperatures used in some runs, and it should be noted that the calculated ΔH° for the hydrolysis reaction over various temperature intervals is not very constant: $\Delta H^\circ = 4.7$ kcal (15 to 25 °C), 8.0 (25 to 35 °C), and 8.1 (35 to 45 °C). It seemed best therefore to take ΔH° as increasing by 0.1 kcal for each 10° interval above these values. This gives extrapolated pK_h values of 4.86 (55 °C), 4.70 (65 °C), and 4.54 (75 °C), and values at other temperatures were interpolated from these.

If we define the rate constant, k_3, in terms of hypobromous acid by

$$\text{Rate of reaction} = k_3[HOBr][X^-]$$

then when X^- is the nitrite ion, k_3 is 1.29 $M^{-1}\,s^{-1}$ at 48 °C and 1.92 $M^{-1}\,s^{-1}$ at 76.3 °C. The values make $\Delta H^{\ddagger} = 2.5$ kcal/mol and $\Delta S^{\ddagger} = -49$ cal/deg mol. Extrapolation to 25 °C makes log $k_3 = -0.05$ at this temperature.

When X^- is the formate ion, k_3 is 6.9 (49.7 °C), 10.5 (59.9 °C), and 13.8 (70.4 °C); from which $\Delta H^{\ddagger}$ is 6.7 kcal/mol and $\Delta S^{\ddagger}$ is −34 cal/deg mol. By extrapolation log k_3 at 25 °C is 0.45.

The dependence on $[OH^-]$ is the same for the analogous reactions of sodium hypochlorite. This suggests that this aspect depends on the properties of the reducing agent. However, presumably both reactions can occur; *i.e.*, HOBr + X^- and BrO^- + HX. At present this property cannot be related to the structure of the reducing agent, X^-.

Various regularities have been observed in the rate constants of reactions of this type. In particular, Edwards (1, 2, 5) related rate constants for oxidations by peroxides to the standard electrode potential for X^-/X_2, and pK_a of HX, and later he proposed that a better correlation could be found with polarizability instead of standard electrode potential. Similarly rate constants for a single reducing agent with a series of peroxides, ROOH, gave a linear relation with pK_a of ROH. These ideas were applied to hypochlorite oxidations (3, 4), which showed some similar regularities, though not as precisely. The correlation with pK_a of ROH is only to be expected if the RO—OH bond breaks about equally easily as the Cl—OH bond. In aqueous solution the relative ΔH°_{298} of $AOH + X^- \rightarrow XOH + A^-$ are very nearly equal for A = OH or Cl, but are about 9 kcal more endothermic for A = Br. Hence if this is a factor in the rates of reaction, hypochlorous acid might be expected to fit in with the peroxides (as it seems to), but not hypobromous acid.

A comparison of the kinetic parameters for analogous reactions of hypochlorite and hypobromite ions is given in Table 6, which includes data on oxalate ions (14). The ionic strengths are approximately 1.0. The results do not follow a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

very regular pattern, but some comments can be made. The rate constants of hypobromite are generally larger, except for the reaction with nitrite, where a very large negative $\Delta S^{\ddagger}$ occurs. Correlations with standard electrode potentials (either for the complex X^-/X_2 or X^-/XO^-) do not seem to hold for hypobromites, and the same applies to correlations with pK_a of HX.

The similar trends in the rates of hypobromite and hypochlorite reactions mean that the correlation of $\Delta H^{\ddagger}$ and the enthalpy of the reaction, which was found earlier for hypochlorites (4), holds to some extent for hypobromite. In both cases, the more exothermic reactions are faster. It had also been noted earlier that $\Delta H^{\ddagger}$ plotted against $\Delta S^{\ddagger}$ gave a rough straight line for reactions of a particular peroxide species, and less accurately for hypochlorites. For hypobromites, the three reactions of hypobromous acid fall fairly close to a line of slope $d\Delta H^{\ddagger}/d\Delta S^{\ddagger} = 240\ °K$, with the points for the reactions of hypobromite ion not on this line. More reactions would have to be investigated to discover if any extensive regularity of this sort exists. The general conclusion must be that the regularities of various sorts found for peroxides or hypochlorites are (so far) scarcely observable for hypobromites.

The Proton Magnetic Resonance Spectra of some Chlorinated Polycyclodiene Pesticide Metabolites. Rapid Assessment of Stereochemistry[1]

J. D. McKinney, L. H. Keith,[2] A. Alford,[2] and C. E. Fletcher[3]

National Institute of Environmental Health Sciences, National Institutes of Health, Public Health Service, and Department of Health, Education, and Welfare, Research Triangle Park, North Carolina 27709

The rapid and accurate determination of the relative stereochemistry of some postulated chlorinated polycyclodiene pesticide metabolites without excessive dependence on chemical methods is described. Proton assignments were made employing the new nuclear magnetic resonance (n.m.r.) shift reagent, $Eu(DPM)_3$, which effected the separation of superimposed signals in these systems. The assignments based on coupling constant information and requiring spin decoupling equipment are in good agreement with those obtained from the $Eu(DPM)_3$ studies. The data presented establishes the relative stereochemistry of these biologically important compounds and demonstrates the utility of one or both approaches in elucidating their overall structures.

On décrit une méthode rapide et précise de déterminer sans dépendre d'une façon excessive sur des méthodes chimiques la stéréochimie relative de quelques métabolites postulés de pesticides de polycyclodiènes chlorés. On a assigné les différents protons en utilisant, en r.m.n., le réactif $Eu(DPM)_3$ qui permet de séparer les signaux qui seraient par ailleurs superposés dans ce système. Les attributions faites en se basant sur des constantes de couplage ou nécessitant l'utilisation d'équipement pour le découplage des spins sont en bon accord avec celles découlant des études faites avec $Eu(DPM)_3$. Les données présentées permettent d'établir la stéréochimie relative de ces composés biologiquement importants et démontrent l'utilité de chacune des méthodes dans l'élucidation des structures.

Canadian Journal of Chemistry, 49, 1993 (1971)

The chlorinated polycyclodiene pesticides have received considerable attention in the past few years since they are among the most stable and persistent insecticides that can contaminate our environment. Although these compounds have been studied extensively both chemically (1) as well as in living organisms (2–7), their mechanism(s) and mode(s) of action on a molecular level still remain, to a large extent, enigmatic. Metabolic studies of these pesticides have been complicated by difficulties in the unequivocal identification of the biotransformation products which in most cases also require proof of stereochemical structures since stereospecific as well as stereoselective transformations are possible. Detailed elucidation and elimination of metabolic possibilities are necessary in illuminating the possible differences in toxicity due to stereochemical factors (3). This paper describes the use of n.m.r. spectroscopy to more rapidly and accurately determine the stereochemical structures of some postulated chlorinated polycyclodiene pesticide metabolites by establishing patterns of identification in their spectra. The use of n.m.r. data in assigning the stereochemistry of analogous compounds without excessive dependence on chemical methods has been previously reported (8, 9).

A representative series of compounds were obtained for the most part by stereoselective syntheses as outlined in Scheme 1: *trans*-4,5-dihydroxy-4,5-dihydroaldrin (**1**), *cis-exo*-4,5-dihydroxy-4,5-dihydroaldrin (**2**), *exo*-4-hydroxy-4,5-dihydroaldrin (**3**), 4-oxo-4,5-dihydroaldrin (**4**), *endo*-4-hydroxy-4,5-dihydroaldrin (**5**), and *cis-exo*-4,5-dihydroxy-4,5-dihydroisodrin (**6**). All of these compounds, with the exception of **6**, have been implicated as metabolites or degradation products in diverse metabolism studies. However, in some cases the authenticity of standards used for obtaining comparison data with metabolites is not corroborated by a description of the synthetic methodology. Delta-keto endrin (**7**) was commercially available[4] and was examined primarily for any similarities its proton magnetic resonance (p.m.r.) spectra had with those of 4-oxo-4,5-dihydroaldrin (**4**).

The preparation of *cis*-diols (**2** and **6**) was accomplished via hydrolysis of their osmic acid esters (11) and gave somewhat higher yields than the previously reported method employing potassium permanganate as an oxidant. The *cis*-diols had identical properties to those obtained by the permanganate procedure [*cis*-dihydroaldrin diol (13); *cis*-dihydroisodrin diol (12)]. Both diols **2** and **6** formed their corresponding acetonides when treated with acetone in the presence of ferric chloride according to the literature method (12), and the facile formation of these acetonides confirms the *cis*-relationship of the two hydroxyl groups. The *trans*-diol (**1**) was prepared according to the literature synthesis (13); however, the yield was significantly increased by the addition of 1,4-dioxane to enhance homogeneity.

The *exo*-alcohol (**3**) was synthesized by hydroboration–oxidation of aldrin. Hydroboration–oxidation of the *endo-exo* octahydrodimethanonaphthalene system is known (14) to give the *exo*-alcohol. Oxidation of alcohol **3** with sodium dichromate in sulfuric acid gave 4-oxo-4,5-dihydroaldrin (**4**), a Lewis acid rearrangement product (15) of the parent pesticide dieldrin. The stereoselective reduction of ketone **4** with disiamylborane (16) afforded the *endo*-alcohol (**5**) which could be reconverted to ketone **4** by oxidation with chromic acid. Alcohols **3** and **5** have been previously characterized (17) as solid materials melting at 125 and 131°, respectively; however, in our hands these compounds, even though chromatographically pure, had no precise melting points. This anomaly has been previously observed (1) for other adducts of hexachlorocyclopentadiene.

The 100 MHz p.m.r. spectra of compounds **1**–**7** were analyzed with the aid of spin decoupling techniques and by addition of the n.m.r. shift reagent (18), *tris*(dipivalomethanato)europium [$Eu(DPM)_3$], which induces paramagnetic shifts in protons via association with lone-pair electron bearing functional groups. The magnitude of the shift is primarily dependent on the distance of each proton from the center of the europium atom (19). A variety of solvents, including chloroform-*d*, acetone-d_6, benzene-d_6, and acetonitrile-d_3, were employed in establishing indentification patterns. Comparison spectra reported in this paper for untreated and $Eu(DPM)_3$ treated samples were obtained in chloroform-*d*. Although the $Eu(DPM)_3$ was normally added to the chloroform solutions of the compounds in approximately one millimolar increments with spectra recorded with each addition, the data from the spectrum which gave the best separation of the protons involved was used for tabulative comparison with the normal spectrum. In almost all cases the p.m.r. data was obtained on 10 mg or less of sample.

A study of the effects of varied concentrations of $Eu(DPM)_3$ on the p.m.r. spectra of some of the parent chlorinated polycyclodiene pesticides has been made (20). The objective of our study was to obtain, for the most part, qualitative information which would permit a rapid and at the same time accurate stereochemical description of these types of compounds. In elaborating the p.m.r. data of these representative compounds, three comparative analyses were made, *i.e.*, dihydroxy compounds (**1**, **2**, and **6**), monohydroxy compounds (**3** and **5**), and ketonic compounds (**4** and **7**).

