Commercial trimethyl (chloro)- and trimethyl(bromo)-stannane (Alfa Inorganics) were used as supplied and their purity checked by their n.m.r. spectra (9). Arsine was prepared by the action of water on sodium arsenide; methylarsine from reduction of sodium methyl arsenate with zinc and hydrochloric acid; and phenylarsine by the lithium tetrahydroaluminate reduction of phenyl-(dichloro)arsine. Arsino-potassium was prepared from arsine and potassium in liquid ammonia and lithium tetra-arsinoaluminate from arsine and lithium tetrahydroaluminate (10). Silylarsine and the methyl(silyl)-arsines were prepared from bromosilane and the appropriate arsinoaluminates (1) and the phenyl(silyl)-arsines from bromosilane and the corresponding lithium phenylarsenides. Diethyl(trimethylstannyl)amine was prepared from lithium diethylamide and trimethyl(chloro)-stannane (11).

Reduction of Trimethylbromostannane with Lithium Tetra-arsinoaluminate

Typically, trimethylbromostannane (2.49 g; *ca.* 10 mmol) was condensed onto a monoglyme solution of lithium tetra-arsinoaluminate (12.5 mmol) and the mixture held at −45° for *ca.* 10 min. Separation of the products by trap-to-trap distillation gave trimethylstannylarsine (0.217 g; 0.9 mmol), in a trap at 0° while the solvent, arsine, and a mixture of methylstannanes passed through into a −196° trap.

Reaction of Trimethylbromostannane with Arsino-potassium

Typically, trimethylbromostannane (2.18 g; *ca.*9 mmol) and arsino-potassium (10.1 mmol) each in diethylether, were mixed together slowly and held at −78° for 3 h. After this time, arsine (identified by its i.r. spectrum) and solvent were distilled off as the vessel was warmed to room temperature. Tris-trimethylstannylarsine (1.53 g; *ca.* 2.7 mmol) was then distilled, by gentle warming, from the reaction vessel. In all cases where the least volatile fraction was the desired product, the latter was distilled from the reaction vessel to the storage trap, usually a tube suitable for n.m.r. analysis, by surrounding the trap with liquid nitrogen and then providing the minimum of heat from a mantle.

In a similar manner, trimethylbromostannane (2.5 g; *ca.* 10.5 mmol) was mixed with excess arsino-potassium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(39 mmol). Arsine was pumped away at −78° and the residue treated with excess hydrogen sulfide for 1 h. After removal of solvent, distillation using a Leroy Column (12) gave three distinct fractions, trimethylstannylarsine (0.55 g; 2.3 mmol), bis-trimethylstannylarsine (0.36 g; 0.9 mmol), and tris-trimethylstannylarsine (0.45 g; 0.8 mmol). A similar residue, when treated with methyl iodide gave dimethyl(trimethylstannyl)-arsine, methyl(bis-trimethylstannyl)arsine, and tris-trimethylstannylarsine.

Further Anion Reactions

(a) Tris-trimethylstannylarsine (1.36 g; 2.4 mmol) and monoglyme were trapped onto potassium (5.0 mmol) and the system allowed to warm to room temperature. The monoglyme solution changed color from blue to various shades of brown. Excess hydrogen sulfide was immediately added and after 10 min the volatile materials, which included arsine, tetramethylstannane, and trimethylstannane (identified by n.m.r. spectra), were pumped away. Bis-trimethylstannylarsine (0.32 g; 0.8 mmol) was then distilled, by gentle warming, from the reaction vessel.

(b) In a similar manner, phenyl(bis-trimethylstannyl)-arsine (1.44 g; 3.0 mmol) and potassium (5.9 mmol) in monoglyme gave, after treatment with H_2S and pumping off volatile products, phenyl(trimethylstannyl)arsine (0.32 g; 1.0 mmol).

(c) In a similar manner, methyl(bis-trimethylstannyl)-arsine (0.79 g; 2 mmol) and potassium (4 mmol) in monoglyme gave only a small amount of methyl(bis-trimethylstannyl)arsine in the less volatile fraction.

Reaction of Trimethylchlorostannane with Dimethyl(silyl)arsine

Typically, dimethyl(silyl)arsine (1.37 g; *ca.* 10.1 mmol) and a small quantity of diethylether were distilled onto trimethylchlorostannane (2.0 g; *ca.* 10 mmol) and allowed to warm from −196° to room temperature. Chlorosilane (identified by its i.r. spectrum) and the ether were pumped away leaving dimethyl(trimethylstannyl)arsine (2.72 g; *ca.* 10.1 mmol) which was poured into a ^1H n.m.r. tube attached as a side-arm to the reaction vessel.

Reaction of Trimethylchlorostannane with Methyl(disilyl)arsine, Diphenyl(silyl)arsine, and Phenyl(disilyl)arsine

As described above, the reaction of trimethylchlorostannane (4.04 g; *ca.* 20 mmol) with methyl(disilyl) arsine (1.49 g; *ca.* 10.5 mmol) gave methyl(bis-trimethylstannyl)arsine (4.12 g; *ca.* 9.9 mmol); trimethylchlorostannane (1.45 g; *ca.* 7.3 mmol) with diphenyl(silyl)-arsine (1.84 g; 7.1 mmol) gave diphenyl(trimethylstannyl)arsine (2.81 g; 7.1 mmol); and trimethylchlorostannane (2.97 g; 14.9 mmol) with phenyl(disilyl) arsine (1.58 g; 7.4 mmol) gave phenyl(bis-trimethylstannyl)arsine (3.65 g; 7.5 mmol).

Reaction of Trimethylchlorostannane with Silylarsine

(a) Silylarsine (*ca.* 1 mmol) and diethylether were distilled onto trimethylchlorostannane (0.2 g; *ca.* 1 mmol) and allowed to warm to —78° when arsine was evolved. On warming to room temperature, trisilylarsine (identified by its i.r. spectrum (13)) distilled off leaving mainly unreacted trimethylchlorostannane.

(b) An equimolar amount of silylarsine was distilled onto trimethylchlorostannane in an n.m.r. tube which was then sealed. The ^1H n.m.r. spectrum only showed peaks attributable to arsine (14), trisilylarsine (15), and trimethylchlorostannane (9).

An equimolar amount of silylarsine was distilled onto trimethylbromostannane in an n.m.r. tube which was then sealed. The ^1H n.m.r. spectrum, taken immediately the tube had warmed to room temperature, only showed peaks attributable to the starting materials. After 1 h the only peaks were those attributable to trisilylarsine and arsine (in a ratio of *ca.* 3:2) and unchanged trimethylbromostannane.

Reaction of Trimethyl(bromo)stannane with Trimethylstannylarsine

Equimolar amounts of trimethyl(bromo)stannane and trimethylstannylarsine were held at room temperature in a 10 ml reaction vessel. Arsine (identified by its i.r. spectrum) was evolved and after *ca.* 6 h the remaining mixture consisted only of tris-trimethylstannylarsine and trimethyl(bromo)stannane; the latter was pumped away leaving the former.

Reaction of Diethyl(trimethylstannyl)amine with Phenylarsine

Typically, phenylarsine (0.4 g; 2.5 mmol) in diethylether was slowly added to a stirred solution of diethyl (trimethylstannyl)amine (1.17 g; 5 mmol) at room temperature. Diethylamine (identified by its i.r. spectrum) was pumped off at room temperature along with the solvent. Phenyl(bis-trimethylstannyl)arsine (0.9 g; 1.9 mmol) was then distilled, by gentle warming, from the reaction vessel.

Reaction of Diethyl(trimethylstannyl)amine with Methylarsine

Typically, gaseous methylarsine (2.5 mmol) was slowly admitted over a stirred diethylether solution of diethyl(trimethylstannyl)amine (1.18 g; 5 mmol) at room temperature. Diethylamine and solvent were pumped away after 40 min at room temperature. Methyl(bis-trimethylstannyl)arsine (0.6 g; 1.4 mmol) was then distilled, by gentle warming, from the reaction vessel.

Characterizations

Tris-trimethylstannylarsine, methyl(bis-trimethylstannyl)arsine, dimethyl(trimethylstannyl)arsine, diphenyl-(trimethylstannyl)arsine, and phenyl(bis-trimethylstannyl)arsine were characterized by their molecular weights and i.r. and ^1H n.m.r. spectra (8), and their cleavage reactions with HBr.

Trimethylstannylarsine

Me_3SnAsH_2 (Mol. Wt. Calcd.: 240.6. Found: 238). Its ^1H n.m.r. parameters are displayed, along with related species, in Table 1. Its i.r. spectrum showed the following main features: 2975s and 2908m (CH_3 stretches); 2076s (AsH_2 stretch); 1415w, 1185m (CH_3 deformations); 950m (AsH_2 deformation); 766m, 715 (CH_3 rocks); 570 v.w.; 519s, 499m (Sn—C_3 stretches).

Bis-trimethylstannylarsine

$(Me_3Sn)_2$ AsH (Mol. Wt. Calcd.: 403.3. Found: 421). Its ^1H n.m.r. parameters are displayed in Table 1. Its i.r. spectrum showed the following main features: 2979s, 2902m (CH_3 stretches); 2089s (AsH stretch); 1420m,

1186m (CH_3 deformations); 938w (AsH bend); 760m, 710w (CH_3 rocks); 522s, 502m (Sn—C_3 stretches).

Phenyl(trimethylstannyl)arsine

$(Me_3Sn)AsHPh$ (Mol. Wt. Calcd.: 317.6. Found: 335). Its ^1H n.m.r. parameters are displayed in Table 1. Its i.r. spectrum showed the following main features attributable to the phenyl-group itself: 3061s, 3098m, 1583s, 1484s, 1335w, 1320w, 1300w, 1155w, 1072m, 1023s, 998m, 842w, 736s, 693s, 665w, 616w, in addition to the following: 2979s, 2909s (CH_3 stretches); 2084s (AsH stretch); 1433s, 1184s (CH_3 deformations); 959m (AsH bend); 765s (CH_3 rock); 520s, 501s (Sn—C_3 stretches); 452s.

Reaction with Hydrogen Bromide

Trimethylstannylarsine (1.0 mmol) and hydrogen bromide (1.0 mmol) were held together at room temperature for 1/2 h giving trimethyl(bromo)stannane (0.9 mmol) and arsine (0.9 mmol). Similarly bis-trimethylstannylarsine (0.5 mmol) and hydrogen bromide (1.0 mmol) gave trimethyl(bromo)stannane (1.0 mmol) and arsine (0.5 mmol) and phenyl(trimethylstannyl)arsine 1.1 mmol) and hydrogen bromide (1.1 mmol) gave trimethyl(bromo)stannane (1.0 mmol) and phenylarsine (1.1 mmol), all identified by n.m.r. spectra.

Other Reactions

Trimethylstannylarsine (1.1 mmol) and hydrogen sulfide (0.7 mmol) were held together at room temperature for 1 h. The products volatile at −78° were removed and sealed up in a 2 mm n.m.r. tube. Integration of the spectrum showed that there was a 5:1 mixture of hydrogen sulfide and arsine. The tube was broken open and the contents returned to the reaction vessel and left at room temperature overnight. The products were then separated to give bis(trimethylstannyl)sulphide (0.5 mmol; identified by its n.m.r. spectrum) and arsine (1.2 mmol; containing a little hydrogen sulfide).

Trimethylstannylarsine (1.6 mmol) and water (0.9 mmol) were maintained at room temperature for 13 h. Arsine (0.9 mmol) was evolved and the water (0.9 mmol) was recovered.

Discussion

Trimethylstannylarsine, Me_3SnAsH_2, is prepared, albeit in low yield, by the reaction between lithium tetra-arsinoaluminate and less trimethylbromostannane than required by the stoichiometry of reaction, eq. 1. Increasing the proportion of bromide to that used in similar reactions involving silanes and germanes (1) gave even lower yields.

$$[1]\quad 4Me_3SnBr + LiAl(AsH_2)_4 = 4Me_3SnAsH_2 + LiBr + AlBr_3$$

Trimethylstannylarsine and bis-trimethylstannylarsine, $(Me_3Sn)_2AsH$, can both be prepared from the reaction of trimethylbromostannane and arsino-potassium under controlled conditions. With equimolar amounts of reactants, tris-trimethylstannylarsine, $(Me_3Sn)_3As$, is formed in good yield, as might be expected because a tertiary product is common in such anion reactions (2). However, with a large excess of arsino-potassium, subsequent acidification with hydrogen sulfide leads to the liberation of mono- and bis-trimethylstannylarsine, eq. 2. The mechanism of formation of related complex ions has been discussed for phosphine systems (2, 4). The rapid condensation of primary and secondary silyl- and germyl-arsines is a familiar feature of their chemistry (16), so condensation to produce

$$[2]\quad [AsH_2]^- \xrightarrow{Me_3SnBr} \begin{cases} [Me_3SnAsH]^- \xrightarrow[(H^+)]{H_2S} Me_3SnAsH_2 \\ [(Me_3Sn)_2As]^- \xrightarrow[(H^+)]{H_2S} (Me_3Sn)_2AsH \end{cases}$$

tris-trimethylstannylarsine is not unexpected. In addition, we find, both under sealed-tube and vacuum-line conditions, that trimethylstannylhalides catalyze such condensation processes, eq. 3.

$$[3]\quad \left.\begin{matrix}3SiH_3AsH_2\\ 3Me_3SnAsH_2\end{matrix}\right\} \xrightarrow[X = Cl, Br]{Me_3SnX} \left\{\begin{matrix}(SiH_3)_3As + 2AsH_3\\ (Me_3Sn)_3As + 2AsH_3\end{matrix}\right.$$

Bis-trimethylstannylarsine and phenyl(trimethylstannyl)arsine can also be prepared when the corresponding trimethylstannylarsine anions, formed by reaction of dry potassium in diglyme, eq. 4, are immediately acidified with hydrogen

$$[4]\quad (Me_3Sn)_2AsR \xrightarrow{2K} [Me_3SnAsR]^- + Me_3Sn^- + 2K^+$$
$$(R = Me_3Sn, Ph, Me)$$

sulfide. Trimethylstannane and tetramethylstannane are also liberated. Evidently, these systems involve complex processes and acidification must be rapid if As—H containing arsines are to be extracted. Hydrogen sulfide has been used successfully in similar systems (3) and in the time of the reaction, it does not attack Sn—As bonds. However, over a longer period, trimethylstannylarsine reacts with H_2S to give some trimethylstannylsulfide and arsine.

The solutions, eq. 4, presumed to contain the methyl(trimethylstannyl)arsine anion, $[Me_3SnAsMe]^-$, did not give $Me_3SnAsMeH$ on acidification. The latter presumably disproportionates to give only the starting material, $(Me_3Sn)_2AsMe$ in the less volatile fraction. Similarly, when the solutions containing trimethylstannylarsine anions, eq. 2, are treated with methyliodide, only methyl(bis-trimethylstannyl)arsine, eq. 5, is found although methyl(trimethylstannyl)arsine might also have been

$$[5]\quad [(Me_3Sn)_2As]^- + MeI \longrightarrow (Me_3Sn)_2AsMe + I^-$$

expected from the corresponding reaction with $[Me_3SnAsH]^-$. The formation of small amounts of dimethyl(trimethylstannyl)arsine in this experiment could result from interaction with excess $[AsH_2]^-$, eq. 6, followed by reaction with methyliodide.

$$[6]\quad \text{"}Me_3SnAsHMe\text{"} + [AsH_2]^- \longrightarrow AsH_3 + [Me_3SnAsMe]^-$$

The use of a lithium alkyl or lithium tetrahydroaluminate (17–19) to cleave an Sn—As bond followed by acidification did not lead to better yields of As—H containing tin arsines than the potassium method.

Tin arsines have previously been prepared by methods outlined in eqs. 7 and 8 (6, 7). Even with a large excess of arsine used as the solvent

$$[7]\quad 3Me_3SnCl + AsH_3 + 3Et_3N \longrightarrow 3Et_3NHCl + (Me_3Sn)_3As$$

$$[8]\quad Me_3SnNMe_2 + R_2AsH \longrightarrow Me_3SnAsR_2 + Me_2NH\ (R = Ph, Me)$$

we were unable to prepare any As—H containing tin arsines by either of these methods. Diethyl(trimethylstannyl)amine reacts smoothly with phenyl- and methyl-arsine, eq. 9, to give the tertiary arsines.

$$[9]\quad 2Me_3SnNEt_2 + RAsH_2 \longrightarrow (Me_3Sn)_2AsR + 2Et_2NH$$
$$(R = Ph, Me)$$

The exchange reactions between silylarsines and methyl(halogeno)germanes have resulted in the formation of mono- and bis-arsino-methylgermanes (1). However, extension to the methyl(halogeno)stannanes is not promising since trimethyl(halogeno)stannanes so effectively catalyze the condensation of silylarsine or trimethylstannylarsine (3). In this the tin halides parallel bromosilane which also assists condensation (20) rather than bromogermanes which exchange.

However, trimethyl(chloro)stannane does react in a similar manner to trimethyl(halogeno)- and halogeno-germanes with dimethyl(silyl)-, diphenyl(silyl)-, methyl(disilyl)-, and phenyl(disilyl)-arsines forming dimethyl(trimethylstannyl)-, diphenyl(trimethylstannyl)-, methyl(bis-trimethylstannyl)- and phenyl(bis-trimethylstannyl)-arsines respectively, eqs. 10 and 11, in excellent yields.

$$[10]\quad SiH_3AsR_2 + Me_3SnCl \longrightarrow Me_3SnAsR_2 + SiH_3Cl$$

$$[11]\quad (SiH_3)_2AsR + 2Me_3SnCl \longrightarrow (Me_3Sn)_2AsR + 2SiH_3Cl$$
$$(R = Me, Ph)$$

The new compounds were characterized by their molecular weights, i.r. and ^1H n.m.r. spectra, and by their reactions with hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

bromide. Anhydrous hydrogen halides quantitatively cleave tin arsines giving well-known easily-identifiable products and thus present a useful method of on-line analysis which has been utilized for other group IV arsines (1, 3). The new arsines are thermally unstable and decompose into the parent arsine and the fully substituted tin arsine. As such, satisfactory mass spectral data are difficult to obtain although the parent peak (*m/e* 236–246) for trimethylstannyl arsine was clear.

The i.r. spectra of the new compounds are listed in the Experimental section together with assignments made by comparison with the spectra of phenylarsine (21), related silyl- (22, 23), germyl- (1, 24), and trimethylstannylarsines (7), and other trimethylstannyl (25) compounds.

The n.m.r. spectra are displayed in Table 1. The Sn*CH* chemical shifts and coupling constants confirm the characterization of the new compounds as tin arsines. In particular the Sn—C—H coupling constants remain in a very narrow range regardless of the differing substitution on arsenic. The coupling constants for other trimethylstannyl compounds fall into quite distinct and characteristic ranges depending on the group of the periodic table to which the element bound to tin belongs, rather than being electronegativity dependent. Although As—H resonances are usually broad due to quadrupole relaxation, we believe our failure to detect those in bis-trimethylstannylarsine and phenyl(trimethylstannyl)arsine was due to exchange processes taking place. We have observed similar phenomena in related trimethylgermyl species but are as yet unable to determine the cause. In view of this and the failure to detect the Sn—C—H satellites in bis-trimethylstannylarsine, the value for the chemical shift for this compound must be regarded as provisional.

Several reactions of trimethylstannylarsine were investigated. The Sn—As bond is cleaved rapidly by hydrogen bromide, slowly by hydrogen sulfide, and water only catalyzes its condensation. This order of reactivity is consistent with their acidity and in this respect the tin arsine parallels primary germyl arsines (1, 26), rather than silyl arsines, which are rapidly cleaved by water. The primary tin arsine parallels both the analogous silicon and germanium arsines in that there is no interaction or insertion with carbon dioxide or carbon disulfide (1). This is not unexpected as even dimethyl(trimethylstannyl)arsine only forms a weak adduct with carbon disulfide (27).

Organobismuth Compounds.[1] III. Preparation and Infrared Spectra of Triphenylbismuth(V) Derivatives of Dibasic Acids

R. G. GOEL AND H. S. PRASAD

Department of Chemistry, University of Guelph, Guelph, Ontario

Received February 8, 1971

Triphenylbismuth carbonate, oxalate, sulfate, selenate, and chromate have been prepared and their solid state infrared (i.r.) spectra have been studied in the frequency region 4000 to 200 cm^{-1}. The i.r. spectroscopic results indicate that, like the corresponding trimethyl- and triphenylantimony(V) derivatives, these compounds also have non-ionic polymeric structures containing bridging anion groups and five co-ordinate bismuth. The i.r. frequencies associated with the bismuth–anion stretching vibrations appear to occur at 300 cm^{-1} for the carbonate and below 300 cm^{-1} for the other compounds.

Le carbonate, l'oxalate, le sélénate et le chromate de triphénylbismuth ont été préparés et leur spectres i.r. étudiés en phase solide dans la région de 4000 à 200 cm^{-1} de fréquence. Les résultats de spectroscopie i.r. indiquent que comme dans les dérivés triméthyl et triphényl antimoine(V) correspondants, ces composés, dont les structures polymériques ne ressemblent pas à celle du fer, contiennent également des groupes anions servant de ponts et des atomes de bismuth pentacoordonnés. Les fréquences i.r. associées avec les vibrations d'élongation bismuth-anion apparaissent à 300 cm^{-1} pour le carbonate et au-dessous de 300 cm^{-1} pour les autres composés.

Canadian Journal of Chemistry, 49, 2529 (1971)

Introduction

Amongst the organic compounds of pentavalent bismuth only the triphenylbismuth(V) derivatives of monobasic acids have been well studied and the information about the constitution and structural features of these compounds has been obtained only recently. We have shown that triphenylbismuth(V) derivatives such as Ph_3BiX_2 (1), where X = halide, pseudohalide, nitrate or carboxylate, are molecular compounds containing five co-ordinate bismuth. The structure of triphenylbismuth dichloride (2) has been shown to be trigonal bipyramidal by X-ray crystallography.

With the exception of the reported preparation of triphenylbismuth carbonate and sulfate (3) no information had been obtained on organobismuth(V) derivatives of dibasic acids. In continuation of our studies on the structural aspects of organic derivatives of pentavalent antimony and bismuth we now report on the preparation and infrared spectroscopic studies of triphenylbismuth carbonate, oxalate, sulfate, selenate, and chromate.

Results and Discussion

Triphenylbismuth carbonate, oxalate, sulfate, and selenate are white solids; the chromate is a yellow solid. Freshly prepared samples of all the compounds are stable at room temperature for a few days, however, the chromate decomposes upon exposure to light. Upon prolonged storage at room temperature all the compounds decompose slowly. Samples stored in a refrigerator did not show any sign of decomposition over a period of several weeks. With the exception of the chromate, these compounds are insoluble in water and most of the common organic solvents such as CH_3CN, CH_3NO_2, DMF, and DMSO. The chromate is slightly soluble in DMF and DMSO. Triphenylbismuth selenate and chromate are also slightly soluble in formamide. The equivalent conductances of 2×10^{-3} *M* solutions of the selenate and the chromate in formamide are 0.31 and 5.92 $ohm^{-1}\,cm^2\,equiv^{-1}$, respectively. No suitable solvent could be found to determine the conductance of other compounds.

Infrared Spectra

The i.r. spectra of these compounds were studied in the solid state in the frequency range of 4000 to 200 cm^{-1}. In the region 4000 to 300 cm^{-1} the i.r. absorption bands due to the triphenylbismuth group for all the compounds studied are almost identical to those observed for triphenylbismuth dihalides (1). The absorption frequencies due to the anion group can therefore be identified

[1]For Part II, see ref. 12.

§Doublet.

for each compound and these frequencies are recorded in Table 1.

On comparing the data in Table 1 with the i.r. frequencies of the respective anions (4) it is evident that these compounds do not contain free anions. The non-ionic nature of these compounds is also demonstrated by the conductance data for the triphenylbismuth selenate and the chromate. Previous i.r. spectroscopic studies (5–7) on trimethyl- and triphenylantimony(V) derivatives of divalent oxy-anions indicate that in each of these compounds the anion group acts as a bridging ligand. The i.r. spectroscopic data shown in Table 1 also indicate a similar function for the anion group in the bismuth compounds included in this investigation. Although the i.r. spectral features of triphenylbismuth(V) derivatives are similar to those observed for the analogous antimony compounds (5–7), a comparison of the anion stretching frequencies in the analogous bismuth and antimony compounds indicates that the anion–metal co-ordinate bond is weaker in bismuth compounds.

Bismuth–Anion Stretching Frequencies and Other Low Frequency Bands

The i.r. spectrum of triphenylbismuth (8) in 400 to 200 cm^{-1} region shows two strong bands at 237 and 220 cm^{-1} and a shoulder at 207 cm^{-1}. The 237 and 220 cm^{-1} bands have been assigned to Whiffen's *t*-vibration (9) and the 207 cm^{-1} shoulder has been attributed to Whiffen's *x*-vibration (9). The bands due to the *t*- and *x*-vibrations in triphenylbismuth dihalides, dinitrate, diacetate, and diisocyanate (1) also occur below 250 cm^{-1}. The i.r. spectra of triphenylbismuth carbonate, oxalate, sulfate, selenate, and the chromate in the region 400 to 200 cm^{-1} are shown in Fig. 1. By comparing these spectra with the spectra of triphenylbismuth (8) and triphenylbismuth dihalides (1) the absorption frequencies below 250 cm^{-1} can be assigned to the *t*- and *x*-vibrations of the triphenylbismuth group. The spectrum of triphenylbismuth carbonate shows a strong band at 300 cm^{-1}. This band can be assigned to the stretching frequency of the bismuth–carbonate bond (O—Bi—O str.). The assignments for the bismuth–anion stretching frequencies for the other compounds cannot be made with certainty. The spectrum of the oxalate shows a strong band at 365 cm^{-1}. This band is more likely due to the oxalate group since the C—O—C bending and the CO_2 rocking modes of the oxalate group (10) have been reported to absorb in this region. Another strong band for the oxalate is observed in the region 252–244 cm^{-1}. This band is not very well resolved but it appears to have two components. It is likely that the two components of this band correspond to the bismuth–oxalate stretching vibration and one of the *t*-vibrations. The spectra of triphenylbismuth sulfate, selenate, and the chromate also show a strong band at *ca.* 250 cm^{-1} and this band may be due to the bismuth–anion stretching vibration. However, due to the presence of *t*-vibration in the 250–200 cm^{-1} region these assignments can only be considered as tentative. The bands at 396 and 370 cm^{-1} in the spectrum of the selenate are certainly due to selenate group. Similarly the bands at 385, 368, and 314 in the spectrum of the chromate arise due to the absorption by chromate group.

In conclusion, the triphenylbismuth(V) derivatives of the divalent oxy-anions appear to be structurally similar to the analogous antimony compounds. Their solid state i.r. spectra are indicative of a polymeric structure involving five co-ordinate bismuth and bridging anion. The

insolubility of these compounds in even very polar organic solvents also suggests the existence of a strong intermolecular bonding. The bismuth–anion stretching frequency in triphenylbismuth carbonate appears to occur at 300 cm^{-1}. For the other compounds this frequency is indicated to occur at *ca.* 250 cm^{-1} or lower.

Experimental

Microanalyses were performed in this department or by Schwarzkopf Microanalytical Laboratory, New York. The analytical data and melting points are recorded in Table 2.

Triphenylbismuth dichloride was prepared as described previously (1). Formamide was purified by the method of Mann (11). Other chemicals were reagent grade and were used without further purification.

Preparation of Compounds

(1) Triphenylbismuth Carbonate, Oxalate, and Chromate

A preparation (3) which involves bubbling carbon dioxide through a solution of triphenylbismuth dibromide containing excess of sodium hydroxide is reported to afford impure triphenylbismuth carbonate. Pure triphenylbismuth carbonate was obtained by the reaction of triphenylbismuth dichloride with an aqueous solution of potassium carbonate. Triphenylbismuth oxalate and chromate were also prepared by this method. In a typical preparation 0.0133 mol of the appropriate potassium salt was dissolved in about 25 ml of distilled water and to this solution was added 0.0033 mol of triphenylbismuth dichloride. The mixture was stirred for 8 h in the dark, and then filtered. The residue was washed several times with water till it was free from the potassium salt. It was further washed with acetone to free it from unreacted triphenylbismuth dichloride and then dried under vacuum at room temperature. The yield in each case (calculated according to the amount of triphenylbismuth dichloride taken) was approximately 40%. The low yields are due to incomplete reaction because in each case unreacted triphenylbismuth dichloride was recovered.

(2) Triphenylbismuth Sulfate

It was prepared by the reaction of concentrated sulfuric acid on triphenylbismuth dichloride as described in the literature (3). Yield, 70%.

(3) Triphenylbismuth selenate

A dilute solution of selenic acid was added dropwise with stirring to triphenylbismuth carbonate at about 10 °C until there was no effervescence. The triphenylbismuth selenate separated as fine white powder. It was filtered, washed with water to remove excess of acid, and finally washed with acetone. It was then dried under vacuum at room temperature. Yield, 100%.

Physical Measurements

Infrared spectra were recorded on a Beckman IR-12 double beam spectrophotometer using KRS-5 and polyethylene windows. The samples were prepared as mulls in Nujol or Halocarbon oil. The conductances were measured at 25° with a Beckman RC-18 conductivity bridge. The melting points were determined with a Gallenkamp melting point apparatus and are uncorrected.

Vibrational Spectra of 1,1-Dichlorocyclopropane

J. M. FREEMAN[1] AND P. J. ROBINSON

Chemistry Department, University of Manchester Institute of Science and Technology, Manchester M60 1QD, England

Received September 23, 1970[2]

Infrared and Raman spectra of 1,1-dichlorocyclopropane are reported. Force constants were determined by an iterative computer procedure for two possible sets of assignments of the normal mode frequencies. It is suggested that in the correct assignment the methylene rocking modes are at higher frequency than the twisting modes.

Les spectres infrarouge et Raman du dichloro-1,1-cyclopropane sont décrits. Les constantes de force ont été déterminées au calculateur par une méthode itérative pour les deux systèmes possibles d'attribution des modes normaux de fréquence. Il est suggéré que dans l'attribution correcte, les modes de rotation des groupes méthyléneques se trouvent à une fréquence plus élevée que les modes de torsion.

Canadian Journal of Chemistry, 49, 2533 (1971)

Introduction

The vibrational analysis for 1,1-dichlorocyclopropane was of interest in connection with unimolecular reaction rate calculations (1). The infrared and Raman spectra and the skeletal analysis had been reported by Kay (2), but the infrared (i.r.) spectra obtained during kinetic work (3) did not entirely agree with Kay's, and errors were found in his **F** and **G** matrices. It was therefore of interest to re-analyze the spectra and to carry out a complete vibrational analysis of the molecule. The vibrational spectra of a number of other three-membered ring systems have been analyzed (2, 4–6), and points of specific interest in the present work were the assignments of the ring deformation and methylene wagging frequencies in A_1 and of the methylene rocking and twisting modes in A_2 and B_1; it has been suggested (4) that the rocks rather than the twists should have the higher frequencies.

Spectra

1,1-Dichlorocyclopropane was prepared as described previously (3) and purified by preparative g.l.c.; it was chromatographically pure on several g.l.c. columns.

Infrared spectra were recorded for capillary films or 10% solutions in carbon tetrachloride or cyclohexane on Unicam SP 100 and Perkin–Elmer 457 or 621 spectrophotometers, and for the vapor on the PE621. The Raman spectrum of the pure liquid was recorded on a Spex instrument using Ar^+ 488 nm laser excitation.[3] For many lines our spectra differed from Kay's by only a few cm^{-1} and Kay's figures were used for consistency.

The molecule of 1,1-dichlorocyclopropane has C_{2v} symmetry and has 21 fundamental vibrations, 4 in the C—H stretching region. The vibrations comprise $7A_1$ (i.r. and Raman active; Raman polarized) $+ 4A_2$ (Raman only, depolarized) $+ 5B_1 + 5B_2$ (i.r. and Raman active; Raman depolarized). The assignments used in the calculations are given in Table 5, together with those of Kay, and are discussed below.

C—H Stretching Vibrations

Four bands are expected in this region, but only two resolvable absorptions were observed; 3022 (s,vs,p) and 3100 (m,m,d) cm^{-1} (here and below the i.r. and Raman strengths and the Raman polarization are quoted in parentheses after the reciprocal wavelength). Kay's band at 3048 cm^{-1} is spurious and his assignments in A_2 and B_2 were reversed (see Table 5).

Other Vibrations

Thirteen of the remaining seventeen fundamentals were reasonably strong and agreed with Kay's spectra, and Kay's assignments were used for these lines: 1454 (s,w,p), 1409 (vs,w,d), 1238 (vs,s,p), 1130 (vs,vw,?), 1037 (vs,vw,p), 952 (s,m,d), 874 (w,s,p), 772 (s,vw,?), 717 (vs,m,d),

[1]Present address: ICS/24, Shell Chemicals Limited, Carrington, Cheshire, England.

[2]Revision received March 15, 1971.

[3]We thank Dr. M. I. Ware (University of Manchester) and Dr. V. Fawcett (University of Bradford) for recording the Raman spectrum, and Professor D. A. Long (University of Bradford) for use of the spectrometer.

TABLE 1. Symmetry coordinates

A_1 coordinates

$S_7 = (\beta_1 + \beta_2 - \beta_3 - \beta_4 - \beta_5 - \beta_6 + \beta_7 + \beta_8)/\sqrt{8}$	(CH_2 wag)
A_2 coordinates	
$S_8 = (t_1 - t_2 - t_3 + t_4)/2$	(CH stretch)
$S_9 = (\alpha_1 - \alpha_2 - \alpha_3 + \alpha_4)/2$	(CCl_2 twist)
$S_{10} = (\beta_1 - \beta_2 + \beta_3 - \beta_4 - \beta_5 + \beta_6 - \beta_7 + \beta_8)/\sqrt{8}$	(CH_2 rock)
$S_{11} = (\beta_1 - \beta_2 - \beta_3 + \beta_4 + \beta_5 - \beta_6 - \beta_7 + \beta_8)/\sqrt{8}$	(CH_2 twist)
B_1 coordinates	
$S_{12} = (s_1 - s_2)/\sqrt{2}$	(CCl stretch)
$S_{13} = (t_1 - t_2 + t_3 - t_4)/2$	(CH stretch)
$S_{14} = (\alpha_1 + \alpha_2 - \alpha_3 - \alpha_4)/2$	(CCl_2 rock)
$S_{15} = (\beta_1 - \beta_2 + \beta_3 - \beta_4 + \beta_5 - \beta_6 + \beta_7 - \beta_8)/\sqrt{8}$	(CH_2 rock)
$S_{16} = (\beta_1 - \beta_2 - \beta_3 + \beta_4 - \beta_5 + \beta_6 + \beta_7 - \beta_8)/\sqrt{8}$	(CH_2 twist)
B_2 coordinates	
$S_{17} = (r_1 - r_2)/\sqrt{2}$	(ring def.)
$S_{18} = (t_1 + t_2 - t_3 - t_4)/2$	(CH stretch)
$S_{19} = (\alpha_1 - \alpha_2 + \alpha_3 - \alpha_4)/2$	(CCl_2 wag)
$S_{20} = (\beta_1 + \beta_2 + \beta_3 + \beta_4 - \beta_5 - \beta_6 - \beta_7 - \beta_8)/\sqrt{8}$	(CH_2 def.)
$S_{21} = (\beta_1 + \beta_2 - \beta_3 - \beta_4 + \beta_5 + \beta_6 - \beta_7 - \beta_8)/\sqrt{8}$	(CH_2 wag)

500 (vs,vs,p), 404 (—,m,d), 300 (—,m,d), 272 (m,m,d) cm^{-1}. The five polarized Raman lines were clearly A_1 fundamentals, and to these was added the apparently depolarized line at 272 cm^{-1}. The bands at 404 and 300 cm^{-1} were both virtually absent from the i.r., but only one frequency as low as this can be assigned to A_2. Following Kay, 300 cm^{-1} was placed in A_2 and 404 cm^{-1} in B_2.

The four remaining vibrations are more problematical. The strong i.r. band at 1292 cm^{-1} in Kay's vapor spectrum was absent from our i.r. spectra,[4] and for the corresponding B_1 vibration we used instead a band at 1212 (m,vw,?) cm^{-1}. The 1292 cm^{-1} Raman line was used in one series of calculations to replace the 1164 cm^{-1} band placed by Kay in A_2, since the latter was also infrared active. Kay's A_2 band at 825 cm^{-1} was absent from our spectra and was replaced by 809 (—,w,?) cm^{-1}. Finally, the 443 cm^{-1} Raman line used by Kay as a B_1 fundamental was very weak in our spectra and must be considered of doubtful validity, although we used it for want of an adequate substitute.

Other Bands

These are listed for completeness, but not discussed further: 2914, 2848, 2826, 2683, 2650, 2556, 2476, 2361, 2326, 2274, 2210, 2166, 2110, 2088, 1983, 1933, 1903, 1871, 1834, 1809, 1748, 1636 (all w or vw,—), 1375 (—,vw,p), 1330 (vw,—), 1163 (m,w,d), 1061 (m,vw,?), 1012 (w,—), 900 (vw,—), 790 (w,—), 633 (vw,—) 596 (—,vw,?), 251 (w,—) cm^{-1}.

[4]In ref. 3 the spurious band was wrongly quoted as 1321 cm^{-1}.

Calculations

Coordinates and Geometry

The internal coordinates were labelled as shown in Fig. 1. The geometry deduced from microwave spectra by Flygare, Narath, and Gwinn (7) was used. In their work the ring was

found to be virtually equilateral, with $r_i = r' =$ 0.1532 nm, $s_i = 0.1734$ nm, $t_i = 0.1085$ nm, $\angle$ HCH = 117.58°, and $\angle$ ClCCl = 114.63°; hence $\angle$ CCH = 116.65° and $\angle$ CCCl = 117.88°. Atomic weights were taken as 1.008, 12.000, and 34.97 for H, C, and ^{35}Cl, respectively. The symmetry coordinates (Table 1) were those of Kay (ref. 2, appendix II),[5] in which B_2 representations are symmetric with respect to the plane of the ring.

G Matrices

In preliminary work, algebraic expressions were used for the **G** elements relevant to the skeletal vibrations. These agreed with those in Kay's Appendix III except for

$$\mathbf{G}_{A_1}(3,5) = 2^{\frac{1}{2}}aC[d(2A^2 - G - 1) + eA(G - 1)]$$

$$\mathbf{G}_{A_1}(5,5) = [d^2(-7A^2 + 3G + 3) + 2deA(4A^2 - 2G - 1) + e^2(3 + 2A^2G - 6A^2)]aC^2 + \tfrac{1}{2}e^2(3 - 4A^2)bC^2$$

$$\mathbf{G}_{B_2}(3,3) = [d^2(G + 1 - A^2) - 2deA + e^2]aC^2 + \tfrac{1}{2}be^2C^2$$

where a, C etc. are as defined by Kay. Later, the **G** elements for the full analysis were obtained by an iterative numerical method (8). These are given in Table 2; the skeletal elements agree well with the values from the algebraic expressions.

[5]Note that on pp. 71 and 92 Kay reverses the representations B_1 and B_2.

F Matrices

The potential function used included the six direct force constants and initially 20 of the 26 interactions between adjacent coordinates. The force constants and simplifying assumptions used are listed in Table 4, together with the shorthand nomenclature used in Table 3, which was produced by computer (9) and gives the corresponding symmetry force constants in terms of valence force constants (*i.e.*, **F**). The skeletal elements agree with those of Kay apart from expected differences and a misprint and error in Kay's version of $\mathbf{F}_{A_1}(2,2)$ and $\mathbf{F}_{A_1}(2,3)$, respectively.

Determination of Force Constants

Force constants for a number of assignments were obtained by iterative fitting of calculated frequencies to the "observed" frequencies, using the computer program described previously (9). An important feature of this program is the attention paid to correct correlation between the calculated and observed frequencies by consideration of the potential energy distribution, without which serious errors can arise (9, 10). The number of indeterminate force constants was reduced to 19 by fixing $f(t)$ and $f(tt)$, assuming that $f(\beta_1\beta_2) = f(\beta_3\beta_4)$ and $f(r_1\beta_1) = f(r'\beta_1)$, and by fixing $f(ss)$, $f(rt)$, and $f(r't)$ at zero after initial itera-

tions showed that these constants were small and had little effect on the results of the calculation.

In no case was the fit as good as might be desired, and the results will be quoted only for two models, which differ essentially in the assignments of the methylene rocks and twists. The derived force constants for the two assignments are given in Table 4 and the assignments are compared with the calculated frequencies in Table 5. Vibrations are assigned to those normal modes having the largest potential energy contribution (9), although in a few cases (noted in Table 5) the mixing is too great for any single assignment to be really meaningful. For example, we attribute little significance to our reversal of Kay's assignments for the A_1 ring deformation and methylene wagging vibrations.

Discussion

It was clear from the progress of the convergence of the iterative method that a close fit between the observed and calculated frequencies could not be obtained using the adopted force field. Although it is possible that further refinement in the force field defined in Table 3 may have improved the agreement between the experiment and theory, it was thought that such action was not worthwhile in view of the substantial doubts concerning the assignments of the observed frequencies. Unavailable information, such as the vibrational frequencies of isotopically substituted dichlorocyclopropanes (*e.g.* $C_3D_4Cl_2$), would help to define the force field more closely, and hence to decide more rigorously on the present doubtful assignments in $C_3H_4Cl_2$.

On the basis of normal coordinate analyses of ethylene oxide, ethylene oxide-d_4, and ethylene sulfide, it has been suggested (4) that the CH_2 rocks should have a higher frequency than the CH_2 twists in three-membered ring systems. The factors involved were the physical acceptability of the force constants defining each assignment

[a]Not calculated; group factorization procedure used.

and the difficulty in defining a valence force field capable of reproducing the symmetry force fields corresponding to the reverse assignment. Similar considerations apply here, the off-diagonal valence force constants being much larger for assignment 1 than for assignment 2. It is also useful to consider Table 6, where group force constants are quoted; the CH_2 def., wag, rock, and twist force constants have much closer values for assignment 2, as may be expected physically. Table 6 also includes the corresponding force constants for ethylene oxide and sulfide (4), and as might be expected the results are rather similar to those for dichlorocyclopropane.

Crystal and Molecular Structure of Difluorochlorine(III)-hexafluoroarsenate(V), ClF_2AsF_6

H. Lynton and J. Passmore

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received March 22, 1971

Crystals of difluorochlorine(III)hexafluoroarsenate(V), ClF_2AsF_6, are monoclinic, space group $A2/a$, $a = 10.676(9)$, $b = 7.673(7)$, $c = 8.064(7)$ Å, $\beta = 113.40(5)°$. The structure was refined by three dimensional least squares methods to $R = 0.045$ for 185 independent observed reflections. The chlorine atom has two nearest fluorine neighbors at 1.541(14) Å, with a F—Cl—F angle of 103.17(0.70) °, and two longer fluorine bonds at 2.339(14) Å. All five atoms lie in a plane. The arsenic atom is octahedrally coordinated to six fluorine atoms and is connected to two ClF_2^+ groups via *trans* fluorine bridges.

Les cristaux de difluorochlorure(III)hexafluoroarsénate(V), ClF_2AsF_6, appartiennent au système monoclinique, groupe espace $A2/a$, $a = 10.676(9)$, $b = 7.673(7)$, $c = 8.064(7)$ Å, $\beta = 113.40(5)°$. La structure a été affinée par la méthode des moindres carrés, avec $R = 0.045$ pour 185 réflexions indépendantes observées. L'atome de chlore a deux atomes de fluor à proximité immédiate, situés à 1.541(14) Å et faisant un angle F—Cl—F de 103.17(0.70)°, et deux atomes de fluor plus éloignés situés à 2.339(14) Å. Les cinq atomes sont dans un même plan. L'atome d'arsenique est coordonné d'une façon octahédrique aux six atomes de fluor et est relié à deux groupes ClF_2^+ au moyen de ponts fluor en position *trans*.

Canadian Journal of Chemistry, 49, 2539 (1971)

Introduction

This work arose out of an attempt to determine the crystal structure of ClF_2IrF_6 (1, 2). The results indicated a greater F—Cl—F angle than that suggested by various spectroscopic investigations of related compounds (3–5) and the corresponding F—Br—F angle in BrF_2SbF_6 (6, 7). As the standard deviations for ClF_2IrF_6 were large, the structural determination of the crystallographically more favorable ClF_2AsF_6 was undertaken. While this work was in progress, the crystal structure of ClF_2SbF_6 was reported (8). ClF_2AsF_6 is of interest as a ClF_3 – Lewis acid adduct, and also as a ClF_2^+-containing compound. Halogen and interhalogen cations have recently been reviewed (9).

Experimental

Chlorine trifluoride and arsenic pentafluoride were supplied by Ozark–Mahoning Company and were used without further purification. Gaseous reagents were manipulated in a Monel vacuum line fitted with Whitey (IKS-316) stainless steel valves and Swagelok compression fittings. The solid was transferred in a "Dri-Lab" manufactured by Vacuum Atmospheres Corporation, Los Angeles, California.

Arsenic pentafluoride was distilled onto chlorine trifluoride in a Kel-F trap. An adduct formed which dissolved in excess chlorine trifluoride. The solid was vacuated at 0° to remove volatile material. The compound was identified as ClF_2AsF_6 from the infrared spectrum (3) of the powdered solid between silver chloride plates. Lumps of the solid were sealed under atmospheric pressure into thin walled quartz capillaries, o.d. 0.5 in. The capillaries were placed horizontally on the sides of a beaker at various distances from its base which was heated at 80°. Good single crystals grew overnight by sublimation.

Crystal Structure Analysis

Crystal data are as follows:

ClF_2AsF_6 f.w. = 262.4

Monoclinic, $a = 10.676(9)$, $b = 7.673(7)$, $c = 8.064(7)$ Å, $\beta = 113.40(5)°$, $v = 606.3$ Å^3, $z = 4$, $\rho_c = 2.874$ (20 °C, MoKα, $\lambda = 0.71069$ Å).

The unit cell dimensions and their estimated standard deviations were obtained from a least squares evaluation of the positions of 12 independent reflections. The volume is consistent with $z = 4$, since 32 fluorine atoms in the unit cell give a volume per fluorine atom of 19 Å^3, comparable with the usual value of 18 Å^3 for approximate close-packing. The space group is $A2/a$ (C_{2h}^6) No. 15 in *International Tables for X-Ray Crystallography*, Vol. 1 (10).

Intensity data were collected on a Picker computer-controlled four-angle diffractometer using a $\theta/2\theta$ scan with β filtered MoKα radiation and a scintillation detector. The region of reciprocal space explored was the two octants hkl and $\bar{h}kl$ to a maximum 2θ of 40°. In this region 292 reflections were accessible, of which 185 were considered to be observed. The threshold was taken as 0.07 × background count. The specimen was roughly rectangular in shape, 0.2 mm long and 0.04 mm in cross section, mounted in a quartz capillary tube. The linear absorption coefficient for MoKα radiation is $\mu = 64.7$ cm^{-1}. No corrections were made for either absorption or extinction.

The positions of all atoms were established from a three dimensional Patterson synthesis. Arsenic and chlorine atoms were found to occupy the special positions *4a* and

*F′ atoms related to F atoms by center of symmetry at the arsenic atom; estimated standard deviations in parentheses.

4e, respectively. The structure was refined by successive cycles of block-diagonal least squares, using 3 × 3 matrices for the positional parameters and 6 × 6 for the anisotropic thermal parameters of each atom. The quantity minimized was $R_2 = \Sigma w(|F_o| - |F_c|)^2$ for observed reflections only, using weighting function $w = 1/\{1 + [(|F_o| - P_2)/P_1]^4\}$, with $P_1 = 45$ and $P_2 = 55$. Scattering factor curves used were those for As, Cl, and F given in *International Tables for X-Ray Crystallography*, Vol. III (11) corrected for anomalous dispersion (12).

After refinement was complete, a difference synthesis showed a small amount of remaining electron density nowhere greater than 0.4 e $Å^{-3}$. The final agreement residual $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$ was 0.045. A set of structure factors for the final parameters given in Table 1 has been placed in the Depository of Unpublished Data.[1]

Discussion

The atomic arrangement is shown in Fig. 1. The arsenic atoms lie on centers of symmetry at 000 and 0, ½, ½ and the chlorine atoms lie on the two-fold axes. Each arsenic is surrounded octahedrally by six fluorine atoms; all F—As—F angles (Table 2) are not significantly different from 90°. Two fluorine atoms from each AsF_6^- anion provide *trans* bridges to two ClF_2^+ cations. The arsenic to bridging fluorine F(*2*) distance 1.740(13) Å is probably significantly longer than As—F(*1*) 1.694(12) Å and significantly longer than the shortest terminal bond As—F(*3*) 1.637 (16) Å. The coordination around the chlorine atom is shown in Fig. 2, and the corresponding distances are given in Table 3. The ClF_2^+ and the bridging fluorines lie within 0.04 Å of the best mean plane through the five atoms (Table 4). The

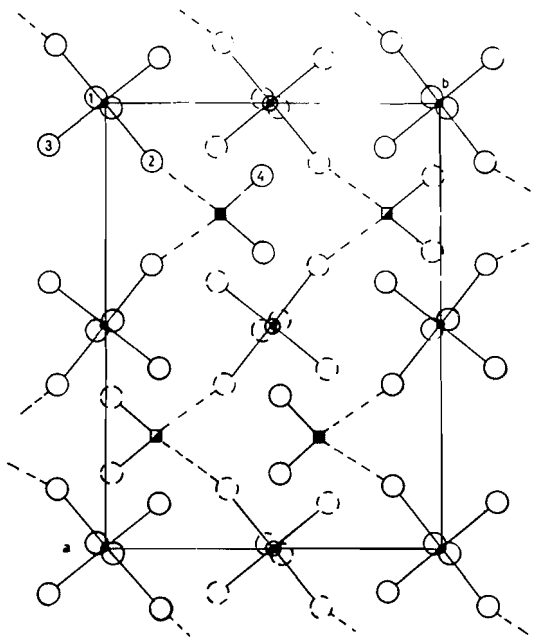

FIG. 1. Projection of the structure along the *c* axis. ○, ○, Fluorine atoms; ◉, arsenic atom at $z = ½$; ●, arsenic atom at $z = 0$; ■, chlorine atom at $z = 0$; ◩, chlorine atom at $z = ½$.

atoms F(*3*), F″(*3*), F(*1*), and F″(*1*) are situated towards the F(*4*), F″(*4*) side of the chlorine atom at about van der Waal's distance away.

Table 5 compares the structural information found for the ClF_2^+ ion in ClF_2AsF_6 and ClF_2SbF_6. The bridging fluorines are also essentially coplanar with the ClF_2^+ in ClF_2SbF_6 (8) (as is the BrF_2^+ in BrF_2SbF_6 (6, 7)). The most obvious difference is the F—Cl—F angle, 103.17(0.70)° in ClF_2AsF_6 compared with 95.9(3.1)° in ClF_2SbF_6,

Atom	Distance from plane (Å)
Cl	0
F(2)	−0.03(1)
F(4)	0.04(1)
F″(2)	−0.04(1)
F″(4)	0.03(1)

*Equation of plane: $-0.423X - Y - 0.906Z + 1.129 = 0$, referred to an orthogonal set of axes, X along a, Y along b, and Z along c^*. Estimated standard deviations in parentheses.

TABLE 5. A comparison of the ClF_2^+ structure in ClF_2AsF_6 and ClF_2SbF_6 (8)*

Parameter	ClF_2AsF_6	ClF_2SbF_6
Cl—F [ClF_2^+] distance	1.541(14) Å	1.57(3) Å 1.58(3) Å
Cl — bridging fluorine distance	2.339(14) Å	2.43(3) Å 2.33(3) Å
F—Cl—F [ClF_2^+] angle	103.17(0.70)°	95.9(3.1)°
F—Cl—F [bridge] angle	93.62(0.47)°	89.9(1.9)°

*Estimated standard deviations in parentheses.

although the difference is only "possibly significant". The chlorine atom in ClF_2SbF_6 also has four fluorine atoms at about van der Waal's distance away 3.08(3), 2.96(3), 3.11(3), and 2.99 (3) Å (8), two above and two below the ClF_2^+ plane, but in a different orientation to that found for ClF_2AsF_6. In other respects the structures are similar.

Interest in the bonding of interhalogen compounds has centered around the question of whether or not d orbital participation is important (13). The F—Cl—F angle of 103.17 (0.70)° in ClF_2^+ suggests that a bonding model that uses exclusively p (14) or d^2sp^3 orbitals would not be appropriate. It is possible that the structure can be represented mainly in terms of valence bond structures **1** and **2**, structure **1** having the most importance.

Both valence structures favor a planar arrangement of the chlorine atom and its four nearest neighbors, structure **1** on steric grounds and structure **2** from electronic considerations. The arrangement of the four fluorine atoms at about van der Waal's distance from the chlorine atom

would favor lone pairs having the orientation of valence bond structure **1** (see Fig. 2). The F—Cl—F angle is larger than the corresponding angle in PF_3, 97.8 ± 0.2° (15) and SCl_2, 100.3° (error unspecified) (16). This could be due to greater p_π–d_π bonding in ClF_2^+. The ClF bond distance is 1.541(14) Å, significantly less than that in ClF gas, 1.6281 Å (17), and is the shortest chlorine–fluorine distance so far reported.

The F—Br—F angle in BrF_2SbF_6 is 93.5(2.1)° and the fluorine bridging is stronger than in ClF_2AsF_6 (see Table 6). It is possible that for the bromine compound, structure **2** has more importance. It has been pointed out that the physical properties of BrF_2SbF_6 suggest extensive fluorine bridging (18). The infrared and Raman spectra of both BrF_2AsF_6 and BrF_2SbF_6 (19, 20) are more complicated than their chlorine analogues (3–5); however, this could be due to the fact that the arsenic and antimony atoms in ClF_2AsF_6 and ClF_2SbF_6 lie on centers of symmetry reducing the number of bands by the operation of the mutual exclusion rule.

The fluorine bridging is probably stronger in ClF_2AsF_6 than in ClF_2SbF_6, and if the arguments concerning bridging and bond angle have any validity, then the F—Cl—F angle in the antimony adduct should be the largest. The evidence suggests that this is probably not the case; however, the large standard deviations for ClF_2SbF_6 make comparisons somewhat speculative.

TABLE 6. Structural data for BrF_2^+ in BrF_2SbF_6 (6, 7)

Parameter	Value
Br—F [BrF_2^+]	1.69(2) Å

Vibrational Spectra of Peroxydisulfuryl Difluoride $S_2O_6F_2$ and the Halogen Derivatives $FOSO_2F$ and $ClOSO_2F$

A. M. QURESHI, L. E. LEVCHUK, AND F. AUBKE[1]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received February 11, 1971

Vibrational spectra of the halogenfluorosulfates $FOSO_2F$ and $ClOSO_2F$ are recorded and C_s symmetry is suggested for the molecules. For peroxydisulfuryl difluoride a staggered non-planar configuration with C_2 symmetry is indicated by the polarized Raman spectra.

Les spectres de vibration d'halogénofluorosulfates, $FOSO_2F$ et $ClOSO_2F$, sont rapportés et une symétrie C_s est envisagée pour ces molécules. Pour le peroxyde de bis (fluorure de sulfuryle), le spectre Raman polarisé révèle une configuration décalée non planaire, avec une symétrie C_2.

Canadian Journal of Chemistry, 49, 2544 (1971)

Peroxydisulfuryl difluoride, $S_2O_6F_2$, has been known for some time (1, 2) and has proven to be an extremely versatile reagent in synthetic inorganic chemistry (3–5). Even though some relevant structural details, such as the infrared spectrum in the NaCl region (1), the ^{19}F nuclear magnetic resonance (n.m.r.) spectrum and the reversible dissociation into SO_3F radicals (6, 7) at elevated temperature, indicating the presence of a peroxy group, are reported, the molecular structure is not known in detail and the complete vibrational spectrum has not been investigated.

The same holds true for the two halogen derivatives fluorine fluorosulfate $FOSO_2F$ (8) and chlorine fluorosulfate $ClOSO_2F$ (9). Infrared spectra, mostly on the gaseous compounds, are reported (8, 10*a*, 10*b*, 11) but these are with one exception (10*b*) limited to the transparency range of AgCl. This has allowed only a limited assignment of the vibrational absorption bands.

Raman spectra, which should be extremely helpful in determining the molecular geometry, and low temperature infrared spectra except for $ClOSO_2F$, are not reported. Both should permit the assignment of the vibrational modes.

A number of related molecules, where vibrational studies are reported, can be used as examples in the attempted assignment. They include HSO_3F (12–14), $BrOSO_2F$ (15), and the polysulfurylfluorides $S_2O_5F_2$ and $S_3O_8F_2$ (16) and the peroxysulfate ion $S_2O_8^{2-}$ (17). It was found necessary to reinvestigate the Raman spectrum of HSO_3F (12), where not all expected vibrational modes had been found previously.

[1]To whom correspondence should be addressed.

Experimental

Peroxydisulfuryl difluoride was prepared according to Cady and Shreeve (18) in a catalytic flow reaction. The compound was distilled repeatedly in a greaseless vacuum line. The purity of $S_2O_6F_2$ and of the halogen fluorosulfates was checked by ^{19}F n.m.r. and vapor density measurements. Fluorine fluorosulfate is obtained in the same flow reaction as a by-product and purified by repeated vacuum distillation. Since handling this compound can be hazardous, only small quantities were prepared and safety precautions were taken. Chlorine fluorosulfate is obtained according to Gilbreath and Cady (9). The compound was distilled in a metal vacuum line. A monel reactor of about 100 ml contents with a Whitey valve was used. Fluorosulfuric acid was purified by double distillation as described previously (19).

Raman samples were contained either in an ordinary 7 mm o.d. Pyrex tube ($S_2O_6F_2$) or quartz tube ($ClOSO_2F$) or in a 12 mm o.d. thick wall Pyrex tube ($FOSO_2F$), all with a flattened bottom. The samples were flame sealed after filling. The starting materials were supplied from Allied Chemical Corporation (F_2, SO_3, HSO_3F) or from Matheson of Canada (Cl_2). The identity and purity of the compounds was checked by ^{19}F n.m.r.

Infrared spectra were obtained on Perkin Elmer grating spectrophotometers 457 (for routine work on gaseous samples) and 225 (for low temperature studies). The spectra on gaseous samples were obtained with a monel infrared cell of 80 mm pathlength fitted with silver chloride windows (Harshaw Chemicals) and Whitey valves. The low temperature spectra were obtained with CsI windows, using a metallic Dewar container (Andonain Associated Inc.).

Raman spectra were obtained on a Cary 81 spectrometer equipped with a Spectra Physics model 125 He–Ne laser.

Results

Well-resolved Raman and infrared spectra were obtained for all three compounds. The Raman spectra for $FOSO_2F$ and $ClOSO_2F$ are shown in Figs. 1 and 2, the Raman spectrum of

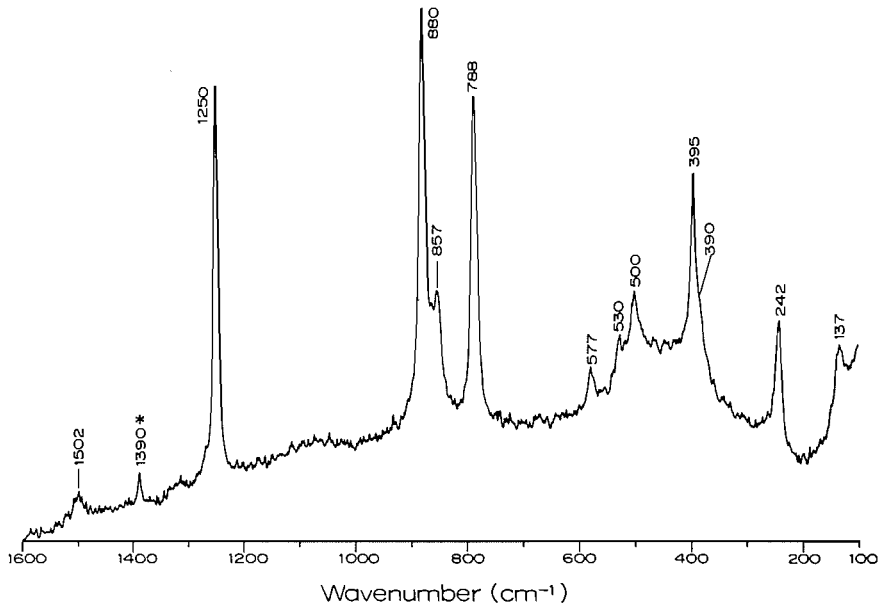

FIG. 1. Raman spectrum of $FOSO_2F$.

$S_2O_6F_2$ is reproduced in Fig. 3. The observed absorption bands are listed together with a proposed assignment in Table 1 for HSO_3F, $FOSO_2F$, and $ClOSO_2F$ and in Table 2 for $S_2O_6F_2$. Also listed are estimated intensities and calculated polarization ratios.

Discussion

From previous infrared and ^{19}F n.m.r. studies it can be concluded that the compounds $XOSO_2F$ with X = H, F, or Cl are true fluorosulfates, the observed chemical shifts fall into the range of other SO_3F compounds (20), with X linked over oxygen to sulfur. It can also be assumed that this X—O—S group is non-linear as postulated by the Gillespie–Nyholm valence shell electron pair repulsion model (21) and as found, for example, in compounds such as SF_5OF (22) or in the triatomic molecules X_2O (23). If in addition a hindrance of free rotation around the S—O bond in this X—O—S group is assumed, presumably caused by some weaker $p\pi \rightarrow d\pi$ bonding as postulated by Cruikshank (24), one would expect two different configurations, one belonging to the point group C_s with X and F co-planar and the other C_1 where both are not co-planar. For the C_S configuration *cis*- and *trans*-isomers are expected.

As can be seen from Table 1, the polarized Raman spectra show the presence of four (HSO_3F, $FOSO_2F$) and three ($ClOSO_2F$) depolarized modes, thus favoring point group C_s over C_1 in good agreement with previous work on HSO_3F (12).

The twelve expected vibrational modes are conveniently described as SO_2 stretching modes (symmetric (a') and asymmetric, S—F, S—OX, and O—X stretching (all a'), SO_2 and OX bonding (a'). S—OX and SF wagging, SO_2 rocking (a''), and SO_3F and SOX torsions (a'') all of which are observed for $FOSO_2F$. In case of $ClOSO_2F$, the SOCl torsion mode is not observed. This band is expected to occur below 100 cm^{-1} judging from the position of the corresponding band for $FOSO_2F$ at 137 cm^{-1}.

The O—H stretching mode for HSO_3F found at 3150 and 3050 cm^{-1} (13) is not observed in the Raman spectrum in agreement with previous work (12). Two new Raman bands are observed for this compound, both fairly weak, a depolarized band at 686 cm^{-1} and a presumably polarized band at 490 cm^{-1}. The former is assigned in agreement with Savoie and Giguère (13) as OH torsion mode, the latter which is not observed in the infrared spectrum is assigned as S—F wagging mode. The proposed assignment for HSO_3F departs only in this regard from previous proposals (13) where coincidence of

this band with the torsion mode at 390 cm^{-1} had been suggested.

Both $FOSO_2F$ and $ClOSO_2F$ are found to have absorption bands in the same region. The fact that hydrogen bridge-bonding in the liquid acid is mainly responsible for the low SO_2 stretching vibrations is obvious from the reported infrared studies on gaseous HSO_3F (13, 14). The corresponding bands are higher for $FOSO_2F$ and also for $ClOSO_2F$, even though some molecular

association, presumably via Cl...OS interaction, is evidenced by the wide liquid range and the observed Trouton constant (9).

No evidence of similar association is apparent for $FOSO_2F$. The vibrational bands are identical for the liquid and the gaseous sample within the error limits and only for the solid spectrum an expected shift to lower frequencies of about 10 cm^{-1} is noted. In addition some bands appear to be split in the low temperature spectrum, presumably due to factor group splitting. Poor resolution in the range lower than 300 cm^{-1} did not allow us to detect the bands at ~240 and 137 cm^{-1} in the infrared spectrum.

Whereas a straightforward assignment is possible in the high and in the low frequency range, some ambiguity is expected in the range of 700 to 900 cm^{-1} where three fundamentals ν_{S-F}, ν_{OF}, and ν_{S-OF} occur, all *a'* modes and thus polarized in the Raman spectrum. The previous assignment (8) based on a comparison of the $FOSO_2F$ and the CH_3OSO_2F bands in this reagent had suggested for ν_{OF} a frequency at 880 cm^{-1}, for ν_{SF} a value of 852 cm^{-1}, and for ν_{S-OF} 789 cm^{-1}. This appears quite reasonable even when compared to more recent assignment made on related molecules.

The O—F stretching frequency is normally found at slightly higher wavenumbers, *e.g.* at 945 cm^{-1} for CF_3OF (25) and at 937 cm^{-1} for $FONO_2$ (26*a*, *b*) but for SF_5OF (27) a lower value of 888 cm^{-1} is suggested. Where covalently bound SO_3F groups are found, the SF stretch is normally expected to be higher than 800 cm^{-1}, thus favoring the 852 cm^{-1} mode over the band at 788 cm^{-1}, which is best described as ν_{S-OF}. All other bands are easily assigned in good analogy to HSO_3F.

For $ClOSO_2F$ similar difficulties are encountered. The strong, polarized band at 706 cm^{-1} is best assigned as ν_{Cl-O} even though for $ClONO_2$ a higher value, 809 cm^{-1}, has been suggested for the identical vibration (28). For chloroxyperfluoroalkanes (29) the Cl—O stretch is found in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the range of 780–750 cm^{-1}, for SF_5OCl a frequency of 720 cm^{-1} is suggested (30). Our assignment is also in good agreement with the interpretation of the infrared spectrum (10*a*, *b*, 11).

Both bands at 856 and at 830 cm^{-1} are in the expected range of the S—F stretching mode. We assign the lower value to ν_{S-F} for the following reasons. In terminal monodentate SO_3F groups, where strong molecular associations as, for example, in HSO_3F is absent, such as $BrOSO_2F$ (15), $[Br(OSO_2F)_4]^-$ (31), $[I(OSO_2F)_4]^-$ (31), CF_3OSO_2F (32), and NF_2OSO_2F (32), ν_{SF} is found in the relatively narrow frequency range of 830–840 cm^{-1}. Furthermore it has been demonstrated by Gillespie and Robinson (33) on a number of examples, that in tetrahedrally coordinated sulfur compounds of the type XSO_2Y both the SO_2 stretching modes and ν_{S-Y} depend on the electronegativity of X as, for example, found for SO_2F_2 *vs.* $ClSO_2F$ (34).

If this argument applies also to $FOSO_2F$ and $ClOSO_2F$ both the SO_2 stretching modes and ν_{SF} should occur at lower wavenumbers for $ClOSO_2F$, as is in fact observed.

The band at 856 cm^{-1} is correspondingly assigned as ν_{S-OCl}. All remaining bands are assigned in close analogy to $HOSO_2F$ and $FOSO_2F$. The low temperature infrared spectrum is reported by Christie *et al.* (10*b*) and was therefore not recorded by us.

For $FOSO_2F$ a spurious, unassigned band at 1390 cm^{-1} was noted in some Raman samples but appeared to be absent in the infrared spectrum. The band is therefore ignored in the interpretation.

Peroxydisulfuryl difluoride can be regarded as a true peroxide, as discussed before, of the type R_2O_2 where $R = SO_2F$. Following an interpretation of the vibrational spectrum in terms of group frequencies, one would expect the SO_2F bands to occur in approximately the same region as previously established for the halogenfluorosulfates and HSO_3F. For the S_2O_2 skeleton in $S_2O_6F_2$, three reasonable structural possibilities can be discussed: (*a*) a planar *cis* configuration belonging to point group C_{2v}, (*b*) a planar *trans* configuration, point group C_{2h}, and (*c*) a non planar, staggered form with C_2 symmetry.

Previous structural studies on related compounds have confirmed model (*c*) for $(SF_5)_2O_2$ (35), H_2O_2 (23), and $(CH_3)_2O_2$ (36) where dihedral angles between the two X—O—O planes are found to be between 100 and 110°. For the ion $S_2O_8^{2-}$ isoelectronic to $S_2O_6F_2$, however, configuration (*b*) has been suggested as a result of a vibrational study (17) in analogy to the ion $P_2O_8^{4-}$ (37). This is confirmed by X-ray diffraction, for $(NH_4)_2S_2O_8$ (38, 39) and $Cs_2S_2O_8$ (38), but for $K_2S_2O_8$ (40) again the staggered configuration is suggested. No precedents could be found for configuration (*a*) among the peroxides. This structural type is only found, where strong multiple bonding between the bridging atoms exists as, for example, in *cis*-N_2F_2 (41, 42), *cis*-$(C_6H_5)_2N_2$ (43), and *cis*-$N_2O_2^{2-}$ (44). For all these compounds the corresponding *trans* isomers are found as well with grossly different vibrational absorption characteristics. This is clearly not the case for $S_2O_6F_2$, where the O—O bond is found to be very weak (6, 7).

Even though a clear distinction between configuration (*a*) and (*c*) by vibrational spectroscopy is feasible but rather difficult, only one torsion mode would be infrared (i.r.) active and Raman polarized for C_2 but i.r. inactive and Raman depolarized for C_{2v}, the transform (*b*) would have a center of symmetry with 3 modes only i.r. active and 3 modes only Raman active as postulated by the mutual exclusion rule and as found for *trans* difluorodiazine (45, 46). Inclusion of the SO_2F groups in the discussion will add a fourth likely structural possibility when both SO_2F groups are oriented in such a way that all symmetry is reduced to C_1. One would expect 24 polarized Raman and i.r. active modes. For point group C_2 all 24 modes would be Raman and i.r. active, but only 13 would be polarized. For C_{2h} 13 modes would be i.r. active and 12 Raman active with 8 polarized modes. And finally for C_{2v} one expects 19 i.r. active and 24 Raman active modes with 8 being polarized.

The vibrational spectra are listed in Table 2. Agreement with the previously reported gas phase infrared spectrum (1) is good. The following features are interesting. Strong vibrational coupling as observed for $S_2O_5F_2$ and other polysulfuryl halides appears to be absent here, because the SO_2F group bands are not split. The appearance of shoulders in the low temperature i.r. spectrum is not observable in the gas phase spectrum and may be considered as solid state splitting. The reason for the absence of coupling in $S_2O_6F_2$ can be seen in the rather weak oxygen–

For personal use only.

oxygen bond (6, 7), linking both SO_2F. Since seven individual vibrational modes can be assigned to this group, ν_{SO_2} symmetric and antisymmetric, V_{S-F}, SO_2 bend, SO_2 rock, SF wag, and a torsion mode, coincidence of these modes for the two SO_2F groups would reduce the number of observable bands from 24 to 17.

Assignment of the seven SO_2F modes shows good agreement with the corresponding bands for $FOSO_2F$. We assign the bands at 1500 and 1252 cm^{-1} as SO_2 stretches, 882 cm^{-1} as SF stretch slightly higher than found for $S_2O_5F_2$ (16), 602 cm^{-1} as SO_2 bending mode, 530 cm^{-1} as SO_2 rock 487 cm^{-1} as SF wag, and 397 cm^{-1} as torsional mode. Of these 3 are clearly polarized and 3 depolarized, the band 397 cm^{-1} is uncertain.

The region between 800 and 900 cm^{-1} shows a certain complexity. In addition to the mentioned SF stretch at 882 cm^{-1} the S—O stretch and the O—O stretch should occur in this region. In fact a very intense, polarized band at 801 cm^{-1} is found in the Raman spectrum with a very low depolarized ratio, assignable as ν_{O-O}. The position is slightly lower than found for the $S_2O_8^{2-}$ ion, where bands in the region of 834 to 810 cm^{-1} are observed depending on the cation type (17). In addition two more absorption bands are observed in this region, a weak shoulder in the Raman spectra at 845 cm^{-1} with a corresponding intense infrared band at 847 cm^{-1} and a Raman band at 827 cm^{-1} observable also in the infrared spectrum at 80 °K. We assign both bands as asymmetric and symmetric SO stretches. The gaseous infrared spectrum does not show this band, probably obscured by the strong 847 cm^{-1} absorption, but a weak band at 795 cm^{-1} becomes visible. This and the band at 878 cm^{-1} had been interpreted previously as P and R branches of the 847 cm^{-1} band (1). Since the 847 mode is not totally symmetrical and both the 878 and the 795 cm^{-1} are observable in the spectrum at 80 °K where typical P and R branches as the ones at 1350 and 1162 cm^{-1} have vanished, the previous assignment is improbable.

The band 795 cm^{-1} is now assigned as ν_{O-O}. The occurrence of this band in the infrared spectrum is in disagreement with the findings for the ions $S_2O_8^{2-}$ (17) and $P_2O_8^{4-}$ (37) and not consistent with the C_{2h} model.

As found for the SO stretches, some splitting seems to occur also for the SOO bending modes at 392 and 397 cm^{-1} and the SO wag at 441 and 435 cm^{-1}. The 397 cm^{-1} bands seem to coincide with the previously assigned torsional mode. As shown in Fig. 3 the bands are indeed rather broad.

The remaining bands are tentatively assigned as SOOS bend at 308 cm^{-1} and two torsional modes at 211 and 191 cm^{-1}. All are clearly polarized. It appears that of the 17 observed bands 8 are clearly polarized and 5 are clearly depolarized. The situation in the remaining four low intensity modes is uncertain. This fact already is inconsistent with point group C_1, where all modes would be polarized. The results are, however, most consistent with a staggered configuration (*c*). Furthermore, all Raman active bands appear also in the infrared spectrum down to 300 cm^{-1}. Beyond this region the resolution in the i.r. spectrum has become too poor.

In addition to the discussed infrared bands and some weak intensity combination bands, two strong absorptions are found in both the low temperature and the gas phase infrared spectrum. Both bands at 1030 and 748 cm^{-1} are without Raman counterparts, whereas the first one is undoubtedly due to a small SiF_4 impurity, the band at 748 cm^{-1} is difficult to explain. In spite of the relatively high intensity it is felt that this absorption band may not be due to a fundamental vibration, because no corresponding Raman band is found. One could, however, argue that a possibly weak and depolarized band in this region might be obscured by the intense band at 801 cm^{-1}, which is somewhat unlikely, considering the sharpness of this band as is evident in the figure. Even then only two possible interpretations of the 748 cm^{-1} absorption could be discussed: as S—O asymmetric stretch or as SO_2 rocking mode. The first possibility would imply that the symmetric SO stretch occurs at higher frequencies than the asymmetric one, in disagreement with findings for $S_2O_8^{2-}$. The second alternative is not very likely because in the spectra of $FOSO_2F$ and $ClOSO_2F$ no evidence for a deformation mode as high up as 750 cm^{-1} is found. The proposed assignment, favoring C_2 symmetry would imply that in the molecular fragment O—OSO_2F the O—O—S—F grouping would be planar otherwise the symmetry would be reduced to C_1. This is in fact identical to the

situation for HSO_3F and the halogen fluorosulfates where the X—O—S—F group was found to be planar.

It follows that $S_2O_6F_2$ and the halogenfluorosulfates are structurally related. The preference for the proposed structures could be seen in lone electron pair repulsion between lone pairs on different oxygen and halogen atoms as suggested for H_2O_2 (47, 48). This reasoning would favor a *trans* arrangement for halogenfluorosulfate rather than a *cis* one. It is hoped that future structural studies will confirm the suggested configurations.

Financial support from the National Research Council of Canada is gratefully acknowledged. We wish to thank Dr. R. D. Spratley and Mr. P. Tchir for their help in obtaining the low temperature infrared spectra and Mr. E. Matter for his help in building the metal manifold and metal reactors used in the preparation.

The Kinetics and Mechanism of the Chloride–Chlorate Reaction in Moderately Concentrated Solutions of $HClO_4$ and H_2SO_4 at 25 °C

P. Crisci and F. Lenzi

Département de génie chimique, École Polytechnique, Université de Montréal, Montréal, Québec

Received December 4, 1970

The stoichiometry and kinetics of the reaction

[1] $$2H^+ + ClO_3^- + Cl^- \rightarrow ClO_2 + \tfrac{1}{2}Cl_2 + H_2O$$

have been determined at 25 °C in 3.0 – 5.8 *M* $HClO_4$ and compare well with the results obtained in aqueous H_2SO_4. A mechanism involving a semi-ideal treatment of the dehydration equilibrium

$$H^+.4H_2O \rightleftarrows H^+.H_2O + 3H_2O$$

is consistent with the kinetic data in both media.

La stoechiométrie et la cinétique de la réaction

[1] $$2H^+ + ClO_3^- + Cl^- \rightarrow ClO_2 + \tfrac{1}{2}Cl_2 + H_2O$$

ont été déterminées à 25 °C pour des solutions de $HClO_4$ de 3.0–5.8 *M*; les résultats se comparent bien avec ceux obtenus dans H_2SO_4 aqueux. Un mécanisme impliquant un traitement semiidéal de l'équilibre de déshydratation:

$$H^+.4H_2O \rightleftarrows H^+.H_2O + 3H_2O$$

est consistant avec les données cinétiques dans les deux milieux.

Canadian Journal of Chemistry, 49, 2552 (1971)

Introduction

Reaction 1 has been postulated (1, 2) to be fundamental to reactions involving the reduction of chlorate to chlorine dioxide in moderately concentrated acid solutions. The stoichiometry and kinetics of reaction 1 in 2–6 *M* H_2SO_4 have been investigated previously (2–4). The stoichiometry was shown to be consistent with [1] if the chlorate:chloride ratio was greater than one (2, 3, 7, 9, 10).

The kinetic data (3, 4) showed that the rate of formation of ClO_2 was: (*a*) first order in chlorate towards high ($\simeq 5$ *M* H_2SO_4) acidities, changing to second order towards low ($\simeq 2$ *M* H_2SO_4) acidities, (*b*) second order in chloride throughout the acidity range, (*c*) 11–13th order in stoichiometric H_2SO_4, with the lower order at lower acidities.

Chlorine was found to have an inhibiting effect on the reaction (as opposed to chlorine dioxide), the effect being greater at lower acidities (3, 4).

The chlorate order had been found to be variable at any given low acidity (2). It was also noted that lithium, sodium, and potassium nitrates had a rate-enhancing effect in the order $Li^+ > Na^+ > K^+$; this was interpreted in terms of increasing hydration causing an increase in effective acidity (4).

The order with respect to chlorate at a fixed sodium ion concentration (the sum of the sodium nitrate and sodium chlorate concentrations being maintained constant) was accordingly redetermined and found (3) to be indeed constant at any given acidity, with values given in (*a*) above. This implied that in the early work (2) the simultaneous change of sodium concentration with that of chlorate had influenced the results, and indicates that for reactions occurring in such an acidity range (2–6 *M* H_2SO_4), specific ionic strength may be more important than general ionic strength.

Mechanism [2], [3] below was proposed (3)

[2] $$3H^+ + 2Cl^- + ClO_3^- \underset{k_2'}{\overset{k_2}{\rightleftarrows}} HClO_2 + Cl_2 + H_2O$$

[3] $$HClO_2 + H^+ + ClO_3^- \xrightarrow{k_3} 2ClO_2 + H_2O$$

which led to the rate expression

[4] $$\frac{d[ClO_2]}{dt} = \frac{2k_2k_3[H^+]^4[ClO_3^-]^2[Cl^-]^2}{k_2'[Cl_2]a_w + k_3[H^+][ClO_3^-]}$$

for large chlorate:chloride ratios, and thus ac-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

counted for the observed kinetics with respect to Cl^-, ClO_3^-, and chlorine.

It was suggested (4) that the equilibrium

$$[5] \qquad H^+.4H_2O \overset{K_5}{\rightleftarrows} H^+ + 4H_2O$$

would account for the very high (11–13) order with respect to stoichiometric H_2SO_4, as well as the rate enhancing effect of highly hydrated ions such as Li^+; substituting

$$[H^+] = K_5[H^+.4H_2O]/a_w^4$$

(see Appendix 1) in equation 4 gave

$$[6] \qquad \frac{d[ClO_2]}{dt} = \frac{2k_2k_3K_5^4[Cl^-]^2[ClO_3^-]^2[H^+.4H_2O]^4}{k_2'[Cl_2]a_w^{17} + k_3K_5[H^+.4H_2O][ClO_3^-]a_w^{12}}$$

which enabled the reaction order with respect to stoichiometric H_2SO_4 for the range 2.0–4.4 *M* to be calculated to be 11, in approximate agreement with experiment (4).

However, the existence of totally unhydrated protons even at relatively low concentration has been questioned.[1]

In order to confirm the above interpretation, which implies that the reaction rate is independent of the acid anion (except for its effect on the water activity term), it was decided to investigate the stoichiometry and kinetics of the chloride–chlorate reaction in aqueous perchloric acid, which is completely dissociated[2] to 6 *M* (6), and for which water activity values are available (12).

Experimental

Stoichiometry

The analytical methods used were those described previously (2, 7) except for the determination of Cl^- and ClO_3^-. Chloride was obtained gravimetrically as AgCl, and chlorate was reduced to chloride by Fe^{2+} which was again determined as AgCl according to the procedure given in Treadwell (8).

Kinetics

The experimental methods used were those described previously (3, 4) except that the "2-syringe method" of mixing the reactants was used exclusively.

Sodium ion concentration was maintained constant for the chlorate order runs at 2.50 and 3.83 *M* $HClO_4$ by adding varying amounts of sodium nitrate in such a way as to keep the sum of $NaNO_3$ and $NaClO_3$ equal to 1.400 *M* at 2.50 *M* $HClO_4$ and 0.625 *M* at 3.83 *M* $HClO_4$ for the reasons previously (3, 4) described.

[1]M. Lister. Private communication.

[2]Although H_2SO_4 is not completely dissociated it so happens that the ratio of H^+ to stoichiometric H_2SO_4 remains approximately constant at 1.3:1 over the range 2–6 *M* as shown by Young's Raman spectral results at 25 °C (5, 11). This enables the approximation [H^+ hydrated] $\simeq$ 1.3[stoichiometric H_2SO_4] to be made in section *Effect of Acidity* under Discussion.

Results

Stoichiometry

Chlorine balances were obtained to within 2% of total chlorine reacted. For 4.9 to 6.4 *M* $HClO_4$ and initial chlorate to chloride ratios of 4:1, the stoichiometry was consistent with

$$[1] \quad 2H^+ + ClO_3^- + Cl^- \rightarrow ClO_2 + \tfrac{1}{2}Cl_2 + H_2O$$

$$[7] \qquad 6H^+ + ClO_3^- + 5Cl^- \rightarrow 3Cl_2 + 3H_2O$$

the ratio of ClO_2:Cl_2 produced being 1.90 $\pm$ 0.06, implying that 99.4% of the chlorate reacted according to reaction 1. The ratio of ClO_2:Cl_2 diminished to 1.6 at acidities below 3 *M* $HClO_4$ for 4:1 initial ClO_3^-:Cl^- ratios, and also diminished to 1.7–1.8 (at 4.9 to 6.4 *M* $HClO_4$) for initial ClO_3^-:Cl^- ratios of 2.5:1 and 1:1.

These stoichiometric results are in accord with those obtained previously in H_2SO_4 and HCl (2, 3, 7, 9, 10): the ratio of ClO_2:Cl_2 obtained, and hence the relative amounts of chlorate reacting according to reactions 1 and 7, is determined by the ratio of ClO_3^- to Cl^- present in the reacting solution. The ratio of ClO_2:Cl_2 approaches 2 (*i.e.* 100% reaction 1) as the ratio of ClO_3^- to Cl^- increases to high values.

The results reported here for $HClO_4$ follow the same trend of increasing ClO_2:Cl_2 ratio as the ClO_3^-:Cl^- ratio increases; even at the lowest ClO_2:Cl_2 ratio of 1.6:1 obtained, 96% of the chlorate reacts according to reaction 1.

A ratio of ClO_3^-:Cl^- of 24:1 was accordingly used in this work for the main kinetic investigation of the effect of acidity (Fig. 6); in the previous work in H_2SO_4 (3, 4) reported in Fig. 8, the ratio used for the acidity effect experiments was 20:1.

The minimum chlorate:chloride ratio used was 1.7:1 at 4.47 and 2.42 *M* $HClO_4$ during the investigation of the order with respect to chloride

reported in Fig. 1. The second point in Fig. 1 is at a ClO_3^- to Cl^- ratio of 2.5:1 followed by a point at a 5:1 ratio. Figure 1 shows little change in kinetic regime with changing chlorate:chloride ratio, which was also the case for the experiments carried out in H_2SO_4 and reported in refs.

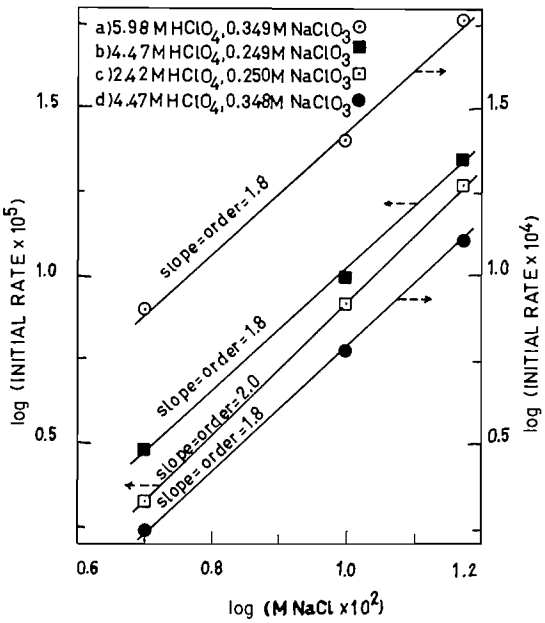

FIG. 1. Order w.r.t. chloride at different chlorate and acid concentrations.

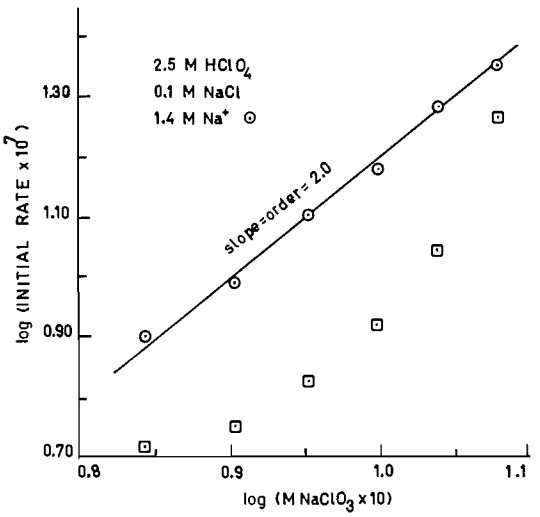

FIG. 2. Order w.r.t. chlorate at 2.5 *M* $HClO_4$, with Na^+ maintained at 1.4 *M* by the presence of varying amounts of $NaNO_3$. The squares represent rate values without the addition of $NaNO_3$.

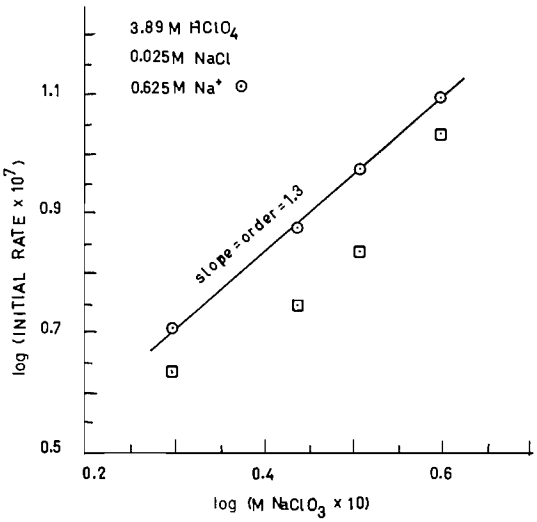

FIG. 3. Order w.r.t. chlorate at 3.89 *M* $HClO_4$, with Na^+ maintained at 0.625 *M* by the presence of varying amounts of $NaNO_3$. The squares represent rate values without the addition of $NaNO_3$.

2, 3, 7, and 9. Again Figs. 2, 3, and 4 show no discernible change in kinetic regimes with changing ClO_3^-:Cl^- ratios.

Kinetics

Initial rates of ClO_2 formation, which are a measure of reaction 1 only, are reported throughout in mol l^{-1} s^{-1}. Each point reported is the mean of the 3 or 4 initial rate measurements for a given set of experimental conditions; however, the results in Table 1 were calculated using individual points.

The deviations from the mean of each set of 3 or 4 initial rates were obtained. The maximum deviation from the mean for any such set was $\pm 10\%$ of the mean. The average maximum deviation from the mean over all the sets was $\pm 7\%$, the higher deviations occurring at the lower acidities, as was also the case for H_2SO_4 (3, 4).

The data are reported in Figs. 1–7.

(*a*) Results of the order with respect to chloride are shown in Fig. 1.

(*b*) Results of the order with respect to chlorate are shown in Figs. 2, 3, and 4.

(*c*) Results of the order with respect to $HClO_4$ are shown in Figs. 5 and 6. In Figs. 5, 6, and 8 the extremities of each vertical line representing a set of runs at each acidity correspond to the

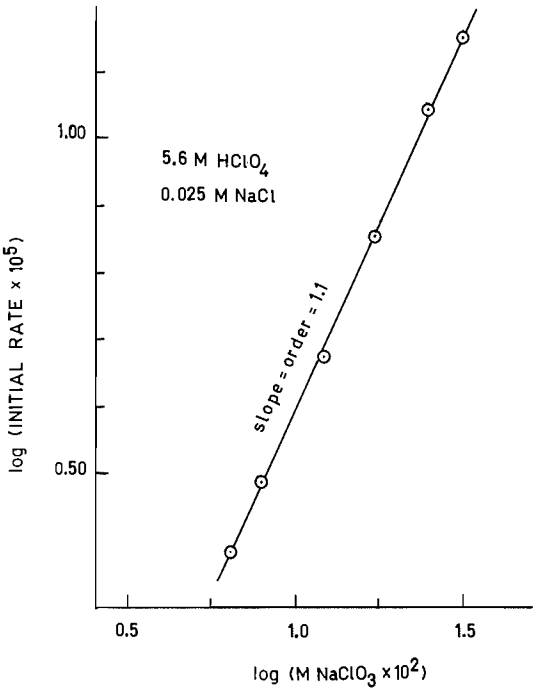

FIG. 4. Order w.r.t. chlorate at 5.6 *M* $HClO_4$. Na^+ was not maintained constant since even the maximum value (0.025 + 0.316 = 0.341 *M*) is small compared to 5.6 *M* in H^+.

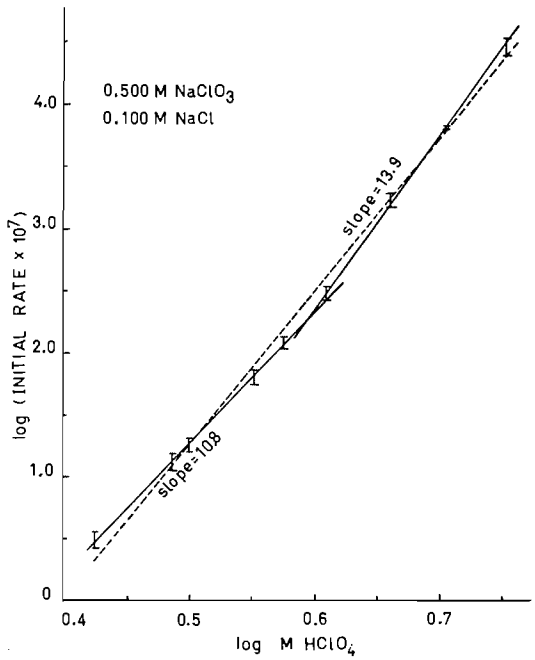

FIG. 5. The effect of stoichiometric $HClO_4$ for 0.500 *M* $NaClO_3$, 0.100 *M* NaCl. The straight lines are those calculated from the data by the 2 straight lines method (see Table 1).

maximum and minimum values of the initial rate of formation of ClO_2 obtained for the set.

(*d*) The effect of chlorine is shown indirectly in Fig. 7, where $1/(d[ClO_2]/dt)$ is plotted *vs.* $[ClO_2]$ at two different acidities. The diminishing slope of the actual experimental $[ClO_2]$ *vs.* time plots or the increase in reciprocal rates with $[ClO_2]$ shown in Fig. 7 cannot be ascribed to the time-diminishing concentration of the reactants, since only a small fraction of the initial chlorate and chloride will have reacted for the experimental conditions in question.

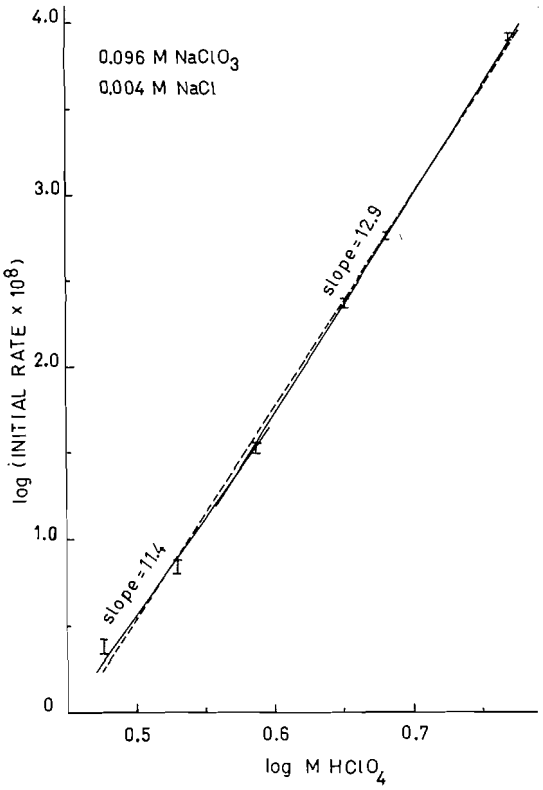

FIG. 6. The effect of stoichiometric $HClO_4$ for 0.096 *M* $NaClO_3$, 0.004 *M* NaCl. The straight lines are those calculated from the data by the 2 straight lines method (see Table 1).

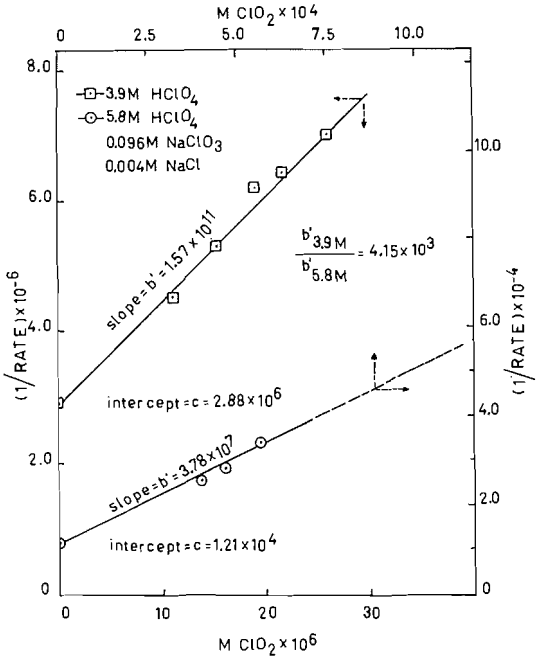

FIG. 7. The differential inhibiting effect of chlorine.