The chemical shifts obtained for the dihydroxy compounds and derivatives with and without the presence of $Eu(DPM)_3$ are given in Table 1. Examination of the data shown for compound **1** reveals the non-equivalency of all protons except the methylene bridge protons (12a, 12s).[5] The most reasonable explanation for this result would be the presence of both an *endo*- and *exo*-hydroxyl group in the molecule at positions C-4 and C-5 destroying the plane of symmetry present in the parent compound. The *trans*-1,2-relationship[6] of the hydroxyls at C-4 and C-5 is supported by the observed coupling constants of $J_{3,4} = 4.5$, $J_{5,6} < 0.5$, and $J_{4,5} = 1.5$ Hz which conform well to the measured dihedral angles of about 35, 80, and 120°, respectively.[7] The presence of the "W effect"[8] coupling ($J_{5n,12a} = 2.0$ Hz) of the C-5 *endo*-proton with the C-12 *anti*-proton and the absence of such a coupling with the C-4 proton, as deduced from decoupling experiments on various combinations of protons, confirm

[5]The p.m.r. spectrum of **1** in acetonitrile-d_3 also demonstrated the non-equivalency of the C-12 protons (H_{12a} τ 8.66, H_{12s} τ 8.41; where *a* and *s* refer to *anti* and *syn* configurations relative to the C-4, C-5 positions).

[6]It was necessary to confirm the 1,2-relationship of these groups since rearrangement equilibria (21) of the bridged norbornyl cation formed during the synthesis of **1** could have led to other isomers.

[7]A study of the variation of coupling constants with dihedral angle in the p.m.r. spectra of the camphane-2,3-diols has been made (22).

[8]Meinwald's "W-letter rule" (23).

the *trans*-stereochemistry of the hydroxyl groups. Eu(DPM)$_3$ treatment of the *trans*-diol (**1**) is complicated by the presence of two different associable oxygen atoms which produce a cumulative and unequal deshielding of the various protons since they are not equidistant from the two europium complexes. However, the C-2 and C-7 protons which are distant (4 bonds away) from both hydroxyl groups show comparatively larger deshielding of the C-2 proton by the C-4 *endo*-hydroxyl than that observed for the C-7 proton ($J_{2,7}$ = 8.0 Hz). On the other hand, H_{12s} experiences larger deshielding than H_{12a} by the *exo*-hydroxyl group at C-5 (see Fig. 1) thus corroborating the H_2, H_7, H_4, H_5, H_{12s}, and H_{12a} signal assignments as well as the *trans*-stereochemistry of the diol. Likewise, the two bridgehead protons experience unequal deshielding; H_6 is shifted downfield 6.77 p.p.m. while H_3 is shifted 4.15 p.p.m. downfield. This confirms the H_3 and H_6 signal assignments since Dreiding models show that the bridgehead protons are spatially closer to the *exo*-hydroxyl oxygen (2.6 Å), and hence to the europium complex, than to the *endo*-hydroxyl oxygen (2.9 Å). The extremely large deshielding observed for the H_4 and H_5 signals would be expected since contact as well as pseudocontact interactions of these protons with the complex are possible.

Since the *cis*-relationship of the hydroxyl groups in diols **2** and **6** has been established on chemical grounds *via* acetonide formation, it was only necessary to verify that the expected *exo*-addition to the double bond had occurred. Although *endo*-attack is unlikely chemically,[9] it is a reasonable possibility in studying the metabolism of these compounds. The occurrence of the equivalent pairs of protons H_2–H_7, H_3–H_6, and H_4–H_5 is consistent with the presence of a plane of symmetry generated by two *cis*-oriented hydroxyl groups at positions C-4 and C-5. The *exo*-stereochemistry of these hydroxyl groups is in agreement with the small difference ($\Delta\delta$ 0.09) in the value of the chemical shift obtained for the C-2–C-7 protons of **2** with the value of the C-7 proton proximal to an *exo*-hydroxyl group in **1**. The "W effect" coupling (J = 2.0 Hz) of H_{12a} with $H_{4,5}$ is also present since $H_{4,5}$ collapses to an apparent singlet on irradiation of 12a, thereby confirming the absence of appreciable coupling (J < 0.5 Hz) for $H_{3,4}$ and $H_{5,6}$. The *cis*-diol (**2**) was not amenable to n.m.r. analysis in the presence of Eu(DPM)$_3$ due to its insolubility in suitable solvents. The more soluble acetonide derivative of **2** might be expected to associate with the europium complex *via* association with the ether type oxygens of the dimethylmethylenedioxy ring system. However, a large excess (saturated solution) of Eu(DPM)$_3$ was required to produce significant deshielding of protons in this compound. Since this has been shown (19) to be an equilibrium association, the weaker association of this acetonide can be attributed to the poorer Lewis base character of the ether type oxygens

[9]An *endo*-epoxide has been isolated as an epoxidation product of norbornene which was attributed to *endo*-attack on the system (24).

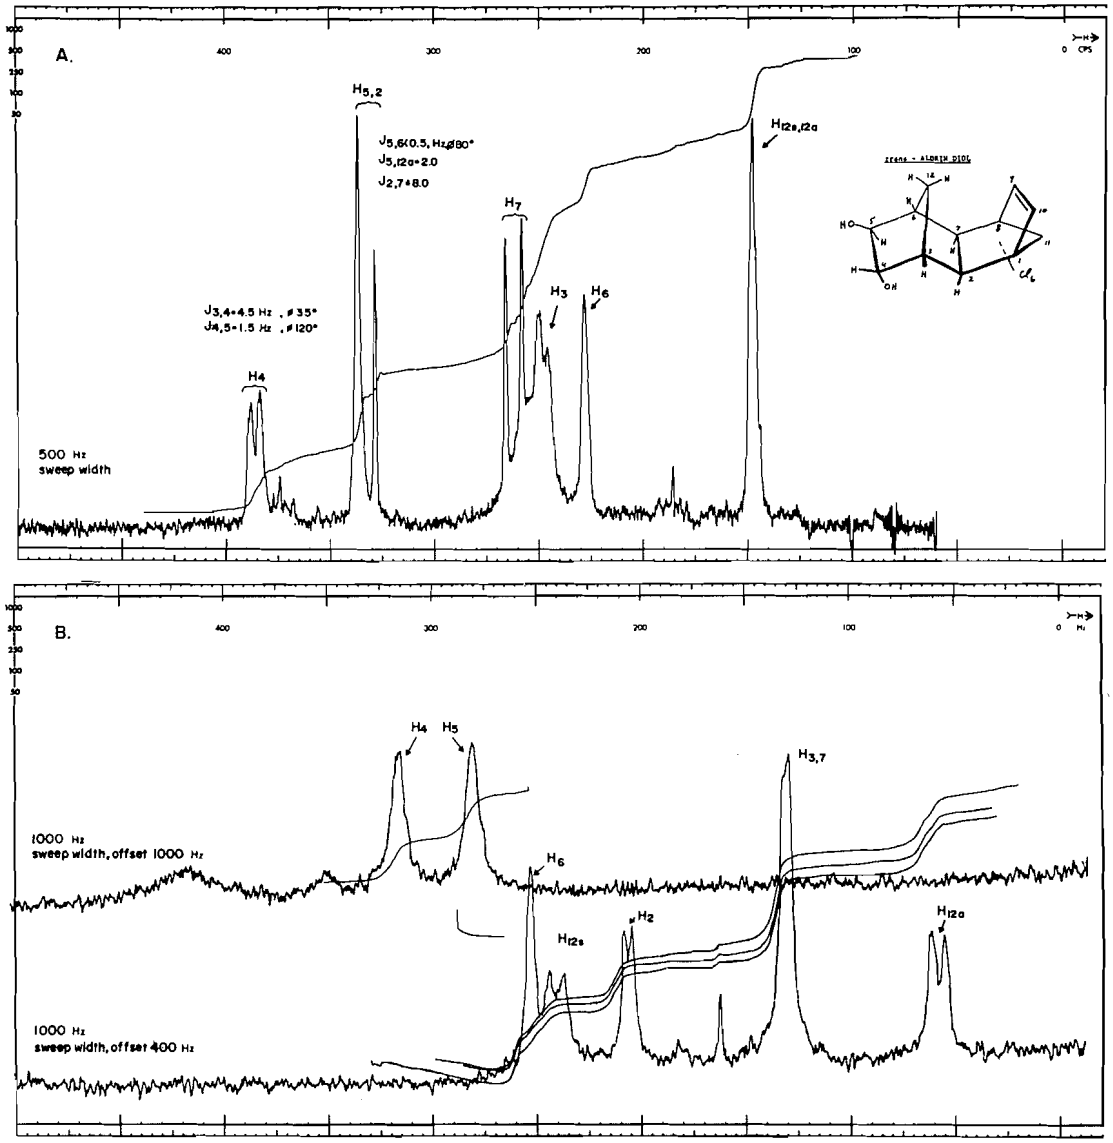

FIG. 1. (*A*) *trans*-Aldrin diol (< 0.1 *M*) without $Eu(DPM)_3$ and (*B*) with 0.2 *M* $Eu(DPM)_3$ in $CDCl_3$ at 100 MHz; 1000 Hz sweep width; sweep offset (*a*) 400 Hz, (*b*) 100 Hz.

as well as the steric requirements of the *gem* dimethyl groups. Nevertheless, the comparatively large deshielding of the H_{12s} signal ($\Delta\delta$ H_{12s} = 1.12 p.p.m.; $\Delta\delta$ H_{12a} = 0.26 p.p.m.) was noted and confirmed the *cis-exo*-stereochemistry of diol **2**.

The formation of the acetonide of diol **6** which is derived from isodrin (*endo–endo* skeleton) not only establishes the *cis*-relationship of the hydroxyl groups but also supports the *exo*-configuration of these groups since such a derivative of the *endo*-isomer of **6**, if it could be formed at all, would have severe steric interactions. The equivalency of protons is also characteristic of this diol as well, with marked differences in chemical shifts for the H_{12s}, $H_{2,7}$, and $H_{4,5}$ signals due to significant differences in the magnetic anisotropy of these protons in the *endo–endo* skeleton. As in diol **2**, the "W effect" coupling (J = 1.8 Hz) of H_{12a} and $H_{4,5}$ and

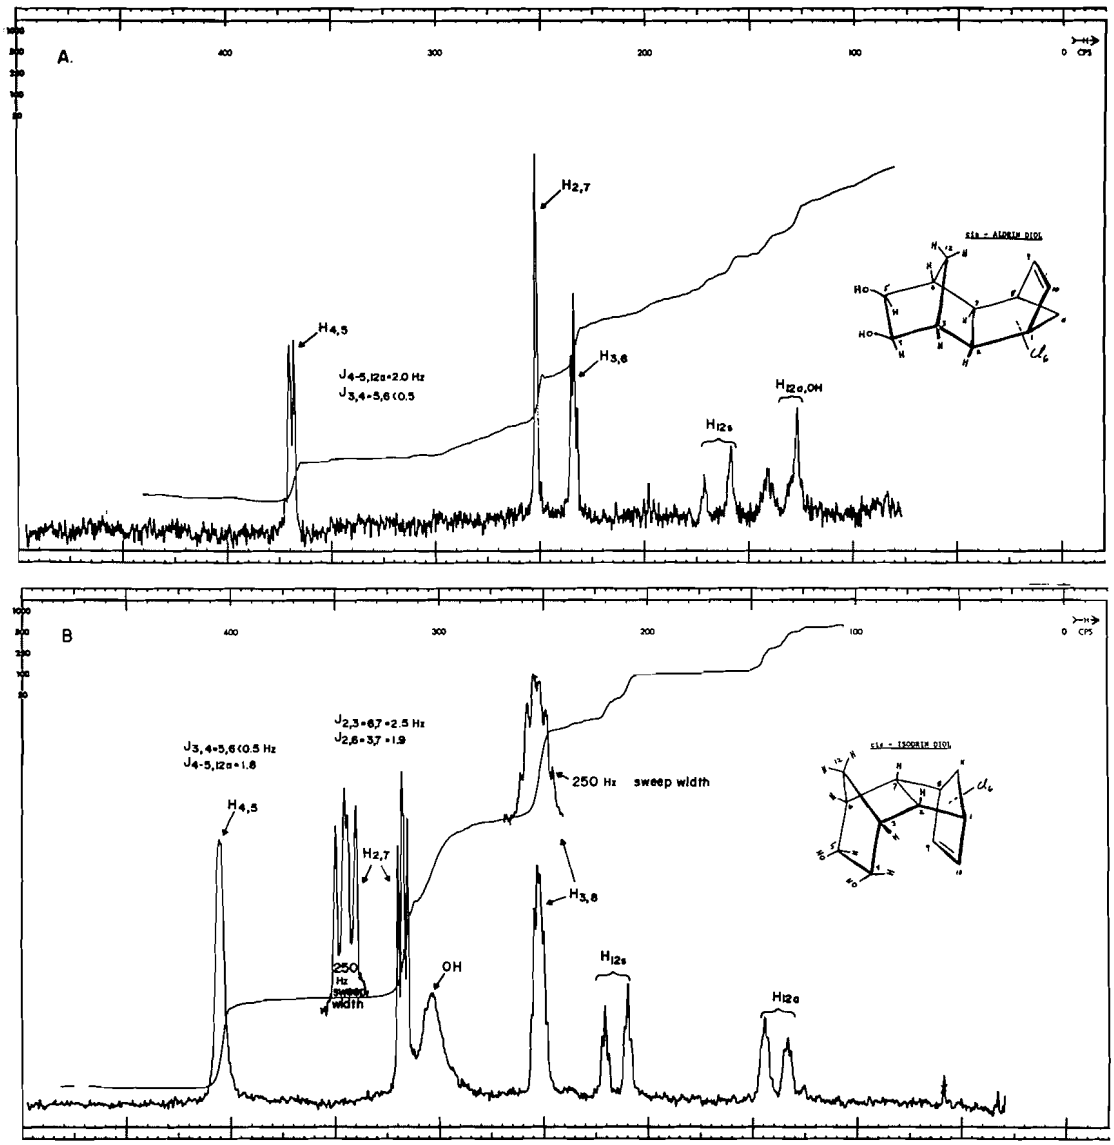

FIG. 2. (*A*) *cis*-Aldrin diol and (*B*) *cis*-isodrin diol in $CDCl_3$ at 100 MHz.

small couplings ($J < 0.5$ Hz) of $H_{3,4}$ and $H_{5,6}$ are characteristic. The most salient difference in the p.m.r. spectrum of diol **6** is the expected pair of doublets for $H_{2,7}$ due to vicinal coupling ($J_{2,3} = J_{6,7} = 2.5$ Hz) with the adjacent bridgehead proton and long-range coupling ($J_{2,6} = J_{3,7} = 1.9$ Hz) with the distant bridgehead proton (Fig. 2) *via* a somewhat distorted "W" (26). As previously reported (25), the presence of these couplings is characteristic of compounds possessing the *endo–endo* skeleton since the $H_{2,7}$ signal in symmetrical compounds possessing the *endo–exo* skeleton appears uniformly as a singlet. In unsymmetrical compounds of the *endo–exo* type such as **1**, **3**, and **5**, the $H_{2,7}$ signals occur as an easily recognizable pair of doublets ($J = 7.5$–8.0 Hz). Addition of $Eu(DPM)_3$ to the chloroform solution of diol **6** produced the larger deshielding of H_{12s} ($\Delta\delta\ H_{12s} = 3.73$ p.p.m.; $\Delta\delta\ H_{12a} = 1.49$ p.p.m.) and completes delineation of the *cis-exo* stereochemistry of the hydroxyl groups.

In light of the information acquired from the dihydroxy compounds, the spectra of the less

discernible monohydroxy compounds **3** and **5** were obtained. The proton chemical shifts of these alcohols are given in Table 2. The most diagnostic observations in rapidly differentiating between *exo*-alcohol **3** and *endo*-alcohol **5** are the appreciable deshieldings of H_2 in the *endo*-alcohol and H_{12s} in the *exo*-alcohol which are markedly increased by the addition of Eu(DPM)$_3$ and the ostensible doublet-character of the H_4 signal in **3** as compared to the octet multiplicity produced by the same proton in **5** (see Fig. 3). The multiplicity differences can be ascribed to large couplings ($J_{4,5x}$ = 10.0 Hz, $J_{4,5n}$ = 3.5 Hz, and $J_{4,3}$ = 5.0 Hz) of H_{4x} in the *endo*-alcohol and comparatively smaller couplings ($J_{4,5x}$ = 1.5 Hz, $J_{4,5n}$ = 6.0 Hz, and $J_{4,3} < 0.5$ Hz) of H_{4n} in the *exo*-alcohol. These couplings are also in good agreement with coupling constants calculated on the basis of dihedral angles. Comparison of $J_{4,5x}$ of **3** and $J_{4,5n}$ of **5** shows the effect of the angle of the hydroxyl substituent to the coupling path and reflects greater distortion of bond angles in the *endo*-alcohol. Greater shielding of H_{5x} by the pseudoaxial hydroxyl substituent in the *endo*-alcohol was also notable. This shielding effect would be consistent with earlier observations (27) on the effect of an axial alkyl substituent on the adjacent equatorial proton in cyclohexane compounds. Although the "W effect" coupling of H_{4n} with H_{12a} was not resolvable in the *exo*-alcohol **3**, the relatively large deshielding of H_{12s} on treatment with Eu(DPM)$_3$ is also in accord with the *exo*-configuration of the hydroxyl group.

The $H_{3,6}$ signals for both alcohols appeared for the most part as broad singlets except for H_3 in the *endo*-alcohol which had doublet character due to its relatively large coupling with H_4 previously described. Decoupling experiments of both alcohols involving H_4 permitted resolution of the H_5 ($J_{5x,5n}$ *exo* and *endo* cpds. = 13 Hz) and H_{12} ($J_{12a,12s}^{exo}$ = 12.5 Hz, $J_{12a,12s}^{endo}$ = 13 Hz) couplings as well as chemical shift assignments of these protons. Addition of Eu(DPM)$_3$ to these alcohols further facilitated the assignment of chemical shifts. The position and configuration of the hydroxyl group in compounds **3** and **5** are consistent both with the p.m.r. spectral data and the methods of preparation.

The p.m.r. spectral characteristics of 4-oxo-4,5-dihydroaldrin (**4**) were investigated as a reference compound for comparing the effects of the carbonyl group on the proton environments of the *endo-exo* skeletal system. *Delta*-keto endrin (**7**) provided less relevant data as a ketonic compound of the *endo–endo* type skeleton. (See Table 3.) The expected non-equivalency of protons at H_2 and H_7 ($J_{2,7}$ = 7.5 Hz) and of H_3 and H_6 in **4** was present but was not as perceptible as in the hydroxy compounds. Double decouplings of $H_{5x,5n}$, $H_{3,6}$, and of $H_{12a,12s}$ provided the most interpretative data for assigning chemical shifts; however, the smaller coupling constants of these protons remained undecipherable. Eu(DPM)$_3$ studies confirmed the assignments and were helpful in revealing the multiplicities of some protons; in particular the characteristic four pairs of doublets produced by the C-5 methylene protons from the large geminal coupling of $H_{5n,5x}$ ($J_{5x,5n}$ = 18.0 Hz) and the smaller vicinal couplings of the $H_{5,6}$ ($J_{5n,6}$ = 5.0 Hz, $J_{5x,6}$ = 4.5 Hz) signals (see Fig. 4). Table 4 summarizes the decoupling experiments employed in establishing the major coupling constants of all compounds discussed thus far. Other decoupling experiments were helpful in some cases to confirm our signal assignments.

The assignments given for δ-keto endrin (**7**) are to some degree tenuous since neither decoupling experiments nor Eu(DPM)$_3$ treatment produced adequate changes in its spectra. The H_2, H_4, and H_6 signals were differentiated primarily on the basis of the expected larger deshielding of H_2 by the proximal C-1 chlorine and the presence of the large vicinal coupling ($J_{2,6}$ = 7.0 Hz) suspected of H_2 and H_6 which conforms well to the dihedral angle of 25° as measured from a Dreiding model. The vicinal coupling of $H_{6,7}$ and $H_{4,8}$ ($J_{6,7} = J_{4,8}$ = 2.0 Hz) and the long-range coupling of $H_{4,7}$ and $H_{6,8}$ ($J_{4,7} = J_{6,8}$ = 1.3 Hz) characteristic of compounds possessing