It has been shown (3) that in H_2SO_4 the ratio of ClO_2:Cl_2 is independent of time for the small chlorate conversion involved, and assuming this to be also true in $HClO_4$ (since both stoichiometric and kinetic results are similar in both media), the $[ClO_2]$ can be interpreted as being equivalent to $\alpha[Cl_2]$, where α is a constant over the conversion range, and $\simeq 2.0$ since the ratio of ClO_3^- to Cl^- used is 24:1.

Thus the linearity obtained in Fig. 7 shows that $1/(d[ClO_2]/dt)$ is of the form $b[Cl_2] + c$, there b and c are constants independent of Cl_2, which is consistent with rate equation 4 with respect to the effect of chlorine.

The ratio of the two slopes of Fig. 7 is 4.15×10^3 showing that the coefficient of the $[Cl_2]$ term in rate equation 4 (or rate equation 8 in Discussion section) is much higher at lower acidity. This supports the interpretation previously made for H_2SO_4 (4): that is, the differential inhibiting effect of chlorine with respect to

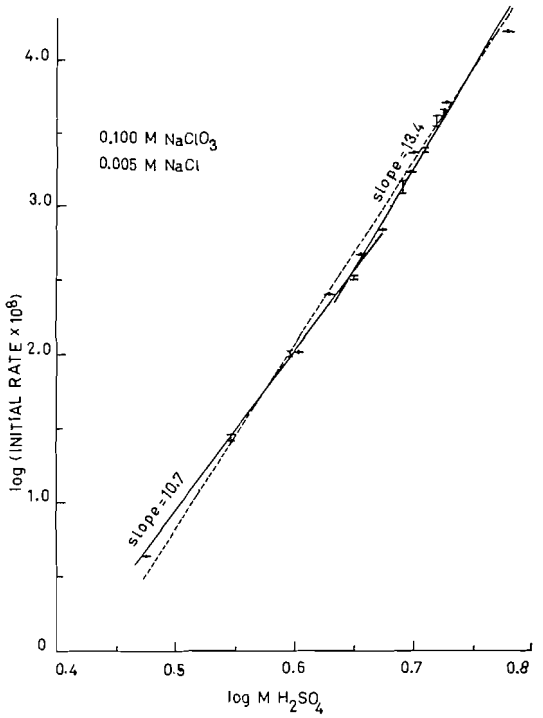

FIG. 8. The effect of stoichiometric H_2SO_4; experimental data from (3). The straight lines are those calculated from the data by the 2 straight lines method (see Table 1).

acidity is due to the presence of a higher power of water activity in the $[Cl_2]$ term of the denominator of the rate-equation than in the $[ClO_3^-]$ term.

Discussion

The orders with respect to Cl^-, ClO_3^-, and $HClO_4$ as well as the effect of chlorine are in good agreement with the data previously obtained for H_2SO_4 as reaction medium (see Introduction). This implies that the role of the acid anion is small, and substantiates mechanism [2], [3], and [4] as far as the effects of Cl^-, ClO_3^-, and Cl_2 are concerned.

The Effect of Acidity

Let

$$H^+.mH_2O \rightleftarrows H^+.(m-n)H_2O + nH_2O$$

be a general dehydration equilibrium with equilibrium constant (in mole fraction units)

$$K = \frac{[H^+.(m-n)H_2O]}{[H^+.mH_2O]} \times a_w^n$$

where $[H^+.(m-n)H_2O]$ and $[H^+.mH_2O]$ are concentrations in mol l^{-1} of solution.

This expression can be derived as in Appendix 1. The "minimum" or less radical assumption, that $f_{H^+(m-n)H_2O}/f_{H^+.mH_2O}$ is independent of concentration (as opposed to the more drastic assumption, $f_{H^+(m-n)H_2O}/f_{H^+.mH_2O} \simeq 1$) is difficult to prove or disprove except operationally, but it is no more radical than, for example, Bell and Bascombe's (13) assumption that $f_{BH^+} \simeq f_{H^+\text{ hydrated}}$.

On the assumption that K is small (that is, there is much more of the more hydrated than the less hydrated species in the experimental acidity range up to 5.8 M $HClO_4$), the stoichiometric acid molarity (or 1.3 × stoichiometric acid molarity in the case of H_2SO_4, see footnote 2) can be substituted for $[H^+.mH_2O]$, and supposing further that the less hydrated (and hence more reactive) species $H^+.(m-n)H_2O$ is the one that mainly participates in steps [2] and [3], rate equation 4 becomes

$$[8] \qquad \frac{d[ClO_2]}{dt} = \frac{2k_2k_3K^4[H^+.mH_2O]^4[Cl^-]^2[ClO_3^-]^2}{k_2'[Cl_2]a_w^{(3m+n+1)} + k_3K[H^+.mH_2O][ClO_3^-]a_w^{3n}}$$

Rate equation 8 is qualitatively consistent with the experimental order change with respect to chlorate from 2 at low acidity towards unity at high acidity, as well as the differential (with respect to acidity) inhibiting effect of chlorine.

At high acidity (where a_w is relatively small, $[H^+.mH_2O]$ is relatively large) the first term in the denominator of rate equation 8 may be small compared to the second term, as shown by the approximately first order in chlorate and reduced chlorine inhibiting effect. Thus at high acidity the reaction rate would depend on $[H^+.mH_2O]^3$ (*i.e.* the stoichiometric acid concentration to the 3rd power) as well as on a_w^{-3n}.

Similar considerations suggest that at low acidity (where a_w is relatively large, $[H^+.mH_2O]$ is relatively small) the second term in the denominator may be small compared to the first term, as shown by the approximately second order in chlorate and enhanced chlorine inhibiting effect. Thus at low acidity the reaction rate would depend on $[H^+.mH_2O]^4$ (*i.e.* the stoichiometric acid concentration to the 4th power) as well as on $a_w^{-(3m+n+1)}$.

A rigorously constant order with respect to stoichiometric concentration would not be expected from rate equation 8 for an extended experimental acid concentration range, since there would be an increasing contribution of the "ClO_3^-" or right hand side term in the denominator of [8] as the acidity increased. In fact, the points in Figs. 5, 6, and 8 appear to lie on curves showing slight slope increases with increasing acidity.

The rate data shown in Figs. 5, 6, and 8 can be correlated by single straight lines obtained by least squares. The sums of the squares of the deviations from these straight lines, together with the ranges of their slopes for a 95% degree of confidence, and linear correlation coefficients are given in Table 1. However, a consideration of the observation of increasing slope (or order) with increasing acidity suggests that a better fit might be obtained with a two straight line correlation.

This was achieved by calculating the sum of the squares of the deviations for all possible combinations of two straight lines and choosing as the best combination the one giving the least overall sum of the squares of the deviations.

These optimum combinations are also given in

$$[8a] \qquad \begin{pmatrix}\text{order}\\ \text{high acidity}\end{pmatrix} = \frac{\log \left[\frac{(M_{acid})_2}{(M_{acid})_1}\right]^3 \left[\frac{a_{w_1}}{a_{w_2}}\right]^{3n}}{\log \frac{(M_{acid})_2}{(M_{acid})_1}}$$

Table 1 (and plotted in Figs. 5, 6, and 8) and show appreciably smaller sums of squares of deviations than the corresponding single straight lines.

Although the direct verification of rate-expression [8] with respect to acidity changes is not feasible at this stage, it is possible to develop two approximate limiting forms, valid at high and low acidity, respectively, which can yield calculated values of the order with respect to stoichiometric H_2SO_4 or $HClO_4$.

At high acidity, when the right or "chlorate side" of the denominator of [8] predominates over the left or "chlorine side" (as indicated by the experimental order with respect to chlorate tending to unity and the reduced inhibiting effect of chlorine), a repeated application of [8] at two acidities, neglecting the Cl_2 side relative to the chlorate side of the denominator, will yield a calculated order with respect to stoichiometric acid between the two acidities.

Similarly at low acidities, neglecting the chlorate side relative to the chlorine side of the denominator of [8] (as indicated by the experimental order with respect to chlorate tending towards 2 and the enhanced inhibiting effect of chlorine), limiting order expression [8*b*] is obtained

$$[8b] \qquad \begin{pmatrix}\text{order}\\ \text{low acidity}\end{pmatrix} = \frac{\log \left[\frac{(M_{acid})_2}{(M_{acid})_1}\right]^4 \left[\frac{a_{w_1}}{a_{w_2}}\right]^{3m+n+1}}{\log \frac{(M_{acid})_2}{(M_{acid})_1}}$$

For eqs. 8*a* and 8*b* to be used to calculate orders (for different assumed values of n and n and m, respectively) for comparison with those experimentally determined, the latter have to be obtained from the rate data determined with $[ClO_3^-]$ and $[Cl^-]$ low enough relative to the acid concentration for the approximation $a_{w(\text{pure aqueous acid solution})} \simeq a_{w(\text{reacting solution})}$ to be valid.[3] This is probably so for the data of Fig. 6, where $M_{NaClO_3} = 0.096$ and $M_{NaCl} = 0.004\ M$ in $HClO_4$ of concentration 3.00 to 5.80 M, since by far the greatest contributor to the lowering of a_w from 1.00 to the actual value will be the 3.00 (or more) M acid compared to the 0.100 M total salt concentration. The cationic or Na^+ hydration is approximately half that of the proton (4), and this will probably lessen even further the dehydrating contribution of the salts relative to that of the acid, on the assumption that cationic hydration is relatively more important than anionic hydration.

[3]More accurately, it is the ratio of $(a_{w_1}/a_{w_2})_{(\text{pure aqueous acid solution})} \simeq (a_{w_1}/a_{w_2})_{(\text{reacting solution})}$ that is involved, and this for fairly close values of a_{w_1} and a_{w_2}, see Tables 2 and 3.

TABLE 2. Values of the order calculated from expression 8*a* at high acidity

Acid	n	Calculated order
$HClO_4$*	2	11.5
	3	15.7

H_2SO_4†	2	10.9
	3	14.8
	4	18.7
	5	22.7

*Figure 6; $M_1 = 4.81$, $M_2 = 5.80$; $a_{w1} = 0.630$, $a_{w2} = 0.484$; experimental order (two straight lines from Table 1) = 12.91 ± 0.28.
†Figure 8; $M_1 = 5.30$, $M_2 = 6.07$; $a_{w1} = 0.565$, $a_{w2} = 0.474$; experimental order (two straight lines from Table 1) = 13.44 ± 0.82.

Similar considerations apply to the data of Fig. 8, *i.e.* 0.100 M $NaClO_3$ and 0.005 M NaCl for a 3–6.1 M range of $[H_2SO_4]$, which is equivalent to a $3 \times 1.3 - 6.1 \times 1.3$ M range in H^+ (see footnote 2). Clearly the data of Fig. 5, where $NaClO_3$ was 0.500 M and NaCl was 0.100 M, are not suitable for comparisons of calculated and experimental orders, and are not included in Tables 2 and 3. However, the orders

*Figure 6; $M_1 = 3.00$, $M_2 = 3.52$; $a_{w1} = 0.828$, $a_{w2} = 0.777$; experimental order (two straight lines) from Table 1 = 11.42 ± 1.55.
†Figure 8; $M_1 = 3.00$, $M_2 = 3.75$; $a_{w1} = 0.824$, $a_{w2} = 0.742$; experimental order (two straight lines) from Table 1 = 10.67 ± 0.44.

obtained in Table 1 for the data of Fig. 5 afford some back-handed justification for the

$$a_{w\ (\text{pure aqueous acid solution})} = a_{w\ (\text{reacting solution})}$$

assumption. The "2-slope analyses" for the data of Fig. 5 and Fig. 6 give results in fairly close agreement, even though the ratio of acid to salt is much lower for the data of Fig. 5. The difference between 0.600 *M* and 0.100 *M* total salt concentration is much greater than that between the 0.1 *M* total salt for Fig. 6 and the ideal zero total salt concentration which would ensure a_w equality.

Values of a_w (12, 13) for the pure acid–water solutions have accordingly been used for Tables 2 and 3 which give a comparison of experimental orders (from Table 1) and those calculated using order expressions 8*a* and 8*b*.

Table 2 compares the experimental order at higher acidity as obtained from Table 1 with that calculated by eq. 8*a* using different values of *n*. Too large an acidity interval cannot be taken for the order calculation, since order expression 8*a* would become less valid as the $[Cl_2]$ term in the denominator of [8] becomes increasingly important as the acidity decreases. On the other hand, too small an acidity range cannot be taken since a reasonably large difference in a_w is required for a meaningful order calculation. Accordingly ranges a_{w_1} to $a_{w_2} = 0.630$ to 0.484 and 0.565 to 0.492 were chosen, respectively, for the $HClO_4$- and H_2SO_4-order calculations, each a_w range corresponding to one half the experimental a_w range from Table 1. The higher a_w's of the ranges correspond to 4.81 *M* $HClO_4$ and 5.30 *M* H_2SO_4 where the order with respect to chlorate is close to 1.1–1.2 (see Figs. 3, 4 and refs. 2, 3), indicating only slight Cl_2-term interference.

Order values calculated via expression 8*a* can be shown (Appendix 2) to be larger than the experimental order. Thus the results in Table 2 indicate that $n > 2$; that values of $n \geqslant 3$ are consistent with experiment, and that values of *n* much larger than 3 would appear to be increasingly improbable.

The acceptance of Lister's comment[1] on the relative improbability of the existence of the bare proton (even as an intermediate) in moderately concentrated acid solutions suggests that the probable reacting intermediate is H_3O^+; thus $m - n = 1$ and hence $m = 4$.

Table 3 compares experimental and calculated orders for different values of *n* and *m* for the lower acidity ranges. Calculated orders were obtained via expression 8*b* and half the experimental a_w ranges of Table 1. The model discrimination is not comparable to that of Table 2 because of the smaller a_w ranges on the one hand (larger a_w ranges would cause more uncertainty in the application of [8*b*] due to the increasing ClO_3^- term contribution), and larger experimental uncertainties on the other. The experimental uncertainties at the lower acidity are due to the low $[ClO_3^-]$ and $[Cl^-]$ imposed by the $a_{w(\text{reacting solution})} \simeq a_{w(\text{pure aqueous acid})}$ restraint. The results of Fig. 5 show better precision but the water activity approximation is less valid.

Table 3 shows that the lower acidity results for both acids are at least not inconsistent with the model $m = 4$, $n = 3$ suggested by the calculations of Table 2, and also confirms the coarser approach previously used (4).

Both hydrated species in the postulated equilibrium

$$[9] \qquad H_9O_4^+ \rightleftarrows H_3O^+ + 3H_2O$$

have previously been proposed (15). Although it would appear over-optimistic to infer that the tetra and mono hydrated proton species are the only ones present, it seems reasonable to conclude that equilibrium [9] treated semi-ideally can be of use in correlating the behavior of systems in moderately concentrated acid solutions when the a_w are known or can be approximated.

Verification

Rate equation 8 can be inverted to give

$$\frac{1}{\frac{d[ClO_2]}{dt}} = \frac{1}{r} = \frac{k_2'}{2k_2k_3K^4}\,\frac{a_w^{3m+n+1}}{M^4[Cl^-]^2[ClO_3^-]^2}\,[Cl_2] + \frac{a_w^{3n}}{2k_2K^3M^3[Cl^-]^2[ClO_3^-]}$$

where M is the stoichiometric acid molarity (for $HClO_4$).

For the low conversion experimental conditions of Fig. 7, all terms other than $[Cl_2]$ (and $[ClO_2]$) can be considered constant and equal to their original values at the start of the reaction. Using the relation $[ClO_2] = \alpha[Cl_2]$ established for H_2SO_4 (3), and taking $\alpha = 1.9$,

$$[8c] \qquad \frac{1}{r} = \frac{k_2'}{2k_2k_3K_4}\,\frac{a_w^{3m+n+1}[ClO_2]}{M^4[Cl^-]^2[ClO_3^-]^2 1.9} + \frac{a_w^{3n}}{2k_2K^3M^3[Cl^-]^2[ClO_3^-]}$$

which is the linear form

$$\frac{1}{r} = b'[ClO_2] + c$$

obtained in Fig. 7.

Comparing the theoretical and experimental inverse rate expressions yields that $b'_{(5.8\,M\,HClO_4)}$, the experimental slope from Fig. 7 for the results at 5.8 M $HClO_4$,

$$b'_{(5.8\,M\,HClO_4)} = 3.78 \times 10^7 = \frac{k_2' a_w^{3m+n+1}}{2k_2k_3K_4M^4[Cl^-]^2[ClO_3^-]^2 \times 1.9}$$

and intercept c

$$c_{(5.8\,M\,HClO_4)} = 1.21 \times 10^4 = \frac{a_w^{3n}}{2k_2K^3M^3[Cl^-]^2[ClO_3^-]}$$

Substituting the numerical values of $a_w = 0.484$ (14) (the water activity at 5.8 M $HClO_4$), $M = 5.8$, $[Cl^-] = 0.004\,M$, and $[ClO_3^-] = 0.096\,M$, corresponding to the experimental conditions for the results at 5.8 M $HClO_4$ reported in Fig. 7, the expressions for $b'_{(5.8\,M\,HClO_4)}$ and $c_{(5.8\,M\,HClO_4)}$ can be solved for $k_2'/2k_2k_3K$ and $1/2k_2K^3$ for different ascribed values of n and m. The values calculated for these constants are given in Table 4 for different combinations of values of n and m.

TABLE 4. Calculations of the grouped constants from the rate data at 5.8 M $HClO_4$ in Fig. 7

	$\frac{k_2'}{2k_2k_3K^4} \times 10^{-9}$	$\frac{1}{2k_2K^3} \times 10^{-3}$
$m = 3, n = 3$	0.159	2.46
$m = 4, n = 3$	1.42	2.46
$m = 4, n = 4$	2.64	22.4
$m = 5, n = 3$	12.1	2.46
$m = 5, n = 4$	25.2	22.4

The values of $k_2'/2k_2k_3K^4$ and $1/2k_2K^3$ in Table 4 can now be used to calculate otherwise *ab initio* reciprocal rates from eq. 8*c* for different combinations of values of n and m.

Reciprocal rates at different values of ClO_2 are available at 3.9 M $HClO_4$ (Fig. 7). These are compared to different values of calculated reciprocal rates in Table 5.

The best integral combination of n and m is verified to be $m = 4$, $n = 3$, although slightly higher values of both parameters would improve the agreement.

Finally, the two terms in the denominator of [8] can be compared at different acidities for a given $[Cl_2] = 10^{-5}$ M/l using the values of $k_2'/2k_2k_3K$ and $1/2k_2K^3$ of Table 4 for model $m = 4$, $n = 3$. This is done in Table 6 where the value of $R = k_2'a_w^{16}[Cl_2]/k_3KM[ClO_3^-]a_w^9$ is compared at high (5.8 M $HClO_4$), intermediate (3.9 M $HClO_4$), and low (2.5 M $HClO_4$) acidities from the point of view of the differential inhibiting effect of chlorine. Table 6 verifies that the model $m = 4$, $n = 3$ conforms with the observation that the inhibiting effect of chlorine is high at low acidities, and conversely.

TABLE 5. Comparison of calculated and experimental values of $1/r$ at 3.9 M $HClO_4$

		$(1/r)_{calcd.} \times 10^{-6}$ (1 s/M)

Appendix 1

On the Activity Coefficients of the more Hydrated and less Hydrated Species

$$H^+.4H_2O \overset{K_5}{\rightleftharpoons} H^+ + 4H_2O$$

K_5, the equilibrium constant in mole fraction units, is given by

$$K_5 = \frac{f_{H^+} x_{H^+} a_w^4}{f_{H^+.4H_2O} x_{H^+.4H_2O}}$$

$$= \frac{f_{H^+} \frac{n_{H^+}}{n_t} a_w^4}{f_{H^+.4H_2O} \frac{n_{H^+.4H_2O}}{n_t}}$$

$$= \frac{f_{H^+}}{f_{H^+.4H_2O}} \frac{n_{H^+}}{n_{H^+.4H_2O}} a_w^4$$

where the f's are the activity coefficients on the mole fraction scale, the x's are the mole fractions, a_w is the water activity of the solution, n_{H^+}, $n_{H^+.4H_2O}$, and n_t are the number of moles of H^+, $H^+.4H_2O$, and the total number of moles present, respectively.

The "maximum" assumption would be that $f_{H^+} \simeq f_{H^+.4H_2O}$; since non-idealities due to Debye–Hückel effects, overall hydration effects and change of water structure effects would already be accounted for in the a_w term, and individual ionic hydration effects would be accounted for by equilibrium [5] itself.

Alternatively, the less radical assumption that $f_{H^+}/f_{H^+.4H_2O} = p$, where p is independent of concentration, will give the expression

$$K_5' = \frac{K_5}{p} = \frac{n_{H^+}}{n_{H^+.4H_2O}} a_w^4$$

whence for 1 l of solution

$$K_5 \text{ or } K_5' = \frac{\text{moles (per litre) of } H^+}{\text{moles (per litre) of } H^+.4H_2O} \times a_w^4$$

and thus

$$[H^+] = K_5 \text{ (or } K_5') \frac{[H^+.4H_2O]}{a_w^4}$$

Appendix 2

On the Comparison Between Calculated and Experimental Orders in Table 2

Let the rate of reaction 1 (at an acid concentration sufficiently high for eq. 8 to hold with no appreciable Cl_2 term contribution) be represented by point *2* in Fig. 9 (a Van't Hoff plot). Let the experimental rate at some lower acidity M_1 be represented by point *1*. The experimental order will be given by the slope of the line *1–2* in Fig. 9.

The rate at acidity M_1 can be calculated using the "no-Cl_2" form of rate expression 8;

$$r_{calcd. \text{ at } M_1} = \frac{2k_2K^3[Cl^-]^2[ClO_3^-]M^3}{a_w^{3n}}$$

Now

$$r_{exp. \text{ at } M_1} = \frac{2k_2K^3[Cl^-]^2[ClO_3^-]M^{3+\delta}}{a_w^{3n+\varepsilon}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

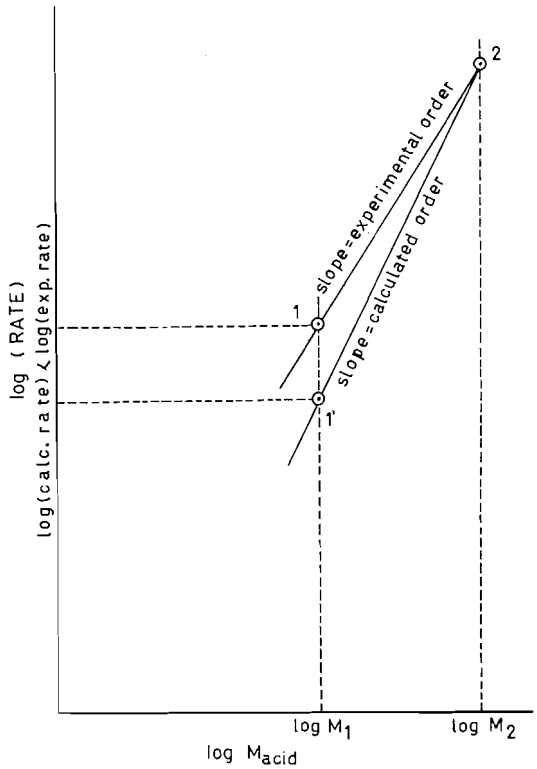

FIG. 9. Comparison of calculated and experimental orders at high acidity.

where δ and ε are positive numbers representing lumped corrections due to the contribution of the Cl_2 term in the denominator of [8]; since $M > 1$ and $a_w < 1$, the numerator in $r_{exp.} >$ numerator in $r_{calcd.}$ and the denominator in $r_{exp.} <$ denominator in $r_{calcd.}$, leading to the result that $r_{exp.} > r_{calcd.}$.

Thus the point *1'* in Fig. 9 representing the calculated rate at M_1 will be lower than the experimental rate represented by point *1*.

Hence the slope of *1'–2* will be greater than the slope of *1–2*, *i.e.* the calculated order will be higher than that determined experimentally.

The authors wish to thank Professor M. Lister for his comment on $H^+.H_2O$ and H^+, Mr. P. Krick for carrying out the experiments on the stoichiometry, and the National Research Council of Canada for operating grant A-4520.

The Influence of Heteroatom-substituted Methyl Groups and of Vinyl Groups (CR_2=CR—) Attached to C-2 of 1,3-Dioxolanes on the Ease and Direction of Hydrogenolysis of the 1,3-Dioxolanes by AlH_2Cl, AlH_3, or $LiAlH_4$[1]

H. A. Davis and R. K. Brown

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received March 26, 1971

Heteroatom substituents on the methyl group of 2-methyl-1,3-dioxolane retard the rate of hydrogenolysis by AlH_2Cl of ether solutions of the 2-substituted 1,3-dioxolanes. The effectiveness of the heteroatoms in decreasing the ease of hydrogenolysis is H < S < O < Br < NR_2. This retardation is thought to be due to the destabilization of the transition state leading to the intermediate oxocarbonium ion, caused by the electronegativity of the heteroatom and/or coordination of some of the AlH_2Cl with the heteroatom.

AlH_2Cl or AlH_3 in diethyl ether at room temperature reduces 2-vinyl- or 2-[alkyl (or aryl) substituted vinyl]-1,3-dioxolanes to only the β,γ-unsaturated alkyl β-hydroxyethyl ether, the product expected from hydride ion addition to C-2 of the 1,3-dioxolane. The ease of hydrogenolysis increases with increasing alkyl (or aryl) substitution on the 2-vinyl group.

$LiAlH_4$ in diethyl ether at room temperature, or in di-*n*-propyl ether or 1,2-dimethoxyethane (DME) at room temperature or reflux temperature, reduces 2-vinyl-1,3-dioxolane only to α-propenyl β-hydroxyethyl ether. This product is the result of hydride addition to the β-carbon of the vinyl group accompanied by ring opening and double bond migration. Alkyl substituents attached to the vinyl group of 2-vinyl-1,3-dioxolane markedly retard the rate of hydrogenolysis by $LiAlH_4$ in the dialkyl ethers at room temperature, but at the reflux temperature (90°) of di-*n*-propyl ether the 2-alkylated vinyl-1,3-dioxolanes are hydrogenolyzed, but only to the β,γ-unsaturated alkyl β-hydroxyethyl ether. In refluxing DME (80°) the 2-alkylated vinyl-1,3-dioxolanes give primarily, if not exclusively, the α,β-unsaturated alkyl β-hydroxyethyl ether. A rationale is suggested to account for these results.

$LiAlH_4$ in diethyl ether reduces 2-styryl-1,3-dioxolane only to β-phenylethyl-1,3-dioxolane, by hydride addition to the olefinic carbon β to the phenyl group.

Les substituants hétéroatomiques situés sur le groupe méthyle du méthyl-2 dioxolane-1,3 ralentissent la vitesse d'hydrogénolyse par AlH_2Cl des solutions éthérées des dioxolanes-1,3 substitués en 2. L'efficacité des hétéroatomes dans la diminution de la facilité d'hydrogénolyse est H < S < O < Br < NR_2. On pense que ce ralentissement est du à la déstabilisation de l'état de transition qui conduit à l'ion oxocarbonium intermédiaire à cause de l'électronégativité de l'hétéroatome et/ou de la coordination d'une certaine quantité de AlH_2Cl avec l'hétéroatome.

AlH_2Cl ou AlH_3 dans l'éther diéthylique réduit quantitativement à la température ordinaire les vinyl-2 ou les vinyl-2 [substitués par un groupe alkyle (ou aryle)] dioxolanes-1,3 en alkyl β,γ-insaturé β-hydroxyéthyl éther qui est le produit attendu lors de l'addition d'un ion hydrure sur le C-2 d'un dioxolane-1,3. La facilité de l'hydrogénolyse croît avec l'augmentation de la substitution par un groupe alkyle (ou aryle) sur le groupe vinyle en position 2.

$LiAlH_4$ dans l'éther diéthylique à la température ordinaire, ou dans l'éther di-*n*-propylique ou dans le diméthoxy-1,2 éthane (DME) à la température ordinaire ou au reflux du solvant, réduit le vinyl-2 dioxolane-1,3 quantitativement en α-propenyl β-hydroxyéthyl éther, le produit se forme par suite de l'addition de l'hydrure sur le carbon en β du groupe vinyle suivie d'une ouverture de cycle et d'une migration de la double liaison. Les substituants alkylés sur le groupe vinyle des vinyl-2 dioxolanes-1,3 ralentissent de façon notable la vitesse d'hydrogénolyse par $LiAlH_4$ dans les dialkyl éthers à la température ordinaire mais, à la température de reflux (90°) de l'éther di-*n*-propylique, les vinyl-2 [substitués par un groupe alkyle] dioxolanes-1,3 subissent l'hydrogénolyse pour donner uniquement l'alkyl β,γ-insaturé β-hydroxyéthyl éther. Au reflux du DME (80°), les vinyl-2 [substitués par un groupe alkyle] dioxolanes-1,3 donnent d'abord, sinon exclusivement, l'alkyl α,β-insaturé β-hydroxyéthyl éther. On propose un raisonnement pour rendre compte de ces résultats.

$LiAlH_4$ dans l'éther diéthylique réduit le styryl-2 dioxolane-1,3 seulement en β-phényléthyl dioxolane-1,3 par addition de l'hydrure sur le carbone olifinique en β du groupe phényle.

Introduction

It has been shown that substituents on C-2 of the 1,3-dioxolane ring have a much greater effect on the rate of reductive cleavage by "mixed hydride" reagents ($LiAlH_4$ + $AlCl_3$) than do the same substituents situated on any other ring carbon atom (1). Electron donor substituents (R = methyl or phenyl in Scheme 1) attached to C-2 accelerate the cleavage by stabilization of the transition state leading to the formation of the intermediate oxocarbonium ion, the step which is considered to be rate determining (1–4), whereas electron-withdrawing groups (chloromethyl, dichloromethyl) attached to C-2 retard the reductive cleavage.

This paper describes the effect of a number of C-2 substituents which could participate in the stabilization of the transition state leading to the formation of such an oxocarbonium ion intermediate, either by electromeric or anchimeric assistance and thus accelerate the rate of hydrogenolysis of the 1,3-dioxolane ring.

Results and Discussion

Hydrogenolysis with AlH_2Cl or AlH_3 was done by first preparing the reducing species in ether solution by mixture of the appropriate amounts of $AlCl_3$ and $LiAlH_4$ (5) followed by the addition of the 1,3-dioxolane. Competitive reductions were made by the addition of an equimolar mixture of the two 1,3-dioxolanes to an ether solution of AlH_2Cl or AlH_3 sufficient to reduce only half of the mixture of dioxolanes. Recoveries of starting material and products were generally 80–95%. Reduction products were stable under the conditions of the reaction as had been found previously (1). Analyses of the products were made by comparison of the g.l.c. retention times with those of known samples, or by isolation and characterization of the product(s) whenever there was any doubt as to identity. The relative peak areas in the g.l.c. were used directly as quantitative measures of the products since it had been found that these differed in detector response at the most by only 10%, and in the great majority of cases by less than 5%. This practice was considered reasonable since the differences in relative amounts of products obtained were generally much greater than 10%. For those few cases in which the differences in proportion of products were small and considered to be significant, the difference in detector response was taken into consideration.

Hydrogenolysis with AlH_2Cl or AlH_3

(i) 2-Methyl-1,3-dioxolanes Containing a Heteroatom Attached to the C-2 Methyl Group

It is known that certain atoms, suitably situated in a molecule, can enhance the rate of a reaction by anchimeric assistance in the rate controlling step (6, 7). In order to determine if this phenomenon could occur in the hydrogenolysis of acetals, several 2-methyl-1,3-dioxolanes were prepared, containing a heteroatom directly attached to the C-2 methyl group. The heteroatoms chosen were O, S, Br, and N, atoms considered to be capable of providing anchimeric assistance and also able to survive under the reaction conditions. These α-substituted 1,3-dioxolanes were hydrogenolized with AlH_2Cl in ether solution at room temperature. The results are shown in Table 1.

It is seen that the replacement of a hydrogen atom on the methyl group of 2-methyl-1,3-dioxolane by a heteroatom *retards* the hydrogenolysis, the order of decreasing rate of reaction

*Complete reduction occurred well within 30 min.
†This recovery could not be improved.

being H > S > O > Br > NR_2. This rate reduction could be due to the following causes either separately or in combination. (*a*) The electronegativity of the heteroatom decreases the ability of the methyl group to stabilize the transition state leading to the intermediate oxocarbonium ion. (*b*) The association of some of the reducing agent (a Lewis acid) with the heteroatom, thus increasing the electron-withdrawing power of the heteroatom. (*c*) The association suggested in (*b*) would decrease the effective concentration of the AlH_2Cl. A similar effect due to O and S substituents on the rate of hydrolysis of diethylacetals of substituted acetaldehyde has been noted by Speck *et al.* (8). They found the rate of hydrolysis of the diethylacetals of the following aldehydes to be acetaldehyde ≫ methylthioacetaldehyde > methoxyacetaldehyde, and attributed this to the electronegativity of the substituent which caused destabilization of the intermediate carbonium ion. The greater retardation for the methoxy- compared to the methylthioacetaldehyde diethylacetal was considered to be due to the greater degree of protonation of the oxygen analogue. The apparently greater degree of association of protons or of Lewis acids with the heteroatom of oxygen ethers compared to sulfur ethers has been noted previously (9 and references therein). The results shown in Table 1 are corroborated by the competitive hydrogenolysis of these compounds with a limited amount of AlH_2Cl. These are shown in Table 2.

TABLE 2. Relative rates of room temperature hydrogenolysis by AlH_2Cl in ether of some 2-methyl-1,3-dioxolanes containing a heteroatom attached to the C-2 methyl group

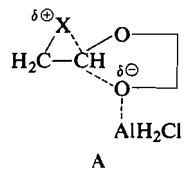
CH_3OCH_2—	0.02
$BrCH_2$—	<0.02

The data in Tables 1 and 2 indicate that anchimeric assistance by formation of the cyclic "onium" species (structure **A**) is insignificant and actually may not occur. If it does, it is well submerged by effects resulting in retardation of the reaction.



A

(ii) 1,3-Dioxolanes Containing a Vinyl or Phenyl Group Attached to C-2

Hydrogenolysis of 2-phenyl-1,3-dioxolane with a 1:1 molar ratio of $LiAlH_4$ and $AlCl_3$ has been reported to proceed more rapidly than does similar reduction of 2-methyl-1,3-dioxolane (1), presumably because of the greater degree of stabilization of the intermediate oxocarbonium ion by the phenyl substituent than by the methyl group at C-2. We were interested in determining whether similar stabilization would be offered by the double bond of α,β-unsaturated aldehyde ethyleneacetals (2-vinyl- or 2-substituted vinyl-1,3-dioxolanes). Accordingly a number of such acetals in ether were hydrogenolyzed at room temperature first separately with AlH_2Cl to determine the product(s) which could be obtained, and then competitively with a limited amount of AlH_3 to discover the relative ease of hydrogenoly-

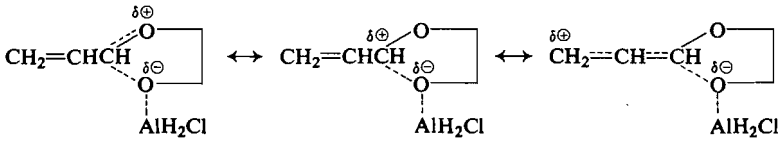

SCHEME 2

sis. The reason for using AlH_3 for the competitive reactions was that the rate of reduction is slower with AlH_3 than with AlH_2Cl (5) and this *might* permit selectivity in rates of reduction to be better perceived. Furthermore it had already been established both in the present work and in that reported previously (5), that the same products are obtained from hydrogenolysis of 1,3-dioxolanes by AlH_3 as by AlH_2Cl. The results are shown in Tables 3 and 4 respectively.

The results in Tables 3 and 4 show that in each case only one and the same product is obtained, in nearly quantitative yield, using either of the two reducing agents, and that this product is the one resulting from hydride addition to the methine carbon (C-2) of the 1,3-dioxolane ring to give the β,γ-unsaturated ether. No evidence was obtained for the formation, even in small amount, of the product resulting from addition of the hydride ion to the β carbon of the vinyl substituent attached to C-2, to give the α,β-unsaturated ether resulting from double bond migration and 1,3-dioxolane ring opening. The exclusive formation of the β,γ-unsaturated ether may be due to the overwhelming predominance of the more stable carbonium ion, that stabilized by both the adjacent oxygen atoms and the allylic system (Scheme 2). The complete absence of the α,β-unsaturated ether supports the view that not only is there the marked predominance of the more stable carbonium ion resulting from considerable C—O bond stretching due to the effect of the Lewis acid, but also that hydride addition to C-2 of the ring might well occur by a four-center transition state (structure **B**).

Hydrogenolysis with $LiAlH_4$

Acetals and ketals are reported to be stable to $LiAlH_4$ in ether solution, and this permits the protection of carbonyl groups of ketones and aldehydes during hydride reduction of other functional groups in the molecule (10). However, the addition of a Lewis acid such as $AlCl_3$ to the $LiAlH_4$ reduction system does permit the hydrogenolysis of dialkylacetals and ketals to simple ethers (11, 12) and of cyclic acetals and ketals (1,3-dioxolanes and 1,3-dioxanes) to β-hydroxyethers (1–4, 9, 13, 14). Since electron donor substituents at C-2 of the 1,3-dioxolane ring greatly increase the ease of hydrogenolysis of one of the C—O bonds (1) by "mixed hydride" ($AlCl_3$ + $LiAlH_4$) (5, 15) the possibility was explored as to whether a Lewis acid such as $AlCl_3$ was necessary for the hydrogenolysis of these more active acetals and whether $LiAlH_4$ alone in ether would be sufficient. Accordingly, several 1,3-dioxolanes containing a vinyl or aryl substituent at C-2 were hydrogenolyzed with $LiAlH_4$, first in diethyl ether at room temperature (Table 5), then in refluxing (80°) 1,2-dimethoxyethane (DME) (Table 6), and finally in refluxing (90°) di-*n*-propyl ether (Table 7).

It is seen that $LiAlH_4$ in diethyl ether at room temperature does hydrogenolyze acrolein ethyleneacetal (2-vinyl-1,3-dioxolane) slowly (32 and 76% in 24 and 48 h respectively) by ring opening and simultaneous double bond migration to form the α,β-unsaturated ether, β-hydroxyethyl α-propenyl ether (experiment 1, Table 5). In di-*n*-propyl ether, $LiAlH_4$ converted 2-vinyl-1,3-dioxolane to the same α,β-unsaturated ether to the extent of 70% in 24 h at 25°, and completely in 2 h at 90° (experiments 1*a* and *b*, Table 7). In DME, $LiAlH_4$ reduced 2-vinyl-1,3-dioxolane also to the α,β-unsaturated ether completely at 80° in 24 h, but barely at all at room temperature in 24 h. In none of these solvents was there any evidence for the formation of the alternate reduction product, the β,γ-unsaturated ether, allyl β-hydroxyethyl ether, the product from direct hydride addition to the methine carbon (C-2) of the 1,3-dioxolane ring.

The 2-vinyl-1,3-dioxolanes possessing one or more alkyl substituents attached to the vinyl moiety, failed to react at all with $LiAlH_4$ at room temperature (or at 25°) in diethyl ether (experiments 2*a–d*, Table 5) or in di-*n*-propyl ether (experiments 2*a–c*, Table 7). However at 90° in di-*n*-propyl ether they were reduced completely within 12 h but only to the β,γ-unsaturated ether, the product expected from ring cleavage and hydride ion addition to the methine carbon (experiments 3–5, Table 7). In DME at 80°, $LiAlH_4$ also hydrogenolyzed the 2-alkylvinyl-1,3-dioxolanes, though more slowly than in di-*n*-propyl ether, but the product in all but one case was primarily, if not totally, the α,β-unsaturated ether, accompanied by 0–6% of the β,γ-unsaturated ether (experiments 2–4, Table 6). The exception was β-methylcrotonaldehyde ethyleneacetal from which the proportion of the β,γ- to α,β-unsaturated ether obtained was ~2:1 (experiment 5, Table 6).

The remarkable difference in the type of product obtained from $LiAlH_4$ hydrogenolysis of these 2-alkylvinyl-1,3-dioxolanes in DME on the one hand and in the dialkyl ethers on the other, is interesting. Those obtained in the dialkyl ether (except for the product obtained from the parent compound 2-vinyl-1,3-dioxolane) are the β,γ-unsaturated ethers which must arise from C_2—O_1 bond breaking and hydride addition to C-2 (*cf.* Scheme 1) as has been observed for the hydrogenolysis of 1,3-dioxolanes by the Lewis acid species AlH_2Cl and AlH_3 (1, 5, and Table 3 of the present work). In DME, hydride ion addition occurs at the olefinic carbon atom remote from the methine carbon, with consequent, or simultaneous, cleavage of the C_2—O_1 bond of the ring and migration of the double bond to the α,β position. The similarity of the hydrogenolysis products obtained in di-*n*-propyl ether with $LiAlH_4$ to those obtained by AlH_2Cl in diethyl ether suggests the participation of a species which can associate with the oxygen atom of the 1,3-dioxolane ring and thus promote C_2—O_1 bond stretching to develop carbonium ion character at C-2 which then would lead to hydride addition at C-2.

The increase in reducing ability of $LiAlH_4$ in DME compared with that in diethyl ether has been ascribed to the greater cation solvating ability of the DME (16). The lower ability of di-*n*-propyl ether to solvate the Li cation, would thus allow $Li^{\oplus}$ to associate to a greater extent with an oxygen atom of the dioxolane. Not only would $Li^{\oplus}$ thus promote C_2—O_1 bond stretching, but the $AlH_4^{\ominus}$ ion would remain in the vicinity of the associated $Li^{\oplus}$ and thus be in a good position to transfer a hydride ion to C-2 (Scheme 3). In DME, the $Li^{\oplus}$ cation is highly solvated by the diether (structure **C**) thus decreasing the extent to which $Li^{\oplus}$ associates with the dioxolane.

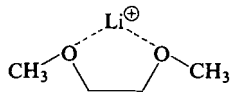
The $AlH_4^{\ominus}$ thus "liberated" cannot easily approach C-2 of the dioxolane ring because of the repulsion due to the partial negative charge on the oxygen atom(s) of the ring. The alternative position of attack by $AlH_4^{\ominus}$ is at the β carbon of



C

the vinyl group, since the latter will be polarized by the electronegative oxygen atoms of the dioxolane ring. This would lead to simultaneous double bond migration and ring cleavage to produce the α,β-unsaturated ether (Scheme 4). Alkyl groups (R) attached to the vinyl moiety would delocalize the partial positive charge developed on the vinyl group and hence attack by $AlH_4^{\ominus}$ on the vinyl moiety would be more difficult (*cf.* Table 6). *Two* alkyl groups on the β carbon of the vinyl substituent would favor electron-donation towards the ring to allow sufficient C_2—O_1 bond stretching to cause $AlH_4^{\ominus}$ to attack C-2 and produce the β,γ-unsaturated ether in greater proportion (Experiment 5, Table 6).

It is significant that in both solvents used, the dialkyl ether or DME, $LiAlH_4$ reduces the parent compound, 2-vinyl-1,3-dioxolane, only to the α,β-unsaturated ether (experiment 1 in Tables 5–7). This must mean that $LiAlH_4$ prefers attack at the β carbon of the vinyl group, and that alkyl substituents attached to the vinyl unit have a pronounced effect in changing the course of reaction. It is possible that a steric effect of these alkyl substituents plays a part by reducing the ease of approach by $AlH_4^{\ominus}$ or $LiAlH_4$ to the β carbon of the vinyl group. However, models show that there is ample room for such approach, and this is corroborated by the fact that the methyl group on the α carbon of the vinyl moiety completely inhibits hydride addition to the β carbon (experiment 3, Table 6) even though the β carbon is sterically as accessible as it is in 2-vinyl-1,3-dioxolane.[3]

A final point of interest is the reduction of only the double bond of cinnamaldehyde ethyleneacetal by $LiAlH_4$ in diethyl ether at room temperature (experiments 5–7, Table 5). Olefinic double bonds normally are not reduced by $LiAlH_4$, although a few cases of such reduction have been reported. For example the double bond of α,β-unsaturated carbonyl compounds has been reduced by $LiAlH_4$ (17, 18) and allyl alcohol has been reduced to *n*-propyl alcohol (19) while ω-nitro styrene is converted to β-phenylethylamine (20). It is clear from the deuteration experiments (experiments 6 and 7, Table 5) that $LiAlH_4$ attacks the olefinic carbon atom β to the phenyl ring, and this occurs very likely because the formation of a negative charge on the carbon α to the phenyl ring is more easily accomplished than it is on the carbon α to the dioxolane ring.

Experimental

Boiling points and melting points are uncorrected. The g.l.c. analyses were made with an F and M Model 700 instrument, equipped with 12′ × 1/8″ columns packed with either butanediol succinate, 20% on Gas-Chrom P (60–80 mesh) or silicone rubber SE30, 20% on Gas-Chrom P(60–80 mesh). Helium was the carrier gas at a flow rate of about 40 ml/min. For preparative g.l.c., an Aerograph Autoprep, Model A-700 (Wilkins Instrument and Research Co.) was employed, with a 12′ × 1/4″ column packed with butanediol succinate, 20% on Gas-Chrom P (60–80 mesh). Helium was the carrier gas. The column temperature and type of column used was dependent upon the boiling points of the compounds. For some analytical work on the F and M Model 700, the temperature was linearly programmed to achieve better resolution. The temperature was increased at the rate of 7.5°/min, starting from 80–100°, with the terminal temperature determined by the column stability. Quantitative analyses were made by measuring the areas of the peaks corresponding to the compounds obtained. In most cases, these areas were compared with those obtained from

[2]The AlH_3 so liberated could also reduce the 2-vinyl-1,3-dioxolane as shown in Tables 3 and 4.

[3]One of the referees has suggested that the reason why acrolein ethyleneacetal hydrogenolyzes only to the α,β-unsaturated ether is that it is less sterically encumbered than all the other α,β-unsaturated acetals employed. Only when the steric requirements increase does there occur a delicate balance between steric requirements and solvent effects.

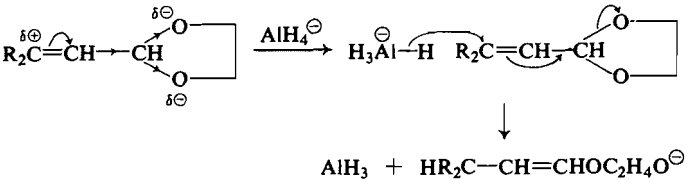

SCHEME 4

known and weighed artificial mixtures, and it was found that equimolar mixtures gave peaks whose areas differed by less than 5%. In a few cases the error was somewhat greater, but within 10%.

The i.r. spectra were recorded with a Perkin–Elmer Model 21 instrument.

The p.m.r. spectra were recorded on either a Varian Associates A-60 or A-55/60A instrument by Mr. R. Swindlehurst and assistants in this Department. All spectra were referred to tetramethylsilane.

The p.m.r. and i.r. spectra were obtained for all compounds and in all cases were consistent with the structure assigned.

Elemental analyses were made by Mrs. D. Mahlow of this Department.

The drying agent for solutions was anhydrous magnesium sulfate unless otherwise stated. Solvents were removed by rotary evaporator under reduced pressure unless otherwise stated.

Preparation of Substituted 1,3-Dioxolanes

2-Methyl-1,3-dioxolane was prepared by the method of Hibbert and Pimm (21). Yield 51%; b.p. 72° at 700 mm° η_D^{25} 1.3912; lit. b.p. 83–85° at 760 mm (21).

2-(Methoxymethyl)-1,3-dioxolane was prepared from methoxyacetaldehyde diethylacetal (Aldrich Chemical Co.) and ethylene glycol according to the alcohol exchange method of McElvain and Curry (22). Yield, 70%; b.p. 130° at 710 mm; η_D^{24} 1.4216; lit. b.p. 57–58° at 18 mm; η_D^{20} 1.4201 (23).

2-(Bromomethyl)-1,3-dioxolane was made from bromoacetaldehyde diethylacetal and ethylene glycol (22). Yield, 70%; b.p. 60° at 15 mm; η_D^{23} 1.4805; lit. b.p. 175° at 745 mm; η_D^{25} 1.4805 (22).

2-(Methylthiomethyl)-1,3-dioxolane. To a stirred solution of 11.5 g (0.24 mol) of methyl mercaptan in 300 ml of dry DME, cooled to −10° by means of an ice–salt bath, was added 5.8 g (0.24 mol) of sodium hydride in 1 g portions. When the hydride had been added, the cooling bath was removed and the reaction mixture stirred at room temperature for 2 h. 2-(Bromomethyl)-1,3-dioxolane (40 g, 0.24 mol) was added and the mixture then heated under reflux for 2 h and subsequently cooled to room temperature. The precipitated sodium bromide was removed by suction filtration, and the filtrate freed from solvent. The pale yellow residue was distilled under vacuum to give 15 g (47%) of colorless liquid, b.p. 64–65° at 15 mm; η_D^{24} 1.4820.

Anal. Calcd. for $C_5H_{10}O_2S$: C, 44.75; H, 7.46; S, 23.85. Found: C, 44.57; H, 7.28; S, 24.00.

The 60 MHz p.m.r. spectrum in CCl_4 showed a triplet at τ 5.09 (1H, $J \sim 4.5$ Hz), a multiplet between 6.05 and 6.32 (4H); a doublet at 7.47 (2H, $J \sim 4.5$ Hz), a singlet at 7.89 (3H).

2-(Dimethylaminomethyl)-1,3-dioxolane was prepared according to published directions (24). From 70 ml of 33% aqueous dimethylamine and 25 g of 2-(bromomethyl-1,3-dioxolane) was obtained 12 g (60%) of liquid boiling at 59–60° at 20 mm; η_D^{25} 1.4320; lit. b.p. 68° at 20 mm (24).

Anal. Calcd. for $C_6H_{13}NO_2$: C, 54.96; H, 9.92; N, 10.69. Found: C, 54.58; H, 9.86; N, 10.51.

The 60 MHz p.m.r. spectrum in CCl_4 showed a triplet at τ 5.21 (1H, $J \sim 4$ Hz); a multiplet centered at 6.22 (4H); a doublet at 7.62 (2H, $J \sim 4$ Hz); a singlet at 7.78 (6H).

2-Vinyl-1,3-dioxolane was made by a modification of a published procedure (25) as described by Davis and Brown (26).

2-(1-Propenyl)-1,3-dioxolane was prepared according to published directions (27). Yield, 56%; b.p. 69° at 50 mm; η_D^{26} 1.4405; lit. b.p. 71° at 50 mm; η_D^{30} 1.4380 (27).

The following five compounds were prepared by the same method used to make 2-(1-propenyl)-1,3-dioxolane above.

2-(α-Methylvinyl)-1,3-dioxolane, described previously (26).

2-Phenyl-1,3-dioxolane from benzaldehyde and ethylene glycol. Yield, 85%; b.p. 87° at 5 mm; η_D^{25} 1.5248; lit. b.p. 101° at 10 mm (28); η_D^{20} 1.5270 (29).

2-(o-Methoxyphenyl)-1,3-dioxolane from *o*-methoxybenzaldehyde and ethylene glycol. Yield, 80%; b.p. 117° at 2 mm; η_D^{24} 1.5325; lit. b.p. 119.5–120.5° at 3 mm; η_D^{20} 1.5343 (30).

2-(p-Methoxyphenyl)-1,3-dioxolane from *p*-anisaldehyde and ethylene glycol. Yield, 83%; b.p. 139° at 8 mm; η_D^{24} 1.5335; lit. b.p. 158–160° at 17 mm; $\eta_D^{19.5}$ 1.4306 (30).

2-Styryl-1,3-dioxolane from cinnamaldehyde and ethylene glycol. Yield, 65%; b.p. 84° at 0.1 mm; η_D^{24} 1.5625. This liquid crystallized on standing at room temperature for 1 h. Recrystallization from petroleum ether gave colorless needles, m.p. 29.5–31°.

Anal. Calcd. for $C_{11}H_{12}O_2$: C, 74.98; H, 6.86. Found: C, 75.03; H, 6.94.

The 60 MHz p.m.r. spectrum in CCl_4 showed a broad multiplet between τ 2.40 and 2.81 (5H); a doublet at 3.22 (1H, olefinic, $J \sim 16$ Hz); a doublet of doublets at 3.88 (1H, olefinic, $J \sim 16$, $J \sim 5$ Hz); a doublet at 4.62 (1H, $J \sim 5$ Hz); a multiplet centered at 6.08 (4 H).

2-(1-Butenyl)-1,3-dioxolane was obtained from the dehydrohalogenation of 2-(1-bromobutyl)-1,3-dioxolane (26).

2-(2-Methyl-1-propenyl)-1,3-dioxolane was obtained from the dehydrohalogenation of 2-(1-bromo-2-methyl-1-propyl)-1,3-dioxolane (26).

Preparation of some Authentic Products of Hydrogenolysis

2-Allyloxyethanol

This was prepared by the following modification of the published method (31).

To a solution of 62 g (1 mol) of dry ethylene glycol in 300 ml of dry DME was added 19.2 g (0.4 mol) of sodium hydride. The resulting mixture was stirred at room temperature for 2 h and then 48.4 g (0.4 mol) of allyl bromide was added. The mixture was heated under reflux for 2 h and was then cooled to room temperature. The solid material was removed by suction filtration and the filtrate was freed from solvent. The residual oil was distilled under reduced pressure, giving 27 g (67%) of colorless liquid, b.p. 46° at 5 mm; η_D^{25} 1.4333; lit. b.p. 63–64° at 18–19 mm; η_D^{20} 1.4356 (31).

2-Crotyloxyethanol

This compound was prepared from crotyl bromide and ethylene glycol by the same method used to synthesize 2-allyloxyethanol above. Yield, 65%; b.p. 81° at 18 mm; η_D^{27} 1.4383; lit. b.p. 85–87° at 21–22 mm; η_D^{20} 1.4428 (32).

The crotyl bromide was prepared by the method of Winstein and Young (33). The b.p. 46–48° at 94 mm; η_D^{23} 1.4787; lit. b.p. 49° at 93 mm; η_D^{25} 1.4795 (33).

2-(2-Methylthioethoxy)ethanol

The precursor, *2-methylthioethanol* was prepared as follows. To a solution of 39 g (0.5 mol) of 2-mercaptoethanol in 300 ml of dry DME was added 12 g (0.5 mol) of sodium hydride. The resulting mixture was stirred at room temperature for 2 h. Iodomethane (71 g, 0.5 mol) was then added and the mixture was stirred overnight at room temperature. The solids were removed by suction filtration and the filtrate was freed from solvent. The residue was taken up in 200 ml of dry ether and the solution filtered to remove the precipitate, and then freed from ether. The residue was distilled to give 25 g (54%) of colorless liquid, b.p. 78° at 30 mm; η_D^{24} 1.4869; lit. b.p. 61° at 10 mm; η_D^{20} 1.4930 (34).

To a solution of 4 g (0.044 mol) of 2-methylthioethanol in 200 ml of dry DME was added 1.05 g (0.044 mol) of sodium hydride. After the mixture had been stirred for 2 h, ethyl chloroacetate (5.4 g, 0.044 mol) was added and the resulting mixture was heated under reflux overnight. The cooled reaction mixture was freed from solids and then from solvent. The residue, in 50 ml of dry ether was filtered from additional precipitate and the filtrate freed from ether. The crude product was added to a solution of 1.7 g (0.044 mol) of $LiAlH_4$ in 100 ml of dry ether. The mixture was stirred for 0.5 h and then treated with 10 ml of a 15% aqueous solution of potassium hydroxide. This was then diluted with 50 ml of water and the resulting mixture extracted continuously with ether for 12 h. The dried ether extract was filtered free of solid, and solvent removed. The residue was distilled under reduced pressure to give 2.3 g (52%) of colorless liquid, b.p. 84° at 2.5 mm; η_D^{24} 1.4837.

Anal. Calcd. for $C_5H_{12}O_2S$: C, 44.10; H, 8.83; S, 23.52. Found: C, 44.01; H, 8.82; S, 23.40.

The 60 MHz p.m.r. spectrum in CCl_4 showed a multiplet between τ 6.20 and 6.81 (7H), a triplet at 7.35 (—S—CH_2—, $J \sim 7$ Hz), and a singlet at 7.88 (CH_3—S—).

The i.r. spectrum (neat) showed a broad band between 3640 and 3210 (OH stretching) and a broad band between 1150 and 1010 cm^{-1} (C—O— stretching).

2-(2-Dimethylaminoethoxy)ethanol

The precursor, *ethyl (2-dimethylaminoethoxy)acetate* was prepared by a modification of the general procedure of Leffler and Calkins (35). To a stirred solution of 30 g (0.337 mol) of 2-(dimethylamino)-ethanol and 41.2 g (0.337 mol) of ethyl chloroacetate in 400 ml of dry DME cooled to −10° by an ice–salt bath, was added sodium hydride (8.1 g, 0.337 mol) in 1 g portions. When the addition was complete, the reaction mixture was allowed to attain room temperature and then stirred for 24 h. The solids were removed by suction filtration and the filtrate was freed from solvent. The residue was dissolved in 100 ml of dry ether and the precipitated solid again removed by filtration. The ether was removed from the filtrate and the residue distilled under reduced pressure. Yield, 25 g (42%); b.p. 64° at 0.5 mm; η_D^{23} 1.4265.

Anal. Calcd. for $C_8H_{17}NO_3$: C, 54.86; H, 9.71; N, 8.00. Found: C, 54.92; H, 9.66; N, 7.81.

The 60 MHz p.m.r. spectrum in CCl_4 showed a quartet at τ 5.89 (2H, $J \sim 7$ Hz), a singlet at 6.08 (2H), a triplet at 6.48 (2H, $J \sim 6$ Hz), a triplet at 7.58 (2H, $J \approx 6$ Hz), a singlet at 7.83 (6H), and a triplet at 8.77 (3H, $J \approx 7$ Hz).

The i.r. spectrum (neat) showed a strong band at 1760 (C═O) and a broad band between 1220 and 1110 cm^{-1} (C—O— stretching).

Ethyl (2-dimethylaminoethoxy)acetate (10 g, 0.06 mol) was added dropwise to a stirred solution of 2.08 g (0.06 mol) of $LiAlH_4$ in 50 ml of dry ether. When the ester had been added, the reaction mixture was stirred for 1 h at room temperature and then 10 ml of a 15% aqueous solution of potassium hydroxide was added. This was diluted with 50 ml of water and the mixture extracted continuously for 12 h with ether. The ether extract was dried, then freed of drying agent and solvent. The residue was distilled under reduced pressure to give 6 g (60%) of colorless liquid, b.p. 60–61° at 4 mm; η_D^{25} 1.4390.

Anal. Calcd. for $C_6H_{15}NO_2$: C, 54.14; H, 11.28; N, 10.53. Found: C, 54.23; H, 11.34; N, 10.65.

The 60 MHz p.m.r. spectrum in CCl_4 showed a singlet at τ 5.31 (1H), a singlet at 6.54 (6H), a triplet at 7.59 (2H, $J \approx 5.5$ Hz), and a singlet at 7.80 (6H).

The i.r. spectrum in CCl_4 showed a broad band between 3600 and 3050 (OH) and a broad band between 1170 and 1030 cm^{-1} (C—O—).

2-Benzyloxyethanol was prepared according to published directions (1).

2-Ethoxyethanol, from Eastman Kodak Co.

Diethyleneglycol monomethyl ether, from Fisher Scientific Co.

2-(β-Bromoethoxy)ethanol was not prepared since hydrogenolysis of 2-bromomethyl-1,3-dioxolane gave only 2-ethoxyethanol as result of loss of Br.

Products Obtained from Hydrogenolysis Reactions

The majority of hydrogenolysis products were obtained by their isolation from the mixture obtained from the hydrogenolysis reactions. These were identified by elemental analysis, i.r. and p.m.r. spectra. These, along with their physical constants and spectral data, are shown in Tables 8 and 9.

Hydrogenolysis with AlH_2Cl

The procedure employed was based on that described by Diner (36). The following reduction of 2-vinyl-1,3-dioxolane is typical.

A solution of $LiAlH_4$ (0.5 g, 0.015 mol) in 15 ml of dry ether was cooled in ice to 5°. To this was added dropwise an ether solution of $AlCl_3$ (previously prepared by the addition of $AlCl_3$ (1.99 g, 0.015 mol) in small portions to 15 ml of dry ether kept at 5°). This mixed hydride solution was stirred at room temperature for 15 min and then 2-vinyl-1,3-dioxolane (3 g, 0.03 mol) was added. The resulting mixture was stirred for 30 min at room temperature and then a solution of 15% potassium hydroxide in water was added dropwise until no further reaction occurred. The colorless precipitate (lithium aluminate) was separated by suction filtration and the ether removed from the filtrate by fractional distillation. The residue (85% recovery) was analyzed by g.l.c. and found to be composed of only 2-allyloxyethanol, identical with an authentic sample.

This procedure was employed for the AlH_2Cl reductions of the compounds shown in Tables 1–3, for the reduction periods shown. Tables 8 and 9 give the physical and spectral properties of those compounds isolated from the hydrogenolysis reactions and then characterized.

Competitive Hydrogenolysis with AlH_2Cl

The following general procedure was used.

An ether solution of AlH_2Cl was obtained from $LiAlH_4$ (0.143 g, 0.0037 mol) and $AlCl_3$ (0.5 g, 0.0037 mol) in 20 ml of dry ether as described above. When this had been stirred for 15 min, a mixture of 2-methyl-1,3-dioxolane (0.66 g, 0.0075 mol) and 2-(methylthiomethyl)-1,3-dioxolane (1 g, 0.0075 mol) was added. The subsequent procedure was the same as that described above except that after the aqueous potassium hydroxide had been added, an additional quantity (50 ml) of water was added and the resulting mixture was extracted continuously with ether overnight. The ether extract was dried, filtered, and the filtrate freed from ether by fractional distillation at atmospheric pressure. The residue (90% recovery), when analyzed by g.l.c., was found to be composed only of a 7:1 ratio of 2-ethoxyethanol and 2-(2-methylthioethoxy)ethanol, identified by comparison of the retention times with those of authentic samples. Other pairs of compounds were reduced similarly and the results are shown in Table 2.

Reduction with $LiAlH_4$

The procedure was the same as that used above for the reduction with AlH_2Cl. By this method, acrolein ethyleneacetal (2-vinyl-1,3-dioxolane) (3 g, 0.03 mol), treated with $LiAlH_4$ (1.14 g, 0.03 mol) in 30 ml of dry ether for 48 h, gave after work-up (85% recovery) a 1:1 mixture of *cis*- and *trans*-2-(α-propenyloxy)ethanol, identified by their elemental analyses, p.m.r. and i.r. spectra after isolation and separation by preparative g.l.c. Tables 5–7 show details of the experiments and the results obtained for other 1,3-dioxolanes, while Tables 8 and 9 provide physical and spectral data for the compounds isolated.

Competitive Reductions with AlH_3

The procedure was the same as that used for the competitive reductions with AlH_2Cl. The AlH_3 was prepared according to published directions (5, 15). The results are shown in Table 4.

Fully Fluorinated Alkoxides. Part V. Derivatives of Tetrafluorocatechol

CELIA MACDONALD, A. J. TOMLINSON, AND C. J. WILLIS[1]
Department of Chemistry, University of Western Ontario, London 72, Ontario

Received March 16, 1971

Tetrafluorocatechol (tetrafluoro-1,2-dihydroxybenzene) has been found to form isolable complexes with transition metals (Ni^{2+}, Cu^{2+}, and Fe^{3+}), and with germanium, acting as a chelating, dinegative, ligand. These complexes are few in number and of limited stability, suggesting that tetrafluorocatechol has less applicability as a ligand than related highly halogenated organic molecules. Complexes of tetrabromocatechol with Ni^{2+} are also described.

Le tétrafluoropyrocathécol (tétrafluoro dihydroxy-1,2 benzène) forme des complexes isolables avec des métaux de transition (Ni^{2+}, Cu^{2+} et Fe^{3+}) et avec le germanium, et fonctionne comme un ligand chélatant porteur de deux charges négatives. Ces complexes sont peu nombreux et leur stabilité est limitée ce qui suggère que le tétrafluoropyrocathécol est moins utile en tant que ligand que des molécules organiques correspondantes fortement halogénées. Les complexes obtenus entre le tétrabromopyrocathécol et le Ni^{2+} sont également rapportés.

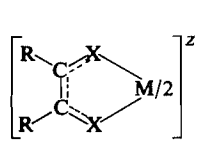
Canadian Journal of Chemistry, 49, 2578 (1971)

Introduction

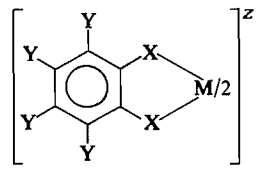
We have previously shown (1) that stable complexes of various first-row transition elements, including Mn(II), Fe(III), Ni(II), Cu(II), and Zn(II), may be produced by reaction of the metal ion with perfluoropinacol in aqueous solution. The pinacol is effectively ionized to the dinegative ion $[OC(CF_3)_2C(CF_3)_2O]^{2-}$ (PFP), and complexes with metal ions have the composition $[M(PFP)_2]^{2-}$ and $[M(PFP)_3]^{3-}$ for M^{2+} and M^{3+} ions respectively.

The ready formation of stable chelated alkoxides by the fluorinated diol may be attributed to the increased proton acidity resulting from the inductive effect of the 12 fluorine atoms in the molecule, and it was of interest to attempt to extend this study to analogous fluorinated aromatic diols. Tetrafluoro-1,2-dihydroxybenzene (tetrafluorocatechol, TFC) is the simplest molecule of this type. Although this compound has been known for some years, no complexes of it have yet been reported, although in the initial account of its preparation (2) it was noted that it gave a blue color with aqueous ferric chloride.

Complexes of TFC would also be of interest because of their relation to the so-called "dithiolene" complexes (**1** and **2**; X = S, Y = H) which often undergo a series of electron transfer processes, resulting in values of Z from -2 to



1



2

$+2$ (3–7). In many of these complexes, the groups R are electronegative (*e.g.* CN or CF_3) and the delocalization of the electron density between metal and ligand orbitals leads to greater stability of the "reduced" members of a series. Complexes of catechol (**2**, X = O, Y = H) have been reported over many years, but only recently has a series of well-characterized compounds containing catechol or tetrachlorocatechol (Y = Cl) been obtained and shown to undergo electron transfer reactions (8).

In a report of reactions of tetrafluorobenzene-1,2-dithiol (**2**, X = S, Y = F), it is suggested that this ligand gives complexes of metals in high oxidation states, such as Ni(III) and Cu(III) (9), but other workers have said that a meaningful oxidation state cannot be assigned to a metal atom in a system of this type (7).

Results and Discussion

Metal complexes of tetrafluorocatechol proved to be considerably less stable and more difficult to prepare than those of perfluoropinacol, and only a limited number could be characterized. Of the metals studied, copper(II) was the only

[1]To whom enquiries should be addressed. For part IV, see ref. 1.

For personal use only.

one for which we were able to prepare a complex having tetrafluorocatechol as the sole ligand on the metal ion; namely $K_2[Cu(TFC)_2]$, a dark purple solid reversibly forming a green dihydrate. This compound was made by the addition of potassium hydroxide to methanolic Cu^{2+} in the presence of the ligand, oxygen being excluded.

With nickel(II), which readily forms the complex $[Ni(PFP)_2]^{2-}$ with perfluoropinacol, no analogous tetrafluorocatechol complex could be isolated. However, neutral mixed ligand complexes of nickel could be prepared with nitrogen or phosphorus donors and tetrafluorocatechol, *e.g.* (TMED)Ni(TFC), where TMED = tetramethylethylenediamine, $(PEt_3)_2Ni(TFC)$, and (diphos)Ni(TFC), where diphos = 1,2-bis(diphenylphosphino)ethane. These three compounds were brown and diamagnetic, with similar electronic spectra, and were assumed to have a square planar configuration, as do the corresponding perfluoropinacol complexes (10). The TMED complex formed a green, paramagnetic (μ_{eff} = 3.18 B.M.), air-sensitive dihydrate, having an electronic spectrum typical of octahedral nickel(II); this is presumably the product of the coordination of two molecules of water to the nickel atom in the complex.

When TMED was added to a copper(II) solution containing tetrafluorocatechol in an attempt to prepare (TMED)Cu(TFC), the amine acted as a base rather than a ligand, and the product was characterized as $[H_2TMED]^{2+}$-$[Cu(TFC)_2]^{2-}$.

No compound could be prepared in which three tetrafluorocatechol molecules were chelated around a metal ion, whereas perfluoropinacol readily forms such complexes with Fe^{3+} and Al^{3+} (1). Tetrafluorocatechol did, as previously reported, give a blue coloration with iron(III), this reaction providing a sensitive test for the presence of the compound, but it was not easy to isolate a stable solid adduct. However, addition of TMED gave a black complex, soluble in methanol to give a blue solution, which analyzed for $(TMED)Fe(TFC)_2$. It did not appear likely that this compound contained iron(IV), as its magnetic moment (6.1 B.M.) was very similar to that of the known perfluoropinacol complex of iron(III) (6.0 B.M.) and in the region usually found for high-spin iron(III) compounds. The Mossbauer spectrum of the complex was also consistent with the presence of iron(III).

To preserve charge balance, this molecule must therefore contain an additional proton. It does not appear that the amine is protonated, as complexes of this type, such as the compound $[H_2TMED]^{2+}[Cu(TFC)_2]^{2-}$ described above, together with analogous perfluoropinacol derivatives (10), have a strong characteristic absorption in the 2300–2700 cm^{-1} region of their i.r. spectra, which is absent in the iron complex. We suggest, therefore, that the proton is attached to the oxygen atom of a TFC molecule, and probably hydrogen-bonded to a second oxygen. The i.r. spectrum does not show any absorption assignable with certainty to such a grouping, but this is frequently the case with hydrogen-bonded hydroxyl groups, *e.g.* in nickel bis(dimethylglyoxime) (11).

The resulting structure, in which six-coordinate iron(III) is chelated by a neutral TMED molecule and two TFC molecules, one singly ionized and the other doubly ionized, is in agreement with the available evidence, but cannot be regarded as conclusively established. Attempts to remove the proton by treatment with base, to give an anionic iron complex, resulted only in decomposition.

A brief investigation was made of the ability of tetrafluorocatechol to form cyclic derivatives of main group elements, as does catechol (12). Of the group IV elements, no simple derivatives of the type $M(TFC)_2$ could be prepared, but, in the presence of base, germanium gave the adduct $Ge(TFC)_2 \cdot 2DMF$ (DMF = dimethylformamide), which was more stable to atmospheric oxidation and hydrolysis than the transition metal derivatives described above. However, no analogous stoichiometric compound of silicon or tin could be isolated using DMF or other donor molecules.

With many other metals, evidence was obtained for complex formation with tetrafluorocatechol, but no stable derivative could be isolated. With manganese(II), for example, pale green crystals of a complex separated when base was added to a solution containing TFC and Mn^{2+}, but the crystals decomposed in the course of a few hours, even when kept under vacuum in the dark.

From the rather meagre range of tetrafluorocatechol complexes isolated, it is difficult to obtain a detailed picture of the properties of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ligand. It appears to produce a smaller ligand field splitting than similar ligands, as the first absorption maximum in the spectrum of the complex $[Cu(TFC)_2]^{2-}$ occurs at 13 500 cm^{-1}, compared with $[Cu(C_6H_4O_2)_2]^{2-}$, 15 000; $[Cu(C_6Cl_4O_2)_2]^{2-}$, 14 800 (8), and $[Cu(PFP)_2]^{2-}$, 15 100 cm^{-1} (10).

The very limited oxidative stability of the tetrafluorocatechol complexes was unexpected, as previous workers (8) have shown that complete replacement of hydrogen by chlorine in a catechol complex leads to much greater stability. In an effort to throw further light on this point, we have briefly investigated the properties of tetrabromocatechol (TBC) as a ligand, since no report of such complexes has yet appeared. Like other catechols studied, tetrabromocatechol is very readily oxidized in basic solution, but it proved a slightly better ligand than tetrafluorocatechol. With nickel(II), the complexes $[Me_4N^+]_2[Ni(TBC)_2]^{2-}$, (TMED)Ni(TBC), and $(PEt_3)_2Ni(TBC)$ were isolated as yellow or brown, diamagnetic, solids, considerably more stable than either the catechol or the tetrafluorocatechol nickel complexes.

The instability of complexes of fully halogenated catechols appears, therefore, to reach a maximum in the tetrafluorocatechol derivatives. We suggest that this may derive from the highly polar nature of the carbon–fluorine bond, which, in the presence of a system where electron transfer processes may readily occur, leads to ready elimination of a fluoride ion and consequent decomposition of the complex. Consistent with this, we have frequently found fluoride ion present in the decomposition products resulting from tetrafluorocatechol reactions. We conclude, therefore, that this ligand will be of restricted use in the preparation of metal complexes, and will lack the general applicability of perfluoropinacol.

Experimental

General

All reactions with tetrafluorocatechol and tetrabromocatechol were carried out under an atmosphere of nitrogen using outgassed solvents. The i.r. spectra were recorded as Nujol mulls on a Beckman model IR-10 instrument and visible spectra on a Beckman DK-1 instrument. Abbreviations used in describing spectra are: vs, very strong; s, strong; m, medium; w, weak; br, broad; sh, shoulder. ^{19}F n.m.r. spectra were recorded on a Varian model HA-100 spectrometer at 94.1 mHz. Magnetic moments were determined at 25° by the Gouy method using $Hg[Co(CNS)_4]$ as standard. Microanalyses were performed by Alfred Bernhardt Laboratories.

Tetrafluorocatechol

This compound was prepared by the procedure of Burdon *et al.* (2) up to the point where the benzodioxin and aluminum chloride were refluxed in benzene for 6 h and the mixture poured on ice. We then extracted the mixture repeatedly with approximately 1 *M* sodium hydroxide solution, the aqueous layer being run *immediately* into 2 *M* hydrochloric acid (the catechol oxidizes rapidly in basic solution). More acid was then added to p*H* about 1.0, and the solution extracted with diethyl ether until the extract no longer gave a coloration with aqueous ferric chloride. The ether was then dried ($MgSO_4$) and evaporated, and the semi-solid residue purified by repeated sublimation to give tetrafluorocatechol (m.p. 66–68°, lit. m.p. 67–69°). The ^{19}F n.m.r. spectrum showed a typical AA′XX′ spectrum (doublet of quartets) centered at 175.5 and 183.7 p.p.m. from $CFCl_3$. The i.r. spectrum showed absorptions at 3640(s), 3550(s), 3200(br), 2700(m), 2440(w), 2340(w), 2110(w), 1750(w), 1635(s), 1520(vs), 1480(s), 1320(s), 1225(s), 1160(w), 1150(w), 1135(w), 1000(s), and 795(m) cm^{-1}.

Use of the work-up procedure given by previous workers resulted in poorer yield and considerable contamination of the product with dibenzyl. Despite many attempts to improve the efficiency of this preparation by varying the reaction conditions, we were unable to obtain a yield over 10% based on hexafluorobenzene.

Reaction of TFC with Fe^{3+} and TMED

Excess TMED (2 ml) was added to TFC (0.8 g) in anhydrous methanol (10 ml) and iron(III) acetate (0.78 g) in methanol was added dropwise. After stirring for 4 h, the deep blue solution was filtered and evaporated to give the iron complex tetramethylethylenediaminebis(tetrafluorocatechol) iron(III) as a black powder.

Anal. Calcd. for $C_{18}H_{17}F_8O_4N_2Fe$: C, 40.6; H, 3.2; F, 28.5; N, 5.3; Fe, 10.5. Found: C, 40.7; H, 3.4; F, 28.9; N, 5.4; Fe, 10.3.

The electronic spectrum (MeOH solution) showed bands at 580 (ε = 3500) and 390 mμ (ε = 2200).

The i.r. spectrum showed absorptions at 2720(w), 1600(w), 1480(s), 1290(w), 1270(w), 1255(w), 1125(m), 1025(s), 1010(s), 980(s), 955(m), 805(m), 770(w), and 725(w) cm^{-1}.

The complex had a magnetic moment of 6.1 B.M. and gave a non-conducting solution in methanol. Its Mossbauer spectrum showed a center shift of 0.68 ± 0.07 mm/s, relative to sodium nitroprusside, a value typical of iron(III) compounds(13).

Reaction of TFC with Ni^{2+} and TMED

TFC (1.3 g) in ethanol (10 ml) was mixed with nickel nitrate hexahydrate (2.08 g) in water (15 ml). TMED was added dropwise with stirring until the p*H* of the solution reached 10, by which time a green precipitate had appeared. After stirring 10 min, the mixture was filtered and the precipitate recrystallized from methanol, washed with dichloromethane, and dried briefly *in vacuo* at 25°. Analysis showed it to be tetramethylethylenediamine nickel tetrafluorocatecholate dihydrate.

Anal. Calcd. for $C_{12}H_{20}F_4O_4N_2Ni$: C, 36.9; H, 5.2; F, 19.4; N, 7.2; Ni, 15.0. Found: C, 36.8; H, 5.3; F, 20.7; N, 7.5; Ni, 15.6.

The electronic spectrum (diffuse reflectance) showed peaks at 400(sh), 720(br), 855(sh), and 920(w) mμ; in solution (MeOH) the peaks were at 475(sh), 650, 1054, and 1452 mμ. The magnetic moment at 25° was 3.18 B.M.

On keeping at 65° *in vacuo* for 48 h, the green dihydrate was converted to the brown anhydrous tetramethylethylenediamine nickel tetrafluorocatecholate.

Anal. Calcd. for $C_{12}H_{16}F_4O_2N_2Ni$: C, 40.6; H, 4.5; F, 21.4; N, 7.9; Ni, 16.5. Found: C, 40.9; H, 4.5; F, 21.5; N, 8.0; Ni, 16.5.

The complex dissolved in anhydrous methanol to give a green solution absorbing at 475(sh), 651, 1055 and 1453 mμ. In dichloromethane, it gave a brown solution absorbing at 380(sh) and 475 mμ.

The i.r. spectrum showed peaks at 1760(m), 1470(br,s), 1290(s), 1243(w), 1200(w), 1132(s), 1100(w), 1077(w), 1047(w), 1000(br,s), 819(s), 772(m), 725(m), and 628(m) cm^{-1}.

This compound and the five succeeding nickel complexes were diamagnetic.

Reaction of TFC with Ni^{2+} and Triethylphosphine

TFC (0.9 g) and nickel nitrate hexahydrate (1.4 g) were dissolved in methanol (10 ml) and PEt_3 (0.6 g) added with stirring. Shiny brown crystals precipitated and were recrystallized from methanol to give bis(triethylphosphine nickel tetrafluorocatecholate.

Anal. Calcd. for $C_{18}H_{30}F_4O_2NiP_2$: C, 45.5; H, 6.4; F, 16.0; Ni, 12.4. Found: C, 45.3; H, 6.0; F, 16.2; Ni, 12.5.

Mol. Wt. Calcd.: 475. Found (osmometric in benzene): 520.

The electronic spectrum (CH_2Cl_2 solution) showed bands at 415 (ε = 530) and 575 mμ (ε = 170). A diffuse reflectance spectrum gave peaks at 412 and 562 mμ. The i.r. spectrum showed peaks at 1470(s), 1295(s), 1250(m), 1128(s), 1000(s,br), 776(s), 730(s), and 685(w) cm^{-1}.

Reaction of TFC with Ni^{2+} and 1,2-Bis(diphenylphosphino)ethane (diphos)

TFC (0.6 g) and nickel(II) sulfate hexahydrate (1.65 g) in methanol (10 ml) were mixed with diphos (1.5 g) in tetrahydrofuran (15 ml) and stirred for 1 h. A brown crystalline material separated which was identified as diphos nickel tetrafluorocatecholate.

Anal. Calcd. for $C_{32}H_{24}F_4O_2P_2Ni$: C, 60.3; H, 3.8; F, 11.9. Found: C, 60.4; H, 3.9; F, 12.2.

The electronic spectrum (CH_2Cl_2 solution) showed one band at 570 mμ (ε = 220). The i.r. spectrum showed peaks at 2405(w), 1915(w), 1815(w), 1760(w), 1700(w), 1465(s), 1280(s), 1180(w), 1155(w), 1115(m), 1095(m), 1000(s), 865(m), 805(m), 745(s), 710(s), 700(s), 685(s), and 645(m) cm^{-1}.

Reaction of Tetrabromocatechol with Ni^{2+} and PEt_3

This preparation was carried out in the same manner as that of the corresponding TFC complex. The compound bis(triethylphosphine) nickel tetrafluorocatecholate formed brown crystals.

Anal. Calcd. for $C_{18}H_{30}Br_4O_2NiP_2$: C, 30.1; H, 4.2; Br, 44.5; Ni, 8.2. Found: C, 29.9; H, 3.9; Br, 44.4; Ni, 8.3.

The electronic spectrum (CH_2Cl_2 solution) showed one band at 560 mμ (ε = 170). The i.r. spectrum showed peaks at 1450(s), 1350(m), 1275(s), 1240(s), 1220(m), 1035(s), 1010(w), 980(w), 945(s), 768(s), 750(s), 730(s), and 635(m) cm^{-1}.

Tetramethylammonium Bis(tetrabromocatechol)nickelate(II)

Stoichiometric amounts of tetrabromocatechol and nickel nitrate were dissolved in methanol and tetramethylammonium hydroxide (15% in methanol) added dropwise with stirring. The complex precipitated as brown plates.

Anal. Calcd. for $C_{20}H_{24}O_4Br_8N_2Ni$: C, 22.8; H, 2.3; N, 2.7; Br, 60.6; Ni, 5.6. Found: C, 22.6; H, 2.5; N, 2.5; Br, 60.5; Ni, 5.6.

The i.r. spectrum showed peaks at 1485(s), 1350(m), 1274(s), 1233(s), 1031(m), 950(s), 935(s), 785(s), 750(s), and 640(w) cm^{-1}.

Reaction of Tetrabromocatechol, Ni^{2+}, and TMED

Tetrabromocatechol (2.0 g) and nickel nitrate (1.4 g) were dissolved in methanol (30 ml) and TMED (6.0 g) added. The dark brown precipitate was recrystallized from methanol to give tetramethylethylenediamine nickel tetrabromocatecholate.

Anal. Calcd. for $C_{12}H_{16}Br_4O_2N_2Ni$: C, 24.1; H, 2.7; N, 4.7; Br, 53.4; Ni, 9.8. Found: C, 24.3; H, 2.8; N, 4.8; Br, 53.5; Ni, 10.0.

The electronic spectrum (acetone solution) showed a band at 485 mμ (ε = 105). The i.r. spectrum showed peaks at 1435(s), 1340(m), 1270(s), 1232(s), 1205(w), 1120(w), 1040(m), 1010(m), 985(w), 940(s), 815(s), 770(s), 745(s), and 645(w), cm^{-1}.

Reaction of TFC with Cu^{2+}

TFC and copper sulfate pentahydrate in a 2:1 molar ratio were dissolved in methanol and methanolic potassium hydroxide added to p*H* 7, at which point an olive-green solid precipitated. On drying *in vacuo* at 65° for 48 h, the solid became purple, in which state it was analyzed as potassium bis(tetrafluorocatechol) cuprate.

Anal. Calcd. for $C_{12}F_8O_4CuK_2$: C, 28.7; F, 30.3; Cu, 12.7. Found: C, 28.9; F, 30.2; Cu, 12.9.

The electronic spectrum (methanol solution) showed one band at 740 mμ (ε = 220). In the i.r. spectrum, peaks were at 1620(m), 1495(s), 1275(m), 1135(m), 1000(s), and 720(m) cm^{-1}.

The purple solid rapidly reverted to the green color on exposure to atmosphere.

Reaction of TFC with Cu^{2+} and TMED

TFC (0.4 g) and copper sulfate pentahydrate (0.55 g) in water (10 ml) were kept under vacuum and TMED (0.5 g) distilled into the flask. The resulting slurry was filtered to give a grey–green powder insoluble in common solvents. Analysis identified it as tetramethylethylenediammonium bis(tetrafluorocatechol) cuprate.

Anal. Calcd. for $C_{18}H_{18}F_8N_2O_4Cu$: C, 39.9; H, 2.6; F, 28.1; N, 5.2. Found: C, 40.3; H, 2.7; F, 28.5; N, 5.1.

The i.r. spectrum showed peaks at 2610(w), 2360(s,br), 1620(m), 1490(s), 1275(s), 1155(m), 1120(s), 1070(m), 1000(s), 790(w), and 725(m) cm^{-1}.

Reaction of TFC and $GeCl_4$ in DMF

To TFC (1.0 g) in DMF (25 ml) was added germanium tetrachloride (0.59 g). A white solid formed initially, then redissolved. After stirring 15 min, the volume of the solution was then reduced to 5 ml, and a white solid

separated. It was recrystallized from methanol to give bis(dimethylformamide) germanium bis(tetrafluorocatecholate).

Anal. Calcd. for $C_{18}H_{14}F_8O_4N_2Ge$: C, 37.4; H, 2.4; F, 26.3; N, 4.8. Found: C, 37.3; H, 2.6; F, 26.5; N, 4.9.

The i.r. spectrum showed peaks at 1760(w), 1650(s), 1510(s), 1490(s), 1350(s), 1270(m), 1250(m), 1170(w), 1150(s), 1130(w), 1080(w), 1000(s), 870(w), 760(w), 710(s), and 675(s) cm^{-1}.

Financial support of this work was provided by the National Research Council of Canada. We are indebted to Dr. G. M. Bancroft, of this department, for kindly determining the Mossbauer spectrum.

A Method for Gas–Liquid Chromatographic Identification of *O*-Methyl Ethers of 2-Deoxy-2-methylamino-D-glucose and 2-Deoxy-2-methylamino-D-galactose[1]

P. A. J. GORIN AND R. J. MAGUS

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received March 23, 1971

A method is described for the g.l.c. identification of *O*-methyl ethers that can be formed on methylation–fragmentation analysis of polymers containing 2-acetamido-2-deoxy-D-glucopyranose or 2-acetamido-2-deoxy-D-galactopyranose units. The possible 2-deoxy-*O*-methyl-2-methylamino-D-glucoses and -D-galactoses and their derived hexitols, were converted to their acetates and trimethylsilyl ethers. The g.l.c. was carried out using a number of liquid phases and the retention times of the derivatives were found to be sufficiently diverse to make positive identifications of unknowns feasible.

Une méthode est décrite pour identifier par c.l.g les éthers *O*-méthylés pouvant se former pendant les analyses par méthylation et fragmentation de polymères contenant soit l'unité acétamido-2 désoxy-2 D-glucopyranose soit l'unité acétamido-2 désoxy-2 D-galactopyranose. Les composés possibles, les désoxy-2 *O*-méthyl méthylamino-2 D-glucoses et D-galactoses ainsi que leurs dérivés hexitols, ont été transformés en acétates et éthers triméthylsililés correspondants. En utilisant un certain nombre de phases liquides, la c.l.g conduit, pour les dérivés, a des temps de retention suffisamment différents pour permettre une bonne identification des composés inconnus.

Canadian Journal of Chemistry, 49, 2583 (1971)

Partially *O*-methylated 2-deoxy-2-methylamino derivatives of D-glucose (1) and D-galactose (2) have been synthesized to serve as standards in structural investigations of polymers or oligomers containing 2-acetamido-2-deoxy-D-glucopyranose and 2-acetamido-2-deoxy-D-galactopyranose units, respectively. These fragments can be formed when methylation by the Kuhn (3) (methyl iodide-*N*,*N*-dimethylformamide – silver oxide) or Hakomori (4, 5) (methyl iodide–sodium hydride–dimethyl sulfoxide) procedures are carried out and the product hydrolyzed by acid. Two effective methods for identification of the *N*-methyl hexosamine derivatives are by means of an amino acid analyzer and by g.l.c. as trimethylsilyl (t.m.s.) ethers (1, 2). The former method can be used (6–8) when a 0.2–1.0 mg sample of *O*-methyl ether is available. Each derivative has a characteristic retention time and gives an absorption maximum of 570 mμ on reaction with ninhydrin. When only microgram quantities are available, however, the g.l.c. method must be used. To increase the effectiveness of the g.l.c. analysis of complex mixtures of *O*-methyl sugars a more detailed investigation of the g.l.c. properties of the above standards was made. The present work describes the preparation of a number of new derivatives and the determination of their retention times on a variety of liquid phases.

A previous g.l.c. examination of the t.m.s. ethers of 2-deoxy-*O*-methyl-2-methylamino-D-glucoses (1) and their D-galactose isomers (2) showed that most of the hexoses can be distinguished, even though each compound generally gives rise to two peaks, arising from the α- and the β-anomer. However, Perry and Webb (9) have obtained a superior separation by g.l.c. of the acetates of derived 2-amino-2-deoxy-*O*-methyl-D-glucitols using a column containing neopentyl glycol sebacate (NPGSb) at 245°, where only one peak is formed from each parent hexitol. Although the acetates of 2-deoxy-*O*-methyl-2-methylamino-D-hexitols could neither be eluted from the column under these conditions nor from a column containing diethylene glycol adipate – diethylene glycol (4:1), a separation was obtained using a UC W-98 (a methyl vinyl silicone) liquid phase at 210° (Table 1). Different emergence orders were observed using the t.m.s. ethers on UC W-98 liquid phase at 160° and NPGSb liquid phase at 140° (Table 1). The acetates were prepared using acetic anhydride – pyridine at 100°, a process which results in formation of *O*-acetyl, *N*-acetyl derivatives. Treatment of the hexitols with trimethylsilyl chloride – hexamethyldisilazanepyridine at 100° (10) should result in formation of *O*-, but

TABLE 1. Retention times, in minutes, of derivatives of 2-deoxy-*O*-methyl-2-methylamino derivatives of D-glucitol and D-galactitol

O-Methyl derivative of 2-deoxy-2-methyl-amino-D-hexitol	Retention time (min)		
	Trimethylsilyl derivatives on NPGSb at 140°*	Trimethylsilyl derivatives on UC W-98 at 160°†	Acetates on UC W-98 at 210°
Glucitol series			
Unsubstituted	9.4	8.40	3.85
3-	8.3	5.81	3.08
4-	7.8	5.63	3.60
6-	6.8	5.32	2.70
3,4-Di-	8.2	4.08	2.53
3,6-Di-	6.6	3.68	2.10
4,6-Di-	5.8	3.53	2.37
3,4,6-Tri-	6.8	2.62	1.65
Galactitol series			
Unsubstituted	8.8	7.99	4.00
3-	9.2	6.28	3.35
4-	7.6	5.55	3.80
6-	7.2	5.38	2.70
3,4-Di-	9.2	4.58	2.87
3,6-Di-	7.6	4.22	2.20
4,6-Di-	6.7	3.70	2.45
3,4,6-Tri-	9.6	3.05	1.88

*NPGSb, neopentylglycol sebacate.
†UC W-98, a methyl vinyl silicone.

not *N*-trimethylsilyl derivatives by analogy with the trimethylsilylation of galactosamine (11). The acetylation and etherification processes are effective since all of the resulting derivatives gave one peak on g.l.c.

Another series of retention times was obtained using the t.m.s. ethers of 2-deoxy-*O*-methyl-2-methylamino-D-hexoses on UC W-98 liquid phase at 160° and the corresponding acetates on UC W-98 at 210° (Table 2). The emergence orders differ from each other and from those obtained with the t.m.s. ethers on NPGSb at 140° (1, 2; Table 2).

It can be seen from Tables 1 and 2 that by use of the six different g.l.c. conditions a good resolution of the 2-deoxy-*O*-methyl-*N*-methyl-amino derivatives of D-glucose and D-galactose can be obtained together with a wide variance in their emergence orders. It should therefore be possible to methylate a polysaccharide known to contain 2-acetamido-2-deoxy-D-glucose or -D-galactose units, hydrolyze the product, and detect the resulting *O*-methyl-*N*-methyl derivative(s) in the presence of other *O*-methyl ethers. It appears that superimposition of the g.l.c. signals of these two types of compound under six analysis conditions is unlikely. An alternative method of identification of *N*-methyl sugars in a methylation product is possible in which they are concentrated by ion-exchange chromatography prior to g.l.c. A suggested procedure is reduction of the methylation mixture by sodium borohydride followed by preferential absorption of the *N*-methyl hexitol on a column of a cation-type ion exchange resin. It can then be eluted with aqueous ammonium hydroxide and examined by the g.l.c. procedure.

Experimental

Preparation of Derivatives for Gas–Liquid Chromatography

(1) Preparation of 2-Deoxy-O-methyl-2-methylamino-D-hexitols

N-Methyl-hexosamine hydrochlorides (10 mg) were dissolved in water (1 ml) containing sodium borohydride (5 mg). After 3 h excess reagent was destroyed with acetic acid and the solutions evaporated to dryness. Boric acid was removed as trimethyl borate by dissolving the residues in methanol and evaporating, a process that was repeated three times.

(2) Preparation of Acetates

Samples of *N*-methyl-hexosamine hydrochloride and *N*-methyl-hexosaminitol containing approximately 1 mg of material were treated with acetic anhydride – pyridine (0.2 ml:0.2 ml) at 100° for 2 h and the solutions then evaporated *in vacuo*. The residues were dissolved in chloroform (0.5 ml) and applied to the g.l.c. columns in 3 μl aliquots.

(3) Trimethylsilyl Ethers

One milligram samples of sugar were converted to the t.m.s. ethers by the method of Sweeley *et al.* (10). Two-tenths of a milliliter of reagent was used and the solutions (3 μl) were applied directly to the g.l.c. column.

Gas–Liquid Chromatographic Procedure

The columns used are as follows: *(1)* a 3 ft × 1/8 in. (i.d.) glass column containing 10% of NPGSb (Applied Science Laboratories, State College, Pennsylvania) on silanized, acid-washed Chromosorb W (80–100 mesh), pretreated with Silyl 8 column conditioner (0.2 ml; Pierce Chemical Company). *(2)* A 4 ft × 1/8 in. (i.d.) glass column containing 3.8% of silicone gum UC W-98 (Chromatographic Specialties Ltd., Brockville, Ontario) on silanized, acid-washed Chromosorb W (80–100 mesh).