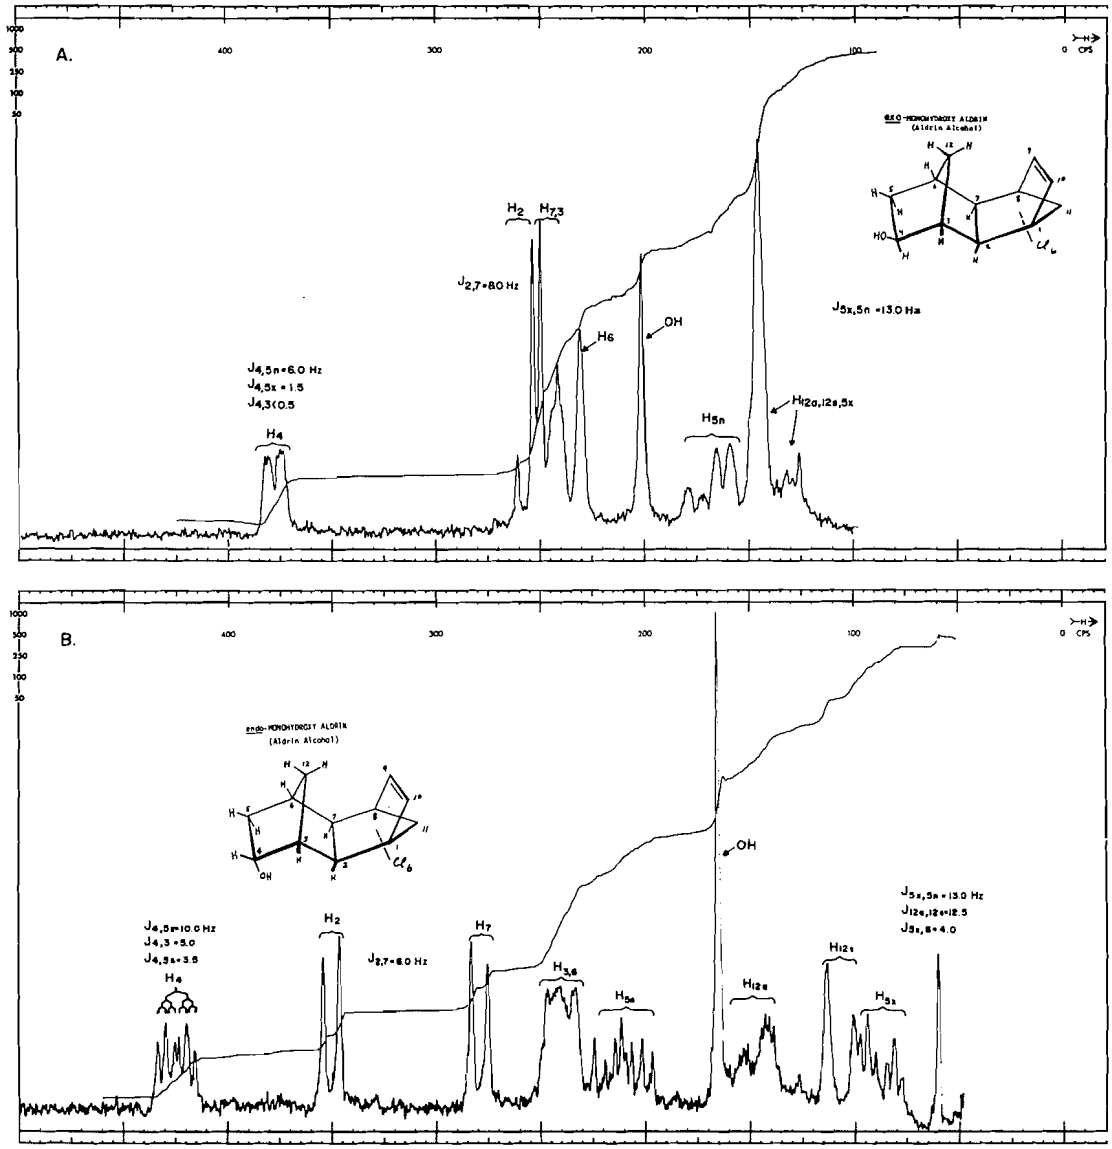

FIG. 3. (*A*) *exo*-Monohydroxy aldrin and (*B*) *endo*-monohydroxy aldrin in $CDCl_3$ at 100 MHz.

the *endo–endo* skeleton were also resolvable. These couplings are smaller in magnitude than those observed (25) for unbridged *endo–endo* systems due to the distortion of bond angles which is a manifestation of the half-cage system. Addition of $Eu(DPM)_3$ to **7** did not provide more substantial data for confirming our signal assignments since sufficient deshielding of protons to resolve all the signals was still not achieved.

In general, addition of $Eu(DPM)_3$ to the keto compounds produced paramagnetic shifts of smaller magnitude than those observed for the hydroxy containing compounds. This finding is consistent with earlier observations (18) and with the stronger associating properties which might be expected for the hydroxyl group on electronic grounds.

The results presented demonstrate that, in rigid systems such as these, a great deal of structural information can be obtained from their p.m.r. spectra. Such information will permit

rapid assessment of the stereochemistry as well as other structural characteristics of these systems whether they be of theoretical or metabolic interest. In addition, the deshielding effects of Eu(DPM)$_3$ were shown to be useful as a confirmatory technique of signal assignments without the requirement of spin decoupling equipment and as a selective shift reagent enabling superimposed signals in these systems to be separated from one another.

Experimental

Melting points were taken on a Fisher–John melting point apparatus and are uncorrected. The n.m.r. studies were made with a Varian HA-100 spectrometer with spin decoupling accessories using tetramethylsilane (TMS) as an internal reference. The Eu(DPM)$_3$ used in these studies was obtained from Alfa Inorganics, Beverly, Massachusetts, and the chloroform-*d* employed in obtaining spectra of Eu(DPM)$_3$ treated samples was stored over anhydrous sodium carbonate. The i.r. spectra were obtained with a Perkin–Elmer Model 337 spectrophotometer, and the low resolution mass spectra were obtained with a Perkin–Elmer Model 270 gas chromatograph-mass spectrometer. The preparative thin layer chromatography (t.l.c.) was done on Uniplate, Silica Gel GF plates 250 microns in thickness. The bands were detected with u.v. light.

Preparation of Dihydroxy Compounds

The *trans*-diol **1** was prepared by a modification of Korte and Arent (13) procedure. To a solution of 243 mg (0.61 mmol) of dieldrin (from Shell Development Co.) in 25 ml of 1,4-dioxane was added 22 ml of water and 3.5 ml of concentrated H_2SO_4. The resulting solution was refluxed for 72 h in oil bath. After cooling, the reaction mixture was diluted with an equal volume of H_2O extracted with two 50-ml portions of ethyl acetate. The combined extracts were washed with sodium carbonate, water and then dried over anhydrous sodium sulfate. Evaporations of these extracts gave a residue which was redissolved and streaked on t.l.c. plates. Elution of the plates with benzene – ethyl acetate (3 to 1) followed by removal of the largest band as detected by u.v. light gave 117 mg (49%) of solid material. Recrystallization from hexane afforded crystalline material melting at 132–134°. Spectral properties were characteristic of *trans*-4,5-dihydroxy-4,5-dihydroaldrin (2).

The *cis*-diols **2** and **6** were prepared according to the following general procedure: To solution of 719 mg (2.1 mmol) of the olefinic compound (aldrin or isodrin) in 10 ml of absolute ether and 1 ml of pyridine was added 500 mg (1.97 mmol) of osmium tetroxide in 50 ml of absolute ether, resulting in the immediate formation of a creamy brown precipitate. The reaction mixture was stirred magnetically for 1 h and allowed to stand overnight unexposed to any light. The light brown precipitate was removed by filtration and dissolved in 50 ml of methylene chloride. The hydrolysis of the olefin–OsO_4–

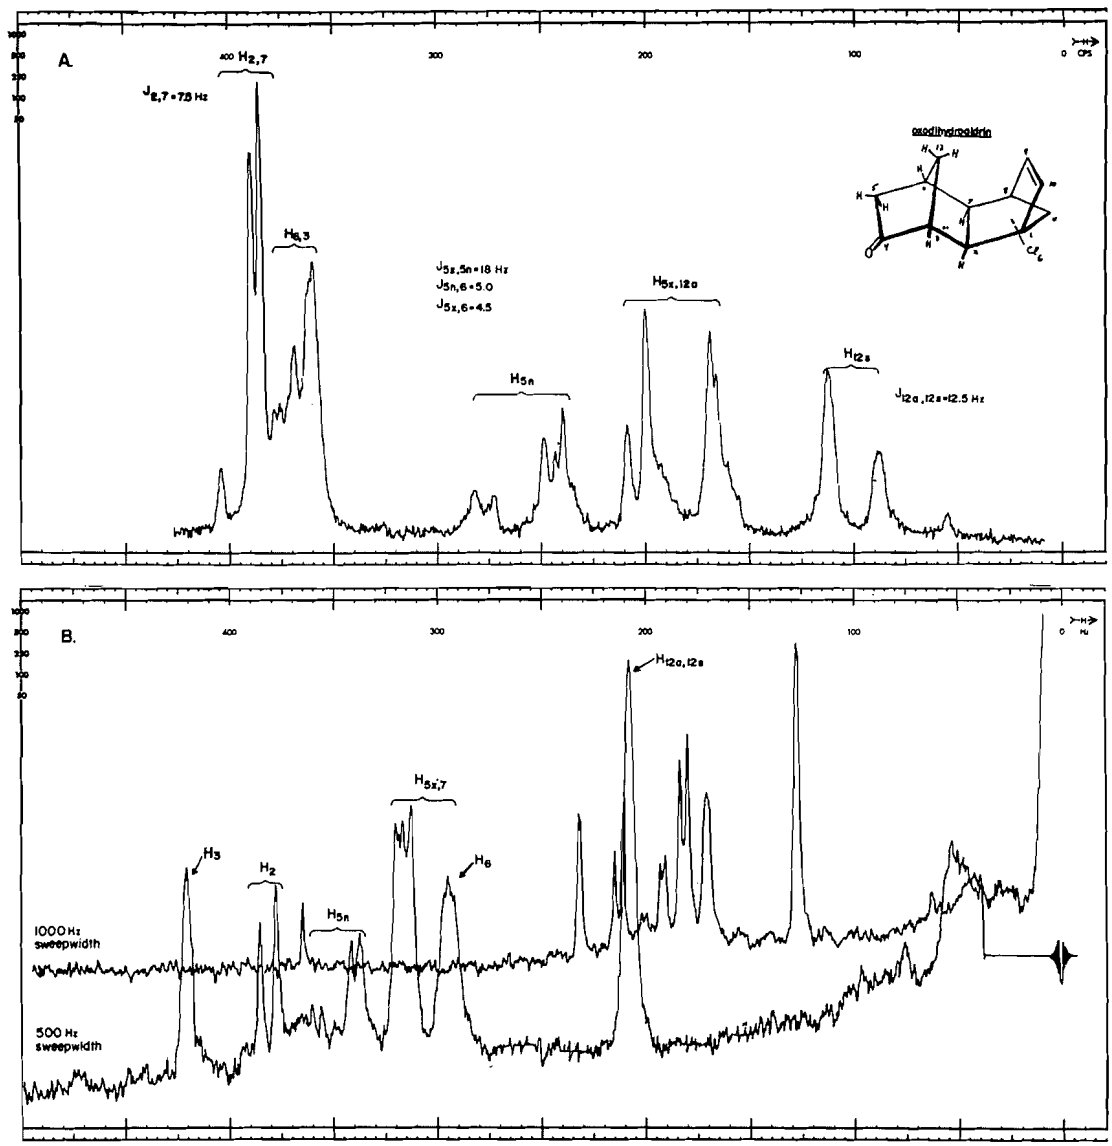

FIG. 4. (*A*) Oxodihydroaldrin (<0.1 *M*) in $CDCl_3$ at 100 MHz; sweep width 250 Hz and (*B*) with 0.14 *M* $Eu(DPM)_3$; sweep width 500 Hz.

pyridine adduct was accomplished by shaking the methylene chloride solution with 65 ml of water containing KOH (11.6 mmol) and mannitol (34.9 mmol) for 2 h or until the brown methylene chloride layer becomes relatively colorless while the aqueous phase acquires a deep reddish brown color. The methylene chloride layer is removed, washed with an equal volume of water, and dried over anhydrous sodium sulfate. Evaporation of this layer left a brown residue from which the *cis*-diol could be obtained by dissolving in hot benzene, decolorizing the resulting solution with charcoal, filtering and cooling the filtrate. Successive recrystallizations afforded 60–75% yields of pure material. The *cis-exo*-4,5-dihydroxy-4,5-dihydroaldrin (**2**) melted at 218–219 °C (m.p. 217 °C (13)) and *cis-exo*-4,5-dihydroxy-4,5-dihydroisodrin (**6**) melted at 201–203 °C (m.p. 199–201 °C (12)). The acetonides of these materials, which were prepared according to the method of Soloway *et al.* (12) in refluxing acetone in the presence of ferric chloride hexahydrate, melted at 151–153 °C (from **2**) and 136–138 °C (from **6**), and had the expected spectral properties for the dimethylmethylenedioxy ring system.