The g.l.c. unit was a Hewlett–Packard Model 402 incorporating a hydrogen flame detector operated under the following conditions: H_2 pressure: 12 p.s.i., rotameter reading 2.5; He pressure: 45 p.s.i., rotameter reading 3; air pressure: 30 p.s.i., rotameter reading 3.75.

Oxydation des alcènes par l'ion thallique. I. Stéréochimie et mécanisme de l'oxydation des cyclohexènes

C. Freppel, R. Favier, J.-C. Richer, et M. Zador
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 15 mars 1971

L'étude de la stéréochimie des diols formés dans l'oxydation du tert-butyl-3 cyclohexène par le sulfate thallique a permis de mettre en évidence la participation du groupe hydroxyle en α lors de la rupture de la liaison C—Tl de l'intermédiaire organothalleux. En effet, seuls les diols *trans* ont été obtenus ce qui exclut la substitution S_N2 par l'eau. Il est suggéré que l'oxydation thallique en milieu aqueux peut constituer une synthèse en une seule étape de diols *trans* dans le cas des systèmes rigides où l'organothalleux intermédiaire a une configuration diaxiale. La formation d'un seul diol diaxial lors de l'oxydation du tert-butyl-4 cyclohexène tend à confirmer cette hypothèse.

The stereochemistry of the diols obtained by oxidation of 3-*t*-butylcyclohexene by thallic sulfate indicates that the α hydroxyl group participates in the breaking of the C—Tl bond of the intermediate organothallous compound. The fact that only the *trans* diols are obtained indicates that an S_N2 substitution of the thallium can be excluded. We suggest that the thallic oxidation in aqueous media of olefin of rigid conformation is an excellent one-step method of preparing *trans* diols. The formation of the *trans* diaxial diol upon oxidation of 4-*t*-butylcyclohexene tends to confirm that hypothesis.

Canadian Journal of Chemistry, 49, 2586 (1971)

Introduction

Au cours des dernières années l'étude de l'oxydation thallique de nombreuses substances organiques a été effectuée (1). L'oxydation thallique des oléfines conduit à la formation de diols-1,2 ainsi qu'à la formation de produits carbonylés qui peuvent être prépondérants en milieu non-aqueux (2, 3).

Bien que le mécanisme réactionnel ait déjà été discuté par plusieurs auteurs (1–5), le mécanisme de rupture du lien C—Tl conduisant aux diols-1,2 n'a pas été élucidé quant à savoir s'il se fait par attaque S_N2 du solvant ou par participation du groupe hydroxyle en α. En vue d'élucider ce point nous avons étudié l'oxydation du tert-butyl-3 cyclohexène par le sulfate thallique en système hétérogène solution aqueuse de sulfate thallique – oléfine surnageant.

Le tert-butyl-3 cyclohexène a été choisi à cause de la rigidité de sa conformation, ce qui permet l'obtention de renseignements univoques sur le mécanisme réactionnel. De plus, l'identification des quatre diols isomères conformationnels est possible par comparaison avec les produits purs (6). La nature des diols obtenus permet de préciser la stéréochimie de la réaction, et ceci en comparaison avec les études d'addition électrophile effectuées sur ce système (7).

Pour compléter les résultats il nous semblait intéressant de les comparer avec ceux pour le cyclohexène, obtenus dans les mêmes conditions.

Le sulfate thallique en milieu aqueux a été choisi comme réactif pour plusieurs raisons: (*i*) il est très facile à préparer, (*ii*) sa réactivité n'est pas trop influencée par la présence d'ions sulfate (8), (*iii*) l'extraction des produits n'est pas affectée par la présence d'acide perchlorique qui est à éviter à cause de son instabilité en milieu anhydre, et (*iv*) il n'y a pas de réactions secondaires avec le solvant.

Résultats et discussions

L'oxydation du cyclohexène (**1**) par le sulfate thallique conduit avec un faible rendement à de nombreux produits d'oxydation (**2**, **3**, **4**, **5**, et **6**).

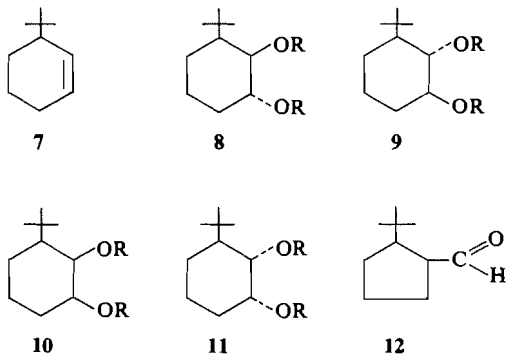
†Colonne *b*: 6′ × 1/8″, DEGS 15% déposé sur gaz chrom. R 80–100 mesh; débit: 1 ml/s; gaz porteur N_2; T = 120 °C; Chromatographe F.M. 700.

Le tableau 1 résume les résultats obtenus. L'identification des produits a été effectuée par c.p.g. par superposition des pics grâce à des produits de référence.

L'oxydation du tert-butyl-3 cyclohexène (**7**) conduit avec un bon rendement principalement à un mélange de diols *trans* (**8** et **9**) isomères (R = H).



7 **8** **9**

10 **11** **12**

Le tableau 2 résume les quantités relatives des produits obtenus.

D'après les résultats obtenus pour les deux systèmes les constatations suivantes s'imposent: (*i*) l'oxydation qui est très peu sélective dans le cas du cyclohexène et qui donne des produits d'oxydation successive, apparaît au contraire très sélective dans le cas du tert-butyl-3 cyclohexène, (*ii*) alors que la réaction est pratiquement instantanée avec le cyclohexène, celle du tert-butyl-3 cyclohexène est très lente, (*iii*) l'oxydation du tert-butyl-3 cyclohexène conduit uniquement à des diols *trans* (**8** et **9**) à l'exclusion des diols *cis* (**10** et **11**), (*iv*) cette réaction permet donc la synthèse en une seule étape des diols *trans* (**8** et **9**).

†Selon toute probabilité d'après des indications spectroscopiques et par analogie au cas du cyclohexène il s'agit de l'aldéhyde **12**.

Le mécanisme du schéma 1 permet de rendre compte d'une manière cohérente des différences observées entre les deux systèmes et permet de préciser le mécanisme intime de formation des diols par oxydation thallique.

Dans toutes les réactions la première étape est celle de formation d'un complexe entre l'ion thallique et la double liaison, un ion ponté à trois centres, comme cela est généralement admis par analogie avec l'oxymercuration (3–5). Ce type d'intermédiaire, semblable à un ion bromonium cyclique, a été proposé récemment lors de l'étude de l'influence des substituants sur la vitesse d'oxydation par l'acétate thallique (10).

Dans le cas du tert-butyl-3 cyclohexène deux différents ions pontés, *cis* **13** et *trans* **14** peuvent exister. L'ouverture de l'ion ponté *cis* **13** donne exclusivement un seul organothalleux **15** alors que son isomère *trans* **14** en donne deux, **16** et **17**. Ceci est analogue à l'ouverture d'ions pontés de ce type observés dans l'addition électrophile sur le tert-butyl-3 cyclohexène (6) et (7).

Le fait que les seuls produits observés soient des diols *trans* (**8** et **9**) à l'exclusion de diols *cis* (**10** et **11**), d'une part indique la nécessité de faire appel à un ion ponté à trois centres et constitue donc une nouvelle preuve de son existence et, d'autre part, est en accord avec un mécanisme faisant intervenir la participation du groupe hydroxyle des intermédiaires organothalleux (**15**, **16**, et **17**). Les résultats prouvent sans ambiguité qu'il n'y a pas de substitution S_N2 du Tl par le solvant tel qu'invoqué par plusieurs auteurs (3–5). Il est évident que le mécanisme de participation ne peut être prépondérant que si l'organothalleux intermédiaire a la configuration *trans* diaxiale **15**. Dans le cas d'un organothalleux diéquatorial, le mécanisme de régression de cycle est sans doute favorisé. Il est à noter que les résultats seraient compatibles avec un mécanisme S_Ni avec rétention de configuration ou avec la formation d'un intermédiaire époxyde à partir de **15**, **16**, et **17**, mais aucune évidence expérimen-

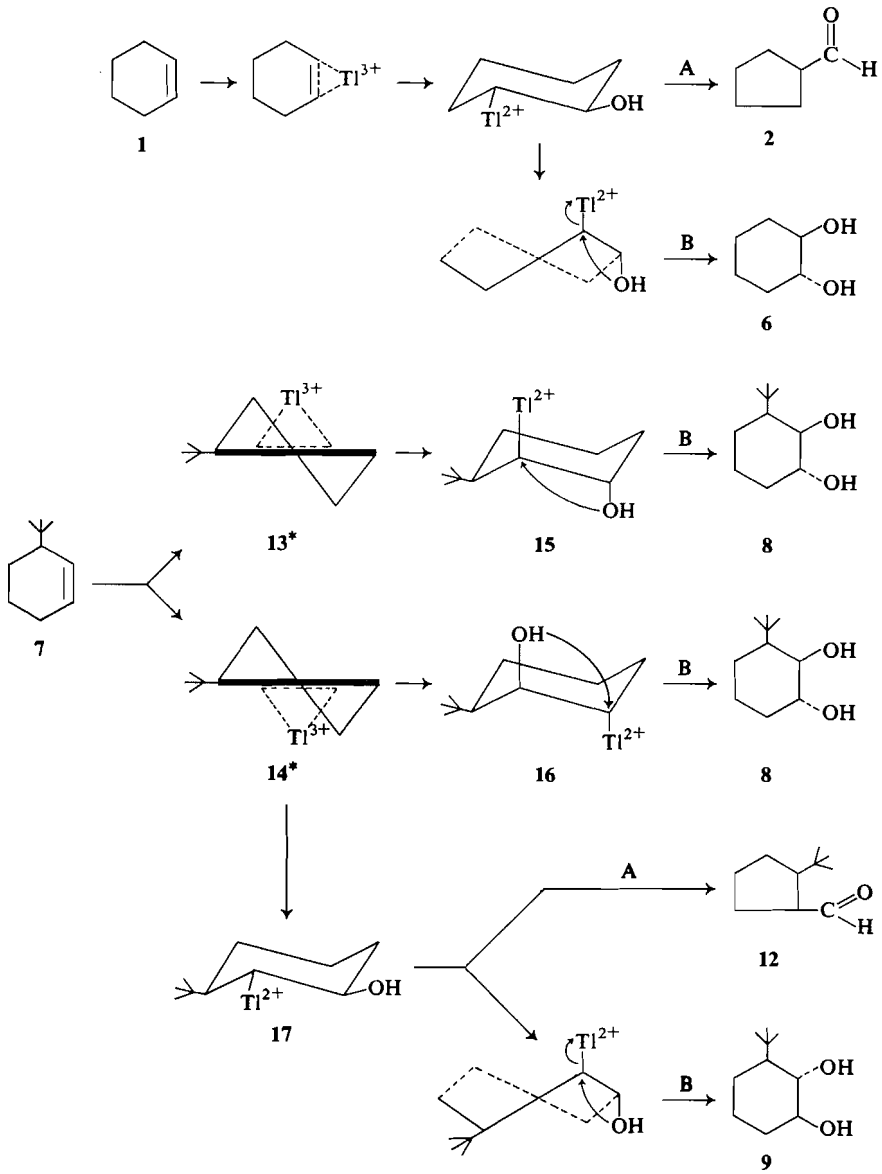

SCHÉMA 1. (A) Régression de cycle, (B) participation, où Tl^{3+} représente diverses espèces thallique en solution (8). *La représentation des conformations est identique à celle souvent utilisée pour les époxydes cyclohexaniques (9).

tale n'est disponible pour confirmer une ou l'autre de ces hypothèses.

Dans le cas du cyclohexène, l'ouverture de l'ion ponté conduit principalement à l'organothalleux diéquatorial, qui par un mécanisme de régression pouvant devenir prépondérant dans certaines conditions (3), conduit à l'aldéhyde **2** correspondant. Bien que l'intermédiaire chaise diaxiale conduirait aussi aux diols *trans*, on n'en a pas tenu compte étant donné qu'il est largement défavorisé par rapport à son isomère diéquatorial.

Pour conclure, le mécanisme, proposé pour la formation de diols-1,2 par oxydation thallique d'oléfines en solution aqueuse, peut être généralisé de la manière suivante: formation d'un ion ponté à trois centres, ouverture en un organothalleux et, participation du groupe hydroxyle lors de la rupture de la liaison C—Tl. L'applica-

tion de ce mécanisme très général à la synthèse de diols-1,2 nécessite cependant une condition: l'organothalleux intermédiaire doit être de nature *trans* diaxial. Cette condition est réalisée dans le cas du tert-butyl-4 cyclohexène et, comme prévu par le mécanisme proposé on obtient exclusivement un diol *trans* diaxial, le tert-butyl-4 *cis* cyclohexane-diol-1,2 *trans*. De plus, si l'on désire des rendements en diols élevés, l'oxydation en milieu aqueux est la plus avantageuse à cause de la prépondérance de la participation du groupe hydroxyle.

En conclusion, il est donc probable que dans d'autres systèmes rigides, tels les stéroides, la méthode d'oxydation thallique en milieu aqueux hétérogène puisse constituer une méthode intéressante de synthèse en une seule étape de diols *trans* et nous poursuivons nos travaux dans ce domaine.

Partie expérimentale

(1) Oxydation du tert-butyl-3 cyclohexène

Dans un ballon à fond rond de 2 l, 2.2 mmol de tert-butyl-3 cyclohexène est ajouté à 900 ml d'eau et à 4 mmol de sulfate thallique obtenu par dissolution de l'oxyde thallique dans 100 ml d'une solution d'acide sulfurique 2 *M*. Le mélange réactionnel est agité 6 jours à 35 °C puis la solution est saturée de sel et extraite trois fois avec 400 ml d'éther. La solution aqueuse est rendue basique et extraite à nouveau avec 400 ml d'éther. Les phases éthérées sont réunies et neutralisées jusqu'à p*H* neutre au moyen d'une solution aqueuse de soude. La solution organique est séchée sur du carbonate de sodium anhydre et concentrée sous vide pour donner 250 mg (ρ = 67%) d'un produit huileux dont la c.p.g. sur une petite partie sililée (11) indique la présence de 73% du diol *trans* diaxial **8**, 10% du diol *trans* diéquatorial **9**, et 18% d'un produit non identifié.

Une expérience similaire réalisée à température ordinaire pendant 4 jours conduit à un produit constitué par 57% de tert-butyl-3 cyclohexène (**1**) n'ayant pas réagit, 6.5% d'un produit non identifié, et 36.5% de diol constitué par 88% de diol diaxial **8** et 12% de diol diéquatorial **9**.

Les diols isomères **8**, **9**, **10**, et **11** ont été préparés par la méthode décrite auparavant (6).

(2) Oxydation du cyclohexène

L'oxydation du cyclohexène a été réalisé dans des conditions analogues mais la réaction a été terminée au bout d'une dizaine de minutes. Par suite de la grande solubilité de certains des composés dans l'eau ainsi que l'instabilité de l'aldéhyde **2**, le pourcentage des produits obtenu après extraction n'a pas de signification. Toutefois l'aldéhyde **2** est le produit majeur et la quantité de diol formé ne dépasse probablement pas 5%.

(3) Oxydation du tert-butyl-4 cyclohexène

L'oxydation du tert-butyl-4 cyclohexène a été réalisée de la même manière que **7**, mais la réaction étant beaucoup plus rapide, elle était terminée au bout de 4 h. En partant de 2 g de tert-butyl-4 cyclohexène, après trois extractions à l'acétate d'éthyle, on a obtenu 1.15 g de tert-butyl-4 *cis* cyclohexanediol-1,2 *trans* cristallin qui est le seul produit obtenu. L'identification du produit a été effectuée par comparaison des spectres r.m.n. et i.r. avec le produit de référence obtenu par l'ouverture des époxydes correspondants (12). Les points de fusions sont identiques, p.f. 143–144 °C (litt. (12) 141–142 °C).

Les auteurs remercient le Conseil National de Recherches du Canada et le Ministère de l'Education du Québec pour les octrois de recherches accordés.

Oxydation des alcènes par l'ion thallique. II. Méthode d'oxydation électrochimique catalysée par l'ion thallique

R. Favier, C. Freppel, J.-C. Richer, et M. Zador
Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 2 avril 1971

L'oxydation électrochimique de substrats organique contenant des liaisons doubles a été réalisée. L'ion thallique joue un rôle d'intermédiaire ou de catalyseur dans l'oxydation:

$$Tl(I) \xrightarrow{\text{anode}} Tl(III)$$

$$Tl(III) + \text{alcène} \longrightarrow \text{produits} + Tl(I)$$

En effectuant l'oxydation à potentiel contrôlé et dans un système à compartiments anodique et cathodique séparés on a obtenu des rendements faradayiques intéressants, ce qui permet l'application de la méthode en synthèse dans les cas où l'oxydation thallique est sélective.

Electrochemical oxidation of organic substrates containing double bonds has been accomplished. Thallic ion is a catalyst in the oxidation:

$$Tl(I) \xrightarrow{\text{anode}} Tl(III)$$

$$Tl(III) + \text{alkene} \longrightarrow \text{products} + Tl(I)$$

Relatively high current efficiencies are obtained while performing the oxidation at controlled potential, and by separating the anodic and cathodic compartments; this fact allows the use of this method in synthesis in cases where the thallic oxidation is selective.

Canadian Journal of Chemistry, **49**, 2590 (1971)

Introduction

Comme le montre la littérature récente, le Tl(III) oxyde des substances contenant une liaison double sans dégrader ces dernières et, dans certains cas, peut conduire à la synthèse en une seule étape d'un produit d'oxydation (1).

Le but du présent travail est la mise au point d'une méthode électrochimique permettant l'oxydation électrochimique de diverses oléfines où le Tl(I) est réoxydé *in situ* et le Tl(III) ne joue donc qu'un rôle d'intermédiaire d'après le schéma:

[1] $$Tl(I) \xrightarrow{\text{anode}} Tl(III)$$

[2] $$Tl(III) + \text{alcène} \longrightarrow \text{produits} + Tl(I)$$

Dans la somme des éqs. 1 et 2, les deux états d'oxydation du thallium disparaissent; le thallium a donc un rôle de catalyseur de l'oxydation électrochimique de l'alcène. La transformation du Tl(I) en Tl(III) est connue (2), et dernièrement une méthode continue a pu être réalisée (3). Toutefois à cause du potentiel d'oxydo-réduction élevé du système Tl^+/Tl^{3+}, $E_0 = 1.25$ V (4), et à cause de la possibilité d'oxydation des substances organiques à des potentiels élevés, une étude approfondie est nécessaire: ceci est aussi important si l'on désire obtenir des rendements faradayiques élevés.

Résultats et discussions

Les considérations théoriques, confirmées par des essais préliminaires, montrent que pour empêcher la réduction du Tl(I) à la cathode, il est indispensable de travailler à l'aide d'un système à deux compartiments.

Pour trouver le domaine d'oxydation du Tl(I), on a étudié les diagrammes d'intensité–potentiel (5) du Tl(I) et du solvant avec l'électrolyte de support, dans les conditions expérimentales, choisies pour l'oxydation par la suite: aux mêmes concentrations, utilisant les mêmes électrodes fixes à grande surface, agitation magnétique etc.

Les résultats montrent qu'aux environs d'un potentiel, E, de 2 V par rapport au calomel saturé, l'oxydation du Tl(I) se fait de manière satisfaisante (courbe *a*, fig. 1). L'étude similaire de l'électrolyte support ($HClO_4$ dans l'eau) en

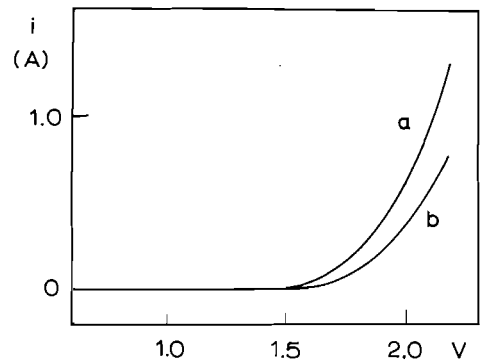

FIG. 1. Diagrammes intensité–potentiel. Solvant, H_2O; $T = 26 \pm 0.5$ °C; agitation magnétique; $[HClO_4] = 1.0\ M$; courbe *a*, $[TlClO_4] = 1.0 \times 10^{-2}\ M$; courbe *b*, $[TlClO_4] = 0$, avec ou sans cyclohexanedione-1,2 cyclohexène, tert-butyl-3 cyclohexène.

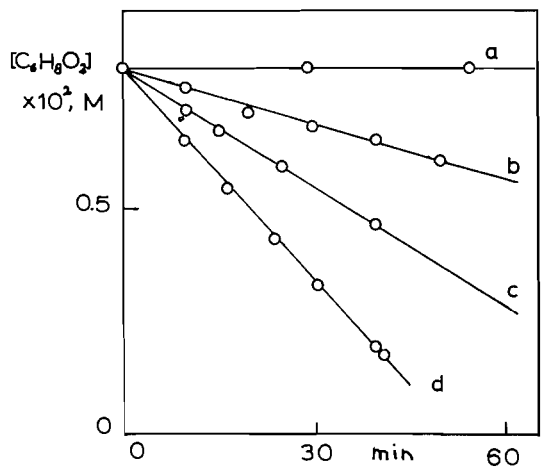

FIG. 2. Oxydation de la cyclohexanedione-1,2. Solvant, H_2O; $T = 26 \pm 0.5$ °C; agitation magnétique; $[HClO_4] = 0.9\ M$; courbe *a*, $[TlClO_4] = 0$, $E = 2.0$ V; courbe *b*, $[TlClO_4] = 1.0 \times 10^{-2}\ M$, $E = 1.9$ V; courbe *c*, $[TlClO_4] = 1.0 \times 10^{-2}\ M$, $E = 2.0$ V; courbe *d*, $[TlClO_4] = 1.0 \times 10^{-2}\ M$, $E = 2.15$ V.

absence de Tl(I) révèle qu'à ces potentiels l'oxydation de l'eau est loin d'être négligeable (courbe *b*, fig. 1) ce qui se manifeste par un dégagement d'oxygène à l'anode. Il en découle qu'il est nécessaire d'opérer à des potentiels aux environs de 2 V et que si on veut un rendement faradayique raisonnable, on ne peut pas augmenter ce potentiel au delà de 2 à 2.2 V; il est impossible donc d'opérer aux potentiels correspondants au courant limite du système Tl^+/Tl^{3+}.

Oxydation de la cyclohexanedione-1,2

Pour trouver les caractéristiques générales de l'oxydation électrochimique, la cyclohexanedione-1,2 a été étudiée comme exemple type étant donné que (*i*) la disparition de sa forme énol prépondérante peut être facilement suivie par spectrophotométrie u.v., (*ii*) sa grande solubilité dans l'eau permet une étude sur un système homogène, et (*iii*) la cinétique de son oxydation par le Tl(III) est connue dans diverses conditions (6, 7).

La fig. 2 montre quelques résultats types obtenus lors de l'oxydation à potentiel contrôlé (8). La courbe *a* représente une expérience en absence de $TlClO_4$; on constate que le réactif seul ne subit aucune oxydation. Les autres courbes représentent la disparition de la cyclohexanedione-1,2 en présence du Tl(I) d'après le schéma suivant:

$$[3] \qquad Tl^+ \xrightarrow{\text{anode}} Tl^{3+} + 2e^-$$

$$[4] \qquad Tl^{3+} + C_6H_8O_2 + H_2O \longrightarrow Tl^+ + C_6H_8O_3 + 2H^+$$

L'oxydation se fait à vitesse constante, qui est d'ailleurs celle de l'éq. 3; l'étape suivante, [4], est très rapide dans les conditions expérimentales (6) et la concentration du Tl(III) reste très petite tant qu'il reste du réactif en solution. Le temps de demi-vie du Tl(III) au début de la réaction est de l'ordre de 0.05 min (6) ce qui est très petit par rapport à l'échelle de temps de la fig. 2. Comme la concentration du Tl(I) reste pratiquement constante, la vitesse d'oxydation anodique reste stationnaire. Les résultats, tels que présentés à la fig. 2 permettent de calculer le rendement faradayique, *R*, dans diverses conditions. Il est défini par:

$$R = -\frac{d[C_6H_8O_2]}{dt} \times \frac{VnF}{i}$$

où *V* est le volume total du compartiment anodique; *n* est le nombre d'électrons impliqués, 2; *F* est le faraday; *i* est le courant moyen; et *t* le temps.

Les rendements faradayiques sont résumés au tableau 1; ils sont tous nettement inférieurs à un ce qui est normal à cause de l'oxydation de l'eau aux potentiels utilisés. La comparaison des expériences *1*, *2*, et *3* montre que bien que la vitesse de l'oxydation du réactif augmente par augmentation du potentiel imposé (fig. 2), le rendement faradayique diminue dans les mêmes conditions, parce que l'oxydation de l'eau

Cyclohexanediol-1,2	144	67.6		15.4
B. tert-Butyl-3 cyclohexène; $R = 0.16 \pm 0.02$				
tert-Butyl-3 cyclohexanediol-1 *trans*, 2 *cis**			14.6	44.3
tert-Butyl-3 cyclohexanediol-1 *cis*, 2 *trans*			16.2	33.2
Inconnu†			12.0	22.5

*Les termes *cis* et *trans* précisent la configuration d'un substituant par rapport au groupe tert-butyl supposé équatorial dans tous les cas.
†D'après les évidences spectroscopiques il s'agit probablement du tert-butyl-2 cyclopentane carboxaldehyde.

devient de plus en plus importante. La diminution du rendement faradayique quand on diminue la concentration du Tl(I) peut être expliquée de la même manière (expériences *1* et *4*). Finalement, l'utilisation d'un mélange d'acétonitrile–eau comme solvant, fait également diminuer le rendement (expérience *5*). Nous avons observé une anomalie de la courbe intensité–potentiel de ce système commençant à ~1.4 V, due probablement à la réaction du solvant (9). L'oxydation dans ce solvant a été étudiée en vue de son utilisation dans le cas de certaines oléfines complètement insolubles dans l'eau.

Les résultats obtenus lors de l'étude à potentiel contrôlé, à l'aide de l'appareillage à trois électrodes, ont permis de trouver les conditions expérimentales, tel que la différence de potentiel entre l'électrode de travail et l'électrode auxiliaire, pour l'utilisation d'une source D.C. à potentiel variable. Ce dernier est beaucoup plus accessible et courant dans les laboratoires ou dans l'industrie et si son utilisation se fait dans de bonnes conditions, permet d'obtenir des résultats semblables aux précédents (expérience *6*).

Oxydation du cyclohexène et du tert-butyl-3 cyclohexène

L'oxydation des cyclohexènes a été effectuée dans un système hétérogène: solution aqueuse–alcène surnageant avec des rapports alcène/Tl(I) = 100–200. Les résultats sont groupés dans le tableau 2. Les rendements faradayiques sont du même ordre de grandeur que ceux obtenus auparavant. Les produits sont les mêmes que ceux obtenus lors de l'oxydation directe par le sulfate thallique (10) avec une augmentation de la proportion des produits d'oxydation successive. Dans le cas du tert-butyl-3 cyclohexène seules les diols *trans* sont obtenus comme lors de l'oxydation directe (10).

L'ensemble des résultats obtenus permet donc de conclure, qu'en choisissant avec soin le potentiel, l'oxydation électrochimique, catalysée par le Tl(III), de composés organiques à liaison double peut être effectuée avec des rendements faradayiques intéressants. Evidemment la sélectivité de cette méthode ne peut pas dépasser celle de l'oxydation directe par le Tl(III) mais elle offre comme avantage d'être relativement peu

For personal use only.

couteuse, nécessitant d'une part une source D.C. à potentiel variable simple et d'autre part, de faibles quantités de sels thalleux pour la transformation de grandes quantités de substrats organiques.

Partie expérimentale

Appareillage

La cellule réactionnelle a deux compartiments cylindriques, d'un volume de 300 ml chacun, qui sont séparés par un verre frité, type M, de 27 mm de diamètre se trouvant au milieu du tube de verre reliant les deux compartiments; dans ce système la diffusion du Tl^+ est négligeable d'un compartiment à l'autre. La cellule a été placée dans un thermostat pour maintenir la température constante. Les courbes intensité–potentiel ont été réalisées à l'aide d'un appareil Tacussel Servovit-9A, un milliampèremètre Tacussel Bluxy 427 et un enregistreur X-Y Sefram TRVAC.

L'oxydation à potentiel contrôlé a été réalisée à l'aide d'un potentiostat Tacussel-PRT 20-2X en utilisant un système à trois électrodes dont deux sont placées dans le compartiment anodique, l'électrode de travail et l'électrode de référence au calomel saturé, la troisième, l'électrode auxiliaire se trouve au compartiment cathodique. L'électrode de travail et l'électrode auxiliaire sont en platine de 10 cm^2 et de 6 cm^2 respectivement.

Le générateur D.C. à potentiel variable est un Electro Product Laboratories Inc. Mode D-612T filtered D.C. Power supply.

Préparation du perchlorate thalleux

Le perchlorate thalleux a été obtenu par réduction du perchlorate thallique en solution par le peroxyde d'hydrogène; par abaissement de la température, le perchlorate thalleux précipite de la solution contenant environ 4 *M* d'ions perchlorate; la solution de perchlorate thallique a été obtenu par dissolution de l'oxyde thallique (Fairmount Chemical Co. Inc.) dans l'acide perchlorique.

Oxydation de la cyclohexanedione-1,2

Les solutions de cyclohexanedione-1,2 ont été fraîchement préparées pour chaque série d'expériences par dissolution du réactif solide (J. T. Baker) étant donné qu'en conservant les solutions pendant de longues périodes la forme énolique se transforme en cétone (6, 11).

L'oxydation a été effectuée à potentiel contrôlé ou en utilisant la source D.C. La disparition de la forme énolique dans le compartiment anodique a été suivie par l'analyse spectrophotométrique des échantillons prélevés à intervalles réguliers à la longueur d'onde $\lambda = 265$ mμ. Le volume des solutions est de 200 ml dans chacun des compartiment; le compartiment cathodique contient de l'acide perchlorique comme électrolyte à la même concentration que celle du compartiment anodique.

Oxydation du cyclohexène

La composition du compartiment anodique est la suivante: 200 ml de solution aqueuse 0.9 *M* en $HClO_4$ et 0.01 *M* en $TlClO_4$ + 20 ml de cyclohexène ($\sim$ 0.2 mol). L'oxydation est effectuée à potentiel contrôlé: 2.1 V (par rapport au calomel): $i = 0.3$ A. Après 96 h la totalité de l'alcène disparaît; l'extraction continue au chloroforme conduit à un mélange de produits correspondant à $\sim$60% de l'alcène de départ, ce qui correspond à un rendement faradayique d'au moins 0.2. L'identification des produits est effectuée par c.p.g. par superposition des pics avec des produits de référence. Le cyclopentane carboxaldéhyde a été obtenu par ozonolyse du cyclopentyl-3 acrylate d'éthyle. Colonne *a*: 12′ × 1/4″, Carbowax 4000, 6% Fluoropak 40 60–80 débit: 12 ml/s; gaz porteur N_2; T = 155 °C; Chromatographe Varian, Aerographe 90P. Colonne *b*: 6′ × 1/8″: DEGS 15% gaz chrom. R 80–100; débit 1 ml/s; gaz porteur N_2; T = 120 °C; Chromatographe F.M. 700.

Oxydation du tert-butyl-3 cyclohexène

Les méthodes et conditions expérimentales sont identiques à celles décrites ci-dessus. La quantité d'alcène étant de 15 ml ($\sim$0.095 mol), après 96 h la totalité a réagit ($R \sim 0.16$). La chromatographie a été effectuée sur les esters sililés. Les produits de référence ont été obtenus par ouverture des époxydes (12). Colonne *c*: 6′ × 1/4″; 10% Sil Gum Rub UC-98 diatoport 80–100; débit: 1 ml/s; T = 160 °C; Chromatographe F. M. 700.

Les auteurs remercient le Conseil National de Recherches du Canada et le Ministère de l'Education du Québec pour les octrois de recherches accordés ainsi que le professeur M. Abraham du Département de Chimie pour avoir bien voulu mettre à leur disposition divers appareils électrochimiques.

Isomérisation des époxydes

KRZYSZTOF JANKOWSKI ET JEAN-YVES DAIGLE
Département de Chimie, Université de Moncton, Moncton, Nouveau-Brunswick

Reçu le 30 mars, 1971

L'isomérisation des époxydes sur les cycles à cinq et à six a été réalisée par l'action du cyanate de potassium en milieu éthanol–eau. Les spectres de r.m.n. des époxydes *trans* et *cis* ont été étudiés.

Isomerization of five and six-membered ring epoxides was realized through the action of potassium cyanate in ethanol–water medium. The n.m.r. spectra of *trans* and *cis* epoxides were studied.

Canadian Journal of Chemistry, 49, 2594 (1971)

En s'inspirant de la réaction d'obtention d'épithiocyclohexane (1), par l'action de thiocyanate de potassium sur l'époxycyclohexane, nous avons réalisé l'isomérisation des époxydes par le traitement avec le cyanate de potassium (schéma 1).

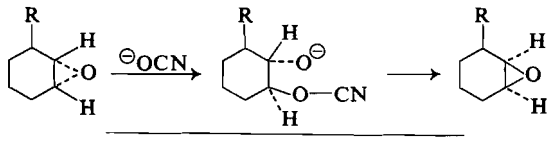

SCHÉMA 1

L'époxyde *trans* (du départ) s'isomèrise donc en époxyde *cis* et la réaction atteint probablement un équilibre. L'isomérisation des époxydes avec notre méthode peut être appliquée là où l'obtention d'un époxyde spécifique est difficile (p. ex. pour des époxydes stéroidaux (2)). Tout d'abord l'époxydation de méthyl-2 cyclopentene (1) avec l'acide *m*-chloroperbenzoïque donne un mélange d'époxydes *trans* **2***a* et *cis* **2***b* avec un rapport 60:40.

L'époxydation de l'hydroxy-2 cyclohexene (**3**) avec même peracide donne principalement l'époxyde *trans* **4***a* (3).

Les preuves de l'isomérisation ont été apportés par l'étude des spectres r.m.n. (tableaux 1 et 2).

Le mélange des époxydes **2***a* et *b* après l'isomérisation dans des conditions standards a révélé la présence de 44% d'isomère **2***a* et 56% d'isomère **2***b*. Nous avons observé que les protons oxiranniques d'époxyde *trans* se trouvent déplacés $\Delta\delta = +0.06$ p.p.m. par rapport aux mêmes protons d'un époxyde *cis*. Cette différence nous a servi pour l'identification des époxydes.

Nous avons observé que les époxycyclohexanes s'isomèrisent mieux que les époxycyclopentanes. Le signal du proton sur le noyau oxirannique d'époxyde *trans* est également déplacé ($\Delta\delta = +0.12$ p.p.m.) vers les champs plus bas par rapport au même proton d'époxyde *cis*. Cette relation a déjà été observée par nous mêmes (2) et par Tori *et al.* (4) et en général la différence est plus grande pour les époxydes sur les cycles à six que des époxydes sur les cycles à cinq.

L'action du cyanate de potassium sur l'époxyde acétylé **6***a* donne en plus de l'isomérisation (20%), le mélange des deux autres époxydes **4***a* et *b* dû à la déacétylation en milieu basique (les protons oxiranniques 3.31 et 3.18, les protons en α d'hydroxyle 4.1 p.p.m.).

Les preuves supplémentaires des structures des époxydes ont été obtenues par l'étude des spectres r.m.n. des dérivés hydroxylés (ouverture des époxydes en milieu basique).

Le mélange des époxydes **2***a* et *b* hydrolysé a donné principalement le méthyl-3 cyclopentanediol-1,2 (**7**) possédant la structure *trans* diéquatorial des deux groupements hydroxylés (déplacement chimiques des C*H*O 2.73 et 3.15). On voit également deux signaux du méthyle 0.37 et 0.44 p.p.m. attribuables aux méthyles axial et équatorial correspondants.

L'époxyde **4***b* hydroxylé (i.r. 3480 cm^{-1} pont hydrogène (5) absent pour la structure **4***a*) a donné le cyclohexane-triol-1,2,3-D,L-1,2/3 (**8**). Nous avons isolé également une petite quantité d'un cyclohexane-triol-1,2,3-*méso*-1,3/2 (**9**) obtenu par l'attaque nucléophile sur l'autre carbone d'époxyde.

Les structures **8** et **9** ont été prouvées par des spectres r.m.n. Le triol **8** donne un spectre identique à celui décrit par McCasland *et al.* (6), déplacements chimiques des protons en α d'hydroxyle 4.10, 3.45, et 3.78 p.p.m.

L'autre triol **9** a donné les signaux pour deux protons en α d'hydroxyle (symmétrie) à 3.40 p.p.m. et un proton à 3.10 p.p.m. Ces données

‡Spectre dans D_2O.

concordent bien avec la littérature (5). On a obtenu également une petite quantité du produit insaturé, l'élimination en milieu basique caractérisée par le proton oléfinique à ~5. 7 p.p.m. (p.é. 45°/25 mm). Finalement l'ouverture d'époxyde **6***a* dans la même condition donne le mélange des triols **8** et **9** à cause de la déacétylation du produit de départ suivi de l'hydrolyse.

Toutefois pour avoir plus de preuves de structures, des études avec l'oxygène marqué seront tentées.

Partie expérimentale

Les spectres de r.m.n. ont été enregistrés à l'aide de spectrophotomètre Varian A-60 et Varian HA-100 dans $CDCl_3$ ou D_2O (concentration ~5%).

Les spectres i.r. ont été enregistrés avec un appareil Perkin–Elmer, modèle 237-B ($CHCl_3$).

Les analyses élémentaires ont été faites par la Compagnie Midwest Microlab, Indianapolis, Indiana.

Les points d'ébullition n'ont pas été corrigés.

Les époxydes ont été purifiés par distillation; le rendement de la distillation est 70–90%.

Le produit **5** a été obtenu avec le rendement de 60% par l'acétylation du produit **3** (Aldrich Chemicals) selon une méthode habituelle (pyridine-anhydride acétique).

Epoxydation des oléfines

Une solution d'oléfine (0.12 mol) en benzène anhydre (200 ml) et une solution d'acide *m*-chloroperbenzoïque 0.48 mol (200 ml) ont été refroidies (0°) et ensuite mélangées. Le mélange a été agité pendant 48 h, puis lavé avec le carbonate de potassium à 10% et le solvant a été évaporé *in vacuo*. Le produit pur a été obtenu par distillation.

Isomérisation des époxydes

L'époxyde (0.01 mol) a été ajouté à une solution de cyanate de potassium (0.01 mol) en éthanol–eau (1:1, 10 ml). Cette solution a été agitée pendant 48 h (25°). Le produit brut a été extrait avec le chloroforme et seché avec le sulfate de sodium anhydre. Le solvant a été évaporé *in vacuo* et le produit a été distillé.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Ouverture des époxydes

L'époxyde (1 g) a été ajouté à une solution d'hydroxyde de sodium à 10% dans l'éthanol (10 ml). Le mélange a été agité pendant 50 h. Le produit a été extrait avec le chloroforme, l'extrait a été seché avec le sulfate de sodium anhydre, puis le solvant a été évaporé sous vide et le produit a été distillé.

Les auteurs remercient le Conseil National de Recherches du Canada, le Département de Chimie de l'Université de Montréal, et la Compagnie Bristol-Myers pour l'aide apportée à ce travail.

Composés de coordination de molécules soufrées. II. Complexes pseudo-tétraédriques et plan du nickel(II) avec quelques dithiole-1,2 thiones-3

FRANÇOIS YVES PETILLON ET JACQUES EMILE GUERCHAIS
Laboratoire de Chimie Minérale, U.E.R. des Sciences, Avenue Le Gorgeu, Université de Brest, 29N, France

Reçu le 10 mars 1971

L'étude dans l'infrarouge lointain permet de distinguer les complexes NiI_2L_2 pseudo-tétraédriques, originaux (L = $R_1R_2C_3S_3$ où $R_1 = CH_3$ et $R_2 = H$, $R_1 = R_2 = CH_3$, $R_1 = C_4H_3S$ et $R_2 = H$) du composé plan $NiI_2L'_2$ (L' = $R_1R_2C_3S_3$ où $R_1 = C_6H_5$ et $R_2 = H$). Les spectres électroniques enregistrés à l'état solide confirment cette distinction. Le déplacement de la bande $\nu_{C=S}$ de la molécule de dithiole-1,2 thione-3, qui rentre dans la sphère de coordination, est plus important dans les composés du cobalt(II) que dans ceux du nickel(II).

The study of the far infrared spectral region permits one to distinguish between the pseudo-tetrahedral complexes NiI_2L_2 (L = $R_1R_2C_3S_3$ where $R_1 = CH_3$ and $R_2 = H$, $R_1 = R_2 = CH_3$, $R_1 = C_4H_3S$ and $R_2 = H$) and the square planar complex $NiI_2L'_2$ (L' = $R_1R_2C_3S_3$ where $R_1 = C_6H_5$ and $R_2 = H$). The electronic spectra recorded in the solid state confirm the distinction. The displacement of the band $\nu_{C=S}$ of the molecule 1,2-dithiol-3-thione which enters the sphere of coordination is more marked in the complexes of cobalt(II) than in the corresponding nickel(II) complexes.

Canadian Journal of Chemistry, 49, 2598 (1971)

Introduction

Jusqu'à ce jour, ce sont essentiellement les complexes avec les sels de métaux lourds qui ont été isolés avec les dithiole-1,2 thiones-3 ($HgCl_2$, $HgBr_2$, $SbCl_3$, $SbCl_5$, CdI_2, $AgNO_3$, $AuCl_4$, $PdCl_4$, $PtCl_4$, $BiCl_3$, $SnCl_4$) (1 à 4), c'est-à-dire en majorité des composés avec les ions métalliques de la classe B définie par Ahrand, Chatt et Davies (5), ceci en raison de leur attrait pour l'atome de soufre polarisable. Parmi les éléments de la première série de transition, seuls les composés avec le cuivre et le fer, respectivement aux degrés d'oxydation deux et trois, ont été mentionnés (6).

Dans le cadre d'une étude sur les complexes métalliques des dithiole-1,2 thiones-3, nous avons dans un travail récent (7), préparé et étudié les composés du cobalt(II).

Dans ces derniers complexes l'entourage pseudo-tétraédrique du métal a été mis en évidence et sa coordination à la molécule organique par le soufre de la fonction thione a été suggérée. Il était intéressant d'étudier le comportement du nickel(II) vis-à-vis de ces coordinats cycliques soufrés. Aussi nous avons isolé les complexes iodés du nickel(II) avec différentes dithiole-1,2 thiones-3 substituées $R_1R_2C_3S_3$, où R_1 et R_2 sont des radicaux hydrogène, méthyle, phényle ou thiényle.

Pour les nouveaux composés obtenus nous proposons un entourage du métal en nous basant sur les spectres électroniques, les propriétés magnétiques et une étude dans l'infrarouge lointain. Nous verrons l'influence de la coordination sur les principales bandes d'absorption des molécules organiques. L'éventualité d'une coordination π sera discutée.

Partie expérimentale

Produits de départ

Les dithiole-1,2 thiones-3 ont été préparées selon des procédés décrits dans la littérature (8) par action du P_4S_{10} soit sur la R_1 dimercapto-propénone, soit sur le β,β'-diéthoxypropionate d'éthyle dans le xylène à reflux; elles ont été recristallisées dans l'acétone. L'iodure de nickel anhydre utilisé est un produit K & K Laboratories, Inc.

Etudes spectroscopiques

Les spectres infrarouges ont été enregistrés sur un appareil 225 Perkin–Elmer. La méthode de suspension dans le nujol a été utilisée dans toute la longueur du spectre.

Les spectres électroniques sont obtenus à l'aide d'un appareil Beckman DK 2A, en utilisant une sphère de réflectance.

Mesures des susceptibilités magnétiques

Les mesures ont été réalisées à la température ordinaire, selon la méthode de Gouy. Les corrections de diamagnétisme ont été calculées à partir des tables données dans la littérature (9).

Préparation des complexes

On dissout à chaud 0.005 mole de dithiole-1,2 thione-3 et 0.0025 mole d'iodure de nickel anhydre dans de

TABLEAU 1. Résultats analytiques

Complexes	C %		H %		S %		I %		Ni %	
	Calc.	Tr.	Calc.	Tr.	Calc.	Tr.	Calc.	Tr.	Calc.	Tr.
$NiI_2(C_3H_2S_3)_2$	12.40	12.4	0.69	0.83	33.11	33.3	43.68	43.4	10.10	9.97
$NiI_2(C_4H_4S_3)_2$	15.77	15.8	1.32	1.48	31.58	31.6	41.67	40.9	9.64	10.07
$NiI_2(C_5H_6S_3)_2$	18.85	18.8	1.89	2.08	30.19	30.2	39.84	39.6	9.21	9.01
$NiI_2(C_7H_4S_4)_2$	22.56	22.6	1.08	1.14	34.42	34.0	34.05	33.4	7.87	7.91
$NiI_2(C_9H_6S_3)_2$	29.48	29.4	1.65	1.66	26.24	26.2	34.62	34.2	8.00	8.05

l'acétone fraîchement distillée (~300 ml). On porte le mélange à reflux pendant 30 min sous agitation. On évapore une partie du solvant, un solide noir ou vert-sombre précipite. On recristallise le complexe dans de l'acétone. On obtient une poudre cristalline.

Analyses

Le carbone, l'hydrogène et le soufre ont été analysés par le service central de microanalyse du C.N.R.S. de Thiais. L'iodure est dosé par potentiométrie avec une solution de nitrate d'argent titrée. Le nickel(II) a été dosé par précipitation avec la diméthylglyoxime sous forme de $Ni(C_4H_7N_2O_2)_2$. Celui-ci a été séché vers 110 °C jusqu'à poids constant.

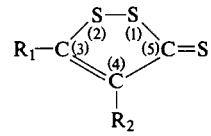
Résultats et discussion

Mesures magnétiques et conductimétriques

Les complexes obtenus sont peu solubles dans les solvants usuels (tétrachlorure de carbone, nitrométhane, nitrobenzène, chloroforme), et s'y décomposent très rapidement. De vert sombre les solutions deviennent jaunes ou brunes, au bout de quelques minutes. Même les solutions acétoniques ne sont pas très stables à faible concentration. Il a donc été impossible de mesurer leur conductivité.

Les résultats de l'analyse centésimale (tableau 1) sont en accord avec la formule NiI_2L_2, où L représente le coordinat organique. Plusieurs entourages du nickel sont possibles. D'autre part, bien qu'une structure ionique du type $[NiL_4]^{2+}[NiI_4]^{2-}$ ne soit pas à exclure a priori en l'absence de données conductimétriques, nous verrons que les spectres obtenus dans l'infrarouge lointain nous permettent d'écarter cette solution.

Les valeurs des moments magnétiques des produits (tableau 4) suggèrent un entourage plan du métal pour le di-iodobis (phényl-5 dithiole-1,2 thione-3) nickel(II) (composé *A*), et une symétrie pseudo-tétraédrique pour les quatre autres complexes (composés *B*). Pour ces derniers la contribution orbitale diminue avec l'encombrement stérique des substituants R_1 et R_2 des dithiole-1,2 thiones-3



ce qui est logique, et le moment magnétique passe de 3.68 mB pour le di-iodobis (dithiole-1,2 thione-3) nickel(II), à 3.29 mB pour le di-iodobis (thiényl-5 dithiole-1,2 thione-3) nickel(II). Notons enfin que certains échantillons du complexe A présentent un léger paramagnétisme (<0.8 mB) qui serait probablement dû à la présence d'un isomère tétraédrique.

Spectres électroniques

Les spectres électroniques des complexes enregistrés à partir de solutions dans l'acétone sont identiques à ceux des coordinats organiques correspondants; cependant, ceux des composés $NiI_2(C_5H_6S_3)_2$ et $NiI_2(C_4H_4S_3)_2$ sont typiques d'une symétrie pseudo-tétraédrique, mais différent des spectres enregistrés à l'état solide. Aucune conclusion ne peut dont être tirée de cette étude en solution.

Composés B

Dans le domaine de fréquence 3000–15000 cm^{-1} les spectres par réflectance mettent en évidence trois à quatre bandes principales, caractéristiques d'un environnement pseudo-tétraédrique du nickel(II) (10) (voir tableau 2). Dans une symétrie T_d, trois transitions autorisées par spin sont attendues dans le visible. Par suite de l'abaissement de la symétrie à C_{2v} la transition ν_3, $^3T_1(F) \rightarrow {}^3T_1(P)$ apparaît en général sous forme de trois composantes ($^3T_1 \rightarrow {}^3A_2$, $^3T_1 \rightarrow {}^3B_1$, $^3T_1 \rightarrow {}^3B_2$), de même que la transition ν_1, $^3T_1(F) \rightarrow {}^3T_2(F)$, seule ν_2 n'est pas affectée. Sur les spectres une bande unique, assez intense, située vers 9000 cm^{-1} peut être assignée à la transition ν_2, $^3T_1(F) \rightarrow {}^3A_2(F)$. Un massif d'intensité notable, apparaissant entre 15000 et 11000 cm^{-1} serait l'enveloppe des pics corres-

pondants à la transition ν_3. L'attribution de ν_1 est plus délicate du fait de la présence dans le proche infrarouge de bandes de vibrations carbone–hydrogène des coordinats organiques. Cependant les absorptions notées entre 4000 et 6000 cm^{-1} peuvent être attribuées à la transition ν_1 qui dans nos composés présentent en général deux composantes. Sur les spectres des complexes $NiI_2(C_7H_4S_4)_2$ et $NiI_2(C_4H_4S_3)_2$ on observe respectivement deux bandes de très faibles intensités à 6780 cm^{-1} et 7750 cm^{-1} et une épaule à 16080 cm^{-1} qui correspondent très probablement aux transitions interdites par spin $^3T_1(F) \rightarrow {}^1D$ d'une part et $^3T_1(F) \rightarrow {}^1G$ d'autre part. Etant donné son intensité le pic noté vers 17000 cm^{-1} est dû à une transition du type $\pi \rightarrow \pi$. Cette bande de transfert de charges, signalée par Ouchi et coll. (11, 12) entre 24000 et 21000 cm^{-1}, se retrouve donc sur nos spectres à une fréquence anormalement basse et est responsable de la couleur noire des produits étudiés. Au-delà de 20000 cm^{-1} il est difficile d'attribuer les différentes absorptions présentes sur les spectres, en effet les bandes dues aux coordinats organiques interfèrent avec celles d'éventuelles transitions des complexes.

Les valeurs des champs des coordinats Δ et celles des intégrales de répulsion électronique de Racah B' (tableau 3) ont été calculées à partir des fréquences ν_2 et ν_3 par la résolution des équations établies par Underhill et Billing (13) dans le cadre d'une symétrie tétraédrique.

Comparons les valeurs du champ Δ dans la série des composés du nickel(II) d'une part, et dans celle correspondante du cobalt(II) d'autre part (tableaux 3 et 4). Alors que ce champ diminue avec un encombrement stérique plus important des substituants R_1 et R_2 des molécules R_1-5 R_2-4 dithiole-1,2 thiones-3, dans le cas des produits cobalteux il augmente, au contraire, dans celui des composés du nickel(II). Pour le cobalt cet abaissement du champ des coordinats dû à un encombrement a été interprété (7) comme résultant d'un allongement de la liaison Co—S. Pour les complexes du nickel(II) on aurait donc un accroîssement du caractère covalent de la liaison Ni—S. Ce phénomène pourrait s'expliquer par l'existence dans les coordinats organiques d'une part d'une conjugaison soit du groupement CH_3 soit d'une liaison π du thiényle avec une double liaison du cycle dithiolique, d'autre part dans le cas de substituants méthyle d'un effet supplémentaire inductif +I du CH_3; ces deux contributions créent un excès de charges négatives sur le soufre de la fonction thione.

Les valeurs de la constante de Racah B' pour tous ces complexes sont de l'ordre de 52 à 63% de celles de l'ion libre Ni^{2+} (1030 cm^{-1}). Ce faible pourcentage s'explique par un recouvrement orbital important résultant de l'entourage du métal par deux atomes de soufre et deux ions iodures volumineux et très polarisables.

Composé A

Le diamagnétisme et le spectre électronique (tableau 2) du complexe vert sombre NiI_2-$(C_9H_6S_3)_2$ militent en faveur d'un entourage plan du métal. Le passage d'une symétrie tétra-

édrique (composés *B*) à une symétrie plane (composé *A*) résulterait d'un encombrement stérique plus important de la phényl-5 dithiole-1,2 thione-3. Dans l'hypothèse d'une symétrie D_{2h} quatre absorptions sont théoriquement attendues (14). Sur le spectre du complexe étudié on observe un seul pic intense à 16030 cm^{-1} qui serait l'enveloppe de trois bandes correspondant aux transitions $b_{2g} \rightarrow b_{1g}$, $e_g \rightarrow b_{1g}$, $a_{1g} \rightarrow b_{1g}$. L'épaulement situé vers 18750 cm^{-1} serait provoqué par la quatrième transition $e_g \rightarrow b_{2g}$. Dans l'ultraviolet il devient délicat d'effectuer une attribution par suite de l'existence de bandes dues aux transitions du coordinat organique.

La non isotypie de *A* et de $CoI_2(C_9H_6S_3)_2$ a été constatée sur les films de Debye–Scherrer, ceci est en accord avec l'existence d'un complexe plan *A* et de composés tétraédriques *B*.

Etude des complexes par spectroscopie infrarouge

La bande caractéristique de la vibration ν_{Ni-X} (où X est un halogène) est située selon Coates et Parkin (15) à des fréquences plus élevées dans les composés plans que dans les tétraédriques. Ils assignent la bande pointée à 280 cm^{-1} à la vibration de valence ν_{Ni-I} dans le composé plan $Ni(Me_3P)_2I_2$, tandis que Clark et Williams (16) l'attribuent à celle située vers 220 cm^{-1} dans les complexes tétraédriques. On observe (tableau 5) sur les spectres des produits (*B*) un pic de forte intensité à 210 cm^{-1} qui par comparaison avec les travaux de Clark peut être considéré comme typique de la liaison Ni–I. Aucune absorption n'existe dans cette région spectrale pour le complexe *A*, par contre deux bandes supplémentaires de forte et faible intensité apparaissent vers 290 cm^{-1}, domaine où sont normalement attendues les vibrations de valence nickel-iode pour un composé plan. Ceci confirme l'hypothèse d'un entourage plan du métal dans le diiodobis (phényl-5 dithiole-1,2 thione-3) nickel(II). D'après ces résultats on voit (tableau 5) qu'une formule ionique du type $[NiL_4][NiI_4]$ n'est pas possible par suite de la présence de l'absorption ν_{Ni-I} à des fréquences supérieures à celle observée par Sabatini et Sacconi (17) pour l'ion $[NiI_4]^{2-}$, soit 189 cm^{-1}.

Alors que dans l'infrarouge lointain les spectres des complexes de la dithiole-1,2 thione-3 avec le cobalt(II) présentent une absorption forte vers 310 cm^{-1} caractéristique d'une vibration ν_{Co-S}, aucune bande intense supplémentaire n'est à signaler, dans cette région, sur ceux des composés du nickel(II). Seul un pic de faible intensité est visible entre 210 et 400 cm^{-1} domaine où est décelée habituellement la bande de vibration ν_{Ni-S} (18). La liaison métal – molécule organique peut s'effectuer selon deux

modes différents: ou le nickel(II) est coordonné à la dithiole-1,2 thione-3 par un soufre, ou il est lié par une coordination π perpendiculaire à la liaison C=S. L'absence de bande intense supplémentaire entre 210 et 400 cm^{-1} serait en accord avec cette dernière solution, puisqu'une bande due à une coordination π est probablement située en dessous de 200 cm^{-1}. Dans le cas d'une telle liaison une structure peut être envisagée à laquelle correspond, dans l'hypothèse généralement admise d'une coordination bidentate (19) une formule brute NiI_2L, en désaccord avec les résultats de l'analyse centésimale. Ceci suggère d'attribuer les bandes de faible intensité, situées vers 310 et 370 cm^{-1} aux vibrations ν_{Ni-S}, symétrique et antisymétrique, et de proposer une coordination par le soufre. La faible perturbation de la vibration $\nu_{C=S}$ (tableau 6) confirme notre hypothèse, en effet une coordination π de la liaison C=S au métal se traduirait par un déplacement très important vers les basses fréquences de la bande caractéristique de cette vibration (18).

La détermination de l'identité du donneur est rendue délicate par la présence de trois atomes de soufre. Pour les composés du cobalt nous avons proposé une coordination du métal par le soufre de la fonction thione (7). Ce travail n'apporte, à ce sujet, aucun argument définitif confirmant ou infirmant cette hypothèse. On note cependant que les bandes attribuées aux vibrations $\delta_{C=S} + \delta_{noyau}$, $\delta_{C=S}$ et $\gamma_{C=S}$ (20) disparaissent ou sont fortement perturbées par la coordination (tableau 6); ce fait milite en faveur d'une liaison du métal par le soufre de la fonction thione. Alors que la fréquence de la vibration $\nu_{C=S}$ (20, 21) augmente systématiquement dans les complexes du cobalt, avec le nickel on constate que le déplacement de cette bande est très faible; dans le cas du composé avec le substituant thiényle elle ne subit aucune altération tandis que dans celui du substituant diméthyle elle est même déplacée vers les basses fréquences. On a interprété (7) le déplacement vers les grands nombres d'onde des composés du cobalt comme résultant d'un draînage des électrons du cycle aromatique de la dithiole-1,2 thione-3 vers le métal, draînage qui compense, au maximum, la diminution de l'ordre de la liaison C=S par suite de la coordination. Pour les complexes du nickel(II) avec les dithiole-1,2 thiones-3 substituées, l'effet mésomère dû au groupement méthyle ou thiényle diminue le caractère π de la liaison C=S; cet effet contrebalance l'influence du déplacement du courant du cycle, ce qui explique dans ce cas les déplacements négligeables ou nuls (tableau 6) vers les hautes fréquences de la bande de vibration $\nu_{C=S}$.

TABLEAU 6. Attribution de quelques bandes d'absorption des molécules organiques et de leurs complexes avec le nickel(II) entre 2000 et 500 cm^{-1}

*Bandes n'apparaissant pas sur les spectres.

Conclusion

Les différents résultats obtenus nous permettent de conclure à un environnement pseudo-tétraédrique du nickel dans les complexes $NiI_2(R_1R_2C_3S_3)_2$ dans le cas où $R_1 = CH_3$ et $R_2 = H$, $R_1 = R_2 = CH_3$, $R_1 = C_4H_3S$ et $R_2 = H$, et à un entourage plan dans le cas où $R_1 = C_6H_5$ et $R_2 = H$. L'examen des spectres infrarouges suggère une coordination du nickel à la molécule organique par le soufre de la fonction thione. Mais seule une étude radiocristallographique complète permettrait d'affirmer l'existence d'une telle liaison.

Nous remercions M. Daniel Gentric pour les discussions fructueuses que nous avons eues au sujet des spectres infrarouges des dithiole-1,2 thiones-3.

Viscosities, Densities, and Refractive Indices of Binary Liquid Mixtures

MIGUEL KATZ, PEDRO W. LOBO, A. SANCHO MIÑANO, AND HORACIO SÓLIMO

Cátedra de Físico-Química, Facultad de Ciencias Exactas y Tecnología, Universidad Nacional de Tucumán. Argentina

Received March 22, 1971

The viscosities, densities, and refractive indices at 25, 30, 35, and 40 °C were determined for the systems: aniline + toluene (A + T), *N*,*N*-dimethylaniline + toluene (DMA + T), and aniline + *n*-butanol (A + B). From the experimental results the excess volume, excess viscosity, and excess molar free energy of activation of flow were calculated. The deviations from ideality for the excess thermodynamic functions are more important for the systems (A + T) and (A + B) than for (DMA + T). This fact is explained by the existence of dispersion forces in the mixture and by the presence of hydrogen bonds in pure aniline and pure butanol.

Les valeurs de la viscosité, densité et indice de réfraction ont été déterminées à 25, 30, 35 et 40 °C pour les systèmes: aniline + toluène (A + T), *N*,*N*-diméthylaniline + toluène (DMA + T) et aniline + *n*-butanol (A + B). Les fonctions d'excès relatives au volume, viscosité et énergie libre molaire d'activation de l'écoulement ont été calculées. Les déviations de l'idéalité pour les fonctions thermodynamiques d'excès sont plus grandes pour les systèmes (A + T) et (A + B) que pour le système (DMA + T). Ce fait trouve son explication dans l'existence de forces de dispersion dans le mélange et par la présence de ponts hydrogène dans l'aniline pure et dans le butanol pur.

Canadian Journal of Chemistry, 49, 2605 (1971)

Introduction

Viscosities of binary liquid non-electrolyte mixtures have been studied to obtain information about the type and degree of interaction between molecules of the components of some binary systems. Positive deviations from ideal behavior means strong interaction between unlike molecules, but if negative deviations are present, dispersion forces are dominant (1).

The following systems: aniline + toluene (A + T), *N*,*N*-dimethylaniline + toluene (DMA + T), and aniline + *n*-butanol (A + B) were chosen because these four substances have polar characteristics and two of them (A and B) show hydrogen bonding.

Densities, viscosities, and refractive indices for the three systems at different mole fractions were measured at 25, 30, 35, and 40 °C. Some data about these three physical constants of the pure compounds and of the systems are tabulated in the literature (2, 3).

From the experimental results the following thermodynamic functions have been calculated: ΔV^E (excess molar volume), $\Delta\eta^E$ (excess of viscosity), and $\Delta^* G^E$ (excess molar free energy of activation of flow).

Experimental

Density

Densities were determined with a Robertson specific gravity bottle (4). The total pycnometer volume was about 20 ml and was calibrated with doubly distilled water at every temperature. All weighings were made on a digital Sartorius Selecta balance and corrected to vacuum.

A thermostatically controlled bath constant to ±0.01 °C was used. Temperatures were read from calibrated thermometers.

Viscosity

Viscosities of pure liquids and mixtures have been determined with a Cannon–Fenske viscosimeter calibrated with doubly distilled water, benzene, and sucrose solutions (5). Kinetic energy corrections were applied to viscosity data.

In making determinations, both pycnometer and viscosimeter were maintained in the bath until at least two consecutive measurements of the liquid height in the capillaries or the flow time indicated that the sample had reached the temperature of the bath.

Refractive Index

The refractive index for the sodium D line of the pure components and mixtures were measured with a Jena dipping refractometer with an accuracy of ±0.00002.

Materials and Solutions

Toluene, Merck p.a., was twice distilled over dried P_2O_5 at reduced pressure and only the middle half of each distillation was recovered. Aniline, Merck p.a., was distilled twice over zinc dust and over anhydrous Na_2SO_4

at reduced pressure. We recover too, only the middle half of each of two distillations. *N,N*-dimethylaniline, Erba RS electronic grade, and *n*-butanol, Merck chromatoquality grade, were used without further purification. Water was twice distilled from alkaline permanganate.

Mixtures were prepared by mixing weighed amounts of the pure liquids to prevent evaporation.

Results

The experimental molar fractions, densities, viscosities, and refractive indices at 25, 30, 35, and 40 °C for the three systems are listed in Tables 1, 2, and 3.

The excess thermodynamic functions (6) were calculated with the following equations

$$\Delta\eta^E = \eta - (x_1\eta_1 + x_2\eta_2)$$

$$\Delta V^E = V - (x_1V_1 + x_2V_2)$$

$$\Delta^*G^E = RT[\ln \eta V - (x_1 \ln \eta_1 V_1 + x_2 \ln \eta_2 V_2)]$$

where η, η_1, and η_2 = viscosity of the mixture and of the pure components; V, V_1, and V_2 = molar volume of the mixture and of the pure components; R = gas constant. The molar volume V of the mixture is defined by

$$V = \frac{x_1M_1 + x_2M_2}{\rho}$$

where M_1 and M_2 are the molecular weights of the components.

Excess thermodynamic functions at 25 °C are plotted against molar fraction of one component: $x_1 = x_A$ (for the system A + T and A + B) and $x_1 = x_{DMA}$ (for the systems DMA + T) in Figs. 1, 2, and 3.

Discussion

The experimental values of viscosities for the A + T system listed in Table 1 show a relatively high decrease on the initial addition of toluene. This behavior is characteristic of systems in which at least one of the components exhibits hydrogen bonding (7). It is possible that for aniline (8), the existence of hydrogen bonding exists between the amine group with another of the same kind (N—H···N) or with the benzene ring of another molecule of aniline. Figure 1 shows for the A + T system a minimum value of $\Delta\eta^E$ at x_1=0.65 in agreement with what has been said above and with the possibility of hydrogen bonding of the aniline group with the benzene ring of toluene.

For the system A + B (see Fig. 1), the minimum is at $x_1 = 0.55$, giving an almost symmetrical curve. This change in position of the minimum value with respect to the A + T system can be explained by hydrogen bonding of the type (O—H···O) between the *n*-butanol

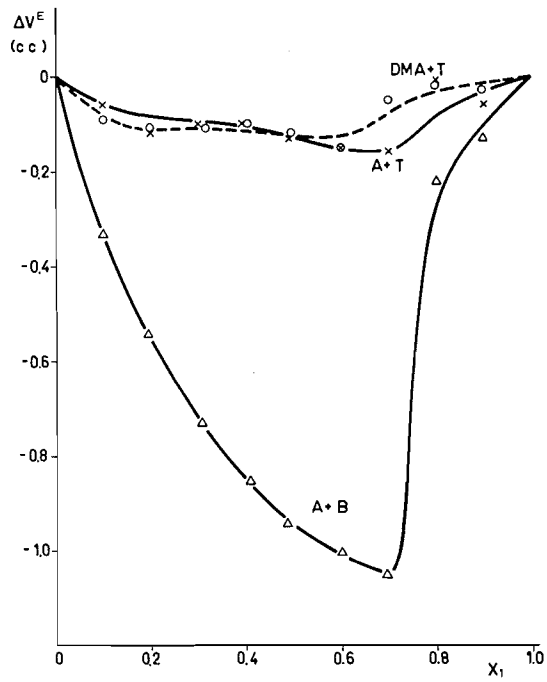

FIG. 3. ΔV^E *vs.* x_1.

molecules (9) and by other types of hydrogen bonding described for the aniline molecule. The DMA + T system (see Fig. 1) shows a $\Delta\eta^E$ value close to zero which would mean the absence of hydrogen bonding in the components.

It is considered that $\Delta\eta^E$ is negative for systems in which dispersion forces are dominant, becoming less negative and then increasingly positive as the strength of interaction increases (1).

From the analysis of Fig. 2 we may conclude that for the system A + B, where both components are associated in the pure state, more negative Δ^*G^E values are obtained than for the A + T system, where only A shows hydrogen bonding. This result is in agreement with the expected variation of the ΔH^* and $T\Delta S^*$ functions for non-ideal mixtures of the type previously described (10).

For the DMA + T system, the value of Δ^*G^E is close to that expected for ideal behavior.

The negative values of ΔV^E are explained by Prigogine (11) in terms of the different sizes of the molecules or the dipole–dipole interaction between them. This effect is observed in the A + B system in a stronger way than in the other two, mainly because of the different sizes of a cycle molecule and a linear one.

We have calculated the excess thermodynamic functions at 25, 30, 35, and 40 °C. The values obtained tend to become less negative and then increasingly positive as the temperature increases, which is in accord with the nature of these functions. Only $\Delta\eta^E$, ΔV^E, and Δ^*G^E at 25 °C are shown, since for the other temperatures the curves are similar.

The almost linear variation of the refractive indices for the three systems in terms of the composition (see Tables 1, 2, and 3) is in agreement with the conclusion of Loiseleur (12) for a large number of ideal and non-ideal systems. Neither the polar characteristics of the substances studied nor the existence of hydrogen bonding in the aniline and *n*-butanol seem to have any important effect on the linear dependence of this property with concentration.

NOTES

A Novel Synthesis of β-Hydroxyvaline

CASIMIR BERSE AND PIERRE BESSETTE[1]

Department of Chemistry, Université de Montréal, Montréal, Québec

Received February 5, 1971

The synthesis of β-hydroxyvaline from ethyl β,β-dimethylacrylate through 1,2-di(ethoxycarbonyl)-3,3-dimethylaziridine as intermediate shows a new way of preparation of this amino acid.

La synthèse de la β-hydroxyvaline à partir du β,β-diméthylacrylate d'éthyle en passant par le diéthoxycarbonyl-1,2 diméthyl-3,3 aziridine comme intermédiaire, illustre une nouvelle méthode de synthèse de cet acide aminé.

Canadian Journal of Chemistry, 49, 2610 (1971)

Until now several methods have been used to synthesize β-hydroxyvaline (1–7). However in none of these methods was 1,2-di(ethoxycarbonyl)-3,3-dimethylaziridine (**3**) used as intermediate.

The objective of our work was the preparation of such an aziridine. The opening of this aziridine with different reagents could be a general method for the synthesis of different derivatives of valine. The hydrolysis of these derivatives will lead to the corresponding amino acids. This note shows that the synthesis of such an aziridine is possible and the opening of the aziridine ring leads to the β-hydroxyvaline. Thus by following the method similar to that described by Lwowski and Maricich (8) the reaction of ethyl β,β-dimethylacrylate with *N*-(*p*-nitrobenzenesulfonoxy)urethan in the presence of triethylamine permitted the formation of the aziridine **3**, b.p. 110–115/0.1 mm Hg (dec.), yield 14% (see Scheme 1). Opening of the aziridine **3** with acetic acid gave ethyl 3-acetoxy-2-(ethoxycarbonylamino)-3-methylbutanoate (**4**), b.p. 115 ± 5°/0.09 mm Hg, yield 25%, and ethyl 2-(ethoxycarbonylamino)-3-methyl-3-butenoate (**5**) b.p. 90–100°/0.09 mm Hg, yield 28%. Compounds **4** and **5** were separated by chromatography. Alkaline hydrolysis of **4** with aqueous potassium hydroxide followed by elution on Rexyn 101 H gave β-hydroxyvaline (**6**), m.p. 221–223° (lit. 226–227° (5)), yield 10%.

[1]Holder of an NRCC Studentship, 1968–1971.

The synthesis of penicillamine using the novel method described herein is presently under active investigation in our laboratory.

Experimental

Solutions were concentrated under reduced pressure using a rotary evaporator and a water bath at a temperature of 40° and less. Reaction mixtures and products were examined by t.l.c. using silica gel GF-254, hexane–ether (50:50 v/v), and spray of 50% sulfuric acid in ethanol followed by heating at 200 °C. Melting and boiling points were uncorrected.

The i.r. spectra were recorded on a Beckman model IR-8 double beam spectrometer. The n.m.r. spectra were recorded on a Varian A-60 spectrometer. Mass spectra were done on a Hitachi–Perkin–Elmer model RMU 6-D. Elemental analyses were performed by Midwest Microlab Inc., Indianapolis, Indiana.

Ethyl β,β-Dimethylacrylate (1)

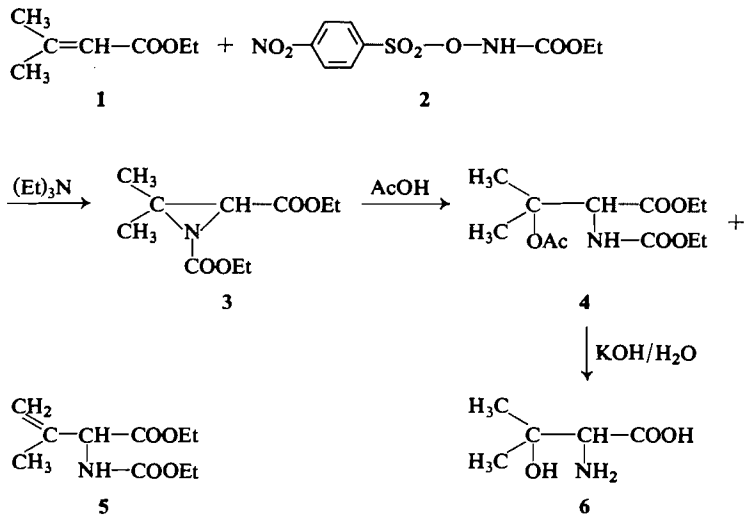
Product **1** was obtained from β,β-dimethyl acrylic acid by the method described by Moureu and Chovin (9); b.p. 152–153 °C (lit. (9) 153 °C).

N-(p-Nitrobenzenesulfonoxy)urethan (2)

Product **2** was prepared from *N*-hydroxyurethan and *p*-nitrobenzenesulfonyl chloride as described by Lwowski and Maricich (8); m.p. 114 °C (lit. (8) 116.4–116.8 °C).

1,2-Di(ethoxycarbonyl)-3,3-dimethylaziridine (3)

To a solution of 4.28 g (0.030 mol) of **1** and of 8.705 g (0.030 mol) of **2** in dichloromethane (100 ml) was added with stirring over a period of 1 h a solution of 3.33 g (0.033 mol) of triethylamine in dichloromethane (20 ml). After the mixture was stirred for 3 h, it was poured into ether (1000 ml). Triethylammonium *p*-nitrobenzenesulfonate was eliminated by filtration and the solution concentrated under reduced pressure. The oily residue was chromatographed on silica gel with hexane–ether



SCHEME 1

(90:10 v/v) as eluant to give the pure aziridine **3**; yield 0.89 g (14%), t.l.c. R_f 0.50; b.p. 110–115°/0.10 mm Hg (dec.); i.r. bands ($CHCl_3$) at 1720, 1382, and 1370 cm^{-1}; τ(CCl_4) 8.76 and 8.74 (6H, triplet), 8.71 and 8.69 (6H, singlet), 7.17 (1H, singlet), 5.91 and 5.96 (4H, quadruplet); mass spectra *m/e* 215.

Anal. Calcd. for $C_{10}H_{17}NO_4$: C, 55.79; H, 7.96. Found: C, 55.51; H, 7.84.

Ethyl 3-Acetoxy-2-(ethoxycarbonylamino)-3-methylbutanoate (4) and Ethyl 2-(Ethoxycarbonylamino)-3-methyl-3-butenoate (5)

Compound **3**, (4.80 g, 0.022 mol), was added slowly during 3 h to glacial acetic acid (35 ml) at reflux. Once the addition finished the acetic acid was removed *in vacuo*, ether (200 ml) was added, the solution was dried over K_2CO_3, filtered, and evaporated. The oily residue was chromatographed on silica gel and eluted with hexane–ether (90:10 v/v) to obtain products **4** and **5**.

Product **4**, 1.720 g (28%); t.l.c. R_f 0.40; b.p. 115 ± 5°/0.09 mm Hg; i.r. bands (CCl_4) at 3460, 1745, 1730, and 1510 cm^{-1}; τ (CCl_4) 8.71 and 8.77 (6H, triplet), 8.47 and 8.53 (6H, singlet), 8.09 (3H, singlet), 5.83 and 5.93 (4H, quadruplet), 5.51 (1H, doublet), and 4.23 (1H, doublet).

Anal. Calcd. for $C_{12}H_{21}O_6N$: C, 52.35; H, 7.68. Found: C, 52.76; H, 7.97.

Product **5**, 1.19 g (25%); t.l.c. R_f 0.50; b.p. 90–100°/0.09 mm Hg; i.r. bands (CCl_4) at 3460, 1730, 1650, and 1500 cm^{-1}; τ (CCl_4) 8.73 and 8.77 (6H, triplet), 8.23 (3H, singlet), 5.83 and 5.93 (4H, quadruplet), 5.35 (1H, doublet), 5.05 (2H, multiplet), 4.43 (1H, doublet); mass spectra *m/e* 215.

Anal. Calcd. for $C_{10}H_{17}NO_4$: C, 55.79; H, 7.96. Found: C, 55.62; H, 7.68.

β-*Hydroxyvaline (6)*

Compound **4**, (1.720 g, 0.0062 mol), was added to 25 ml of an aqueous solution of 1.00 *N* potassium hydroxide and heated at reflux for 18 h. The solution was concentrated *in vacuo* and passed on Rexyn 101H (10 g) and eluted with water. After evaporation of the water the yellow residue was crystallized in methanol to give β-hydroxyvaline 75 mg (10%), m.p. 221–223° (lit. (5) 226–227°); i.r. bands (Nujol) at 3200, 1670, 1600, and 1560 cm^{-1}; τ (D_2O) 8.53 and 8.73 (6H, singlet), 6.38 (1H, singlet) 6.15 (4.6H, DHO singlet).

Anal. Calcd. for $C_5H_{11}NO_3$: C, 45.03; H, 8.25. Found: C, 44.91; H, 7.94.

Action du chloroformiate d'éthyle sur les lactames. Préparation sélective d'éthers lactimiques et de *N*-éthoxycarbonyl-lactames

R. GAUTHIER,[1] P. BLONDEAU,[2] C. BERSE, ET D. GRAVEL
Département de Chimie, Université de Montréal, B.P.6128, Montréal, Québec

Reçu le 3 mars 1971

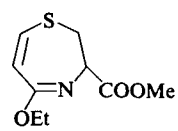
La réactivité de quelques lactames carbocycliques et de quelques γ-thiolactames vis-à-vis du chloroformiate d'éthyle est étudiée. A 25°, lorsqu'il y a réaction, on observe la formation du chlorhydrate de l'éther lactimique correspondant, en accord avec la littérature. A 110°, la *N*-éthoxycarbonyl-lactame correspondante est formée avec de bons rendements. Des essais ont montré que l'éther lactimique libre est très probablement un intermédiaire dans cette réaction.

The reactivity of some carbocyclic lactams and some γ-thiolactams with ethyl chloroformate has been studied. At 25°, when reaction takes place, the corresponding lactim ether hydrochloride is formed in accord with the literature. At 110° however, the reaction yields the corresponding *N*-ethoxycarbonyl lactam in good yield. Investigation showed the free lactim ether to be a probable intermediate in this reaction.

Canadian Journal of Chemistry, 49, 2612 (1971)

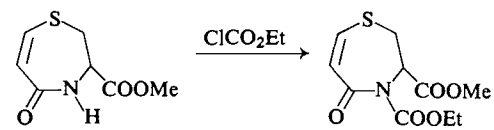
La formation de chlorhydrates d'éthers lactimiques par l'action du chloroformiate d'éthyle sur des lactames ou des amides est déjà connue (1–3). Hechelhammer (1), en particulier, a obtenu l'éthoxy-7 tétrahydro-3,4,5,6 azépine-2*H* (**1**) en faisant réagir une quantité stoechiométrique de caprolactame (**2**) avec le chloroformiate d'éthyle dans le benzène à 25°, et en neutralisant le chlorhydrate du produit formé avec du carbonate de calcium.

Dans le cadre de nos travaux sur la réactivité des oxo-5 thiazépines-1,4, nous avons tenté la formation d'éthers lactimiques du type de l'éthoxy-5 méthoxycarbonyl-3 dihydro-2,3 thiazépine-1,4 (**3**).



3

Pour ce faire, nous avons mis en réaction la méthoxycarbonyl-3 oxo-5 tétrahydro-2,3,4,5 thiazépine-1,4 (**4**) avec le chloroformiate d'éthyle dans le benzène à 25°. Cependant, dans ces conditions, la thiazépine **4** n'a donné aucune réaction. En répétant la réaction à différentes températures (25, 50, 75, 80, et 110°) avec le toluène comme solvant, aucune réaction n'a eu lieu jusqu'à la température de reflux; après 12 h de reflux cependant, une chromatographie sur couche mince de gel de silice a montré que le produit de départ s'était complètement transformé en un seul produit de réaction: non pas l'éther lactimique attendu **3**, mais bien l'éthoxycarbonyl-4 méthoxycarbonyl-3 oxo-5 tétrahydro-2,3,4,5 thiazépine-1,4 (**5**) avec un rendement quantitatif. La structure du produit **5** a été établie sans difficulté à l'aide des spectres u.v., i.r., de r.m.n., et de masse.



4 **5**

Devant le résultat surprenant de cette réaction, nous l'avons répétée sur une série de lactames, pour deux raisons principales: d'abord tenter d'en faire une préparation générale des *N*-éthoxycarbonyl-lactames et aussi pour essayer d'obtenir une ébauche du mécanisme de la réaction. On sait que si les *N*-alkoxycarbonyl-amides (*N*-acyl carbamates) sont facilement préparées par acylation des carbamates correspondants (4–6), les *N*-alkoxycarbonyl-lactames par contre sont très mal connues: une seule préparation est décrite dans la littérature. En effet, Falkenstein et Dörfel (7) rapportent la préparation d'une série de ces composés selon une méthode non-publiée de Kiefer; la séquence des réactions utilisées est représentée par l'éq. 1.

[1] 
Quoique cette préparation fournisse d'excellents rendements, elle nécessite néanmoins une série de quatre étapes.

Etant donné la simplicité de la méthode au chloroformiate d'éthyle, la réaction a donc été reprise à 25° et à 110° sur les lactames suivantes: méthoxycarbonyl-3 oxo-5 perhydrothiazépine-1,4 (**6**), oxo-5 perhydrothiazépine-1,4 (**7**), caprolactame (**2**), et valérolactame (**8**). Un excès de 9 mol de chloroformiate d'éthyle a été utilisé dans

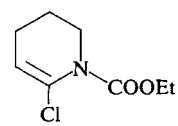
,us les cas. Les produits majeurs obtenus sont décrits dans le tableau 1.

On remarque dans le tableau 1 que dans tous les cas, il a été possible d'isoler la *N*-éthoxycarbonyl-lactame. Dans le cas des produits **4** et **6**, il a été impossible d'obtenir l'éther lactimique correspondant, même en variant les conditions de température et de concentration; en élevant la température, on voit plutôt apparaître la *N*-éthoxycarbonyl-lactame. Il est à noter également que l'expérience a été tentée sur une amide, la *N*-éthylacétamide (**9**). Quelles que soient les conditions utilisées, il a été impossible d'obtenir la *N*-éthoxycarbonyl-amide[3] correspondante (**17**) avec un rendement supérieur à 2 ou 3%. Les rendements de réaction, ainsi que les constantes physiques des produits, sont rapportés dans le tableau 2. Les déplacements chimiques des groupements éthoxyles des différents produits dans le spectre de r.m.n. ainsi que certaines absorptions caractéristiques en i.r. sont rapportés dans le tableau 3.

Il est intéressant de noter que lors de la réaction de la valérolactame (**8**) avec le chloroformiate d'éthyle, un produit secondaire a pu être isolé par chromatographie sur gel de silice, avec un rendement de 18%. Ce produit donne un test de Beilstein positif ainsi qu'un précipité avec le nitrate d'argent à chaud; d'après les spectres i.r., de r.m.n., et de masse,[4] la structure **18** est attribuée au produit.

Il est très probable que des produits secondaires du même type se forment avec les autres lactames étudiées mais toutefois, ils n'ont pas été remarqués lors de la purification du produit de réaction.



18

A la lumière des résultats obtenus, il semblait logique de supposer que l'éther lactimique ou son chlorhydrate pouvait être un intermédiaire dans la formation de la *N*-éthoxycarbonyl-lactame. Pour vérifier cette hypothèse, nous avons fait réagir l'éthoxy-7 tétrahydro-3,4,5,6 azépine-2*H* (**1**) ainsi que son chlorhydrate avec un excès de chloroformiate d'éthyle dans le toluène à 110°. Dans les deux cas, nous avons pu isoler la *N*-éthoxycarbonylcaprolactame (**15**) avec des rendements de même ordre qu'avec la caprolactame (**2**). Des résultats analogues ont aussi été observés avec l'éther lactimique **11**.

Il faut faire remarquer également qu'avec les lactames **6**, **7**, et **8**, on observe en cours de réaction à 110° la formation d'un précipité; si on filtre ce précipité, on constate qu'il s'agit du chlorhydrate

[3]Le produit **17** n'a pu être obtenu parfaitement pur; il a été identifié par comparaison des spectres i.r. et de r.m.n. avec ceux du produit authentique préparé par les méthodes connues (4, 8).

[4]Le produit est trop instable pour qu'on puisse en obtenir une analyse élémentaire.

TABLEAU 3. Données spectrales des produits formés

Produit	Résonance magnétique nucléaire (—O—C_2H_5)(δ) CH_3	CH_2	Infrarouge (cm^{-1}) C=N	
(A) Ethers lactimiques				
10	1.25	4.00	1675	
1	1.25	4.00	1670	
11	1.15	3.95	1675	
	CH_3	CH_2	C=O ester*	C=O lactame
(B) N-Ethoxycarbonyl-lactames				
5	1.40	4.35	masqué	1715
13	1.25	4.25	1770 (épaulement)	1715
14	1.40	4.35	1775	1715
15	1.40	4.35	1770	1715
16	1.40	4.30	1775	1715

*La bande carbonyle de la partie ester (—$COOC_2H_5$) est toujours de faible intensité, alors que la bande carbonyle de la partie lactame (—C(=O)—N) est toujours de forte intensité.

de l'éther lactimique correspondant;[5] si, d'autre part, on laisse la réaction suivre son cours, ce précipité disparaît graduellement.

Les résultats décrits ci-haut permettent donc de suggérer le mécanisme décrit au schéma 1.[6]

Dans le cas de réactions effectuées soit sur la caprolactame (**2**) soit sur l'éther lactimique correspondant **1**, nous avons isolé et caractérisé du chlorure d'éthyle par condensation des produits volatils émanant du mélange réactionnel à 110°. Toutefois, il est connu que les chlorhydrates des éthers lactimiques se décomposent à haute température pour redonner la lactame de départ ainsi que le chlorure d'alkyle correspondant (2). La présence du chlorure d'éthyle dans le cas présent n'est donc pas un argument définitif. Quant à la formation du chlorhydrate de l'éther lactimique, Suydam *et al.* (3) ont déjà suggéré un mécanisme plausible pour rendre compte de sa formation.

Le mécanisme suggéré, sans être totalement prouvé, rend toutefois compte des produits formés et pourrait éventuellement servir de base à une étude quantitative de la réaction.

Notons enfin que la méthode au chloroformiate permet de préparer en une seule étape les *N*-alkoxycarbonyl-lactames, agents d'activation utiles en polymérisation anionique des lactames (7).

Partie expérimentale

Les spectres i.r. ont été pris sur un spectrophotomètre "Beckmann" modèle IR-8 à double réseau.

Les spectres de masse ont été enregistrés sur un spectromètre de masse "Hitachi–Perkin–Elmer" modèle RMu 6-D.

Les spectres de r.m.n. ont été déterminés sur un spectromètre modèle JNM-4H-100 de la Compagnie Jeolco. Le tétraméthylsilane est utilisé comme référence interne et le $CDCl_3$ comme solvant.

Les points de fusion et d'ébullition ne sont pas corrigés.

Les analyses élémentaires ont été effectuées par Midwest Microlab Inc., Indianapolis, Indiana.

(1) Réaction à 25 °C (procédure-type)

La lactame[7] (~0.02 mol) est dissoute dans du toluène anhydre (200 ml) et le chloroformiate d'éthyle (20 ml, ~0.2 mol) est ajouté en une portion. Le mélange est agité à 25 °C pendant 12 h. Le précipité est ensuite filtré et lavé avec du toluène, puis agité quelques minutes avec du carbonate de potassium 50% (50 ml). Le mélange est extrait trois fois à l'éther, et la solution éthérée séchée sur carbonate de sodium. L'éther est évaporé *in vacuo*, et le résidu distillé sous vide.

(2) Réaction à 110 °C (procédure-type)

La lactame (~0.02 mol) est dissoute dans du toluène anhydre (200 ml) et le chloroformiate d'éthyle (20 ml,

[5]L'identification a été faite à l'aide du spectre i.r. du produit après neutralisation.

[6]Le mécanisme est illustré à l'aide de la valérolactame (**8**). La voie *a* semble générale pour toutes les lactames alors que la voie *b* n'a été mise en évidence que dans le cas particulier représenté.

[7]Avec les lactames **4** et **6**, aucune réaction n'a été observée, même en élevant la température. Si on élève trop la température, on voit plutôt apparaître la *N*-éthoxycarbonyl-lactame.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

SCHÉMA 1

~0.2 mol) est ajouté en une portion. Le mélange est porté à reflux pendant 12 h. Le solvant et l'excès de chloroformiate d'éthyle sont ensuite évaporés *in vacuo*, et le résidu distillé sous vide poussé à l'aide d'une colonne Vigreux (15 po), ou chromatographié sur gel de silice.

Dans le cas de la pipéridone-2 (**8**), on peut isoler par chromatographie le produit secondaire **18**, qui est repurifié par distillation dans un appareil semi-micro, p.éb. ~70°/0.2 mm.

En i.r., ce produit montre des bandes caractéristiques à 1715 (C=O) et 1660 cm^{-1} (C=C(N)Cl). En r.m.n., on observe des absorptions à δ 1.38 (t, 3H), 1.8 (m, 2H), 2.2 (m, 2H), 3.67 (m, 2H), 4.20 (q, 2H), et 5.38 (t, 1H). Le spectre de masse montre un ion moléculaire à *m/e* 189 ainsi qu'un pic à *m/e* 191 dans le rapport de 3:1.

(3) Mise en évidence du chlorure d'éthyle

La caprolactame (**2**) (20 g, 0.177 mol) est dissoute dans du toluène anhydre (500 ml) et le chloroformiate d'éthyle (50 ml, 0.5 mol) est ajouté en une portion. Pendant que le mélange est chauffé à reflux, on recueille les gaz qui se dégagent au bout du réfrigérant à l'aide d'un piège à glace sèche. Après le traitement habituel, on peut isoler la *N*-éthoxycarbonylcaprolactame (**15**) (14.0 g, 0.076 mol) avec un rendement de 43%. Après distillation fractionnée des produits de condensation dans le piège froid, on peut caractériser une certaine quantité de chlorure d'éthyle (5 ml, 0.075 mol), p.éb. 13 °C. L'identification a été faite par comparaison du spectre de r.m.n. avec celui d'un échantillon authentique. L'expérience a été répétée à partir de l'éther lactimique **1**, et des résultats à peu près identiques ont été obtenus.

Les auteurs remercient le Conseil National de Recherches du Canada pour l'aide financière apportée sous forme de bourses d'études (R.G. et P.B.) et d'octrois de recherche (C.B. et D.G.).

The Master Equation for the Dissociation of a Dilute Diatomic Gas. IV. The Bottleneck Phenomenon

E. KAMARATOS AND H. O. PRITCHARD
Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received April 2, 1971

Once the initial transients have died out, the rate constant for the dissociation or recombination of a dilute diatomic gas bears the same kind of relationship to individual translation–vibration transition probabilities as does the conductance of a generalized resistance network to the individual resistance components. Thus, it is not possible to single out any one transition which "controls" the rate of dissociation or recombination.

Une fois que les phénomènes initiaux ont disparu, la constante de vitesse de la dissociation ou de la recombinaison d'un gaz diatomique dilué apporte le même genre de relation aux probabilités de transition individuelle translation-vibration que ne le fait la conductance d'un réseau généralisé de résistances aux résistances composantes individuelles. Ainsi, il n'est possible d'isoler aucune transition qui "contrôle" la vitesse de dissociation ou de recombinaison.

In Part III[1] of this series (1), it was shown empirically that the rate constant for the dissociation (or recombination) of a diatomic gas can be determined by finding the numerically smallest eigenvalue d_{n-1} of a submatrix $\mathbf{A}_{00}$ of the relaxation matrix. The off-diagonal elements of $\mathbf{A}_{00}$ are simply the specific transition rates W_{ij} $(= ZP_{ij})$ between all the bound states, and each diagonal element is the negative sum of the specific dissociation rate from that state and all the other elements in the row (eq. III (5)). The eigenvalue d_{n-1} is related to the desired rate constants through eqs. III (21) and III (22) *viz.*

$$k_{d,M} = -[M]^{-1}d_{n-1}$$

and

$$k_{r,M} = -K^{-1}[M]^{-1}d_{n-1}$$

where K is the equilibrium constant and [M] is the inert gas concentration. The minuteness of the inaccuracies of these two relationships is now well established (1–3).

Also in Part III, we found considerable circumstantial evidence for the existence of some kind of bottleneck in the dissociation process: the two most compelling points were that an increase of a factor of 1000 in the dominant bound-continuum rate coefficient caused only a 5% increase in the rate of dissociation; and that when sets of transition probabilities were chosen which did not have this property, the rate constant for recombination changed its behavior completely from a slow decline with increasing temperature to a very rapid increase with increasing temperature (Fig. III (3)). An attempt was made to define the bottleneck by determining which pair of transition probabilities P_{ij} and P_{ji} perturbed the eigenvalue d_{n-1} (*i.e.* the rate constant) the most; it was found that with the particular set of transition probabilities chosen, this criterion characterized the bottleneck as being somewhat diffuse, extending approximately over the levels $v = 9$ to $v = 13$ in H_2, with the $v = 10 \leftrightarrow 11$ and $v = 11 \leftrightarrow 12$ transitions the most important contributors.

In this Note we examine, by numerical experiment, the sensitivity of the rate constant for the recombination of H atoms by a third body M to variations in the assumed transition probabilities in the bottleneck region; the calculations were performed for two temperatures 2000 and 3000 °K to try to connect the temperature coefficient of $k_{r,M}$ to those of the bottleneck transition probabilities. The standard set of T–V transition probabilities were taken to be those given by the prescription eq. III (1), and Fig. 1(*a*) shows the variation of $k_{r,M}$ at 2000 °K for gross variations in the $10 \leftrightarrow 11$, $11 \leftrightarrow 12$, and $12 \leftrightarrow 13$ transition probabilities; similar data for 3000 °K are shown in Fig. 1(*b*). As already noted, $k_{r,M}$ is most sensitive to perturbations in the $10 \leftrightarrow 11$ and $11 \leftrightarrow 12$ transition probabilities. However, the most striking feature is the remark-

[1]Equations in this paper are designated by a prefix III; the reader is referred to refs. 1 and 2 for further clarification of the symbols used.

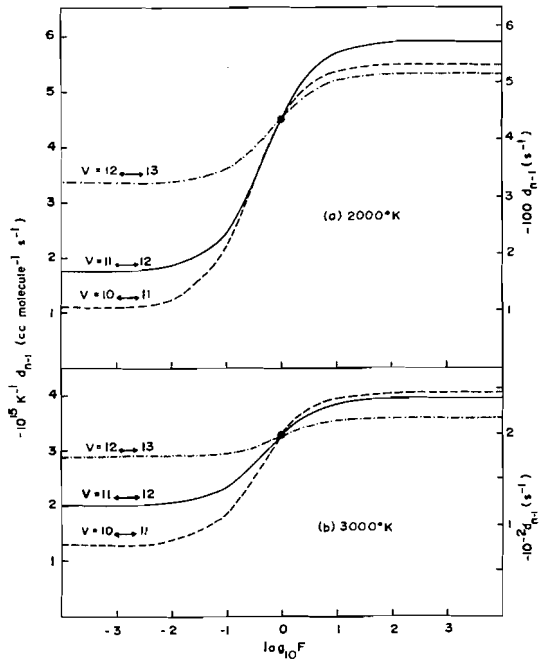

FIG. 1. Variation of the rate constants $k_{r,M}$ and $k_{d,M}$ for variations in the transition probabilities $P_{i,i+1}$ and $P_{i+1,i}$ when each pair of probabilities was multiplied in turn by the factor F. The left-hand ordinate is $-10^{15}K^{-1}d_{n-1}(= 10^{15}[M]k_{r,M}$ from eq. III (22)) and the right hand ordinate is proportional to $-d_{n-1}(= [M]k_{d,M}$ from eq. III (21)); [M] = 3.5×10^{19} molecules cc^{-1} in each case.

able insensitivity of the rate constant to large changes in the probabilities. For example, a decrease in the $11 \leftrightarrow 12$ transition probability by a factor of 100 reduces $k_{r,M}$ by a factor of about 2.5 at 2000 °K and 2.3 at 3000 °K: the rate constants are about a factor of two less sensitive to large increases in transition probability than to large decreases; and that beyond a factor of 100 change in $P_{i,i+1}$ and $P_{i+1,i}$ there is no further change in the rate constant. Small variations were also examined, and the rate constants were found to be roughly linear functions of the logarithm of the perturbed probability for variations of less than a factor of two, becoming rapidly non-linear beyond that. However, since the rate constant $k_{r,M}$ has different sensitivities to each individual transition probability at each temperature, and each transition probability has its own individual temperature coefficient, there is obviously no *simple* factor which determines the temperature coefficient of $k_{r,M}$; the temperature coefficient of the dissociation rate constant $k_{d,M}$ is of course *dominated* by the Boltzmann factor $\exp(-D_0/kT)$, this being to first order the temperature coefficient of the equilibrium constant K.

Some calculations were made to examine the actual differences that would occur in the reaction process, using dissociation as an example. It was found that if the transition probability for the $11 \leftrightarrow 12$ transition was reduced, all pseudo-steady populations $v = 0$ to 11 were higher, whilst those of $v = 12$, 13, and 14 were lower than in the unperturbed calculation at the same reaction time. As a result, all transition rates $R_{ij}(= W_{ij}n_j)$ between states $v = 0$ to 11 increased, both upwards and downwards: above $v = 12$, all rates decreased, again in both directions. Also, since the lower populations were inflated and the upper populations were depressed, upward multiple quantum jumps across the bottleneck increased in rate, whilst downward multiple quantum jumps across the bottleneck decreased in rate; nevertheless, since single quantum jumps are dominant during the pseudo-steady regime (2), the overall rate of dissociation *decreases*. On the other hand, if the $11 \leftrightarrow 12$ transition probability was increased, all these properties were reversed; also, the behavior in recombination processes is complementary.

Returning to the discussion of the behavior demonstrated in Fig. 1, the explanation in qualitative terms is very simple. If we increase the ease of the transition $v = 11 \leftrightarrow 12$, we increase the rate; but if we increase it so far that it no longer presents any impediment to the flow of molecules, other transitions (co-operatively) become rate determining, so the rate does not increase unboundedly. Alternatively, if we reduce the ease of this transition, we decrease the rate, but if we reduce it so far that it presents an infinite barrier to the flow of molecules, they can still get round the barrier by multiple quantum jumps (mainly in this case $v = 11 \leftrightarrow 13$ and $v = 10 \leftrightarrow 12$) so that the rate does not fall to zero. An analogy which is easy to visualize is that of an n-point resistance network, with resistances r_{ij} connecting each point in the network. If one of the elements $r_{i,i+i}$ is decreased to zero, there is a small increase in the conductance c of the network, whereas if $r_{i,i+i}$ becomes an open circuit there is a small decrease in the conductance of the network, since there are many other paths that the current can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

take. In fact, there is a remarkable similarity between eq. III (5) and the network conductance equations, *viz.*

$$i = Cv$$

In this equation i is a column vector whose first element is $-i$ (the current), the last element is $+i$ and all other elements are zero (the precise analogue of the steady-state assumption for dn_i/dt in dissociation); v is a column vector of the voltages at each network point; and $\mathbf{C}$ is a symmetric matrix with off-diagonal elements c_{ij} (the individual conductances) and diagonal elements equal to the negative sum of all other elements in the row. We have performed some calculations on arbitrary 16-point resistance networks, and verified that the behavior of the network conductance[2] is similar to that observed in Fig. 1. Other network systems, *e.g.*, the flow of traffic through city streets, are equally useful in trying to achieve a *qualitative* understanding of these dissociation–recombination processes.

In summary, our calculations demonstrate the complexity of the factors determining the dissociation or recombination rate of a molecule; it is clear that what has been termed the bottleneck (4) is a diffuse and co-operative phenomenon, and that no single element in it has a significant causal relationship to the overall rate. In our view, it seems that future advances in our understanding of this aspect of the problem will more likely come from the establishment of eigenvalue theorems for the matrix $\mathbf{A}_{00}$ than by further numerical experiment. For example, the variation of every pair of single-step bound–bound transition probabilities in $\mathbf{A}_{00}$ gives rise to an effect on the rate constant similar to those shown in Fig. 1 except that the dispersion can vary from a factor of about 6 as seen in Fig. 1(*a*) to parts-per-million or even less. These tiny dispersions occur when the perturbation of a pair of transition probabilities simply perturbs one eigenvalue only as described in Part III; the larger dispersions discussed here arise almost like a residue in d_{n-1}, when the resultant perturbation happens to spread over several of the other eigenvalues.

We would like to acknowledge assistance from R. A. Koehler and D. L. S. McElwain in these calculations.

Stereoselective Total Synthesis of (+)-Copaborneol, (+)-Copaisoborneol, and (+)-Copacamphor[1]

EDWARD PIERS,[2] RONALD W. BRITTON, ROBERT J. KEZIERE, AND R. DEAN SMILLIE
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received May 11, 1971

A stereoselective total synthesis of the novel tricyclic sesquiterpenoids (+)-copaborneol (**1**), (+)-copacamphor (**2**), and (+)-copaisoborneol (**3**) is described. This work fully corroborates the structure and absolute stereochemistry assigned to the three sesquiterpenoids.

Une synthèse totale et stéréosélective de nouveaux sesquiterpènes tricycliques, le (+)-copabornéol (**1**), le (+)-copacamphre (**2**), et le (+)-copaisobornéol (**3**), est décrite. Ce travail confirme pleinement la structure et la stéréochimie absolue attribuée à ces trois sesquiterpènes.

Canadian Journal of Chemistry, 49, 2620 (1971)

The novel tricyclic sesquiterpenoid (+)-copaborneol is the major C_{15}-alcohol occurring in the wood of *Pinus silvestris* L. (1) and in Swedish sulfate turpentine (2) and has been assigned (3, 4) structure and absolute stereochemistry as depicted in **1**. Oxidation of this alcohol afforded (+)-copacamphor (**2**) (3, 4). Reduction of the latter with lithium aluminum hydride gave (+)-copaisoborneol (**3**), while reduction with sodium in ethanol yielded (+)-copaborneol (**1**) (3, 4). We report here a stereoselective total synthesis of these three sesquiterpenoids via a route which fully corroborates the structural and absolute stereochemical assignments.

Conversion of (+)-carvomenthone (**4**), with absolute configuration as shown (5), into the corresponding *n*-butylthiomethylene derivative **5** was accomplished by standard procedures (6). Alkylation (potassium *t*-butoxide in *t*-butyl alcohol) of the latter with methyl 2-iodopropionate was highly regioselective[3] and stereoselective and gave, after removal of the blocking group (6) and esterification of the resulting keto acid, the keto ester **6** in 62% yield.[4] Treatment of keto ester **6** with sodium bis(trimethylsilyl)amide (8) in refluxing dimethoxyethane, followed by quenching of the reaction mixture with acetic acid, afforded a 90% yield of the substituted bicyclo[3.2.1]octadione **7**, m.p. 76–77°, $[\alpha]_D^{20}$ −56°.

When the diketone **7** was reacted with 1 equiv of sodium bis(trimethylsilyl)amide (8) in benzene, and the resulting solution was treated with excess acetyl chloride, the enol acetate **8** was obtained in 90% yield. Hydrogenation (platinum oxide, ethanol) of the latter gave only one keto acetate and the p.m.r. spectrum of this material was in full accord with the assigned structure **9**. In particular, the proton on C-6 appeared as a pair of doublets (τ 4.65) with $J_{5,6} = 7.5$ and $J_{6,7} = 10.5$ Hz. Furthermore, the bridgehead proton at C-5 also produced a pair of doublets (τ 7.16), with $J_{4,5} = 3.5$ and $J_{5,6} = 7.5$ Hz. Molecular models clearly indicate that these spectral data are consistent only with the keto

[1]Financial support for this work by the National Research Council of Canada is gratefully acknowledged.

[2]Fellow of the Alfred P. Sloan Foundation, 1970–1972.

[3]Interestingly, alkylation of **5** with methyl 2-bromopropionate under a variety of conditions consistently gave mixtures of *O*- and *C*-alkylation products. For an excellent discussion regarding *O*- *vs.* *C*-alkylation of ambident anions, see ref. 7.

[4]The stereochemistry of **6** and of other synthetic intermediates was unambiguously established on the basis of chemical correlation with compounds of known stereochemistry, conformational analysis, and/or analysis of spectral data. New compounds gave satisfactory analytical data and showed spectral properties in complete accordance with the assigned structures.

acetate possessing the stereochemistry depicted in **9**, assuming that the hydrogenation proceeded in a *cis* manner.[5]

Treatment of keto acetate **9** with methoxymethylenetriphenylphosphorane in ether gave an isomeric mixture of the enol ether acetates **10**, accompanied by some of the corresponding alcohols **11**. Successive subjection of this mixture to reduction (lithium aluminum hydride), hydrolysis (aqueous perchloric acid in ether), and equilibration (aqueous potassium carbonate in methanol) afforded, in 50% yield from **9**, the hydroxy aldehyde **12**. Reaction of the latter with methylenetriphenylphosphorane in dimethyl sulfoxide (9) gave, in 92% yield, the olefinic alcohol **13**, $[\alpha]_D^{20}$ +43°. Hydroboration–oxidation (10) of **13** led to the diol **14**, which upon treatment with *p*-toluenesulfonyl chloride in pyridine followed by Collins oxidation (11) of the resulting mono tosylate **15**, afforded the crystalline keto tosylate **16**, m.p. 114–114.5° (45% yield from **13**).

Treatment of **16** with 0.1 *M* methylsulfinyl carbanion (12) in dimethyl sulfoxide afforded in 82% yield, (+)-copacamphor (**2**), $[\alpha]_D^{23}$ +106°; i.r. (film) 5.75, 9.60, 9.87 μ; p.m.r. τ 9.06, 9.10 (singlets, tertiary methyls), 9.09, 9.11 (doublets, J = 6.4 Hz, isopropyl methyls). This material was shown to be identical (i.r., p.m.r., g.l.c. retention times, specific rotation) with authentic (+)-copacamphor.[6] Since the latter compound had previously (3, 4) been converted into both (+)-copaborneol (**1**) and (+)-copaisoborneol (**3**), the work described above also completes the total synthesis of these two sesquiterpenoids.

Stereoselective Total Synthesis of (−)-Copacamphene and (−)-Cyclocopacamphene[1]

EDWARD PIERS,[2] RONALD W. BRITTON, ROBERT J. KEZIERE, AND R. DEAN SMILLIE
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received May 11, 1971

An efficient and highly stereoselective total synthesis of the novel sesquiterpenes (−)-copacamphene (**1**) and (−)-cyclocopacamphene (**3**) is described. This work fully corroborates the structure and absolute stereochemistry assigned to the two sesquiterpenes.

Une méthode de synthèse totale, efficace et hautement stéréosélective de nouveaux sesquiterpènes, le (−)-copacamphène (**1**) et le (−)-cyclocopacamphène (**3**), est décrite. Ce travail confirme pleinement la structure et la stéréochimie absolue attribuée à ces deux sesquiterpènes.

Canadian Journal of Chemistry, 49, 2623 (1971)

The structure (1) and absolute stereochemistry (2) of the novel tricyclic sesquiterpene (+)-copacamphene have been assigned as depicted in **1**. Although this material has apparently not as yet been isolated from a natural source, it has been obtained by rearrangement of a copaborneol derivative (1, 2). Very recently, racemic copacamphene has been obtained by total synthesis (3). A closely related compound, (+)-cyclocopacamphene (**2**) has been obtained from cyclocopacamphenic acid (4) and, apparently, occurs in vetiver oil (4). Although it has been suggested that (+)-cyclocopacamphene has absolute stereochemistry as depicted in **2** (4), this point has not yet received unambiguous verification. We report here the total synthesis of (−)-copacamphene (**1**)[3] and of (−)-cyclocopacamphene (**3**) via a highly stereoselective route which provides unambiguous evidence for the structure and absolute stereochemistry of these compounds.

Reaction of the diketone **4**, of known absolute stereochemistry (5), with 1 equiv of sodium borohydride in methanol gave the keto alcohol **5**.[4] Conversion of the latter into the corresponding tosylhydrazone **6**, followed by reaction of the latter with methyllithium in tetrahydrofuran (6) gave the olefinic alcohol **7**. Collins oxidation (7) of **7** afforded, in 67% overall yield from the diketone **4**, the keto olefin **8**, $[\alpha]_D^{23}$ −29°.

Reaction of **8** with methoxymethylenetriphenylphosphorane in dimethyl sulfoxide (8) (40°, 1.5 h) gave, in high yield, a mixture of isomeric enol ethers **9**. Successive subjection of the latter to hydrolysis (35% perchloric acid in ether), equilibration (potassium carbonate in methanol), Wittig reaction (methylenetriphenylphosphorane in dimethyl sulfoxide), and hydroboration–oxidation (disiamylborane in tetrahydrofuran; hydrogen peroxide – sodium hydroxide (9)) afforded (66% yield from **9**) the olefinic alcohol **10**, $[\alpha]_D^{20}$ +8.5°. Treatment of **10** with *p*-toluenesulfonyl chloride in pyridine at 25° gave the olefinic tosylate **11** which, presumably largely due to the proximity of the tosylate functionality and the olefinic double bond, exhibited a high propensity toward eliminative cyclization. Thus, merely allowing **11** to stand at room temperature gave, after filtration of the resultant material through a silica gel column, a 90% yield (from **10**) of a mixture consisting nearly entirely of (−)-copacamphene (**1**), accompanied by very small amounts of two as yet unidentified compounds. Pure synthetic (−)-copacamphene (**1**), readily obtained from this mixture by chromatography of the latter over silver nitrate impregnated silica gel, exhibited $[\alpha]_D^{21}$ −159°; i.r. (film) 3.26, 6.03, 6.83, 7.20, 7.30, 11.42 μ; p.m.r. τ 5.21, 5.49 (singlets, olefinic protons), 7.54 (broad signal, allylic proton), 9.00 (singlet, tertiary methyl), 9.10 (doublet, J = 6.0 Hz, isopropyl methyls). These spectral data are in excellent agreement with

[1]Financial support for this work from the National Research Council of Canada is gratefully acknowledged.

[2]Fellow of the Alfred P. Sloan Foundation, 1970–1972.

[3]Although Kolbe-Haugwitz and Westfelt (2) were correct in their assignments regarding absolute stereochemistry, we have found that copacamphene of absolute configuration as shown in **1** is levorotatory ($[\alpha]_D^{21}$ −159°, *vide infra*) and not dextrorotatory ($[\alpha]_D$ +28.9°) as reported (1, 2). Neither we nor Dr. Westfelt (private communication) have as yet been able to trace the reason for this discrepancy.

[4]New compounds gave satisfactory analytical data and showed spectral properties in complete accord with the assigned structures.

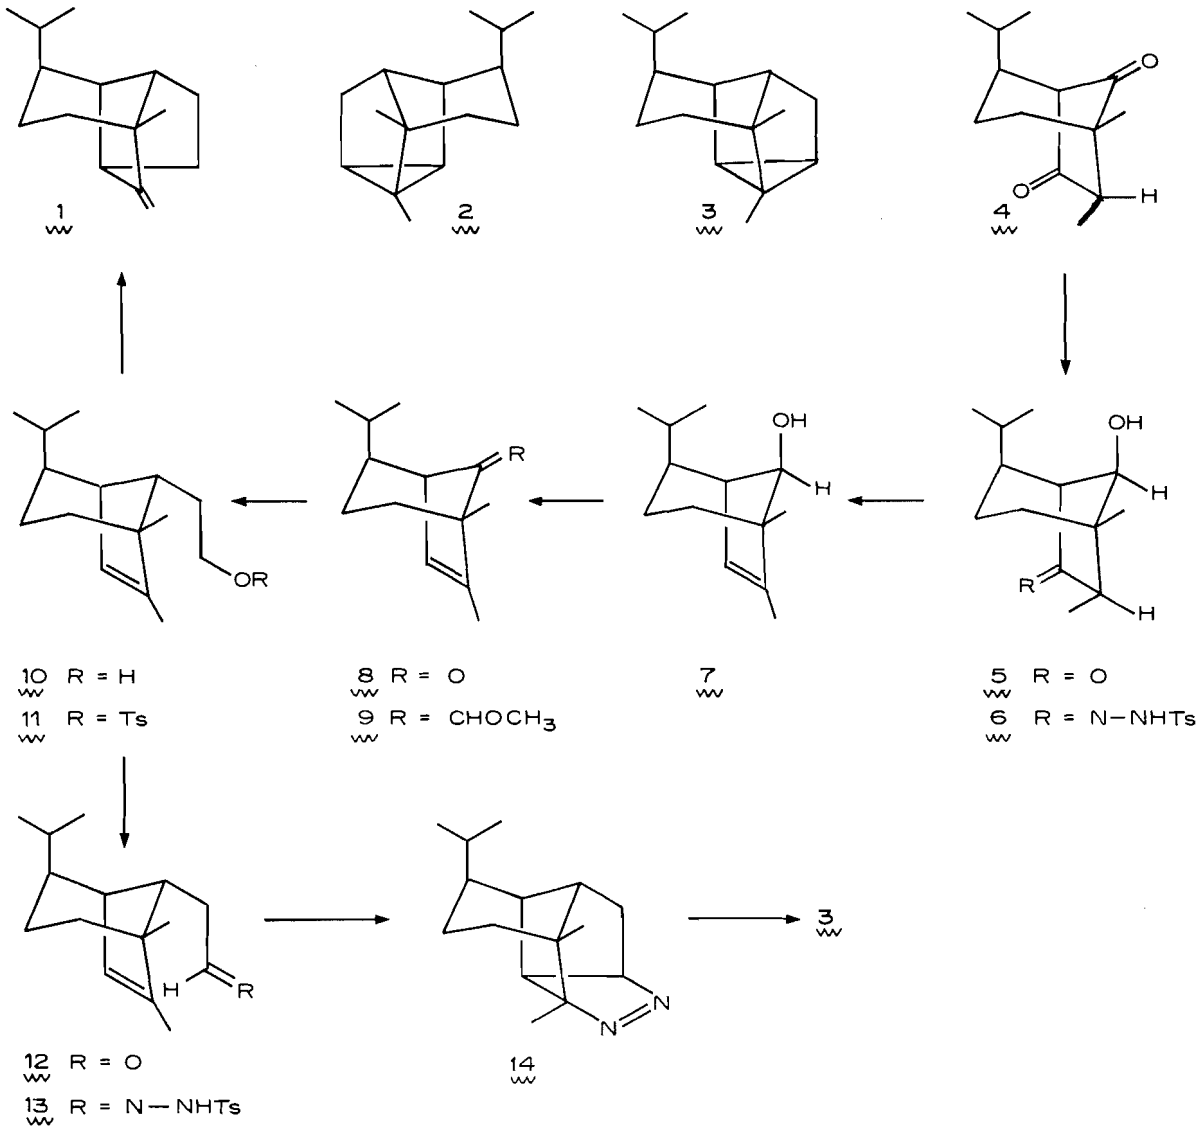
For personal use only.



those published for copacamphene (2, 3) and, indeed, our synthetic (−)-copacamphene exhibited spectral data and g.l.c. retention times identical with those of (±)-copacamphene (3).[5]

Oxidation (7) of **10** gave, in 91% yield, the olefinic aldehyde **12**, $[\alpha]_D^{21}$ −39°, which was converted, by reaction with *p*-toluenesulfonylhydrazide in benzene, into the corresponding tosylhydrazone **13**. Pyrolysis (120–140°) of the lithium salt of the latter under reduced pressure (0.25 mm) with direct distillation of the product (10) afforded (81% yield from **12**) the pyrazoline **14**,[6] $[\alpha]_D^{22}$ +95°. The structure of the latter was clearly shown by the p.m.r. spectrum, which exhibited only one proton (τ 5.11) adjacent to the —N=N— moiety (12). Photolysis of **14** in ether gave a quantitative yield of (−)-cyclocopacamphene (**3**), $[\alpha]_D^{21}$ −42°; i.r. (film) 3.29, 6.85,

[5]We are very grateful to Professor J. E. McMurry for a sample of this compound.

[6]The facile intramolecular 1,3-dipolar cycloaddition of the intermediate olefinic diazoalkane to give **14** is presumably a function of the proximity of the two reacting functional groups and of the fairly strained nature of the olefinic double bond (see ref. 11).

The Kinetics of the Thermal Insertion Reaction of Tin(II) Halides with Cyclopentadienylnickel Carbonyl Dimer

P. F. BARRETT AND RONALD R. CLANCY

Department of Chemistry, Trent University, Peterborough, Ontario

Received March 23, 1971

The kinetics of the thermal insertion of $SnCl_2$ and $SnBr_2$ into the metal–metal bond of $[\pi\text{-}C_5H_5NiCO]_2$ have been studied. On the basis of the kinetic data a bimolecular mechanism, involving direct attack of the tin(II) halide on the nickel dimer, has been proposed. The thermal insertion with tin(II) bromide was found to proceed with an activation enthalpy of 19.4 ± 0.2 kcal/mol and an activation entropy of -8.8 ± 0.4 cal deg^{-1} mol^{-1}. For the thermal insertion with tin(II) chloride a $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ of 22.5 ± 0.2 kcal/mol and -4.0 ± 0.2 cal deg^{-1} mol^{-1}, respectively, were observed.

La cinétique de l'insertion thermique de $SnCl_2$ et $SnBr_2$ dans la liaison métal-métal de $[\pi\text{-}C_5H_5NiCO]_2$ a été étudiée. Sur la base des données cinétiques, on propose un mécanisme bimoléculaire, impliquant une attaque directe du halogénure d'étain(II) sur le dimère du nickel. L'insertion thermique avec le bromure d'étain(II) procède avec une enthalpie d'activation de 19.4 ± 0.2 kcal/mol et avec une entropie d'activation de -8.8 ± 0.4 cal deg^{-1} mol^{-1}. Pour l'insertion thermique avec le chlorure d'étain(II), on observe pour $\Delta H^{\ddagger}$ et $\Delta S^{\ddagger}$ respectivement les valeurs de 22.5 ± 0.2 kcal/mol et -4.0 ± 0.2 cal deg^{-1} mol^{-1}.

Canadian Journal of Chemistry, 49, 2627 (1971)

Introduction

Cyclopentadienylnickel carbonyl dimer exists as a doubly carbonyl bridged species (1, 2) containing a covalent Ni—Ni bond. The insertion of tin(II) chloride into this bond was first reported by Patmore and Graham (3) and we have found that tin(II) bromide forms a similar insertion product.

Previous studies (4, 5) have reported the kinetics of the insertion of tin(II) halides into the metal–metal bonds of hexacarbonylbis(tri-*n*-butyl-phosphine)dicobalt and cyclopentadienyl-iron dicarbonyl dimer. From these investigations information regarding the strength of metal–metal bonds has been obtained as well as details of the mechanisms of insertion reactions.

In this paper we report the kinetic investigation of the thermal insertion of $SnCl_2$ and $SnBr_2$ into the metal–metal bond of cyclopentadienylnickel carbonyl dimer.

Experimental and Results

Materials

Cyclopentadienylnickel carbonyl dimer, $[\pi\text{-}C_5H_5NiCO]_2$, was prepared from dicyclopentadienylnickel and nickel carbonyl (Alpha Inorganics Inc.) using methods previously described (1, 2). Anhydrous tin(II) chloride was prepared by dehydrating the dihydrate (Fisher Scientific Co.) with acetic anhydride (6). Anhydrous tin(II) bromide (K & K Laboratories Inc.) was prepared in a similar manner but under a nitrogen atmosphere. The anhydrous $SnCl_2$ and $SnBr_2$ were stored in light-tight containers in vacuo over P_2O_5. Tetrahydrofuran (Fisher Scientific Co.; Certified grade) was dried by refluxing over sodium wire and was freshly distilled immediately before use in the kinetic runs.

Preparation of Insertion Products

Dichlorobis(π-cyclopentadienylcarbonylnickel)tin(IV) was prepared using the method of Patmore and Graham (3). Dibromobis(π-cyclopentadienylcarbonylnickel)tin(IV) was prepared in a similar manner, all work being done in a nitrogen atmosphere. The product gave dark green, air stable, needlelike crystals, m.p. 116°.

Anal. Calcd. for $[\pi\text{-}C_5H_5NiCO]_2SnBr_2$: C, 24.75; H, 1.72; Br, 27.39. Found: C, 24.71; H, 1.98; Br, 27.31.[1]

Kinetics

The thermal insertion of tin(II) chloride into the metal–metal bond of cyclopentadienylnickel carbonyl dimer was studied by recording the appearance of the insertion product at 600 mμ using a Unicam SP800 spectrophotometer. The reaction mixture underwent a color change

[1]This analysis was carried out by Dr. Franz Pascher, Microanalytical Laboratory, Bonn, West Germany.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

from red to green during the course of the reaction and gave an isosbestic point at 556 mμ indicating that there was a simple conversion from reactants to product. For each run 10 ml of a THF solution of known tin(II) chloride concentration was thermostated to the desired temperature and then used to completely fill a 1 cm stoppered silica cell containing an amount of $[\pi\text{-}C_5H_5NiCO]_2$ required to give an approximately 1.5×10^{-3} *M* solution. Pseudo first-order kinetics were observed in all cases. Plots of log $(A_\infty - A_t)$, where A_∞ and A_t are the absorbances at 600 mμ for times ∞ and t, respectively, were linear for over 50% reaction.

A_∞ was due solely to the absorbance of the product $[\pi\text{-}C_5H_5NiCO]_2SnCl_2$ but because of the uncertainty in the initial concentration of $[\pi\text{-}C_5H_5NiCO]_2$, a value for A_∞ could not be determined directly. The following outlines the method used to calculate A_∞ at 600 mμ from the absorbance at the isosbestic point (556 mμ). The molar absorptivity (ε) of $[\pi\text{-}C_5H_5NiCO]_2$ must be identical with that of $[\pi\text{-}C_5H_5NiCO]_2SnCl_2$ at 556 mμ and was calculated to be 1.37×10^3 from a Beer's law plot of $[\pi\text{-}C_5H_5NiCO]_2SnCl_2$ at this wavelength. In a given run, the final concentration of product could then be determined from the absorbance at the isosbestic point. Using this value for the final concentration of product, A_∞ could be calculated from a Beer's law plot of $[\pi\text{-}C_5H_5NiCO]_2SnCl_2$ at 600 mμ, the wavelength at which the kinetics were studied. The molar absorptivity at this wavelength was found to be 1.41×10^3. Data for the Beer's law plots of $[\pi\text{-}C_5H_5NiCO]_2SnCl_2$ were obtained from THF solutions which were 0.5 *M* in $SnCl_2$ under which conditions the insertion product was considerably more stable.

The thermal insertion reaction with tin(II) bromide could not be studied in the visible by following the appearance of the insertion product because of the instability of this product and the resulting uncertainties in interpreting the absorbance data. The reaction could however, be studied kinetically by following the disappearance of the bridging carbonyl band of $[\pi\text{-}C_5H_5NiCO]_2$ in the infrared (1844 cm^{-1}) since the subsequent decomposition of the insertion product did not affect this region of the spectrum. $[\pi\text{-}C_5H_5NiCO]_2$ was found to be stable under actual reaction conditions for times well in excess of those of the actual kinetic runs. For the runs themselves, 10 ml of a THF solution containing a known concentration of $SnBr_2$ was thermostated and quickly added to a three-necked flask containing the nickel dimer. A nitrogen atmosphere was maintained in the vessel throughout and the bridging carbonyl region in the infrared spectrum was scanned using a Perkin–Elmer 621 spectrophotometer immediately upon removal of an aliquot by means of a syringe. As samples were removed the nitrogen atmosphere was maintained by means of a small positive pressure. Time intervals were taken from the moment the samples were removed from the reaction vessel. From the transmittances, linear plots of log $(A_t - A_\infty)$ against time were obtained where A_t and A_∞ are the absorbances at time t and ∞, respectively. Plots were linear for well over two half-lives. A base line of the spectrum was obtained from the absorbance of a solution of $SnBr_2$ run against the reference solvent THF. A_∞ was found to be zero in all cases.

The observed pseudo first-order rate constants for the $SnBr_2$ and $SnCl_2$ insertions reactions, k_{obs}, are plotted in Figs. 1 and 2 as functions of tin(II) halide concentration. The lines were fitted by a least squares analysis (7) using the origin as an experimental point since there was no evidence for decomposition of the cyclopentadienylnickel carbonyl dimer.

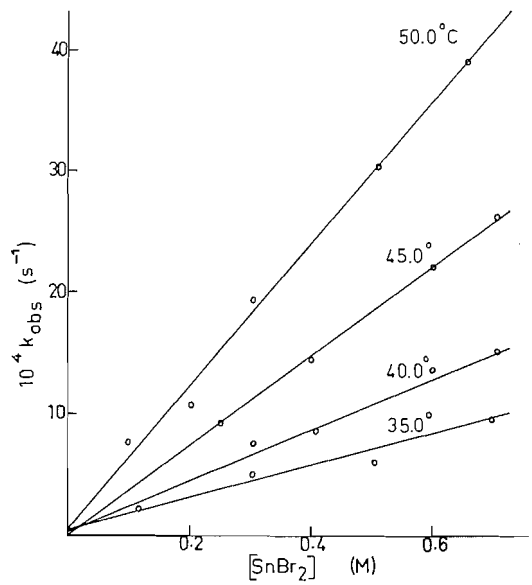

FIG. 1. Plot of the observed pseudo first-order rate constant *vs.* tin(II) bromide concentration for the thermal reaction $[\pi\text{-}C_5H_5NiCO]_2 + SnBr_2 \rightarrow [\pi\text{-}C_5H_5NiCO]_2SnBr_2$ in THF.

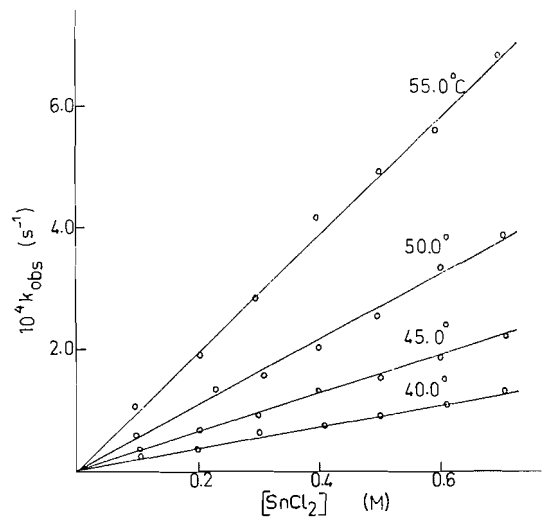

FIG. 2. Plot of the observed pseudo first-order rate constant *vs.* tin(II) chloride concentration for the thermal reaction $[\pi\text{-}C_5H_5NiCO]_2 + SnCl_2 \rightarrow [\pi\text{-}C_5H_5NiCO_2]SnCl_2$.

Discussion

Figures 1 and 2 show that the pseudo first-order rate constant, k_{obs}, for the insertion of tin(II) halides into the metal–metal bond of $[\pi\text{-}C_5H_5NiCO]_2$ varies directly with tin(II) halide concentration over the range of concentrations studied. The most obvious mechanism to account for this behavior would involve the direct bimolecular attack of the tin(II) halide on the $[\pi\text{-}C_5H_5NiCO]_2$ dimer. In the insertion of tin(II) halides into the metal–metal bonds of the similar complexes $[PBu_3Co(CO)_3]_2$ (4) and $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ (5), however, the kinetic data could only be explained by invoking the following two stage mechanism

$$A_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A_2^* \xrightarrow[B]{k_2} ABA$$

where A_2 represents the metal dimer, A_2^* is a reactive intermediate, B is the tin(II) halide, and ABA the insertion product. In the case of the $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ reaction, this was the only mechanism proposed while in the case of the $[PBu_3Co(CO)_3]_2$ reaction, it was one of two mechanisms which were suggested to operate concurrently. In the light of these results one might have expected the $[\pi\text{-}C_5H_5NiCO]_2$ complex to react by a similar mechanism, and indeed when the concentration of A_2^* is small and $k_2[B] \ll k_{-1}$ the rate law for this two-step mechanism reduces to

$$[1] \qquad \frac{-d[A_2]}{dt} = \frac{k_1 k_2}{k_{-1}}[B][A_2]$$

which is consistent with our kinetic data since the k_{obs} then becomes directly proportional to the tin(II) halide concentration.

Although the kinetic data alone cannot distinguish between these two mechanisms, other indirect evidence suggests that it is unlikely that the $[\pi\text{-}C_5H_5NiCO]_2$ complex reacts in the same way as the $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ and $[PBu_3Co(CO)_3]_2$ complexes via a two-step mechanism, but rather is subjected to direct bimolecular attack by the tin(II) halides. In the first place a two-step mechanism was proposed in the reactions of $[PBu_3Co(CO)_3]_2$ and $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ in order to account for curvature of the plots of k_{obs} against tin(II) halide concentration, whereas no such curvature is observed in the insertion reactions of $[\pi\text{-}C_5H_5NiCO]_2$. Secondly, in the substitution reactions of $Mn_2(CO)_{10}$ and $Re_2(CO)_{10}$ (8), and in the insertion reactions of $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ and $[PBu_3Co(CO)_3]_2$, which are all proposed to occur via the two-step mechanism, the reactive intermediates involved, A_2^* have all been suggested to be species in which the two halves of each of the dimers are held together solely by a single carbonyl bridge. Since the $[\pi\text{-}C_5H_5NiCO]_2$ complex shows no evidence of existing in a non carbonyl bridged form, (1, 2) the proposal of a singly carbonyl bridged reactive intermediate would seem less plausible in this case. Finally, Ellgen (9) has studied the reactions of $[\pi\text{-}C_5H_5NiCO]_2$ with carbon monoxide, triphenylarsine, triphenylphosphite, and other similar ligands and has found no evidence to suggest that the mechanism involved anything but the direct attack of the incoming ligand on the nickel dimer.

Values of k, the calculated second-order rate constant, and the thermodynamic parameters calculated from the observed rate data are listed in Tables 1 and 2. The negative $\Delta S^{\ddagger}$ is consistent with an associative type of mechanism. The $\Delta S^{\ddagger}$ for the insertion of $SnBr_2$ into the metal–metal bond of $[\pi\text{-}C_5H_5NiCO]_2$ is more negative than for the $SnCl_2$ insertion reaction. This is consistent with $SnBr_2$ being a better nucleophile than $SnCl_2$ for the soft (10) nickel dimer, thus forming a "tighter" or more ordered transition state in an associative reaction mechanism. The $\Delta H^{\ddagger}$ is also slightly lower for the $SnBr_2$ insertion reaction,

TABLE 1. Kinetic parameters for the $SnBr_2$ thermal reaction*

Temperature (°C)	10^4k (l mol^{-1} s^{-1})
50.0	49.3±3.7
45.0	37.2±0.5
40.0	21.5±1.3
35.0	13.1±0.8

*The uncertainties are standard deviations; $\Delta H^{\ddagger}$ = 19.4 ± 0.2 kcal mol^{-1}; $\Delta S^{\ddagger}$ = −8.8 ± 0.4 cal deg^{-1} mol^{-1}.

TABLE 2. Kinetic parameters for the $SnCl_2$ thermal reaction*

Temperature (°C)	10^4k (l mol^{-1} s^{-1})
55.0	9.75±0.27
50.0	5.93±0.18
45.0	3.09±0.05
40.0	1.76±0.06

*The uncertainties are standard deviations; $\Delta H^{\ddagger}$ = 22.5 ± 0.2 kcal mol^{-1}; $\Delta S^{\ddagger}$ = −4.0 ± 0.2 cal deg^{-1} mol^{-1}.

again consistent with $SnBr_2$ being better for direct nucleophilic attack than $SnCl_2$.

It is interesting that the insertion of tin(II) halides into the metal–metal bonds of $[\pi\text{-}C_5H_5NiCO]_2$ and $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ involves two completely different mechanisms. In the insertion reaction with $[\pi\text{-}C_5H_5Fe(CO)_2]_2$ the only mechanism appears to be a two-stage one involving a reactive intermediate, while the insertion of tin(II) halides into $[\pi\text{-}C_5H_5NiCO]_2$ seems to proceed solely by a one-step, bimolecular type mechanism. Part of the explanation for this may lie in the fact that on going from Fe to Ni across the first transition series, the effective nuclear charge on the metal is increasing, making it more susceptible to direct nucleophilic attack by the incoming tin(II) halide. In addition, $[\pi\text{-}C_5H_5NiCO]_2$ contains two fewer carbonyl groups which would make this dimer sterically more susceptible to direct attack than the more hindered $[\pi\text{-}C_5H_5Fe(CO)_2]_2$.

The insertion reaction of tin(II) halides with $[PBu_3Co(CO)_3]_2$ has been found to proceed via both a two-step, dissociative type mechanism as well as by a one-step, bimolecular mechanism. Although this complex is not entirely analogous to the nickel and iron dimers, there does appear to be an increasing tendency for these insertion reactions to proceed via a single-step, bimolecular mechanism rather than by a two-stage type mechanism as the atomic number of the metal increases along the first transition series.

Since the insertion reaction involving the $[\pi\text{-}C_5H_5NiCO]_2$ dimer is postulated to proceed solely via a bimolecular mechanism, it has not been possible to interpret the data in a way which would give any information regarding the strength of the Ni—Ni bond.

Application of the Congruence Principle to Viscosities of 1-Chloroalkane Binary Mixtures

B. M. COURSEY[1] AND E. L. HERIC[2]

Department of Chemistry, University of Georgia, Athens, Georgia

Received April 13, 1971

Viscosities are reported at 25 °C in five 1-chloroalkane binary systems. Mixture data are presented both as kinematic viscosity and as excess Gibbs free energy of activation for flow. The latter quantity is correlated with the average chain length in the mixtures by graphical and analytical forms of Brønsted and Koefoed's principle of congruence. This correlation serves as a basis for prediction of mixture viscosities for 1-chloroalkane pairs having chain lengths within the observed extremes: 1-chlorobutane and 1-chlorooctadecane. Errors as kinematic viscosity by this method are less than 5.5% for the systems studied.

Les viscosités de cinq systèmes binaires de chloro-1 alcanes sont rapportées à 25 °C. Pour l'écoulement, les données d'un mélange sont présentées en termes de viscosité cinématique et d'excès d'énergie libre d'activation de Gibbs. Cette dernière quantité est reliée à la longueur moyenne de chaine dans les mélanges au moyen des formes graphiques et analytiques du principe de congruence de Brønsted et Koefoed. Cette corrélation est utilisée comme base de prédiction pour les viscotiés de mélanges formé de paires de chloro-1 alcanes ayant de longueurs de chaine comprises entre les extrêmes observés, à savoir le chloro-1 butane et le chloro-1 octadécane. Pour les systèmes étudiés, les erreurs de viscosité cinématique par cette méthode sont inférieures à 5.5%.

Canadian Journal of Chemistry, 49, 2631 (1971)

Introduction

The congruence principle of Brønsted and Koefoed (1) is often used for demonstrating internal consistency of *n*-alkane mixtures. Mixtures are said to be congruent which have the same average chain length, n, through the requirement that

$$[1] \qquad n = \sum_i x_i n_i$$

where x_i and n_i are mole fraction and chain length, respectively, of species i. Although the principle was originally used for free energies, it has since been applied to a number of equilibrium properties of *n*-alkane mixtures (2–5). In a previous paper (6), the authors have shown that the principle is also applicable to viscosities of *n*-alkane mixtures.

The present work demonstrates that the congruence principle may also be used for correlation and prediction of viscometric properties in mixtures of 1-chloroalkanes. For mixtures of homologs, the principle may be expressed as (7)

$$[2] \qquad \Delta_{pq:n} = f(n) - x_p f(n_p) - x_q f(n_q)$$

where $\Delta_{pq:n}$ is the molar excess thermodynamic mixing property for two species of chain length n_p and n_q, and $f(n)$ is some state function of the homologous series. The function, of course, is dependent on the property considered and intensive variables of the system. At various times the following functions have been used

$$f(n) = \sum_j A_j n^j \qquad \text{McGlashan (7)}$$

$$= \sum_j B_{-j}/n^j \qquad \text{Diaz-Peña and Martin (8)}$$

$$= \sum_j C_{-j}/(n-2)^j \qquad \text{Hijmans and Holleman (9)}$$

$$= \Delta_{mt:n} \qquad \text{Hijmans (3)}$$

The first three are analytical functions which are series expansions in various powers of the average chain length with constants A_j, B_{-j}, C_{-j}, respectively. The last is a graphical method based on the observed behavior in a mixture of the extreme components of chain lengths n_m and n_t. All of these functions are evaluated for some pair of extreme components and then used to predict the behavior of component pairs within the extremes through eq. 2. Both the series expansion in $(1/n)$ and the graphical method have been examined in the present study.

[a]From five sources identified in ref. 11.
[b]Supercooled liquid.

In order to apply the congruence principle to mixture viscosities (6), the transport property is first converted to a thermodynamic activation property. Kinematic viscosity, ν, may be related to the Gibbs free energy of activation for flow, Δ^*G, by the Eyring viscosity equation (10)

$$[3] \qquad \nu = (hN/M) \exp (\Delta^*G/RT)$$

where h = Planck's constant, N = Avogadro's number, M = molecular weight, R = molar gas constant, and T = temperature in °K. If free energy activation barriers are assumed additive for mixtures, then for an ideal mixture

$$[4] \qquad \Delta^*G^{ideal} = \sum_i x_i \Delta^*G_i$$

Molar excess Gibbs free energy of activation for flow

$$[5] \qquad \Delta^*G^E = \Delta^*G - \Delta^*G^{ideal}$$

which on rearrangement of eqs. 3–5 becomes

$$[6] \quad \Delta^*G^E = RT\left[\ln (\nu M) - \sum_i x_i \ln (\nu_i M_i)\right]$$

If $\Delta^*G^E > 0$, then the viscosity is greater than that of an ideal mixture. Equation 6 provides a property suitable for treatment with the congruence principle.

Equipment

The equipment and techniques used in this work have been described previously (11, 12). A water bath thermostatically controlled to ±0.01 °C was used. Bath temperature was monitored with a Beckman thermometer which had been set with a calibrated thermometer. The calibration of the latter was against an NBS certified standard. Times were measured with an electric stop clock which had been calibrated against an electronic time standard. All weighings were made with a Mettler 300-g-capacity precision balance with certified weights.

Viscosities were determined with Cannon–Fenske ASTM viscometers with different capillary diameters because of the 20-fold increase in viscosity in the 1-chloroalkane series. Three NBS oils of certified viscosity were employed as primary standards for the ASTM 50 and 100 viscometers. Kinetic energy corrections compared favorably with those predicted for the given capillary diameters (13).

The viscometers were maintained in the bath until constant flow time was obtained. As room temperature was only slightly lower than 25 °C, temperature equilibrium was established rapidly. Evaporation losses from the viscometers were negligible.

Liquids were mixed in a 50-ml modified glass syringe sealed by glass at the needle end. Again, evaporation rates were negligible. Transfer to viscometers was by overpressure through capillary tubing installed within the syringe plunger. The glass equipment was provided with ball and socket joints to minimize evaporation on transfer. Joints were treated with hexane to remove traces of non-volatile components.

Materials

Purification procedures for the materials used in this study have been described (11). The referenced study contains a comparison of experimental and literature values for densities and refractive indices as well as viscosities. Some properties of the pure components are given in Table 1. Experimental values represent the mean of at least three determinations.

Results

It is evident from Table 1 that there are some significant differences between experimental and literature values for kinematic viscosities. The comparison with literature values must be qualified, however, because no single work has reported viscosities for the range of compounds. The greatest disagreement is for 1-chlorobutane, although the present value is within the range of literature values. Moreover analytical chromatographs for all the compounds used in this work (11) indicated satisfactory purity.

Experimental kinematic viscosities for mixtures in the five binary systems are given in Table 2.

TABLE 2. Viscosities of 1-chloroalkane binary mixtures at 25 °C

Binary mixture	Mole fraction of first-named component	Kinematic viscosity (cS)	Δ^*G^E (cal/mol)
1-Chlorododecane + 1-chlorobutane	0.2298	0.8880	145.0
	0.2967	1.026	162.1
	0.4384	1.354	174.7
	0.5232	1.571	168.2
1-Chlorohexadecane + 1-chlorohexane	0.2988	1.857	176.1
	0.4443	2.548	188.8
	0.5461	3.104	179.0
	0.6874	3.975	144.3
1-Chlorotetradecane + 1-chlorooctane	0.3092	2.067	61.3
	0.4608	2.515	67.5
	0.4966	2.625	66.6
	0.5383	2.759	65.0
1-Chlorooctadecane + 1-chlorodecane	0.3008	3.528	83.1
	0.4486	4.398	89.9
	0.4943	4.691	89.3
	0.5496	5.052	85.6
1-Chlorooctadecane + 1-chlorohexadecane	0.4625	7.320	4.8
	0.4934	7.390	4.7
	0.5449	7.505	4.4

Also shown there are the excess molar Gibbs free energies of activation for flow calculated with eq. 6. Replication of measurements on the pure components indicate an estimated precision of $\pm 0.1\%$ in kinematic viscosity. This corresponds to experimental error of ± 0.7 cal/mol in Δ^*G^E.

Discussion

For the application of the congruence principle, results will also be considered from two systems reported previously (12): 1-chlorobutane + 1-chlorohexane and 1-chlorobutane + 1-chlorooctadecane. As stated previously, the graphical form of the congruence principle (3) is a special case of eq. 2. This method is demonstrated in Fig. 1 for Δ^*G^E in the 1-chloroalkane systems. The experimental values for the excess for the extreme components, in this case $\Delta_{418:n}$, are plotted *vs.* the average chain length. The excesses for the other component pairs, $\Delta_{pq:n}$, within the extremes, n_m, n_t, are superimposed as described previously (6). The agreement of the data in Fig. 1 parallels that found for other properties within homologous series (3, 8). The error by this method in predicting mixture viscosities is shown in Table 3. Errors have been expressed both as Δ^*G^E and as kinematic viscosity.

An analytical form of the congruence principle (8) utilizing a series expansion in reciprocal powers of n has also been examined. The function $f(n)$ has the following form

$$[7]\quad f(n) = B_1 n + B_0 + B_{-1}/n + B_{-2}/n^2 + B_{-3}/n^3 + \cdots$$

The first two terms do not contribute to the excess.

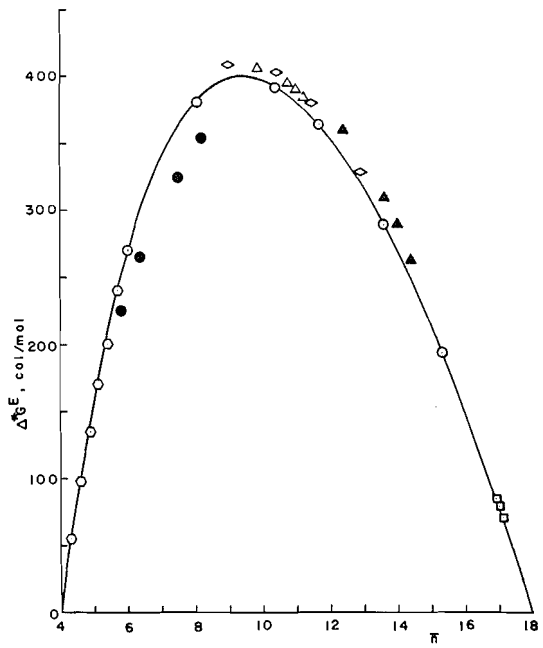

FIG. 1. Application of Hijmans' graphical form of the congruence principle (3) to Δ^*G^E in 1-chloroalkane binary mixtures. ○, $C_4Cl + C_{18}Cl$; ●, $C_4Cl + C_{12}Cl$; ⬡, $C_4Cl + C_6Cl$; ◇, $C_6Cl + C_{16}Cl$; △, $C_8Cl + C_{14}Cl$; ▲, $C_{10}Cl + C_{18}Cl$; □, $C_{16}Cl + C_{18}Cl$.

TABLE 3. Application of the congruence principle to Δ^*G^E in 1-chloroalkane mixtures

System[a]	Range of average chain length	Range of kinematic viscosity (cS)	Error by graphical method		Error by analytical method	
			As[b] Δ^*G^E (cal/mol)	As[c] %v	As[b] Δ^*G^E (cal/mol)	As[c] %v
$C_4Cl + C_{18}Cl$[d]	6.01–15.27	1.042 –6.272	—	—	—	—
$C_4Cl + C_{12}Cl$	5.84– 8.19	0.8880–1.571	28.9	5.3 (−)	29.9	5.4 (−)
$C_4Cl + C_6Cl$[d]	4.31– 5.72	0.5315–0.7511	3.2	0.6 (−)	10.7	1.8 (−)
$C_6Cl + C_{16}Cl$	8.99–12.87	1.857 –3.975	11.5	2.0 (+)	10.7	1.8 (+)
$C_8Cl + C_{14}Cl$	9.86–11.23	2.067 –2.759	8.5	1.4 (+)	6.4	1.1 (+)
$C_{10}Cl + C_{18}Cl$	12.41–14.40	3.528 –5.052	20.3	3.4 (+)	21.0	3.5 (+)
$C_{16}Cl + C_{18}Cl$	16.93–17.09	7.320 –7.505	3.1	0.5 (+)	2.0	0.3 (+)

[a]The number of hydrogens and the prefix *n*- have been deleted for the system components.
[b]Standard error for the system is defined as $[\Sigma(\text{experimental value} - \text{calculated value})^2/\text{number of observations}]^{1/2}$.
[c]Standard % error as kinematic viscosity, v, is defined as $[\Sigma\ 100[(\text{experimental value} - \text{calculated value})/\text{experimental value}]^2/\text{number of observations}]^{1/2}$. The predominant sign of the error is indicated in parentheses.
[d]Data for these systems are given in ref. 12.

Substitution of the above function into eq. 2 on rearrangement yields

$$[8]\quad \Delta_{pq:n} = B_{-1}\delta_{-1} + B_{-2}\delta_{-2} + B_{-3}\delta_{-3} + \cdots$$

where Δ is an abbreviation for Δ^*G^E, and δ is composition variable with δ_{-j} defined by

$$\delta_{-j} = (1/n^j) - (x_p/n_p{}^j) - (x_q/n_q{}^j)$$

The constants B_{-j} were found by a least-squares fit of the experimental data (12) for the reference system: 1-chlorobutane + 1-chlorooctadecane. The following three constants were sufficient to fit the data for this system within experimental error

$$B_{-1} = -24\,350 \text{ cal/mol}$$

$$B_{-2} = 76\,390 \text{ cal/mol}$$

$$B_{-3} = -104\,800 \text{ cal/mol}$$

The analytical method has a disadvantage noted previously (9). Contributions from individual terms exceed the value of the excess itself and this makes the predicted excess dependent on the physically irrelevant number of terms taken. Columns 6 and 7 of Table 3 show the error in predicted Δ^*G^E and kinematic viscosity by eq. 8 using the three coefficients.

A comparison of errors by the analytical and graphical techniques in Table 3 indicates little difference in the two methods. The greatest error by either method occurs in the 1-chlorobutane + 1-chlorododecane system where the predicted kinematic viscosities are ~5% greater than the experimental values.

Previous applications of the congruence principle have been limited to the approach given thus far: *i.e.*, calculated and experimental values are tabulated for several systems and a general discussion is given of the relative agreement. It must be noted, however, that there are 105 possible binary systems of the 1-chloroalkanes having carbon numbers between 4 and 18. It is possible with the congruence principle to predict the excess as a function of composition in all of these systems with roughly the same error as shown in Table 3. Using a digital computer we have examined Δ^*G^E in these 105 systems.

The principles of the method are straightforward. We have already established the functional dependence of the excess on the three variables n_p, n_q, and x_p by eqs. 2 and 8. It is possible to display the excess graphically as a function of n_p and n_q for two cases: (*1*) the composition is held constant, for instance at $x_p = 0.5$, or (*2*) the excess is maximized with respect to composition. The method is demonstrated here using the maximum value of the excess.

An iterative technique was used to calculate the excess for a large number of pairs, n_p, n_q, and a Newton–Raphson method was used to find the maximum excess for each pair. The resultant excess "surface" is shown in Fig. 2. Each of the 105 real systems is represented by a point in the x,y plane. Systems along the diagonal correspond to $n_p = n_q$, for which the excess must equal zero. Coordinates for each of the systems examined in this work are indicated on the figure. The error associated with the surface at each of these points is essentially the same as that given in column 6 of Table 3. Closer

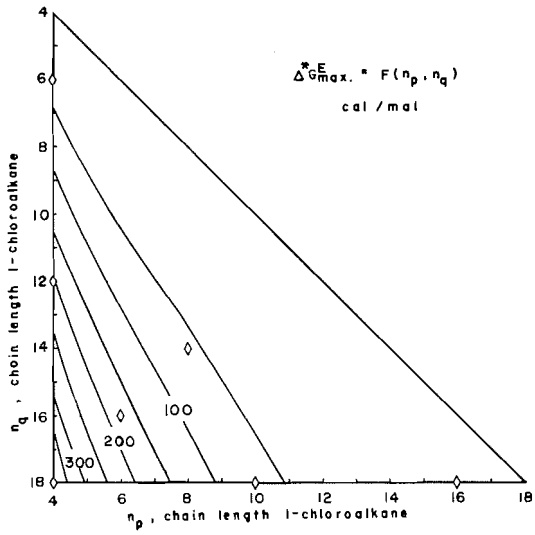

FIG. 2. $\Delta^*G_{max}{}^E$ as a function of chain length of the component species in 1-chloroalkane binary mixtures, eq. 8. The curves represent constant values of the excess function at 50 cal/mol increments. The x-y coordinates of systems studied are indicated by a ◇.

agreement between experimental and calculated values would not substantially affect the shape of the surface.

Examination of Fig. 2 yields some useful information about the general viscometric behavior of these systems. All of the systems exhibit positive deviations from ideal mixing (Δ^*G^E positive) and the magnitude of the excess increases with the difference in chain lengths when a single component is mixed with successive homologs. This parallels the behavior observed for n-alkane systems (6). It is also observed that a given difference in chain lengths for two short components has a more pronounced effect on the excess than the same difference for two long chain components.

An explanation of the observed viscometric behavior in 1-chloroalkane systems based on molecular arguments was given in a previous paper (12). Basically the positive deviations from ideal mixture viscosity are ascribed to the difference in flow mechanisms for the two components. The short chain molecules are assumed to flow by gross molecular rotation while the longer chain molecules flow by a combination of segmental jumping and rotation about carbon–carbon bonds. These assumptions are further substantiated by reference again to Fig. 2. The excess is slight for mixtures of long chains since they have a similar flow mechanism. However, the excess increases sharply for 1-chlorobutane mixed with longer chains which are assumed to have a different flow mechanism.

No attempt has been made in this work to resolve hydrocarbon (or chain) effects and dipole effects for 1-chloroalkane mixtures. In a previous paper, however, we have resolved these effects for n-hexadecane mixed with the same 1-chloroalkanes studied here (14).

This work was supported in part by the Petroleum Research Fund which is administered by the American Chemical Society.

The Thermal Pressure and Energy–Volume Coefficients of the Methyl Alcohol – Water and *t*-Butyl Alcohol – Water Systems

DIGBY D. MACDONALD[1] AND J. B. HYNE
Department of Chemistry, University of Calgary, Calgary, Alberta

Received April 30, 1971

Thermal pressure and energy–volume coefficients have been determined for various methyl alcohol – water and *t*-butyl alcohol – water mixtures at several temperatures in the range 19–55 °C. The energy–volume coefficient is found to pass through a maximum at 0.3–0.4 mole fraction methyl alcohol and 0.1 mole fraction *t*-butyl alcohol. This behavior is consistent with the average intermolecular distance passing through a minimum in both systems at the corresponding solvent compositions. The relationship between the energy–volume coefficient, the cohesive energy density, and the structure of aqueous binary systems is examined. The temperature dependence of the thermal pressure coefficient is discussed in terms of the effect of temperature on the susceptibility of the entropy of the two systems to isothermal expansion.

Le coefficient thermique de la pression et le coefficient d'énergie–volume ont été déterminés pour divers mélanges d'alcool méthylique-eau et alcool *t*-butylique-eau à plusieurs températures entre 19 et 55 °C. Le coefficient énergie–volume passe par un maximum pour une fraction molaire d'alcool méthylique comprise entre 0.3 et 0.4 et pour une fraction molaire d'alcool *t*-butylique de 0.1. Ce comportement concorde avec le fait que la distance intermoléculaire moyenne passe par un minimum pour les deux systèmes aux compositions correspondantes en solvant. La relation entre le coefficient d'énergie–volume, la densité d'énergie de cohésion et la structure des systèmes aqueux binaires est examinée. La variation du coefficient thermique de la pression avec la température est analysée en termes d'effet de température sur la sensibilité de l'entropie des deux systèmes à l'expansion isotherme.

Canadian Journal of Chemistry, 49, 2636 (1971)

Introduction

The thermodynamic and physical properties of alcohol–water mixtures have been studied extensively and are well reviewed by Franks and Ives (1). In spite of the great deal of work performed on these systems doubt still remains as to the detailed interactions and structure present in these liquid mixtures. In two recent publications (2, 3), however, we have demonstrated that additional information on the structure of binary liquid systems may be obtained from an examination of the behavior of the energy–volume coefficient and cohesive energy density. In this paper we report detailed studies of the energy–volume coefficient and the cohesive energy density behavior of methyl alcohol – water and *t*-butyl alcohol – water mixtures. These two systems were chosen since they exhibit positive deviations from Raoult's Law (1). This behavior is determined by large negative excess entropies, suggesting considerable changes in liquid structure on mixing the components.

[1]Present address: Research Chemistry Branch, Atomic Energy of Canada Ltd., Pinawa, Manitoba.

Experimental

Materials

Reagent grade methyl alcohol and *t*-butyl alcohol were dried over calcium oxide and distilled twice at atmospheric pressure in an efficient still. The refractive indices of both liquids agreed well with accepted values and no impurities could be detected by vapor phase chromatography (v.p.c.).

Aqueous mixtures were prepared by weight using doubly distilled water and were degassed by the freeze–pump–thaw technique.

Apparatus and Method

Thermal pressure coefficients were measured at four temperatures in the range 19–55 °C for various alcohol–water mixtures using the constant-volume thermometer described earlier (3). The same precautions described in this earlier study (3) were exercized here in order to eliminate errors due to the heat of compression of the oil (pressurizing medium) and sample liquid.

Results

Plots of applied pressure (P) *vs.* temperature (T) at constant volume over the range of temperature employed in each determination (0.8–2.0 °C) were linear, demonstrating that the data are adequately represented by eq. 1.

$$P = mT + C \qquad [1]$$

*Reference 16, reports $\gamma_V = 9.7$ atm deg^{-1} at 20 °C.

The gradient m is equal to the observed thermal pressure coefficient $\gamma_V^{obs} = [(\partial P/\partial T)_V^{obs}]$. Each γ_V^{obs} value, however, requires correction for the finite expansion and compression of glass. This correction is made using eq. 2 (3),

$$[2] \qquad \gamma_V = \gamma_V^{obs}\left(\frac{\alpha_1}{\gamma_V^{obs}\beta_g + \alpha_1 - \alpha_g}\right)$$

where α_g and β_g are the coefficients of thermal expansion and compressibility of Pyrex glass (9.9×10^{-6} deg^{-1} and 3.06×10^{-6} atm^{-1}, respectively, (4)) and α_1 is the coefficient of expansion of the sample liquid. Numerical values for α_1 were calculated from temperature–density data (5, 6) taken from the literature.

Energy–volume coefficients, $(\partial U/\partial V)_T$, were calculated from the thermal pressure coefficients using the "thermodynamic equation of state".

$$[3] \qquad \left(\frac{\partial U}{\partial V}\right)_T = T\left(\frac{\partial P}{\partial T}\right)_V - P$$

For all the mixed and pure liquids investigated in this work $T\gamma_V$ is very much greater than the applied pressure P and eq. 3 reduces to eq. 4.

$$[4] \qquad \left(\frac{\partial U}{\partial V}\right)_T = T\gamma_{V,P=1\text{ atm}}$$

The thermal pressure and energy–volume coefficients computed at several temperatures using eqs. 2 and 4, respectively, are listed in Tables 1 and 2. Both parameters were reproducible to $\pm 1 - 2\%$ and where comparison is possible the values obtained in this work are in good agreement with data taken from the literature.

Numerical values for γ_V, $(\partial U/\partial V)_T$ and the temperature dependence of γ_V were calculated graphically at 25 °C and are listed in Table 2. The $(\partial\gamma_V/\partial T)$ values are considered accurate to ± 0.015 atm deg^{-2}.

The energy–volume coefficient is related (3) to the cohesive energy density $(\Delta U_V/V)_T$ by eq. 5.

$$[5] \qquad \left(\frac{\partial U}{\partial V}\right)_T = n\left(\frac{\Delta U_V}{V}\right)_T$$

where ΔU_V is the energy of vaporization of the liquid to the perfect gas state and V is the molar volume of the liquid at temperature T. The energy of vaporization per mole of mixture can be calculated (3) using eq. 6.

$$[6] \quad \Delta U_V = X_1\Delta H_{V,1} + X_2\Delta H_{V,2} - \Delta H_M - RT$$

The quantities $\Delta H_{V,1}$ and $\Delta H_{V,2}$ are enthalpies of vaporization of components 1 and 2, respec-

tively, to the perfect gas state and ΔH_M is the heat of mixing per mole of mixture. The enthalpies of vaporization of water, methyl alcohol, and *t*-butyl alcohol to the perfect gas state at 25 °C are 10.52 kcal mol^{-1} (7), 8.96 kcal mol^{-1} (7), and 11.15 kcal mol^{-1} (8, 9), respectively. Energies of vaporization for the various alcohol–water mixtures were calculated using these data and heats of mixing taken from the literature (6, 10). Division of the ΔU_V values by the corresponding molar volumes results in the cohesive energy densities. The cohesive energy densities are listed in Tables 3 and 4 together with energy–volume coefficients interpolated at 25 °C from data listed in Table 1. Numerical values for *n* are also listed and were calculated using eq. 5.

Discussion

Energy–Volume Coefficients

The variation of the energy–volume coefficient, $(\partial U/\partial V)_T$, with solvent composition for the methyl alcohol – water and *t*-butyl alcohol – water systems is illustrated in Figs. 1 and 2, respectively. Both systems exhibit a maximum in the variation of $(\partial U/\partial V)_T$ with composition. Many other properties (both intensive and extensive) of these aqueous organic binary systems exhibit extremum behavior in the same region of solvent composition (1).

In terms of classical mechanics the total energy of a fluid, *U*, may be regarded as the sum of three terms (3, 11–13).

$$[7] \qquad U = U(T) + U_A + U_R$$

The quantity $U(T)$ is the mean kinetic energy of the molecules at their equilibrium positions and U_A and U_R are the potential energies due to attractive and repulsive interactions, respectively. Since $U(T)$ depends only on temperature then differentiation of *U* with respect to volume at constant temperature yields eq. 8 for the energy–volume coefficient of the system.

$$[8] \qquad \left(\frac{\partial U}{\partial V}\right)_T = \left(\frac{\partial U_A}{\partial V}\right)_T + \left(\frac{\partial U_R}{\partial V}\right)_T$$

Equation 8 demonstrates that the behavior of the experimentally measured energy–volume coefficient is determined by the separate components for intermolecular attraction and repulsion. This treatment has been used previously to interpret the energy–volume coefficient behavior of pure liquids (11–13) and dimethyl sulfoxide – water mixtures (3).

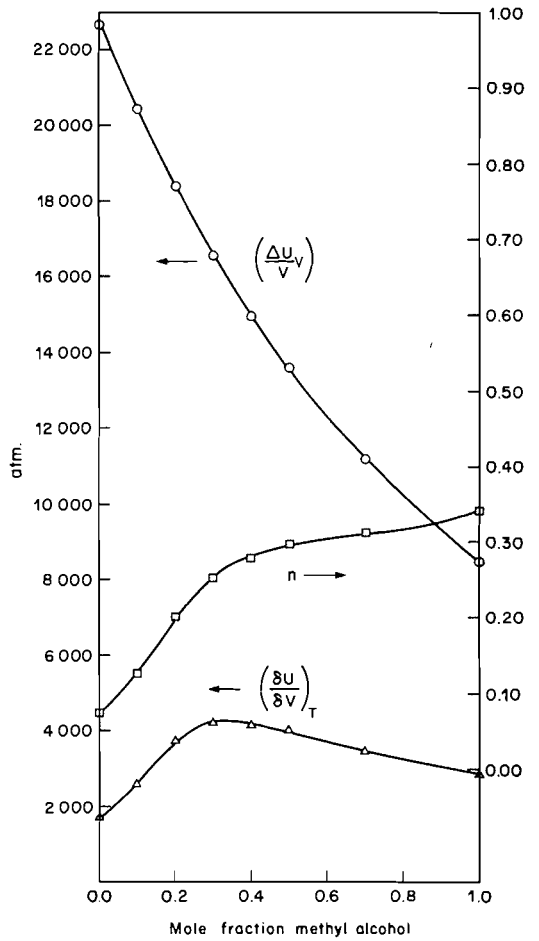

FIG. 1. Energy–volume coefficients and cohesive energy density parameters form ethyl alcohol – water mixtures at 25 °C.

U_A and U_R are known to vary with intermolecular distance (*r*), and therefore volume (*V*), as shown in Fig. 3. It is clear from this schematic representation that $(\partial U_A/\partial V)_T$ and $(\partial U_R/\partial V)_T$ are positive and negative, respectively, and vary with volume as has been recently elaborated by Barton (14). Since the sum of these two terms, $(\partial U/\partial V)_T$, is observed to be positive, the attractive term must be numerically larger than the repulsive term (see eq. 8). The behavior of $(\partial U/\partial V)_T$ as a function of solvent composition must therefore be determined principally by the corresponding behavior of the attractive interaction term $(\partial U_A/\partial V)_T$. Since this dominant

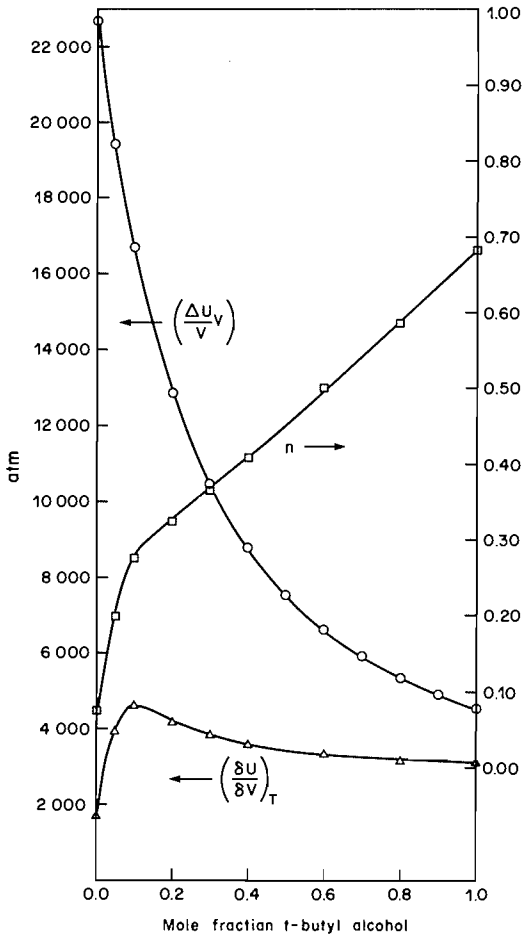

FIG. 2. Energy–volume coefficients and cohesive energy density parameters for *t*-butyl alcohol – water mixtures at 25 °C.

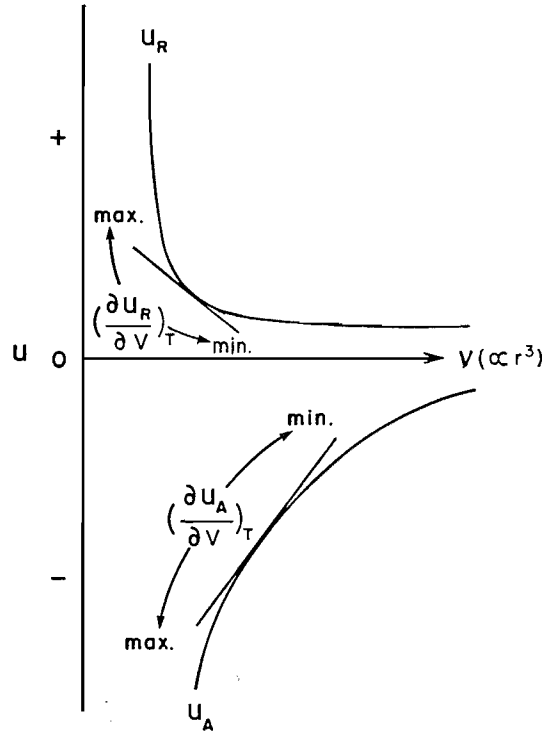

FIG. 3. Schematic representation of intermolecular interaction potential energy curves.

term is required to pass through a maximum to yield the observed behavior of the sum term, $(\partial U/\partial V)_T$, the free volume V or intermolecular distance r, as represented by the x-axis in Fig. 3, must pass through a minimum. Hence it can be concluded that the observed positive maximum in $(\partial U/\partial V)_T$ for both methyl and *t*-butyl alcohol mixtures with water is indicative of minimum free volume and intermolecular separation at these solvent compositions in both binaries.

This conclusion provides an interesting rationale for the recently reported behavior of the volume of activation for the solvolysis of benzyl chloride in aqueous alcohol solvent mixtures (15). It was found in these studies that the minimum in the activation volume as a function of solvent composition was largely if not exclusively the result of a corresponding *maximum* in the initial state partial molal volume. Benzyl chloride, in this initial state is non-ionic and only weakly polar and hence its partial molal volume should reflect predominantly "hole formation". Hence if the free volume (and intermolecular separation) of the solvent passes through a minimum, as has been concluded in this work, the expansion of the solvent required to form a hole of sufficient size to accommodate the solute and hence the solute's partial molal volume must pass through a maximum. Accordingly, the partial molal volume behavior of benzyl chloride in the two alcohol–water systems of interest is consistent with the free volume model proposed above to account for the variation of $(\partial U/\partial V)_T$ with solvent composition.

Cohesive Energy Densities

The relationship between the energy–volume coefficient and the cohesive energy density is expressed by eq. 5. This relationship has been examined for one component systems (16, 17)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and recently for dimethyl sulfoxide – water mixtures (3). Equivalent analyses for the alcohol–water systems investigated in the present study are presented in Figs. 1 and 2. These plots show that neither n nor $(\Delta U_V/V)_T$ exhibit extremum behavior as a function of solvent composition although their product, $(\partial U/\partial V)_T$, does. This extremum behavior of $(\partial U/\partial V)_T$ is clearly the result of the non-compensatory behavior of the component n and $(\Delta U_V/V)_T$ terms. It is interesting to note that these same non-compensatory trends in the behavior of n and $(\Delta U_V/V)_T$ found for the alcohol–water systems are also found in the dimethyl sulfoxide – water system (3) despite the fact that the alcohol–water mixtures exhibit positive deviations from Raoult's law as opposed to the dimethyl sulfoxide – water system which exhibits large negative deviations from ideality (18).

The physical significance of n is not clear (16) so that any relationship between this parameter and "liquid structure" remains tenuous. However, compilations of values of n by Allen, Gee, and Wilson (16) and Hildebrand (17) reveal that for non-polar liquids n is approximately equal to one. For strongly associated liquids, however, n is much less than unity and especially so for hydrogen bonded liquids. Thus, the overall increase in n from pure water to pure alcohol may reflect a general decrease in the overall hydrogen bonding in the system. Additionally, n is almost twice as large for the more hydrophobic pure *t*-butyl alcohol as for pure methyl alcohol suggesting a greater degree of hydrogen bonding in the latter system. This conclusion agrees with the results of infrared spectroscopy (1).

In as much as n may be a measure of the extent to which the solvent systems are hydrogen bonded, it is worth observing that the value of n at that mole fraction at which $(\partial U/\partial V)_T$ is a maximum is virtually the same in both systems, *viz.* 0.26. Since the maximum in $(\partial U/\partial V)_T$ was associated with a corresponding minimum in both free volume and intermolecular distance it is not unreasonable that the degree of hydrogen bonding in both systems would be similar under these conditions. In the case of dimethyl sulfoxide – water mixtures (3), however, the value of n at the $(\partial U/\partial V)_T$ maximum is 0.45. This considerable difference between the hydroxyl containing cosolvents and the sulfoxide is in keeping with the reasonable expectation that it is the polar groups within the cosolvents that determine the degree of hydrogen bonding and hence the value of n at minimum free volume.

Entropy–Volume–Temperature Relationship

The thermodynamic relationship between the thermal pressure coefficient and the volume derivative of the entropy of a system at equilibrium is given by eq. 9.

$$[9] \qquad \gamma_V = \left(\frac{\partial S}{\partial V}\right)_T$$

Data compiled in Tables 3 and 4 show that γ_V passes through a maximum in both systems at 0.3–0.4 mole fraction methyl alcohol and 0.1 mole fraction *t*-butyl alcohol. According to eq. 9 these are the compositions at which the entropy and hence the degree of ordering of both systems is most susceptible to isothermal expansion.

The temperature dependence of γ_V as a function of solvent composition for both alcohol–water systems is illustrated in Fig. 4. These plots exhibit the same general trends that were found for the dimethyl sulfoxide – water system (3), *i.e.* $(\partial\gamma_V/\partial T)$ changes sign from positive to negative in highly aqueous mixtures and is quite insensitive to changes in solvent composition at high organic mole fractions. The change in sign can be rationalized as follows.

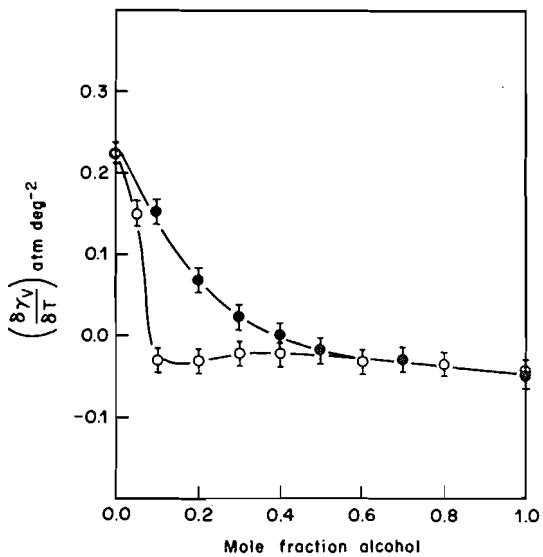

FIG. 4. Plot of $(\partial\gamma_V/\partial T)$ *vs.* solvent composition for methyl alcohol – water mixtures (●) and *t*-butyl alcohol – water mixtures (○) at 25 °C.

The open "flickering cluster" configurations in water are not favored energetically at smaller volumes, *i.e.* entropy increases as volume decreases and hence for *these configurations* $(\partial S/\partial V)_T$ is negative.[2] With increasing temperature, however, these "flickering cluster" configurations are broken down and their contribution to the total $(\partial S/\partial V)_T$ of the system is less negative. This may account for the positive value for $(\partial\gamma_V/\partial T) = (\partial^2 S/\partial T\partial V)$ in the highly aqueous system. The pure alcohols, however, do not possess the open structure characteristic of water, but rather the molecules tend to associate in chains of varying lengths (1). These structures should be less favored energetically at higher volumes and therefore make a positive contribution to $(\partial S/\partial V)_T$ for the system. As the temperature is increased the alcohol chains are broken down and their contribution to $(\partial S/\partial V)_T$ for the system is less positive, *i.e.* $(\partial\gamma_V/\partial T)$ is negative. The solvent composition at which $(\partial\gamma_V/\partial T)$ is zero represents the point at which the negative contributions to $(\partial\gamma_V/\partial T)$ exactly balance the positive ones. It is interesting to note that this point occurs at a much lower organic mole fraction in *t*-butyl alcohol – water mixtures than in methyl alcohol – water mixtures. This suggests that the positive contribution to $(\partial\gamma_V/\partial T)$ from the "flickering clusters" is more rapidly reduced by addition of *t*-butyl alcohol to water than by the addition of methyl alcohol to water. A molecular interpretation of this observation must, however, await more detailed investigation of the highly aqueous systems. It is possible that the rapid reduction in the positive contribution to $(\partial\gamma_V/\partial T)$ on the addition of *t*-butyl alcohol to water reflects the ability of this alcohol to "buttress" flickering clusters (1) and therefore stabilize the open structure of liquid water against disruption by compression.

[2]For water in the temperature range 0 to 3.98 °C $(\partial S/\partial V)_T = \gamma_V$ is negative (19). In this case few of the "flickering cluster" configurations have been disrupted by thermal agitation and the sign of $(\partial S/\partial V)_T$ for the system is determined by the influence of volume changes on the stability of the clusters.

Kinetics of Charge Scavenging in γ-Irradiated Liquid Cyclohexane: A Comparison Between Different Ion–Electron Spacial Distribution Functions Used with Two Diffusion Approximations[1]

JEAN-POL DODELET AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alberta

Received January 13, 1971

The form of the spacial distribution function of ions and electrons in an irradiated liquid is not accurately known and several types of function have been assumed by different workers. The various forms are compared and used in the calculation of electron–solute reaction yields in liquid cyclohexane. Our previously used semi-empirical distribution function (YSE) and a power function (YP) give satisfactory results, but a three dimensional, single parameter Gaussian (YG1) and a delta function (YD) do not. The prescribed diffusion approximation has also been inserted into the model for comparison with earlier work. No improvement was obtained. Whereas our previous approximations may lead to an underestimate of the geminate neutralization times, the prescribed diffusion approximation may lead to an overestimate of them.

La forme de la fonction de distribution spatiale des ions et électrons dans un liquide irradié n'est pas connue avec précision et plusieurs types de fonctions ont été proposés par différents chercheurs. Les différentes formes sont comparées et utilisées dans le calcul des rendements des réactions électrons–solutés dans le cyclohexane liquide. On obtient des résultats satisfaisants en utilisant une fonction de distribution semi-empirique (YSE), que nous avons déjà définie dans des travaux antérieurs, ainsi qu'une fonction faisant intervenir une puissance (YP); il n'en est pas de même si on utilise une fonction Gausienne tri-dimensionelle à paramètre unique ou une fonction delta (YD). A titre de comparaison, l'approximation de diffusion a également été introduite dans le modèle; elle n'apporte aucune amelioration. Alors que nos approximations précédentes sembleraient conduire à une sous-estimation des temps de neutralisation géminées, l'approximation de diffusion conduirait au contraire à une sur-estimation de ceux-ci.

Canadian Journal of Chemistry, 49, 2643 (1971)

I. Introduction

The kinetics of ion and electron reactions in γ-irradiated liquid hydrocarbons have been described by a stochastic model (1–3). For example, the yield of product from an electron–solute reaction is calculated from the probability that a radiation produced electron will meet and react with a solute molecule before it reacts with a radiolytic positive ion. The calculations involve the relative spacial distributions of the ions and electrons and the relative motions of the ions and electrons under the dual influence of their mutual coulombic field and thermal forces. In previous publications from this laboratory a semiempirical spacial distribution function has been used (3). The relative motions of the ions and electrons have been represented by a simple but approximate equation (2, 3).

To further our understanding of the reaction kinetics we have now tested several types of distribution function and a different motion-equation in the model. The results are reported in this article.

[1]Supported by the National Research Council of Canada.

II. Effect of the Form of the Initial Spacial Distribution of the Charges

The initial distance y between a thermalized electron and its parent ion is not the same for all ion–electron pairs. The form of the distribution function $N(y)$ is not precisely known and several types of function have been used by different workers (see Section II-2). One of the purposes of this article is to compare them.

The effect of the form of the $N(y)$ function on the calculated nitrogen yields from solutions of nitrous oxide in cyclohexane (4) is described in the following sections.

(1) The Model

Readers are referred to ref. 3 for a detailed description of the model. The required equations are summarized below.

The number of molecules of nitrogen formed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

per 100 eV absorbed by the solvent, $g(N_2)$, is given by eq. 1.

$$[1] \quad g(N_2) = [\sum N(y)\Phi_-/\sum N(y)]g(N_2)_{max}$$

where $N(y)$ is the relative number of thermalized electron–ion pairs that have an initial separation distance y and Φ_- is the total probability that an electron with a given y value will be scavenged.

$$[2] \quad \Phi_- = \phi_{fi} + \phi_-(1 - \phi_{fi})$$

where ϕ_{fi} is the fraction of ion pairs with a given value of y that become free ions.

$$[3] \quad \phi_{fi} = \exp(-\xi^2/\varepsilon ykT)$$

where ξ is the charge on an electron, ε is the dielectric constant of the liquid, k is Boltzmann's constant, and T is the absolute temperature. The probability that a certain pair of charges will undergo geminate neutralization is $(1 - \phi_{fi})$ and the probability that the electron in such a pair will be scavenged by a solute molecule before the former meets its counter ion is ϕ_-.

$$[4] \quad \phi_- = 1 - (1 - f_-N_s)^{\beta-\nu}$$

where f_- is the encounter efficiency of the reaction between the electron and the solute, N_s is the mole fraction of solute in the solution, β_- is an adjustable parameter, and ν is given by

$$[5] \quad \nu = 1.39 \times 10^7\varepsilon(y^3 - r_0^3)\ \text{cm}^2/\text{V}$$

where r_0 is the distance of the last electron jump to undergo neutralization. The units of y and r_0 in eq. 5 are cm.

Attention is focussed on the reactions of the electrons that are undergoing geminate neutralization. When the solute concentration is great enough to scavenge a significant fraction of the electrons undergoing geminate neutralization, all the "free ion" electrons become scavenged; eq. 2 refers to this region.

Finally, the free ion yield is given by eq. 6.

$$[6] \quad g(N_2)_{fi} = [\sum N(y)\phi_{fi}/\sum N(y)]g(N_2)_{max}$$

(2) Calculations Using Different Forms of the Initial Distribution Function N(y)

Ion–electron distribution functions that have been used or discussed by different workers fall into six categories. In general, simpler distribution functions have been used in more complex kinetics models, and vice versa.

In probability calculations the shapes of the distribution functions, rather than their absolute magnitudes, are important. To facilitate a comparison of the functions used, each was normalized to $\int_0^\infty N(y)dy = N_0 = 5000$, where 5000 is a convenient arbitrary number.

(a) Semi-empirical Function (YSE)

This type of function is partially derived from secondary electron energy distributions and range–energy relations (3, 7–9). The YSE $N(>y)$ function used in the present work (Fig. 1) was constructed from data in ref. 3. The resulting calculated free ion yield is $g_{fi} = 0.13$, in agreement with the experimentally measured value 0.13 ± 0.02 (5, 6).

The experimental yields of nitrogen from solutions of nitrous oxide in cyclohexane (4) are plotted in Fig. 2. The value of $g(N_2)_{max}$ is taken as 5.0 (Fig. 2). To calculate "theoretical" nitrogen yields a value of β_- in the vicinity of 10^{15} V/cm^2 and $r_0 = 1 \times 10^{-7}$ cm were assumed. With a given value of β_-, a value of $g(N_2)$ was calculated for each of the nitrous oxide concentrations used experimentally. The calculated and

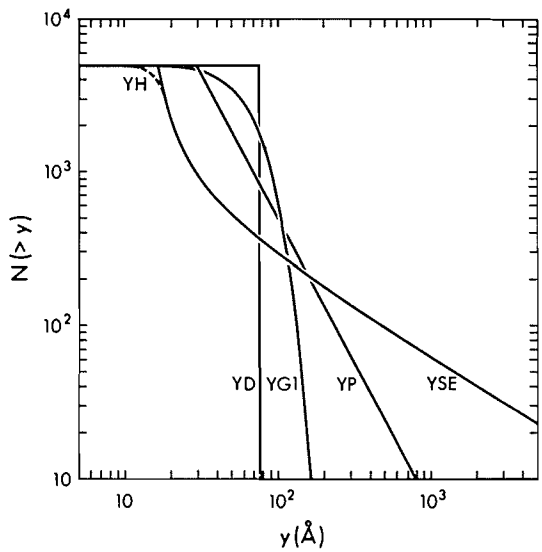

FIG. 1. Different $N(>y)$ functions that give "best" $g(N_2)$ curves for solutions of nitrous oxide. YD, $N(y) = 5000\ \delta(y - 76\ \text{Å})$; YG1, $b = 59$ Å, see eq. 12; YP, $N(>y) = 2.0 \times 10^{-9}\ y^{-1.9}$ for $y \geq 2.9 \times 10^{-7}$ cm, $N(>y) = 5000$ for $y \leq 2.9 \times 10^{-7}$ cm; YSE, semi-empirical, full curve; YH, $y_0 = 8$ Å, $j = 21$ Å (see eq. 15), dashed-curve upper portion and lower portion same as YSE.

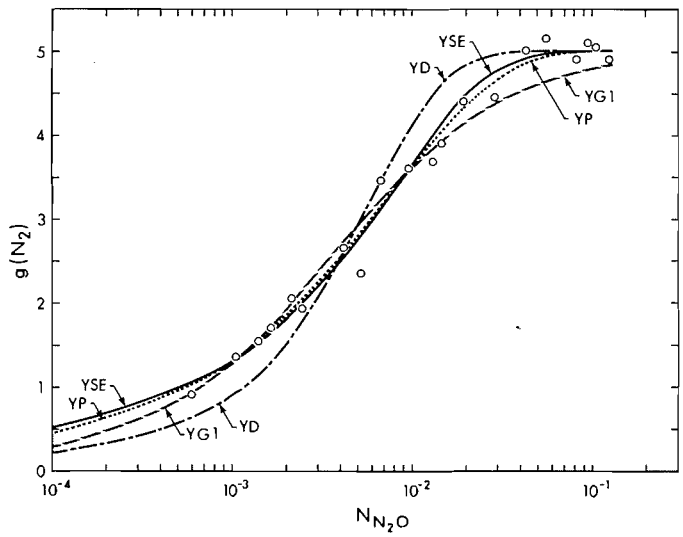

FIG. 2. $g(N_2)$ as a function of the mole fraction of nitrous oxide, N_{N_2O}. ○, experimental (4). The curves are the best calculable with the $N(y)$ functions indicated. The same curves are obtained whether r_0 is taken as 0 or 10 Å.

experimental yields were then compared. The magnitude of error in the calculated yields was estimated by averaging the absolute quantity $|g(N_2)_{exp} - g(N_2)_{calcd}|$ over all the points.

$$[7]\quad \text{Error} = \left(\sum_{i=1}^{n} |g(N_2)_{exp} - g(N_2)_{calcd}|_i\right) \Big/ n$$

The error was calculated for a series of β_- values, and a minimum error was sought. The minimum error was 0.13 g units per point obtained with $\beta_- = 6.9 \times 10^{14}$ V/cm^2. The corresponding calculated nitrogen yields are represented by the full curve in Fig. 2.

The above calculations were repeated with $r_0 = 0$. The minimum error in this case was 0.14 g units per point, only slightly greater than that obtained with $r_0 = 10$ Å.

(b) Power Function (YP)

This function is an arbitrary simplification of YSE and has the form (10, 11)

$$[8a]\quad N(>y) = Ky^{-x} \qquad y \geq y_{min}$$

$$[8b]\quad N(>y) = N_0 \qquad y \leq y_{min}$$

YP is adjusted to fit the free ion yield, $g_{fi} = 0.13$. Only two of the three parameters K, x, and y_{min} are independently adjustable because the behavior is limited by eq. 8*b*. Furthermore, reasonable values of the free ion yield can only be obtained with positive values of x.

The stages of the YP calculations were as follows.

A. (*1*) Choose an arbitrary value of x and calculate g_{fi} as a function of y_{min} (or K). (*2*) Repeat *A*(*1*) for a series of values of x.

B. Pick the value of y_{min} (or K) for each x that gives the value of $g_{fi} = 0.13$.

C. (*1*) With a pair of values of x and y_{min} from *B*, and $r_0 = 1 \times 10^{-7}$ cm, calculate $g(N_2)$ curves for a series of values of β_- and pick the β_- that gives the minimum error. (*2*) Repeat *C*(*1*) for each value of x and its corresponding y_{min}.

D. Pick the best value of x as the one that gives the smallest error.

E. Repeat *C* and *D* with $r_0 = 0$.

The results of the stage *A* calculations are shown in Fig. 3 for x values ranging from 0.5 to 4.5. The experimental value of g_{fi} is marked on each curve, indicating the appropriate value of y_{min} for each x (stage *B* of the calculations). The value of y_{min} that gives the correct g_{fi} increases with increasing x. A value of y_{min} less than 1 Å would have no physical significance, so x must be greater than 0.5.

From the calculations of stage *C* the best value of β_- for each value of x was determined. It was found that as x decreased the best value of β_- increased in a roughly hyperbolic fashion.

Stage *D*: a plot of the minimum error at each x against x contained a distinct minimum. The

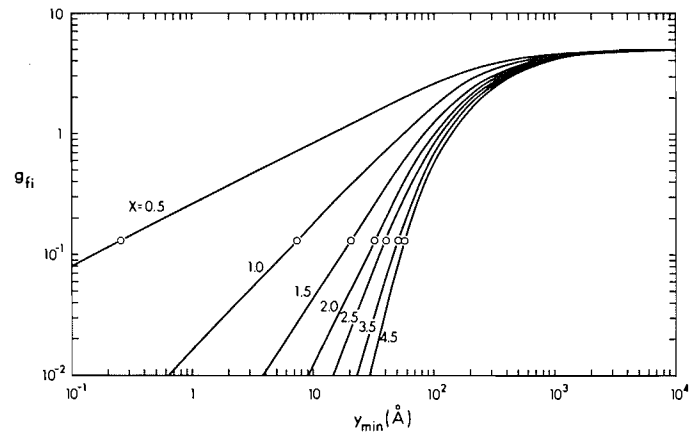

FIG. 3. Calculated values of g_{fi} as a function of y_{min} for several values of x in YP (eq. 8). ○, experimental $g_{fi} = 0.13$.

smallest error with $r_0 = 1 \times 10^{-7}$ cm was 0.12 g units per point, obtained with $x = 1.9$.

The above calculations were repeated with $r_0 = 0$ (stage E). The results were the same as those with $r_0 = 1 \times 10^{-7}$ cm.

The nitrogen yields calculated with the best YP function [9] are displayed by the curve labelled YP in Fig. 2.

$$[9a] \quad N(>y) = 2.0 \times 10^{-9} y^{-1.9} \qquad y \geqslant 2.9 \times 10^{-7} \text{ cm}$$

$$[9b] \quad N(>y) = 5000 \qquad y \leqslant 2.9 \times 10^{-7} \text{ cm}$$

(c) Delta Function (YD)

This function represents the gross approximation that all secondary electrons have the same range (12–15).

$$[10] \quad N(y) = N_0 \delta(y - y_d)$$

Equation 10 is the limiting case of eq. 8 with $x = \infty$ and $y_{min} = y_d$.

The free ion yield $g_{fi} = 0.13$ leads to the value $y_d = 7.6 \times 10^{-7}$ cm. Thus,

$$[11] \quad N(y) = 5000\delta(y - 7.6 \times 10^{-7} \text{ cm})$$

The nitrogen yields calculated from eq. 11 gave a minimum error of 0.30 g units per point, with r_0 equal to either zero or 10 Å. The best nitrogen yields calculable from the YD function are shown in Fig. 2.

(d) One-parameter Gaussian Function (YG1)

The Gaussian function most often used is a three dimensional function with one adjustable parameter (13, 14)

$$[12] \quad N(y) = N_0(4y^2/\pi^{1/2}b^3) \exp(-y^2/b^2)$$

where the parameter b indicates the width of the distribution and in the present instance is also the most probable value of y.

The free ion yield in cyclohexane requires $b = 59$ Å. Using this value of b and r_0 equal to either 0 or 10 Å, the calculated nitrogen yields give a minimum error of 0.18 g units per point. The calculated curve is shown in Fig. 2.

(e) Two-parameter Gaussian Function (YG2)

A more general Gaussian than eq. 12 is eq. 13, which is a three dimensional function with two adjustable parameters (y_0 and b, see Fig. 4).

$$[13] \quad N(\bar{y}) = N(y_b) = N_0(4y_b^2/\pi^{1/2}b^3) \exp(-y_b^2/b^2)$$

where $\bar{y}$ is the value of y averaged over all angles, for a given pair of values of y_0 and b.

$$[14] \quad \bar{y} = \int_0^\pi y \frac{\sin\theta}{2} d\theta = \int_0^\pi (y_0^2 + y_b^2 + 2y_0 y_b \cos\theta)^{1/2} \frac{\sin\theta}{2} d\theta$$

Equation 13 is equivalent to eq. 12 when $y_0 = 0$, and to eq. 10 when $b = 0$. Equations analogous to eq. 14 are also used to average y^2 and y^3 over all angles, when required.

The nitrogen yields calculated with eq. 13 give a minimum error of 0.15 g units per point, with $y_0 = 18$ Å, $b = 58$ Å. The calculated nitrogen yield curve is very similar to that for YG1 in Fig. 2, except that the lower end is shifted slightly

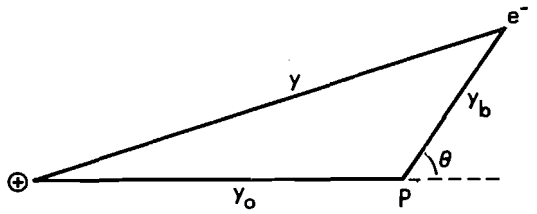

FIG. 4. Illustration of the symbols in the 3-dimensional Gaussian YG2. y_0 is a constant. y_b has a 3 dimensional Gaussian distribution about the point P, and the most probable value of y_b is the b in eq. 13. The value of y is $y = (y_0^2 + y_b^2 + 2y_0y_b \cos\theta)^{1/2}$. The distribution of y is symmetrical about the y_0 axis, and the probability of occurrence of a given value of θ is proportional to sin θ.

downwards and the upper end is shifted upwards by 0.07 g units.