Preparation of Monohydroxy and Keto Compounds

To a solution of 145 mg (3.8 mmol) of sodium borohydride and 1.62 ml of boron trifluoride etherate in 10 ml

of tetrahydrofuran (THF) was added dropwise a 10 ml solution of 2.88 g (7.9 mmol) of aldrin. The resulting solution was stored for 70 h at room temperature and then 1.4 ml of 3 *N* NaOH solution was added followed by 1.4 ml of 30% hydrogen peroxide. The mixture was stirred at room temperature for 3 h and then diluted with 50-ml portions of ether. The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated under vacuum. The residue was transferred to preparative t.l.c. plates which were eluted with a mixture of chloroform – ethyl acetate (9 to 1). Two major bands were detected with u.v.-light. The material in the band nearest the solvent front was cochromatographical with aldrin. The material in the band nearest the origin was removed and repeatedly chromatographed until pure. Solid material (1.19 g, 39%) obtained from crystallization of the latter purified material from *n*-hexane had no precise melting point but had the expected mass spectral properties ($C_{12}H_{10}O^{35}Cl_{4.5}{}^{37}Cl_{1.5}$, *m/e* 383, 347, 329, 311, and 301) of the *exo*-alcohol (**3**).

A solution of 1.15 g (3.0 mmol) of (**3**) in 10 ml of ether was added dropwise to 10 ml of water containing 880 mg (3.0 mmol) of sodium dichromate and 0.66 ml of 96% H_2SO_4 over a 15-min period while maintaining the temperature below 20 °C. The solution was stirred for 3 h and allowed to reach room temperature followed by stirring for an additional 22 h. The ether layer was separated and the aqueous phase extracted with three 25-ml portions of ether. The combined ether extracts, including the initial ether phase, were washed twice with 50-ml portions of saturated sodium bicarbonate solution, water, and then dried over anhydrous sodium sulfate. A white solid was obtained on evaporation of the extracts to dryness under vacuum and recrystallization from hot *n*-hexane afforded 1.03 g (90% yield) of 4-oxo-4,5-dihydroaldrin (**4**). The material melting at 136–137 °C was chromatographically pure and had the expected spectral properties (i.r., (KBr), C=O, 5.72 μ; MS, $C_{12}H_8O^{35}Cl_{4.5}{}^{37}Cl_{1.5}$, *m/e* 381, 339).

Anal. Calcd. for $C_{12}H_8OCl_6$: C, 37.82; H, 2.10; O, 4.20; Cl, 55.89. Found: C, 37.93; H, 2.26; O, 5.05; Cl, 55.32.

The *endo*-alcohol (**5**) was prepared from (**4**) by the following procedure. Ketone **4** (130 mg, 0.34 mmol) was dissolved in 10 ml of 1 *M* disiamylborane in THF and stirred at room temperature for 20 h. The excess disiamylborane was destroyed by the cautious addition of 0.5 ml of water followed by stirring for 4 h. The reaction was then diluted further with 20 ml of water and extracted with two 15-ml portions of ethyl acetate. The combined dried extracts were taken to dryness and the residue was dissolved in 1 ml of 1,4-dioxane to which was added 0.1 ml of concentrated HCl. (The organoborane had resisted earlier attempts at hydrolysis *in situ* with acetic acid.) The resulting solution was heated at 85 °C for 0.5 h. The reaction solution was diluted to 5 ml with water and extracted with two 4-ml portions of ether. The combined ethers were washed with water, dried, and evaporated to dryness under vacuum. The residue was transferred to preparative t.l.c. plates and developed with a mixture of chloroform – ethyl acetate (9 to 1). Two major bands were detectable with u.v.-light. The band nearest the solvent front was identified as starting ketone **4**. The material in the band nearest the origin was repeatedly chromatographed until pure and crystallized from *n*-hexane. The pure solid (40 mg, 30%) had no precise melting point, but appeared to melt over a long range. This material had the expected mass spectral properties ($C_{12}H_{10}O^{35}Cl_{4.5}{}^{37}Cl_{1.5}$, *m/e* 383, 347, 329, 301) of the *endo*-alcohol (**5**) and was reconverted, in part, to ketone **4** using the dichromate oxidation procedure. The oxidation product had identical gas-chromatographic retention time and superimposable mass spectrum to an authentic sample of **4**.

Conductance Mechanism in the Solid Phase

PUSHTI PRAKASH RASTOGI
Department of Chemistry, Lucknow University, Lucknow, India

Received October 9, 1970

From the conductance measurements, the effect of solidification of solvent on the mobility of common ions (*e.g.*, Na^+, K^+, Cs^+, Cl^-, Br^-, I^-), in *N*-methylacetamide (NMA) solutions has been studied and the energy of activation for the conduction of electrolytes in both solid and liquid states calculated from Arrhenius plots. The conductance behavior in solid phase (or better in solid solutions) has been indicated to be through the "hole-formation mechanism".

On a étudié, à l'aide de mesures de conductivité, l'effet de la solidification du solvant sur la mobilité d'ions communs (par exemple, Na^+, K^+, Cs^+, Cl^-, Br^-, I^-) en solution dans la *N*-méthylacétamide; on a de plus calculé, à partir de diagrammes d'Arrhenius, l'énergie d'activation pour la conduction d'électrolytes soit à l'état liquide soit à l'état solide. On interprête les résultats de conductivité en phase solide (ou mieux en solutions solides) par le "mécanisme de la formation de trous".

Canadian Journal of Chemistry, 49, 2004 (1971)

Introduction

The variation of specific conductance and viscosity with temperatures near the freezing point of water has been the subject of recent critical studies (1–3). The studies aimed, mainly, at checking the mechanisms of conductance and viscous flow in the region where abnormal structural changes occur in water. Glasstone, Laidler, and Eyring (4) have suggested that "the mechanism of ionic conduction, in water, is through the formation of a 'hole' followed by the jump of a nearby 'solvent molecule' or 'solvated ion' into the 'hole'," a contention supported by Horne and co-workers (1, 2). This prompted us to study the effect of solidification of solvent on the mobility of common ions, and to investigate the mechanism of conductance in solid phase *N*-methylacetamide solutions as this solvent freezes at a very convenient temperature (≈29.8 °C) and is fairly stable.

Experimental

N-methylacetamide (NMA), obtained from Eastman Organic Chemicals Co., Rochester, N.Y., was twice fractionally recrystallized, treated with freshly ignited quicklime, and kept overnight. It was distilled under reduced pressure (b.p. 60–70 °C) and the middle fraction of the distillate collected. The process of purification was repeated until the specific conductance of the distillate was reduced to about 10^{-7} ohm^{-1} cm^{-1} (about 6×10^{-7} ohm^{-1} cm^{-1} at 35 °C and 1×10^{-9} ohm^{-1} cm^{-1} at 0 °C). This was stored in a colored bottle, kept inside a dry nitrogen box, and was always used immediately after distillation.

Et_4NI supplied by Eastman Organic Chemicals Co., Rochester, N.Y. was dissolved in a minimum amount of absolute alcohol, precipitated from the solution with ether, and dried in a vacuum desiccator. The KI and CsI were Merck's A.G. reagents and were used without further purification. Reagent grade NaI and KCl were recrystallized from conductivity water and dried in an air oven.

Cell resistance measurements were made at 1000-cycles with a Kohlrausch bridge assembly. Considerable attention was paid during the measurements of conductance at low temperatures, especially near the freezing point of solvent. Data were only taken when the cells containing solid had attained the thermostatic bath temperature (ascertained by the constant values of cell resistance, which were recorded after long intervals). A closed conductivity cell with arrangements for passing dry nitrogen, when desired, was used in the experiments. The cell constant (0.6858 cm^{-1}) was determined with 0.02 *N* KCl solution and checked after every experiment, and was found to be unchanged. The system was observed to be opaque in solid phase. The temperature variation in thermostatic bath was ±0.01° near room temperature and ±0.03° in ranges 0–10 and 40–50 °C.

Results

The specific conductance, Λ, of decinormal solution of KCl, KBr, NaI, KI, CsI, and Et_4NI in *N*-methylacetamide obtained at different temperatures (0–50 °C) are given in Table 1[1]. The Λ values are plotted against temperature. The plots are almost linear above the temperature of crystallization and the Λ can be related to t as $\Lambda = \Lambda_0 (1 + \alpha t)$. The values of Λ *vs.* t are in increasing order in the series Et_4NI, CsI, KI, and NaI in the solid phase, and quite the opposite to that in the liquid phase where the curves become regular, *i.e.* without any hysteresis over the temperature range 0–25 °C, as shown in Figs. 1*a* and 1*b*.

TABLE 1. The specific conductance data for 0.1 *N* solution of alkali halides and Et_4NI in NMA between 0 and 50 °C

Calculations

The energy of activation, E_a, for the conduction of electrolytes in both the liquid and solid phases of solvent has been calculated from the usual $\log \Lambda$ *vs.* $1/T$ plots based on Arrhenius equation, namely,

$$\Lambda = A\, e^{-E_a/RT}$$

or

$$\log \Lambda = \log A - \frac{E_a}{4.576}\frac{1}{T}$$

and been summarized in Table 2.