The $N(>y)$ curve for YG2 is essentially the same as that for YG1 in Fig. 1, but the left-hand end is shifted to higher y values by 2–3 Å.

(f) YH

A hybrid between the semi-empirical function and a Gaussian (3, 16, 17) was made by cutting off the low-y end of the YSE function and fitting the amputated portion into a Gaussian form. The junction between the Gaussian and YSE portions is denoted by j (Fig. 5).

In YH, any arbitrary value of $y_0 < j$ can serve as the origin for the Gaussian. The values of y_0 and j automatically fix the value of the Gaussian dispersion parameter b. The YH function is

$$[15a] \qquad N(y) = 0 \quad y \leqslant y_0$$

$$[15b] \qquad N(y) = N_0[4(y - y_0)^2/\pi^{1/2}(b - y_0)^3] \exp[-(y - y_0)^2/(b - y_0)^2] \quad y_0 \leqslant y \leqslant j$$

$$[15c] \qquad N(y) = \text{YSE} \quad y \geqslant j$$

where $N_0 = 5000$.

The values of y and j were each varied in 1 Å jumps over a sufficiently wide range to locate the smallest minimum error. The smallest error was 0.13 g units per point, obtained for $j = 21$ Å and $y_0 = 8$ Å. The corresponding $g(N_2)$ curve was essentially the same as that for YSE in Fig. 2, except that it was shifted slightly towards the YP curve at high N_2O concentrations.

(g) YC

$N(y)$ = constant, *i.e.* all values of y are equally probable (14). This function corresponds to YP with $x = -1$. However, x must be >0.5 (Section II *2b*), so the YC function is impossible.

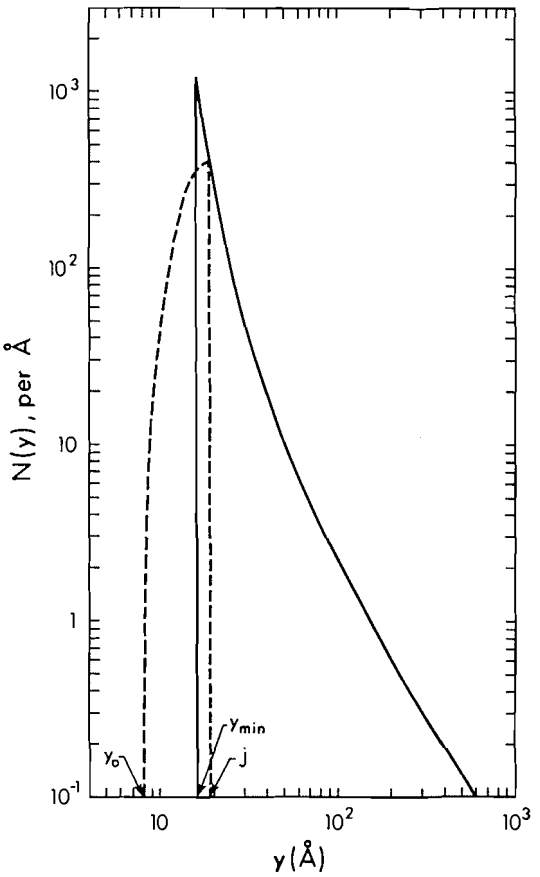

FIG. 5. YSE- and YH-$N(y)$ functions: full curve is the YSE-$N(y)$ function obtained by differentiating the YSE-$N(>y)$ curve in Fig. 1; dashed curve is the Gaussian portion of the YH function that gives the best fit to the experimental nitrogen yields; $y_0 = 8$ Å, $y_{min} = 16$ Å, $j = 19$ Å.

(3) Comparison of the Results from the Different N(y) Functions

(*a*) The functions YP, YG2, and YH each have two freely adjustable parameters, while YD and YG1 each have one. As expected the two-parameter functions gave better results than did those with one parameter (Table 1). However, it is interesting that YSE, in which no parameter was freely adjusted, gave results that were almost as good as those from the two-parameter functions. The YSE function was originally constructed during the interpretation of the variation of the free ion yields in a series of liquids (7) and

*Median value of y.

has been applied without alteration to the scavenging model.

(*b*) The results are not sensitive to the choice of the value of r_0 from zero to 10 Å.

(*c*) Within the present framework, the broader forms of $N(y)$ function tend to give the smaller errors (Fig. 1 and Table 1).

(*d*) By way of comparison with other models (16–18), it should be mentioned that the scavenging yields $[g(N_2) - g_{fi}]$ calculated from the present model using the YSE function vary linearly with the square root of the scavenger concentration at low concentrations (Fig. 6). The yields calculated with the other $N(y)$ distribution functions deviate from linear square root plots; the amount of deviation from linearity obtained from the different functions increased in the order YSE < YP < YG1 < YD (Fig. 6). Experimental scavenging yields give linear "square root plots" at low concentrations (2, 9, 16, 18, 19), so from this point of view the YSE and YP functions are satisfactory while YG1 and YD are not.

It is also instructive to see the calculated yields plotted against the first power of the scavenger concentration at low concentrations (Fig. 7). The plots obtained using the YG1 and YD functions have linear regions in the vicinity of zero concentration. Thus the YD and YG1 function lead to G(scavenged) $\propto$ [S]$^{1.0}$ at low [S], which is

the wrong mathematical form. This is an alternative demonstration that the functions YD and YG1 are unsatisfactory in this model.

III. Effect of the Form of the Diffusive Motion of the Charge Pairs

In previous publications from this laboratory it has been assumed that the lifetime t_{gn} of an ion pair that undergoes geminate neutralization is simply governed by the ion mobilities $(u_+ + u_-)$, the mutual electric field between the two charges, and the drift distance $(y - r_0)$ (2, 3).

$$[16]\quad t_{gn} = \varepsilon(y^3 - r_0^3)/4.32 \times 10^{-7}(u_+ + u_-)\ \text{s}$$

However, eq. 16 tends to underestimate the neutralization time because it underemphasizes the effect of the random diffusion on the drift of the ions in their mutual electric field. A more complete description of the ion lifetimes is given by the prescribed diffusion approximation (13, 15). It is therefore desirable to insert the prescribed diffusion approximation into our kinetic equations to determine its effect on the calculated results.

The method in Section II used an average geminate neutralization time for a thermalized electron–ion pair that had a certain initial separation distance y. The prescribed diffusion method, on the other hand, considers the probability of neutralization as a function of time for each initial distance y. The probability F_y that an ion pair will remain unneutralized at time t, having started their Brownian motion from time zero at the initial separation y, is described by eq. 17 (15).

$$[17]\quad -\mathrm{d}F_y = \frac{e^2F_y}{\varepsilon kT(4\pi D)^{1/2}t^{3/2}}\exp(-y^2/4Dt)\,\mathrm{d}t$$

where $-\mathrm{d}F_y$ is the fraction of ion pairs that undergo neutralization during the interval between the times t and $t + \mathrm{d}t$, and D is the sum of the diffusion coefficients of the positive and negative species (taken approximately equal to that of the electron, 9×10^{-3} cm^2/s (20)).

In the prescribed diffusion method eqs. 1, 3, and 6 remain unchanged, but the total probability Φ_- that an electron with a given y value will be scavenged when the mole fraction of solute is N_s becomes

$$[18]\quad \Phi_- = 1 - \int_{t=0}^{\infty}(1 - f_-N_s)^{\alpha t}\,\mathrm{d}F_y$$

where $\alpha = b/t_1$, b is the number of new neighbors

*Median value of y.

that an electron meets during the time t_1, and t_1 is the average time required for one diffusive jump of the electron.

The calculations have five general steps: (*a*) pick a form of $N(y)$ function from Section II; (*b*) pick a specific $N(y)$ function of that form that gives the correct free ion yield; (*c*) use the function and eqs. 1, 17, and 18 to calculate $g(N_2)$ at different nitrous oxide concentrations, adjusting the value of α to find the one that gives the smallest error (eq. 7); (*d*) pick another $N(y)$ function of the same form, if another exists, and repeat (*b*)–(*d*); (*e*) pick another form of $N(y)$ function and repeat (*b*)–(*e*).

The forms of $N(y)$ function used were YSE, YP, YD, YG1, and YG2. The function YSE is not freely adjustable and there is only one function of each of the forms YD and YG1 that gives the correct free ion yield. Thus the YSE, YD, and YG1 functions used here were exactly the same as those used in Section II. However, YP and YG2 each have two adjustable parameters, and the "best fit" functions of these forms are not the same in the prescribed diffusion method as they were in Section II.

The results of the calculations are summarized in Fig. 8 and Table 2. The YG1 distribution gave the largest error. The other functions gave satisfactory agreement.

IV. Comparison

The only striking contrast between the results of the y^3 method (Section II) and the prescribed diffusion method is that the narrowest $N(y)$ distribution function, YD, gave the largest error in the former and one of the smallest errors in the latter. The YD function is unrealistically narrow, and the preceding results might indicate that the prescribed diffusion method overestimates the spread of neutralization times in the liquid.

Effect of Pressure on the Rates of Reaction of Radiolysis Intermediates in Liquid *n*-Hexane[1]

KAMAL N. JHA AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton 7, Alberta

Received April 20, 1971

The yield of hydrogen from pure hexane, $G(H_2) = 5.3 \pm 0.2$ was independent of pressure in the range 1 bar to 4.6 kbars. The G values of H_2, HD, and D_2 obtained from 11 mol% C_6D_{14} in C_6H_{14} were independent of pressure and were respectively, 4.85, 0.34, and 0.11. The electron and hydrogen atom scavenging efficiencies of carbon tetrachloride and hexadiene-1,3, and the hydrogen atom scavenging efficiency of hexene-1 were independent of pressure. The positive ion scavenging efficiencies of benzene and aniline increased with increasing pressure. The volume of activation for the hydrogen atom reaction with *n*-hexane is essentially the same as that for the reaction with hexene-1. The pressure dependence of the charge scavenging reactions has been interpreted in terms of the kinetics of spur processes. The treatment is consistent with the fact that the efficiency of the electron scavenging reactions is independent of pressure. The increased efficiency of positive ion reaction under pressure implies that the ratio of the diffusion coefficients of the radiolytic positive ion and electron, D_+/D_-, increases with increasing pressure.

Le rendement en hydrogène pour l'hexane pur, $G(H_2) = 5.3 \pm 0.2$, est indépendant de la pression dans le domaine de 1 bar à 4.6 kbar. Les valeurs G de H_2, HD et D_2 obtenues à partir de 11 mole% de C_6D_{14} dans C_6H_{14} sont indépendantes de la pression et sont respectivement de 4.85, 0.34 et 0.11. L'efficacité du tétrachlorure de carbone et de l'hexadiène-1,3 pour capturer les électrons et les atomes d'hydrogène ainsi que l'efficacité de l'hexène-1 pour capturer les atomes d'hydrogène est indépendante de la pression. L'efficacité du benzène et de l'aniline pour capturer les ions positifs augmente en même temps que la pression. Le volume d'activation pour la réaction d'atomes d'hydrogène avec le *n*-hexane est essentiellement le même que pour la réaction avec l'hexène-1. La dépendance de la pression sur les réactions de capture des charges est interprétée en termes de cinétique des reactions dans les grapées. L'augmentation de l'efficacité des réactions des ions positifs, sous l'effet de la pression, implique que le rapport des coefficients de diffusion des ions positifs crées sous irradiation et des électrons, D_+/D_-, augmente avec la pression.

Canadian Journal of Chemistry, 49, 2651 (1971)

Introduction

Information about the behavior of radiolysis intermediates in liquids can be obtained by studying the effect of pressure upon their relative rates of reaction (1–4). To this end, charge scavenging reactions have been studied in *n*-hexane at the pressures 1 bar and 4.6 kbars.

A similar investigation of charge scavenging in liquid cyclopentane has recently been reported (5). The charge scavengers N_2O, ND_3, and C_2H_5OD were used. The results obtained were similar to those reported here for liquid *n*-hexane.

Experimental

Phillips Research Grade *n*-hexane was used after the removal of traces of olefin by treatment with concentrated sulfuric acid (3). The treated hexane was then washed with water, dried, and distilled by standard techniques. Phillips Research Grade hexene-1 and benzene, Reagent Grade aniline from Shawinigan Chemicals and hexadiene-1,3 from Sapon Laboratories were distilled before use. Carbon tetrachloride from Fisher Scientific Co. was washed with sodium carbonate solution prior to use. Ethanol from United States Industrial Chemicals and perdeuterio *n*-hexane from Merck, Sharp and Dohme were used as received.

The high pressure system has been described elsewhere (1–3). The hydrostatic liquid used in the high pressure system was Esso Bayol 35 from Imperial Oil Limited. Specially ground 5 cm^3 glass syringes (East Rutherford Syringes, Inc.) sealed to 5/20 standard-taper inner joints (Fischer and Porter Ltd), capped with corresponding outer joints were used as reaction vessels for most of the experiments. The hydrogen yields obtained from the syringe technique were reproducible at 1 bar but at 4.6 kbars it was observed that the syringes began to jam after several (~5) runs and resulted in low hydrogen yields. For this reason no syringe was used more than three times under high pressure. The hydrogen yields under such conditions were reproducible and found to be independent of pressure. To check the reliability of the syringe technique a goosenecked cell was used, in which a mercury column separates the sample from the pressurizing oil and transmits the pressure (5). The hydrogen yields from such cells gave $G(H_2) = 5.3 \pm 0.2$ independent of pressure, equal to those obtained from the syringe technique.

[1]This work was presented in part at the C.I.C.–A.C.S joint meeting in Toronto, May 28, 1970.

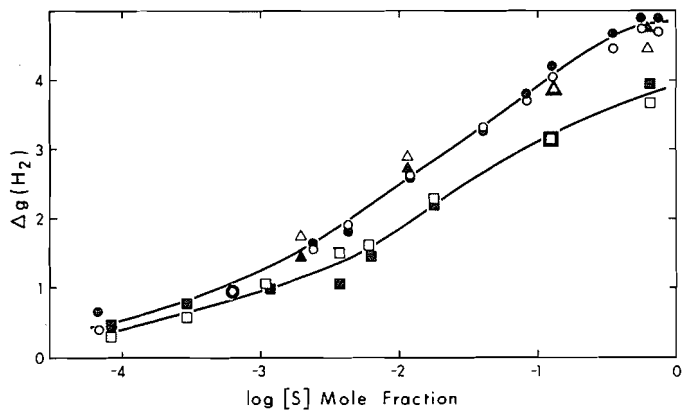

FIG. 1. $\Delta g(H_2)$ from *n*-hexane as a function of solute concentration. Carbon tetrachloride, ○; hexadiene-1,3, △; hexene-1, □. Open symbols, 1 bar; filled symbols, 4.6 kbars.

Several samples were irradiated in mercury-free Pyrex cells to compare the hydrogen yields in the presence and absence of mercury. The value obtained under this condition was $G(H_2) = 5.3$, which shows that mercury has no detectable effect on the hydrogen yield.

For the syringe samples, *n*-hexane and its solutions were deaerated by bubbling with argon for 10 min before irradiation. The change in concentrations of solutions after such treatment was negligible because the vapor pressures of the solutes are close to that of *n*-hexane, and secondly, evaporation of the solutions was less than 3%. Solutions of known concentrations of scavengers were prepared volumetrically or gravimetrically. Analysis of the irradiated samples was performed with a modified Van Slyke apparatus attached to a gas chromatograph with a thermal conductivity detector (6). For the separation of hydrogen, an 8 ft molecular sieve (Linde 5A from Union Carbide) column was used with argon carrier gas.

Samples were prepared in the goosenecked and Pyrex cells by standard vacuum techniques. Hydrogen from the irradiated samples was collected by a Toepler pump and injected into the gas chromatograph (11).

Irradiation was performed at 23° with a ^{60}Co γ-source. Special sample holders were used for the different types of cells to reproduce their position in the high pressure vessel. The amount of sample used was chosen such that the volume at the irradiation pressure equalled 3.2 cm^3. This required 2.10 g at 1 bar and 2.62 g at 4.6 kbars (*7a*). The same volume was used at each pressure to simplify the dosimetry inside the pressure bomb. The dose rate, determined by a Fricke dosimeter, was 8.1×10^{16} eV/g min in *n*-hexane (*7b*). The dose was 6.5×10^{17} eV/g.

The isotopic composition of hydrogen from the C_6D_{14}–C_6H_{14} solution was determined using a CEC 21-614 mass spectrometer.

Results

The yields of hydrogen obtained from the different cells agreed with each other within experimental error. Pure *n*-hexane gave $G(H_2) = 5.3 \pm 0.2$, independent of pressure over the range 1 bar to 4.6 kbars. This value is in agreement with previously published values at atmospheric pressure (8–10).

The yields from the solutions are expressed as *g* values, based on the energy initially absorbed in the solvent only. That is, $g = G/\varepsilon_s$, where ε_s is the electron fraction of solvent in the solution. A correction was made to the hydrogen yields for the direct radiolysis of ethanol, hexene-1, and hexadiene-1,3 in the solutions using $G(H_2) = 5.1$ for ethanol, 0.8 for hexene-1, and 0.2 for hexadiene-1,3 (assumed equal to that from cyclohexadiene-1,3 (11)). The hydrogen yield from benzene is so low (0.04) that no correction was necessary.

The *G* values of H_2, HD, and D_2 obtained from 11 mol% C_6D_{14} in C_6H_{14} were, respectively, 4.86, 0.33, 0.11 at 1 bar and 4.84, 0.35, 0.11 at 4.6 kbars. The yields are independent of pressure.

Figure 1 displays $\Delta g(H_2) = g(H_2)_0 - g(H_2)$ against the mole fractions of carbon tetrachloride, hexadiene-1,3, and hexene-1 at 1 bar and 4.6 kbars. $\Delta g(H_2)$ is independent of pressure for all three solutes. Carbon tetrachloride and hexadiene-1,3 are equally efficient as scavengers, while hexene-1 is about three-fold less efficient.

Figure 2 depicts $\Delta g(H_2)$ against mole fraction of aniline at 1 bar and at 4.6 kbars. The efficiency of scavenging hydrogen precursors by aniline increases with increasing pressure. Unfortunately, higher concentrations of aniline could not be used because of its limited solubility in *n*-hexane.

The effect of benzene is similar to that of aniline, but the pressure effect on the former is greater than that on the latter (*cf.* Figs 2 and 3).

TABLE 1. Relative efficiencies of scavengers in liquid *n*-hexane

Solute	$k_{1\ bar}$	$k_{4.6\ kbars}$	Probable species scavenged
Carbon tetrachloride	1.0	1.0	e^-, H
Hexadiene-1,3	1.0	1.0	e^-, H
Hexene-1	0.4	0.4	H, +
Aniline	0.2	0.4	+, H
Benzene	0.2	0.6	+, H
Benzene + 10% ethanol	0.1	0.5	H, +

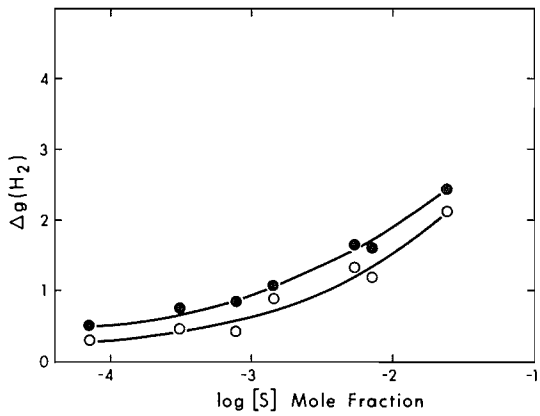

FIG. 2. $\Delta g(H_2)$ from *n*-hexane as a function of aniline concentration. ○, 1 bar; ●, 4.6 kbars.

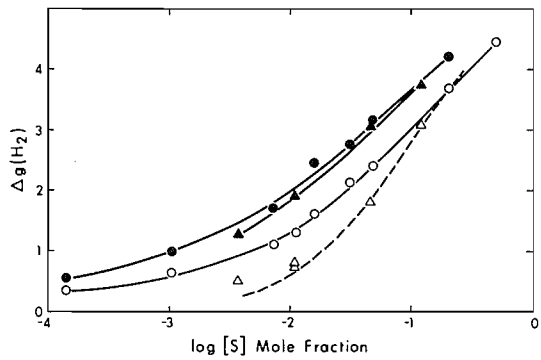

FIG. 3. $\Delta g(H_2)$ from *n*-hexane as a function of solute concentration. Benzene: ○, 1 bar; ●, 4.6 kbars. 10 mol% ethanol + benzene: △, 1 bar; ▲, 4.6 kbars (dashed line at 1 bar was calculated using $k_{17}/k_{16} = 13$).

Addition of 10 mol% ethanol to the *n*-hexane benzene solutions decreases the scavenging efficiency of benzene at 1 bar but at 4.6 kbars the effect of ethanol is greatly reduced (Fig. 3). At 4.6 kbars benzene solutions more concentrated than 0.2 mole fraction broke the cells, probably due to freezing of the solutions.

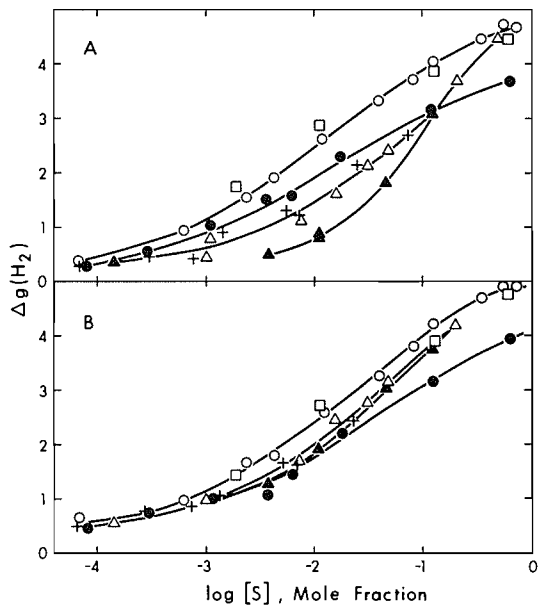

FIG. 4. $\Delta g(H_2)$ from *n*-hexane as a function of solute concentration. *A*: 1 bar; *B*: 4.6 kbars. ○, carbon tetrachloride; □, hexadiene-1,3; ●, hexene-1; +, aniline; △, benzene; ▲, benzene + 10 mol% ethanol.

The different effects of pressure on the different scavenger solutions are strikingly demonstrated in Fig. 4. The aniline and benzene curves at 1 bar are lower than the hexene-1 curve at low solute concentrations, but they are above the hexene-1 curve at 4.6 kbars.

The relative efficiencies of the different scavengers at 1 bar and 4.6 kbars are listed in Table 1.

Discussion

The mechanism for hydrogen formation in the γ radiolysis of liquid *n*-hexane can be represented as follows

[1] $C_6H_{14} \rightsquigarrow C_6H_{14}^+ + e^-$

[2] $C_6H_{14} \rightsquigarrow C_6H_{14}^*$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[3] $C_6H_{14}^+ + e^- \rightarrow C_6H_{14}^*$

[4] $C_6H_{14}^* \rightarrow H, H_2$, products

[5] $H + C_6H_{14} \rightarrow H_2 + C_6H_{13}$

The lack of a pressure effect on the yield of hydrogen from pure hexane or on the isotopic composition of the hydrogen from the C_6D_{14}–C_6H_{14} solution indicates that the yields of reactions 4 and 5 are unaffected by pressure. It also seems probable that there is no net effect of pressure on reactions 1–3 over the range used. No pressure effect on the yields of reactions 3 and 5 would be expected, since they have no competing reactions in the mechanism.

The hydrogen yield from liquid cyclopentane was also independent of pressure (5).

A. Carbon Tetrachloride, Hexadiene-1,3, and Hexene-1 Solutions

Carbon tetrachloride and conjugated diolefins have been shown to scavenge both electrons and hydrogen atoms in hydrocarbon and aqueous solutions (12, 13).

[6] $e^- + CCl_4 \rightarrow CCl_4^- (\rightarrow CCl_3 + Cl^-)$

[7] $e^- + C_6H_{10} \rightarrow C_6H_{10}^-$

[8] $C_6H_{14}^+ + (Cl^- \text{ or } C_6H_{10}^-) \rightarrow$ no H or H_2

[9] $H + CCl_4 \rightarrow HCl + CCl_3$

[10] $H + C_6H_{10} \rightarrow C_6H_{11}$

The absence of an appreciable pressure effect on the scavenging efficiencies of these solutes (Fig. 1) indicates that the net influences of pressure on reactions 3, 6, and 7 are equal to each other, and that the influences on reactions 5, 9, and 10 equal each other. This is in agreement with similar observations in other systems (5, 14, 15).

Mono-olefins such as hexene-1 scavenge hydrogen atoms at low concentrations (13, 16) and possibly also positive ions at high concentrations (17). The lack of a pressure effect on the scavenging efficiency of hexene-1 is consistent with the occurrence of reaction 11 in competition with reaction 5, since the two types of reaction have similar volumes of activation (14).

[11] $H + C_6H_{12} \rightarrow C_6H_{13}$

B. Benzene, Benzene + Ethanol, and Aniline Solutions

Benzene has been suggested to scavenge hydrogen atoms in the liquid phase (12, 13, 18). In solid phase solutions it has also been reported to scavenge electrons (19–22) and positive charge (19, 22–24).

The scavenging efficiency of benzene increased with increasing pressure (Fig. 3), whereas the efficiencies of the electron and hydrogen atom scavengers were unaffected by pressure (part *A*). This seemed to indicate that the pressure effect on the benzene solutions was due to positive ion reactions. To test this possibility, ethanol was added as a competitive scavenger for the positive ions.

[12] $C_6H_{14}^+ + C_6H_6 \rightarrow C_6H_{14} + C_6H_6^+$

[13] $C_6H_6^+ + e^- \rightarrow$ negligible H_2

[14] $C_6H_{14}^+ + C_2H_5OH \rightarrow C_6H_{13} + C_2H_5OH_2^+$

[15] $C_2H_5OH_2^+ + e^- \rightarrow C_2H_5OH + H$

Whereas benzene inhibits hydrogen formation and ethanol does not, so addition of ethanol should diminish the effectiveness of benzene as a hydrogen inhibitor. Such was found to be the case at atmospheric pressure, but the ethanol effect was much reduced at 4.6 kbars (Fig. 3). It therefore appears that $\Delta V_{14}^{\ddagger} > \Delta V_{12}^{\ddagger}$, where $\Delta V^{\ddagger}$ is the volume of activation.

To obtain further evidence about the effect of pressure on positive ion reaction efficiencies, aniline was used as a scavenger (25–28). Amines have been shown to react with radiolytic cations (17, 25–28). Increasing the pressure on the aniline solutions increased the scavenging efficiency (Fig. 3). The main effect of low concentrations of benzene and aniline on the radiolysis of *n*-hexane at 1 bar appears to be the scavenging of positive ions. However, in the presence of 10 mol% ethanol benzene acts mainly as a hydrogen atom scavenger. The dashed curve in Fig. 3 was calculated using homogeneous kinetics with $k_{17}/k_{16} = 13$ and $\Delta g(H_2)_{max} = 4.8$; RH in reaction 16 can be either hexane or ethanol.

[16] $H + RH \rightarrow H_2 + R$

[17] $H + C_6H_6 \rightarrow C_6H_7$

The value $\Delta g(H_2)_{max} = 4.8$ was estimated from the carbon tetrachloride experiments, in which both hydrogen atoms and the geminate neutralization reaction were being scavenged.

At 4.6 kbars reaction 12 is favored over reaction 14, and the ethanol interferes relatively little with the benzene reaction.

It has been suggested that benzene scavenges electrons prior to solvation in methanol–water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

glassy solids at 77 °K (20) and that phenol, which is analogous to our aniline, scavenges unsolvated electrons in the above matrices as well as in water (20, 21). However, there is no evidence that these compounds scavenge electrons in liquid *n*-hexane.

Kinetics Considerations

The fact that the volume of activation for the hydrogen atom reaction with hexane (abstraction) is essentially the same as that for the reaction with hexene-1 (addition) can be rationalized by assuming that there is a tight activated complex in each reaction. It has been estimated that $\Delta V^{\ddagger}$ for $H + CH_4 \rightarrow H_2 + CH_3$ is about -9 cm^3/mol (14). In the same way one may estimate $\Delta V_5^{\ddagger} \approx -9$ cm^3/mol and $\Delta V_{11}^{\ddagger} \approx -10$ cm^3/mol.

The pressure dependence of the charge scavenging reactions must be interpreted in terms of the kinetics of spur processes. Several treatments of the kinetics of charge scavenging in the γ radiolysis of liquids have been made (29–32). In general, they indicate that the concentration of scavenger required to scavenge a given fraction of the geminate electrons or positive ions is related to a reaction efficiency parameter. To interpret the pressure results in terms of the stochastic model the complete exponent $v\beta$ of the concentration factor (29, 32) must be considered. For electron scavenging (29),

$$[18]\quad v\beta_- = \frac{1.39 \times 10^7 \varepsilon y^3}{(u_+ + u_-)} \left\{ \frac{b_- D_-}{\lambda_-^2} + \frac{b_s D_s}{\lambda_s^2} \right\}$$

The pressure sensitivities of the dielectric constant ε, the secondary electron range y, and the mean free path λ are approximately $\varepsilon \propto \rho$, $y \propto \rho^{-1}$, $\lambda \propto \rho^{-1}$, where ρ is the density. One may therefore write

$$[19]\quad v\beta_- \approx c'(D_- + D_s)/(u_+ + u_-) = c(D_- + D_s)/(D_+ + D_-)$$

where c' and c are factors that are essentially independent of pressure, D is a diffusion coefficient, u is a mobility, and the subscripts $+$, $-$, and s refer to the geminate positive ions and electrons and the scavenger, respectively. From the data presently available (29–31) values of D_+ and D_s are much smaller than D_- and therefore, eq. 19 reduces to eq. 20,

$$[20]\quad v\beta_- \approx c$$

which implies that the efficiency of electron scavenging should be independent of pressure. The results demonstrate that this is essentially true (Fig. 1).

For positive ion scavenging, the equation analogous to [19] is

$$[21]\quad v\beta_+ \approx c(D_+ + D_s)/(D_+ + D_-)$$

Results from benzene, benzene + ethanol, and aniline solutions in hexane indicate that $v\beta_+$ increases with an increase in pressure. The respective increases are ~3-fold, 4-fold, and 2-fold on going from 1 bar to 4.6 kbars (Figs. 2 and 3). The increase in $v\beta_+$ with increasing pressure is ascribed to an increase in the ratio $(D_+ + D_s)/(D_+ + D_-)$ because c is essentially independent of pressure. D_s will decrease with increasing pressure as a result of the increasing viscosity of the solution, so the value of the ratio $D_+/(D_+ + D_-)$ must increase more than does $v\beta_+$; the value of the ratio D_+/D_- must increase even more.

The increase in D_+/D_- has a spectrum of possible causes, ranging from both diffusion coefficients decreasing but with D_+ decreasing less rapidly than D_-, to both coefficients increasing, but with D_+ increasing more rapidly than D_-. A definite choice cannot yet be made among the various possibilities. However, considering that electrons can be trapped in disordered systems (33–39) and that the positive charges appear to migrate limited but significant distances by charge exchange during radiolysis of solid hydrocarbons (24, 40), we tend to favor the interpretation that D_+ increases or remains the same while D_- remains the same or decreases with increasing pressure. Hentz and Brazier (5) came to a similar conclusion regarding the cyclopentane system.

Preliminary experiments were done by W. Skrlac and G. B. Evans. We are grateful to the National Research Council of Canada for financial assistance.

The Electroreduction of Periodate Anion in Alkaline Media

W. R. FAWCETT AND Y. C. KUO LEE
Department of Chemistry, University of Guelph, Guelph, Ontario

Received February 1, 1971

The electroreduction of periodate anion was studied at a dropping mercury electrode in aqueous solutions in the pH range 11–13.3 where the process is markedly affected by the double layer. The electrode reaction was found to be complex, its mechanism depending on both pH and ionic strength. The effects of the double layer on the component reactions are discussed with respect to current theoretical developments.

L'électroréduction de l'anion périodate a été étudiée au moyen d'une électrode à gouttes de mercure, en solution aqueuse et dans une zone de pH comprise entre 11 et 13.3, où le processus est pronfondément influencé par la double couche. La réaction à l'électrode est compliquée et son mécanisme dépend à la fois du pH et de la force ionique. Les effets de la double couche sur les réactions des constituants sont discutés par rapport aux résultats théoriques actuels.

Canadian Journal of Chemistry, 49, 2657 (1971)

Introduction

As the result of several experimental investigations (1–4), it has been found that periodate anion in aqueous solution is reduced at a dropping mercury electrode in two steps, the first being a two electron reduction to iodate anion, and the second, a six electron reduction of iodate to iodide anion. The first polarographic wave was normal in acidic media (1, 2); however, in alkaline media, an anomalous current minimum, whose depth depended on pH, ionic strength, and the nature of the base electrolyte cation, appeared at potentials cathodic of the working electrode's electrocapillary maximum (e.c.m.) where the diffusion limited current was expected (1, 3, 4). Lamy (4) attributed the minimum to a double layer effect, namely, repulsion of the reacting anion from the similarly charged electrode (5), and thereby accounted for the dependence on ionic strength. On the basis of existing thermodynamic data for the solution equilibria of periodate (6), he assumed that the predominant species at high pH was $H_3IO_6^{2-}$ and concluded that the pH dependence resulted from the fact that the electroactive species was $H_4IO_6^-$ formed from the dinegative anion in a labile protonation reaction preceding electron transfer. However, more recent studies of periodate equilibria (7–9) have shown that the species $H_2IO_6^{3-}$ and $H_2I_2O_{10}^{4-}$ are present in the pH range 11–14 so that pH dependence also results from variations in the bulk concentrations of the various anions. On reexamining the double layer effect in this system, it was found that the charge on the predominant reacting species depended on both pH and ionic strength (10). Further details of the results of this reexamination are presented in the following paper.

Experimental and Method of Data Analysis

Current–voltage curves for the reduction of periodate anion were measured at a dropping mercury electrode with various combinations of alkali metal hydroxides and fluorides as base electrolytes. The base electrolytes were chosen so that kinetic data would be obtained with a given cation as a function of pH at constant ionic strength and vice versa. The apparatus, experimental procedure, and general methods of reagent purification have been described previously (10). CsOH was prepared from a solution of CsCl by electrolysis according to the method outlined by Vogel (11). AnalaR grade sodium and potassium periodate were used as depolarizers without further purification. The depolarizer concentration was always 5×10^{-4} M.

The rate of charge transfer at a given potential was calculated from the current measured at the end of the lifetime of a given mercury drop, the droptime, and the corresponding current which would flow if the process were diffusion controlled. The calculation was based on Koutecký's theory for irreversible electrode processes and included corrections for electrode sphericity (10). The necessary double layer data, namely values of electrode charge density, q, and outer Helmholtz plane (o.H.p.) potential, ϕ_2 as functions of electrode potential were calculated from the capacity data of Grahame and Payne as outlined previously (10). For convenience, the kinetic data are reported in terms of $(\ln k)/f$ where k is the rate constant (cm s^{-1}) and $f = F/RT$ (V).

Results and Discussion

A typical current–potential curve for periodate anion reduction at a mercury electrode is shown

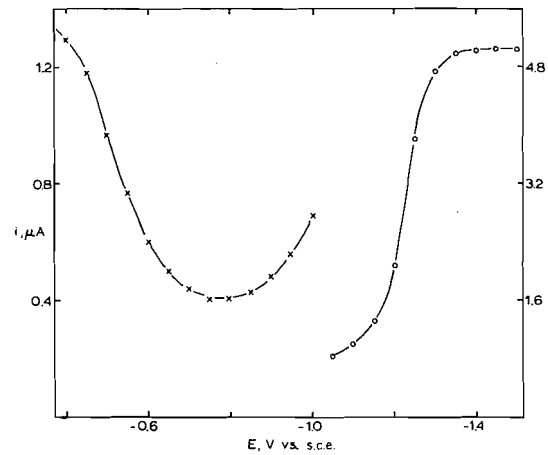

FIG. 1. Current–potential curve for the electroreduction of 5×10^{-4} *M* $NaIO_4$ at a dropping mercury electrode in 0.1 *M* NaOH at 25 °C. Capillary characteristics: flow rate = 0.296 mg s^{-1}, drop time = 8.75 s at −0.4 V, 6.86 s at −1.5 V. Points (×) correspond to the left hand ordinate scale and (○) to the right hand scale.

in Fig. 1. The kinetic data of interest in this investigation, namely that for reduction of periodate to iodate, were obtained in the region of the current minimum. The potential at which current due to the second process, reduction of iodate to iodide, became significant was determined by a simple extrapolation procedure. A plot of log $[i/(i_{d2} - i)]$ *vs.* electrode potential was made with data in the potential region of the second wave; i is the observed current and i_{d2}, the diffusion limited current for the second process. The resulting plot was linear over the rising portion of the second wave and had a slope of 12 V^{-1}. The potential at which a current of 6×10^{-3} μA would flow according to the above linear relationship was determined by extrapolation. This current was the smallest which could be detected for typical experimental conditions of current measurement in the region of the minimum. By this procedure it was found that current flowing due to the second process could be considered negligible at potentials anodic of −0.950 V with respect to the standard calomel electrode.

The diffusion coefficients required for calculation of the diffusion limited current over the potential range of the current minima were determined from the limiting current for the second wave. These constants could not be calculated from current densities measured at potentials anodic of the e.c.m. because of the presence of polarographic maxima of the second kind. The apparent diffusion coefficients obtained were found to decrease with increase in both ionic strength and p*H*. These changes are attributed respectively to the effects of ionic atmosphere on diffusion of the reacting ions, and to the participation of more than one ion in the mass transfer process. According to the equilibrium constants determined by Buist *et al.* (9), both $H_3IO_6^{2-}$ and $H_2IO_6^{3-}$ were present in the solutions to a significant extent under the given experimental conditions. For a stoichiometric periodate concentration of $5 \times 10^{-4}M$, the concentration of $H_2I_2O_{10}^{4-}$ was negligible except at lower p*H*. Since the largest amount present in any of the systems corresponded to approximately 2% of the total periodate concentration, its presence was neglected in the calculations described below. If both the dinegative and trinegative ions react at the electrode, then, according to the Ilkovič equation[1] one may write (12)

$$[1] \quad D_{app}^{1/2} = \frac{K_{b3}}{K_{b3} + C_{OH}} D_2^{1/2} + \frac{C_{OH}}{K_{b3} + C_{OH}} D_3^{1/2}$$

where D_{app} is the apparent value of the diffusion coefficient calculated from the diffusion limited current, D_2 and D_3, the diffusion coefficients for the two anions at a given ionic strength, K_{b3}, the basicity constant for $H_2IO_3^{3-}$ at the given ionic strength, and C_{OH}, the hydroxyl ion concentration. The parameters K_{b3}, $D_2^{1/2}$, and $D_3^{1/2}$ were determined from the values of $D_{app}^{1/2}$ as a function of C_{OH} at constant ionic strength using the generalized least squares procedure of Wentworth (14). The results are summarized in Table 1. Values of K_{b3} at zero ionic strength were calculated using single ion activity coefficients estimated according to Davies' equation (15). The weighted average for K_{b3} ($\mu = 0$) from the results in Table 1 is $(1.53 \pm 0.14) \times 10^{-2}$, a result which agrees well with that of Buist *et al.* (9). As expected,

[1]Strictly speaking this calculation should be based on Koutecký's equation (13) for the diffusion limited current which includes a correction for electrode sphericity. However, the precision with which the diffusion coefficients could be determined was too low to warrant this refinement.

TABLE 1. Parameters obtained by least squares fit of diffusion coefficient data to eq. 1

Ionic strength (μ, M)	Number of data points	$K_{b3} \times 10^3$	$D_2^{1/2} \times 10^3$ (cm $s^{-1/2}$)	$D_3^{1/2} \times 10^3$ (cm $s^{-1/2}$)
0.01*	11	10.2	2.73	2.60
0.02	18	6.65 ± 11.0	2.71 ± 0.05	2.52 ± 0.09
0.05	22	9.2 ± 6.4	2.71 ± 0.04	2.43 ± 0.05
0.1	23	5.1 ± 3.2	2.67 ± 0.05	2.39 ± 0.03
0.2	21	5.0 ± 2.7	2.66 ± 0.07	2.31 ± 0.02

*The non-linear least squares procedure was not convergent in this case. K_{b3} was calculated as described in the paper from values obtained at other ionic strengths; $D_2^{1/2}$ and $D_3^{1/2}$ were then determined from a linear least squares fit of the data to eq. 1.

the values of D_2 and D_3 decrease with increase in ionic strength, the decrease for the trinegative ion being greater than that for the dinegative. Finally, it was assumed that the diffusion limited current in the region of the current minimum was due to diffusion of $H_3IO_6^{2-}$ only, and accordingly, calculated using the tabulated values of $D_2^{1/2}$. This assumption is discussed below.

Kinetic data obtained at ionic strength 0.05 for varying pH with Na^+ as the base electrolyte cation are shown in Fig. 2. At constant electrode potential on the rational scale, ϕ_m, the structure of the double layer for the various base electrolytes involved was the same assuming that neither fluoride or hydroxyl anions are specifically absorbed at cathodic potentials (16). The variation of reaction rate with pH at constant ϕ_m is attributed to variation in the concentration of the electroreducible species, or of another species involved in a chemical reaction preceding the electron transfer step and producing the electroreducible species. It was also noted that the potential at which the current reached a minimum changed with pH, becoming slightly more anodic as the pH increased. This observation can be ascribed to a gradual change in mechanism with change in concentration of the electroreducible species. Kinetic data for varying ionic strength at pH 12 are shown in Fig. 3. These results are obviously attributable to a double layer effect. As the ionic strength is decreased, the potential drop across the diffuse layer, ϕ_2, increases at

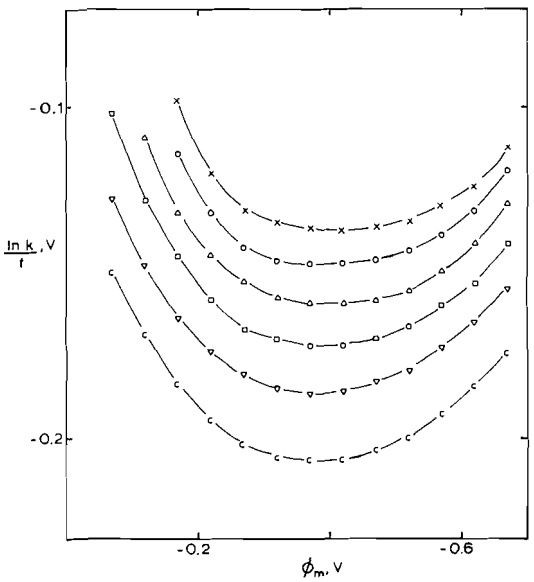

FIG. 2. Kinetic data for the electroreduction of periodate anion as a function of pH and potential at constant ionic strength (0.05). The hydroxyl ion concentrations are 0.001 (×), 0.002 (○), 0.005 (△), 0.01 (□), 0.02 (▽), and 0.05 (C).

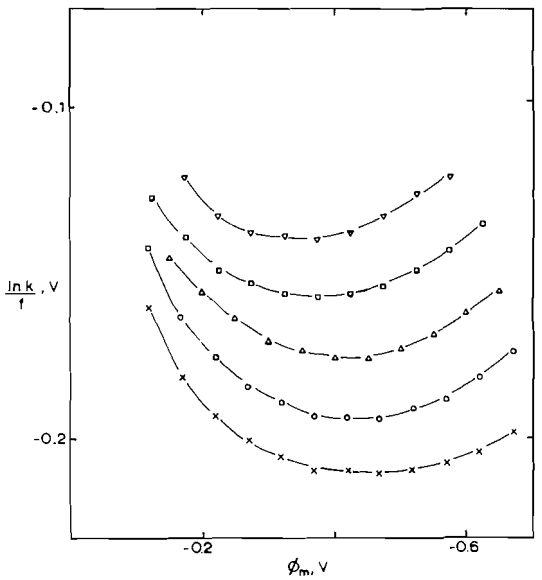

FIG. 3. Kinetic data for the electroreduction of periodate anion as a function of ionic strength and potential at constant pH (12). The ionic strengths are 0.01 (×), 0.02 (○), 0.05 (△), 0.1 (□), and 0.2 (▽).

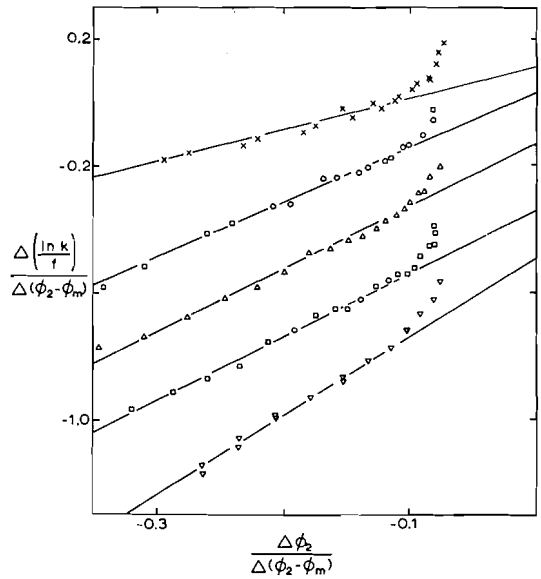

FIG. 4. Differential plots of kinetic data for the electroreduction of periodate anion in NaOH solutions of varying concentration: 0.01 (×), 0.02 (○), 0.05 (△), 0.1 (□), and 0.2 (▽). The ordinate scale is correct for the uppermost plot; for the sake of clarity the other plots have been shifted down by 0.2 units each.

constant ϕ_m so that the reacting anion is increasingly repelled from the electrode.

A simple differential technique described earlier (10) was used to determine the charge on the reacting species. Typical differential plots for data obtained in NaOH solutions of varying concentration with finite differences calculated at 50 mV increments in ϕ_m are shown in Fig. 4. The slope of the plots depended on both p*H* and ionic strength, increasing with increase in ionic strength, and in some cases, with p*H*. In summary, the slopes in the limit of low ϕ_m were approximately 1 for $\mu = 0.01$, between 1 and 2 for $\mu = 0.02$, 2 for $\mu = 0.05$ and 0.1, and between 2 and 3 for $\mu = 0.2$ *M*. In all cases the corresponding intercepts were greater than zero, indicating that the rate controlling step was electron transfer. Then, the slope is equal to the charge z on the ion transported through the double layer to the reaction site. In contrast to results for the peroxydisulfate system (17, 18), the differential plots did not always display a smooth increase in slope, and in some cases, had distinct points of inflection.

From the above results it was concluded that the mechanism of periodate reduction involves parallel reaction steps, the important step being direct reduction of the divalent species. At low ionic strength and p*H*, the reduction of a monovalent anion produced from the divalent species in a preceding protonation or ion-pairing reaction is predominant, whereas at high ionic strength and p*H* reduction of the trivalent ion is possible. The higher slope in differential plots at $\mu = 0.2$ is not conclusive evidence of participation of $H_2IO_6^{3-}$ in the electrode reaction in the potential region of the minimum. As the ionic strength increases the range of $\Delta\phi_2/\Delta(\phi_2 - \phi_m)$ decreases. All differential plots had higher slopes at the most negative values of $\Delta\phi_2/\Delta(\phi_2 - \phi_m)$ due to distortion of the current–potential curves in the region of the e.c.m. by polarographic maxima. For $\mu = 0.2$, this potential region corresponds to values of $\Delta\phi_2/\Delta(\phi_2 - \phi_m)$ between -0.28 and -0.18. In addition, an increase in the slope of the differential plots with increase in the abscissa variable similar to that found for peroxydisulfate (17, 18) is apparent in the differential plots. These two effects probably distort the differential plots at $\mu = 0.2$ sufficiently that they cannot be used to determine the charge. If reduction of the trivalent ion contributed significantly to the current in the region of the minimum, this current would not decrease with increase in p*H* since an increase in p*H* results in an increase in $H_2IO_3^{3-}$ concentration. From the intercepts obtained with integral slopes in the limit of low ϕ_m, transfer coefficients of 0.26 ± 0.01 for reduction of $H_3IO_3^{2-}$ and 0.11 ± 0.01 for reduction of the monovalent anion were determined.

The validity of the conclusions drawn from the differential plots was confirmed by analyzing the p*H* dependence of kinetic data at constant ionic strength. Neglecting any contribution of ion pairs to the total current, the rate of reaction at constant potential may be written

$$[2] \qquad v = k_1a_1 + k_2a_2 + k_3a_3$$

where a_z is the activity of the periodate species with charge $-z$ and k_z, the corresponding rate constant. When current–potential data are analyzed according to Koutecký's theory, a rate constant is calculated with the assumption that there is only one reactant at a concentration equal to the stoichiometric concentration of the depolarizer, C_s. Defining an apparent rate

constant k_{app} equal to v/C_s and assuming that the predominant species in solution are $H_3IO_6^{2-}$ and $H_2IO_6^{3-}$, eq. 2 may be rewritten

$$[3] \quad k_{app} = \frac{k_1\gamma_1 K_{b2} K_{b3}}{K_{b3}C_{OH} + C_{OH}^2} + \frac{k_2\gamma_2 K_{b3}}{K_{b3} + C_{OH}} + \frac{k_3\gamma_3 C_{OH}}{K_{b3} + C_{OH}}$$

where K_{b2} is the basicity constant for $H_3IO_6^{2-}$ and γ_z the single ion activity coefficient. The mechanism of periodate reduction was confirmed by determining the dependence of k_{app} $(K_{b3} + C_{OH})$ on C_{OH}. In order to minimize the effects of possible errors in correcting for concentration overpotential, values of k_{app} were calculated from data in the vicinity of the minimum current. For ionic strengths in the range 0.01–0.2 with K_{b3} calculated from $K_{b3}(\mu = 0) = 1.53 \times 10^{-2}$, $k_{app}(K_{b3} + C_{OH})$ decreased with increase in C_{OH}, indicating that reduction of $H_4IO_6^-$ and $H_3IO_6^{2-}$ contributed to the observed current. There was no indication of increase in $k_{app}(K_{b3} + C_{OH})$ with C_{OH}, that is, of a contribution from reduction of $H_2IO_6^{3-}$ even at the highest pH and ionic strength where this reaction would be favored. On this basis, it was concluded that k_3C_3 was negligible in the potential region of the current minimum. Furthermore, the major species diffusing to the electrode from the bulk was $H_3IO_6^{2-}$ so that the reversible current in this potential region would be the diffusion limited current for $H_3IO_6^{2-}$, its calculation being based on the diffusion coefficient D_2.

The rate constants k_1 and k_2 were determined at constant ionic strength and constant potential from a least squares fit of the equation

$$[4] \quad k_{app}(K_{b3} + C_{OH}) = \frac{k_1\gamma_1 K_{b2} K_{b3}}{C_{OH}} + k_2\gamma_2 K_{b3}$$

to the kinetic data. The equilibrium constants and activity coefficients were calculated as described above, $K_{b2}(\mu = 0)$ being set equal to 2.05×10^{-6} (9). Results at $\mu = 0.01$ and 0.02 are presented in the form of corrected Tafel plots in Fig. 5. The plots were linear in the potential range $\phi_m = -0.2$ to -0.5 V and yielded transfer coefficients of 0.26 for reduction of $H_3IO_6^{2-}$ and 0.11 for reduction of $H_4IO_6^-$. These results agree with those obtained from the differential plots and are excellent confirmation of the proposed mechanism. It was observed

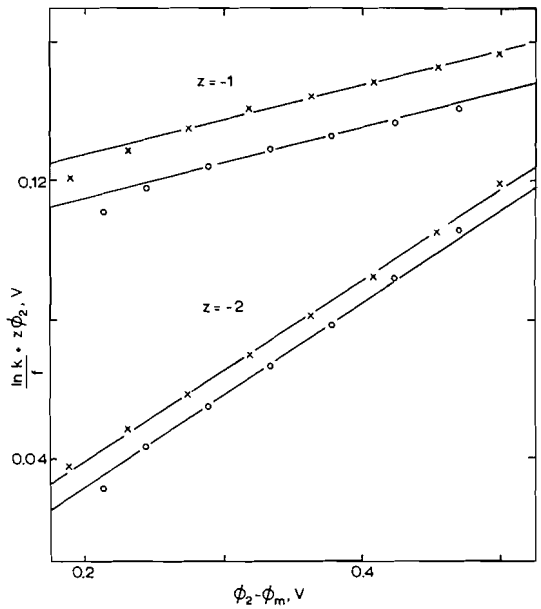

FIG. 5. Corrected Tafel plots of kinetic data for the electroreduction of $H_4IO_6^-$ (upper curves) and $H_3IO_6^{2-}$ (lower curves) at ionic strengths 0.01 (×) and 0.02 (○).

that the rate constant for reduction of the monovalent species was always greater than that for the divalent species at a given ionic strength. It is difficult to offer a qualitative explanation of this observation because the data were obtained at potentials far cathodic of the standard potentials,[2] and because the reactions are complex. However, if electron transfer is the rate controlling step in both reactions, current theories (19, 20) predict that the exchange current for the $H_3IO_6^{2-}$ would be less than that for the $H_4IO_6^-$ reaction since the work of solvent reorganization would increase with the charge on the reacting anion. It was also noted the rate constant for a given reaction decreased at constant potential with increase in ionic strength. A similar observation was made with data for the electroreduction of peroxydisulfate anion (18) where it was attributed to errors in the ϕ_2 potential as estimated by the Gouy–Chapman theory.

In the above analysis it was assumed that ion pairs such as $NaH_3IO_6^-$ and $NaH_2IO_6^{2-}$ do not participate in the reaction mechanism.

[2]The standard potentials are approximately 0.7 and 0.9 V with respect to standard hydrogen electrode for the $H_3IO_6^{2-}$ and $H_4IO_6^-$ reactions, respectively.

The concentration of $NaH_2IO_6^{2-}$ in the bulk of the solution will be proportional to the concentration of $H_2IO_6^{3-}$ and therefore will increase with pH at constant ionic strength. Thus, on the basis of the same arguments presented above for $H_2IO_6^{3-}$, it can be assumed that reduction of $NaH_2IO_6^{2-}$ does not contribute significantly to the observed current. If $NaH_3IO_6^-$ participates in the reaction scheme, then eq. 4 must be rewritten as follows

$$[5]\quad k_{app}(K_{b3} + C_{OH}) = \frac{k_1\gamma_1 K_{b2}K_{b3}}{C_{OH}} + k_2\gamma_2 K_{b3} + k_1'\gamma_2 K_{f2}K_{b3}C_M$$

where k_1' is the rate constant for reduction of $NaH_3IO_6^-$, C_M, the concentration of cations and K_{f2}, the formation constant for $NaH_3IO_6^-$. In deriving eq. 5 it is assumed that the concentration of $NaH_3IO_6^-$ is very much less than that of $H_3IO_6^{2-}$. At first sight, it would appear that, if $NaH_3IO_6^-$ contributed to the observed current, values of k_2 calculated by fitting the data to eq. 4 would increase with increase in ionic strength. However, this conclusion is invalid if the individual rate constants k_2 and k_1' are given by the Frumkin equation. From eq. 5 and Frumkin's theory, one may write

$$[6]\quad k_2 + k_1'K_{f2}C_M = k_{20}\exp(2f\phi_2) \times \exp[\beta_2 f(\phi_2 - \phi_m)] + k_{10}'K_{f2}C_M\exp(f\phi_2) \times \exp[\beta_1' f(\phi_2 - \phi_m)]$$

where k_{20} and k_{10}' are the corresponding rate constants at the e.c.m., and β_2 and β_1', the respective transfer coefficients. From the Gouy–Chapman theory, at potentials sufficiently cathodic of the e.c.m.

$$[7]\quad \exp(f\phi_2) = \frac{\theta C_M}{K_i^2(\phi_m - \phi_2)^2}$$

where K_i is the integral capacity of the inner layer and θ, a constant for a given solvent. Thus, eq. 6 may be written

$$[8]\quad k_2 + k_1'K_{f2}C_M = k_{20}\exp(2f\phi_2) \times \exp[\beta_2 f(\phi_2 - \phi_m)] + k_{10}'K_{f2}K_i^2(\phi_2 - \phi_m)^2 \times \exp(2f\phi_2)\exp[\beta_1' f(\phi_2 - \phi_m)]/\theta$$

Since K_i is independent of ionic strength in the absence of specific adsorption, corrected Tafel plots ($\ln(k_2 + k_1'K_{f2}C_M) - 2f\phi_2$ *vs.* $\phi_2 - \phi_m$) would be independent of ionic strength; however, they would not be linear if $k_1'K_{f2}C_M$ is comparable in magnitude to k_2. In the present case, since the corrected Tafel plots are linear over a wide potential range, it is concluded that $NaH_3IO_6^-$ does not participate significantly in the reaction scheme.

The reduction of periodate anion was also studied in base electrolyte solutions of KOH and CsOH. The cation effect observed was similar to that reported for other systems (5), the reaction rate increasing at constant overpotential with increase in the base electrolyte cation's atomic number. From differential plots, it was concluded that the charge on the reacting anion varied with ionic strength and pH in a manner which paralleled exactly changes in base electrolytes where the cation was Na^+. Furthermore, the slope of corrected Tafel plots in the limit that $\phi_2 - \phi_m$ approached zero depended on the nature of the cation, increasing in the order $Na^+ < K^+ < Cs^+$. Similar observations have been made with kinetic data for anion reduction in both water and formamide (21). Values of the limiting slopes for the two reactions with different base electrolyte cations are summarized in Table 2.

The observed variations in Tafel slope with nature of the double layer cation can be accounted for if the reacting species is in the inner part of the double layer in the transition state (17). In this case the limiting Tafel slope is given by

$$[9]\quad \beta_0 = \alpha - \lambda_0(\alpha - z)$$

where α is the overall transfer coefficient for a complex electrode reaction, and $(1 - \lambda_0) = x_r/x_{20}$, x_r being the distance of the charge center of the reacting particle in the transition state from the electrode and x_{20}, the thickness of the inner layer at the e.c.m. The variation with double layer cation is due to a change in inner layer thickness with the nature of the cation

TABLE 2. Limiting Tafel slope β_0 as a function of charge on the reacting anion and nature of the base electrolyte cation

	β_0 when charge on anion =	
Base electrolyte cation	−1	−2
Na^+	0.11	0.26
K^+	0.13	0.29
Cs^+	0.17	0.40

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

at the o.H.p., the thickness of the inner layer decreasing as the atomic number of the alkali metal cation increases. An increase in x_{20} results in a decrease in λ_0 and thus a decrease in β_0, as is observed. The validity of this explanation can be tested easily with the above results. For a given reaction it is reasonable to assume that α and x_r do not vary with variation in the double layer cation. Thus, the relative change in $\beta_0 - z = (\alpha - z)x_r/x_{20}$ will reflect the relative change in $1/x_{20}$. From the observed Tafel slopes it was found that $(\beta_0 - z)_{Na^+}$: $(\beta_0 - z)_{K^+}$: $(\beta_0 - z)_{Cs^+}$ was constant within experimental error for the two reactions and had an average value of 1:1.02:1.06. This result agrees favorably with that found with the same cations for the electroreduction of peroxydisulfate in water (1:1.03:1.06) (17).

Several explanations can be offered for the variation in Tafel slope with charge on the reaction anion. This could be attributed to a change in overall transfer coefficient α. On the other hand, if the transfer coefficients for the two reactions are the same, the variation in β_0 could be ascribed to an increase in x_r, that is, a decrease in λ_0, with increase in charge on the reacting anion. However, variation in β_0 with x_r would have to be sufficient to offset the explicit variation with z which is in the opposite direction.

Finally, there was some curvature in the corrected Tafel plots at potentials greater than $\phi_m = -0.2$ V, their slope increasing somewhat with increase in potential in the anodic direction. Although there are several theoretical explanations of curvature in corrected Tafel plots (17, 22) other than ion pairing, no conclusions can be drawn in the present case. The curvature was observed in a potential region where errors in the calculated reaction rate are liable to be large due to the difficulties involved in correcting for mass transfer.

The authors wish to thank Dr. R. K. Boyd and M. Anderson for suggesting the non-linear least squares technique used in the data analysis and for making available their computer program. Reactions of Tertiary Hypohalites[1]

V. BOIDO[2] AND O. E. EDWARDS
Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada

Received April 5, 1971

Metallic silver initiates short-chain homolytic decomposition of tertiary alkyl hypochlorites and hypobromites. Evidence is presented that the reaction of tertiary alcohols with silver oxide – mercuric oxide – bromine involves formation and homolytic decomposition of alkyl hypobromite followed by cyclization of γ-bromo alcohols. A convenient synthesis of tricyclo[4.3.1.0^{3,8}]decan-4-one (4-proto-adamantanone) is described.

L'argent métallique initie la décomposition homolytique en chaîne courte d'hypochlorites et d'hypobromites d'alkyles tertiaires. On présente une preuve d'après laquelle la réaction entre les alcools tertiaires et le réactif oxyde d'argent-oxyde de mercure-brome implique la formation et la décomposition homolytique d'hypobromite d'alkyle, suivie par la cyclisation des γ-bromo alcools. On décrit une voie d'accès facile à la tricyclo [4.3.1.0^{3,8}] décanone-4 (protoadamantanone-4).

Canadian Journal of Chemistry, **49**, 2664 (1971)

Recent work in these laboratories has shown that the action of metallic silver on chloramides (1) and chloramines (2) produces the corresponding nitrogen radicals. Since no hydrogen chloride or chloride ions are produced, the possibility of radical chains involving chlorine atoms (3) is precluded. In addition no metallic ions are present in solution to provide complications due to oxidation–reduction processes (4). Hence this method of generating the radicals has valuable potential for the study of the reactions of nitrogen radicals in the ground state in solution.

A comparable possibility existed for the preparation of alkoxy radicals from hypohalites (eq. 1). The formation of a number of tertiary alkoxy radicals by this method

[1] $$ROCl + Ag^0 \rightarrow RO\cdot + AgCl$$

and study of their reactions is reported in this paper.

The first cases studied were those of 2-methylpent-2-yl hypochlorite (**1**) and hypobromite. The monomeric products characterized when **1** reacted with metallic silver at room temperature in acetonitrile are shown in eq. 2.

The γ-chloro alcohol produced could be readily cyclized to 2,2-dimethyltetrahydrofuran (**2**). The ratio of hypochlorite decomposed to silver chloride formed was 4:1.

2-methylpent-2-yl hypobromite behaved similarly when treated with Tollens' silver, but the chain length was shorter.

In a reexamination of the work of Sneen and Matheny (5) we treated 2-methylpentan-2-ol with bromine, mercuric oxide, and silver oxide at 0–5 °C in pentane. The product was the corresponding hypobromite. This decomposed near room temperature into acetone, 2-pentanone, and 5-bromo-2-methylpentan-2-ol. The latter cyclized slowly at room temperature to 2,2-dimethyltetrahydrofuran (**2**). The cyclization was markedly accelerated by silver oxide.

When the bromine, oxides, and alcohol reagents were mixed rapidly at room temperature in an attempt to duplicate the conditions of Sneen and Matheny, the temperature rose and reaction was complete in 10 min. No hypobromite was left, and 2,2-dimethyltetrahydrofuran had been formed. In addition acetone was shown to be present, hence the overall reaction was the same as thermal decomposition of the hypobromite followed by silver oxide induced cyclization of the γ-bromo alcohol.

As an example of a monocyclic tertiary hypohalite, 1-methylcyclopent-1-yl hypochlorite (**3**) was chosen for study. Cairns and Englund had shown (6) that this decomposed thermally to give a high yield of 6-chloropentan-2-one (**4**). Metallic silver converted **3** into **4** rapidly at room temperature. The ratio of hypochlorite converted to silver chloride produced was 9.7:1.

[2] 
1 2

The next examples studied were 1-methyl-1-phenylethyl hypochlorite (**5**) and 1,1-diphenylethyl hypochlorite (**6**). Somewhat to our surprise

3 4

5 gave nearly exclusively fission to acetophenone (eq. 3). The ratio of ROCl/silver chloride produced was 2.4. In contrast 6 gave predominantly

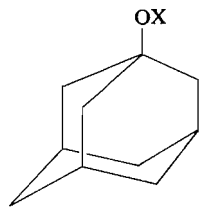
[3] 
5

1,1-diphenylethanol, 22% of acetophenone, but no benzophenone (eq. 4). The ROCl/AgCl ratio was 1.7.

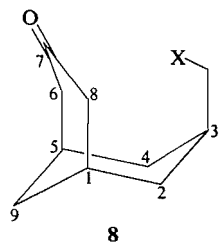
[4] 
6

Our attention was attracted to recent syntheses (7) of tricyclo[4.3.1.$0^{3,8}$]decane (protoadamantane) and its derivatives. It occurred to us that 1-adamantyl hypohalites (**7**) might be converted under homolytic conditions into the corresponding 3-*endo*halobicyclo[3.3.1]nonan-7-ones (**8**), which could be cyclized to 4-protoadamantanone (**9**).

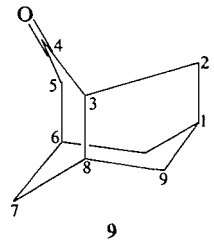
Treatment of 1-adamantyl hypochlorite in acetonitrile with Tollens' silver led to rapid reaction to give a mixture of 1-adamantanol, chlorinated adamantanols, the bicyclic ketone **8** (X = Cl), and dichloro ketones. Under the conditions chosen 4 mol of hypochlorite were decomposed for each mol of silver chloride produced. The yield of chloro ketones (calculated as **8**, X = Cl) was estimated to be 40.5%. In comparable experiments at 0° 1-adamantyl hypobromite gave an estimated 33% of bromo ketones (calculated as **8**, X = Br).



7



8

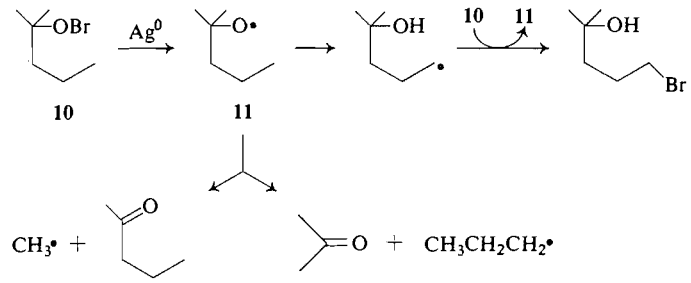


9

The thermal decomposition of 1-adamantyl hypochlorite was very slow in refluxing carbon tetrachloride or chlorobenzene at 110°. However it decomposed rapidly in refluxing acetonitrile. The estimated yield of chloro ketones produced was 64%. The hypobromite decomposed quite rapidly when heated in all three solvents giving approximately 63% of bromo ketones rich in **8** (X = Br).

Finally photolysis of 1-adamantyl hypochlorite in carbon tetrachloride gave a lower yield of **8** (X = Cl) than the silver initiated reaction hence was not studied in detail.

The chloro or bromo ketones **8** could be cyclized at room temperature using sodium hydride in tetrahydrofuran to give good yields (*ca.* 37% based on hypohalite used) of 4-protoadamantanone (**9**). While this work was in progress Black and Gill (8) reported the preparation of **8** (X = I) from "1-adamantyl hypoiodite",



[5]

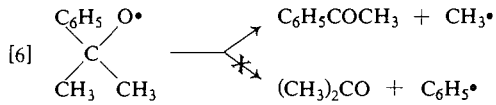
and its conversion into protoadamantanone in an overall yield of 34%. Lunn (9) has also prepared and characterized the bicyclic iodoketone (**8**, X = I), and described its cyclization into 4-protoadamantanone (overall yield 32%). A synthesis of **9** by deamination of 2-aminoadamantan-1-ol has recently been reported by Lenoir and Schleyer (10).

Discussion

The products from the silver initiated decomposition of 2-methylpent-2-yl hypochlorite and hypobromite are exactly what would be expected for a homolytic chain reaction (eq. 5). The fact that the Sneen and Matheny (5) conditions produce hypobromites which are thermolabile, and that the products from 2-methylpent-2-yl hypobromite fit the above homolytic pattern, suggest that their postulate of reaction involving cationic oxygen is in error. It appears that the unique role of the silver oxide is to cyclize the γ-bromo alcohol. This conclusion is in harmony with those of Akhtar and co-workers (11) and Smolinsky and Feuer (12).

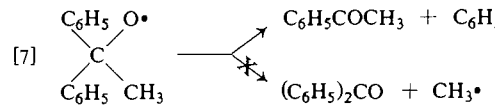
The cyclization of primary and secondary alcohols using the bromine – silver oxide or iodine – mercuric oxide combination recently described by Mihailovic and co-workers (13) is not inconsistent with homolytic decomposition of intermediate hypohalites. Finally, the claim by Sommer and co-workers (14) that their observed solvent effects support a cationic oxygen mechanism for the silver oxide – bromine – secondary alcohol reactions is not convincing. The addition of tetrahydrofurans, or the use of ethers as solvents was shown to eliminate an induction period and increase the yield of cyclic ethers at the expense of ketonic products. We suggest that this effect is most simply explained as initiation of homolytic decomposition of the alkyl hypobromites by peroxide in the ethers (see ref. 1).

The direction of fission of 1-methyl-1-phenylethoxy radical suggests that the transition state for the decomposition resembles the products, and that the difference in energy of formation of phenyl or methyl radicals is more than offset by development of acetophenone resonance[3] (eq. 6).



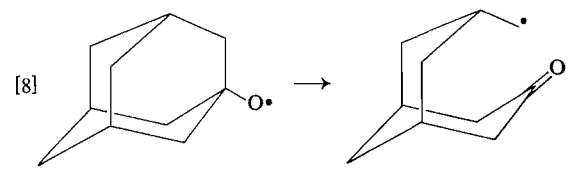
[6]

In the case of 1,1-diphenylethoxy radical however, the resonance energy gain in producing benzophenone is probably slightly more than that for formation of acetophenone.[4] Hence the nearly exclusive formation of the latter and phenyl radicals (eq. 7) suggests that these radicals are at least 5 kcal/mol more stable than methyl radicals.



[7]

In view of the compactness of the adamantane skeleton, it was an open question whether or not the 1-adamantoxy radical would undergo fission to the keto alkyl radical (eq. 8). However, the



[8]

free energy of activation for the fission must be low since the reaction competes favorably with

[3]However there is no clear correlation with the accepted value for acetophenone resonance (only 1 kcal/mol more than benzene) (15).

[4]The resonance contribution of the benzophenone carbonyl is estimated to be zero (15) but this seems improbable.

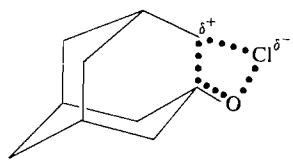
the abstraction of hydrogen from solvent and other molecules.

Black and Gill (8) considered the thermal decomposition of 1-adamantyl hypoiodite[5] and the other hypohalites studied to be homolytic. Our results with metallic silver prove that the adamantoxy radical does give the bicyclic ketone. However, the solvent effect on the thermal decomposition of the hypochlorite is only consistent with charge development in the transition state, which probably resembles **12**. Even in



12

acetonitrile, however, considerable adamantanol and chlorinated adamantanol were produced, hence a simultaneous homolytic fission of the hypochlorite was taking place. In view of the apparent absence of a solvent effect, the thermal decomposition of the hypobromite appears to be more homolytic in character. However the yield of bromoketones (*ca.* 63%), in contrast to the 33% yield for the pure homolytic process (silver initiated), suggests that a bond reorganization process is the main reaction path rather than reaction via adamantoxy radicals.

Experimental

The acetonitrile used was spectroscopic quality. The metallic silver used was a light brown solid produced by the action of formaldehyde on silver ammonium ion solution (Tollens' reagent), then thorough washing with water. It was prepared fresh for each experiment.

The g.l.c. was done on a 1/4″ × 6′ column of silicone rubber (10% SE30 on acid-washed silanized chromosorb W). Alumina was Woelm neutral grade, with activities according to Brockmann and Schodder (16).

Silver chloride was estimated by extraction into aqueous ammonia, filtration, reprecipitation by acid, filtration, and drying at 100°. Silver bromide was estimated by dissolving unreacted silver in nitric acid, filtration, washing, and drying. Yields and ratios are corrected for aliquots removed for titration.

Action of Silver on 2-Methyl-pent-2-yl Hypochlorite

Glacial acetic acid (10 ml) was added with stirring to an ice-cold mixture of 2.38 g of 2-methylpentan-2-ol and 150 ml of strongly alkaline 8% sodium hypochlorite solution. After 2 h stirring at 5 °C, the mixture was extracted with pentane. The pentane solution was washed with sodium carbonate solution then dried over sodium sulfate. The solvent was removed below room temperature on a rotating evaporator leaving 2.48 g of yellow oil. Its i.r. spectrum in methylene chloride showed the presence of a small amount of parent alcohol and a ketone.

The oil was dissolved in 22.5 ml of acetonitrile and 2.5 ml of water (final volume near 27 ml). Titration of 1 ml showed the presence of 1.57 g of hypochlorite. The remaining solution was purged with a stream of nitrogen. Tollens' silver from 2.6 g of silver nitrate was then added in portions over 20 min while stirring under nitrogen. After a total reaction time of 30 min only 1% of the hypochlorite remained. This was destroyed by addition of more silver, then the suspension was filtered. The precipitate was washed with acetonitrile.

The combined filtrates were distilled through a short Vigreux column giving (*a*) 2 ml of fore-run and (*b*) 20 ml b.p. near 80° (bath up to 120°). A residue (*c*) of 1.3 g remained.

The fore-run (*a*) and a methanol solution of trimethylamine was heated in a sealed tube at 100° for 5 h. The solvent was then distilled leaving 87 mg of crystalline salt. Its n.m.r. spectrum in D_2O had signals near δ 1.0 (triplet, J = 7 Hz), 1.2–2.1 (broad multiplet), 3.1 (sharp singlet), and 3.3 (triplet, J = 7) in intensity ratios of 3:2:11:2. This corresponds to a mixture containing 85% of trimethyl propylammonium iodide and 15% of tetramethylammonium iodide.

The main distillate (*b*) was partially dried using sodium sulfate. To this was added 1 g of *p*-nitrophenylhydrazine and the mixture held near 75° for 1 h by which time no carbonyl absorption was left in its i.r. spectrum. The solvent was removed under reduced pressure and the residue taken up in methylene chloride. The solution was washed twice with 2 *N* sulfuric acid, then with sodium carbonate solution.

The distillate from quaternary salt formation of fore-run (*a*) was treated in the same way. The combined hydrazone weighed 824 mg. Its n.m.r. spectrum contained peaks at δ 1.18 (triplet, J = 7 Hz) and at 1.96 and 2.10 corresponding to the *p*-nitrophenylhydrazones of 2-pentanone (1.18, 1.96, and 2.10) and acetone (1.93 and 2.08).

The intensities corresponded to 55% acetone derivative and 45% 2-pentanone, with a total ketone yield of 47%.

The residue (*c*) was dissolved in acetonitrile and stirred at room temperature with silver oxide from 657 mg of silver nitrate for 3 h. The suspension was filtered, the filtrate diluted with an equal volume of water, and extracted with pentane. The dried pentane solution was concentrated to small volume using a Vigreux still head. The residue gave n.m.r. signals at δ 1.24 (sharp) and 3.88 (triplet, J = 7 Hz) corresponding to the signals from authentic 2,2-dimethyltetrahydrofuran. The i.r. spectrum of the residue had seven peaks in the fingerprint region identical with those of 2,2-dimethyltetrahydrofuran, and the mixture gave a g.l.c. peak at the same retention time as authentic ether.

In another run, the fraction corresponding to (*c*) was distilled over a short path under 10 mm pressure. Distillate collected at a bath temperature up to 70° was a bad mixture but that collected at 70–100° contained approximately 50% of 5-chloro-2-methylpentan-2-ol as indicated

[5]Lunn (9) points out that the hypoiodite may not be involved in the cleavage by lead tetraacetate – iodine reagent.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

by n.m.r. signals at δ 0.74 (sharp) and 4.15 (triplet, J = 6.5 Hz).

Anal. Calcd. for $C_6H_{13}ClO$: Cl, 38.53. Found: 40.76.

This fraction and the residue gave an n.m.r. triplet at δ 5.85 (J = 6 Hz) corresponding to the presence of 5,5-dichloro-2-methylpentan-2-ol.

The silver chloride produced weighed 307 mg. Hence the ROCl/AgCl ratio was 4.

Action of Silver on 2-Methylpent-2-yl Hypobromite

Hypobromous acid was prepared from 3.99 g of bromine in 120 ml of water at 0° using 9.3 g of silver sulfate in the dark. The solution was decanted from silver bromide and added to a solution of 2.3 g (22.5 mmol) of 2-methylpentan-2-ol in 50 ml of trichlorofluoromethane. After 15 min vigorous mixing at 0° the organic layer was separated, washed with ice-water, and dried over sodium sulfate. The solvent was removed at 0° on a rotating evaporator and the residue dissolved in 30 ml of acetonitrile. Iodimetric titration showed the presence of 15.5 mmol of hypobromite.

Tollens' silver from 4.29 g of silver nitrate was added under nitrogen to a solution of the hypobromite (15.2 mmol) in 30 ml of acetonitrile. After 0.5 h stirring at 0° under nitrogen, all the hypobromite had reacted.

The solids were removed by filtration then the bulk of the acetonitrile removed by distillation (oil bath). The residue was dissolved in ether, the ether solution washed four times with water, dried, and distilled. The brown mobile oil had an n.m.r. spectrum corresponding to 5-bromo-2-methylpentan-2-ol (221 mg, 1.22 mmol). The characteristic signals were a singlet at δ 1.31 and a triplet (J = 6.5 Hz) at δ 3.63 in the ratio of 3:1.

To the distilled acetonitrile was added 1.5 g of *p*-nitrophenylhydrazine and a few drops of acetic acid. The mixture was refluxed for 1 h, then the solvent removed under reduced pressure. The residue was taken up in methylene chloride. The solution was washed three times with 2 *N* sulfuric acid, with sodium carbonate solution, then with water, dried, and distilled. A crystalline residue (1.1 g) remained. Examination of its n.m.r. spectrum showed it to consist of 63% *p*-nitrophenylhydrazone of 2-pentanone (3.14 mmol) (δ 1.18 (triplet J = 7 Hz), 1.96, and 2.1) and 37% acetone derivative (δ 1.93 and 2.08).

The amount of silver bromide produced was 1.79 g (9.5 mmol) *i.e.* ROBr/AgBr = 1.6.

Thermal Decomposition of 2-Methylpent-2-yl Hypobromite

(1) In an attempt to duplicate the conditions of Sneen and Matheny (5) a suspension was prepared of 1.6 g of 2-methyl-2-pentanol, 5.10 g of yellow mercuric oxide, and 2.37 g of silver oxide in 30 ml of dry pentane. To the stirred mixture in dim light, 1.0 g of bromine was added. The temperature of the mixture rose to 35° due to heat of reaction. After 10 mins stirring the mixture was filtered and the salts washed with pentane. The bulk of the solvent was removed by distillation. Both the distillate (*A*) and residue (*B*) contained carbonyl compounds (i.r.). The carbonyl compound in the distillate (*A*) was converted to its *p*-nitrophenylhydrazone by addition of 1.4 g of *p*-nitrophenylhydrazine, 20 ml of acetonitrile, 20 ml of ethanol, and 4 drops of acetic acid, then refluxing the solution for 1 h. The solvents were removed and the derivative purified as described in the silver catalyzed reaction. It proved to be 325 mg of quite pure acetone *p*-nitrophenylhydrazone (two 3H singlets at δ 1.98 and 2.13).

The residue (*B*) gave an i.r. band at 1050 cm^{-1} (C—O—C) and had n.m.r. signals characteristic of 2,2-dimethyltetrahydrofuran (δ 1.25 (singlet), 3.92 (triplet, J = 6.5 Hz)).

(2) The above reaction was repeated, except that the bromine was added slowly while the temperature was kept below 5 °C. After 10 min the solution was filtered. The filtrate did not show any —OH or C=O stretching bands in the i.r., nor the characteristic C—O—C band, hence the product was apparently 2-methylpent-2-yl hypobromite.

The solution was then refluxed in the dark until colorless (15 min), at which time no hypobromite remained (iodimetry). The i.r. spectrum now showed bands at *ca.* 3200 (OH), 1720, and a very weak band at 1056 cm^{-1}. The solution was divided into two equal parts.

From one part, the solvent was removed at 0° under 20 mm pressure. The residue contained 5-bromo-2-methylpentan-2-ol as indicated by n.m.r. signals at δ 3.53 (triplet, J = 6.5 Hz) and 1.28 (singlet) in the ratio 1:3 and a pair of peaks with equal intensity at *m/e* 162 and 164 (M^+-H_2O) in its mass spectrum. The presence of 5,5-dibromo-2-methylpentan-2-ol was indicated by an n.m.r. triplet at δ 5.90 (J = 6 Hz).

To the other part was added 1.2 g of silver oxide and the mixture stirred at room temperature for 10 min. The i.r. spectrum of the solution now had bands at *ca.* 3450 cm^{-1} (weaker) while one at 1050 cm^{-1} (C—O—C) had become very strong. Stirring for 4 h effected no further marked change in the spectrum.

After filtration, the solution was passed through a column of 14 g of alumina, activity IV. The substance eluted with pentane was very volatile, some passed with the pentane when this was distilled through a short Vigreux column. The residue (312 mg) which still contained a little pentane had spectra characteristic of 2,2-dimethyltetrahydrofuran (ν_{max}(pentane) 1050 cm^{-1}; n.m.r signals at δ 1.25 (singlet) and 3.9 (triplet, J = 7 Hz) in the ratio 3:1).

Action of Silver on 1-Methylcyclopentyl Hypochlorite

A solution of 2.5 g (25 mmol) of 1-methylcyclopentanol and 5.7 ml of acetic acid in 10 ml of acetonitrile was added slowly with stirring in the dark to 50 ml of ice-cold 11.6% aqueous sodium hypochlorite solution. After 45 min stirring at 0°, the mixture was diluted with cold water and extracted twice with pentane. The pentane solution was washed with 3 20 ml portions of 3% sodium bicarbonate solution then with water. The dried pentane solution contained 20.2 mmol of hypochlorite. Its i.r. spectrum showed the absence of alcohol, but a weak carbonyl band was present at 1720 cm^{-1}.

Moist Tollens' silver, freshly prepared from 3.98 g of silver nitrate, was added over 20 min under dry nitrogen in semi-darkness to a stirred solution of 14.2 mmol of the hypochlorite in 40 ml of acetonitrile. The hypochlorite was completely destroyed in less than 0.5 h (a blank run without silver showed no reaction under these conditions).

The solution was filtered. The filtrate was reduced to small volume under reduced pressure, then the residual liquid distilled over a short path under 15 mm pressure. The first fraction of 0.21 g (bath up to 70°) was a mixture of 1-methylcyclopentanol and 6-chlorohexan-2-one in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ratio 1:5 as estimated by g.l.c. (105°; retention time 105 and 375 s, respectively). The second fraction of 1.518 g was nearly pure 6-chlorohexan-2-one (1% 1-methylcyclopentanol). The n.m.r. spectrum of the ketone had peaks at δ 1.78 (m, 4H), 2.18 (s, 3H), 2.53 (t, 2H, J = 6.5 Hz), 3.60 (t, 2H, J = 6.5 Hz). It was further characterized as its 2,4-dinitrophenylhydrazone, m.p. 80–81°, (lit. (17) m.p. 81.5°). The yield of the chloro ketone was estimated to be 1.77 g (13.2 mmol, 93%).

The silver chloride produced in the reaction weighed 0.21 g (1.47 mmol). Hence the ratio of ROCl/AgCl was approximately 9.7.

Action of Silver on 2-Phenylprop-2-yl Hypochlorite

A solution of 2.04 g of 2-phenylpropan-2-ol in 5 ml of acetonitrile was added to 50 ml of ice-cold sodium hypochlorite solution (chlorine bubbled into a solution of 9 g of sodium hydroxide in 50 ml of water until the pH reached 5). The mixture was stirred in an ice bath for 3 h then extracted with pentane. The dried pentane solution was concentrated under reduced pressure leaving a faintly yellow oil. This was dissolved in acetonitrile to make 25 ml of solution containing 13.4 mmol of hypochlorite and a trace of ketone (ν_{max} 1695 cm^{-1}).

Tollens' silver from 907 mg of silver nitrate was added to the stirred hypochlorite solution, maintained at 0–5° under nitrogen. After 0.25 h 32% of the hypochlorite had reacted; after 1 h, 53%; 2 h, 68%. The reaction was pushed to completion by addition of fresh silver. The remaining 21.5 ml of solution was filtered. To the filtrate was added 2.1 g of *p*-nitrophenylhydrazine. The mixture was maintained at *ca.* 80° for 1 h then the bulk of the solvent was removed under reduced pressure. The residue was taken up in methylene chloride and excess *p*-nitrophenylhydrazine removed by washing with dilute sulfuric acid, then with water. The methylene chloride was removed, and the residue boiled with hexane. The crystals were collected by filtration, giving 1.58 g, m.p. 165–175°. After two recrystallizations it had m.p. 181°. Its mixed m.p. with acetophenone *p*-nitrophenylhydrazone (184°) was 182° and their n.m.r. spectra were identical. There was no sign of acetone in the original reaction mixture (i.r.) or the *p*-nitrophenylhydrazone.

The hexane extract from the *p*-nitrophenylhydrazone contained 695 mg of oil whose n.m.r. and i.r. spectra showed it to be mainly 2-phenylpropan-2-ol.

The amount of silver chloride produced was 727 mg corresponding to an ROCl/AgCl ratio of approximately 2.4.

In a parallel run (1.2 g hypochlorite in 30 ml of acetonitrile) in which the weight ratio of hypochlorite to silver was 3.4 the reaction was very fast; 68% reacted in 0.5 h, 86% in 1 h. The chain length produced, as measured by silver chloride, was 4.5. Hence the reaction is sensitive, probably to traces of oxygen.

A blank run showed that the hypochlorite was only partially converted to ketone when left at 0° for 64 h.

Action of Silver on 1,1-Diphenylethyl Hypochlorite

A solution of 2.48 g of 1,1-diphenylethanol (12.5 mmol) in 10 ml of acetonitrile containing 2.4 ml of acetic acid was added dropwise to a stirred ice-cold 11% sodium hypochlorite solution (strongly basic) in diffuse light. The mixture was stirred at 0–5 °C for 45 min. It was then diluted with water and the product extracted into carbon tetrachloride. This was washed twice with 3% sodium bicarbonate solution. The dried solution ($MgSO_4$) had no OH stretching absorption and contained 12.5 mmol of hypochlorite (iodimetry). The solvent was removed under reduced pressure at 0–5 °C and the crystalline residue dissolved in 40 ml of acetonitrile.

Tollens' silver (acetonitrile washed) from 2.85 g of silver nitrate (16.8 mmol) was added in portions during 20 min to the stirred ice-cold solution of the hypochlorite under nitrogen in semi-darkness. The extent of reaction was: 0.5 h, 74%; 1 h, 78%; 2 h, 84%; 3.5 h, 86%. The reaction was pushed to completion by adding silver from 0.47 ml of silver nitrate, then the suspension was filtered. The g.l.c. examination of the filtrate showed the major products to be 1,1-diphenylethanol, acetophenone, and chlorobenzene. The solvent was removed under reduced pressure at 5 °C. The crystalline solid was recovered by filtration using pentane for washing. It proved to be 508 mg of 1,1-diphenylethanol. The pentane filtrate was passed through a column of 50 g of alumina, activity II. Forty-five milliliters of benzene eluate left an oil on evaporation at 0°. The g.l.c. showed the presence of chlorobenzene, acetophenone, and 1,1-diphenylethanol. Its n.m.r. spectrum had signals corresponding to the methyl groups of acetophenone (δ 2.5) and 1,1-diphenylethanol (δ 1.92) and to the presence of a trace of ω-chloroacetophenone (δ 4.6).

A second 45 ml of benzene eluted 0.417 g of 1,1-diphenylethanol, and 100 ml of benzene containing 5% of methanol eluted a further 0.55 of this carbinol.

The oil from the first benzene eluate was dissolved in 20 ml of ethanol containing 1 g of *p*-nitrophenylhydrazine. The solution was refluxed for 45 min then the solvent removed under reduced pressure. The residue was dissolved in methylene chloride. The solution was washed twice with 2 *N* sulfuric acid then four times with water. The dried solution was distilled, and the crystalline residue extracted repeatedly with boiling hexane. The insoluble material had m.p. 178–181° and mixed m.p. with acetophenone *p*-nitrophenylhydrazone 180–184°; yield 0.52 g (2.04 mmol). The hexane extracts yielded 0.138 g of 1,1-diphenylethanol.

The yield of once-recrystallized 1,1-diphenylethanol, m.p. 80–81°, was 1.29 g (6.5 mmol).

The amount of silver chloride produced in the reaction was 1.062 g (7.4 mmol). The ROCl/AgCl ratio was 1.7.

The yield of acetophenone, corrected for aliquots removed, was 22%. No benzophenone was detected among the products.

1-Adamantyl Hypobromite

Hypobromous acid was prepared from 1.05 g of bromine and 2.18 g of silver sulfate in 30 ml of water at 0–5 °C in semi-darkness. A solution of 765 mg of 1-adamantanol in 10 ml of methylene chloride was added and the mixture stirred in an ice bath. More solid silver sulfate was added at intervals during 1 h of stirring. The light brown organic layer was separated and the aqueous layer washed with more methylene chloride. Evaporation of the methylene chloride under reduced pressure left a pale brown crystalline residue. Iodimetry showed this to contain 4.2×10^{-3} mol of hypobromite (84%).

Action of Silver on 1-Adamantyl Hypobromite

A solution of 4.2×10^{-3} mol of hypobromite in 15 ml

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of acetonitrile was prepared. Its i.r. spectrum showed that only a trace of carbonyl compounds were present.

The solution was purged with nitrogen, then Tollens' silver from 1.25 g of silver nitrate (washed with acetonitrile) was added. After 0.5 h stirring at 0° under nitrogen, 98.5% of the hypobromite had reacted. After a further half hour of stirring the mixture was filtered and the solid washed with acetonitrile. The filtrate was taken to near dryness below room temperature under reduced pressure. The residue was dissolved in methylene chloride, then the solution washed with water, dried, and the solvent evaporated. The residue was adsorbed from benzene onto 17.5 g of silica gel. Benzene – methylene chloride mixture and methylene chloride eluted ketonic material and finally mixtures of ketone and alcohol. The total yield of ketone produced was estimated to be 33% (monobromo ketone). This was cyclized using excess sodium hydride in tetrahydrofuran at room temperature during 18 h. The product was passed in pentane solution through a column of 1 g of alumina, activity II. The pentane eluate was sublimed at temperatures up to 190°, 1 atm giving 136 mg of fairly pure protoadamantanone (**9**). Its identity was confirmed by t.l.c. and i.r. spectrum in comparison with authentic material. The precipitate contained 100 mg of nearly pure 1-adamantanol which was removed by a chloroform wash.

The silver bromide produced weighed 413 mg. The ratio of hypobromite reacted to silver bromide was 1.9.

Thermal Decomposition of 1-Adamantyl Hypobromite

A solution of 3.0 mmol of the hypobromite in 25 ml of acetonitrile was refluxed in semi-darkness under nitrogen. Decomposition was complete in 0.5 h. The solvent was removed under reduced pressure, leaving a residue of 940 mg whose i.r. spectrum showed the presence of hydroxyl and carbonyl groups. It was extracted twice with hot pentane. The pentane insoluble fraction (180 mg) contained 20.4% bromine, and appeared to be a mixture of brominated adamantanols.

The pentane-soluble products were adsorbed from methylene chloride onto 14 g of silica gel. Eluates (15 ml each) 1 and 2 gave 127 mg whose n.m.r. and i.r. spectrum showed it to be 3-bromomethylbicyclo[3.3.1]nonan-7-one (**8**, X = Br) and a component with ν_{max} 1730 cm^{-1} and extra n.m.r. signals at δ 4.18 (doublet) and 4.9 (doublet). Eluates 3–10 (325 mg) were nearly pure **8** (X = Br). Eluates 11–15 (methylene chloride – ether) contained some ketone but were rich in alcohols. Their bromine content was only 6.6%. The total yield of ketonic product (calculated as **8** (X = Br)) was 63% based on original hypobromite.

After removal of an analytic sample, fractions 3–10 were cyclized using sodium hydride (see preparation of protoadamantanone), giving 180 mg of sublimed crystalline product. By g.l.c. this contained 90% of protoadamantanone. The total possible yield of protoadamantanone was estimated to be 40%.

The decomposition of 1-adamantyl hypobromite in refluxing carbon tetrachloride was fast (0.5 h). The ratio of carbonyl absorption to CH stretching absorption in the i.r. spectrum of the total product showed the yield of **8** to be comparable to that in the thermal decomposition in acetonitrile.

*3-Bromomethylbicyclo[3.3.1]nonan-7-one(**8**, X = Br)*

After recrystallization from pentane this formed plates, m.p. 62–63°. It had $\nu_{max}(CHCl_3)$ 1705 cm^{-1} and n.m.r. signals at δ 3.23 (2H, doublet, J = 6.5 Hz), 2.75 to 1.5 (11H, multiplet), and 0.98 (2H, broad signal).

Anal. Calcd. for $C_{10}H_{15}BrO$: C, 51.97; H, 6.54; Br, 34.57. Found: C, 51.87; H, 6.47; Br, 34.90.

Tricyclo[4.3.1.$0^{3,8}$]decan-4-one (4-Protoadamantanone)

To a solution of 88 mg of 3-bromomethylbicyclo[3.3.1]-nonan-7-one in 5 ml of anhydrous tetrahydrofuran was added 50 mg of a 50% dispersion of sodium hydride in oil. The mixture was stirred overnight while protected from moisture and carbon dioxide. The suspension was filtered through Celite, and the solid washed with pentane. The residue after removal of the pentane was sublimed at 35–40° under 10^{-2} mm. The 53 mg of crystalline sublimate had m.p. 205–208° (sealed capillary). After removal of two minor impurities by t.l.c., recrystallization from pentane, and resublimation, it had m.p. 208–210°. It gave a parent ion with *m/e* 150, $\nu_{max}(CHCl_3)$ 1705^{-1} and an n.m.r. signal at δ 2.72 (approximately 2H) probably arising from the proton on C-3 and the equatorial proton on C-5.

Anal. Calcd. for $C_{10}H_{14}O$: C, 79.95; H. 9.39. Found: C, 79.78; H, 9.22.

1-Adamantyl Hypochlorite

1-Adamantanol (810 mg, 5.33 mmol) was dissolved in 10 ml of acetonitrile and 4 ml of acetic acid. The solution was added dropwise to 40 ml of a stirred ice-cold 11% solution of sodium hypochlorite in water (strongly alkaline) over the course of 15 min. The mixture was stirred vigorously at 0° in diffuse light for 1 h. The product was extracted into pentane and the pentane solution washed with water then twice with 3% sodium bicarbonate solution. After drying the pentane was evaporated, leaving a white solid. This was dissolved in 20 ml of acetonitrile. Its i.r. spectrum showed the presence of only a trace of carbonyl compound, but the carbonyl peak grew steadily in intensity in the i.r. beam. Iodimetry showed the presence of 4.84×10^{-3} mol (91%) of hypochlorite.

Action of Silver on 1-Adamantyl Hypochlorite

A solution of 4.8 mmol of the hypochlorite in 20 ml of acetonitrile was purged with nitrogen. Tollens' silver from 1.5 g of silver nitrate (washed with acetonitrile) was added and the mixture stirred under nitrogen in an ice bath. After 0.5 h no hypochlorite was left. The solids were removed by filtration and the solvent removed nearly completely under reduced pressure below room temperature. The residue was taken up in methylene chloride then the solution washed with water, dried, and distilled. The products were adsorbed from benzene onto 25 g of silica gel. Benzene – methylene chloride (1:1) eluted 329 mg of colorless oil which was the chloroketone **8** (X = Cl) contaminated with dichloroketone.

Anal. Calcd. for $C_{10}H_{15}ClO$: Cl, 18.99. Found: Cl, 23.4.

Methylene chloride eluted 44 mg of the chloroketone containing some alcohols. The total yield of chloroketones (calculated as **8**) was estimated to be 1.86 mmol (40.5%). Methanol in chloroform eluted 521 mg of crystalline alcohols. The chlorine content (12.7%) cor-

For personal use only.

responded to 67% of monochloroadamantanol in the mixture.

The yield of silver chloride (1.14 mmol) corresponded to a hypochlorite to silver chloride ratio of 4.

Thermal Decomposition of 1-Adamantyl Hypochlorite

(a) In Acetonitrile

A solution containing 3.36 mmol of the hypochlorite and 250 mg of adamantanol in 25 ml of acetonitrile was refluxed in dim light under nitrogen. After 0.5 h, 70% had reacted; 1.5 h, 83%; 2 h, 87%. The reaction was complete in 4 h. The solvent was removed under reduced pressure and the residue adsorbed from benzene onto 16 g of silica gel. The benzene eluates (50 ml) gave 66 mg of oil with $\nu_{max}(CH_2Cl_2)$ 1730 cm^{-1} and containing 37.3% chlorine. Methylene chloride eluted 381 mg of oil with ν_{max} 1705 cm^{-1} and an n.m.r. spectrum coincident with that of 3-chloromethylbicyclo[3.3.1]nonan-7-one. Further methylene chloride eluates (61 mg) were partly crystalline and contained considerable alcohol as well as the chloro ketone. The monochloroketone yield was estimated to be 64% based on starting hypochlorite. Methanol eluted 320 mg of crystalline alcohols containing 16.1% chlorine.

(b) In Carbon Tetrachloride

A solution of 3.9 mmol of the hypochlorite in 40 ml of carbon tetrachloride was refluxed under nitrogen. Decomposition was complete in 24 h.

(c) In Chlorobenzene

A solution of 2.94 mmol of the hypochlorite in 25 ml of chlorobenzene was heated at 110° under nitrogen. Decomposition was complete in 20 h. The products from both (*b*) and (*c*) after removal of solvents under reduced pressure gave i.r. spectra in methylene chloride with ν_{max}3600, 3420, and 1715 cm^{-1}. The relative intensity of the peaks was comparable to that for the crude product from the silver-initiated decomposition of the hypochlorite.

Photochemical Decomposition of 1-Adamantyl Hypochlorite

Nitrogen was bubbled for a few minutes through a solution of 2.3 mmol of the hypochlorite in 35 ml of carbon tetrachloride at 0 °C. The solution was then irradiated with light from a 100 W Hanovia high pressure mercury lamp filtered by a Corax sleeve. Decomposition was complete in less than 0.5 h. The solution now had i.r. absorption at 3600, 3370, and 1725 cm^{-1}. The intensity of the carbonyl absorption relative to the CH stretching absorption was less than that in the thermal or silver-initiated reactions in acetonitrile.

Comparable results were obtained when the hypochlorite was photolyzed at −10° in trichlorofluoromethane.

3-Chloromethylbicyclo[3.3.1]nonan-7-one

The colorless oil from thermal decomposition of 7 (X = Cl) was distilled over a short path under 10^{-2} mm at a bath temperature of 60°. It had $\nu_{max}(CH_2Cl_2)$ 1705 cm^{-1} and gave n.m.r. signals at δ 3.35 (2H doublet), 2.18–1.6 (11H mult.), and a broad 2H signal centered at δ 1.10.

Anal. Calcd. for $C_{10}H_{15}ClO$ (mol. ion *m/e* 186): C, 64.33, H, 8.10; Cl, 18.99. Found (186): C, 64.11; H, 7.92; Cl, 19.18.

The chloro ketone cyclized smoothly when treated with sodium hydride in tetrahydrofuran at room temperature (see cyclization of the bromo ketone). From 350 mg of the crude chloro ketone from the thermal reaction 186 mg of crude 4-protoadamantanone was obtained. The g.l.c. showed this to be over 90% pure. The contaminant was a chloro ketone as shown by analysis (1.4% chlorine).

We are grateful to the Consiglio Nazionale delle Ricerche (Rome) for fellowship support. We thank Mr. H. Seguin for analyses and Mr. M. Lesage for assistance with g.l.c.

Eistert's Methyl Enol Ethers of Acetylacetone

DENNIS V. C. AWANG
Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada

Received April 5, 1971

The configuration and conformation of the two isomeric methyl enol ethers of acetylacetone (**1**) have been unequivocally demonstrated. The n.m.r. solvent shift data and observation of nuclear Overhauser effects support an s-*cis* conformation for the more stable isomer **2** bearing acetyl *trans* to methoxyl while indicating an s-*trans* conformation for the less stable enol ether **3** having acetyl *cis* to methoxyl. The facile acid-catalyzed isomerization of **3** to **2** apparently proceeds by reversible protonation of carbonyl oxygen since no deuterium incorporation is observed when the isomerization is performed in acetic acid-d_4.

La configuration et la conformation des deux éthers méthyl énoliques de l'acétylacétone (**1**) ont été démontrées sans ambiguité possible. La r.m.n., les données relatives aux déplacements chimiques par les solvants ainsi que l'observation de l'effet nucléaire Overhauser confirment une conformation s-*cis* pour l'isomère le plus stable (**2**) ayant le groupe acétyle en position *trans* par rapport au groupement méthoxyle. Une conformation s-*trans* est attribuée à l'éther énolique le moins stable (**3**) ayant le groupe acétyle en position *cis* par rapport au groupe méthoxyle. L'isomérisation acido-catalysée très facile de **3** en **2** procède apparemment par une protonation réversible de l'oxygène du carbonyle puisqu'aucune incorporation de deutérium n'est observée lorsque l'isomérisation est effectuée dans l'acide acétique-d_4.

Canadian Journal of Chemistry, 49, 2672 (1971)

Eistert *et al.* (1) by careful manipulation, were able to isolate from the reaction of acetylacetone (**1**) and diazomethane in absolute ether, two compounds which they designated "*cis*"- and "*trans*"-methyl enol ethers. On the basis of qualitative rate data and the difference in chemical behavior of the two ethers towards ferric chloride and aqueous sodium hydroxide solutions it was concluded that the initially formed, higher-boiling enol ether was the "*cis*" isomer; the latter was transformed into the low-boiling "*trans*" isomer at a rate dependent upon conditions. The mechanism suggested by these workers for the reaction of **1** with diazomethane involves methylation of the s-*cis* enol **1***a*, but while this implies initial formation of an enol ether bearing acetyl *cis* to methoxyl and in the s-*cis* conformation, the question of conformation of the material isolated was not specifically addressed; no direct reference was made to the structure of their "*trans*" enol ether.

Recently (2) it has been noted that the less stable isomer, also referred to as "*cis*", can be converted to the more stable "*trans*" isomer by heating. It was reported also that the n.m.r. signal for the vinylic proton of the "*cis*" isomer appears at higher field than that of the "*trans*"; but neither the conditions under which the spectra were observed nor the chemical shifts of the other protons in the molecules were recorded.

Results and Discussion

The results here communicated firmly establish that the ethers of Eistert *et al.* are *cis–trans* configurational isomers and that the *configuration* of their "*cis*" isomer is as was then suggested. The conformation of the latter isomer as well as the configuration and conformation of their "*trans*" isomer have also been elucidated.

The stable isomer (**2**) was the only enol ether observed when **1** was methylated using dimethylsulfate or methanol – sulfuric acid. The unstable isomer (**3**) is the exclusive *primary* product of the diazomethane reaction. Attempted distillation of crude **3** at atmospheric pressure resulted in quantitative conversion to **2**, although **3** could be purified without isomerization by careful distillation under reduced pressure.

Relatively free rotation about the central bond of the α,β-unsaturated ketone system affords enol ethers **2** and **3** a choice of s-*cis* and s-*trans* conformations, as illustrated in Scheme 1. By analogy with mesityl oxide, whose conformation has been established by a variety of approaches (4), **2** may reasonably be expected to exist predominantly in the s-*cis* conformation **2***a*. However, a survey of the literature reveals no precedent which dictates the choice of conformation for **3**.

The conformation and configuration of the two enol ethers are dramatically portrayed by the solvent-induced chemical shifts (Table 1) ob-

TABLE 1. Chemical shifts induced in the n.m.r. signals of the methyl enol ethers of acetylacetone and dimedone by aromatic solvents

Compound	$\Delta_{aromatic}^{CCl_4}$ (p.p.m.)	=CH	=CCH	OCH	COCH

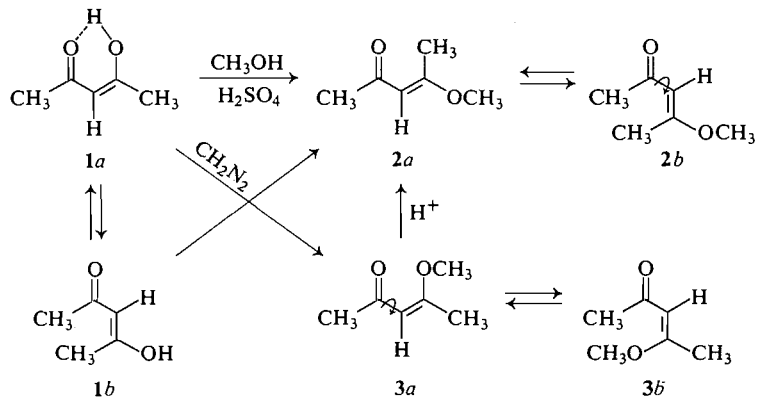
*See ref. 9.
†The *gem*-dimethyl proton signal suffers shifts of +0.12 and +0.13 p.p.m. on passing to solution in benzene and pyridine, respectively.



SCHEME 1

served in the n.m.r. spectrum on passing from dilute solution in carbon tetrachloride to dilute solution in benzene or pyridine ($\Delta = \delta_{CCl_4} - \delta_{aromatic}$ p.p.m.); the signs and magnitudes of the observed shifts are in accord with the generalization, well established for α,β-unsaturated ketones, that the signals of protons lying behind a reference plane[1] suffer positive shifts whereas those of protons in front of the plane undergo negative shifts and those of protons close to the plane exhibit very small and variable shifts (4, 5).

For ether **2**, the large and positive values of $\Delta_{C_6H_6}^{CCl_4}$ for the methoxy and vinylic proton resonance signals, concomitant with an appreciable negative value for the allylic methyl proton signal are compatible only with s-*cis* formulation **2***a*. By contrast, ether **3** exhibits positive values of $\Delta_{aromatic}^{CCl_4}$ for methoxyl and allylic methyl protons and negative values for its vinylic proton, consistent with its representation as the s-*trans* conformer **3***b*.[2]

The assignments of the signals for acetyl methyl and allylic protons made on the basis of line width[3] are reinforced by observation of the chemical shifts induced on passing from dilute solution in carbon tetrachloride to dilute solution

[1]Perpendicular to the αC—CO—α′C plane, through the carbonyl carbon atom for benzene-induced shifts and through the α-carbon atoms in the case of pyridine-induced shifts.

[2]Note that for **3** the benzene-induced shifts are appreciably greater on the positive side of the reference plane, whereas the emphasis is reversed in the case of pyridine hifts. Also, compared with ether **3**, the shifts induced by pyridine in the protons of **2** are neither as decidedly different nor as obviously rationalized; this is possibly a consequence of interference with solvent complexing at carbonyl by the ether grouping which is closer to the "collision plane" in **2**. These observations suggest that pyridine-induced shifts should be regarded with rather greater caution than benzene-induced shifts when used in the diagnosis of conformational attitudes.

[3]Although neither *cis* nor *trans* coupling constants for vinylic-allylic proton interaction, clearly observed in mesityl oxide (J = 1.2, 1.4 Hz) (3), could be ascertained for these enol ethers, appreciable broadening of the β-methyl signals, compared with those of the acetyl methyls, could be perceived.

TABLE 2. Chemical shifts induced in the n.m.r. signals of the methyl enol ethers of acetylacetone and dimedone by "proton-donating" solvents

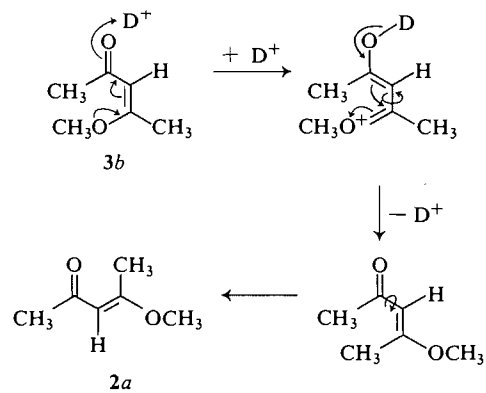
Compound	$\Delta_{CDCl_3}^{CCl_4}$ or $\Delta_{CH_3OH}^{CCl_4}$ (p.p.m.)	=CH	=CCH	OCH	COCH
2*a*	$CDCl_3$	−0.10	−0.07	−0.03	−0.10
	CH_3OH	−0.23	−0.04	−0.05	−0.10
3*b*	$CDCl_3$	−0.15	−0.02	−0.20	−0.10
	CH_3OH	−0.19	−0.07	−0.25	−0.09
Methyl enol ether of dimedone	$CDCl_3$	−0.13	−0.08	0.00	−0.13
	CH_3OH	−0.18	−0.12	−0.05	−0.13

in "proton-donating" solvents (Table 2). These effects although not as dramatic as those observed on passing to aromatic solvents can be rationalized using the generalization that the magnitude of the chemical shift (resulting from association of solvent with carbonyl oxygen) is inversely proportional to the distance by which the proton is separated from the carbonyl oxygen atom.[4] The large anomalous effect observed for the methoxy protons of **3***b* is imputed to participation of a lone pair on methoxyl oxygen in neutralization of positive charge generated at the carbonyl carbon atom; this observation also argues against structure **2***b*.[5]

The configurations of ethers **2** and **3** are further confirmed by observation of nuclear Overhauser effects (n.O.e.'s) (7). Irradiation of the methoxyl and acetyl protons of **2** results in 30 and 12% increases, respectively, in the integrated intensity of the vinylic proton signal while no such enhancement occurs upon irradiation of the allylic methyl protons; in sharp contrast, irradiation of the methoxyl protons produced no appreciable change in the integrated intensity of the signal for the vinylic proton of ether **3**, but irradiation of its allylic and acetyl methyl protons effected increases of 20 and 13% respectively.

The formation of enol ether **3** is readily rationalized on the basis of a mechanism involving methylation of the s-*cis* enol of acetylacetone **1***a* (8). Loss of the enolic proton would expose the carbonyl and enolic oxygen atoms to the unshielded mutual repulsion of their respective lone pairs; rotation about the carbonyl to olefinic bond produces the more stable s-*trans* conformation **3***b*, a reversal of the order of stability of s-*cis* and s-*trans* isomers which obtains when methoxyl is replaced by methyl (in mesityl oxide).

It has not been possible to assess the importance of the intermediacy of either s-*trans* enol **1***b* or ether **3** in the formation of **2** by the other methods of methylation.



SCHEME 2

The isomerization of **3** and **2** is acid-catalyzed, quantitative conversion occurring within seconds at the probe temperature of the n.m.r. spectrometer (40 °C), when a few crystals of *p*-toluenesulfonic acid are added to a 10% chloroform-*d*

[4]Shifts induced by trifluoroacetic acid, usually helpful in making such assignments, could not be determined for these enol ethers since they were readily degraded by the acid at the probe temperature of the spectrometer.

[5]It should be noted that although appearance of the n.m.r. signal for the vinylic proton of **2** at lower field than that of **3** (Δ = 0.44 p.p.m.) is consistent with deshielding of the former proton due to the anisotropic effect of a *cis* enoxy group (6) an accurate assessment of the magnitude of this effect cannot be made. The major contribution to the difference in chemical shift is probably due to the change in the anisotropic effect of the carbonyl group brought about by purely conformational change: for example, in carbon tetrachloride, the signal for the vinylic proton of mesityl oxide appears at 0.33 and 0.30 p.p.m., respectively, downfield from that of isophorone and 3-methylcyclohex-2-enone.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solution of **3**. The mechanism of this acid-catalyzed isomerization is probably that illustrated in Scheme 2 since isomerization in acetic acid-d_4[6] does not lead to any detectable deuterium incorporation: mechanisms involving the intermediacy of enol or the protonation of the olefinic bond would result in reduction and enhancement, respectively, of the ratio of integrated intensities of methyl to vinylic proton signals in the n.m.r. spectrum.

Experimental

The n.m.r. spectra were recorded using a Varian A-60A spectrometer; spectral grade solvents containing tetramethylsilane (TMS) as internal reference were employed in all cases. The i.r. spectra were obtained with a Perkin–Elmer Model 621 spectrophotometer, and u.v. spectra on a Beckman DB spectrophotometer.

Enol Ether 3

An ice-cold ethereal-alcoholic solution (0.36 M, 100 ml) of diazomethane (Diazald) was added in one portion to 3 g (0.03 mol) of acetylacetone. The solution was magnetically stirred in the dark at room temperature overnight (approximately 16 h), dried over anhydrous potassium carbonate, and solvent removed under reduced pressure below 40 °C. The residue consisted of enol ether **3** better than 95% pure by n.m.r. The ether was purified by distillation under reduced pressure, b.p. 56–58°/3.5 mm; spectral characteristics for **3** are: n.m.r. (CCl_4, internal TMS) δ 4.96 (s, 1H), 3.80 (s, 3H, OCH_3), 2.13 (s, 3H, $—COCH_3$), 2.00 (s, 3H, $=CCH_3$) p.p.m.; i.r. (neat) ν 1650, 1615 (C=), 1075 (C—O—C) cm^{-1}; u.v. (95% EtOH) λ_{max} 260 nm (ε 10 910).

Enol Ether 2

Distillation at atmospheric pressure of the residue from methylation yielded pure **2**, b.p. 162–164°/758 mm. Spectral characteristics for **2** are: n.m.r. (CCl_4, internal TMS) δ 5.40 (s, 1H), 3.61 (s, 3H, OCH_3), 2.18 (s, 3H, $=CCH_3$), 2.03 (s, 3H, $—COCH_3$) p.p.m.; i.r. (neat) ν 1680, 1580 (C=), 1070 (C—O—C) cm^{-1}; u.v. (95% EtOH) λ_{max} 250 nm (ε 13 700).

[6]Isomerization takes place during minutes at 40 °C; a singlet due to ether **3** can be observed at δ 5.27 (**2** at δ 5.62) which disappears during the time taken for a second n.m.r. scan.

The author acknowledges the technical assistance of Mr. A. Vincent and is grateful to Mr. H. W. Avdovich for recording the 60 MHz n.m.r. spectra. Special thanks are due to Dr. R. A. Bell of McMaster University for examination of the n.O.e.'s. The counsel and assistance of Prof. J. W. ApSimon of Carleton University, as well as helpful discussions with my colleague Dr. W. L. Wilson, are also appreciated.

Synthetic Cardenolides and Related Products. II.[1] Lactams[2]

J. M. FERLAND, Y. LEFEBVRE, R. DINOI, AND R. DEGHENGHI
Ayerst Research Laboratories, Montreal, Quebec

Received March 25, 1971

On treatment of cardenolides with ammonia or methylamine two isomers are obtained, 21-amino-14β,21-oxidonorcholan-23-oic acid lactam and 21-amino-14β-hydroxy-16β,21-oxidonorcholan-23-oic acid lactam. The assignment of stereochemistry to each isomer is based on the n.m.r. spectra and the correlation with the structure of isodigitoxigenin or isogitoxigenin.

Les cardénolides réagissent avec l'ammoniaque ou la méthylamine pour conduire à deux isomères à savoir les lactames des acides amino-21 oxydo-14β,21 norcholanoïque-23 et amino-21 hydroxy-14β oxydo-16β,21 norcholanoïque-23. La stéréochimie de chaque isomère a été établie au moyen des spectres de r.m.n. et par corrélation avec la structure de l'isodigitoxigénine ou l'isogitoxigénine.

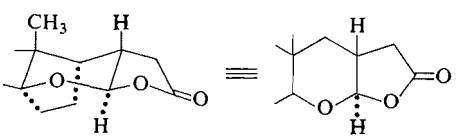
Canadian Journal of Chemistry, 49, 2676 (1971)

Naturally occurring cardenolides such as digitoxin and gitoxin or their aglycones were treated with ammonia or methylamine at room temperature to yield a lactol-amide (**5**). Two isomeric lactams (**A** and **B**), consistent with structure (**6**), were obtained when the lactol-amides were treated under acidic conditions or when cardenolides were heated in an autoclave at 110 °C. These isomers were separated only in the case of the aglycones (R = H or Ac).

As shown in Scheme 1 the same products were obtained by treating isodigitoxigenin (**4**) with ammonia or amines.

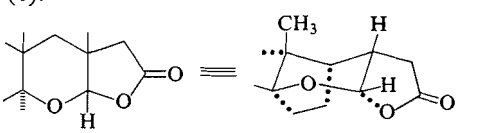
These results are not surprising in view of the acetal-type structure of isodigitoxigenin (3, 4) or in view of the great tendency of cardenolides to cyclize to the "iso-" form **4** in basic medium (5).

The stereochemistry of the predominant isodigitoxigenin (**4**) (R = R_2 = H) has been postulated on conformational grounds by Schindler and Reichstein (5) as having the 20(*S*), 21(*R*) fusion of the E/F rings (**7**).



7 [20(*S*),21(*R*)]

Our n.m.r. data, however, do not support the *trans* configuration.[3] The coupling constant *J* for the 21-proton is 5 Hz and consistent with an axial–equatorial angle of *ca.* 40° indicating a *cis* junction, which we describe as 20(*S*),21(*S*) (**8**)[4] (6).



8 [20(*S*),21(*S*)]

In order to prove that the product described as **8** possesses the more stable equatorial side chain and not the opposite *cis* conformation, the following experiments were performed. Isodigitoxigenin (**4**) was converted into the known ester **11***b* according to the method described by Jacobs and Gustus (7) (Scheme 2).

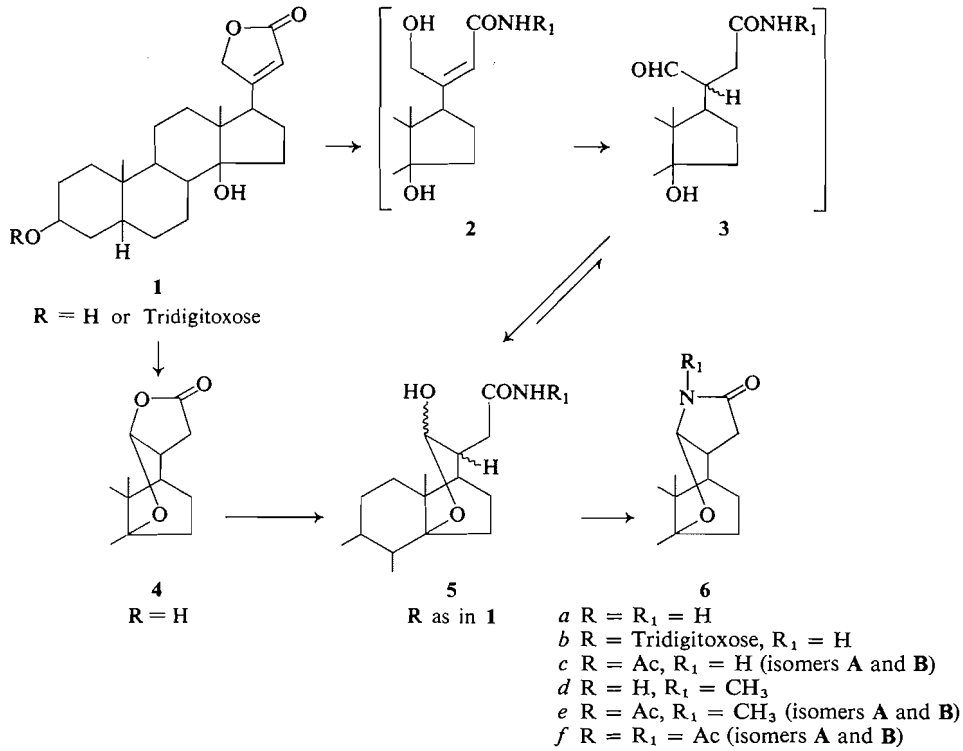
Under acidic conditions one would expect to lose control of the stereochemistry at C-21 going through the carboxonium ion **10** but not at C-20. The lactol-ester (**11***b*), isolated in low yield, has now a half-width (*w*/2) of 14 Hz indicating a *trans*-diaxial configuration of the 20–21 protons. Moreover, its mutarotation in

[1]See ref. 1.

[2]The work described in this paper was presented in part at the 155th A.C.S. Meeting, San Francisco. California, April 5, 1968. Abstract Papers A.C.S. No. 155, 69N (1968), and at the 6th International Symposium on the Chemistry of Natural Products, Mexico, April 22, 1969 (2).

[3]The *trans* junction of the lactone ring in α-santonin, as a classical example, shows a coupling constant of *J* = 11 Hz for the C-1 proton.

[4]The same conclusion was drawn by Pettit *et al.* (6) using the coupling constant.



SCHEME 1

THF–water containing a trace of hydrochloric acid (α_D +5.7 increasing to 10.4°) is consistent with the epimerization of an equatorial alcohol to an axial one (8). Reacidification of the lactol-acid **11***a* regenerates isodigitoxigenin (**4**) in excellent yield. Carbon-20 must be equatorial, and it follows structure 20(*S*),21(*S*) for isodigitoxigenin accepting the physical data cited above.

The major lactam "**A**" isolated in 25% yield (**6***c*), has a coupling constant $J = 6$ Hz for the C-21 proton (axial–equatorial) and we assign the same *cis*-structure 20(*S*),21(*R*) (**13**) present in isodigitoxigenin.[5] The minor lactam "**B**" (**6***c*) (3% yield) has a half-width $w/2 = 6$ Hz for the C-21 proton and therefore must possess the alternative *cis* configuration 20(*R*),21(*S*) (**14**) as indicated in Scheme 3 (9).

The lactamization must occur from **5** through the carboxonium ion **12** to **13** and **14**. Additional evidence for the structure of the minor lactam **14** is provided by a deshielding of the C-18 protons (1.12 p.p.m.) while C-18 of **13** absorb at 1.0 p.p.m. due to proximity of the lactam function. Partial formation of the less stable axial side chain during the shift of the double bond from **2** to **3** or epimerization at C-20 of the intermediate amine-aldehyde **3** followed by lactamization are the probable mechanisms of the formation of this minor isomer.

An analogous reaction took place with gitoxigenin (**15**), which possesses a 16β-hydroxyl function, when similarly treated with methyl amine (Scheme 4).

A major and a minor isomer (**A** and **B**) were isolated in a 10/1 ratio. Similar lactamizations are reported by Barton *et al.* (3) in their paper on the diterpenoid bitter principle clerodin,

[5]Katzung *et al.* (9) have repeated our work and assigned *trans*-structure 20(*S*),21(*S*) to our *cis* product **13** and *cis*-structure 20(*S*),21(*R*) to the alternative *cis* (**14**) in agreement with our earlier communication in San Francisco (1*c*) but not consistent with our later (2) and present analysis.

and more recently by German workers (4) who describe the bicyclic system hexahydrofuro-[2,3*b*]pyrrol-2-one. Clearly, only the two *cis* structures are possible (Scheme 5).

The major isomer is assigned the 20(*S*),21(*R*) structure **18** on steric grounds; a strong interaction is found in the minor isomer **19** between the 18-angular methyl group and the CH_2 at C-22. The 21-proton coupling constant is $J = 5$ and 6 Hz respectively as expected for a *cis*-junction.

Experimental[6]

3β-Acetoxy-21-amino-14β,21-oxidonorcholan-23-oic Acid Lactams (6c)

Procedure A

Digitoxigenin (9.6 g) in methanol (500 ml) was saturated with dry ammonia at 0 °C. It was then heated at 110 °C in a Paar bomb apparatus for 24 h. After cooling, the solution was evaporated and the solid obtained, dissolved in ethanol (500 ml) and sulfuric acid 2% in water (50 ml) and refluxed for 2 h. The alcohol was evaporated to one quarter of its initial volume and poured into ice-cold water. The solid appearing was filtered, washed with water, and dried to give the crude 3β-hydroxy title compound, m.p. 254–256 °C (6.9 g).

The crude lactams (6.9 g) were acetylated in pyridine (70 ml) and acetic anhydride (35 ml) overnight. The solution was poured into ice-cold water and the solid obtained, filtered, washed with water, and dried. The crude acetates (6.9 g) were chromatographed on silica gel (300 ml fractions collected). Both isomers were eluted with a mixture of methylene chloride – ethyl acetate (45/55). The fractions containing mainly the more polar isomer (as shown by t.l.c.) were combined and crystallized from methylene chloride – ether to give 2.3 g of the analytical sample of isomer **13**, *3β-acetoxy-21-amino-14β,20(S),21(R)-oxidonorcholan-23-oic acid lactam*, m.p. 256–258 °C, $[\alpha]_D$ ($CHCl_3$) −35.8°.

Anal. Calcd. for $C_{25}H_{37}NO_4$: C, 72.26; H, 8.97; N, 3.37. Found: C, 72.07; H, 8.82; N, 3.35.

The i.r.: ν_{max}($CHCl_3$) 3400, 3200, 1710, and 1690 cm^{-1}; n.m.r. ($CDCl_3$): 5.47 (21H, $J = 5$ Hz doublet), 1.0 (C-18 and -19 CH_3), 6.56 p.p.m. (N—H).

[6]Melting points are uncorrected. The i.r. spectra were taken on a Perkin–Elmer 21 apparatus and n.m.r. were recorded on a Varian A-60-A spectrometer operating at 60 MHz/s; TMS was used as internal standard. Grace Davidson silica gel was used.

The richer fractions in the less polar isomer (as shown by t.l.c.) were combined and crystallized from methylene chloride – ether to give 0.210 g of the analytical sample of isomer **14**, *3β-acetoxy-21-amino-14β,20(R),21(S)-oxidonorcholan-23-oic acid lactam*, m.p. 227–229 °C, $[\alpha]_D$ ($CHCl_3$) −28.6°.

Anal. Calcd. for $C_{25}H_{37}NO_4$: C, 72.26; H, 8.97; N, 3.37. Found: C, 71.97; H, 8.87; N, 3.37.

The i.r.: ν_{max}($CHCl_3$) 3400, 3200, 1710, and 1690 cm^{-1}; n.m.r. ($CDCl_3$): 5.28 (C-21 H, $w/2 = 6$ Hz), 1.12 (C-18 CH_3), 1.0 (C-19 CH_3), and 6.56 p.p.m. (N–H).

Procedure B

A solution of digitoxigenin (3.0 g) in methanol (50 ml) and water (1 ml) was saturated with ammonia at 0 °C. The well-stoppered flask was left at room temperature for 8 days. The solid which had deposited (1.6 g) was filtered and dried to give the crude *3β-hydroxy-14β,21-oxido-21-hydroxy-norcholan-23-oic acid amide* (**5**), m.p. 259–262 °C.

The crude amide was refluxed in ethanol (160 ml) containing sulfuric acid 2% (16 ml) for 2 h. It was acetylated and chromatographed as in procedure A. Both products isolated were identical in all respects to the two isomers isolated in procedure A.

Procedure C

A suspension of isodigitoxigenin (1.0 g) in methanol (100 ml) was saturated with dry ammonia at 0 °C. It was treated as in procedure A and the isomers isolated were in all respects identical with products isolated in procedure A.

3β-Tridigitosyl-14β,21-oxido-21-amino-norcholan-23-oic Acid Lactam (6b)

A solution of digitoxin (2.0 g) in methanol (120 ml) was saturated with dry ammonia at 0 °C. It was then heated at 110 °C in a Paar bomb for 16 h. The solution was evaporated under vacuum to one half of its initial volume, acidified with 0.1 *N* sulfuric acid, and poured into water. The solid appearing was filtered, washed with water and taken into chloroform. The organic solution was dried and evaporated. The crude product was crystallized three times from methylene chloride – ether to give 400 mg. The analytical sample was obtained after one more recrystallization from the same solvents, m.p. 244–246 °C, $[\alpha]_D$ ($CHCl_3$) −6.7.

Anal. Calcd. for $C_{41}H_{65}NO_{12}$: C, 64.46; H, 8.57; N, 1.82. Found: C, 64.37; H, 8.59; N, 1.77.

The i.r.: ν_{max}($CHCl_3$) 3400 and 1690 cm^{-1}.

3β-Hydroxy-20(S),21(R)-(N-acetylamino)-14β,21-oxidonorcholan-23-oic Acid Lactam-3-acetate (6f) (Isomer 13)

A solution of lactam-3-acetate (isomer **13**) (0.300 g) in pyridine (3 ml) and acetic anhydride (3 ml) was heated for 16 h on the steam bath. After cooling, the solution was poured onto ice-cold water and the solid obtained filtered, washed with water, dried, and chromatographed on silica gel. The fractions eluted (0.260 g) with 25% ethyl acetate in methylene chloride were crystallized from ether, m.p. 221–223 °C, $[\alpha]_D$ ($CHCl_3$) −81.5°.

Anal. Calcd. for $C_{27}H_{39}NO_5$: C, 70.87; H, 8.50; N, 3.06. Found: C, 71.37; H, 8.13; N, 3.15.

The i.r.: $\nu_{max}(CHCl_3)$ 1720 and 1110 cm^{-1}; n.m.r. ($CDCl_3$): 5.85 (C-21 H, doublet J = 7 Hz), 1.07 (C-18 CH_3) 1.00 (C-19 CH_3), 2.47 p.p.m. (N—Ac).

3β-Hydroxy-20(R),21(S)-(N-acetylamino)-14β,21-oxidonorcholan-23-oic Acid Lactam-3-acetate (6f) (Isomer 14)

A solution of lactam-3-acetate (isomer **14**) (0.125 g) was acetylated as in the previous case and chromatographed. The fractions eluted with 6% ethyl acetate in methylene chloride (0.070) were crystallized from ether, m.p. 208–210 °C, $[\alpha]_D$ ($CHCl_3$) +33.9°.

Anal. Calcd. for $C_{27}H_{39}NO_5$: C, 70.87; H, 8.59; N, 3.06. Found: C, 70.91; H, 8.67; N, 3.22.

The i.r.: $\nu_{max}(CHCl_3)$ 1720 and 1110 cm^{-1}; n.m.r.: 5.85 (C-21 H, doublet J = 7 Hz), 1.12 (C-18 Me), 0.93 (C-19 CH_3), 2.47 p.p.m. (N—Ac).

3β-Acetoxy-21-(N-methylamino)-14β,21-oxidonorcholan-23-oic Acid Lactam (6e)

A solution of digitoxigenin (2.6 g) in methanol (70 ml) saturated at 0 °C with methylamine was left in a well-stoppered flask at room temperature for 40 h. The solvent was then evaporated and the solid obtained refluxed in ethanol (100 ml) and sulfuric acid 2% (10 ml) for 2 h. The alcohol was evaporated to one quarter of its initial volume and poured into ice-cold water. The solid appearing was filtered, washed with water to leave the crude *3β-hydroxy-21-(N-methylamino)-14β,21-oxidonorcholan-23-oic acid lactam* (**6d**) (2.6 g).

This crude alcohol (1.0 g) was acetylated and chromatographed as in procedure A. Two isomers were eluted in methylene chloride – ether 50/50. The richer fractions in the less polar isomer (as shown by t.l.c.) were combined and crystallized twice from methylene chloride – ether to give the pure *3β-acetoxy-20(R),21(S)-(N-methylamino)-14β,21-oxidonorcholan-23-oic acid lactam* (6*e*) (0.030 g) (isomer **13**), m.p. 242–244 °C, $[\alpha]_D$ ($CHCl_3$) −26.8°.

Anal. Calcd. for $C_{26}H_{39}NO_4$: C, 72.69; H, 9.15; N, 3.26. Found: C, 72.44; H, 8.99; N, 3.53.

The i.r.: $\nu_{max}(CHCl_3)$ 1720, 1675, 1255, 1088, and 1020 cm^{-1}; n.m.r. ($CDCl_3$): 5.1 (C-21 H, doublet J = 6 Hz), 1.05 (C-18 Me), 1.02 (C-19 Me), 2.80 p.p.m. (N—CH_3).

The richer fractions in the more polar isomer (as shown by t.l.c.) were combined and crystallized twice from methylene chloride – ether to give the pure *3β-acetoxy-20(S),21(R)-(N-methylamino)-14β,21-oxidonorcholan-23-oic acid lactam* (**6e**) (isomer **14**) (0.600 g), m.p. 212–214 °C, $[\alpha]_D$($CHCl_3$) −33.8°.

Anal. Calcd. for $C_{26}H_{39}NO_4$: C, 72.69; H, 9.15; N, 3.26. Found: C, 72.61; H, 8.95; N, 3.37.

The i.r.: $\nu_{max}(CHCl_3)$ 1720, 1675, 1255, 1082, and 1020 cm^{-1}; n.m.r. ($CDCl_3$): 5.1 (C-21 H, doublet J = 6 Hz), 1.05 (C-18 Me), 1.00 (C-19 Me), 2.88 p.p.m. (N—CH_3).

3β,14β-Dihydroxy-21-(N-methylamino)-16β,21-oxidonorcholan-23-oic Acid Lactam (16)

A solution of gitoxigenin (1.0 g) in methanol (100 ml) was saturated at 0 °C with dry methylamine and left in a well-stoppered flask at room temperature for 40 h. The solution was then evaporated and refluxed in methanol (60 ml) containing 0.1 *N* sulfuric acid (30 ml) for 15 min. After neutralization with pyridine, the solution was evaporated to one half of its initial volume, salt saturated and extracted with chloroform. The organic layer was washed with water, dried, and evaporated to leave the crude *3β,14β-dihydroxy-21-(N-methylamino)-16β,21-oxidonorcholan-23-oic acid lactam* (**16a**).

This alcohol was acetylated and chromatographed as in procedure A. The fractions eluted in methylene chloride – ethyl acetate (50/50) were combined and crystallized from methylene chloride – ether to give (0.250 g) the pure *3β,14β-dihydroxy-20(S),21(R)-(N-methylamino)-16β,21-oxidonorcholan-23-oic acid lactam acetate* (isomer **18**), m.p. 225–227 °C, $[\alpha]_D$ ($CHCl_3$) +23.9°.

Anal. Calcd. for $C_{26}H_{39}NO_5$: C, 70.08; H, 8.82; N, 3.14. Found: C, 69.76; H, 8.55; N, 3.15.

The i.r. $\nu_{max}(CHCl_3)$ 3600, 1720, and 1685 cm^{-1}; n.m.r. ($CDCl_3$): 5.0 (C-21 H, doublet J = 5 Hz), 1.05 (C-18 Me), 0.93 (C-19 Me), 2.42 (N—CH_3), 4.55 p.p.m. (C-16 H, triplet J = 7 Hz).

The fractions eluted with ethyl acetate were combined and crystallized several times from methylene chloride – ether to give (0.025 g) of the pure *3β,14β-dihydroxy-20(R),21(S)-(N-methylamino)-16β,21-oxidonorcholan-23-oic acid lactam acetate* (isomer **19**), m.p. 274–276 °C, $[\alpha]_D$ ($CHCl_3$) −28.5°.

Anal. Calcd. for $C_{26}H_{39}NO_5$: C, 70.08; H, 8.82; N, 3.14. Found C, 70.37; H, 9.03; N, 3.43.

The i.r.: $\nu_{max}(CHCl_3)$ 3600, 1720, and 1685 cm^{-1}; n.m.r. ($CDCl_3$): 5.38 (C-21 H, doublet J = 6), 1.08 (C-18 Me), 0.93 (C-19 Me), 2.81 (N—CH_3), 4.63 p.p.m. (C-16 H, triplet J = 7 Hz).

The authors wish to thank Dr. G. Schilling and his associates for analytical data and Mr. W. Turnbull for rotation measurements.

Electrolysis of α-Chloro- and α-Fluorocarboxylic Acids

PARKASH C. ARORA AND R. G. WOOLFORD
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received March 8, 1971

The electrolysis of α-chlorovaleric, α-chlorocaproic, and α-chloroisobutyric acids in methanol gave none of the Kolbe dimer; the main products were chloroester and hydrogen ester with aldehydes and acetals formed in lesser amounts. In water, straight chain α-chloroacids gave dimeric esters as the major product. However, Kolbe dimer was formed in fairly good yields together with small amounts of fluoro-ester and acetal, when α-fluorocaproic and α-fluoroheptanoic acids were electrolyzed in methanol. No Kolbe dimer was produced from 2-fluoro-2-ethylbutanoic and α-fluorophenylacetic acids; the corresponding ketone or aldehyde was the major product.

Les électrolyses dans le méthanol des acides α-chlorovalérique, α-chlorocaproïque, et α-chloroisobutyrique ne conduisent pas aux dimères de Kolbe; les produits principaux sont les chloro-esters et les hydrogénoesters; en plus petite quantité se forment des aldéhydes et des acétals. Dans l'eau, les α-chloroacides en chaine droite conduisent aux esters dimériques en tant que produits majoritaires. Cependant, dans l'électrolyse dans le méthanol des acides α-fluorocaproïque et α-fluoroheptanoïque, des dimères de Kolbe se forment avec un assez bon rendement avec toutefois de petites quantités de fluoro-esters et d'acétals.

Canadian Journal of Chemistry, 49, 2681 (1971)

In a previous paper (1) from this laboratory, the electrolysis of α-bromocarboxylic acids in methanol produced hydrogen ester and bromoester as major products. The results were regarded as the result of attack of an initial carboxy radical on the solvent. Reduction of C—Br to C—H in both the ester and acid occurred at the cathode with migration of Br^- to the anode and oxidation there to Br_2. Electrolysis experiments with branched chain α-bromoacids in water indicated production of carbonium ions. In all the acids studied, no Kolbe dimer was detected, nor were other possible products such as alcohols, ethers, and paraffins obtained. Hoping to understand better the electrochemical processes involved with α-halo substituents, the behavior of α-chloro- and α-fluorocarboxylic acids during Kolbe electrolysis was examined. It was anticipated especially that the smaller, more stable fluoro-substituent might allow dimer formation to occur. Conway and Dzieciuch (2) previously found that normal Kolbe coupling took place with trifluoroacetic acid; this reaction was the only previous example of successful coupling with an α-fluoro substituent present.

The electrolyses of α-chlorocarboxylic acids were carried out in methanol and water. The results of various electrolysis reactions of α-chlorovaleric, α-chlorocaproic, and α-chloroisobutyric acids in methanol (Scheme 1) are summarized in Table 1 and show that chloroester is the major organic product. Hydrogen ester is formed in low yields with the ratio of hydrogen ester to chloro ester increasing as the time of electrolysis is increased. The straight-chain α-chloroacids also produced acetals in low yield but this behavior was not observed with the branched-chain acid. It is probable that the corresponding acetal was formed from the branched-chain chloroacid, but because of volatility was lost under the experimental conditions used.

The presence of 1-chloropentane in trace amounts in the electrolysis products of α-chlorocaproic acid shows that, at least in part, radical

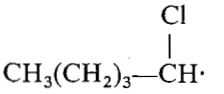
*Approximately 2% free aldehyde also isolated in these cases. Trace amounts of 1-chloropentane were also found.



was converted to saturated chloroalkane. Such behavior was not observed in the case of α-chlorovaleric or α-chloroisobutyric acid. Divided cell and control experiments for the chloroacids similar to those conducted for the bromoacids showed essentially the same results. Reduction of C—Cl to C—H occurred at the cathode, with Cl^- migration to the anode and formation there of Cl_2. Esterification occurred at the anode only, whereas some of the side products such as aldehydes and acetals were found in the cathode compartment. Control experiments on esterification (with no electrolysis) showed that prolonged heating of α-chloroacids in methanol produced very little (*ca.* 5–8%) ester.

In water, α-chlorovaleric and α-chlorocaproic acid (straight-chain acids) behaved differently from the analogous α-bromoacids. With the straight-chain chloroacids the major electrolysis product was 1′-chloro-1′-butyl 2-chloropentanoate (40%) from α-chlorovaleric acid and 1′-chloro-1′-pentyl 2-chlorohexanoate (38%) from α-chlorocaproic acid. Such esters were not isolated from α-bromoacids. No Kolbe dimer was detected, nor were other possible esters found (*i.e.* those in which one or two C—Cl → C—H conversions occurred); some unidentified high molecular weight compounds were also produced. The formation of esters in electrolysis reactions in water can be explained by combination of carboxy and alkyl radicals absorbed on the electrode surface and is consistent with mechanisms proposed by Troeger and Ewars (3) and Kaufler and Herzog (4). Alternatively a further oxidation of the alkyl radical could occur yielding the corresponding carbonium ion, which would give the same ester by combination with the initial carboxylate anion (Scheme 2). Carbonium ions are usually produced only when secondary or tertiary species can form (a good general discussion of radical and carbonium ion intermediates during Kolbe electrolysis may be found in recent work by Skell and coworkers (ref. 5 and articles cited therein) and by Eberson (6)). Perhaps in this case some stabilization by the resonance form $CH_3(CH_2)_n—CH{=}Cl^+$ may be involved. Such ester formation from a carbonium ion intermediate avoids the involvement of a carboxy radical which is known to have a short lifetime (*ca.* 10^{-9} s) in chemical processes, although it is believed to be longer-lived when absorbed on a platinum electrode. Lack of Kolbe dimer from these α-chloroacids would also be consistent with a carbonium ion species. The present results also indicate that the C—Cl bond is more stable than C—Br in the α-bromoacids and there is negligible or very little reduction of this C—Cl bond during electrolysis.

Electrolysis in water of α-chloroisobutyric acid (a branched-chain acid) produced mainly ketones rather than esters. Products obtained were acetone (18.3%), 1,1-dichloroacetone (2.4%), and 1,3-dichloroacetone (0.8%). As discussed for the bromo analog, it is likely that acetone was the major reaction product at the electrode but, being miscible in water and very volatile, either reacted further with chlorine or was lost in the exit gas stream. Some high molecular weight substances were also formed which could not be obtained pure. The similarity of products from electrolysis of α-chloroisobutyric acid in water and the corresponding α-bromoacid reported earlier (1) indicates that product formation can be interpreted in terms of the production of a carbonium ion $(CH_3)_2\overset{+}{C}—Cl$ which picks up OH^- from water with the ketone resulting.

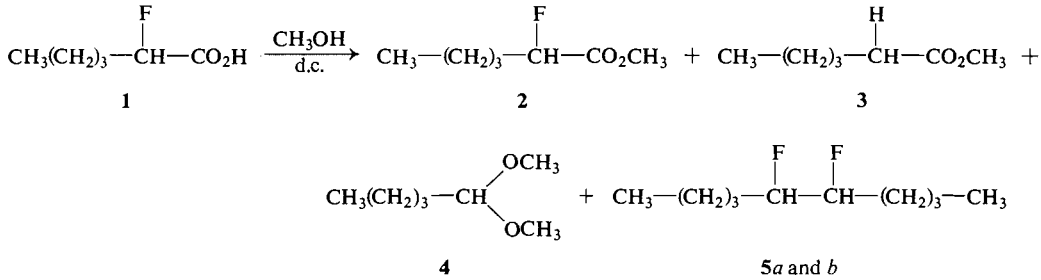
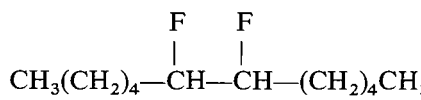


SCHEME 3

α-Bromo- and α-chloro-substituted acids did not produce normal Kolbe coupling reactions and while similar to some extent in their reactions, the chloro-substituent was not as easily lost by reduction to C—H. Therefore it seemed reasonable to ascertain if a halogen atom smaller in size would allow dimer formation (also a C—F bond would be expected to be even less easily converted to C—H). As a start, efforts were concentrated on α-fluorocaproic acid. The results of various electrolysis reactions of this fluoroacid in methanol are given in Table 2 and products are illustrated in Scheme 3.

Fluoroester **2** was produced in poor yield compared to the analogous chloroester and the acetal yield was variable. The major products were difluorides **5***a* and *b*. Both showed essentially identical n.m.r. absorption attributable to methyl at 9.03 τ, methylene at 8.4 and 8.2 τ and methine, four broad multiplets centered at 5.7 τ (*gem* $J_{HF} \sim 50$ and *vic* $J_{HF} \sim 20$ Hz); both showed similar i.r. absorption at 1060 (C—F) cm^{-1}. This evidence in conjunction with microanalytical data confirms structure **5** and indicates the two dimers are the anticipated diastereomers formed in essentially equal amounts. Both these compounds appeared as two separate peaks (g.l.c.) and could easily be isolated at temperature programming of 170–190°. Further efforts to distinguish between these diastereomers were not attempted. Monomeric 1-fluoropentane $CH_3(CH_2)_3CH_2F$ was anticipated as a possible product but no trace was found. In all the electrolyses of α-fluorocaproic acid, changes in concentration and time appeared to have little effect but at higher temperature the ratio of dimeric compounds to other products is increased. 1,1-Dimethoxypentane, **4**, formed in *ca.* 20% yield was identified by its n.m.r. and i.r. spectra and comparison of its g.l.c. retention time with an authentic sample. A small quantity of valeraldehyde was also detected by g.l.c.

To determine how typical dimer formation was during Kolbe electrolysis, we decided to extend our study to some other α-fluoroacids, *viz.* α-fluoroheptanoic acid, 2-fluoro-2-ethylbutanoic acid, and α-fluorophenylacetic acid. Electrolysis of α-fluoroheptanoic acid in methanol gave the Kolbe dimer 6,7-difluorododecane (both diastereomers),



Structures were confirmed as in the previous case. On the other hand the branched-chain fluoroacid, 2-fluoro-2-ethylbutanoic acid, gave 3-pentanone (24–32%) as major electrolysis product as well as the expected fluoroester (6–9%). Several electrolyses of this acid in methanol revealed that changes in temperature, current density, temperature, concentration, or time did not result in dimer formation. Similar behavior was observed when α-fluorophenylacetic acid was electrolyzed where the only product formed was benzaldehyde (for comparison, the corresponding α-bromophenylacetic acid gave hydrogen ester as major product (80%) along with very little (2.5%) bromoester but essentially no benzaldehyde). The lack of dimer formation from these latter two acids is not surprising since carbonium ion formation leading to carbonyl products is much more likely.

The work described herein represents the first detailed study of the electrolysis of α-chloro and α-fluorocarboxylic acids. The results for α-chloroacids in methanol are essentially the same as for α-bromoacids, except that the reduction of C—Cl is less pronounced in the chloroacids. In water the straight-chain α-chloroacids produced

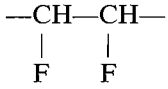
esters. With the α-fluoroacids the straight-chain α-fluoro-caproic and -heptanoic acids produced the Kolbe dimers possibly because the fluorine atom being smaller allows the



linkage to form more easily. Also C—F is less easily reduced to C—H. The difluoro dimer should also be more stable under electrolysis conditions, since Br_2 and Cl_2 can be lost[1] from the appropriate dihalide but not F_2 from the difluoride.

Experimental

General

α-Chlorovaleric acid (7, 8), α-chlorocaproic acid (7, 8), and α-chloroisobutyric acid (9) were prepared according to methods described in the literature. The fluoroacids were synthesized according to the method of Pattison *et al.* (10, 11) but yields on large scale preparations were poor especially for the branched-chain acid. Microanalyses were obtained from Schwarzkopf Microanalytical Laboratory, Woodside, New York. The g.l.c. analyses and separations were carried out on an Aerograph Autoprep model 700 with a 10′ × 3/8″ column with a 30% loading on Chromosorb W of either silicon gum rubber SE-30 or Carbowax 20M. Temperature programming was used in the range 170–250°. Detector temperature was kept *ca.* 25° above the column temperature when collection of the sample was desired. The i.r. spectra were taken with a Beckman IR-10 spectrophotometer either on thin liquid films or in CCl_4 solution. The n.m.r. spectra were obtained with a Varian T-60 spectrometer, absorptions being quoted in τ values against tetramethylsilane.

The conventional electrolysis cell, general method of electrolysis, isolation of products, and divided cell experimental details have been described before (1, 12).

Electrolysis of α-Chloro Acids in Methanol

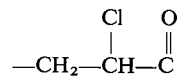
The results of these electrolyses at various temperatures and concentrations are found in Table 1. The products were identified by comparison with authentic samples, especially in their g.l.c. behavior and i.r. spectra.

For comparison, certain control reactions were run. Refluxing of α-chloro acids under electrolysis conditions, but with no current resulted in some esterification (10–13%). Prolonged heating (40–50°) of α-chloro acids (no electrolysis) gave no conversion to hydrogen acid but did produce some (5–8%) esterification. However, when some methyl α-chloroesters were subjected to electrolysis (under similar condition to those shown in Table 1), they gave considerable amounts of the appropriate hydrogen esters (35–40%).

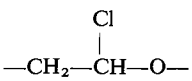
[1]We have observed the loss of Br_2 under our electrolysis conditions from *vic*-dibromoacids but have not done any detailed studies. Other than studies on α,β-dihaloacids, there are not many recorded examples in this area.

Electrolysis of α-Chlorovaleric and α-Chlorocaproic Acids in Water

Potassium hydroxide (4.2 g, 0.075 mol) was dissolved in water (60 ml) and α-chlorovaleric acid (25.5 g, 0.187 mol) was added. A current of 1.25 A was passed for 40 h and the temperature was kept at 10–15° with an ice bath. After isolation of neutral and acidic fractions in the usual manner, a light brown neutral oil (12.9 g) was collected. The neutral fraction showed (g.l.c.) a major fraction (40%); a small sample of this compound was isolated with the Autoprep-700 using an SE-30 column, temperature programming from 160–200°, and a detector temperature of 250°, and was identified as 1′-chloro-1′-butyl 2-chloropentanoate. The i.r. spectrum showed strong absorption at 1770 cm^{-1} (CCl_4). The n.m.r. spectrum showed peaks at τ 9.1, 8.8, 5.9, and 3.8 with integrated areas of 6:4:4:1:1. The triplet at τ 5.9 indicated



whereas the triplet at τ 3.8 indicated



Anal. Calcd. for $C_9H_{16}O_2Cl_2$: C, 47.60; H, 7.51; Cl, 31.24. Found: C, 47.85; H, 7.15; Cl, 31.18.

Similarly α-chlorocaproic acid (31.0 g, 0.2 mol) was electrolyzed at 1.2 A for 36 h. A dark brown neutral oil (14.1 g) was collected which when subjected to fractional distillation under reduced pressure decomposed. From a fresh sample of neutral oil 1′-chloro-1′-pentyl 2-chlorohexanoate was isolated by g.l.c. This ester has the same spectral features as 1′-chloro-1′-butyl 2-chloropentanoate.

Anal. Calcd. for $C_{11}H_{20}O_2Cl_2$: C, 51.78; H, 7.84; Cl, 27.81; Found: C, 51.87; H, 7.74; Cl, 28.00.

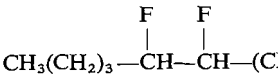
Electrolysis of α-Chloroisobutyric Acid in Water

α-Chloroisobutyric acid (30.6 g, 0.25 mol) was added to a solution of potassium hydroxide (5.7 g) in water (65 ml). A current of 1.5 A was passed for 28 h and the temperature was kept at 20–25°. Work-up as usual gave 9.4 g of neutral product, which was mainly acetone (18.3%), 1-chloroacetone (6.1%), 1,1-dichloroacetone (2.4%), and 1,3-dichloroacetone (0.8%).

Electrolysis of α-Fluorocaproic and α-Fluoroheptanoic Acids in Methanol

The results of several electrolyses of α-fluorocaproic acid are shown in Table 2. The fluoroester was confirmed by use of an authentic sample. Hydrogen ester was absent. Three other components were isolated by g.l.c. using the SE-30 column, temperature programming of 170–190°, and a detector temperature of 220°. One component was identified as 1,1-dimethoxypentane $CH_3(CH_2)_3—CH(OCH_3)_2$. The i.r. spectrum in CCl_4 solution showed bands at 1050 and 1130 cm^{-1}; the n.m.r. spectrum showed four groups of peaks at τ 8.9, 8.7, 6.8, and 5.8 with relative intensities of 3:6:6:1. This compound had identical g.l.c. behavior when compared with an authentic sample prepared according to the method of Lorette and Howard (13). The other two components appeared from the elemental analysis to be diasterioisomers.

Anal. Calcd. for



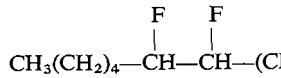
$CH_3(CH_2)_3—CH—CH—(CH_2)_3—CH_3$, $(C_{10}H_{20}F_2)$:

C, 67.41; H, 11.23; F, 21.34. Found for one diastereomer: C, 67.18; H, 11.00; F, 21.72. Found for the other diastereomer: C, 67.77; H, 11.61; F, 21.32.

The i.r. spectrum in each case showed a band at 1060 (C—F) cm^{-1}. The n.m.r. spectra of each isomer showed signals for methyl at 9.03 τ, methylene at 8.4 and 8.2 τ, and methine, four broad multiplets centered at 5.7 τ (*gem* J_{HF} 50 and *vic* J_{HF} 20 Hz). The refractive indices of these diastereomers were very similar (n_D^{24} 1.4018 and 1.4027 respectively); the first isomer remained a colorless oil on cooling in ice but the second isomer solidified.

Similar electrolysis of α-fluoroheptanoic acid was carried out in methanol under identical conditions with that of α-fluorocaproic acid. The neutral fractions from three runs were examined only for dimeric compounds which constituted *ca.* 40–60% of the neutral fraction. Two compounds were isolated with the Autoprep Model 700, in a similar fashion to the isolation of the two diasterioisomers obtained from the electrolysis of α-fluorocaproic acid (g.l.c., two separate peaks).

Anal. Calcd. for



$CH_3(CH_2)_4—CH—CH—(CH_2)_4—CH_3$, $(C_{12}H_{24}F_2)$:

C, 69.90; H, 11.65; F, 18.90. Found for one diastereomer: C, 69.56; H, 11.65; F, 18.50. Found for the other diastereomer: C, 69.72; H, 11.82; F, 18.58.

The Dichloroiodine(III) and Dibromoiodine(III) Cations in Sulfuric Acid

J. B. SENIOR AND J. L. GROVER

Department of Chemistry, St. Paul's College, University of Manitoba, Winnipeg 19, Manitoba
and
Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan[1]

Received February 8, 1971

The results of measurements of the conductivities and freezing points of solutions formed by adding chlorine or bromine to solutions of iodic acid and iodine (mole ratio $I_2/HIO_3 = 2.0$) in sulfuric acid are reported. The results provide evidence for the formation of the ions ICl_2^+ and IBr_2^+ in these solutions. Ultraviolet–visible spectra of the solutions are reported.

On rapporte les résultats des mesures de conductivité et de détermination des points de congélation de solutions obtenues en ajoutant du chlore ou du brome à des solutions d'acide iodique et d'iode (rapport molaire $I_2/HIO_2 = 2.0$) dans l'acide sulfurique. Les résultats apportent des preuves quant à la formation d'ions ICl_2^+ et IBr_2^+ dans ces solutions. On rapporte les spectres u.v.—visible des solutions.

Canadian Journal of Chemistry, 49, 2688 (1971)

Introduction

Garrett, Gillespie, and Senior (1) reported the formation of the polyhalogen cations I_3^+, I_5^+, I_2Cl^+, and I_2Br^+ in solutions prepared by adding iodine alone or iodine and iodine monochloride or monobromide, respectively, to solutions of iodic acid in sulfuric acid. These workers also reported conductance data which suggest that the dichloroiodine(III) cation, ICl_2^+, is formed, along with I_2Cl^+, when iodine monochloride alone is added to solutions of iodic acid in sulfuric acid. They pointed out that the hitherto unreported dibromoiodine(III) cation, IBr_2^+, would be isoelectronic with the known compound $TeBr_2$ and hence that its existence was very probable. The cation ICl_2^+ is known to exist in the compounds $ICl_3.AlCl_3$ and $ICl_3.SbCl_5$ whose crystal structures were determined by Vonk and Wiebenga (2). Aubke and Cady (3) prepared ICl_2SO_3F as a low-melting, apparently impure solid. They did not report on its behavior in solution, although they found that the related compound I_3SO_3F gave I_3^+ in solution in fluorosulfuric acid.

While our work was in progress, Gillespie and Malhotra (4) presented conductometric and cryoscopic evidence for the formation of ICl_2^+ in solutions of iodine trichloride in disulfuric acid.

In the present work, chlorine or bromine was added to solutions in 100% sulfuric acid, containing iodic acid and iodine in the mole ratio $I_2/HIO_3 = 2.0$, corresponding to the formal +1 oxidation state of iodine. The freezing points and electrical conductivities of the resulting solutions provide evidence for the formation of the cations ICl_2^+ and IBr_2^+, respectively.

[1]Present address of J. B. Senior, to whom correspondence should be addressed.

Results and Discussion

The Systems $(HIO_3 + 2I_2) - Cl_2$ and $(HIO_3 + 2I_2) - Br_2$

In each conductometric experiment the starting solution contained iodic acid and iodine in the mole ratio $I_2/HIO_3 = 2.00 \pm 0.03$. Successive additions of the halogen X_2 (X = Cl or Br) were made, and the conductance measured following each addition. Graphs of specific conductance *vs.* the mole ratio $X_2/(HIO_3 + 2I_2)$ were plotted. Conductance values at the mole ratio 5.0, obtained from these graphs by interpolation, are shown in Table 1.

In each cryoscopic experiment, the starting solution had a different value of the mole ratio $X_2/(HIO_3 + 2I_2)$. This solution was diluted by successive additions of 100% sulfuric acid to give a range of concentrations. A curve of freezing point *vs.* the stoichiometric concentration of iodic acid was plotted from the results of each experiment, and values of the freezing point at round molal concentrations of iodic acid were obtained by interpolation. The interpolated data were plotted to give a set of graphs of freezing point *vs.* the mole ratio $X_2/(HIO_3 + 2I_2)$, each for a fixed stoichiometric molality of iodic acid. Values of the freezing point at the mole ratio 5.0, obtained from these curves, are given in Table 2.

*Uncorrected for solvent used in reaction.

The curves of conductance and freezing point *vs.* the mole ratio $X_2/(HIO_3 + 2I_2)$ for X = Cl and the conductance curves for X = Br showed breaks close to the mole ratio 5.0. The conductance increased very little beyond this mole ratio, while the freezing point continued to be depressed but less steeply. Cryoscopic experiments were not done for high enough mole ratios to show clearly whether or not there was a break in the freezing point curves in the case X = Br. Before addition of X_2, the solutions were a dirty green color. As X_2 was added, the color gradually changed to a bright orange-red (X = Cl) or a deep red-brown (X = Br), the color change being complete at the mole ratio 5.0. At mole ratios less than 5.0, free halogen vapor was not visible over the solutions, but at mole ratios greater than 5.0 the solutions had an appreciable vapor pressure of X_2. Values of ν, the number of moles of particles produced in solution per mole of iodic acid, were calculated from the freezing point data for the 5.0 mole ratio (Table 2). These values have been corrected for the repression of solvent self-ionization (5) and for solvent used up in the reaction. Values of γ, the number of moles of hydrogensulfate ions produced per mole of iodic acid, were calculated by comparison of the curves of conductance *vs.* concentration at the 5.0 mole ratio, with that for the solute water (6) (Table 1).

Reaction to give ICl_2^+ or IBr_2^+ would take place according to the overall equation

$$[1]\quad HIO_3 + 2I_2 + 5X_2 + 8H_2SO_4 \rightleftharpoons 5IX_2^+ + 3H_3O^+ + 8HSO_4^-$$

$$\nu = 16,\ \gamma = 8\ (X = Cl \text{ or } Br)$$

The experimental values of ν and γ are in good agreement with the predicted values in both cases. The small decrease in ν with increasing concentration can probably be explained by incomplete ionization of the water formed (7). No other reasonable ionization scheme can be found, consistent with the observed ν and γ values.

It should be emphasized that eq. 1 is a net stoichiometric equation only, and there is no suggestion that it represents a mechanism for the formation of IX_2^+. It has been shown (1) that the

main iodine-containing species in a solution of $HIO_3 + 2I_2$ in 100% H_2SO_4 are IO^+, $IOSO_4H$, and I_3^+, and these species are no doubt involved in a possibly quite complicated sequence of reactions leading to the final products shown.

The fact that the conductance does not increase significantly after the mole ratio 5.0, while the freezing point continues to be depressed, suggests that the excess of chlorine dissolves in the molecular form rather than reacting to give an ICl_4^+ ion, analogous to I_5^+.

The u.v.–visible absorption spectrum of the ICl_2^+ ion in these solutions shows absorption maxima at 360 nm ($\varepsilon = 56.7 \pm 1.3$) and 452 nm ($\varepsilon = 44.9 \pm 1.2$) while IBr_2^+ gives a maximum at 358 nm ($\varepsilon = 544 \pm 20$) and a broad shoulder at about 540 nm.

In a single conductivity experiment, iodine trichloride was added to a solution of $HIO_3 + 0.33I_2$. The conductivity curve showed a break close to $ICl_3/(HIO_3 + 0.33I_2) = 3.33$, and the value of γ at this mole ratio was 7.7, in agreement with reaction according to the overall equation

$$[2] \quad 3HIO_3 + I_2 + 10ICl_3 + 24H_2SO_4 \rightleftharpoons 15ICl_2^+ + 9H_3O^+ + 24HSO_4^- \qquad \gamma = 8$$

It is of interest that iodine trichloride alone is only sparingly soluble in 100% sulfuric acid, and does not appear to give ICl_2^+ in this solvent, in contrast to its reported behavior in disulfuric acid (4).

Experimental

Iodic acid was recrystallized from dilute (1:4) nitric acid and air-dried at room temperature. *Iodine* (reagent grade) was used without further purification. *Bromine* (reagent grade) was dried over phosphorus pentoxide and distilled. *Chlorine* (Matheson of Canada Ltd.) was dried by passing it over Drierite, then over phosphorus pentoxide.

Freezing points were measured by the Beckman method (8), using a solid stem mercury-in-glass thermometer, graduated in 0.01 °C and read to 0.001 °C, which was calibrated against a platinum resistance thermometer. Freezing of the supercooled solutions was induced by dropping into the cryoscope a small piece of platinum which had been cooled in liquid nitrogen. This has been found to be more reliable than the method used by the earlier workers (8).

The conductivity cells used for the $(HIO_3 + 2I_2) - Br_2$ system have been described previously (9). In early conductance experiments on the $(HIO_3 + 2I_2) - Cl_2$ system, the same cells were used, and the mole ratio $Cl_2/(HIO_3 + 2I_2)$ was determined by removing aliquots of solution for analysis immediately following each conductance measurement. In later experiments, a cell was used which was small enough to be weighed to 1 mg before and after each addition of chlorine. Undissolved chlorine was swept from the cell by a stream of dry nitrogen before each weighing. The cell consisted of a small mixing flask and a side-arm containing the electrodes. The solution was withdrawn into the side-arm for measurements. The initial solution for each cryoscopic experiment on the $(HIO_3 + 2I_2) - Cl_2$ system was prepared in this cell, and a weighed amount transferred to the cryoscope. Conductance measurements were made with the cells immersed in an oil thermostat regulated at 25 ± 0.002 °C by means of a Bayley Instrument Co. Model 116 Precision Temperature Controller. The temperature of the bath was measured by a calibrated solid stem mercury-in-glass thermometer. Resistances of solutions were measured using a Beckman Model RC 18 conductivity bridge.

Full details of the conductometric and cryoscopic results are available elsewhere.[2]

Ultraviolet–visible spectra were recorded on a Cary 14 spectrophotometer, using 1 cm quartz cells.

Composition of Tetrahydrofuran Hydrate and the Effect of Pressure on the Decomposition[1]

S. R. GOUGH AND D. W. DAVIDSON
Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received March 12, 1971

The decomposition temperature of the structure II clathrate hydrate of tetrahydrofuran has been followed to pressures above 3 kbars, where the hydrate is found to decompose incongruently in the regions of stability of ices III and II, with no evidence of formation of a denser hydrate. From measurements of liquid solution densities and of volume changes at hydrate decomposition the density of the hydrate was obtained. Comparison with the X-ray lattice dimension indicates that at least 98% of the large cages are occupied, the principal uncertainty being in the lattice parameter. A similar treatment is made of Tammann and Krige's data (23) for chloroform hydrate. Analysis of the results of 18 composition determinations of structure II hydrates shows no statistical evidence of departure from the ideal composition of 17 mol of water per mol of hydrate former.

La température de décomposition du clathrate hydraté de structure II du tétrahydrofuranne a été suivie jusqu'à des pressions supérieures à 3 kbar; il a été trouvé que dans ces régions de stabilité des glaces III et II l'hydrate se décompose d'une façon aberrante sans preuve de formation d'un hydrate plus dense. A partir des mesures de densité des solutions liquides et des changements de volume à la décomposition de l'hydrate, il a été possible d'obtenir la densité de l'hydrate. La comparaison avec la dimension du réseau obtenu par rayons X indique qu'au moins 98% des grandes cages sont occupées, l'incertitude principale étant dans le paramètre rétuculaire. A partir des données de Tamman et Krige une analyse similaire est effectuée pour le chloroforme hydraté. Les analyses des résultats se rapportant à 18 déterminations de composition d'hydratés ayant la structure II ne montrent aucune preuve statistique d'écart par rapport à la composition idéale de 17 mol d'eau par mole de générateur d'hydrate.

Canadian Journal of Chemistry, 49, 2691 (1971)

Among the diverse molecules now known to form "gas hydrates" of von Stackelberg's structures I and II (1) are a number of ethers and ketones which are distinguished from the classical gas-hydrate formers by their solubility in water and by the possibility of hydrogen bonding with the host water molecules of the clathrate structures. Ethylene oxide (2, 3) and trimethylene oxide (4) form hydrates of type I. Structure II hydrates are formed by dimethyl ether (1), by trimethylene oxide, tetrahydrofuran, 2,5-dihydrofuran, propylene oxide, and 1,3-dioxolane (4, 5) and by acetone (6, 7) and cyclobutanone (5, 8). With the exception of the study by Glew and Rath (9) of the variable composition of ethylene oxide hydrate, there appears to be no accurate information about the degree of occupancy of the cages or the heat of formation of these hydrates.

Trimethylene oxide (4) and acetone (8) hydrates decompose incongruently. Of the other structure II hydrates only tetrahydrofuran hydrate melts appreciably above 0 °C. This hydrate is therefore most easily distinguished from ice and has been chosen for further study.

Tetrahydrofuran hydrate was first reported by Palmer (10) who found from melting point *vs.* concentration curves a composition of between 13 and 16 molecules of water per molecule of tetrahydrofuran (THF), with a probable formula of $THF \cdot 14H_2O$. Erva (11) obtained a congruent melting point of 4.38 °C at an approximate composition of $THF \cdot 16H_2O$. Several nugatory irregularities in the melting points of solutions of higher THF content were interpreted as peritectic points of lower hydrates (11) or in terms of discrete association complexes in liquid solution (12). They are more likely to be related to the incorporation of different amounts of air in different hydrate samples.

Among several indirect methods (13) of determining the composition of clathrate hydrates, one which is particularly applicable to the hydrates of water-soluble molecules depends on comparison of measured hydrate density with the composition-dependent density calculated from the X-ray unit cell dimensions. Glew and Rath (9) have used the results of flotation mea-

[1]NRCC No. 12002.

surements of the density of ethylene oxide hydrate in conjunction with the lattice parameter to obtain compositions of this hydrate. We have determined the density of THF hydrate from measurements of the volume change at hydrate decomposition and of the density of the liquid solution. Volume, capacitance, and thermal-analysis measurements were made to high pressures to determine the effect of pressure on the hydrate–solution equilibrium and to look for evidence of a transformation of the hydrate to a denser crystallographic form. Heats of formation of the hydrate were estimated from the results.

Experimental Methods

The initial measurements were made to define the region of stability of THF hydrate in the pressure–temperature plane. The decomposition of the hydrate was followed by the capacitance, conductance, and volume changes which accompanied increase of temperature or pressure through the decomposition region. Some experiments were also made with pressure decreasing. The cell used was that previously described (Fig. 1(*b*) of ref. 14), with essentially the same methods of control and measurement of temperature and pressure. The electrical measurements were normally made at 20 kHz. The driving piston was coupled to a slow-speed motor to effect rotational oscillation through $\pm 4°$ and thereby to reduce piston friction. Volume changes were measured in terms of displacement of this piston which was monitored to 10 μin. by a dial gauge.

Solutions were prepared from conductivity water and THF which had been distilled over calcium hydride. Analysis by vapor phase chromatography showed the THF to contain 0.1% of volatile impurity. Compositions ranged from $THF{\cdot}17.0H_2O$ to $THF{\cdot}16.8H_2O$. Hydrate was normally prepared by cooling to below 0 °C and conditioning at +2 °C and 1 atm for about 12 h, followed by over-night conditioning at a temperature and pressure near the starting point of the decomposition measurements.

Most hydrate samples showed relatively small capacitance and volume changes associated with the melting of ice: conductance was particularly sensitive to such eutectic melting. For these samples both ice and hydrate melting data were recorded. Since the measuring thermocouple was outside the pressure vessel (14) in these measurements, melting points were taken as the temperatures at the onset of melting, upon which there was usually agreement to within a few tenths of a degree among the parameters measured. Figure 1 illustrates such warming curves. Measurements with varying pressure refer to equilibrated temperatures, but the transitions tended to occur over a range of pressure and to show hysteresis when the pressure change was reversed (Fig. 2). Nevertheless, the hydrate and ice melting points appear to have been generally defined to better than 1° and 100 bars.

Considerably more accurate determination of the variation of hydrate decomposition temperature (and volume) with pressure to 1400 bars was realized by insertion of a calibrated Chromel–Alumel thermocouple into the center of the sample, the insulated leads, swaged in a stainless steel tube, being brought out through the lower electrode and piston. Since the presence of the thermocouple interfered with the electrical measurements, the decomposition temperature was determined from the dilatometric and thermal (temperature *vs.* time) measurements only, as the mid-points of the volume changes or of the thermal steps. An example is shown in Fig. 3. All such measurements were made with a sample of composition $THF{\cdot}16.69H_2O$ at a heating rate of about 0.2°/min.

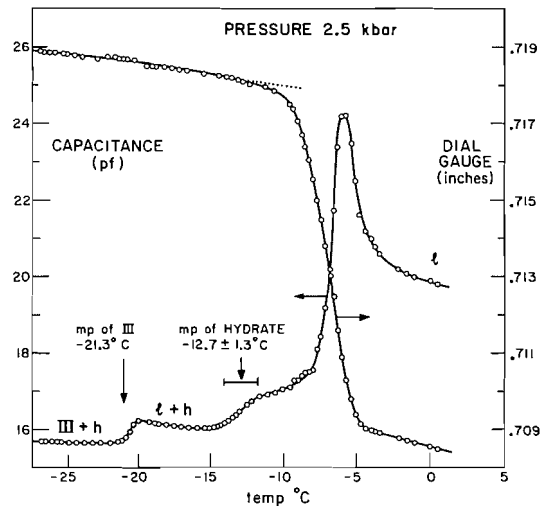

FIG. 1. Illustration of capacitance and volume changes at temperatures of phase changes in the THF–water system.

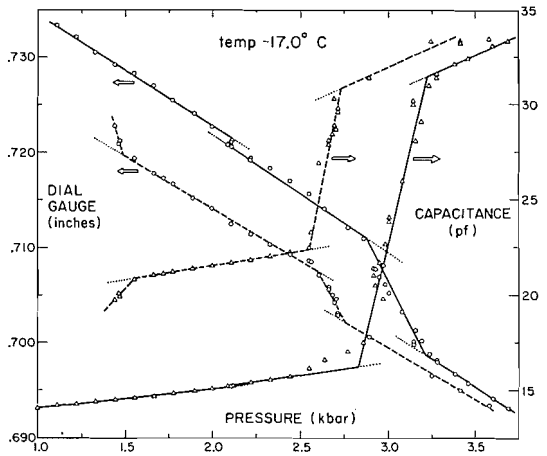

FIG. 2. Capacitance and volume changes at pressures of hydrate decomposition (pressure increasing, solid lines) and formation (pressure decreasing, broken lines).

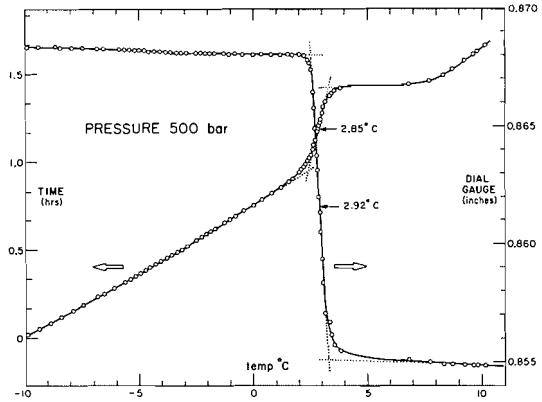

FIG. 3. Example of determination of temperature and volume change of decomposition of THF hydrate.

Densities of liquid solutions near 4 °C were measured with a quartz pycnometer of 11 ml capacity designed after Kirshenbaum (15) and calibrated with mercury and water at 4 °C. The bath temperature was regulated to ±0.01 °C and measured with a platinum resistance thermometer.

Results

Solution Densities

The densities of a solution of composition THF·16.98H_2O at four temperatures near the hydrate decomposition point at 1 atm are given in Table 1, along with a single measurement of a more dilute solution. The accuracy is considered to be ±0.00003 g/cm³, with a relative accuracy with respect to temperature change of the first solution of ±0.00001 g/cm³. These data are sufficient to define the dependence on composition and temperature necessary for determination of the density at the decomposition temperature and over the range of possible hydrate compositions considered below. The appreciable decrease of density with increase of temperature is not surprising, since Wada and Umeda (16) found that THF lowers the temperature of maximum density of water. Extrapolation of their results suggests this temperature to be about −15 °C for a composition of THF·17H_2O.

Phase Equilibria of THF Hydrate

Figure 4 (heavy line) shows the region of stability of THF hydrate. At pressures below 3.05 kbar the hydrate melts congruently to a liquid of greater density, the curvature of the temperature–pressure line being determined by the larger compressibility and thermal contraction of the liquid. This part of the hydrate decomposition curve intersects the freezing curve of ice III in the presence of liquid of hydrate composition at −19.8 °C and 3.05 kbar. At higher pressures the hydrate (h) "melts" incongruently to give ice III and a peritectic liquid (l), the dependence of decomposition temperature on pressure becoming increasingly great as ice III is formed in greater proportion. The decomposition curves in this region were not well enough defined to distinguish between the h → III + l and h → V + l curves, ice V (as shown by its melting behavior) having been obtained in most pressurizing runs within the region of stability of ice III. When the ice formed is V, the melting of the hydrate remains congruent to about −21.4 °C and 3.12 kbar. At lower temperatures the equilibrium decomposition is to ice II and THF-rich liquid. Dielectric studies (to be published elsewhere) show the hydrate to be stable to at least 3.5 kbar at −62 °C.

There was no evidence of formation of a denser hydrate.

TABLE 1. Densities of THF solutions

Composition	Temperature (°C)	Density (g/cm³)
THF·16.98H_2O	4.03_5	0.99730
	4.13_3	0.99726
	4.31_1	0.99719
	4.67_5	0.99706
THF·17.99H_2O	3.98_0	0.99768

Melting of Ice in the Presence of THF

Over its full range, the curve corresponding to eutectic melting of ice I in the presence of hydrate (Fig. 4) lies about 1° below the melting curve of ice I given by Bridgman (17). This suggests that the eutectic composition shows little variation over this pressure range from its value (0.9 mol% THF (11)) at 1 bar and that the partial molar volume of water (V_1) in the eutectic liquid is not much different from the molar volume of pure water (V_1^0) at the same pressure. The increasing depression of the freezing point of ice III with increase of pressure corresponds to increasing THF content of the eutectic solution, which reaches the hydrate composition at the intersection with the hydrate melting curve. On the other hand, the increasing depression of the freezing point of ice V, 5° at 6.2 kbar, is due to an increasing value of $V_1^0 - V_1$, where V_1 refers to the liquid of the same composition as the hydrate.

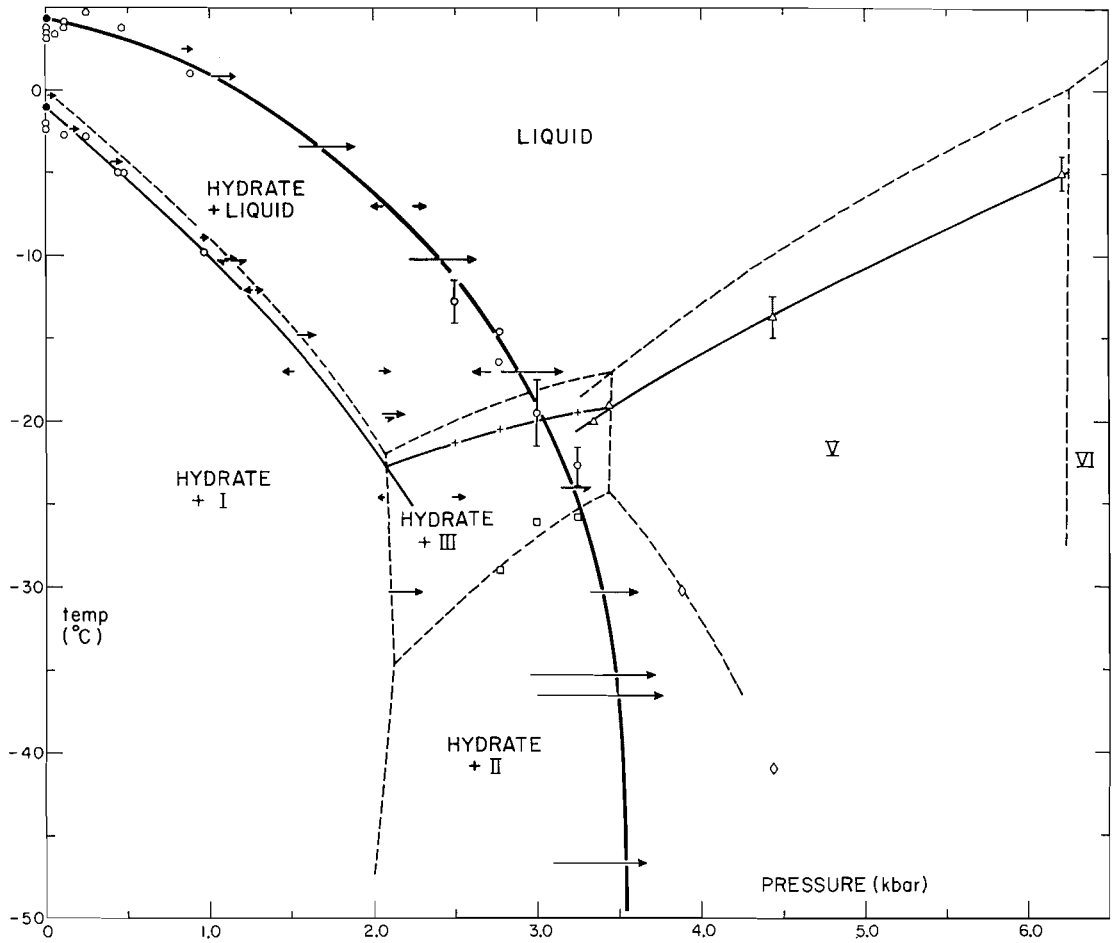

FIG. 4. Phase diagram of the THF–water system. The heavy line is the decomposition curve of THF hydrate, light lines are water-rich eutectic points (to left of heavy line) or melting points of ice in the THF·17H_2O system (to right), and broken lines are Bridgman's phase boundaries in the water system.

Dependence of Decomposition Temperature on Pressure

The decomposition temperature of THF·16.69-H_2O given by the mid-points of the thermal steps in the temperature *vs.* time curves were measured at 17 pressures between 1 and 1400 bars. The results (Fig. 5) are given, to a standard deviation (σ) of 0.080°, by

$$[1] \quad t(°C) = (4.126 \pm 0.035) - (2.280 \pm 0.139) \times 10^{-3} P - (1.150 \pm 0.112) \times 10^{-6} P^2$$

where P is the pressure in bars.

The temperatures at the mid-points of the corresponding volume changes were measured at 14 pressures (Fig. 5) and are given, with $\sigma = 0.093°$, by

$$[2] \quad t\,(°C) = (4.279 \pm 0.082) - (2.375 \pm 0.259) \times 10^{-3} P - (1.169 \pm 0.176) \times 10^{-6} P^2$$

No reduction of variance was achieved by the inclusion of terms in P^3 in the least squares analyses.

The mid-points of the decomposition curves were chosen for greatest accuracy of the pressure dependence of the melting points. Equations 1 and 2 are expected to underestimate the melting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

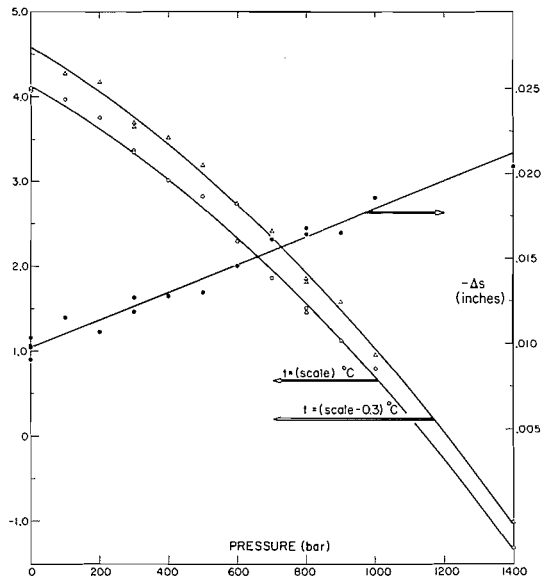

FIG. 5. Pressure dependence of decomposition temperature from thermal (○) and volume (△) measurements and of change of piston displacement (●) at decomposition. (The decomposition temperatures from volume measurements are displaced upward by 0.3 °C.)

point of the hydrate at 1 bar because of the central position in the sample of the measuring thermocouple. This appears to be less true of eq. 2, possibly because of some lag of the piston behind the change of volume.

The linear coefficients in eqs. 1 and 2 may be combined to yield

$$[3] \quad \left(\frac{dt}{dP}\right)_{P\to 0} = -(2.301 \pm 0.122) \times 10^{-3}$$

degrees per bar, the error quoted, like those of eqs. 1 and 2, being the standard error.

Volume Change of Hydrate Decomposition

Seventeen measurements of the change of dilatometer gauge reading for THF·16.69H_2O at pressures between 1 and 1400 bars (Fig. 5) gave

$$[4] \quad \Delta s \text{ (in.)} = -(0.00972 \pm 0.00021) - (8.22 \pm 0.35) \times 10^{-6} P$$

The value of σ (0.00057 in.) was scarcely improved, and the constant term hardly affected, by inclusion of a term in P^2.

Division of Δs for $P = 1$ bar, by the length of the column of liquid solution at 4.4 °C gave

$$[5] \quad \Delta v/v = \Delta s/s = -(0.01470 \pm 0.00034)$$

for the relative change of volume. From Table 1 the density of liquid THF·16.69H_2O at 4.4 °C may be taken as 0.99705 ± 0.00004 g cm^{-3}, whence the change of volume is -5.496 ± 0.129 cm^3 per mol of THF·16.69H_2O.

This volume change is not quite the desired volume change for congruent melting of 1 mol of hydrate of composition THF·nH_2O, since $n > 16.69$. Some melting of the hydrate occurs over the whole temperature between the THF-rich eutectic temperature and the final melting point. Examination of the volume *vs.* temperature curves shows that a contribution to the *measured* volume change is first detected about 1° below the temperature of final melting. Erva's data (11) show the liquid composition to be THF·7.5H_2O at this temperature. The measured volume change then corresponds to

$$[6] \quad x[\text{THF}\cdot n\text{H}_2\text{O(h)}] + (1 - x)[\text{THF}\cdot 7.5\text{H}_2\text{O(l)}] \rightarrow [\text{THF}\cdot 16.69\text{H}_2\text{O(l)}]$$

where $x = 9.19/(n - 7.5)$ is the fraction of THF present in the hydrate at the onset of melting.

Reaction 6 may be considered as the sum of the processes of melting x mol of hydrate and of mixing x mol of liquid THF·nH_2O with $(1 - x)$ mol of liquid THF·7.5H_2O. The volume change of mixing is zero for an ideal solution. The density measurements of THF–water solutions at 25 °C by Critchfield *et al.* (18) give zero for this volume change, with n near 17, to within the experimental accuracy of 0.02%. We ascribe the whole of the measured volume change to the melting of x mol of hydrate and put for the melting of 1 mol

$$[7] \quad \Delta V(\text{h} \rightarrow \text{l}) = \frac{-5.496}{x} \pm \frac{1}{x}\sqrt{30.25(1 - x)^2 + 0.0640}$$

The error estimate[2] has been conservatively written to include an uncertainty in the correction $(1/x)$ of the order of magnitude of the correction itself and the original standard error of the measured volume change has been expanded to the 95% confidence level.

[2]The error in x is assumed to be $x(1 - x)$ and in the measured volume change 1.96×0.129 cm^3.

Hydrate Composition

The molar volume of THF·nH$_2$O(l) at 4.4° may be written as

$$[8] \quad V(\mathrm{l}) = \frac{72.10 + 18.015n}{0.99716 + 0.000364(n - 16.98)} \text{ cm}^3$$

and that of the solid hydrate as

$$[9] \quad V(\mathrm{h}) = \frac{Nna^3}{136} \text{ cm}^3$$

where N is Avogadro's number and a is the dimension of the cubic unit cell which contains 136 water molecules. Unfortunately, a is not accurately known at the decomposition temperature of the hydrate. Von Stackelberg and Meuthen's value (2) of 17.18 Å at −10 °C appears to be uncertain by as much as 0.10 Å. The more accurate values of Sargent and Calvert (5), *viz.*, 17.13 ± 0.03 Å at −163 °C and two values of 17.170 ± 0.004 and 17.162 ± 0.007 Å at −137 °C (the errors are σ's), refer to much lower temperatures. The values (5) for the closely related hydrate of dihydrofuran, almost identical with those of THF hydrate at −137 °C, include 17.22 ± 0.01 Å at −40 °C. Extrapolation of the combined data for THF and dihydrofuran hydrates to 4 °C gives 17.24 Å, to which we assign a maximum uncertainty of ±0.03 Å.

In Fig. 6 volumes given by eq. 7 and by the difference between eqs. 8 and 9 are plotted against n for values of a between 17.21 and 17.27 Å.

The most probable value of n is 16.86. For the range of lattice parameters allowed, values between about 16.4 and 17.5 are formally permitted. It is unlikely, however, that THF (maximum diameter 5.9 Å (2)) can occupy the small cages of free diameter 4.9 Å and therefore that n is less than 17. It may also be noted that a = 17.21 Å, for which n is 17.34 ± 0.20, is much less likely than a = 17.23 Å, with n = 17.01 ± 0.16. We conclude, at about the 90% confidence level, that at least 98% of the large cages are occupied.

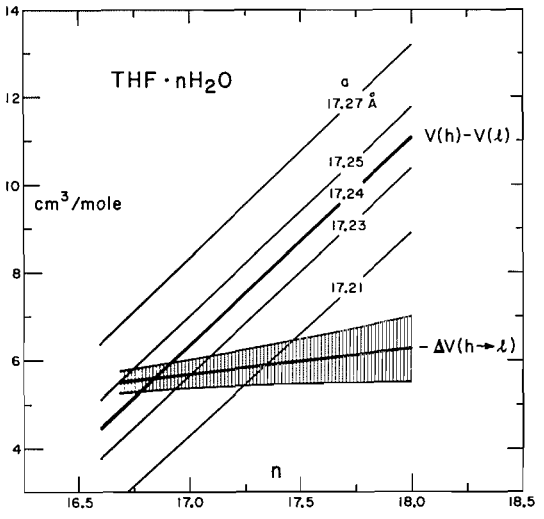

FIG. 6. Dependence of volume change at decomposition on composition of THF hydrate.

Effect of Air on Hydrate Properties

Under the conditions of our experiments, in which the only air present was that initially dissolved in the liquid, the effect of air on the volume changes discussed above may be shown to be negligible. Saturation with air at 1 atm affects the density of liquid water only in the sixth decimal place (19) and therefore may be assumed to have a negligible effect on the density of the THF solution. If the air present in the solution (assumed to be the amount soluble in water at 4 °C) is entirely taken into the small cages of the hydrate, the hydrate density is increased by 0.000034 g/cm^3 and the volume change of melting reduced by only 0.013 cm^3/mol.

It is well-known that some hydrates grown in the presence of air incorporate large quantities of air in their cages, with a consequent increase of stability (see refs. 13 and 20, for example). A simple experiment showed this to be true of THF hydrate. A sample of THF·16.79H$_2$O was slowly frozen and conditioned in an ice bath for several hours. The warming curve obtained in an air-jacketed glass vessel showed the great bulk of the sample to melt at 4.45 °C. With further warming the remaining crystals gradually melted with the evolution of air bubbles and only completely disappeared at 5.0 °C. It is likely that the presence of air accounts for Palmer's report (10) of two maximum melting points at 5.07 and 5.37 °C. The available data suggest that the melting point of THF hydrate containing little or no air lies at 4.4 ± 0.1 °C.