TABLE 2. The activation energy for the conduction of various electrolytes in liquid and solid states of NMA

	E_a in kcal/mol	
Electrolytes	Liquid state E_a^l	Solid state E_a^s
KCl	4.57	14.19
KBr	4.12	13.73
KI	3.66	13.16
NaI	4.45	12.82
KI	4.40	13.16
CsI	4.29	16.48
Et_4NI	4.18	9.15

Discussion

It has been suggested by Bonner *et al.* (5) that solute–solvent interaction accounts for solvation in such solvents. The solvation of cation arises from an electrostatic interaction between the positively charged cation and the negatively charged oxygen-atom of carbonyl group of associated *N*-methylacetamide molecule, whereas hydrogen bonding is responsible for the solvation of anions. Such specific solvation of cations *vs.* anions in NMA could be best demonstrated by plotting the limiting ionic equivalent conductances (λ_0^+ and λ_0^-) reported by Dawson *et al.* (6) against their crystal ionic radii determined by Robinson and Stokes (7) as shown in Fig. 2. A linear plot is obtained for anions whereas cations show no specific behavior. This supports the view that at least in NMA the anions and cations are definitely solvated in different ways. The linearity of the solvation of anions may be questioned and the relative order of anionic mobilities are difficult to explain.

(1) Liquid Phase (30–50 °C)

The higher the charge density, the greater the

[1]The reported values in Table 1 do not represent the specific conductances due to crystal radii, which, of course, are of a very low order. Moreover, the concentrated 0.5 *N* KI solution was found to be highly conducting in the solid state region, ruling out the separation of solute from the frozen solvent. These observations suggest the formation of a solid solution, which is further supported by the following evidence. (*a*) Precautions were taken to exclude atmospheric moisture from the system when measuring depressions of freezing points; yet a continuous depression was observed. There was also a range of temperature over which frozen solvent NMA melted, and this range was extended in the case of solutions. Thus a long melting range, instead of a sharp melting point, very strongly supports the formation of a solid solution (10). (*b*) A 100 ml 0.1 *N* KI solution was prepared and was frozen while stirring in a clean and dry beaker. About six samples were taken from the frozen solution. They were each melted, and a measured amount of 10 ml from each was put into a conical flask. The amount of iodide present in each flask was estimated gravimetrically as AgI, which was found almost to be the same in all the cases as well as very close to the calculated amount. The estimated amounts of AgI were found to be within the maximum deviation of 0.5%. This observation not only suggests the formation of a "solid solution", but very strongly supports the formation of a "homogeneous solid solution". The products of partial freezing were also analyzed and the results were found to support the same conclusion.

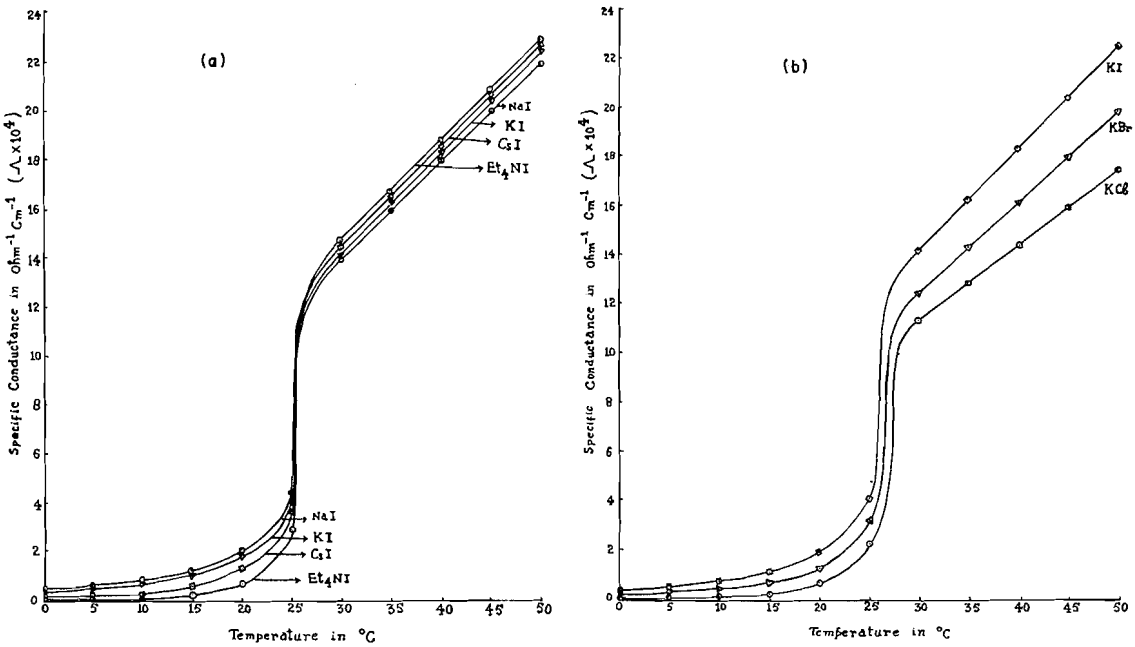

FIG. 1. Plot of specific conductance *vs.* temperature.

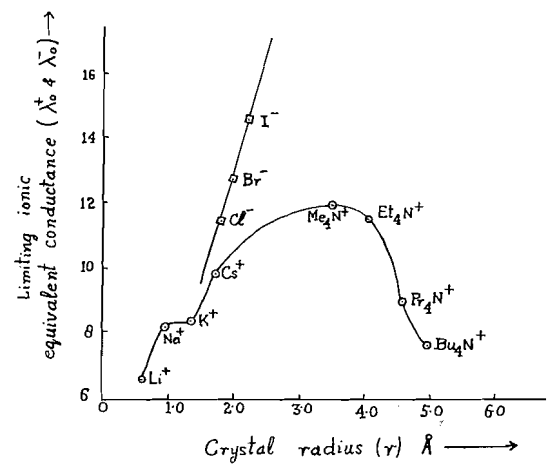

FIG. 2. Plot of limiting ionic equivalent conductance *vs.* crystal radius.

electrostatic interaction, which accounts for the higher solvation and consequently the smaller mobilities[2] of the ions. The absolute mobilities of the ions cannot be calculated from the present data, but the relative order of magnitudes is the same as reported by French and Glover (8) and Dawson *et al.* (9), *i.e.*, $\lambda_0^l(I^-) > \lambda_0^l(Br^-) > \lambda_0^l(Cl^-)$ and $\lambda_0^l(Et_4N^+) > \lambda_0^l(Cs^+) > \lambda_0^l(K^+) > \lambda_0^l(Na^+)$.

(2) Crystallization Phase (25–30 °C)

The sharp inflexion in Λ–t curves around the temperature of crystallization is due to an abnormal increase in the viscosity of solvent as it solidifies on freezing, which hampers the free movement of the ions and consequently accounts for the corresponding sharp decrease in conductance.

(3) Solid Phase (0–25 °C)

It may be noted from Figs. 1*a* and 1*b* that there is an inversion of order in the mobility of cations going into the solid phase but not for the anions; Na^+ conducts more than Et_4N^+ in the solid phase but not in the liquid phase. This leads to a conclusion of "desolvation" in mobility of cations going into solid phase or the speculation of a jumping mechanism in the solid phase that reflects the relative radii of the bare ions. On the contrary the anions seem to retain their relative mobility trend (Fig. 1*b*), an indication either of constant solvation or lack of it. However, anion solvation is supported by Fig. 2, showing the larger ion I^- moving faster. Thus the effect of

[2]Where μl, μf, and μs represent the conductance of liquid, crystallization, and solid phase or solid solutions and that their corresponding ionic mobility is indicated by λ_0^l, λ_0^f, and λ_0^s.

solidification of solvent on the solvated ions is that the bare cations are trapped out in the solvent lattices, whereas the anions are left still solvated in solid solutions. The data presented in Table 1 indicate that the relative order of ionic mobility in solid solutions decreases in the increasing order of solvated anionic and bare cationic sizes, *i.e.*, $\lambda_0^s(I^-) > \lambda_0^s(Br^-) > \lambda_0^s(Cl^-)$ and $\lambda_0^s(Na^+) > \lambda_0^s(K^+) > \lambda_0^s(Cs^+) > \lambda_0^s(Et_4N^+)$. It has therefore been tentatively suggested that the smaller the size of solvated anion or bare cation the more conducting it would be in solid solution. The same behavior was also represented with other alkali halides like LiCl, NaCl, and KCl.

It may be noted from Table 2 that the activation energy for the conduction of electrolytes is, in general, about three- to four-fold higher in solid state as compared to that in liquid state; which very strongly maintains an easier ionic conduction in the liquid phase than in the solid phase. It may be noted further that the E_a decreases, in general, with an increase of the size of anion w.r.t. common cation in liquid state, whereas E_a for the cations w.r.t. common anion also decreases in liquid state in contrast to its regular increase in solid state (except for Et_4N^+); suggesting thereby that the phenomenon of ionic conduction in solid phase is through the bare cationic lattices in the case of cations and through the solvated anionic lattices in the case of anions, solely depending upon their sizes, and appears to follow the jumping of ion into the "hole" as suggested earlier (4) in case of H_2O. However, a comparatively smaller value of E_a for bare Et_4N^+ ion in solid state, despite its larger size in comparison to bare Na^+, K^+, and Cs^+ ions may be on account of its organic origin or otherwise remains unexplained.

In conclusion, the reported results appear to indicate that the behavior of ionic conduction in solid phase of NMA solutions (or in solid solutions) occurs through the "hole-formation mechanism". This observation, although it needs a wider study, seems to have a very potential applicability in determining the relative size of the ions.

The financial assistance given by the Society of Sigma Xi of America for carrying out the research project is gratefully acknowledged.

Near Infrared Spectra of Water in Aqueous Solutions of Organic Salts. A Solvation Study of Bu_4NBr, ϕ_4AsCl, and $NaB\phi_4$

C. JOLICOEUR[1]

Department of Chemistry, State University of New York at Stony Brook, Stony Brook, Long Island, N.Y. 11790

AND

NGUYEN DINH THE AND A. CABANA

Département de chimie, Université de Sherbrooke, Sherbrooke, Québec

Received December 29, 1970

The near-infrared spectrum of water at various temperatures and in aqueous solutions of Bu_4NBr, $NaB\phi_4$, and ϕ_4AsCl is studied in the region 0.8–1.2 μ. The spectra are recorded differentially with respect to water by varying the cell lengths as to take into account density changes or the volume occupied by the solutes. A simple analysis of these spectra illustrates the qualitative similarity between the effects of the Bu_4N^+ ion and that of a temperature decrement on the spectrum of water. On the other hand striking differences are observed in the differential spectra obtained with Bu_4NBr and the phenyl substituted salts. Further differences are exhibited in the relative solute–solvent interactions of $B\phi_4^-$ and ϕ_4As^+.

Les spectres de l'eau à diverses températures et de quelques solutions aqueuses de Bu_4NBr, $NaB\phi_4$ et ϕ_4AsCl ont été examinés dans la région 0.8–1.2 μ. Le spectre différentiel (solution *vs.* eau pure) de l'eau est obtenu directement en compensant les variations de densité ou le volume occupé par l'électrolyte en solution par une variation de la longueur des cellules. Une analyse qualitative des spectres démontre que l'effet de l'ion Bu_4N^+ sur le spectre de l'eau est semblable à celui d'un abaissement de température. Par ailleurs une différence marquée apparaît entre les spectres différentiels obtenus pour Bu_4NBr et ceux pour les sels contenant des noyaux benzéniques. On observe également une différence dans les interactions soluté-solvant des ions $B\phi_4^-$ et ϕ_4As^+.