Heats of Decomposition

The enthalpy change of congruent melting at negligible pressure is given by

$$[10] \quad \Delta H(\mathrm{h} \rightarrow \mathrm{l}) = \frac{T\Delta V(\mathrm{h} \rightarrow \mathrm{l})}{\left(\frac{\mathrm{d}t}{\mathrm{d}P}\right)_{P \rightarrow 0}}$$

The pressure coefficient of the melting point is

TABLE 2. Enthalpies of decomposition of THF hydrate

Decomposition	Temperature (°C)	ΔH (kcal/mol)
$h \rightarrow l$	4.4	16.7±1.9
$h \rightarrow l_1 + l_2$	4.4	19.5±2.0
$h \rightarrow l_1 + g$	4.4	27.1±2.0
$h \rightarrow l_1 + g$	0	26.5±2.1
$h \rightarrow I + g$	0	2.1±2.1

given by eq. 3. With $\Delta V(h \rightarrow l) = -5.8 \pm 0.3$ cm^3, $\Delta H(h \rightarrow l) = 16.7 \pm 1.9$ kcal/mol, at about the 95% confidence level.

We have crudely measured the heat of mixing of 1 mol of THF and 17 mol of water at a mean temperature of 4 °C, and found $\Delta H(l_1 + l_2 \rightarrow l) = -2.8 \pm 0.2$ kcal. This value is consistent with values read from Erva's figure (21), *viz.*, −2.25 and −2.60 kcal for mixing at 25 and 15 °C, respectively. The heat of vaporization of liquid THF at 4.4 °C is found from the vapor pressure equation (22) to be $\Delta H(l_2 \rightarrow g) = 7.6 \pm 0.1$ kcal/mol. These quantities, together with estimates of specific heats between 4.4 and 0 °C, give the enthalpy changes shown in Table 2.

Discussion

Chloroform Hydrate

The only comparable study of the volume change of decomposition of a structure II hydrate appears to be that of Tammann and Krige (23), who measured the volume change and temperature of decomposition of chloroform hydrate to the sparingly miscible liquids at pressures to 2 kbar. Analysis of their data gives, with $\sigma = 0.00144$ cm^3/g,

$$[11] \quad \Delta v = (0.01956 \pm 0.00174) - (5.547 \pm 0.470) \times 10^{-5} P + (1.0353 \pm 0.2476) \times 10^{-8} P^2$$

for the change in volume per gram of hydrate. These volume changes were measured indirectly from the changes of pressure at decomposition and were corrected (23) for the considerable amounts of excess water present. From eq. 11, $\Delta V(h \rightarrow l_1 + l_2)$ per mol of hydrate at 1 bar (and about 2 °C) may be written as a function of n.

The solubility at 2 °C of chloroform in water is only 0.96 and of water in chloroform only 0.02 weight % (24). Little error is introduced by assuming additivity of molar volumes in these dilute solutions:

$$[8'] \quad V(l_1 + l_2) = \frac{119.39}{1.5222} + \frac{18.015n}{0.999947}$$

where the density of chloroform is from Timmermans (25). $V(h)$ is given by eq. 9 with $a = 17.33 \pm 0.10$ Å (26).

The volume differences for chloroform hydrate are shown in Fig. 7. The uncertainty shown for $\Delta V(h \rightarrow l_1 + l_2)$ is double the standard error of the constant term in eq. 11.

The most probable value of n is 17.25, but a value as high as 19.0 cannot be definitely excluded because of the large uncertainty of the lattice parameter. Conversely, if, as there is good reason to assume (see below), the large cages are at least 98% occupied, the value of a is defined between 17.30 and 17.37 Å.

The pressure-dependence of the decomposition temperature of chloroform hydrate was not measured (23) with sufficient accuracy to permit a useful estimation of $\Delta H(h \rightarrow l_1 + l_2)$ from eq. 10. This quantity was found to be 22.9 kcal/mol by a calorimetric study made in 1885 (27). Addition of the heat of vaporization of chloroform at 2 °C gives $\Delta H(h \rightarrow l_1 + g) \simeq 30.7$ kcal/mol.

Critical Decomposition Temperatures of Structure II Hydrates

For THF and chloroform hydrates the decomposition temperature is highest in the absence of externally-applied pressure. The melting tempera-

ture measured under the saturated vapor pressure of the hydrate is therefore a true "critical decomposition temperature", a result probably generally true of all simple structure II hydrates which decompose to give liquids. On the other hand, acetone hydrate decomposes to ice (and relatively acetone-rich liquid) at its incongruent melting point (8), which may be expected to rise somewhat with the application of pressure.

Compositions of Structure II Hydrates

Table 3 gives the results of earlier composition studies of structure II hydrates. The second and third columns show, respectively, the molar heats of decomposition into liquid water and gaseous hydrate-former and into ice I and gaseous hydrate-former, as derived from the dependence of pressure on temperature along the respective three-phase equilibrium lines. The difference between these heats at 0 °C is $n\Delta H(\mathrm{I} \rightarrow l_1)$ (28). The value *n* so obtained, with the heat of fusion of ice taken as 1435.7 cal/mol, is given in column 4. These values of *n* vary greatly in accuracy, not only with the number and accuracy of the original data, but also with the adequacy of the corrections made for gas imperfection, the presence of water vapor in the gas, and the effect of finite solubility of hydrate-former in water. Only Glew (29) appears to have combined accurate measurements with a proper statistical study of the errors. We have attempted to represent the relative accuracy of individual values of *n* in terms of weights (*w*) assigned on a scale of 0 to 4.

Values of *n* in column 6 were derived from the shift of the h–l_1–g equilibrium produced by addition of NaCl, according to the method of Miller and Strong (30). The values in the final column are the results of various attempts at direct analysis and are generally of lower accuracy. An exception is the analysis of chloroform hydrate by Barrer and Ruzicka (31) who found the large cages to be 94 to 98% occupied by chloroform with measurements made in the presence of various "help gases".

Consideration of these results suggests that in no case has a statistically significant departure from the ideal composition of $n = 17$ been demonstrated. Certainly this is true of the results as a whole. With cases of $w = 0$ omitted, the unweighted mean of the values of *n* in columns 4 and 6 is 16.99 ± 0.54. More realistically, weighting according to w^2 gives 17.01 ± 0.31. Thus at about the 85% level of confidence, more than 98% of the large cages are occupied.

We conclude that the available composition data for structure II hydrates are of insufficient accuracy to test the extent of applicability of the relation between the μ-potential of water in equilibrium with the clathrate (μ_1) and that of

the empty lattice (μ_1^0),

$$[12] \qquad \mu_1 = \mu_1^0 + \frac{kT}{17}\ln\left(1 - \frac{17}{n}\right)$$

given by the ideal solid solution theory (32). Equation 12 predicts an invariable composition for these hydrates in equilibrium with ice at a fixed temperature and pressure and gives $(\mu_1^0 - \mu_1) > 125$ cal/mol for more than 98% occupancy of the cages at 0 °C.

Thermodynamic Constants of Tetracyanoethylene Complexes with Methylated Benzenes

S. C. LIAO[1] AND R. K. CHAN[2]

Department of Chemistry, University of Western Ontario, London, Ontario

Received October 8, 1970

Formation constants, and enthalpy, free energy, and entropy changes for the tetracyanoethylene complexes with a *complete* series of methyl-substituted benzenes have been evaluated from the charge-transfer spectra over a temperature range of 1–50 °C in carbon tetrachloride solutions. From the literature data, it is deduced that various competing side interactions may not be significant compared to 1:1 electron donor–acceptor complex formation under certain experimental conditions. Some correlations among thermodynamic properties and vertical ionization potentials of the donors are discussed.

Les constantes de formation et les changements d'enthalpie, d'énergie libre et d'entropie de complexes du tétracyanoéthylène avec une série complète de benzènes substitués par des groupes méthyles ont été évalués à partir des spectres de transfert de charges déterminés en solution de tétrachlorure de carbone à des températures entre 1 et 50 °C. D'après les données de la littérature, il est déduit que les diverses interactions compétitives ne seraient pas significatives, dans certaines conditions expérimentales, comparées avec la formation d'un complexe 1:1 entre les donneurs et accepteurs d'électrons. Quelques corrélations entre les propriétés thermodynamiques et le potentiel vertical d'ionisation des donneurs sont discutées.

Canadian Journal of Chemistry, 49, 2700 (1971)

Introduction

The formation constants of tetracyanoethylene (TCNE) complexes with methyl-substituted benzenes have been investigated in different solvents and in gas phase (1–14). Compared with many evaluations of the formation constants, relatively few values for the ΔH^0 and ΔF^0 have been reported for the TCNE complexes in carbon tetrachloride solutions (Table 1). In this work the thermodynamic properties of the TCNE complexes with a *complete* series of methyl-substituted benzene donors have been determined in carbon tetrachloride over the temperature range 1–50 °C from the visible charge-transfer spectra. Some correlations among thermodynamic properties and vertical ionization potential are discussed.

Experimental

Materials were purified as described previously (15).

The charge-transfer spectra were measured by determining the variations in the intensity of visible absorption by the TCNE complexes as a function of the concentrations of the complex components in carbon tetrachloride solutions. The standard TCNE stock solutions for benzene, dimethylbenzenes, and trimethylbenzenes were prepared at room temperature by dissolving TCNE in donor. Different concentrations of solutions for spectral determinations were then prepared by diluting a set of stock solutions with carbon tetrachloride in a 10 ml volumetric flask. The concentrations, in the order of $1\text{–}4 \times 10^{-4}$ M/l, were chosen so that the measured absorbances were in the region of 0.3–0.8 at room temperature. A slightly different method was used for preparing the stock solutions of tetramethylbenzenes, pentamethylbenzene, and hexamethylbenzene. Enough carbon tetrachloride was added to a 50 ml volumetric flask containing 6–8 mg of TCNE and 3–4 mg of donor. The stock solution was diluted again as before.

The samples of TCNE were weighed in a Cahn Electrobalance M-10 with an accuracy of 0.001 mg. The initial concentrations of all solutions were established through the mixing of known volumes of solutions or of pure components, the densities of which were known. It was assumed that the volumes were additive in all cases for evaluating the initial concentrations of TCNE and donor. The temperature corrections for concentrations of solutions between 1 and 50 °C were calculated to be $\pm 2\%$ with respect to 25 °C corresponding to ± 0.02 in $\ln K_N$ or ± 0.01 kcal mol^{-1} in ΔF^0_N which were within the estimated experimental errors of ± 0.02 kcal mol^{-1}. Therefore, the corrections were neglected.

All visible spectra were taken on a Cary 14 recording spectrophotometer with 1 cm cells from 1 to 50 °C at 5 to 10° intervals. The temperature was maintained to ± 0.5 °C by circulation of water from a thermostat to the sample cell block and was measured by means of a copper–constantan thermocouple with a Hewlett–Packard 7100B recorder. No variation in absorbance was found within ± 0.5 °C.

Formation constants, K_N, in terms of mole fraction were evaluated from Benesi–Hildebrand (B–H) equation (16)

$$[1] \qquad \frac{C_A l}{A_{max}} = \left(\frac{1}{K_N \varepsilon_{max}}\right)\frac{1}{N_D} + \frac{1}{\varepsilon_{max}}$$

where C_A is the initial molar concentration of TCNE and N_D refer to the initial donor concentration in mole fraction units, l represents the thickness of the cell in cm, and A_{max} and ε_{max} are maximum absorbance and molar absorptivity of the complex, respectively.

The enthalpy changes at the standard state, ΔH^0_N, were calculated from the temperature dependence of the corresponding K_N. Values of ΔF^0_N and ΔS^0_N were obtained from

$$[2] \qquad \Delta F^0_N = -RT \ln K_N = \Delta H^0_N - T\Delta S^0_N$$

Results and Discussion

Because inconsistent results were found in the literatures for the formation constants of electron donor–acceptor complexes in the solution, many alternate equations, similar to B–H equation, for evaluating the formation constants have been introduced as summarized by Briegleb (17) and Foster (18). These equations give divergent results and some of them are in good agreement with the values obtained from B–H equation within the experimental errors (11). Therefore the simple B–H equation should be valid in the system of 1:1 complex under the conditions of large excess of donor compared to the acceptor and of negligible solvent competition with either donor or acceptor.

The results for formation constants are affected adversely by the misuse of B–H equation for some complex systems. Besides D + A $\rightleftharpoons$ DA in solution, the contact charge-transfer complex (19), carbon tetrachloride complexes with methylated benzenes (20–24), TCNE complex with dichloromethane (1, 13), and the possible presence of termolecular complexes (8, 14, 25) have been discussed in the literatures. Furthermore, there is a possibility that either of the components may self-associate in some systems (26) or that the free donor, acceptor, and complex occur in solution each with a solvation shell (27).

For the TCNE systems with methylated benzene in carbon tetrachloride, we may neglect the complications due to their insignificant effects in view of the experimental conditions and errors. The most serious interference is probably the formation of carbon tetrachloride complexes with methylated benzenes. However, as shown in Table 2, the values are small compared with the formation constants of the corresponding TCNE complexes. For instance, K_c of benzene complex with TCNE in cylcohexane at 22 °C is 2.00 l/mol (5) while the complex with carbon tetrachloride at 25 °C is 0.076 ± 0.057 l/mol (24).

The present experimental conditions of the TCNE complexes have met the requirements of the B–H equation presented by Person (28) that the donor concentration in the most concentrated solution must be greater than about one tenth of the formation constant. Foster (18) also has pointed out that if the initial concentration ratio of donor to acceptor is about 10:1, the changes in the apparent values of formation constant are less than the experimental error. Recently, Deranleau (29) has proposed that the most accurate values of formation constant or molar absorptivity are obtained when the saturation fraction of the most dilute component lies between 0.2 and 0.8; outside this region, the determined values become somewhat uncertain.

*For the complexes having doublet maximum intensities, the values on the first row are calculated from shorter wavelength and the second from longer wavelength.

The points which define the straight line in B–H equation or others are measured experimentally and, therefore, subject to errors. Hence, the straight line has some uncertainty in its slope and intercept leading to some uncertainty in formation constants (30). The accuracy of the absorbance is about 0.002–0.003, especially for the absorbance beyond the range of 0.3–0.8 leading to estimated errors of ± 0.02 kcal mol^{-1} in ΔF^0_N, ± 0.2 kcal mol^{-1} in ΔH^0_N, and ± 0.6 cal deg^{-1} mol^{-1} in ΔS^0_N. The values of formation constants, K_N, are tabulated in Table 3. For those complexes exhibiting doublets in the spectra, the values evaluated from two different maximum absorption bands agree within the experimental errors.

The formation constants evaluated from the charge-transfer spectra (Table 1) increase with increasing refractive index of the solvent, from dichloromethane ($n_D^{20} = 1.424$), 1,2-dichloroethane (1.445), chloroform (1.446), to carbon tetrachloride (1.460). The trend of increasing formation constant presumably arises through the decreasing competition of solvation with either donor or acceptor. Therefore, carbon tetrachloride may be regarded as the most "inert" solvent in this series. In addition, there is no evidence of deviation from linearity for the ln K_N against $1/T$ plot over a 50° temperature range for the systems studied. This indicates that only 1:1 complex exists (9) under the present experimental conditions. Thus, the formation of carbon tetrachloride complexes with methylbenzenes is comparatively insignif-

icant. Foster and Matheson (9) also have indicated that, under the conditions of approximately equal concentrations of donor and acceptor used, a single 1:1 hexamethylbenzene–TCNE complex in 1,2-dichloroethane is formed with no significant contributions from isomeric complexes or from contact charge transfer.

The thermodynamic constants, ΔF^0_N, ΔH^0_N, and ΔS^0_N based on K_N values are tabulated in Tables 4 and 5, respectively. The decreases (*i.e.*, more negative) in ΔH^0_N with increasing methylation on the benzene ring are accompanied by parallel decreases in ΔF^0_N and ΔS^0_N. There is little difference in the thermodynamic quantities for the isomers having the same number of methyl substituents, which implies that the evidence for the steric repression of complex formation by the methyl groups in these $b\pi$–$a\pi$ complexes is lacking. It is apparent that the entropy changes show a slight decrease with increasing number of methyl substituents. However, the entropies do not vary widely for the series of TCNE complexes, from 5 to 7 cal/mol deg only. Similar phenomena are also reported

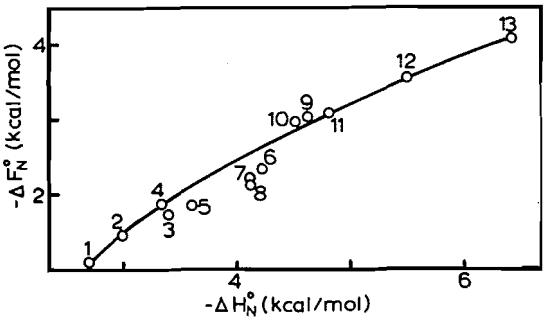

FIG. 1. Relation between free energy and enthalpy of formation for TCNE complexes with methylbenzenes in carbon tetrachloride at 25 °C. Numbers refer to the donors in Table 4.

for the entropies of formation for a number of iodine complexes with methylbenzenes, which are all of the order of 4 to 5 cal/mol deg (31).

The expected correlation between $\Delta F^0{}_N$ and $\Delta H^0{}_N$ (Fig. 1) implies that the decrease in free energy or entropy on forming the complex becomes greater due to the more restricted configuration of the atoms as the complex become more stable. It has been shown that the contribution to enthalpy of formation is mainly from the energy of electron donor–acceptor interaction with a small contribution from the changes in translational, rotational, and vibrational energy levels of the reactants on complex formation (32). Values of $-\Delta H^0{}_N$ are usually of the order of 3 to 7 kcal/mol which show that interaction between the components is weaker than the classical or ionic bonding. The correlations between the relative strength of the electron donor–acceptor interaction as estimated from $\Delta H^0{}_N$ or $\Delta F^0{}_N$ and the strength of the donor as measured by its vertical ionization potentials (15) for the TCNE complexes are shown in Fig. 2. In general, regular, though non-linear, relationships are observed between $\Delta H^0{}_N$ and I_D, and between $\Delta F^0{}_N$ and I_D for a series of complexes involving a common acceptor. It is deduced that the complex formation increases with the donor strength to release an electron from the bonding π orbital similar to parallel studies by infrared and proton resonance spectroscopy and by calorimetry (33).

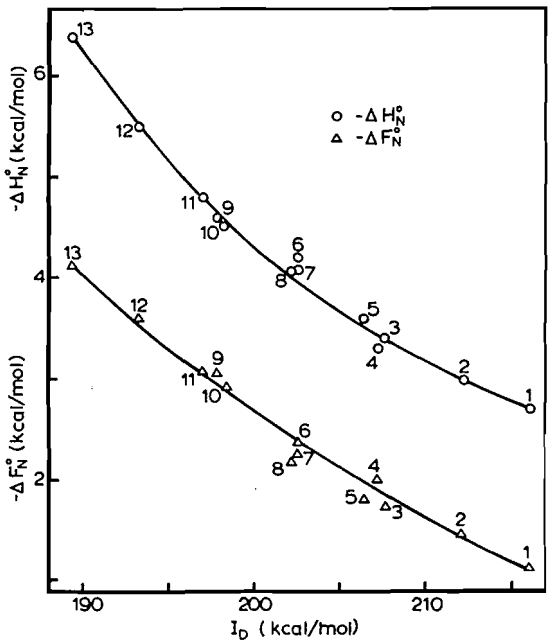

FIG. 2. Correlations of the free energies, and enthalpies of the TCNE complexes at 25 °C with the vertical ionization potentials of methylbenzenes. Numbers refer to the donors in Table 4.

Synthesis of Some New Phosphino Acetylenes

A. J. CARTY, N. K. HOTA, T. W. NG, H. A. PATEL,[1] AND T. J. O'CONNOR
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received November 30, 1970

The synthesis and characterization of the new phosphino acetylenes $(C_6H_5)_2PC{\equiv}CCF_3$, $(C_6H_5)_2PC{\equiv}CC(CH_3)_3$, $(C_6H_5)_2PC{\equiv}CP(C_6F_5)_2$, $(C_6F_5)_2PC{\equiv}CCH_3$, $(C_6F_5)_2PC{\equiv}CC_6H_5$, $(C_6H_5)_2PC{\equiv}CP[N(C_2H_5)_2]_2$, the mixed arsine–phosphine $(C_6H_5)_2PC{\equiv}CAs(C_6H_5)_2$, and the arsino acetylene $(C_6H_5)_2AsC{\equiv}CCF_3$ are reported.

On rapporte la synthèse et la caractérisation des nouveaux phosphino-acétylènes $(C_6H_5)_2PC{\equiv}CCF_3$, $(C_6H_5)_2PC{\equiv}CC(CH_3)_3$, $(C_6H_5)_2PC{\equiv}CP(C_6F_5)_2$, $(C_6F_5)_2PC{\equiv}CCH_3$, $(C_6F_5)_2PC{\equiv}CC_6H_5$, $(C_6H_5)_2PC{\equiv}CP[N(C_2H_5)_2]_2$, de l'arsine-phosphine mixte $(C_6H_5)_2PC{\equiv}CAs(C_6H_5)_2$, et de l'arsino-acétylène $(C_6H_5)_2AsC{\equiv}CCF_3$.

Canadian Journal of Chemistry, 49, 2706 (1971)

Introduction

During the past decade a number of tertiary phosphines containing α-acetylenic groups have been characterized (1). These include trialkynylphosphines $P(C{\equiv}CR)_3$ (2–4), dialkyl or diaryl alkynylphosphines $R_2'PC{\equiv}CR$ (5–10), aryldialkynylphosphines $R'P(C{\equiv}CR)_2$ (3), acetylenic diphosphines $R_2PC{\equiv}CPR_2$ (5, 11–13), and a variety of organometal phosphines with α-acetylenic substituents (14). Our interest in the coordinating properties of acetylenic phosphines and diphosphines (15) prompted us to attempt the synthesis of several ligands having substituents of varying electronegativity on the phosphorus atom or hydrocarbon residue. In this paper we report the preparation and characterization of $(C_6H_5)_2PC{\equiv}CCF_3$, $(C_6H_5)_2AsC{\equiv}CCF_3$, $(C_6H_5)_2PC{\equiv}CC(CH_3)_3$, $(C_6F_5)_2PC{\equiv}CCH_3$, $(C_6F_5)_2PC{\equiv}CC_6H_5$, $(C_6H_5)_2PC{\equiv}CP(C_6F_5)_2$, $(C_6H_5)_2PC{\equiv}CP[N(C_2H_5)_2]_2$, and $(C_6H_5)_2PC{\equiv}CAs(C_6H_5)_2$.

Experimental

The following compounds were obtained commercially: C_6F_5Br (Fluorochem Ltd.), $(C_6H_5)_2PCl$ (Orgmet Inc.), $(CH_3)_3CC{\equiv}CH$ (Farchan Research Laboratories), $CF_3C{\equiv}CH$ (Pierce Chemical Co.) $(C_6H_5)_2AsCl$ (Strem Chemicals), n-C_4H_9Li (Alfa Inorganics).

Phosphine and Arsine Syntheses

$(C_6H_5)_2PC{\equiv}CCF_3$

Two methods were used for the synthesis of this compound.

(*a*) Diethylaminodiphenylphosphine $(C_6H_5)_2PN(C_2H_5)_2$ was prepared from diethylamine and diphenylchlorophosphine by the method of Ewart and co-workers (16). Diethylaminodiphenylphosphine (5.0 g) was weighed into a Carius tube, pentane (5 ml) added, and a slight excess (3.0 g) of 3,3,3-trifluoropropyne condensed into the tube *in vacuo*. The tube was sealed and allowed to warm to room temperature. Reaction appeared to be complete after *ca.* 3 h. The tube was cooled, vented, and washed with pentane. Fractionation of the liquid remaining after pentane removal afforded the required product in 45% yield.

(*b*) 3,3,3-Trifluoropropyne (9.4 g) was condensed at −78° into a Carius tube, the tube cooled, opened, and the propyne added to ether (25 ml) at −78° in a two-necked flask equipped with magnetic stirrer, dropping funnel, and nitrogen inlet. The stoichiometric reaction quantity of *n*-butyllithium (3 *M* in hexane) with ether (20 ml) was then added dropwise via the funnel, the temperature being maintained at −78°. After 1 h diphenylchlorophosphine (22.1 g) in ether (25 ml) was added slowly while stirring. The reaction mixture was then allowed to warm to room temperature and stirred for 1 further h. Ether was removed on a rotary evaporator and benzene added to precipitate lithium chloride. After filtration, benzene was removed and the black filtrate was distilled under reduced pressure to yield colorless $(C_6H_5)_2PC{\equiv}CCF_3$ (65%).

$(C_6H_5)_2AsC{\equiv}CCF_3$

This compound was prepared as above using $(C_6H_5)_2AsCl$ for $(C_6H_5)_2PCl$. Method (*b*) again gave better yields.

$(C_6H_5)_2PC{\equiv}CC(CH_3)_3$[2]

The lithium salt of 3,3-dimethyl-1-butyne was made by the reaction of the acetylene (8.2 g) with *n*-butyllithium at −78°. After addition of $(C_6H_5)_2PCl$ (22.1 g) in ether (25 ml) the flask was warmed to room temperature. The white precipitate was dissolved in a minimum of chloroform and water (30 ml) added. The organic layer was dried over magnesium sulfate, evaporated to half volume, and cooled overnight at 0°. The product was obtained as white needles (68%).

$(C_6F_5)_2PC{\equiv}CCH_3$

Bis(pentafluorophenyl)chlorophosphine was synthe-

†Solutions in $CHCl_3$.
‡Raman measurement in CCl_4.

sized as described by Magnelli and co-workers (17). To lithium propynylide (0.1 mol) in ether/hexane 1:1 at −78° (from $CH_3C{\equiv}CH + n\text{-}C_4H_9Li$) was added an ether solution of bis(pentafluorophenyl)chlorophosphine (0.1 mol). The solution was allowed to reach room temperature then stirred for a further 2 h to give a reddish solution. Ether was removed *in vacuo*, petrol ether (40–60°) (50 ml) added, and the mixture filtered. The filtrate was distilled under reduced pressure yielding $(C_6F_5)_2PC{\equiv}CCH_3$ as a colorless liquid in 52% yield based on the chloride.

$(C_6F_5)_2PC{\equiv}CC_6H_5$

This compound was prepared in an identical fashion to the above using phenylacetylene for propyne. Colorless crystals (62%) were obtained.

$(C_6H_5)_2PC{\equiv}CP(C_6F_5)_2$

Diphenylethynylphosphine $(C_6H_5)_2PC{\equiv}CH$ was prepared according to the method of Charrier and co-workers (10). To an ether/hexane solution of $(C_6H_5)_2PC{\equiv}CLi$ (from $(C_6H_5)_2PC{\equiv}CH$ (4.0 g) and $n\text{-}C_4H_9Li$ (9.6 ml of 2/m) in hexane) was added with stirring 7.2 g of $(C_6F_5)_2PCl$ in ether (25 ml). Work-up was similar to that for $(C_6F_5)_2PC{\equiv}CCH_3$ and yielded colorless crystals (66%) which were recrystallized from ethanol.

$(C_6H_5)_2PC{\equiv}CAs(C_6H_5)_2$

This compound was prepared from $(C_6H_5)_2PC{\equiv}CLi$ and $(C_6H_5)_2AsCl$ in a similar manner to the above. Recrystallization of the product from chloroform/ethanol gave colorless needles (50%).

$(C_6H_5)_2PC{\equiv}CCH_3$ and $(C_6H_5)_2PC{\equiv}CC_6H_5$

These were prepared from the appropriate acetylene via the *n*-butyllithium method above. This gives superior yields to the Grignard preparation used earlier by Charrier and co-workers (10).

$(C_6H_5)_2PC{\equiv}CP[N(C_2H_5)_2]_2$

Bis(diethylamino)chlorophosphine $[(C_2H_5)_2N]_2PCl$ was obtained as a liquid b.p. 60–62° (0.6 mm) from phosphorus trichloride and diethylamine as previously described (18). The chlorophosphine (14.5 g) in ether (25 ml) was added dropwise to $(C_6H_5)_2PC{\equiv}CLi$ (from $(C_6H_5)_2PC{\equiv}CH$ (15.0 g) + $n\text{-}C_4H_9Li$ (36 ml of 2 *M*)) in ether/hexane at −78°. After warming to room temperature the reaction was completed by stirring for 1 h. The brown suspension remaining was filtered under nitrogen and the solvent removed *in vacuo*. Dry petrol-ether (40–60°) was added to precipitate lithium chloride, then the mixture filtered. After removal of solvent the residue was distilled at 10^{-3} mm. The fraction collected at 145–148° was the desired product. Considerable decomposition occurred on distillation, the yield being 44%.

Physical Measurements

The i.r. spectra were recorded on a Beckman IR 9 spectrometer as solutions in chloroform. Mass spectra were measured with a Perkin–Elmer RMU-6E instrument. The mass spectra of the phosphines are given in Table 2 and ν (C≡C) stretching frequencies of the ligands in Table 1.

Results and Discussion

The compounds prepared (Table 1) considerably extend the range of known phosphino acetylenes. The derivative $(C_6H_5)_2PC{\equiv}CAs(C_6H_5)_2$ is the first acetylenic mixed phosphine–arsine to be described. Compounds $(C_6H_5)_2PC{\equiv}CP(C_6F_5)_2$ and $(C_6H_5)_2PC{\equiv}CP[N(C_2H_5)_2]_2$ represent the first examples of unsymmetrical acetylenic diphosphines. Compounds of this type are expected to be of importance in the direct measurement of three-bond P–P coupling constants in n.m.r. spectroscopy (19).

We wish to draw attention to the synthetic utility of the compound $(C_6H_5)_2PC{\equiv}CH$ which is readily preparable (10) from $(C_6H_5)_2PCl$ and the mono-Grignard of acetylene. Reaction of $(C_6H_5)_2PC{\equiv}CH$ with *n*-butyllithium in ether or hexane gives high yields of lithium diphenylphosphinoethynylide $(C_6H_5)_2PC{\equiv}CLi$. This salt can then be used for the preparation of unsymmetrical species in good yield via reaction with R_2PCl or R_2AsCl.

Unlike the alkyldiphenylphosphines, the α-

*Spectra were measured at 70 eV.

acetylenic phosphines (Table 1) show little tendency to oxidize spontaneously in air although P=O stretching bands can be found in the i.r. spectra of samples recovered after long periods in non-degassed solvents. Other workers have likewise noted the stabilizing effect of α-acetylenic substituents on tertiary phosphines (4, 20). The presence of strongly electron-withdrawing substituents on either phosphorus or the hydrocarbon residue appears to have no marked effect on the ease of oxidation of the phosphorus atoms. Slow decomposition of $(C_6H_5)_2MC{\equiv}CCF_3$ (M = P, As) and $(C_6H_5)_2PC{\equiv}CP[N(C_2H_5)_2]_2$ occurs on prolonged standing at room temperature. We have, however, noted distinct differences in the behavior of $(C_6H_5)_2PC{\equiv}CCH_3$ and $(C_6H_5)_2PC{\equiv}CCF_3$ toward iron carbonyls with the C≡C bond of the latter being considerably more reactive (21).

The i.r. spectra of the compounds in the range 2000–650 cm^{-1} resemble those of trivalent phosphorus compounds with similar substituents (10, 16, 22) and are not reported here. The main feature of interest concerns the ν (C≡C) frequency of the acetylenes. For the compounds $(C_6H_5)_2PC{\equiv}CCF_3$, $(C_6H_5)_2AsC{\equiv}CCF_3$, $(C_6F_5)_2PC{\equiv}CCH_3$, $(C_6F_5)_2PC{\equiv}CC_6H_5$, and $(C_6H_5)_2PC{\equiv}CCH_3$, the C≡C stretching vibration appears at the lower end of the range (2300–2175 cm^{-1}) normally found for disubstituted acetylenes (23). The compound $(C_6H_5)_2PC{\equiv}CC(CH_3)_3$ exhibits two bands in the ν (C≡C) region, as observed for several derivatives of $HC{\equiv}CC(CH_3)_3$ (4). The two unsymmetrical diphosphines show a weak–medium intensity band due to ν (C≡C) in the i.r. at frequencies close to the value of 2097 cm^{-1} observed for ν (C≡C) of $(C_6H_5)_2PC{\equiv}CP(C_6H_5)_2$ in the Raman (12). The mixed phosphine–arsine ligand has no band in the i.r. attributable to ν (C≡C) but in the Raman a strong line appears at 2092 cm^{-1}. As we have previously pointed out (24) these low C≡C stretching frequencies may be indicative of a π type interaction between phos-

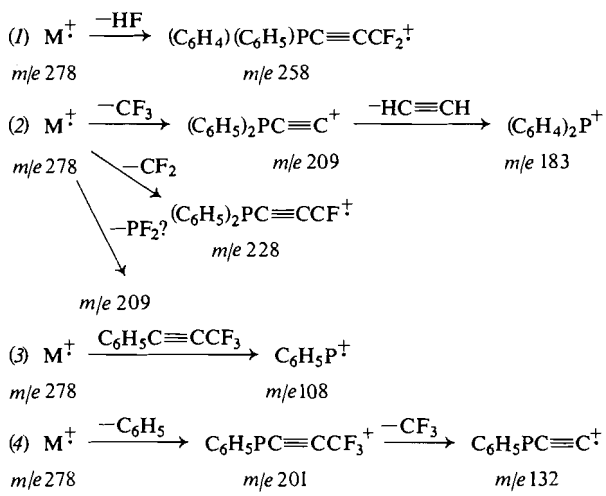

SCHEME 1. SOME possible fragmentation pathways for $(C_6H_5)_2PC{\equiv}CCF_3$.

phorus and the acetylenic carbon atom. A similar effect, but to a lesser extent, may be operative in the acetylenes having only one phosphorus or arsenic substituent. Similar conclusions have been reached from an X-ray study of $(C_6H_5)_2PC{\equiv}CP(C_6H_5)_2$ (25) and from i.r. studies of the analogous silicon species (26).

Mass Spectra

The abundances of major ions in the mass spectra of the phosphines prepared are given in Table 2. Spectra were recorded to obtain accurate molecular weights and to provide confirmation of the stoichiometries of the products. With the exception of $(C_6H_5)_2PC{\equiv}CP[N(C_2H_5)_2]_2$ all the phosphines exhibit parent ion peaks in the mass spectra. The absence of peaks at *m/e* higher than that of the parent ion testifies to the purity of the products. For $(C_6H_5)_2PC{\equiv}CCF_3$, $(C_6H_5)_2PC{\equiv}CCH_3$, and $(C_6H_5)_2PC{\equiv}CAs(C_6H_5)_2$ the $M^{+\cdot}$ ions are most abundant. The fragmentation patterns for $(C_6H_5)_2PC{\equiv}CCF_3$ and $(C_6H_5)_2AsC{\equiv}CCF_3$[3] are complex, apparently involving at least four mechanistic pathways as given for $(C_6H_5)_2PC{\equiv}CCF_3$ in Scheme 1. The initial fragmentation steps involving loss of HF, CF_3, and $C_6H_5C{\equiv}CCF_3$ are all supported by the appearance of appropriate metastable ions. It should be kept in mind however that $C_6H_5P^{+\cdot}$ could be the end product of several different fragmentation pathways in addition to *3*. From the ion abundances *2* and *3* appear to be dominant. In addition however rearrangement occurs during fragmentation since ions such as $C_6H_5C{\equiv}CC_6H_5^+$ (*m/e* 178) and $C_6H_5C_3F_4^+$ (*m/e* 189) are found in reasonable abundance. Similar behavior has been noted in the mass spectra of related fluorophosphines (27). For $(C_6H_5)_2AsC{\equiv}CCF_3$ biphenylene (or $C_6H_5As^{\cdot+}$) (*m/e* 152) is the base ion and mechanisms *1* and *3* are apparently more important than *2* or *4*. The relative abundances of $(C_6H_4)_2As^+$ (*m/e* 227) and $(C_6H_4)_2P^+$ (*m/e* 183) do not differ significantly. $(C_6H_5)As^{+\cdot}$ (*m/e* 152) is however more abundant than $(C_6H_5)P^{+\cdot}$ (*m/e* 108). A similar trend has been noted by Miller and Rake (28) in the mass spectra of pentafluorophenyl phosphorus and arsenic derivatives. An ion of *m/e* 209 carries a significant amount of ion current in $(C_6H_5)_2AsC{\equiv}CCF_3$. This may arise via loss of AsF_2 from $M^{+\cdot}$ followed by rearrangement. The appropriate metastable ion was found for this reaction. For both $(C_6H_5)_2PC{\equiv}CCF_3$ and $(C_6H_5)_2AsC{\equiv}CCF_3$ the presence of fragments $(C_6H_5)_2MC{\equiv}C^+$ (*m/e* 209, M = P; 253, M = As), $C_6H_5MC{\equiv}CCF_3^+$ (*m/e* 201, M = P; 245, M = As) and $C_6H_5MC{\equiv}C^{+\cdot}$ (*m/e* 132, M = P) provide confirmation of the expected structures.

The spectra of the unfluorinated species $(C_6H_5)_2PC{\equiv}CR$ (R = CH_3, C_6H_5, $C(CH_3)_3$) are simpler than their fluorinated analogues. The base ions are M^+ for R = CH_3, $C_6H_5C{\equiv}CC_6H_5^+$

[3]NOTE ADDED IN PROOF: Exact mass measurements on ions in the mass spectrum of $(C_6H_5)_2AsC{\equiv}CCF_3$ confirm the identity of fragments arising from loss of HF, AsF_2, C_6H_5, and $C_6H_5C{\equiv}CCF_3$ from $M^{+\cdot}$.

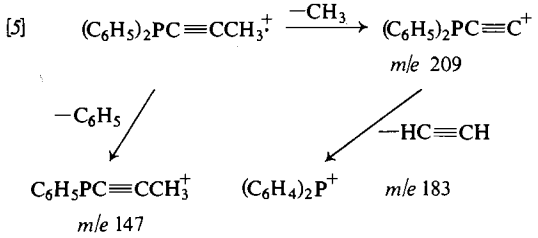

SCHEME 2

for R = C_6H_5, and $(CH_3)_3C^+$ for R = $(CH_3)_3C$. Two fragmentation patterns of importance are *5* shown in Scheme 2 for $(C_6H_5)_2PC{\equiv}CCH_3$. Metastables were found for both reactions. A similar mechanism is operative for $(C_6H_5)_2PC{\equiv}CC_6H_5$ and again supported by appropriate metastable peaks. The high abundance of $C_6H_5C{\equiv}CC_6H_5^+$ in the phenyl acetylene suggests either rearrangement of $(C_6H_5)_2PC{\equiv}C^+$ after elimination of P or direct elimination of C_6H_5P from $(C_6H_5)_2PC{\equiv}CC_6H_5^{\cdot+}$. The latter reaction gave a strong metastable at *m/e* 110.8. For $(C_6H_5)_2PC{\equiv}CR$ (R = CH_3, C_6H_5) the fragments $(C_6H_4)_2P^+$ (*m/e* 183), $(C_6H_4)_2CR^+$ (*m/e* 115, R = CH_3; 177 R = C_6H_5), $C_6H_5P^{\cdot+}$ (*m/e* 108), $C_6H_5^+$ (*m/e* 77), $C_5H_3^+$ (*m/e* 63), $C_4H_3^+$ (*m/e* 51), $C_4H_2^+$ (*m/e* 50), $C_3H_3^+$ (*m/e* 39) appear in reasonable abundance. For $(C_6H_5)_2PC{\equiv}CC(CH_3)_3$ the major ions apart from M^+ appear at low *m/e*.

The diphosphine $(C_6H_5)_2PC{\equiv}CP(C_6H_5)_2$ and the mixed P, As compound $(C_6H_5)_2PC{\equiv}CAs(C_6H_5)_2$ show similar fragmentation patterns with loss of $(C_6H_5)_2P$ and $(C_6H_5)_2As$ being the major reactions. Both decompositions were supported by metastable transitions. The ions $(C_6H_4)_2M^+$ (M = P), which appear in most spectra presumably result from loss of $HC{\equiv}CH$ from $(C_6H_5)_2PC{\equiv}C^+$ (*m/e* 209).

No parent ion was observed for $(C_6H_5)_2PC{\equiv}CP[N(C_2H_5)_2]_2$. However, the occurrence of fragments $(C_6H_5)_2PC_2PH_2^+$ (*m/e* 242), $[(C_2H_5)_2N]_2PC{\equiv}C^+$ (*m/e* 199), $(C_6H_5)_2P^+$ (*m/e* 185), and $(C_6H_4)_2P^+$ (*m/e* 183) leave little doubt that the compound is correctly formulated.

In $(C_6H_5)_2PC{\equiv}CAs(C_6H_5)_2$ and $(C_6H_5)_2PC{\equiv}CP[N(C_2H_5)_2]_2$ cleavage of *either* the $C{-}P(C_6H_5)_2$ or $C{-}MR_2$ (M = As, R = C_6H_5; M = P, R = $N(C_2H_5)_2$) bonds may occur as a first fragmentation step. In the unsymmetrical pentafluorophenyl derivative $(C_6F_5)_2PC{\equiv}CP(C_6H_5)_2$ the most abundant peak is $(C_6H_5)_2PC{\equiv}C^+$, suggesting preferential cleavage of the $C{-}P(C_6F_5)_2$ bond. A strong metastable ion supports this assignment. Loss of $HC{\equiv}CH$ from $(C_6H_5)_2PC{\equiv}C^+$ then leads to $(C_6H_4)_2P^+$ at *m/e* 183.

For the compounds $(C_6F_5)_2PC{\equiv}CR$ (R = C_6H_5, CH_3) the dominant reactions (both give metastable peaks) involve loss of C_6F_5 from M^+ and loss of C_6F_5P (or $C_6F_5C{\equiv}CR$) from $M^{\cdot+}$. Loss of R appears to be of minor importance in the fragmentation of these phosphines in contrast to the behavior of the unfluorinated analogues. Compound $(C_6F_5)PC{\equiv}CC_6H_5^+$ is the base ion for $(C_6F_5)_2PC{\equiv}CC_6H_5$ and CF_3^+ (or PF_2^+) for $(C_6F_5)_2PC{\equiv}CCH_3$. Rearrangement following fragmentation also appears to be essential in order to account for several ions in high abundance in the mass spectra of these derivatives.

We thank Arapahoe Chemicals, Division of Syntex Corporation, for financial support of this work. The continued support of the National Research Council of Canada is appreciated.

Synthetic Studies of Hydronaphthacenic Antibiotics. I. The Synthesis of 4-Demethoxy-7-*O*-methyl Daunomycinone

C. M. WONG, D. POPIEN, R. SCHWENK, AND J. TE RAA
Department of Chemistry, University of Manitoba, Winnipeg 19, Manitoba

Received March 23, 1971

Daunomycin is a new and very promising antitumor antibiotic. This communication reports the synthesis of (*dl*)-4-demethoxy-7-*O*-methyl daunomycinone as part of a scheme toward the total synthesis of daunomycin.

La daunomycine est un antibiotique nouveau et prometteur contre les tumeurs. Cette communication relate la synthèse du *dl* déméthoxy-4 *O*-méthyl-7 daunomycinone en tant qu'étape en vue de la synthèse totale de la daunomycine.

Canadian Journal of Chemistry, 49, 2712 (1971)

Introduction

In the last two decades numerous antibiotics with a linear tetracyclic skeleton have been isolated from different kinds of bacterial cultures (1). The tetracyclines attracted the attention of many organic chemists due to their very complicated structures and their potent antibacterial properties. Thus the syntheses of tetracyclines have been reported by many research groups since 1962 (2). Rhodomycins (3) are another group of antibiotics having a linear tetracyclic skeleton but which are not as potent against bacteria as the tetracyclines. However, two members recently isolated, daunomycin (rubidomycin) (**1**) and adriamycin (**2**) (5), have shown very high activity against tumors (4) and have been used successfully in treating acute lymphomas.

Daunomycin under mild acid hydrolysis gives an amino-sugar daunosamine (**3**) and a tetracyclic hydronaphthacenequinone aglycone daunomycinone (**4**). The synthesis of **3** and its derivatives was reported recently (6). A synthesis of the tetracyclic system **5** and the condensation of **5** with glucose was also reported (7). However, the synthesis of the tetracyclic aglycone **4** has not been reported and we are reporting our synthesis of 4-demethoxy-7-*O*-methyl daunomycinone (**6**) as a working model toward the total synthesis of daunomycin and adriamycin.

Results and Discussion

Condensing 2,5-dimethoxybenzaldehyde with 2,4-pentanedione in benzene solution in the presence of piperidine and acetic acid gave almost quantitatively the diketone **7**, which upon hydrogenation in ethanol using 5% Pd/C as catalyst, gave the diketone **8**. This compound, when freshly distilled, existed in an equilibrium between the keto and the enol form. This was evident from the n.m.r. spectrum which showed a small peak at $-6.50\ \tau$ corresponding to the enol proton with an area integrated to about one-third of a hydrogen; a singlet at $6.58\ \tau$ corresponding to the benzylic hydrogens of the enol-form and a doublet at $7.06\ \tau$ corresponding to the benzylic hydrogens of the keto-form. On standing, the diketone **8** crystallized entirely in the enol-form; this was shown by the n.m.r. spectrum which now had a singlet at $-6.63\ \tau$ for the enol proton integrating to exactly one hydrogen.

The diketone **8** was then alkylated with ethyl-bromoacetate and sodium hydride in anhydrous tetrahydrofuran to give the keto-ester **9** which on treatment with aqueous sodium hydroxide solution underwent a reversed Claisen followed by the hydrolysis of the ester to give the keto-acid **10**. Cyclization of **10** in the presence of hydrofluoric acid gave the tetralone **11** or the lactone **12** depending on the concentration and the reaction temperature. At 35 °C and low concentration of **10**, the tetralone **11** was isolated in 72% yield together with the lactone **12** in about 5% yield. At 0 °C and high concentration of **10**, the lactone **12** was isolated as the major product.

Hydrogenolysis of **11** in acidic ethanolic solution in the presence of 5% Pd/C gave the tetralin **13**, which upon oxidation in *t*-butyl alcohol with potassium *t*-butoxide and oxygen followed by reduction with zinc gave the hydroxyketone **14** in

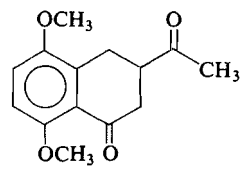
10



11

excellent yield. The use of sodium *t*-butoxide however, gave less than 5% yield, possibly due to the low solubility of the sodium salt at the reaction temperature.

In order to ascertain that the hydroxy group is in the tertiary position, the tetralin **13** was reduced with sodium borohydride to the corresponding alcohol and eventually converted to the olefinic mixture **15** by tosyl chloride and pyridine. Osmium tetroxide oxidation of **15** to the diol **16** followed by oxidation with dicyclohexylcarbodiimide and dimethylsulfoxide gave the identical hydroxyketone **14**.

Condensing **14** with phthalic acid monomethyl ester in trifluoroacetic anhydride solution followed by basic hydrolysis and then cyclization with hydrofluoric acid gave the tetracyclic hydroxyketone **17**. This was then converted to

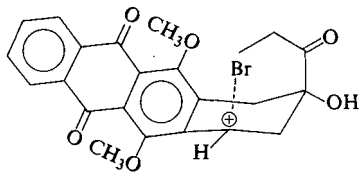
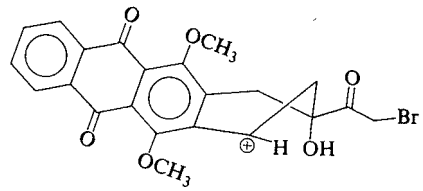
the ketal **18** making the two benzylic positions different enough to be selectively attacked by *N*-bromosuccinimide on the less hindered position. Thus refluxing the ketal **18** with *N*-bromosuccinimide in carbon tetrachloride in the presence of a trace of benzoyl peroxide gave the unstable bromoketal **19** and the dibromide **20**. This mixture, without purification, was then refluxed in anhydrous methanol to give **21**, **22**, and **23** which were separated from each other by t.l.c. on silica.

The stereochemistry of **21**, **22**, and **23** was assigned mainly on the basis of the n.m.r. spectra of **14**, **17**, **18**, **21**, **22**, and **23**. Under identical conditions, the hydroxy protons of **14**, **17**, **18**, and **22** had chemical shifts higher than 6 τ while those of **21** and **23** were lower than 5 τ. The chemical shift differences are interpreted as being a result of the existence of hydrogen bonding between the hydroxy proton and the C_7—OCH_3 groups in **21** and **23**.

The fact that the C_7-isomer of **21** was not observed and that there was twice as much of **23** produced as **22** would indicate that the conversion



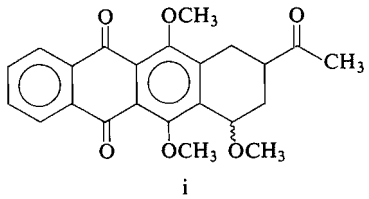
24
26 Br replaced by H



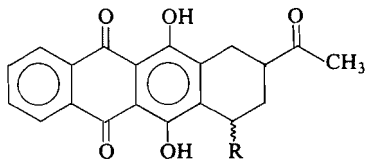
25
27 Br replaced by H

of **19** and **20** to **21**, **22**, and **23** went through a partially stereospecific S_N1 process.[1] The C_7-carbonium ion formed when **20** is refluxed in methanol exists mainly in the conformation **24** which is more stable than the other conformation **25** due to the presence of a bridging between the bromine atom and the carbonium ion.[2] Thus methanol can only come from the α-side giving the C_7-*O*-methyl group *cis* to the C_9-hydroxy group. On the other hand, the carbonium ions **26** and **27** are very similar energetically. In the former case methanol will come mainly from the α-side due to the steric effect of the axial C_9-acetyl group while in the latter case, approach of methanol from the β-side is slightly favored.

[1]In another series of investigations, the conversion of **i** to **ii** by aluminum chloride in refluxing benzene was accompanied by the formation of **iii**, also dissolving **ii** in chloroform in the presence of trifluoroacetic acid gave the corresponding trifluoroacetate **iv**. These results would indicate that the formation of a carbonium ion was very easy.



i



ii R = OCH_3
iii R = C_6H_5
iv R = $O-\overset{O}{\overset{\|}{C}}-CF_3$

[2]This will be proven further in the synthetic approach to adriamycin.

The hydroxyketone **23** was then hydrolyzed to the red crystalline 4-demethoxy-7-*O*-methyl daunomycinone (6) in benzene solution in the presence of aluminum chloride (5*b*).

Experimental

Melting points and boiling points are uncorrected. The i.r. spectra (cm^{-1}) were recorded on a Perkin–Elmer model 700 spectrophotometer using methylene chloride as solvent or as otherwise specified. The n.m.r. spectra (τ) were recorded on a Varian Model A56/60A MHz spectrometer using deuterated chloroform as solvent and tetramethylsilane as internal standard. Mass spectra were recorded on a Hitachi Perkin–Elmer Model RMU-6D or a Finnigan Model 1015 mass-spectrometer. High resolution mass spectra were recorded on the MS9 mass-spectrometer of the Chemistry Department, University of Alberta, Edmonton, Alberta. Microanalyses were performed by Dr. Daesslé of Montreal and Dr. Yates of Arizona.

Preparation of 3-Acetyl-4-(2′,5′-dimethoxyphenyl) 3-Buten-2-one (7)

A benzene solution (500 ml) containing 2,5-dimethoxybenzaldehyde (100 g), 2,4-pentanedione (80 g), piperidine (4 ml), and acetic acid (12 ml) was refluxed in a 1 l flask equipped with a condenser and a water separator, for 2 h. The benzene was then removed under reduced pressure and the residue which crystallized on standing (148 g) could be purified by recrystallization from methanol; m.p. 65–66 °C; i.r. 1710 and 1700 (ketones), 1665 (C=C), 1620 and 1595 (aromatic); n.m.r. 2.51 (s, 1H, olefinic), 3.33 (s, 3H, aromatic), 6.33 (s, 3H, OCH_3), 6.45 (s, 3H, OCH_3), 7.82 (s, 3H, $COCH_3$), 8.00 (s, 3H, $COCH_3$).

Preparation of 3-Acetyl-4-(2′,5′-dimethoxyphenyl) 2-Butanone (8)

The crude product **7** above was dissolved in 200 ml of distilled ethanol and filtered into a 3 l flask containing Pd/C (5%, 13 g) and distilled ethanol (1.3 l). The solution was then hydrogenated at atmospheric pressure until the uptake of hydrogen ceased. The catalyst was removed by filtration and the ethanol evaporated under reduced pressure. The residue was purified by distillation (b.p. 150–155 °C at 0.5 mm Hg) (133 g). The distillate crystallized on standing and was recrystallized from carbon tetrachloride and petroleum ether; m.p. 63–68 °C; i.r. 1600 (broad); n.m.r. −6.63 (s, 1H, enol), 3.17–3.58 (m, 3H, aromatic), 6.24 (s, 3H, OCH_3), 6.34 (s, 3H, OCH_3), 6.47 (s, 2H, benzylic), 8.00 (s, 6H, $C-CH_3$).

*Preparation of 3-Acetyl-4-(2',5'-dimethoxyphenyl) Butanoic Acid (**10**)*

To a 1 l flask equipped with a mechanical stirrer, a condenser, and a dropping funnel, freshly distilled dry tetrahydrofuran (600 ml), the diketone **8** (30 g), and sodium hydride (6 g 50% mineral oil suspension) in small portions were added. The tetrahydrofuran solution was heated to a gentle reflux and ethyl bromoacetate (21 g) in dry tetrahydrofuran (50 ml) was added through the dropping funnel over a period of 15 min. After refluxing for 1 h, most of the tetrahydrofuran was distilled off and water (100 ml) was added to the residue. The aqueous solution was extracted exhaustively with benzene. The benzene solution was dried over magnesium sulfate, and evaporated under reduced pressure to give the crude crystalline keto-ester **9** (40 g) which could be recrystallized from methanol; m.p. 66–67 °C; i.r. 1735 (ester), 1700 (ketone), 1600 (aromatic); n.m.r. 3.35 (m, 3H, aromatic), 5.86 (q, 2H, $COOCH_2$—CH_3), 6.30 (s, 3H, OCH_3), 6.37 (s, 3H, OCH_3), 6.58 (s, 2H, benzylic), 7.18 (s, 2H, CH_2—$COOC_2H_5$), 7.80 (s, 6H, $COCH_3$), 8.75 (t, 3H, $COOCH_2CH_3$).

Anal. Calcd. for $C_{18}H_{24}O_6$: C, 64.27; H, 7.19. Found: C, 64.11; H, 6.99.

The keto-ester **9** was then hydrolyzed by heating in a sodium hydroxide solution (8%, 250 ml) at 65 °C for 3 h. The basic solution was then washed with benzene and acidified with cold concentrated hydrochloric acid. The keto-acid precipitate **10** was filtered and dried in a desiccator to give 27 g of white solid which was further purified by recrystallization from methanol, m.p. 106–107 °C; i.r. 1740 (acid), 1700 (ketone); n.m.r. −2.10 (s, 1H, COOH), 2.70 (m, 3H, aromatic), 5.97 (s, 3H, $COCH_3$).

Anal. Calcd. for $C_{14}H_{18}O_5$: C, 63.13; H, 6.76. Found: C, 63.30; H, 6.58.

*Cyclization of Keto-acid **10***

The keto-acid **10** (10 g) was added with stirring into a polyethylene reaction flask containing hydrofluoric acid (100 ml). After stirring for 3 h in a water bath at 20 °C, the temperature was raised to 40 °C to evaporate the remaining hydrofluoric acid. The residue was diluted with water and extracted exhaustively with chloroform. The chloroform solution was washed with sodium bicarbonate solution, dried, and then evaporated to dryness under reduced pressure. Upon addition of methanol to the residue, the tetralone **11** crystallized and was then collected by filtration. The mother liquor was evaporated to dryness and the residue was dissolved in benzene. After stirring the benzene solution with sodium hydroxide solution (25 ml, 8%) for 2 h, the benzene layer was separated, washed with water, and dried over magnesium sulfate and evaporated to dryness. Upon addition of methanol and ether, another crop of tetralone **11** crystallized and was collected as before. The combined tetralone **11** (6.7 g) was further purified by recrystallization from methanol ether; m.p. 123–125 °C; i.r. 1710 (ketone), 1685 (conjugated ketone), 1590 (aromatic); n.m.r. 3.20 (q, 2H, aromatic), 6.20 (s, 3H, OCH_3), 6.23 (s, 3H, OCH_3), 7.97 (s, 3H, $COCH_3$); mass spectrum 248 (m^+/e), 205 (M-$COCH_3$).

The aqueous sodium hydroxide solution was acidified with concentrated hydrochloric acid and then extracted with chloroform. Evaporating the chloroform solution to dryness gave lactone **12** (450 mg) which was purified by recrystallization from methanol; m.p. 137–138 °C; i.r. 1765 (lactone), 1610 (aromatic); n.m.r. 3.38 (s, 3H, aromatic), 6.26 (s, 3H, OCH_3), 6.30 (s, 3H, OCH_3), 8.21 (s, 3H, t-CH_3); mass spectrum 248 (m^+/e), 233 (M-CH_3), 190 (2-methyl, 4,7-dimethoxyindene cation).

*Preparation of 1,4-Dimethoxy-6-hydroxy-6-acetyl Tetralin (**14**)*

A solution of the tetralone **11** (10 g), distilled ethanol (400 ml), concentrated hydrochloric acid (10 ml), water (40 ml), and 5% Pd/C (2 g) was hydrogenated at atmospheric pressure and room temperature for 6 h with mechanical shaking. After filtering the catalyst, the alcoholic solution was evaporated to dryness under reduced pressure. The residue was recrystallized from ethanol and petroleum ether to give the crystalline monoketone **13** (8.4 g); m.p. 81–82 °C; i.r. 1715 (ketone), 1610 (aromatic); n.m.r. 3.41 (s, 2H, aromatic), 6.26 (s, 6H, OCH_3), 7.80 (s, 3H, $COCH_3$).

The monoketone **13** (5.7 g) dissolved in dry t-butyl alcohol (50 ml) was added to an oxygen-saturated t-butyl alcohol solution (400 ml) in a 1 l flask containing potassium t-butoxide prepared by dissolving freshly cut potassium (8 g) in the t-butyl alcohol. Dry oxygen was bubbled through a gas dispersion tube into the solution for exactly 5 min keeping the reaction temperature at 35 °C. The solution was then cooled in an ice bath and glacial acetic acid was added until the solution became acidic. Zinc dust (20 g) was added immediately and the solution was then stirred at room temperature for 6 h. The zinc was then removed by filtration and the filtrate was evaporated to a syrupy residue at 50 °C under reduced pressure. The residue was diluted with water and extracted exhaustively with chloroform. The chloroform solution was dried over magnesium sulfate and evaporated to dryness to give the crude crystalline hydroxyketone **14** (5.5 g) which was purified by recrystallization from methanol and ether; m.p. 100–102 °C; i.r. 3525 (OH), 1705 (ketone), 1600 (aromatic); n.m.r. 3.40 (s, 2H, aromatic), 6.26 (s, 3H, OCH_3), 6.30 (s, 3H, OCH_3), 6.42 (s, 1H, OH), 7.75 (s, 3H, $COCH_3$).

Anal. Calcd. for $C_{14}H_{18}O_4$: C, 67.12; H, 7.20. Found: C, 67.18; H, 7.20.

*Preparation of the Tetracyclic Hydroxyketone **17***

Trifluoroacetic anhydride (10 ml) was added to a mixture of the hydroxyketone **14** (2 g) and the phthalic acid monomethyl ester (4 g). The solution was refluxed under dry nitrogen atmosphere overnight. After removing the trifluoroacetic anhydride under reduced pressure, the residue was hydrolyzed by 8% sodium hydroxide solution (30 ml) at 65 °C. The basic aqueous solution was washed with chloroform and then acidified by concentrated hydrochloric acid. The acidic solution was then extracted exhaustively with chloroform. Evaporating the chloroform solution to dryness as usual gave a dark brown residue which, without purification, was then dissolved in hydrofluoric acid (10 ml) in a polyethylene flask and then worked-up as described in the preparation of the tetralone **11**. The dark yellow residue was purified by preparative t.l.c. on alumina to give the yellow crystalline tetracyclic hydroxyketone **17** (700 mg) which could be recrystallized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

from methanol; m.p. 184–186 °C; i.r. 3510 (OH), 1710 (ketone), 1670 (quinone), 1600 and 1560 (aromatic); n.m.r. 1.73–2.34 (m, 4H, aromatic), 6.10 (s, 3H, OCH_3), 6.15 (s, 3H, OCH_3), 6.20 (s, 1H, OH), 6.91 (broad s, 4H, benzylic); mass spectrum 380 (m^+/e), 362 (M-H_2O), 337 (M-$COCH_3$).

Anal. Calcd. for $C_{22}H_{20}O_6$: C, 69.49; H, 5.29. Found: C, 69.55; H, 5.13.

Preparation of 4-Demethoxy Daunomycinone Trimethyl Ether (23)

A benzene solution (60 ml) of the hydroxyketone **17** (600 mg), ethylene glycol (1 ml), and anhydrous *p*-toluenesulfonic acid (50 mg) was distilled at a very slow rate. After about 30 ml of benzene was collected, the residual benzene was washed with sodium carbonate solution and then evaporated to dryness under reduced pressure to give quantitatively the crystalline ketal **18** which could be recrystallized from benzene, m.p. 185–186 °C; i.r. showed the absence of 1710 peak. The ketal **18** was then refluxed in carbon tetrachloride solution (50 ml) containing *N*-bromosuccinimide (290 mg) and a trace of benzoylperoxide for 45 min under dry nitrogen atmosphere. The solution was then evaporated under reduced pressure at room temperature to about 10 ml and the succinimide was then removed by filtration. The orange solution, without further purification, was refluxed in anhydrous methanol (50 ml) overnight under dry nitrogen. After evaporating the methanolic solution to dryness under reduced pressure, concentrated hydrochloric acid (3 ml) and water (10 ml) in 30 ml of tetrahydrofuran were added and the solution was stirred at room temperature for 4 days. After most of the tetrahydrofuran was removed under reduced pressure, the residue was diluted with water and extracted by chloroform exhaustively. Washing the chloroform solution with dilute sodium bicarbonate solution and evaporating the chloroform solution to dryness gave a dark orange residue which was separated by t.l.c. on silica into three major fractions corresponding to compounds **21**, **22**, and **23**.

The bromoketone **21** (95 mg) was further purified by recrystallization from methanol; m.p. 176–178 °C; i.r. 3475 (OH), 1735 (ketone), 1670 (quinone), 1595 and 1560 (aromatic); n.m.r. 1.74–2.35 (m, 4H, aromatic), 4.81 (s, 1H, OH), 5.08 (t, 1H, C_7—H), 5.20 (s, 2H, $CO\mathit{CH}_2Br$), 6.04 (s, 3H, OCH_3), 6.13 (s, 3H, OCH_3), 6.43 (s, 3H, C_7—OCH_3); mass spectrum 490 (m^+/e Br-81), 488 (m^+/e Br-79), 367 (M-$COCH_2Br$), 359 (M-H_2O, CH_3OH, Br), 335 (M-CH_3OH, $COCH_2Br$). This bromoketone was converted to **23** via zinc and acetic acid.

The crude hydroxyketone **22** (110 mg) was further purified by t.l.c. on silica followed by recrystallization from methanol; m.p. 192–193 °C; i.r. 3525 (OH), 1715 (ketone), 1675 (quinone), 1600 and 1575 (aromatic); n.m.r. 1.70–2.33 (m, 4H, aromatic), 4.95 (q, 1H, $J = 2$, $J = 4.5$ Hz, C_7—H), 6.03 (s, 3H, OCH_3), 6.08 (s, 3H, OCH_3), 6.14 (s, 1H, OH), 6.50–7.12 (q, 2H, $J = 15$ Hz, C_{10}—H_2), 6.65 (s, 3H, C_7—OCH_3), 7.29 (d of d, 1H, $J = 2$, $J = 15$ Hz, C_8—H), 8.04 (d of d, 1H, $J = 4.5$, $J = 15$ Hz, C_8—H); mass spectrum 410 (m^+/e), 392 (M-H_2O), 335 (M-CH_3OH, $COCH_3$), 307 (M-$COCH_3$, CH_3OH, CO).

The hydroxyketone **23** (220 mg) was recrystallized from methanol; m.p. 194–195 °C; i.r. 3475 (OH), 1710 (ketone), 1670 (quinone), 1595 and 1560 (aromatic); n.m.r. 1.70–2.33 (m, 4H, aromatic), 4.96 (s, 1H, OH), 5.04 (d of d, 1H, $J = 2$, $J = 4$ Hz, C_7—H), 6.01 (s, 3H, OCH_3), 6.10 (s, 3H, OCH_3), 6.42 (s, 3H, C_7—OCH_3), 6.70–6.85 (m, 2H, C_{10}—H_2), 7.35–7.67 (m, 1H, C_8—H), 7.93–8.24 (d of d, 1H, $J = 4$, $J = 15$ Hz, C_8—H); mass spectrum 410 (m^+/e), 392 (M-H_2O), 360 (M-H_2O, CH_3OH), 335 (M-CH_3OH, $COCH_3$), and 307 (M-CH_3OH, $COCH_3$, CO).

Anal. Calcd. for $C_{23}H_{22}O_7$ (mol. ion 410.1365): C, 67.31; H, 5.36. Found (410.1360 (high resolution mass spectrum)): C, 67.30; H, 5.33.

Preparation of 4-Demethoxy-7-O-methyl Daunomycinone (6)

The hydroxyketone **23** (140 mg) and aluminum chloride (300 mg) in benzene solution (20 ml) were stirred together with sea sand at 50 °C overnight under dry nitrogen atmosphere. The benzene solution was then extracted twice with an aqueous oxalic acid solution (20 ml, 5%) and the combined oxalic acid solution was extracted with chloroform. The combined benzene and chloroform solutions were then dried over sodium sulfate and evaporated to dryness under reduced pressure giving a red solid residue. The residue was then purified by t.l.c. on silica to give the red crystalline 4-demethoxy-7-*O*-methyl daunomycinone (**6**) (96 mg) which was recrystallized from a large volume of chloroform; m.p. 250–254 °C; i.r. ($CHCl_3$) 3400 (OH), 3400–2700 (phenols), 1715 (ketone), 1625 (quinone), 1595 (aromatic); n.m.r.[3] −3.50 (s, 1H, phenol), −3.20 (s, 1H, phenol), 1.50–2.03 (m, 4H, aromatic), 4.80 (s, 1H, C_9—OH), 4.92 (d of d, 1H, C_7—H), 6.20 (s, 3H, OCH_3), 6.64 (q, 2H, C_{10}—H_2), 7.37 (s, 3H, $COCH_3$); mass spectrum 382 (m^+/e), 332 (M-H_2O, CH_3OH), 307 (M-$COCH_3$, CH_3OH), 289 (M-$COCH_3$, H_2O, CH_3OH).

Mol. Ion Calcd. for $C_{21}H_{18}O_7$: 382.1053. Found (high resolution mass spectrum): 382.1050.

The synthesis toward daunomycin and adriamycin is progressing and results will be reported later.

The authors would like to express their gratitude to the National Research Council of Canada for financial support and Drs. Camerino and Mondelli for a sample of daunomycinone for spectroscopic comparison.

Mössbauer Spectra and Electric Dipole Moments of Organotin(IV) Complexes with Monodentate Donor Ligands

F. PATRICIA MULLINS

Department of Chemistry, Mount St. Vincent University, Halifax, Nova Scotia

Received March 8, 1971

Mössbauer spectra and electric dipole moment data are reported for R_2SnCl_2 and $RSnCl_3$ complexes with Y type ligands where R = C_4H_9, C_6H_5 and Y = Ph_3PO, Ph_3AsO, Bu_3PO, and Ph_3P. Quadrupole splittings and dipole moments are consistent with *trans* C—Sn—C bonds in the $R_2SnCl_2Y_2$ complexes. In the trigonal bipyramidal Ph_2SnCl_2Y complexes, the two phenyl groups are assumed to be in equatorial positions. Data for the $RSnCl_3Y_2$ complexes suggest that in $BuSnCl_3(Ph_3AsO)_2$ and $BuSnCl_3(Ph_3P)_2$ two Cl atoms are *trans* and that in $BuSnCl_3(Ph_3PO)_2$ and $PhSnCl_3(Ph_3PO)_2$ the three Cl atoms are *cis*.

On rapporte les données obtenues à partir des spectres de Mössbauer et des moments dipolaires électriques pour les complexes R_2SnCl_2 et $RSnCl_3$ avec des ligands du type Y, ou R = C_4H_9, C_6H_5 et Y = Ph_3PO, PhAsO, Bu_3PO et Ph_3P. Les dédoublements quadrupolaires et les moments dipolaires sont consistants avec des liaisons C—Sn—C *trans* dans les complexes $R_2SnCl_2Y_2$. On suppose que dans le complexe Ph_2SnCl_2Y trigonal bipyramidal, les deux groupes phényles occupent la position équatoriale. Les données obtenues pour les complexes $RSnCl_3Y_2$ suggèrent que dans $BuSnCl_3(Ph_3AsO)_2$ et $BuSnCl_3(Ph_3P)_2$, les atomes de chlore sont en position *trans* et que dans $BuSnCl_3(Ph_3PO)_2$ et $PhSnCl_3(Ph_3PO)_2$ les trois atomes de chlore sont en position *cis*.

Canadian Journal of Chemistry, 49, 2719 (1971)

Introduction

Within the past ten years there has been considerable interest in the interpretation of Mössbauer spectra of SnX_4, $RSnX_3$, R_2SnX_2, and R_3SnX complexes as a means of determining the structure of these compounds. Most of the work on organotin(IV) complexes has been done with bidentate and to a lesser extent monodentate ligands containing N, O, S, and P donor atoms. In some cases the study of the Mössbauer parameters of these tin complexes has been linked with other experimental methods of structural determination, for example, using X-ray (1), electron spin resonance (2), nuclear quadrupole resonance (3), nuclear magnetic resonance (4–6), infrared spectra (6–12), and electric dipole moments (13–16).

The purpose of the present study was to broaden the correlation between the Mössbauer and electric moment studies previously undertaken on R_2SnX_2 and $RSnX_3$ complexes (13–16) by using monodentate rather than bidentate ligands, as well as to compare the present results with those obtained in an investigation of SnX_4 complexes with similar O and P donor ligands (10, 11, 15). It was of interest to discover whether the R groups in the R_2SnCl_2 complexes would remain *trans* in $R_2SnCl_2Y_2$ complexes where the monodentate ligands are more bulky than R and whether these ligands would have a *trans* or *cis* arrangement in the complexes. It was also of interest to ascertain the effect of the monodentate *vs.* bidentate ligand on the position of the lone R in $RSnCl_3$ complexes. It is true, of course, that the configurations of molecules may differ from the solid state to solutions. However, previous studies (13, 14) have shown an *excellent* correlation between the configurations of octahedral tin(IV) complexes containing two carbon–tin bonds as revealed by Mössbauer measurements on solids and as indicated in solution by dielectric constant measurements. This observed correlation certainly makes it worthwhile to extend the comparison of Mössbauer and dielectric constant measurements to $R_2SnCl_2 \cdot L_2$ compounds. The previous correlations also suggest that in the absence of determining crystal packing factors the configurations of $RSnCl_3 \cdot L_2$ complexes may well be similar in the solid state and in solution. Two of the complexes were not sufficiently soluble in benzene to allow for dielectric constant measurements. Although 1:2 complexes have been reported for Ph_2SnCl_2 with Ph_3PO and Ph_3AsO (17), the various

methods attempted yielded compounds whose analyses and Mössbauer parameters indicated the presence of 1:1 complexes.

Experimental

Preparation of Compounds

Phenyltin and *n*-butyltin trichloride, diphenyl and di-*n*-butyltin dichloride were obtained from Alfa Inorganics Inc. Triphenylphosphine was purchased from Matheson, Coleman and Bell. Triphenylphosphine oxide, triphenylarsine oxide, and tributylphosphine oxide were obtained from Eastman Organic Chemicals. All solvents were Baker Analyzed Reagents. Thiophene-free benzene was refluxed over phosphorus pentoxide for several hours before being distilled.

Complexes of $R_2SnCl_2Y_2$ were prepared by mixing the ligand and R_2SnCl_2 or $RSnCl_3$ in a 2:1 ratio in an appropriate solvent: hot absolute ethanol was used for R_2SnCl_2 and $BuSnCl_3$ complexes with Ph_3PO; absolute ether for $PhSnCl_3(Ph_3PO)_2$; ether–benzene for $BuSnCl_3$ with Ph_3P; ether-ethanol for the Ph_3AsO and Bu_3PO complexes. The Ph_3AsO complexes of PH_2SnCl_2 and Bu_2SnCl_2 and the Ph_2SnCl_2 complexes of Ph_3PO and Bu_3PO were obtained as white precipitates. The other complexes were obtained as white powders, except $BuSnCl_3(Ph_3P)_2$ which was cream colored, by evaporation of cooled solutions of benzene and absolute ether. All solids were washed with petroleum ether (b.p. 30–60°) and dried under vacuum at room temperature overnight. Attempts to isolate other complexes of these ligands and Ph_3As with the starting compounds were not successful.

Analytical data and melting points for the complexes are given in Table 1.

Mössbauer Spectra

These were obtained with an Austin Science Associates Mössbauer Spectrometer Drive Model S3, with Model K3 constant acceleration linear motor, pre-amplifier, a Reuter Stokes Model RSG-61 proportional counter tube filled with krypton–carbon dioxide, a Northern Scientific Inc. modified 512 channel analyzer with a single channel analyzer and time base generator, Model NS-600 and a Teletype readout. A 10 mC $Ba^{119m}SnO_3$ source obtained from New England Nuclear Corporation was used at room temperature. The finely divided solid absorbers were placed between beryllium windows and mounted in a copper sample holder attached to a metal Dewar automatically filled with liquid nitrogen. Data were accumulated until at least 2×10^5 counts per channel were collected to reduce statistical error. The data thus obtained were treated by computer analysis as described previously (16).

The spectrometer was calibrated periodically against chemically pure SnO_2 and natural iron foil obtained from New England Nuclear Corporation. The parameters were read from the plotted curves and the difference between replicate measurements was less than 0.05 mm s^{-1}. The spectrum of Bu_2SnCl_2 $(Bu_3PO)_2$ is illustrated in Fig. 1.

Dielectric Constants of Benzene Solutions

These were obtained at 25 °C as in previous investigations (18) using an oscillator similar to that described by Estok (19). The reproducibility of dielectric constants of benzene and solutions was ± 0.0005 and this was taken as the relative precision of measurements (Table 2). Electric moments were calculated by the method of Higasi (20), using a value of 0.8481 for β (21).

Infrared spectra of potassium bromide discs and benzene solutions were obtained with a Perkin–Elmer 521 and a Beckman IR-33 spectrometer.

Discussion of Results

The isomer shifts relative to SnO_2, quadrupole splittings and dipole moment data obtained for the compounds studied are listed in Table 3. Asymmetries in the doublet Mössbauer spectra are present in most of the compounds. The programmed data yielded intensity ratios (area of peak *1*/peak *2*); **1** (1.41), **2** (0.65), **3** (0.81), **6** (1.17), **7** (0.87), **11** (1.19). Previous comparisons of dipole moments obtained by calculations of Higasi with those from the LeFevre and Vine modification of the Hedestrand equation indicate that density and index of refraction measure-

ments are unnecessary (13, 14). The moments of R_2SnCl_2 and $RSnCl_3$ with Ph_3PO compare with values of 9.5 and 10.1 D reported for dioxane solutions of $SnCl_4$ and $SnBr_4$ respectively with Ph_3PO (15).

R_2SnCl_2 Compounds

The quadrupole splittings obtained indicate that these complexes have octahedral configurations with the R groups *trans* except for **6** and **7** which, in accord with the chemical analyses obtained, are indicative of five-coordinate tin.

For compounds **3**–**5** the splittings are similar to those of the corresponding α,α′-dipyridyl and *o*-phenanthroline complexes (13), indicating similar electron releases to tin by the oxygen and nitrogen donors. The splitting obtained for **2** larger than that previously obtained for *trans* diphenyl compounds (14) may be attributed to a differing degree of distortion from octahedral symmetry, as suggested by Poller *et al.* (8). The smaller isomer shifts obtained for the diphenyl *vs.* the dibutyl compounds are as expected from the difference in the electron releasing ability of the two R groups.

In a crystal structure of $[Me_2SnClterpy]^+$-$[Me_2SnCl_3]^-$ (22), the methyl groups were found to be *trans* with a C—Sn—C angle of 159° in the distorted octahedral cation and in the equatorial plane with a C—Sn—C angle of 140° in the trigonal bipyramidal anion; the more electronegative Cl ligands were bonded preferentially in the axial positions as observed in other examples of trigonal bipyramidal structures with different ligands coordinated to a main group element (23). Equatorial positions have also been assigned to R groups in series of trigonal bipyramidal compounds studied by Zuckermann and co-workers (24), Parish and Platt (25), and Brill and Long (26). The quadru-

pole splitting (q.s.) values for **6** and **7** are in agreement with the values calculated by Parish and Platt for such a configuration (25). Zuckerman (24) also interpreted his observed increases in J ($^{119}Sn—C—^1H$) as arising from increasing concentration of s character in the Sn—C bond. Therefore, the values of 100 *vs.* 88 Hz obtained for J in dimethyltin dichloride complexes with Ph_3AsO and Ph_3PO, respectively (17), would lead one to expect greater i.s. and q.s. values for the triphenylarsine oxide complexes as obtained by Yeats *et al.* for the $SnCl_4$ complexes with these ligands (10). For the R_2SnCl_2 complexes with these two donor ligands, **4** and **5**, and **6** and **7**, the R_3PO complexes show the larger i.s. and q.s. values. The explanation for this reversal is not evident at this time. Steric effects resulting in distortions, particularly of the C—Sn—C angle, may be responsible for this anomaly (27, 28).

Stretching frequencies for Y ligands have been reported as follows: ν(P—O) 1190–1202 cm^{-1} (Ph_3PO), 1166 cm^{-1} (Me_3PO), ν(As—O) 880–881 cm^{-1} (Ph_3AsO) (9, 17, 29–33); ν(P—O) 1160 cm^{-1} (Bu_3PO, this work). Shifts to the following frequencies were noted on complex formation: ν(P—O) 1107 cm^{-1} (**2**), 1115 cm^{-1} (**3**), 1155 cm^{-1} (**4**), 1140 cm^{-1} (**7**), 1142 cm^{-1} (**8**), 1160 cm^{-1} (**9**); ν(As—O) 850 cm^{-1} (**5**), 860 cm^{-1} (**6**), and 855 cm^{-1} (**10**). These values agree well with values reported for these or similar compounds (9, 17, 30). Infrared spectra were taken of benzene solutions of the complexes, where solubility permitted, to determine whether or not dissociation was taking place in solution. Most of the complexes showed both shifted and unshifted peaks in solution, evidence of partial dissociation. The extent of dissociation varied from very slight for **2**, **7**, and **10** to considerable for **4** and **9**. In general, frequencies were shifted to slightly higher values in benzene solutions as compared to KBr disc values. Unfortunately, as stated by Jensen and Nielsèn (32), the frequencies of triphenylphosphine complexes do not differ much from those of the ligand; therefore, it was not possible to determine the degree of dissociation of **11** in solution from the infrared spectrum. From dielectric constant measurements of rather dilute solutions of $BuSnCl_3(Ph_3P)_2$ an electric moment of 5.77 D was calculated which compares with a moment of 4.75 D for complete dissociation.

In a crystal structure determination of $Me_2SnCl_2(C_5H_5NO)_2$ (34), all identical ligands were found to be *trans* with little distortion from octahedral symmetry, and the Sn—O—N bond angle 117°, which is quite close to the Sn—O—P angle assumed below. In their study of the electric moments of transition metal complexes, Schafer and Curran (35) obtained a good correlation between calculated and experimental values in $ZnCl_2(HMPA)_2$ (HMPA = hexamethylphosphoramide) by assuming the P—O—M angle to be 125°, with one ligand in the conformation of minimum moment and the other in conformation of maximum moment. As previous work has indicated similar polarizabilities for Sn(IV) and Zn(II) (14), this same value has been taken for the P—O—M angle in the octahedral tin phosphine oxide complexes, along with the

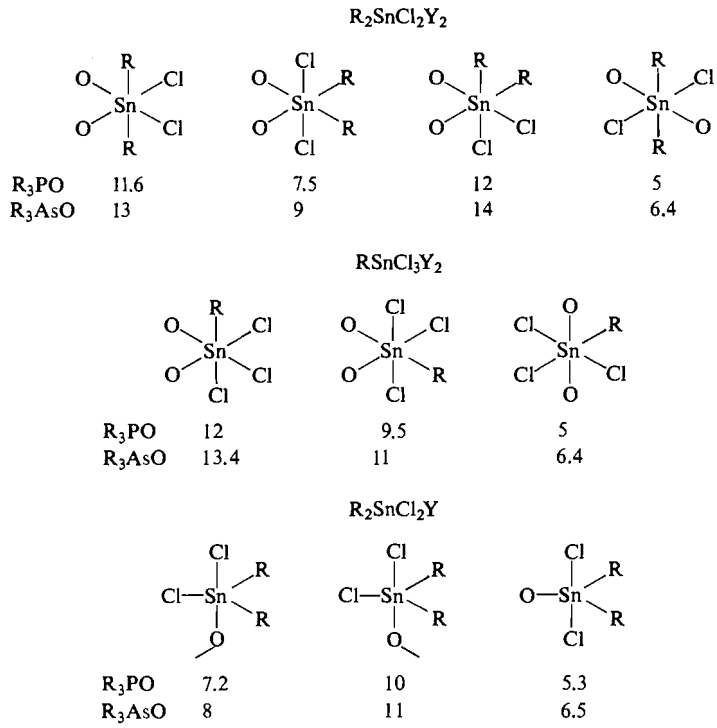

FIG. 2. Dipole moments calculated for various configurations of complexes.

assumption that the N→M—Cl moment in pyridine type complexes is 0.3 D greater than the O→M—Cl moment in HMPA type complexes (35). Using this assumption, the O→Sn—Cl resultant for two vectors at 90° has been obtained from the following calculations

$$N{\rightarrow}Sn{-}Cl_{resultant} = \mu_{Bu_2SnCl_2\cdot o\text{-phen}} - \mu_{o\text{-phen}} = 11.3 - 4.1 = 7.2 \text{ D (ref. 13)}$$

$$O{\rightarrow}Sn{-}Cl_{resultant} = N{\rightarrow}Sn{-}Cl_{resultant} - 1.16(0.3) = 7.2 - 0.4 = 6.8 \text{ D (ref. 35)}$$

The O→Sn—Cl vector can then be taken as 6.8/1.414 = 4.8 D, so that if the moment of Sn—Cl is from 3.2–3.4 D (13), a value of approximately 1.5 D is obtained for O→Sn. This is to be distinguished from the value of 2.8 D estimated for a normal covalent Sn—O bond moment (14). From the moment of 4.37 D for Bu_2SnCl_2 (13), the Bu—Sn—Cl vector can be taken as 3.77 D. The resultant of two R_3Y bond moments at 90° to each other is 6.09 D for Ph_3PO, 6.08 D for Bu_3PO, 7.83 D for Ph_3AsO(μ_{Ph_3PO} = 4.31 D, μ_{Ph_3AsO} = 5.54 D (36); μ_{Bu_3PO} = 4.30 D). The equal electric moments of Bu_3PO and Ph_3PO indicate a balance between the greater σ electron release by the alkyl group and the

π-electron delocalization in the triphenyl compound.

In the calculation for possible configurations, the angle which these resultants make with the rest of the molecule must be taken into account. Varying degrees of distortion from the assumed Y—O—M angle must be considered as well as distortions from octahedral symmetry. The small Sn—C bond moment has been neglected in most cases; this would yield a difference of approximately ±0.4 D for butyl *vs.* phenyl compounds. The calculated moment for complete dissociation values were obtained from the square root of the sum of the squares for the moments of the components (μ_{BuSnCl_3} = 4.32 D, $\mu_{Ph_2SnCl_2}$ = 4.32 D (37)). The values calculated for *cis* Y groups assume maximum and minimum orientation for the two groups as stated previ-

ously. In calculating the moments of *trans* Y groups, one has to consider random orientation of these groups. The moment for the R_3PO random orientation about the O—Sn—O axis has been calculated from the equation $\mu = 1.41\ m \sin\theta$ (38), where m is the moment of R_3PO, θ is the angle that the moment makes with the O—Sn—O axis, 55° in the present case; this gives a value of 5.0 D for configurations with *trans* R_3PO groups, 6.4 D for *trans* R_3AsO groups, lower than the experimental values obtained.

As stated previously q.s. values for **3–5** indicate a *trans*-R configuration is present in the solid state and experimental dipole moments suggest a *trans*-R, *cis*-Cl, *cis*-O configuration is present in solution. In the case of Ph_2SnCl_2-$(Bu_3PO)_2$, dipole moment data indicate a possible mixture of *cis* and *trans* Bu_3PO groups in solution. A comparison of experimental and calculated moments for **6** and **7**, suggests equatorial diphenyl groups, axial–equatorial Cl atoms, and random orientation of the O group in axial position, as indicated previously for solid R_2SnX_3 compounds (22–25). Some possible configurations with calculated values are shown in Fig. 2.

$RSnX_3Y_2$ Complexes

The Mössbauer data for **10**, **11** are sufficiently close to the values obtained for complexes having bidentate nitrogen groups (16) to postulate similar configurations, with two Cl atoms *trans* in both cases. However, in accord with the observation of Parish and Platt (27), the relatively large quadrupole splitting for $BuSnCl_3$-$(Ph_3PO)_2$ suggests the possibility of a different configuration for this complex in the solid form and electric moment calculations indicate that in solution this complex has three *cis* Cl atoms and two *cis* PO groups. The dipole moment data for $BuSnCl_3(Ph_3AsO)_2$ does not clearly distinguish between this configuration and one in which two Cl atoms are *trans*. The smaller i.s. and q.s. values for $PhSnCl_3(Ph_3PO)_2$, **8**, than for $BuSnCl_3(Ph_3PO)_2$, **9**, reflect the greater tin share of the electrons of the C—Sn bond in the butyl compound. Again, the smaller isomer shift for $BuSnCl_3(Ph_3AsO)_2$ *vs.* $BuSnCl_3(Ph_3PO)_2$ appears as an interesting anomaly, which it is hoped may be resolved in the course of further research on another series of compounds.

The author is grateful to the National Research Council of Canada for financial support and to Dr. M. Falk of the Atlantic Regional Laboratory in Halifax for the use of research facilities. Special thanks are due to Dr. W. Lieper and his research assistants of the Physics Department of Dalhousie University for the use of a Mössbauer spectrometer and computer program. Gratitude is expressed to Br. C. Curran of the University of Notre Dame for helpful discussions.

Reactions of Sodium *N,N*-Diethyldithiocarbamate and Potassium Ethyl Xanthate with some 3d Transition Metal Halides in the presence of 2,2′-Bipyridyl and 1,10-Phenanthroline

D. G. Holah and C. N. Murphy

Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received April 13, 1971

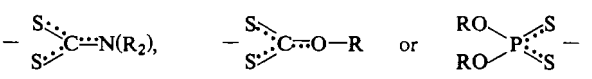
The synthesis and some properties of ethylxanthate (Xan^-) complexes, $MXan_2$ and $MXan_3^-$ (M = manganese(II) and iron(II)) are reported. Reactions between divalent metal halides (manganese, iron, cobalt, nickel, copper, and zinc) and Xan^- and between the metal halides and *N,N*-diethyldithiocarbamate (dtc^-) in the presence of nitrogen bases 1,10-phenanthroline (phen) and 2,2′-bipyridyl (bipy) are described. The major products of these reactions are complexes of the type $MXan_2$.Base and $Mdtc_2$.Base (with notable exceptions). In the former series with bipy, two different crystalline modifications of the manganese, iron, and cobalt complexes are formed, and copper(II) is reduced to copper(I) by Xan^- in the presence of both bases. In the nickel–dtc system with bipy, $Nidtc_2$ is produced, while with phen, the complex $[Niphen_3]dtc_2$ is formed. The latter reacts very rapidly with methylene chloride. $Cudtc_2$ is produced from the copper(II)/base/dtc reactions.

On rapporte la synthèse et quelques propriétés des complexes obtenus avec l'éthyl xanthate (Xan^-), $MXan_2$ et $MXan_3^-$ (M = manganèse(II) et fer(II)). On décrit les réactions entre les halogénures de métaux divalents (manganèse, fer, cobalt, nickel, cuivre et zinc) et Xan^- ainsi qu'entre les halogénures métalliques et le *N,N*-diéthyldithiocarbamate (dtc^-) en présence de composés azotés servant de base, à savoir la phénanthroline-1,10(phen) et la bipyridyle-2,2′(bipy). Les produits principaux de ces réactions sont des complexes du type $MXan_2$.Base et $Mdtc_2$.Base (avec certaines exceptions). Dans les premières séries, avec la bipy, deux modifications cristallines différentes se forment pour les complexes avec le manganèse, le fer et le cobalt; de plus, le cuivre(II) est réduit en cuivre(I) par le Xan^- en présence des deux bases. Dans le système nickel–dtc, avec la bipy, on forme $Nidtc_2$, alors qu'avec la phen, on forme le complexe $[Niphen_3]dtc_2$. Ce dernier réagit très rapidement avec le chlorure de méthylène. On forme le complexe $Cudtc_2$ par les réactions entre cuivre(II)/base/dtc.

Canadian Journal of Chemistry, 49, 2726 (1971)

Introduction

A study of the electronic and molecular structure of transition metal complexes of the type ML_2, where L are 1,1-dithiolate ligands such as



R = Et, L = dtc R = Et, L = Xan R = Et, L = dtp

are often made difficult by the instability of these species, particularly in the case of dithiocarbamates and xanthates. For example, the $Mdtc_2$ complexes (M = Cr, Mn, Fe) are exceedingly sensitive to air oxidation (1) while there seems to be no reliable documentation of $Codtc_2$ (1, 2). The $Mdtp_2$ and $MXan_2$ complexes (M = Cr, Mn, Fe, Co) are less studied although there is a brief mention (3) of $FeXan_2$. It is interesting that one tris(xanthate) complex, $(R_4N)NiXan_3$, has been characterized (4–6) while in the dithiocarbamate series the formulation (7) of a complex as $Na[Codtc_3]$ has been questioned (8), and there seems to be no authentic example of a $Mdtc_3$ species.

The stability of the MS_4 entity does appear (9, 10) to be affected by varying the size of the group R, but is clearly increased by incorporating a base adduct onto the MS_4 species (10). Adducts of the dtp complexes with various bases, such as 2,2′-bipyridyl (bipy) 1,10-phenanthroline (phen) and various substituted derivatives of the latter, have been studied and some structures which include both 5 and 6 coordinated metal ions determined (10). Much less information is available on adducts of dithiocarbamates and xanthates. With the latter, $NiXan_2$.bipy has been studied, one report (11) suggesting four coordinate nickel with another suggesting a *cis*-octahedral arrangement (12). Very recently (5), various adducts of $NiXan_2$ including $NiXan_2$.bipy and $NiXan_2$.phen have been studied particularly regarding the assignment of infrared vibrations. With dithiocarbamates, $Codtc_2$.phen has been synthesized (13) and contains high spin cobalt(II).

Considering the fact that no reliable report of the preparation of $Codtc_2$ exists, the base has clearly had a profound stabilizing influence on the cobalt(II)–dtc system.

This paper reports our studies aimed at (*i*) isolating new bis and tris(xanthate) and tris-(dithiocarbamate) metal complexes and (*ii*) examining the ability of nitrogen bases 2,2′-bipyridyl and 1,10-phenanthroline to stabilize the metal xanthates and dithiocarbamates.

Experimental

Reagent grade phen, bipy, KXan, and $Nadtc.3H_2O$ were used without further purification, as were the hydrated metal chlorides. Many of the complexes prepared in this work are air-sensitive and much of the experimental work was therefore carried out in a nitrogen-filled glove box (~100 p.p.m. oxygen).

Preparation of Complexes

$MXan_2$ (M=Mn,Fe)

The complexes were prepared in a nitrogen atmosphere by reacting a 1:2 mole ratio of the metal(II) halide and KXan in aqueous solution. The yellow manganese complex is appreciably water soluble and the solution was therefore evaporated to dryness. The insoluble iron(II) complex was dried under vacuum. Acetonitrile solutions of the complexes, which are extremely air-sensitive, were allowed to run down an alumina column (deactivated with ethylacetate) and the brightly colored liquors concentrated by removal of the solvent at room temperature under vacuum. Addition of ether or benzene produced solids which were dried under vacuum. $FeXan_2$ decomposes after several days even when stored under vacuum.

$(Et_4N)MXan_3$ (M=Mn, Fe)

Crude oily products were obtained by adding in a nitrogen atmosphere, an aqueous solution of KXan to one of the metal(II) halide and Et_4NCl until the mole ratio was 3:1:1, respectively. The oils, which solidified after scratching, were dried under vacuum and recrystallized from acetonitrile or methylene chloride on addition of ether.

$MXan_2.phen$ (M=Mn, Fe, Co, Ni, Zn)

These compounds were prepared by adding aqueous KXan to a solution of the metal(II) chloride and phen (mole ratio 2:1:1, respectively). The solids were dried under vacuum and recrystallized from methylene chloride on addition of ether (For M=Co, in a nitrogen atmosphere) in approximately 50% yields.

$MXan_2.bipy$ (M=Mn, Fe, Co, Ni, Zn)

Two different crystalline modifications, α and β, were obtained for M=Fe, Co, and Ni. In all cases low yields (between 25 and 40%) were observed, and the reactions, although usually reliable, occasionally gave unexpected and non-reproducible products (particularly the reaction involving the α-Fe complex).

In all cases, except for α-Co, an aqueous solution of KXan was added to a solution of the metal(II) chloride and bipy (2:1:1 or 2:1:2 mole ratios), the crude product washed several times with water, and dried under vacuum. (For the α and β cobalt complexes the reactions were carried out in a nitrogen atmosphere.)

Mn: The crude product was recrystallized several times from methylene chloride by addition of ether. The solid decomposes within hours in air and within several days when sealed under vacuum.

β-*Fe*: This is the red material remaining after the above crude product was washed with water. Most organic solvents resulted either in the oxidation of the iron or transformation of the complex to the α-phase.

α-*Fe*: The red β-phase becomes deep blue in methylene chloride and brown crystals of the α-phase were obtained by addition of ether. The solid becomes red and amorphous after several days.

α-*Co*: The $KXan/CoCl_2$/bipy reaction using 2:1:1 stoichiometries was carried out in acetone. Crystals of the α-phase were obtained by removal of the acetone under vacuum and recrystallizing the residue from a methylene chloride solution by addition of ether.