Canadian Journal of Chemistry, 49, 2008 (1971)

Introduction

One of the major contemporary advances of solution chemistry is the recognition of solvent structural changes in aqueous solutions of hydrocarbon-like solutes. Hydrophobic solutes, such as the larger tetraalkylammonium ions, are believed to promote in water a three dimensional structure (1). The nature of the structure induced by the hydrocarbon chains still remains to be elucidated: whether the hydrophobic groups simply enhance the short range structure already present in liquid water (2), or promote a new type of structure, is still unknown. We report here a simple differential analysis of the near-infrared spectra of aqueous solutions, which provides a sensitive method for comparing the effect of temperature to that of hydrophobic solutes on the solvent spectrum. Near-infrared spectroscopy has often been employed as a means of studying solvent modifications in aqueous solutions (3–13). Discussion of the methods can be found in several recent papers and review articles (14, 15). In essence, these investigations consist in following changes in either the absorption intensity of bands assigned to distinctly bonded water molecules (or —OH— oscillators) or in following the shifts of an absorption maximum when the temperature is changed or when solutes are added. In practice, the interpretation of such results in terms of the structural influence of an organic ion is often complicated by (*1*) absorption due to the ion itself (overtones and combination bands of the organic ions), (*2*) the volume occupied by the salt which in some cases will reduce the solvent concentration by more than 25%, (*3*) the effect of the co-ion on the water spectra and for combination modes involving ν_2, (*4*) the opposite shifts caused by hydrogen bonding on the bending (ν_2) and stretching (ν_1, ν_3) normal modes. Finally, investigations based upon measurements of integrated absorption intensity always suffer from the fact that the absorption coefficients of the

[1]NRCC Postdoctorate Fellow, 1969–1971.

For personal use only.

postulated species are unknown. (In the near-infrared, the integrated intensity usually decreases upon hydrogen-bonding (14, 16).)

In our work, suitable corrections will be applied in order to eliminate the first three difficulties listed above. Although we do not know how to account for the last two drawbacks mentioned above, these will be circumvented by the use of a phenomenological approach. Thus our results are not subjected to the usual criticisms. The method is applied to solutions of Bu_4NBr in order to compare specifically the effect of the Bu_4N^+ ion to that of a temperature decrement on the water spectrum. Similar studies of ϕ_4AsCl and $NaB\phi_4$ are also carried out to help solve the current question regarding the relative solution behavior of alkyl and aryl substituted salts in water (17, 18).

Experimental

The differential spectra of water at various temperatures and of the aqueous solutions were recorded in the 0.8–1.2 μ region. The choice of this particular band over other near-infrared components of the spectra seems desirable for the following reasons: (*1*) This combination mode assigned to $2\nu_1 + \nu_3$ (4) or $3\nu_3$ (19) probably does not involve the bending vibrational mode at all. (*2*) The absorption intensity of the mode is such that a cell of ~5 cm is required to produce one full scale of absorbance; therefore, good accuracy on the cell lengths is easily achievable. (*3*) In this region, the solute absorption is rather weak; thus it can be corrected without introducing large uncertainties (absorption due to $NaB\phi_4$ and ϕ_4AsCl is negligibly small). (*4*) Since D_2O absorbs only very faintly, it can be used to record the spectrum of the salt in conditions very similar to their aqueous environment.

The solutions were prepared volumetrically with water doubly distilled over alkaline permanganate or from 99.7% D_2O purchased from Merck, Sharp and Dohme of Canada Ltd. Alkali halides (Baker Reagent quality) were used without further purifications. Bu_4NBr, ϕ_4AsCl, and $NaB\phi_4$ were purchased from K & K Laboratories Inc. and purified with standard methods. To the extent possible, manipulations were carried out under dry nitrogen atmosphere.

The spectra were recorded on a Cary-14 spectrometer; the length of the reference cell containing H_2O or D_2O was fixed at 10.00 cm for most spectra, while the length of the sample cell was adjusted to provide an equivalent quantity of water molecules in both beams. The sample cell was made of two concentric tubes; a fine pitch thread which served as a micrometric adjustment was machined on the outside of the smaller tube and, over a short length, inside the larger tube. The remaining portion of the larger tube provided space for an O-ring seal (Viton).

Optical quartz was used as window material. The cell length was measured with an accuracy of 0.01 cm. Both cells were thermostated by water jackets to ±0.3 °C. With 10 cm of water in each compartment the baseline was reasonably straight up to 1.15 μ, the stability being better than 0.01 absorbance unit; at longer wavelengths, so little energy is transmitted that the results become unreliable.

Results and Discussion

The absorption of liquid water at 25 °C in the region 0.8–1.1 μ is shown in Fig. 1*a* for a cell thickness of 0.5 cm. The differential spectrum obtained with 10 cm cells when the reference cell is kept at room temperature (28.0 ± 0.3 °C), while the temperature of the sample cell is varied from 2 to 50 °C, is shown in Fig. 1*b*. The absorbance at 0.96 μ increases with temperature while that observed at 1.02 μ decreases. The occurrence of isobestic points, respectively, near 1.0 and 1.1 μ agrees well with similar observations by Luck (14)

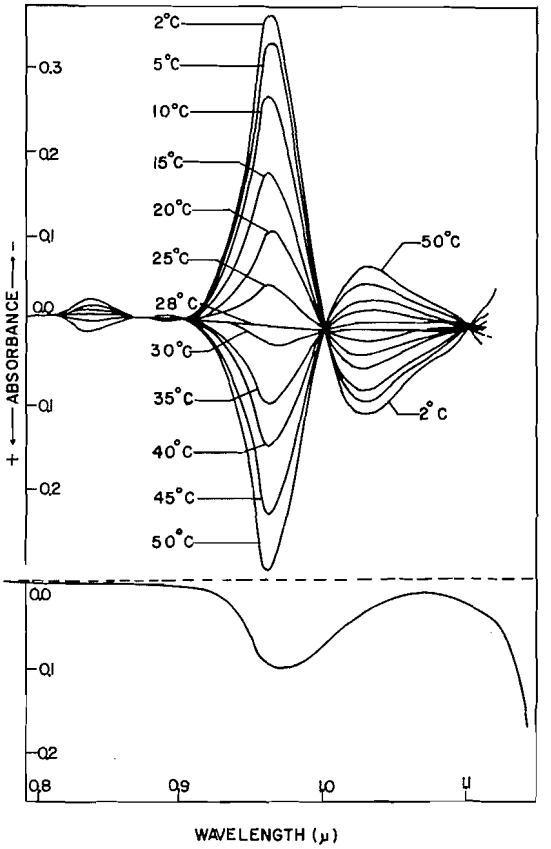

FIG. 1. (*a*) Spectrum of liquid water at 25 °C; cell thickness: 0.5 cm. (*b*) Differential spectra of water at various temperatures; the reference cell is kept at 28 °C and its length is 10.00 cm. The length of the sample cell is varied to correct for density changes.

for non-differential spectra. It has been shown through detailed analysis (20) that the existence of such points strongly supports the idea of an equilibrium mixture of at least two widely different types of OH oscillators *e.g.* those strongly coupled (hydrogen-bonded) absorbing at the longer wavelengths (1.02 μ) and those un- or weakly coupled responsible for the higher frequency component (0.96 μ). The relative intensities of these two components is consistent with the usual behavior of combination modes. How the two sets of species involved in this equilibrium interact with their neighbors is hard to specify (21); nonetheless, the thermal differential spectra can be used as a basis for comparing the effects of solutes on the water–water interactions.

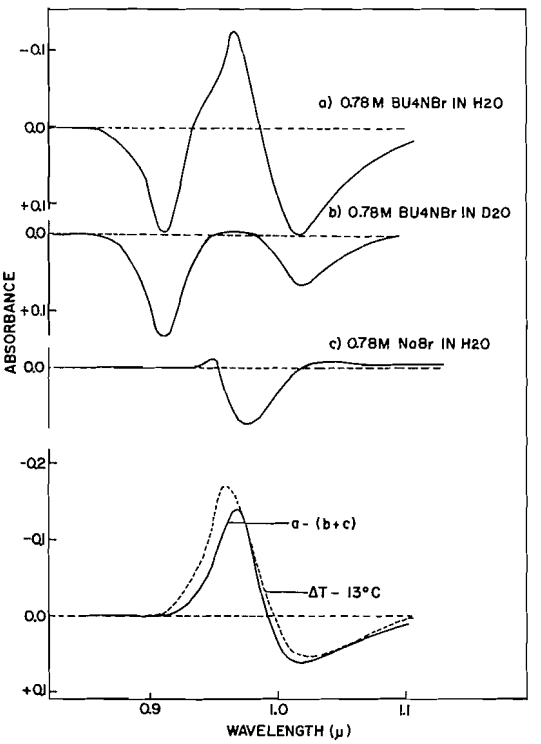

FIG. 2. Differential spectra at 25 °C of solutions against pure H_2O or D_2O; reference cell length: 10.00 cm. (*a*) 0.78 *M* Bu_4NBr in H_2O; cell length: 13.00 cm. (*b*) 0.78 *M* Bu_4NBr in D_2O; cell length: 13.00 c.m. (*c*) 0.78 *M* NaBr in H_2O; cell length: 10.18 cm. Bottom curves: the full line shows spectrum *a* after subtraction of spectra *b* and *c*; the dotted line is the differential spectrum recorded for water at 15 °C against water at 28 °C. In these and following differential spectra, the uncertainty at maximum absorption ranges between ±0.01 to ±0.02 absorbance units, depending on the number of operations performed on the original recordings. Note that the absorbance scale of the trace labelled $a - (b + c)$ applies to all traces of this figure.

The differential spectra of a 0.78 *M* solution of Bu_4NBr is reproduced in Fig. 2*a*; Fig. 2*b* illustrates the salt absorbance recorded in D_2O and the effect of NaBr on the water spectra is shown in Fig. 2*c*. For these and all following solutions, the cell length required to provide the equivalent of 10.00 cm of water in the reference cell was calculated[2] from known apparent molal volumes.[3] The differential spectra observed for NaBr is believed to be mostly due to the presence of the bromide ion. It has been known for some time that the anions have a much greater influence than cations on the spectrum of water (4) simply because anions can interact with the hydrogens of the water molecules. In fact we have observed that the differential spectra of NaBr, KBr, and CsBr are all very similar below 1.0 *M*, the difference being small compared to the effects sought here. With the assumption that the ionic influences on the spectra are additive, the effect of Bu_4N^+ on the water spectrum can be obtained by subtracting spectra *2b* and *2c* from spectrum *2a*. The resultant curve is plotted in the lower part of Fig. 2 (full line). The dotted lines show one of the temperature effects from Fig. 1*b* with $\Delta T = -13$ °C. The striking resemblance of these two curves indicates that the effect of the hydrophobic ion on the hydrogen-bonding equilibrium of water is similar to a decrease in temperature. The discrepancies are of the order of the overall uncertainty and no new absorption is found to confirm the existence of widely different hydrogen bonds in the solution.

The spectra obtained at several concentrations of Bu_4NBr are reported in Fig. 3; comparing these with the thermal differential spectra (Fig. 1), one can evaluate a molar "structural" ΔT (ΔT_{str}) for the Bu_4N^+ ion. The structural temperature idea has been introduced in an early paper by Bernal and Fowler (24). Over the concentration range studied, $\Delta T_{str} = -13 \pm 2$ °C;

[2]From the density, concentration, and solute molecular weight we can calculate the number of moles of solvent per unit volume. The volume of the sample cell can then be varied (at constant cross-section) to contain the same number of moles of water as the reference cell. Since the relevant cross-section is that of the light beam, only the cell lengths need to be considered.

[3]For alkyl halides, see ref. 22*a*; Bu_4NBr, ref. 22*b*; $NaB\phi_4$ and ϕ_4AsCl, ref. 23.

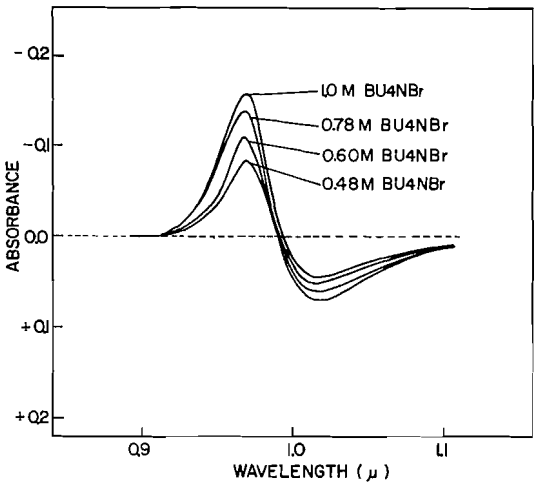

FIG. 3. Differential spectra at 25 °C of Bu_4NBr solutions at various concentrations against H_2O, corrected for solute absorption and for the effect of Br^-.

within the accuracy of the present results, no concentration dependence could be ascertained. This ΔT_{str} is of the same order of magnitude as that estimated by Bunzl (8) from shifts of the 0.97 μ band. Because of unaccounted solute absorption in the latter work (see Fig. 2*b*) and the effect of the bromide ion (Fig. 2*c*), good agreement would be fortuitous. The present results apparently disagree with those of Worley and Klotz (7) who report a ΔT_{str} of ~ -1.0 °C for an experimental temperature of 5 °C. However, from their spectra and the data given on absorption ratios at 25 °C, it can be seen that ΔT_{str} should be much more negative near room temperature.

It is interesting to compare the observed ΔT_{str} with the effect of this salt on the viscosity. The magnitude of the *B*-coefficient of the viscosity equation depends on the size of the solute and its local effects on the solvent (24, 25). Knowing the radii of the ions, the size effect can be estimated and Kay *et al.* (25) found that in MeOH the calculated *B*-coefficient agrees quite well with the experimental one (respectively 0.81 and 0.85). In water, *B* is equal to 1.24 (25); if one pictures the ΔB, $B_{CH_3OH} - B_{H_2O} = 0.39$, as a measure of the change in the local viscosity of water around the solute, this increase in viscosity is equivalent to a temperature increment of -14 °C. The agreement with the present estimate is certainly better than what can be expected.

A more formal comparison of the effect of a decrease in temperature and the structural changes promoted by the Bu_4N^+ ions can be devised through the following scheme. Let us assume that the absorption maximum (λ_I) and minimum (λ_{II}) observed on the differential spectra in Fig. 2*c* characterize the two species involved in the hydrogen-bonding equilibrium of water: II $\rightleftarrows$ I; so defined, form II would be the more structured component. The changes in absorbance (A) at λ_I and λ_{II} with temperature or solute concentration are related to the changes in concentration of the two species. The variation of the mole fraction of species I (x_I) with temperature is given by

$$[1] \quad \frac{dx_I}{dT} = \left[\frac{A_{\lambda I}}{dA_{\lambda I}/dT} - \frac{A_{\lambda II}}{dA_{\lambda II}/dT}\right]^{-1}$$

where A_{λ_I} and $A_{\lambda_{II}}$ are measured on a non-differential spectrum. Neglecting the small differences between the two curves in Fig. 2*c*, a similar expression can be written for dx_I/dc where c is the molar concentration of the solute added.

To picture the significance of dx_I/dc in terms of the solvent co-sphere of the Bu_4N^+ ion, we can write that the number of moles of species I, n_I, in a solution containing a given weight of solvent is

$$[2] \quad n_I = n_I^0 + n_i \int_{r_i}^{r_s} [c_I(r) - c_I^0]\, d^3r$$

Here, n_I^0 is the number of moles of species I before the addition of solute and n_i is the number of solute particles of species i. r_i is the radius of particle i while r_s is the radius of the co-sphere of solvent available to it. c_I^0 and $c_I(r)$ are, respectively, the equilibrium concentration of species I in pure water at 25 °C and the local concentration of I in the solution as a function of distance from the surface of the solute particle. This leads to an expression for dx_I/dc

$$[3] \quad \frac{dx_I}{dc} = \frac{N}{10^{27}} \int_{r_i}^{r_s} [x_I(r) - x_I^0]\, d^3r$$

where N is Avogadro's number and the factor of 10^{27} allows r to be in Å. Since we do not know how x_I varies with r, we can try setting $x_I(r)$ constant at $x_I(r) = x_I(0\ °C)$ in a co-sphere between r_i and r_c. Evaluating dx_I/dT, dx_I/dc, and $x_I(0\ °C) - x_I°$, we find that for $r_i = 4.5$ Å, $r_c = 7.0$ Å. Thus, according to such calculations, if the water in the co-sphere of Bu_4N^+ ion is like water at 0 °C, the co-sphere extends out to approximately 7 Å. It follows that in a solution of Bu_4NBr the

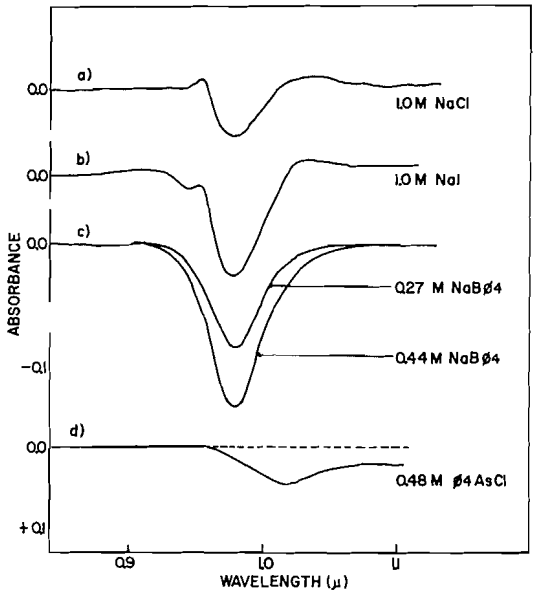

FIG. 4. Differential spectra at 25 °C of various solutions against pure water: (*a*) 1.0 *M* NaCl, (*b*) 1.0 *M* NaI, (*c*) 0.27 and 0.44 *M* $NaB\phi_4$, (*d*) 0.48 *M* ϕ_4AsCl. *c* and *d* were corrected for solute absorption which is very weak around 1.0 μ. The spectrum given for ϕ_4AsCl was also corrected for the effect of Cl^- by subtracting spectrum *a*.

co-spheres of the hydrophobic ions would be forced to overlap at concentrations greater than 0.6 *M*. Though this result is the end product of many assumptions, it may provide some measure of the extent of solvent structural rearrangement around hydrophobic solutes.

The differential spectra of $NaB\phi_4$ (0.27, 0.44 *M*) and ϕ_4AsCl (0.48 *M*) are reported in Fig. 4 along with those of NaCl and NaI (1.0 *M*). In spite of some similarities between the properties of aqueous solutions of $NaB\phi_4$ and Bu_4NBr, *e.g.* partial molal heat capacities (27), the two salts exhibit very different effects on the water spectrum. The main feature of the differential spectrum obtained with $NaB\phi_4$ suggests that the interactions of the water molecules with $B\phi_4^-$ are similar to those occurring with Cl^-, Br^-, and I^-. For the latter ions, the composite nature of the differential band might suggest that part of it is due to structure-breaking, *i.e.* analogous to an increase in temperature on the pure water spectrum. The greater changes of the water spectrum induced by NaI compared to NaCl or NaBr has often been interpreted as resulting from the greater structure-breaking ability of the I^- ion (3, 5, 7). Apart from a slight asymmetry of the differential band, there is no indication that $B\phi_4^-$ stabilizes hydrogen bonds in water as does Bu_4NBr. If such an effect is present, it is totally obscured by the stronger absorption which occurs at 0.98 μ (slightly lower than the "unbonded" —OH groups discussed previously). The structure-breaking character of $B\phi_4^-$ suggested by the spectral results does not agree with conclusions drawn from heat capacity measurements. The large partial molal heat capacity of $NaB\phi_4$ had been explained on the basis of the structure promoting effect on the $B\phi_4^-$ ion due to its hydrophobic properties (27).

The influence of ϕ_4As^+ on the water spectrum was obtained by subtracting the differential spectrum of NaCl from that of ϕ_4AsCl (Fig. 2*d*); this influence is much smaller than that observed for Bu_4N^+ or $B\phi_4^-$. Only a weak and broad absorption band is seen at 1.02 μ and again, there is no direct correlation between the effect of the organic ion with that of a temperature increment. Similar results are found for ϕ_4P^+. Compared to Bu_4N^+, ϕ_4As^+ does not appear to be hydrophobic and its interactions with water are different from those of $B\phi_4^-$. The hydrogen-bonding between water and the phenyl rings of ϕ_4As^+, suggested by other workers from osmotic coefficient measurements (18), is not apparent in the present observations.

It cannot be excluded, however, that in the case of ϕ_4As^+ (or ϕ_4P^+) the differential spectra results from two or more contributions, the effect of which could partly cancel out (*e.g.* a curve similar to those in Fig. 3 added to curve *4e* could yield a spectrum resembling Fig. 4*d*).

The spectral results, on the other hand, confirm the conclusions derived from heats of transfer studies (17, 28). The different behavior of alkyl and aryl substituted ions was emphasized from opposite signs in their heat of transfer from H_2O to D_2O (17). Similar inferences were also possible from heats of solution in water, propylene carbonate, and dimethyl sulfoxide (28). The different interaction of water with $B\phi_4^-$ and ϕ_4As^+ illustrated by the spectra may cast doubt on the assumption of equal heats of hydration for these two ions (28), which is crucial in the assignment of ionic contributions. Recent heat of solution measurements[4] also tend to discredit the equal-heat assumption.