β-*Co*: The crude product from the aqueous reaction was recrystallized from benzene on addition of high boiling petroleum ether.

β-*Ni*: The aqueous reaction involving nickel(II) differed from the other reactions in that yields were considerably improved when the mixture was allowed to stand for several days. The β-phase was recrystallized several times from methylene chloride on addition of ether.

α-*Ni*: A methylene chloride solution of the β-phase was run down an alumina column (deactivated with ethylacetate). The α-phase was obtained from the green layer after concentration and addition of ether, although occasionally a brown layer was also observed, from which the β phase could be isolated as above.

Zn: This was obtained by recrystallizing the crude product from methylene chloride on addition of ether.

Reactions involving Copper(II)

Addition of an aqueous solution of KXan to one of copper(II) chloride and the base in 2:1:1 mole ratios resulted in the formation of red precipitates both for bipy and phen. The latter product contains dixanthogen and a compound identical (X-ray isomorphous) with a compound prepared from copper(I) chloride, KXan, and phen in a 1:1:1 mole ratio. The above red product could not be recrystallized from organic solvents, since the yellow CuXan was immediately produced on addition of the solvent, with dixanthogen being recovered from the solution.

$Mdtc_2.phen$ (M=Mn, Fe, Co, Zn)

These complexes were prepared by reacting metal(II) halides and phen (1:3 ratio) in water followed by the slow addition, with stirring, of the stoichiometric amount of Nadtc in water. The complexes were washed with water in which they are insoluble, and dried under vacuum. The complexes were recrystallized from methylene chloride (Mn, Fe, Co in a nitrogen atmosphere), washed with ether and dried under vacuum. The blue species, formed by reacting copper(I) chloride with phen in water reacted immediately with Nadtc to give a precipitate of $Cudtc_2$, while the $CrCl_2$/phen/dtc reaction resulted in oxidation of the metal.

$Niphen_3dtc_2$

A bright yellow solid is formed when an aqueous solu-

tion of a stoichiometric amount of Nadtc is added to the red aqueous solution of nickel(II) chloride and phen (1:3). After washing with water, the complex was dried under vacuum, when the color slowly changed from yellow to orange. The resultant red solid was recrystallized from acetonitrile–ether, washed with ether and dried under vacuum, yielding bright yellow-orange crystals of $Niphen_3dtc_2$. This compound is very soluble in methylene chloride giving initially a deep blood-red solution but within 2–5 s the color is largely discharged and yellow crystals appear. These were removed, washed with methylene chloride, dried under vacuum and identified as $Niphen_3Cl_2.2CH_2Cl_2$. The methylene chloride solution and washings were evaporated at room temperature and the residue extracted into benzene solution, which yielded crystals (14) of dtc_2CH_2 on addition of ether.

The yellow crystals of $Niphen_3Cl_2.2CH_2Cl_2$ dissolve in ethanol and on addition of ether pink crystals which analyzed close to $Niphen_3Cl_2.2EtOH$ are precipitated. This product is identical with the pink solid formed by reacting nickel(II) chloride with 3 mol of phen and recrystallizing from ethanol.

$Mdtc_2.bipy$ (M=Mn, Fe, Co, Zn)

These complexes were made in an analogous manner to the phen complexes, with the manganese, iron, and cobalt complexes being recrystallized in a nitrogen atmosphere. Reactions of the nickel and copper systems both resulted in the formation of $Nidtc_2$ and $Cudtc_2$, respectively.

Analyses and Physical Measurements

Element analyses were carried out under the supervision of W. J. Buis at the Micro-Analytical Department of the Institute for Organic Chemistry TNO, Utrecht, The Netherlands, and are recorded in Table 1. X-Ray powder photographs and mass spectral studies were carried out as previously described (14). Magnetic moments were measured in a double ended Gouy tube suspended from a semi-micro balance between the poles of a Varian electromagnet. The tube was calibrated with $HgCo(CNS)_4$, $Nien_3S_2O_3$, and $CuSO_4.5H_2O$, using standard diamagnetic corrections (15). The tube constant β, measured using $HgCo(CNS)_4$ was used to calculate the susceptibilities of the latter two complexes. Agreement was within 1% of the published values. Visible solution and reflectance spectra were recorded on a Cary 14 spectrophotometer.

Results and Discussion

All the complexes prepared in this work are listed in Table 1, together with chemical analyses and colors.

Like the corresponding bis(dithiocarbamate)-metal(II) complexes, the bis(xanthate) complexes of manganese and iron are air sensitive, and indeed the iron complex appears to decompose slowly when stored under vacuum. The complexes have identical X-ray powder photographs which are radically different from those (12) of the previously reported square planar $NiXan_2$ and tetrahedral $ZnXan_2$. Both appear to have magnetic moments (Table 1) somewhat lower than required for high spin d^5 and d^6 configurations, although reflectance spectra (Table 1) suggest the presence of essentially 6-coordinated metal ions. It is possible that this is achieved through polymerization, which may, through slight metal–metal interaction, account for the lowering of the magnetic moments. It is significant that the xanthate series form compounds of the type $MXan_3^-$ and these species can be obtained as solid, tetraethylammonium salts, as has been previously reported (4–6) for M = Ni. The analogous manganese(II) and iron(II) complexes have now been prepared and both show normal high spin magnetic properties and reflectance spectra again indicative of 6 coordination. The X-ray powder photographs of the iron and nickel(II) complexes are identical, with the manganese(II) pattern very similar. All attempts, in both aqueous and non aqueous solutions, at preparing $MXan_2$ and $MXan_3^-$ compounds for M = chromium(II), cobalt(II), and copper(II) resulted in oxidation of the first two species and reduction of the latter. However, there is a report (16) of the formation of cobalt(II) xanthate in acid solution (p*H* 2.5–3.5), although our attempts at the preparations of $CoXan_2$ and $(R_4N)CoXan_3$ in sulfuric acid solutions under oxygen free conditions resulted in the formation of $CoXan_3$. Also all attempts to make complexes of the type $Mdtc_3^-$ either by reactions of metal halide, tetraalkylammonium halide, and Nadtc (1:1:3) or by reactions of $Mdtc_2$ with excess Nadtc in the presence of R_4NCl in various solvents resulted in the isolation of starting materials or the $Mdtc_2$ species. This is likely due to the increased strength of the M—S bonds in dithiocarbamates compared to the xanthates and may also be a reflection of the considerable stabilities of the dimeric $Mdtc_2$ species and the square planar $Nidtc_2$ (12). The previous report (7) of the complex $NaCodtc_3$ appears to be in error (8) although recently (17) an octahedral complex of nickel with three dithiocarbamate ions has been studied.

There are significant differences in the way in which KXan and Nadtc react with the metal halides when the bases phen and bipy are present. Thus in the dithiocarbamate system, two moles of dithiolate react with a solution or suspension of $MBase_3^{2+}$. When less base is used, *e.g.*, a ratio

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of metal:base:ligand of 1:2:2 or 1:1:2, extensive oxidation of the metal can occur, particularly with manganese(II). However, with reactions involving xanthate, ratios of 1:1:2 appear to be adequate for the isolation of the $MXan_2$.Base complexes. It is interesting that in this series when the base is bipyridyl, two crystalline forms of the same complex are obtained for M = Fe, Co, and Ni and are arbitrarily labeled α and β. The α phases are all X-ray isomorphous with the manganese complex. We have repeated the literature method (16) for the preparation of $NiXan_2$.bipy, namely the reaction between $NiXan_2$ and bipy in ether, and find the complex to be isomorphous with the α-phase. Furthermore, reported magnetic and electronic spectral properties of this material (and $NiXan_2$.phen) are identical with our data which are therefore omitted from Table 1. The β phases are all different crystalline forms. When the base is phen, then only complexes of cobalt and nickel show isomorphism. However, all the complexes including the nickel complex (16) show normal high spin behavior and reflectance and solution spectra consistent with octahedral metal ions. While both bases have clearly stabilized cobalt(II) in the presence of xanthate, many of the complexes, particularly with bipy, tend to decompose slowly both in air and when stored under nitrogen. Indeed no satisfactory chemical analysis was obtained for $MnXan_2$.bipy, rather the analysis always indicating the presence of approximately 0.9 molecule of base.

However, it was not possible to stabilize the copper(II) xanthate system in the presence of base. The red products isolated from the reactions of solutions of copper(II) and base with xanthate were washed with water and dried under vacuum. All attempts to recrystallize the diamagnetic red products from organic solvents resulted in the immediate appearance of the yellow CuXan. Chemical analyses (C 42.2, H 3.9, N 6.5%) of the red phen product while approximating to that required for $CuXan_2$.phen (C 44.4, H 3.7, N 5.8%), is also consistent with the presence of an intimate mixture of CuXan.phen and dixanthogen (the latter being insoluble in water and readily identified by bands in its infrared spectrum (18)). These results can be rationalized by considering the potential data of Table 2.

Thus, it is apparent that the reduction of either Cu^{2+} or $Cubipy_2^{2+}$ by Xan^- is thermodynamically favorable and that the presence or absence of base makes little difference to the stability of the copper(II) system.

TABLE 2. Potential data

Reaction	Potential (V)	Reference
$Xan^- \rightarrow \frac{1}{2} Xan_2 + e$	0.136	19
$Cu^{2+} \rightarrow Cu^+ - e$	0.15	20
$Cubipy_2^{2+} \rightarrow Cubipy_2^+ - e$	0.12	21

Reactions between the metal halides, base, and xanthate in 1:3:2 mole ratios give different products which will be described in a later publication (22).

There are significant differences in the way that Nadtc reacts with $Mphen_3^{2+}$ and $Mbipy_3^{2+}$ when M = Ni. With elements manganese, iron, and cobalt both bases give similar adducts, $Mdtc_2$.Base with members of each series being isomorphous and therefore probably isostructural, except for $Mndtc_2$.bipy. All these solid complexes appear to be air stable in marked contrast to the behavior of the $Mdtc_2$ complexes themselves. In both series the electronic properties are similar to those of the xanthate complexes.

It is interesting that reactions involving copper(II) result in the immediate formation of $Cudtc_2$, with no evidence of any formation of $Cudtc_2$.Base. A similar reaction occurs with nickel(II) when the base is bipy, although with phen, $Niphen_3dtc_2$ is the final product.

The formation and reactions of this compound are summarized in Fig. 1. The nature of the yellow solid is not clear and little can be done to establish its composition since as soon as it is dried it begins to turn to the orange product.

$[Niphen_3]dtc_2$ dissolves in methylene chloride to give a deep red solution, although within several seconds the color is largely discharged and tan colored crystals deposit. The reaction between dtc^- and CH_2Cl_2 is clearly extremely fast, much faster in fact than the reaction (14) between Nadtc and methylene chloride, which must be refluxed for several hours in order to obtain an appreciable yield of CH_2dtc_2. It may be that the latter reaction is relatively slow because of the insolubility of Nadtc in methylene chloride, while in the above reaction the dtc^- species is in solution and therefore probably able to react with the solvent much more rapidly.

Chemical analyses indicate the presence of close

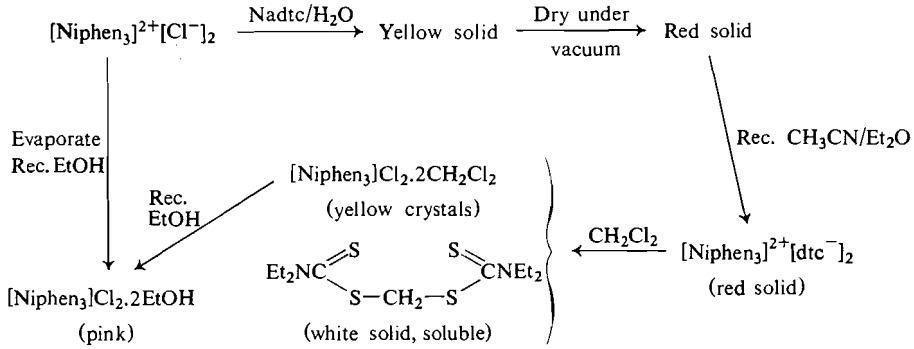

FIG. 1. Reactions of $[Niphen_3]Cl_2$.

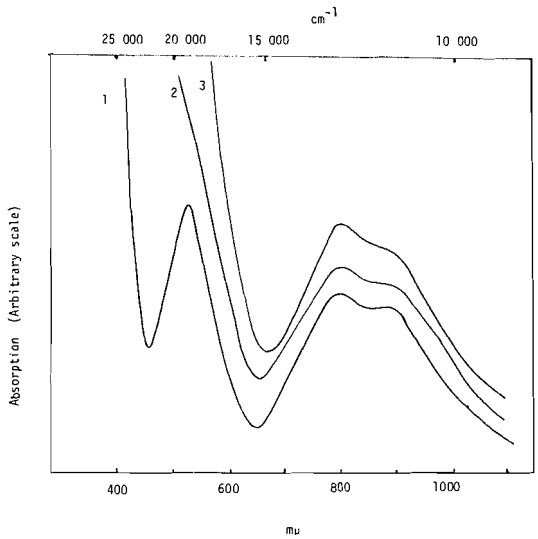

FIG. 2. Reflectance spectra of species containing the $[Niphen_3]^{2+}$ ion. (*1*) $[Niphen_3]Cl_2.2EtOH$, (*2*) $[Niphen_3]Cl_2.2CH_2Cl_2$, (*3*) $[Niphen_3]dtc_2$.

to two molecules of both methylene chloride and ethanol associated with the $[Niphen_3]Cl_2$ species. This was verified by mass spectral studies which clearly indicate the presence of both solvents. Thus, the mass spectrum (direct inlet, 80 eV, 160 °C) of the methylene chloride adduct shows very strong bands at *m/e* 86, 84, 51, and 49 while the ethanol adduct has a particularly strong peak at *m/e* 46. These molecules do not appear to be readily removed at 10^{-3} Torr at room temperature although they are removed at 10^{-6} Torr at slightly higher temperatures. The only indication of solvent in the infrared spectra of these compounds is the presence of a small band at 3220 cm^{-1} in the ethanol adduct. The reflectance spectra in Fig. 2 clearly indicates that the cation $[Niphen_3]^{2+}$ is present in all three compounds, although it is surprising that the presence of methylene chloride has resulted in the charge-transfer band moving to lower energies compared to its position in the ethanol adduct. The splitting of the $^3A_{2g} \rightarrow {}^3T_{2g}$ transition may arise from distortions of the $Niphen_3^{2+}$ ion, although the $^3A_{2g} \rightarrow {}^3T_{2g}$ band does not show similar splittings, at least at room temperature (23). Phenanthroline does not appear to react readily with $Nidtc_2$ once the latter has formed, probably an indication of the strength of the Ni—S bonds in the square planar molecule.

Several attempts have been made, by ebulliometry in methylene chloride solutions, to measure the molecular weight of a variety of the complexes reported here. In all cases the complexes either proved too insoluble or amorphous residues, indicative of decomposition of the complexes, appeared in the ebulliometer, making accurate measurements impossible (6).

The assignment of various bands in the infrared spectra of these complexes will be considered with the report of the products from the metal–base–Xan reactions in 1:3:2 mole ratios, as these products shed some light on the assignments.

We thank the Senate Research Committee of Lakehead University Thunder Bay, Ontario, the National Research Council of Canada, and the Ontario Department of University Affairs for generous financial support of this work.

Étude cinétique de quelques cellules électrochimiques de métaphosphate de sodium ($NaPO_3$) fondu[1,2]

E. J. Casey et A. R. Dubois

Centre de recherches pour la défense, Ottawa, Canada

Reçu le 31 août 1970[3]

Les métaphosphates fondus et déshydratés ne réagissent pas avec le platine et le quartz à 650 °C; il a donc été possible d'etudier en détail les processus chimiques et électrochimiques d'abord avec des électrodes de platine puis ensuite avec des électrodes de nickel. Des études ont aussi été faites avec les métaux suivants: Fe, Cu, Ca, Ag.

Le dégagement anodique d'oxygène sur le platine à partir du métaphosphate de sodium fondu laisse voir un hystérésis dans la courbe V/I et un comportement Tafel ($d\eta/d \log i = 2.3RT/\beta nF$) d'une exactitude surprenante impliquant que la décharge lente d'un électron détermine la vitesse de réaction sur un domaine étendu de vitesses. Le processus cathodique est complexe et le dépôt contient du sodium élémentaire dans le platine.

Le phosphure de nickel $Ni_{12}P_5$ prédomine comme produit d'autocorrosion sur le Ni. Ce produit est réduit activement s'il est couplé électrochimiquement avec le Ca, et de la même façon est activement oxydé par O_2. L'électrolyse poussée introduit du nickel supplémentaire à l'anode ou du phosphore à la cathode et modifie la structure cristalline du produit.

Les résultats de l'analyse thermique différentielle (ATD), de l'analyse par spectroscopie r.m.n.-phosphore et de la solubilité du sel résiduel dans l'eau démontrent que la structure trimérique du sel fondu est modifiée par l'électrolyse. L'anolyte diffère du catholyte. Le sel fondu électrolysé présente une conduction ionique et électronique à 650 °C mais les facteurs de transport électronique semblent être déterminés par un processus d'injection à la cathode.

Plusieurs réactions se produisent aux interfaces électrodes–électrolyte et dans l'électrolyte, dont la nature chimique et électrochimique et la cinétique sont envisagées. Les résultats expérimentaux obtenus conduisent à penser qu'un contrôle de la cellule électrochimique permet d'orienter sélectivement les produits de la réaction, phosphures métalliques, phosphore, phosphine, métaphosphates polymériques, le dépôt métallique et produits métal-phosphore semiconducteurs. On envisage également la possibilité d'une pile $Ca|NaPO_3|Ni$ et d'une pile à combustible sur $Ni|NaPO_3|O_2$.

Interest in the possible use of molten metaphosphates as electrolyte and as reactant in electrochemical cells has been examined from the points of view of both electrochemical synthesis and sources of electrical energy. Both are shown to be possible.

The anodic evolution of O_2 from carefully dried molten $NaPO_3$ on Pt shows hysteresis in the V/I curve, and also shows Tafel behavior ($d\eta/d \log i = 2.3RT/\beta nF$) with surprising exactness, which implicates one-electron slow discharge as rate-determining over a considerable range of rate of reaction. The cathodic process is complex, but includes deposition of Na into the Pt if the melt is dry.

On Ni the phosphide $Ni_{12}P_5$ predominates as the autocorrosion product. This material is actively reduced if electrochemically coupled with Ca, and can be electrochemically oxidized by O_2. Forced electrolysis inserts extra nickel into a phosphide anode, or phosphorus into a phosphide cathode, and modifies its crystal structure. The trimeric structure of the melt is modified by electrolysis, as shown by DTA tracings, by phosphorus-n.m.r. spectra, by changes of color and of solubility of the products in water. Anolyte product differs from catholyte product. The electrolyzed melt can leak charge both electronically and electrolytically at 650 °C, but electronic transport is tenuous and seems to be determined by an injection process at the cathode. Reactions and mechanisms are proposed for the various processes, including a phosphate shuttle to account for loss of charge.

Indications are that metal phosphides, phosphorus, phosphine, polymeric metaphosphates with various physical properties, metal cladding, and semiconducting metallo-phosphorus products could be selectively produced if sufficient controls were to be imposed on a suitably designed electrochemical reactor.

Introduction

Cet exposé décrit une étude entreprise sur des cellules électrochimiques utilisant comme électrolyte du métaphosphate de sodium fondu à 650 °C. Le but initial de ce travail était de mieux comprendre les phénomènes chimiques et électrochimiques qui y prennent place.

La littérature concernant l'électrolyse ignée du métaphosphate de sodium est très disposée et fragmentaire. Ainsi Couch (1) mentionne la formation de couches de phosphures dures de nickel formées sur une électrode de nickel, lors d'une simple immersion ou d'une électrolyse. Grueber et aussi Frank et Inman (2) rapportent la préparation de phosphore très pur à la cathode par électrolyse. Bekturov (3) montre que le phosphore pouvait être obtenu par action d'un gaz reducteur sur le métaphosphate de sodium fondu. Le travail analytique le plus complet semblent cependant être encore celui de Chêne (4).

Bien qu'on ait observé que l'évolution anodique d'oxygène et le dépôt cathodique de sodium ainsi que la corrosion rapide de la plupart des métaux (même le platine sous les conditions réductrices) apparaissent dans les metaphosphates fondus, la démonstration est incomplète et peu convaincante, surtout en ce qui concerne le méchanisme des réactions. Dans son livre Van Wazer (5) passe en revue presque toute la littérature pertinente antérieure.

En 1960, Delimarskii *et al.* (6) présentèrent une communication expliquant en détail l'effet d'additifs solides sur le métaphosphate pur fondu. Frank et Inman (2) mentionnent de l'évidence pour la dépolymérisation de chaînes du métaphosphate avant de perdre leurs charges à la cathode. Certain auteurs prétendent également que le P^{5+} du métaphosphate peut subir une réduction de plusieurs électrons, jusqu'à P^{3-}. Une telle réaction de transfert présente un grand intérêt à la fois fondamental (compréhension du mécanisme des réactions) et pratique (synthèse électrochimique et piles énergétiques utilisant des sels fondus). Cette étude des métaphosphates fondus provient directement du travail de Senderoff (7) décelant le présence de phosphine du cours de la réduction de cet oxyanion dans les piles thermiques.

Nous avons étudié le comportement de plusieurs métaux dont le platine, le calcium, le nickel, le cuivre et le fer, en présence de sel fondu pur, soit par immersion simple, soit par traitement anodique et cathodique. La première partie décrit les caractéristiques chimiques de l'électrolyte et la cellule de mesures. La seconde partie est consacrée aux comportements électrochimiques.

Phénomènes chimiques

Le métaphosphate de sodium (B & A réagent) contenait 2% d'eau en plus des autres impuretés décrites (métaux lourds: Pb et Fe, 0.005%; As, 0.001%; sulfate, 0.01% et chlore, 0.003%). Les travaux préliminaires ont montré que ce produit attaquait un grand nombre de matériaux utilisés comme creusets à 650 °C et réagissait violemment avec le Ca métallique pour produire du phosphine; il attaque même le Pt dans des conditions réductrices. Toutefois la déshydratation a pu être réalisée efficacement par le procédé suivant: sous pression réduite ($\simeq$10 nm), la température du sel fondu était élevée à près de 900 °C dans un tube en quartz (Fig. 1) pour une période de trois heures; on le refroidissait ensuite à 800 °C sous vide pour 16 h. Après un

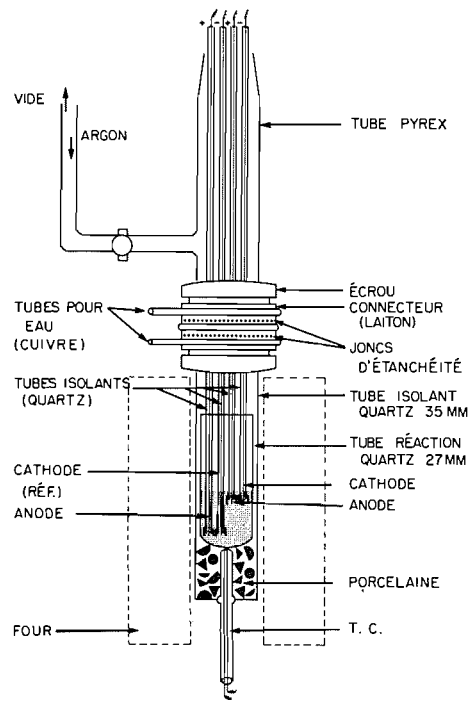

FIG. 1. Appareil. A noter que la chemise, les gaines des électrodes, les cloches d'échantillonage et le récipient de la cellule sont en quartz. Deux électrodes auxiliaires Pt/sel/Pt composent le potentiel de référence: à 10 μA/cm² le potentiel était 1.15 V sûr, et l'anode était utilisée comme référence.

tel traitement, le sel fondu n'attaquait plus le Pt dans des conditions réductrices et était inerte vis à vis calcium métallique, et l'analyse du sel fondu par la méthode Karl Fisher a montré une teneur en eau de moins de 0.02%, apparemment retenue dans la structure polymérique du sel fondu. Une analyse spectrographique d'un tel sel fondu déshydraté révéla de faibles traces de Cu, Al, Mg, Fe, un trace de Si mais ne put déceler du Pt ou du Ni. Hydraté ou non, le sel fondu est visqueux entre 600 et 750 °C et la viscosité de NaH_2PO_4 soigneusement déshydraté jusqu'à $NaPO_3$ a été étudiée (8*a*). Bien qu'on ait révélé l'existence d'une part d'une structure trimérique cyclique et d'autre part d'une structure polymérique à longue chaîne (5), la composition anionique précise du sel fondu dépend probablement de la teneur en eau du sel fondu considéré et de l'histoire thermique du sel fondu bien que ce dernier point n'ait pas encore été étudié expérimentalement d'une façon systématique. Le montant de Na_2O en excès est aussi très important: avec son excès la conductibilité ne change pas, mais la viscosité diminue beaucoup (8*b*).

Les diagrammes de diffraction de rayons-X de sels déshydratés ne diffèrent pas sensiblement de celui de $NaPO_3$, mais il apparaît parfois dans le thermogramme différentiel un grand pic exothermique à 320 °C indiquant une réaction (probablement la formation d'un polymère) qui ne peut être isolé des effets de l'histoire thermique antérieure de l'échantillon.

Le chauffage de mélanges équivalents de Na_2O et de P_2O_5 donne une vive réaction exothermique vers 300 °C. On en conclut que le sel fondu ne peut être considéré comme une simple solution de Na_2O et P_2O_5. Ce point a été soulevé et discuté par d'autres auteurs (9).

Produits d'électrolyse dans le sel fondu

Dans le sel fondu déshydraté, le Pt résiste aussi bien à l'attaque anodique que cathodique. (L'inertie du calcium dans le sel fondu après immersion indique que ce dernier est suffisamment déshydraté.) A des faibles densités de courant, l'anode de Pt atteint rapidement une tension stable tandis que celle de la cathode s'accroît lentement et au début de façon erratique; puis après quelques heures il s'établit une différence de potentiel d'environ 1.1–1.2 V entre l'anode et la cathode, potentiel stable à quelques mV près. A des densités de courant plus élevées, la cellule atteint le potentiel d'environ 1.2 V plus rapidement, et si l'électrolyse persiste, un dépôt noir apparaît à la cathode tandis qu'un produit jaune-orange soluble est produit à l'anode.

Le spectre de diffraction de rayons-X du sel fondu déshydraté solidifié et refroidi présente très peu d'intérêt car coloré ou non, le verre ainsi formé était généralement inerte aux rayons-X. L'analyse thermique différentielle était souvent aussi indéfinie; le thermogramme dépend plus du taux de refroidissement antérieur que de la présence de la substance colorée.

Ce chromophore jaune persiste parfois même quand le sel solidifié et refroidi est dissout dans l'eau; il présente une large bande d'absorption avec un maximum à 410 nm. Si l'on prolonge l'électrolyse du sel fondu déshydraté à 650 °C entre les deux électrodes de Pt, le composé formé à l'anode devient plus foncé (brun doré). Comme un complexe à transfert de charge, la couleur change avec la température, réversiblement: du brun doré à 650 °C au brun à 750 °C, au jaune à 610 °C. (On peut noter les couleurs Munsell (10) dans le tableau 1. Ce n'était pas possible d'obtenir des spectra d'absorption parce que le fondu électrolysé était un peu brumeux, un peu bourbeux.)

De plus, le $NaPO_3$ avant l'électrolyse montre dans l'eau une absorption r.m.n.-P à $+21 \pm 1$ p.p.m. en prenant de la H_3PO_4 à 85% comme le zéro de référence; mais l'anolyte jaune montre en plus une résonance à $+10 \pm 1$ p.p.m. indiquant qu'il existe un nouvel environnement du phosphore dans l'anolyte formé par le traitement anodique. La résonance se produit à un niveau d'énergie caractéristique d'un "polymétaphosphate" (11). Un modèle de ce qui se produit a été conçu à partir de (*a*) ces nouveaux faits, (*b*) les travaux de Griffith et Rutt (12) qui associent le groupe C_{3v} (trimère en forme de chaise) à $NaPO_3$ dans l'état solide (basé sur les spectres i.r. et Raman), (*c*) la supposition que le groupe C_{3v} persiste dans le sel fondu, (*d*) des idées basées sur des revues récentes des complexes chromophoriques inorganiques par Jørgensen (13). Le mécanisme que nous proposons pour l'oxydation anodique du sel fondu est illustré dans la Fig. 2. On peut donc voir que le nouveau modèle explique, du moins qualitativement, le dégagement d'oxygène, le nouvel environnement du phosphore ainsi que la présence du chromophore; de plus, il suggère

TABLEAU 1. Couleurs du sel fondu ($NaPO_3$) électrolysé à diverses températures (électrodes de nickel)

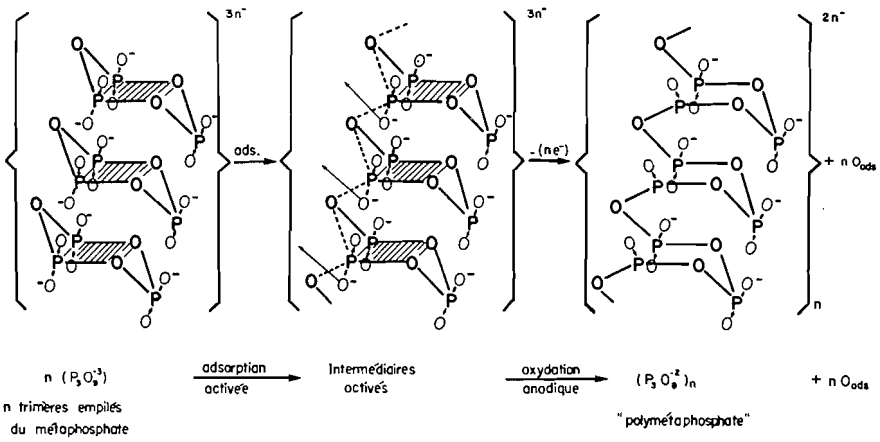

FIG. 2. Représentation schématique de l'oxydation anodique du sel fondu.

pourquoi la solubilité de l'anolyte est beaucoup plus faible que celle du $NaPO_3$ avant l'électrolyse. En effet, le modèle suggère que l'oxydation anodique produit une espèce polymérique inhabituelle en ouvrant les trimères et en créant de nouvelles liaisons P—O—P transversales. Hélices et serpentins désordonnées sont tous les deux possibles, mais il est très peu probable que les liaisons transversales se fassent tout à fait au hasard. La configuration pourrait avoir des modes capables de semiconductivité par liaison π. Toutefois, notre image de l'activité chromophorique n'est pas encore très claire, parce qu'on doit avoir égard au lieu spectral du maximum d'absorption d'O_3^- (14) ainsi que des quelques bandes fortes de PO (15), dont les maxima sont aussi près de 410 nm.

L'anolyte solidifié se dissout généralement plus rapidement dans l'eau à la température de la pièce que le catholyte, ce dernier laissant un

résidu fibreux amorphe aux rayons-X. Les structures de l'anolyte et du catholyte sont évidemment différentes.

Oxydation métallique

Le platine et l'or ne sont pas attaqués appréciablement après qu'on a soigneusement déshydraté le sel fondu. L'oxygène se dégage à l'anode de platine. Par contre, les métaux plus actifs tel Ca, Ni, Cu, Fe sont attaqués lentement. Nous décrivons tout d'abord les aspects phénomènologiques.

Le nickel, immergé pendant deux heures à 650 °C dans un électrolyte de $NaPO_3$ fondu déshydraté, se revêt d'une couche métallique grise très dure (Fig. 3*a*) dont le diagramme de diffraction des rayons-X était celui de $Ni_{12}P_5$ (Ni_7P_3 dans la littérature antérieure), tel que décrit par Rundqvist (16). Ce dépôt est fortement magnétique et insoluble dans l'eau. Il se solubilise lentement dans les acides forts. Les neuf autres phosphures connus du nickel, tableau 2, n'apparaissent pas. De plus, le $Ni_{12}P_5$ est produit en assez grande quantité sous forme apparemment de cristaux isolés. Ce sont des lamelles minces, brillantes, à fractures conchoïdales, d'une longueur d'environ 0.1 mm, ressortant de la surface du Ni dans le sel fondu (Fig. 3*a*).

L'oxydation anodique du nickel immédiatement après son immersion dans le sel fondu ne produit pas de lamelles. On a pu déterminer que le produit sous forme d'une mince couche grise était composé de $Ni_{12}P_5$ en plus d'un autre composant encore inconnu.

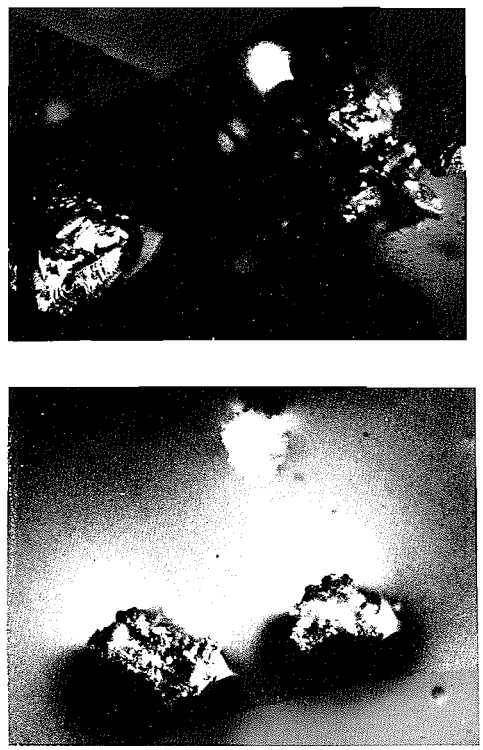

FIG. 3. Photographie des produits formés sur le Ni: (*a*) des cristaux de $Ni_{12}P_5$ (*b*) produit cathodique inconnu. Grandeur des photos: 125×.

Des spécimens de nickel coulé, corrodé à l'acide, ainsi que du nickel fritté en poudre (85% poreux), ont montré sensiblement les mêmes produits, bien que la substance frittée anodisée produisait des lignes supplémentaires

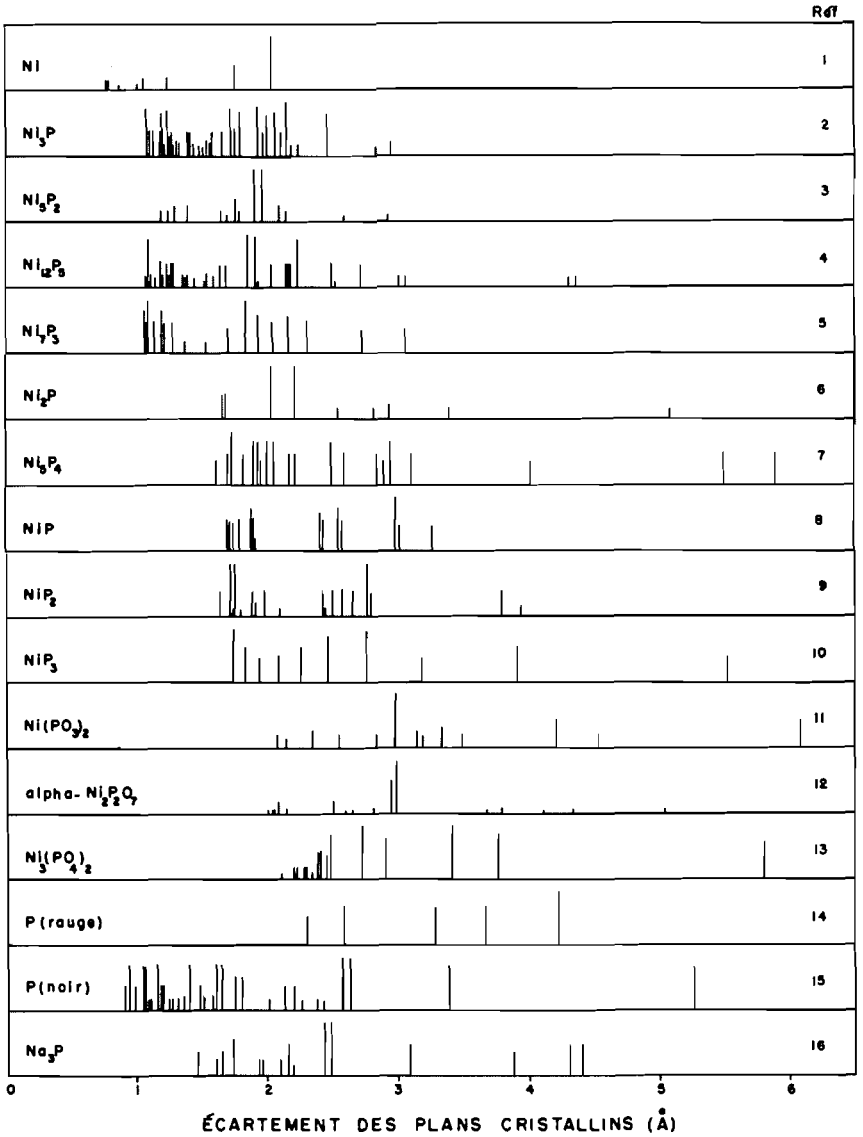

FIG. 4. Diagrammes de diffraction des rayons-X de phosphures connus et de quelques produits de réaction possibles: *1*, "X-ray Powder Data File" ASTM fiche numéro 4-0850; *2*, réf. 26; *3*, réf. 29; *4*, même que 2; *5*, ASTM fiche numéro 3-1101; *6*, ASTM fiche numéro 3-0953; *7*, réf. 27; *8*, même que 7; *9*, réf. 26; *10*, même que 2; *11*, réf. 33; *12*, même que 11; *13*, même que 11; *14*, ASTM fiche numéro 2-0266; *15*, ASTM fiche numéro 9-20; *16*, ASTM fiche numéro 4-0764.

dans le diagramme de diffraction, résultant probablement d'une couche d'oxyde sur le produit du départ. Un ensemble de diagrammes connus pour les phosphures de nickel ou d'autres produits de réactions probables est donné dans la Fig. 4. Ces diagrammes peuvent être comparés avec un produit de réaction anodique non identifié dont le diagramme apparait dans la Fig. 5*a*.

Les produits de réactions anodiques de cuivre, de fer et de calcium n'ont pas été étudiés avec autant de précision que ceux de nickel, mais les phosphures de cuivre et de fer ont été identifiés surtout.

Réduction cathodique

Dans le but de préciser un point expérimental qui veut que le Pt soit attaqué par le méta-

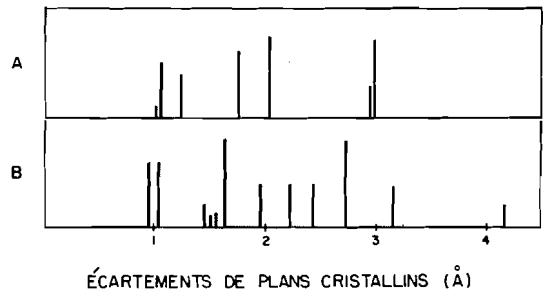

FIG. 5. Diagramme de diffraction des rayons-X du (*a*) produit anodique (*b*) produit cathodique, non identifiés.

phosphate fondu sous des conditions réductrices (17), nous soulignons que l'attaque ne se fait pas si le sel fondu est soigneusement déshydraté jusqu'au point d'être inerte au calcium.

Pendant la réduction cathodique à 650 °C du Pt dans le métaphosphate fondu déshydraté une couche mince du produit de réaction est deposée sur le Pt. L'identification de ce matériel suit.

Par l'analyse quantitative spectroscopique à flamme d'échantillons en surface, il a été démontré que la charge accumulée par le dépôt électrolytique pouvait être attribuée au dépôt de sodium sur et dans le Pt. Toutefois du phosphore (pas nécessairement élémentaire) apparaît toujours dans l'analyse. Etant donné le mince dépôt (estimé par les mesures coulombiennes à environ de 100 couches atomiques sur le Pt), le produit de réaction pourrait être un phosphure tel que PtP_2 ou Na_3P, ou même un phosphite. Toutefois on s'attendrait à ce que ces deux derniers, réagissent violemment quand le produit est introduit dans l'eau. Les connaissances actuelles nous portent à croire que le produit sur le Pt est du Na, tout probablement dans le Pt sous forme d'un alliage Pt–Na, avec aussi la possibilité de trouver du phosphore élémentaire. D'autres auteurs ont trouvé du phosphore élémentaire sur des cathodes de tungstène et de charbon (2), mais nous n'avons jamais pu obtenir d'indications certaines du phosphore sur la surface du platine; la couche était toujours trop mince.

Le nickel se comporte différemment. Tandis que le potentiel du Pt varie et devient graduellement plus négatif pendant une réaction cathodique, le nickel se charge et il prend immédiatement un potentiel qui est le même que le potentiel stable du platine comme cathode. La réduction du Ni se produit très bien à une légère surtension, et une mince pellicule (Fig. 3*b*) d'un gris pâle en résulte. Quand des échantillons lavés de ce produit (non-magnétique) sont isolés du sel solidifié vitreux, à la température ambiante, ils donnent une simple structure cubique, dont le diagramme de diffraction des rayons-X n'est pas connu (Fig. 5*b*). Le produit non lavé, qui contient probablement une portion du sel réduit ainsi que la substance grise fournit en plus deux autres diagrammes séparables mais non identifiables, révélant deux autres produits. Chacun d'eux présente deux larges distances (5–10 Å) réticulaires, distinctes et séparables, tel qu'on trouve dans une structure défectueuse (18).

Ainsi, nos connaissances indiquent la présence de 5 produits cathodiques différents: *A*, $NaPO_3$ amorphe, vitreux, fibreux, soluble lentement à l'eau chaude; *B*, Na en alliage avec le Pt, et possiblement avec le Ni ainsi qu'avec d'autres métaux étudiés; *C*, un "phosphure gris" avec une structure cubique (appelé ultérieurement "P(Na)", formé sur le Ni; *D–E*, deux autres substances cristallines avec des défectuosités dans le réseau cristallin, tout probablement des formes défectueuses du phosphure gris inconnu de *C*.

Une attention particulière a déjà été porté au "phosphure gris" (*C*). Chêne, dans un travail remarquable, a déclaré en 1941 que des phosphures massifs de plusieurs compositions différents peuvent être produits à la cathode, selon la température, la densité du courant et les solides ajoutés au sel fondu. D'autres chercheurs ont aussi déclaré la formation de phosphures cependant sans évidence. Grueber en 1956 prétendait que le phosphore très pur est en lui-même un constituant majeur. Cependant, dans toutes ces études anciennes, les analyses ont été faites sur des échantillons macroscopiques, qui, d'après nos expériences, devraient être hétérogènes.

Dans le présent travail, le dépôt gris *C* est cristalline mais n'est pas fortement magnétique. Les cristallites présentent un spectre de diffraction (cubique simple) à 7 lignes, qui n'a pas encore été identifié. La Fig. 5 montre les quatre plus fortes espaces à: 2.73, 1.64, 1.05 et 0.96 Å. L'analyse à la microsonde a révélé que les cristallites contiennent principalement du phosphore avec du nickel comme partie composante mineure et une quantité indéterminée de Na.

Ainsi *C* n'est peut-être pas simplement un des phosphures de nickel à haute teneur en phos-

phore. Ceci pourrait être un phosphure de sodium, ou bien un nouvel allotrope du phosphore élémentaire. Puisque le comportement électrochimique du dépôt Na-sur-Pt, Pt(Na), est semblable à celui du dépôt gris qui a été produit cathodiquement sur le Ni, il semble probable que le dépôt cathodique est une solution de sodium–phosphore qui peut être stabilisée, soit dans le nickel, soit dans le platine. Il semble donc y avoir deux possibilités pour le Ni, soit un composé tel que Na_3P rapporté, ou une substance semi-métallique, sodium-dans-phosphore, P(Na), retenue dans une matrice de Ni limité. En l'absence de preuves par diagrammes de diffraction des rayons-X pour Na_3P, nous devons supposer que ce dernier est plus probable.

La stabilité de la charge retenue par le phosphure gris est variable.

Phénomènes électrochimiques

Observations générales

Avec une telle variété dans les possibilités de réactions découvertes par les études des changements chimiques et rapportée dans la section précédente, on voit que l'interprétation des mesures électrochimiques sur ce système est capricieuse. Toutefois certaines mesures ont été faites qui non seulement décrivent le comportement du système mais conduisent à une meilleure compréhension des processus dont il est le siège.

Les méthodes utilisées sur des électrodes simples étaient toutes conventionnelles: (*a*) mesures de la quantité d'électricité, (*b*) comportement *V*/*I*, (*c*) décroissance de potentiel en circuit ouvert. Quelques caractéristiques électriques des cellules de conversion d'énergie ont aussi été déterminées. Les observations les plus générales peuvent être résumées de la façon suivante:

(*a*) Le potentiel pendant le dégagement de l'oxygène du Pt est assez stable pout être utilisé comme potentiel de référence. Son comportement *V*/*I* est remarquablement semblable à celui en solution aqueuse, par exemple d'une part l'hystérésis et d'autre part des valeurs semblables de la pente Tafel sont observées.

(*b*) Les potentiels en circuit ouvert du Ni, Cu, Fe sont tous semblables à celui du Pt une fois ce dernier réduit cathodiquement dans le sel fondu: environ 1.2 V cette électrode étant négative par rapport à l'électrode de référence Pt/O_2; mais celle du Ca est environ 2.6 V négative elle aussi par rapport à l'électrode de référence.

(*c*) Les surtensions sont de façon prédominante, non-ohmiques. Après l'interruption du courant, le potentiel décroît lentement sur une période de quelques secondes.

(*d*) Les densités de courant limites pour des oxydations de métaux actifs sont basses: généralement de l'ordre de 0.1 A/cm^2.

L'électrode à gaz O_2

Le sel déshydraté se décompose à l'anode pour libérer un gaz constitué principalement d'oxygène. La réaction anodique globale pourrait suivre

$$2PO_3^- \rightarrow P_2O_5 + \tfrac{1}{2}O_2 + 2e^-$$

Nous la discuterons en détail plus tard, après que nous examinerons les résultats électrochimiques.

Le comportement Tafel et la décroissance de potentiel ont été déterminés. Contrairement à la cathode, le potentiel de l'anode décroît très rapidement vers la valeur réversible deux ou trois secondes après l'interruption du courant; par la suite, la décroissance sur les derniers 100 mV est très lente. dη/d log t varie d'un essai à l'autre. La moyenne est d'environ 49 mV/décade de temps et correspond probablement à un processus de désorption lente contrôlé par la diffusion. Nous n'avons pas fait de mesures rapides de la décroissance du potentiel pour des temps inférieurs à 1.0 s.

Le comportement de Tafel sur 2½ ordres de grandeur (Fig. 6) a révélé l'existence probable de deux types différents de sous-couches à partir

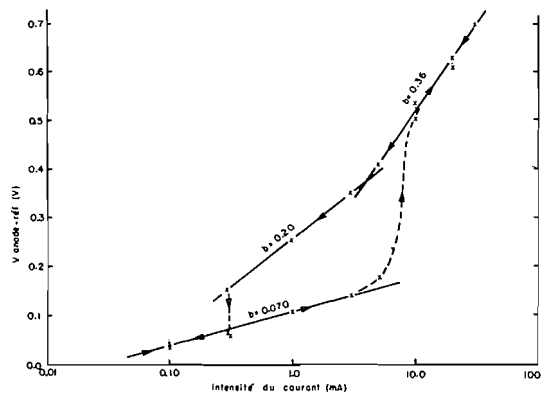

FIG. 6. Renseignement *V*/*I* de l'évolution d'oxygène sur le Pt dans le $NaPO_3$ à 650 °C. Si $\beta = 0.5$ et $n = 1$, alors $b = 2 \times 2.3RT/n\beta F = 0.36$, impliquant que la décharge lente à partir de PtO_x est l'étape déterminante de la vitesse. Ref: O_2 sur Pt à 10 μA/cm^2.

For personal use only.

desquelles l'oxygène peut évoluer. Une des sous-couches est stable à une faible densité de courant avec une faible valeur de $b \equiv d\eta/d \log I$ (de l'ordre de 0.07 V/décade), et l'autre existe principalement à une forte densité de courant avec une valeur de b environ 0.36 V/décade. Cependant une fois formée, cette dernière peut continuer à exister si la densité de courant est réduite lentement et systématiquement à des valeurs où on ne trouve généralement que le premier type de sous-couche. Il a été suggéré que la sous-couche pourrait être du PtP_2 ou du PtO, existant aux faibles densités de courant, et PtO_x formé à des densités de courant élevées. Le comportement est tel que chacun d'eux semble pouvoir remplacer l'autre, l'oxyde supérieur remplaçant le phosphure ou l'oxyde inférieur à une densité de courant élevée et l'inverse à des densités de courant faibles.

Aux plus hautes densités de courant, la pente mesurée, 0.36, concorde remarquablement avec la valeur théorique prédite par $2 \times 2.3RT/F$ pour un processus dans lequel la décharge lente d'une espèce adsorbée de la solution est l'étape déterminante de la vitesse pourvu qu'un seul électron soit transféré et que le facteur de symétrie soit de 0.5. Ceci n'est apparemment pas un cas isolé car on a trouvé (19) que la réaction d'évolution gazeuse anodique de $NaNO_2$ fondu a aussi des valeurs de b données par $2 \times 2.3RT/F$ sur trois ordres de grandeur de densité de courant aussi bien à 244 qu'à 310 °C. Dans ce cas on croyait que la réaction primaire devait être $NO_2^- \rightarrow NO_2 + e^-$. De la même façon, la décharge du nitrate montre le même genre de comportement de Tafel, impliquant une décharge lente de NO_3^- du moins sur un domaine limité de densités de courant (20). Ainsi, par analogie, nous avons conclu dans le cas du $NaPO_3$ que l'étape lente est la décharge de PO_3^- du polymère absorbé sur la surface PtO_x saturé en oxygène.

Pour des densités de courant intermédiaires, b devient constant à 0.20 et non pas à 0.18 comme on s'y attendrait si l'étape déterminante était la combinaison lente d'atomes d'oxygène sur le PtO_x; cette valeur supérieure est peut-être due au fait que x est maintenant moindre ou bien encore due au remplacement partiel de l'oxygène par le phosphore de la sous-couche. Même aux densités de courant plus faibles, il est possible que la couche d'oxyde soit remplacée par une couche beaucoup plus catalytique de phosphure. (Dans un cas, du PtP_2 a été isolé du sel fondu et identifié par diffraction des rayons-X à la fin de l'expérience.) Aux densités de courant intermédiaires et faibles, la situation semble être aussi compliquée que dans les bisulfates, les sulfates et les carbonates (21).

La région de transition a été étudiée en détail en examinant les effets de l'interruption du courant. A 5 mA, par exemple, on note souvent le phénomène de surtension anodique. On observe surtout ce phénomène chez des métaux actifs qui peuvent donner lieu à deux oxydes (Ag en solution aqueuse de KOH; Pb en solution aqueuse de H_2SO_4, *e.g.*), cette surtension transitoire se produit lorsqu'on passe d'un oxyde inférieur à un oxyde supérieur. Dans le cas présent, la surtension se produit seulement si l'électrode a un repos d'au moins 2 min en circuit ouvert avant l'oxydation anodique et de façon générale la surtension est d'autant plus marquée que ce repos est prolongé. Décrit d'une autre façon: si le potentiel baisse de plus de 400 mV durant le repos, la surtension anodique peut se produire lors de la prochaine charge anodique. On peut expliquer cette surtension en l'attribuant au phosphore élémentaire qui, provenant du phosphure, pénètre dans la couche PtO_x lors que la réaction a lieu après une période de repos au cours de laquelle le phosphure a pu s'accumuler.

La tension à laquelle l'oxygène se dégage dans la région transitoire semble dépendre largement du degré de saturation de PtO_x en O ou de l'activité catalytique de PtO_x pour la libération d'oxygène. Ainsi la tension finale atteinte par l'électrode faiblement catalytique (i_0 faible) peut dépasser de 60 mV celle d'une électrode fortement catalytique (i_0 élevé).

Il existe donc trois types de sites sur lesquels PO_3^- peut se décharger et où l'oxygène peut se dégager du sel fondu trimérique: Pt pur, qui existe avant l'anodisation de la surface et possiblement après sur la surface de l'électrode; les sites PtP_2; et les sites PtO_x.

Considérons deux routes alternatives pour l'oxydation de PO_3^-. Supposons que la "simple décharge"

$$PO_3^- \rightarrow PO_{3\ ads.} + e^-$$

soit suivie de la décomposition non électrochimique pour produire O_2

$$PO_{3\ ads} \rightarrow P + 3/2\ O_2\uparrow$$

ou

$$PO_{3\ ads} \rightarrow PO + O_2\uparrow$$

ou

$$PO_{3\ ads} \rightarrow PO_2 + \tfrac{1}{2}O_2\uparrow$$

Alternativement, si le sel $NaPO_3$ fondu a été décomposé partiellement jusqu'à Na_2O dissout dans P_2O_5 (9), du "Na_2O" venant du sel fondu se décharge sur l'anode pour donner O_{ads} et la "décharge électrochimique" de PO_3^- procède comme

$$PO_3^- + O_{ads} \rightarrow O_2\uparrow + PO_{2\ ads} + e^-$$

suivie de la décomposition

$$PO_{2\ ads} \rightarrow P + O_2\uparrow$$

ou

$$PO_{2\ ads} \rightarrow PO + \tfrac{1}{2}O_2$$

Il est concevable que O_2 provienne directement de la décharge d'ions O_2^-. Dans ce cas, le transfert d'électron en une seule étape requise pour que $b = 0.36$ doit être le suivant:

$$O^-_{ads} \rightarrow O_{ads} + e^-$$

suivie d'une réaction de combinaison conduisant au dégagement d'oxygène. Toutefois, les produits phosphoreux doivent encore être expliqués de façon rationnelle.

Maintenant nous pouvons décrire la Fig. 6 comme suit: Aux faibles densités de courant l'oxygène se dégage à partir d'une sous-couche dont la composition PtO/PtP_2 varie en fonction de la densité de courant, et $b = 0.07$. Cependant, au-dessus d'une densité de courant critique, PtO_x se développe, et O_2 évolue à une vitesse limitée par la décharge lente de PO_3^-, et $b = 0.36$. En abaissant la densité de courant même d'un facteur de dix, le PtO_x demeure protégé, mais la vitesse devient limitée par la décharge électrochimique de PO_3^- avec O_{ads}, et $b = 0.2$. Enfin, si nous voulons réduire la densité de courant à des valeurs trop faibles, le PtO_x n'est plus protégé par l'oxygène évolué, et la sous-couche se reforme.

Les faits suivants s'accordent avec les deux mécanismes de décharge: (*a*) Le phosphore rouge élémentaire a été identifié une fois sublimé de l'anode; (*b*) Le composé noirâtre PtP_2 a été isolé et identifié par diffraction de rayons-X, (*c*) Il n'y a aucune preuve de l'échappement d'un PO_2 gazeux.

Réductions cathodiques

Le sel fondu fournit un produit de réaction de telle sorte que la cathode de Pt agit comme

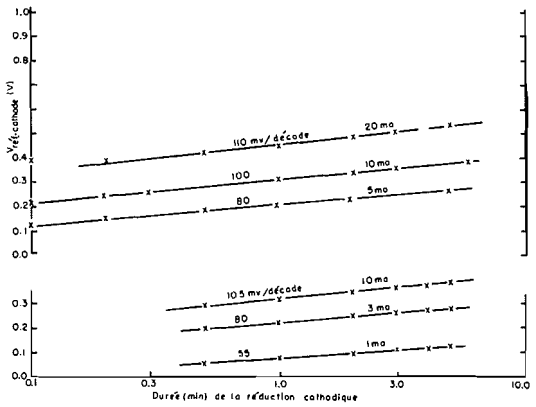

FIG. 7. Potentiel de la cathode à 650 °C durant le dépôt électrolytique de "P(Na)" sur le Pt à partir du $NaPO_3$ asséché. Deux expériences, équation de Nernst: $V \propto \log a_{Na(Pt)} = \log (it/nF)$.

une électrode métal-amalgame. Bien que Brester ait proposé un comportement semblable en 1866 dans réf. 24 nous pouvons maintenant présenter trois sortes de preuves. Ainsi dès le début de la réduction cathodique, la tension prend une valeur de 0.8 V cathodique à l'électrode d'oxygène et devient progressivement plus cathodique suivant l'équation de Nernst, $E\alpha \log q$, lors du passage de la charge q. La Fig. 7 illustre ce fait. De plus, en circuit ouvert, la tension décline lentement et tout se passe comme si le produit cathodique (Na ?) diffuse dans le Pt ou est corrodé par le sel fondu ou les deux. Le déclin est classique en ce que sur deux ordres de grandeur du temps, $d\eta/d \log (t + \theta)$ est constant et égal à 15 mV/décade de temps si le traitement cathodique préalable a été réalisé à de fortes densités de courant, sinon les valeurs sont quelque peu plus faibles. Ce fait est illustré dans la Fig. 8. Ceci est le comportement attendu si une espèce active électrochimiquement s'échappe par un mécanisme sous le contrôle de la diffusion soit dans l'électrode ou dans l'électrolyte sur une surface plane infinie (22).

Enfin, la phase formée par la réduction cathodique peut être oxydée anodiquement pour récupérer la charge. Ainsi, le produit de réaction tenant la charge coulombienne peut subir une oxydation anodique, et la quantité de la charge coulombienne associée, q_a, peut être mesurée. On trouve que le rendement, q_a/q_a^0, du dépôt électrolytique est de 100% aux fortes densités de courant, mais il diminue jusqu'à 20% aux faibles densités de courant (Fig. 9).

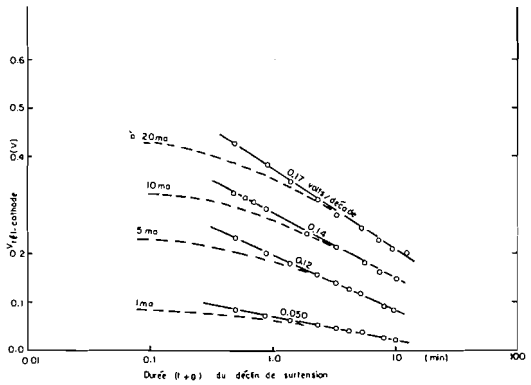

FIG. 8. Déclin de potentiel du dépôt électrolytique de la cathode en circuit ouvert sous contrôle de la diffusion du Na (?) des profondeurs du solide à la surface. Ligne pleine: $\theta = 0.4$ min.

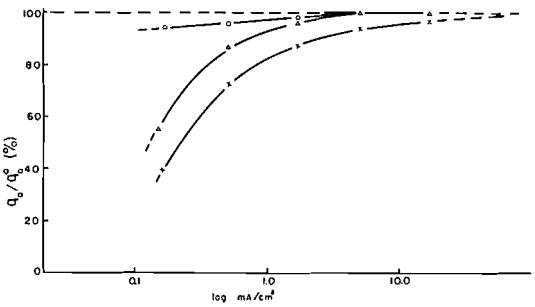

FIG. 9. Fraction de charge cathodique retrouvée à 650 °C par oxydation anodique immédiate sur le Pt dans le $NaPO_3$ asséché, en fonction de la densité de courant. ×, électrode fraîche; ○, électrode ayant complété plusieurs cycles. Dépôt électrolytique constant à 300 mC. $I_a = I_c$. Semiconductivité ou navette?

Parfois la quantité récupérée est moindre que celle qui a été déposée. Une partie de la charge perdue peut parfois être retrouvée par un second traitement anodique suivant un court intervalle en circuit ouvert; tout se passe comme si Na diffusait du sein de l'électrode de Pt vers la surface durant cet intervalle. Toutefois, surtout à de faibles densités de courant, une majeure fraction est perdue et ne peut être retrouvée.

Nous pouvons imaginer deux explications de ces phénomènes: (*1*) la conductivité électronique se produit; (*2*) il existe une "navette électrochimique" dans le sel fondu électrolysé. Nous avons déjà indiqué (Fig. 2) comment la conductivité électronique est possible dans cet électrolyte.

En détail nous supposons une "navette" dans laquelle des ions et des espèces neutres produiraient un court-circuit dans l'électrolyte entre les deux électrodes, quand le circuit extérieur est ouvert, par exemple

Réactions anodiques

[1a] $2PO_3^- \rightarrow 2PO_3 + 2e^-$

[2a] $PO_3 \rightarrow PO_2 + \frac{1}{2}O_2$

[3a] $PO_2 + PO_3 \rightarrow P_2O_5$

$$2PO_3^- \rightarrow P_2O_5 + \tfrac{1}{2}O_2 + 2e^-$$

Réactions cathodiques

[1c] $P_2O_5 + e^- \rightarrow PO_3^- + PO_2$

[2c] $PO_3 + e^- \rightarrow PO_3^-$

[3c] $\frac{1}{2}O_2 + PO_2 \rightarrow PO_3$

$$\tfrac{1}{2}O_2 + P_2O_5 + 2e^- \rightarrow 2PO_3^-$$

On connait bien que l'électrolyte doit être saturé avec de l'oxygène à l'anode. Nous suggérons qu'à la cathode il y aurait assez d'oxygène pour supporter la réaction 3c (l'entredeux n'est que 2 cm). Le P_2O_5 et l'oxygène pourraient diffuser à la cathode, et les ions PO_3^- à l'anode. Donc les deux réactions électrodiques contiennent un court-circuit électrolytique entre les deux électrodes. Ce procédé cyclique nous appelons "la navette électrochimique": c'est un système rédox PO_3^-/P_2O_5 qui conduit la charge entre les deux électrodes quand le circuit est ouvert. On voit qu'il pourrait y avoir un transfert de charge mais aucune réaction globale.

Ainsi, on voit dans la Fig. 9 que le rendement de charge est une fonction de la densité de courant ($I_{cath} = I_{anod}$). De ces renseignements, l'effet d'une "navette" de phosphate ou de la conduction électronique (laquelle réaction se passe) peut être estimée à 0.2 mA/cm^2, mais variable (3 expériences avec le même sel fondu et les mêmes électrodes: 3 courbes Fig. 9). Comme autres exemples, citons Al^+/Al^{3+} une navette dans les cryolytes fondus, et NO_2^-/NO_3^- une navette des solutions aqueuses de KOH.

La rétention de charge du dépôt cathodique dans le sel fondu peut être mesurée pendant des périodes prolongés de repos. Ceci est illustré dans la Fig. 10. Le courant aussi bien pour la charge que la décharge est de 10 mA/cm^2 et l'efficacité du courant (Fig. 9) est de 100%. Dans la Fig. 10 on peut noter que la stabilité varie, voir même améliorée, avec le vieillissement de l'électrode, et qu'une charge de 30% est retenue

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

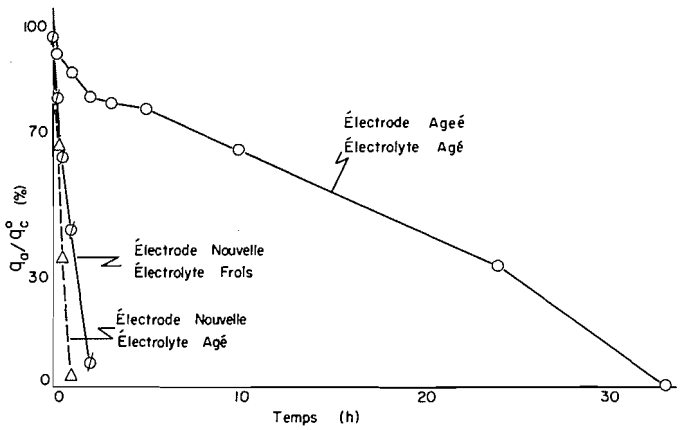

FIG. 10. Rétention de charge du "P(Na)" déposé cathodiquement et contrôlé par son état solide à la surface de l'électrode.

même après 24 h. Tandis que la variation dans le rendement du dépôt électrolytique peut être interprétée comme étant due à la semiconductivité ou à l'action de navette dans l'électrolyte; la rétention de charge est d'abord une propriété de l'électrode et non de l'électrolyte. Basée sur les travaux analytiques réalisés sur des dépôts cathodiques sur le Pt et le Ni, la variation de conductivité électronique et de stabilité peut être due au fait que la composition du dépôt cathodique varie avec la densité du courant et la charge totale traversée, étant donné que c'est probablement un composé hétérogène. D'une part, si le Pt et le Ni métallique sont à découvert et peuvent injecter des électrons dans le sel fondu, le P_2O_5 peut être réduit; donc l'opération de navette sera possible et la rétention de charge sera faible. D'autre part, si le semiconducteur P ou Na_3P sépare le métal de l'électrolyte, la navette peut être inopérante; donc le Pt(Na) ou le P(Na) ne sera pas facilement attaqué par le sel fondu. Il faut noter le fait que les fortes densités de courant favorisent des phosphures avec une forte teneur en phosphore et il en résulte une haute efficacité de courant. Il semble que la pellicule cathodique exercerait un grand nombre de contrôles subtils sur le procédé de ce système électrochimique. Il est intéressant que ce comportement est semblable à celui de l'électrode à oxyde de vanadium (23) dont la composition contrôle le processus d'injection anodique qui se produit sur sa surface catalytique. Il faut bien noter que le comportement cathodique des électrons de Pt dans le sel fondu seché est tout a fait différent de celui rapporté par les autres chercheurs (2) qui ont utilisés les électrodes de charbon et de tungstène. A 650 °C même un petit peu d'eau rendra les cathodes très actives.

Nous tenons à remercier sincèrement MM. L. G. Wilson (diffraction des rayons-X) et C. L Gardner (r.m.n.-P), de ces laboratoires, pour leur contribution scientifique. Nos remerciements aussi à MM. K. N. Campney et L. Ricard qui ont effectué quelques essais préliminaires d'électrolyse dans notre laboratoire; à M. J. F. Rowland et ses collègues du Ministère des Energie, Mines et Ressources qui ont fait les analyses spectroscopiques et au microsonde; à M. P. Lenfant et ses collègues de l'Institut de recherches de l'Hydro-Québec, qui nous ont envoyé beaucoup de commentaires utiles pendant la préparation du rapport; et enfin à Mlle Louise Nadon de l'Université de Montréal et adjointe aux recherches ici durant l'été 1970, et Mme F. Holmes de ce laboratoire, pour l'assistance technique et l'encouragement linguistique.

Les renseignements reçus de M. S. Rundqvist, Université d'Uppsala, nous ont facilité l'identification des produits de nickel.

NOTES

Protonated Cyclopropanes. VI.[1] Solvolyses of 1-^{14}C-1-Propylmercuric Perchlorate

C. C. Lee and Joyce Law

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received April 26, 1971

The solvolysis of 1-^{14}C-1-propylmercuric perchlorate in 10% dioxane – 90% H_2O, HOAc, or HCOOH gave, respectively, about 0.6, 2.5, or 3.5% isotopic scramblings, the rearranged ^{14}C-label being distributed approximately equally over C-2 and -3. The results are considered in relation to protonated cyclopropanes as possible intermediates.

La solvolyse du perchlorate de ^{14}C-1 propyl-1 mercure dans des mélanges 10% dioxane – 90% H_2O, ACOH, ou HCOOH a donné respectivement environ 0.6, 2.5, et 3.5% d'échanges isotopiques. Le ^{14}C-marqué se distribue à peu près également sur les carbones en position 2 et 3. Les résultats sont interprétés en fonction de cyclopropanes protonés comme intermédiaires possibles.

Canadian Journal of Chemistry, 49, 2746 (1971)

In recent years, there has been considerable interest in protonated cyclopropanes as reaction intermediates and isotopic scrambling studies have provided some of the definitive experimental data in support of such intermediates (1). As an extension of our recent work on isotopic scramblings in the 1-propyl system (2, 3), solvolytic studies on 1-^{14}C-1-propylmercuric perchlorate (**1**-$HgClO_4$-1-^{14}C) have been carried out. The acetolysis of 1-^{14}C-1-propyl tosylate (**1**-OTs-1-^{14}C) gave no isotopic scrambling (4), while the formolysis of **1**-OTs-1-^{14}C at reflux temperature was found to give a product with 0.83% of the label rearranged from C-1 to -2 and -3 (4). However, this latter small amount of isotope position rearrangement was not observed by Karabatsos and coworkers (5) in the formolysis at 75° of deuterium-labeled **1**-OTs-1,1-d_2 and **1**-OTs-2,2-d_2. Since the solvolytic demercuration of an alkylmercuric perchlorate generates an alkyl cation with neutral mercury as the leaving group (6, 7), the resulting cation may be destabilized, a so-called "hot" carbonium ion, as the leaving group is incapable of forming a stable ion-pair with the cation. It would, therefore, be of interest to study the solvolysis of **1**-$HgClO_4$-1-^{14}C and compare the isotopic scrambling data with previous results such as those from the solvolysis of **1**-OTs-1-^{14}C.

1-$HgClO_4$-1-^{14}C, derived from equimolar quantities of **1**-HgOAc-1-^{14}C and $HClO_4$, was solvolyzed in 10% dioxane – 90% H_2O (by volume), HOAc, or HCOOH. Both 1-propyl and 2-propyl alcohols, acetates, or formates were obtained. The yields and product distributions as determined in preliminary trials with ordinary **1**-$HgClO_4$ are given in Table 1.

In the experiments with **1**-$HgClO_4$-1-^{14}C, the acetate and formate products were hydrolyzed to the alcohols and these as well as the mixture of 1-propanol and 2-propanol from the solvolysis in aqueous dioxane were separated by preparative v.p.c. The samples of **1**-OH-x-^{14}C so obtained were degraded to give the isotopic distribution in the 1-propyl group by conversion to propionic acid, to acetic acid, and then to methylamine as previously described (8). The results are summarized in Table 2.

The formation of both 1-propyl and 2-propyl products (Table 1), the latter resulting from a 1,2-hydride shift in the 1-propyl cation, and the finding that the major part of the 1-propyl product is isotopically unrearranged with the ^{14}C-label remaining at C-1 (Table 2) suggest that in the solvolyses of **1**-$HgClO_4$ under the present conditions, the reaction pathways may be concurrent direct displacement and cationic processes. Such concurrent processes would be analogous to the recent conclusions of Schleyer and coworkers (9–11) that solvolyses of β-arylalkyl systems involve separate and discrete solvent-assisted and aryl-assisted pathways. The

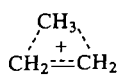
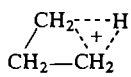
‖A similar solvolysis with the solvent containing 10% NaOH gave a product with essentially no scrambling (less than 0.1%) of the ^{14}C from C-1 to -2 and -3.

isotopic scrambling from C-1 to C-2 and -3 as summarized in Table 2 may be interpreted as resulting from some involvement of protonated cyclopropane as part of the ionic processes. The extent of such scrambling is lowest in the product from solvolysis in aqueous dioxane, and this may be attributed to a predominant direct displacement in this nucleophilic solvent system. It may also be of interest to note that the amounts of scrambling in the 1-propyl products from acetolysis and formolysis of **1**-$HgClO_4$-1-^{14}C are greater than the analogous data from acetolysis and formolysis of **1**-OTs-1-^{14}C (4), but are roughly of the same order of magnitude as observed in the deamination of **1**-NH_2-1-^{14}C (8, 12), the deamination being another reaction involving a "hot" carbonium ion.

Isotopic scramblings in the 1-propyl group have generally been discussed in terms of equilibrating corner-protonated (**2**) or edge-protonated (**3**) cyclopropanes. Collins (13) has predicted that in reactions with a 1-propyl



2



3

substrate labeled at C-1 with isotopic carbon, if products were formed before equilibrium has been established, for processes involving equilibrating corner-protonated cyclopropanes, isotope position rearrangement from C-1 to -3 can never be greater than from C-1 to -2, while for processes involving equilibrating edge-protonated cyclopropanes, rearrangement of the label from C-1 to -3 can be greater than from C-1 to -2. Recent attempts in this laboratory (2, 3) to obtain evidence for edge-protonation in accordance with this prediction have failed. The present finding of approximately equal amounts of rearrangement of the ^{14}C-label from C-1 to -2 and to -3 again failed to provide a differentiation between corner- and edge-protonation. Since the carbonium ion generated from solvolytic demercuration may be "hot" or of high energy,

that small portion of the reaction which may have proceeded via equilibrating protonated cyclopropanes likely would have been completely equilibrated before product formation, resulting in equal amounts of scrambling of the label from C-1 to -2 and to -3.

In connection with the representation of the structure of protonated cyclopropane as corner- or edge-protonated **2** or **3**, it may be of interest to point out that very recently, *ab initio* calculations on the structures and relative stabilities of $C_3H_7^+$ cations with complete geometry optimization have been carried out by Radom *et al.* (ref. 14 and private communications from L. Radom). The results suggested that besides the stable 2-propyl cation, a "methyl eclipsed 1-propyl cation" with distorted geometry, which could be regarded as a "distorted corner-protonated cyclopropane", may well correspond to the only other potential minimum in the complete $C_3H_7^+$ surface. These conclusions are in sharp contrast to earlier interpretations of experimental data in terms of corner- and edge-protonated cyclopropanes **2** and **3**, neither of which was found by Radom and coworkers to correspond to an energy minimum. However, these calculated energies apply only to ions in the gas phase and solvation may alter the picture. Professor Schleyer (P. v. R. Schleyer, private communications) has also used the term "partially-bridged" structure in describing the methyl eclipsed 1-propyl cation. These calculations do suggest the possibility that isotopic scramblings such as those observed in the present work could have resulted from equilibrating partially-bridged structures with **2** and **3** as transition states.

Experimental

1-^{14}C-1-Propylmercuric Acetate (1-HgOAc-1-^{14}C)

The preparation of **1**-HgOAc-1-^{14}C was carried out using the general method described by Ouellette (15), involving the conversion of 1-^{14}C-1-chloropropane (**1**-Cl-1-^{14}C) (3) to the Grignard reagent, treatment with $HgCl_2$ to give **1**-HgCl-1-^{14}C, m.p. 140–141° (lit. (16), m.p. 140°), and reaction of the latter with AgOAc to give **1**-HgOAc-1-^{14}C, m.p. 55–56° (lit. (15), m.p. 55.4–56.2°).

Solvolysis Reactions

The solvents employed were 10% dioxane – 90% H_2O (by volume), redistilled, reagent grade glacial acetic acid, and redistilled, reagent grade, 98–100% formic acid. A solution of 8.0 g (0.026 mol) of **1**-HgOAc-1-^{14}C and 2.5 ml (0.027 mol) of 70% $HClO_4$ in 50 ml of solvent was heated under reflux for 8 h. The resulting material was then cooled in an ice–salt bath and neutralized with 25% NaOH solution. In the case of acetolysis of formolysis, more NaOH was added to give a final concentration of about 10% and the alkaline mixture was refluxed for 2 h to hydrolyze the ester products. The 1-propanol and 2-propanol obtained were recovered by continuous ether extraction and purified by preparative v.p.c. using a Carbowax column as previously described by Lee and Kruger (8). The degradation of the 1-propanol to give the ^{14}C-distribution in the 1-propyl group was also effected as described by Lee and Kruger (8).

The financial support given by the National Research Council of Canada and the valuable discussions on the structure of the protonated cyclopropane given by Professor P. v. R. Schleyer are gratefully acknowledged.

Reaction of Bis(trifluoromethyl)diazomethane with Bis(trimethylsilyl)acetylene

W. R. CULLEN AND F. L. HOU
Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received April 29, 1971

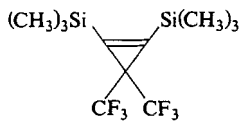
The reaction of bis(trifluoromethyl)diazomethane with bis(trimethylsilyl)acetylene yields 1,2-bis-(trimethylsilyl)-3,3-bis(trifluoromethyl)cyclopropene in low yield. The cyclopropene has an unexpectedly high C=C stretching frequency.

La réaction du bis(trifluorométhyl) diazométhane avec le bis(triméthylsilyl) acétylène conduit au bis(triméthylsilyl)-1,2 bis(trifluorométhyl)-3,3 cyclopropène avec un faible rendement. Le cyclopropène a une fréquence d'élongation C=C anormalement élevée.

Canadian Journal of Chemistry, 49, 2749 (1971)

Although a number of cyclopropenes have been prepared containing a single sigma-bonded metal or metalloid substituent (1–3), no examples were known where two or more of the substituents on the cyclopropene were of this nature. We wish to report that the reaction of bis(trifluoromethyl)diazomethane with bis(trimethylsilyl)acetylene under the influence of u.v. irradiation produces 1,2-bis(trimethylsilyl)-3,3-bis(trifluoromethyl)cyclopropene in low (6%) yield.

[1] $(CF_3)_2CN_2 + (CH_3)_3SiC{\equiv}CSi(CH_3)_3 \xrightarrow{h\nu}$



The same method has been used to prepare 3,3-bis(trifluoromethyl)cyclopropenes from the acetylenes $CF_3C{\equiv}CR$ (R = H, CF_3, $(CH_3)_3Sn$, $(CH_3)_3Ge$) (2). The "organic" acetylenes give mainly isopyrazoles by 1,3-dipolar addition together with some cyclopropenes. The former yield cyclopropenes by nitrogen elimination on heating. No evidence for an intermediate isopyrazole was obtained from the reaction of eq. 1 although we recognize that here also the isopyrazole could have been the source of the cyclopropene.

The structure of the product follows from its singlet ^1H and ^{19}F n.m.r. spectra, which have the expected chemical shift values, and the strong "double-bond" stretching frequency (4) in the i.r. spectrum at 1946 or 1928 cm^{-1}. This frequency is one of the highest recorded for a cyclopropene and is unexpected in view of the previously observed trend that electropositive groups in the vinylic position lower the frequency (2).

Experimental

All volatile reagents and products were manipulated in a standard vacuum system. The i.r. spectra were recorded on a Perkin–Elmer 457 spectrophotometer. The n.m.r. spectra were recorded using a Varian T60 instrument. Microanalyses were performed by Mr. Peter Borda of this Department.

Bis(trimethylsilyl)acetylene (0.85 g, 5.0 mmol) (5) and bis(trifluoromethyl)diazomethane (1.0 g, 5.6 mmol) (6) were sealed in a Pyrex tube and irradiated with a 200 W u.v. lamp at a distance of 10 cm for 6 days. The less volatile contents of the tube which condensed in a trap at −78°, were separated by v.p.c. (20% SF-96 at 140°) into 11 components. Only the seventh and eleventh fractions could be collected and identified. The former proved to be unreacted acetylene (0.40 g) and the latter the cyclopropene (0.091 g, 5.7% yield).

Anal. Calcd. for $C_{11}H_{18}Si_2F_6$: C, 41.2; H, 5.62; F, 35.6. Found: C, 41.3; H, 5.73; F, 35.3.

The ^1H n.m.r. spectrum (CCl_4 solution) consisted of a singlet at 0.29 p.p.m. downfield from internal TMS. The same solution gave a ^{19}F spectrum consisting of a singlet at 57.5 p.p.m. upfield from external $CFCl_3$. The i.r. spectrum showed the following absorptions (liquid film): 2975(m), 2905(w), 1946(s), 1928(s), 1396(s), 1332(s), 1300(m), 1258(s), 1160(s,br.), 1020(w), 970(s), 860(s,br.), 822(m,sh.), 768(m), 712(s), 700(m,sh.), 688(m,sh.), 650(w), 620(m) cm^{-1}.

We thank the National Research Council of Canada for financial support.

Preparation of 7-Ethyl-2-naphthoic Acid[1]

D. K. R. STEWART
Research Station, Canada Department of Agriculture, Kentville, Nova Scotia

Received January 28, 1971

7-Ethyl-2-naphthoic acid was synthesized by cyclization of the formylation product of ethyl-4-(4′-ethylphenyl)-butyrate and dehydrogenation of the resulting 7-ethyl-3,4-dihydronaphthoic acid.

L'acide éthyl-7 naphthoïque-2 a été synthétisé par cyclisation du produit de formylation de l'ester éthylique de l'acide (éthyl-4′ phényl)-4 butanoïque et par déshydrogénation de l'acide éthyl-7 dihydro-3,4 naphthoïque résultant.

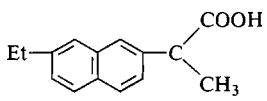
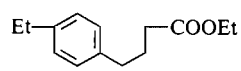
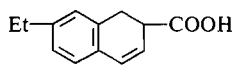
Some time ago while the author was engaged in the synthesis of 1-methyl-6-ethyl-3-azaphenanthrene, a key degradation product of atisine, Locke and Pelletier (1) published a preliminary account of their work. Their synthesis (2) proceeded from 7-ethyl-1-tetralone via a mixture of isomers of 2-(7′-ethyl-1′-oxo-1′,2′,3′,4′-tetrahydro-2′-naphthyl)-propionic acid to α-methyl-7-ethyl-2-naphthaleneacetic acid (**1**), Pictet–Spengler cyclization of the corresponding amine and dehydrogenation to the azaphenanthrene.



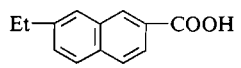
1



2



3



4

Our route proceeded from ethyl-4-(4′-ethylphenyl)-butyrate (**2**) via 7-ethyl-3,4-dihydronaphthoic acid (**3**) and 7-ethyl-2-naphthoic acid (**4**) to **1** and followed the same course thereafter. Since the acids **3** and **4** have not yet been described and may be of some value in the chemistry of natural products, their preparation is reported here.

In a series of reactions similar to that employed by Holmes and Trevoy (3) for the preparation of 7-methoxy-2-naphthoic acid, ethyl-4-(4′-ethylphenyl)-butyrate (**2**) was formylated with isoamyl formate/sodium ethoxide and the product cyclized with H_3PO_4/H_2SO_4 to yield a mixture of esters of **3**. Dehydrogenation of **3** with sulfur yielded **4** which was converted via Wolff rearrangement of the ethyldiazoketone to the known acid **1**. This route thus provides an alternate pathway to the azaphenanthrene.

[1]Contribution No. 1407.

Experimental

7-Ethyl-3,4-dihydro-2-naphthoic Acid (3)

Isoamyl formate (40.7 g) in ether (150 ml) was added to a cold ethereal suspension of alcohol-free sodium ethoxide prepared from sodium (6.8 g). A solution of ethyl-4-(4′-ethylphenyl)-butyrate (4) (65.5 g) in ether (100 ml) was then added with stirring and cooling. The reaction mixture was kept at 0 °C for 2 h and room temperature for 4 days. The deep red solution was then stirred into 500 g of ice and water. The unreacted starting material was recovered by separating the ether layer and extracting the aqueous layer twice with ether. The aqueous solution of the sodium enolate of ethyl-2-formyl-4-(4′-ethylphenyl)-butyrate was acidified and the oily formyl derivative was extracted with ether. The ether solution was washed with water and bicarbonate solution, then dried over sodium sulfate and the isoamyl formate removed under water aspirator vacuum. The heat sensitive formylation product (43.4 g) was added dropwise to a vigorously stirred mixture of orthophosphoric acid, sp. gr. 1.75 (170 ml), and sulfuric acid, sp. gr. 1.83 (36 ml), cooled to −10°. The mixture was stirred for 2 h, poured into ice water, and extracted with ether. The extract was washed with water and bicarbonate solution, then dried over sodium sulfate. A mixture of the ethyl and isoamyl esters of 7-ethyl-3,4-dihydro-2-naphthoic acid (29.5 g) was obtained. Saponification with NaOH in ethanol and crystallization from benzene yielded 15.0 g acid **3**, m.p. 133–134°; λ_{max} (EtOH) 234 (ε 23 300), 280 mμ (ε 17 200).

Anal. Calcd. for $C_{13}H_{14}O_2$: C, 77.20; H, 6.98. Found: C, 77.38; H, 7.12.

7-Ethyl-2-naphthoic Acid (4)

Acid **3** (4.00 g) was mixed with powdered sulfur (0.64 g) in a round-bottom flask and heated in a wax bath at 240°. H_2S was freely evolved for 15 min and heating was continued for an additional 30 min. The melt was cooled, dissolved in aqueous NaOH, and extracted with chloroform. The basic solution was then acidified and the acid **4** extracted with ether. The methyl ester was formed by

refluxing for 4 h with methanol (100 ml) and H_2SO_4 (4 ml). The crude ester was purified by vacuum distillation (120°/0.5 mm) yielding 3.02 g methyl ester which was crystallized from methanol, m.p. 46–47°. The free acid **4** was obtained by saponification and crystallized from acetone, m.p. 174–175°; λ_{max} (EtOH) 236 (ε 54 200), 280 (ε 6740), 338 mμ (ε 1380).

Anal. Calcd. for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04. Found: C, 77.84; H, 5.95.

Acid **4** was converted, via Wolff rearrangement of the ethyldiazoketone prepared from the acid chloride and diazoethane, to the known α-methyl-7-ethyl-2-naphthaleneacetic acid (**1**), m.p. 109–110° (2).

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06. Found: C, 79.11; H, 6.87.

Structure of the Second Coordination Sphere of Transition Metal Complexes. III. Ion Pairing involving Cobalt Complexes

D. R. Eaton and Linda Seville
Department of Chemistry, McMaster University, Hamilton, Ontario

AND

J. P. Jesson
Central Research Department, E. I. Du Pont de Nemours and Co., Wilmington, Delaware

Received March 16, 1971

The structure of the ion pair formed between Co(II) bistripyrazolylmethane ions and PF_6^- ions in acetonitrile solution has been investigated. Isotropic shifts observed in the ^{19}F nuclear magnetic resonance (n.m.r.) spectra of the anion have been used for this purpose. It is concluded that the preferred position of the anion lies close to the symmetry axis of the cobalt complex and that a contact ion pair is involved. This result is contrasted with previous studies of second sphere coordination involving neutral molecules.

On examine la structure de la paire d'ion formée dans une solution d'acétonitrile entre les ions Co(II) bistripyrazolylméthane et PF_6^-. On utilise à cet effet le déplacement isotrope observé dans le spectre r.m.n. de ^{19}F de l'anion. Il en a été déduit que la position préférentielle de l'anion est celle qui se trouve proche de l'axe de symétrie du complexe avec le cobalt; de plus une paire d'ion de contact est impliquée. Ce résultat est en désacord avec des études précédentes ou des molécules neutres étaient impliquées dans une deuxième sphère de coordination.

Canadian Journal of Chemistry, **49**, 2751 (1971)

In previous papers (1, 2) in this series we have discussed the role of neutral molecules in the second coordination sphere of Co(II) complexes. Evidence for a "double layer" structure in which the dipoles of the second sphere ligands were oriented in the opposite sense to those of the first sphere ligands was brought forward. The main thrust of our interest in this area is towards an understanding of the detailed mechanisms of the ligand exchange reactions involved in homogeneous catalysis. Most such reactions occur in non-aqueous solvents and in the absence of ionic species. Nevertheless it is of interest to ask how ionic second sphere ligands fit into this picture of second coordination sphere structure and the question may well be one of importance for enzymatically catalyzed reactions in aqueous media. Relatively little (3) is known about the detailed geometry of such ion pairs. In the present note we wish to report data on an ionic system closely related to the cobalt complexes previously studied.

The complexes in question are based on the Co(II) bis(tripyrazolylmethane) (4) ion $Co[HCpz_3]_2^{2+}$. The structure of this ion is shown in

Structure of the Second Coordination Sphere of Transition Metal Complexes. III. Ion Pairing involving Cobalt Complexes

D. R. Eaton and Linda Seville
Department of Chemistry, McMaster University, Hamilton, Ontario

AND

J. P. Jesson
Central Research Department, E. I. Du Pont de Nemours and Co., Wilmington, Delaware

Received March 16, 1971

The structure of the ion pair formed between Co(II) bistripyrazolylmethane ions and PF_6^- ions in acetonitrile solution has been investigated. Isotropic shifts observed in the ^{19}F nuclear magnetic resonance (n.m.r.) spectra of the anion have been used for this purpose. It is concluded that the preferred position of the anion lies close to the symmetry axis of the cobalt complex and that a contact ion pair is involved. This result is contrasted with previous studies of second sphere coordination involving neutral molecules.

On examine la structure de la paire d'ion formée dans une solution d'acétonitrile entre les ions Co(II) bistripyrazolylméthane et PF_6^-. On utilise à cet effet le déplacement isotrope observé dans le spectre r.m.n. de ^{19}F de l'anion. Il en a été déduit que la position préférentielle de l'anion est celle qui se trouve proche de l'axe de symétrie du complexe avec le cobalt; de plus une paire d'ion de contact est impliquée. Ce résultat est en désacord avec des études précédentes ou des molécules neutres étaient impliquées dans une deuxième sphère de coordination.

Canadian Journal of Chemistry, **49**, 2751 (1971)

In previous papers (1, 2) in this series we have discussed the role of neutral molecules in the second coordination sphere of Co(II) complexes. Evidence for a "double layer" structure in which the dipoles of the second sphere ligands were oriented in the opposite sense to those of the first sphere ligands was brought forward. The main thrust of our interest in this area is towards an understanding of the detailed mechanisms of the ligand exchange reactions involved in homogeneous catalysis. Most such reactions occur in non-aqueous solvents and in the absence of ionic species. Nevertheless it is of interest to ask how ionic second sphere ligands fit into this picture of second coordination sphere structure and the question may well be one of importance for enzymatically catalyzed reactions in aqueous media. Relatively little (3) is known about the detailed geometry of such ion pairs. In the present note we wish to report data on an ionic system closely related to the cobalt complexes previously studied.

The complexes in question are based on the Co(II) bis(tripyrazolylmethane) (4) ion $Co[HCpz_3]_2^{2+}$. The structure of this ion is shown in

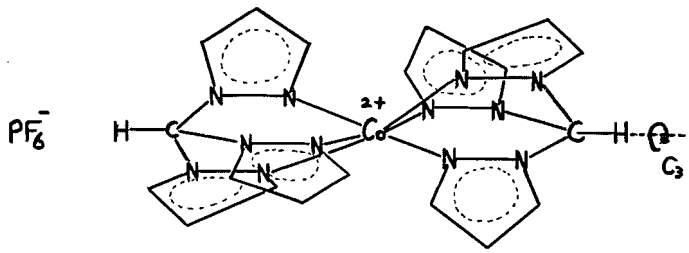

FIG. 1. Structure of the $Co[HCpz_3]_2^{2+}$ ion.

Fig. 1. They are derived from the Co(II) pyrazolyl borates studied previously by replacing the two boron atoms with carbon atoms. The two series of complexes are isoelectronic but the additional nuclear charge of carbon gives rise to a dipositive ion rather than a neutral molecule. Jesson (5) has studied the electron spin resonance (e.s.r.) spectra of these compounds and has shown that they have g values closely similar to the boron analogues. The large anisotropy of the g values makes them particularly suitable for ion pairing studies based on the dipolar interactions (6) between magnetic nuclei of the counter ion and the unpaired electrons located on the cobalt (7). There have been several previous studies of ion-pairing based on dipolar shifts but most have been hampered by a lack of information regarding the directions of the magnetic axes within the molecule and the sign and magnitude of the magnetic anisotropy (8–13).[1]

Dipolar interaction gives rise to shifts in the n.m.r. frequencies of the nuclei in question given by the formula[2]

$$\frac{\Delta\nu}{\nu} = -D\frac{(3\cos^2\theta - 1)}{r^3}(g_{\parallel} - g_{\perp})$$

In principle D and $(g_{\parallel} - g_{\perp})$ are known from Jesson's work and measurement of the dipolar shift $\Delta\nu/\nu$ leads to the geometric factor $(3\cos^2\theta - 1)/r^3$ where r is the distance of the interacting nucleus from the Co atom and θ is the angle between a line joining this nucleus to the Co and the threefold principal axis of the molecule (see Fig. 1). In practice, as will become apparent below, the lability of the ion pairs limits the amount of quantitative information which can be obtained from this type of measurement. Nevertheless it is possible to carry out a qualitative analysis of the data which provides an informative comparison of the role of ions and neutral molecules in the second coordination sphere.

An initial problem is presented by the choice of a counter ion. Six or seven complexes were tried but the solubility of the majority of them, particularly those involving doubly charged anions, was insufficient to allow n.m.r. studies. $Co[HCpz_3]_2(PF_6)_2$ has reasonable solubility in acetonitrile and the fluorine nuclei on the anion provide a suitable probe. One may therefore compare ^{19}F chemical shifts of $Co[HCpz_3]_2(PF_6)_2$ with those of $Zn[HCpz_3]_2(PF_6)_2$. The zinc complex is structurally very similar to the cobalt complex and differs from it significantly only in that it lacks unpaired electrons so that the possibility of dipolar shifts does not arise. In both cases the ^{19}F spectrum shows a doublet of spacing 708 Hz. The doublet splitting arises from coupling with the ^{31}P nucleus. The observation of this simple spectrum shows that the PF_6^- ion is changing its environment sufficiently rapidly to make all the fluorines appear equivalent. The chemical shifts for the zinc complex, relative to Freon 112 internal standard, vary only slightly with concentration (10–20 Hz). Those of the cobalt complex vary substantially. In Table 1 the chemical shifts of the Co complex relative to the Zn complex at different concentrations are given. Several points should be

[1]It has been suggested several times in the literature (14–16) that isotropic shifts in ion pairs may be contact rather than dipolar in nature. This implies that the forces holding together the ions are to some extent covalent. The present case does not seem at all favorable for such an interaction. There is no extensive delocalization of the spin and the closest possible approach of the PF_6^- to the Co ion is 5 or 6 Å at which distance orbital overlap would be negligible. In addition the known large magnetic anisotropy of these complexes forms the basis for a positive prediction of a dipolar shift mechanism. We therefore feel justified in disregarding the possibility that contact interactions may determine the observed shifts.

[2]This formula assumes a threefold or higher axis, which we have in the present case, and also neglects the second order Zeeman term. This latter limitation would be important for quantitative applications.

TABLE 1. Concentration and temperature dependence of ^{19}F resonance of $Co[HCpz_3]_2(PF_6)_2$ in acetonitrile

Concentration (M/lt)	Δν* (Hz)	Temperature (°C)	Δν* (Hz)
0.006	− 69	76	−199
0.011	−113	64	−212
0.023	−171	50	−227
0.046	−241	40	−237
0.093	−336	17	−259
0.185	−463	5	−274
		− 5	−285
		−15	−300
		−25	−310
		−35	−318

*Shifts at 56.4 MHz relative to Zn complex.

noted. The PF_6^- resonance in the cobalt compound always occurs to low field of that in the zinc compound with the difference increasing to 400–500 Hz at the highest obtainable concentration of cobalt complex. The difference approaches zero at low concentration of cobalt complex. The most plausible explanation is that in both cases there is ionic dissociation

$$M[HCpz_3]_2(PF_6)_2 \rightleftharpoons M[HCpz_3]_2(PF_6)^+ + PF_6^-$$

$$M[HCpz_3]_2(PF_6)^+ \rightleftharpoons M[HCpz_3]_2^{2+} + PF_6^-$$

At low concentrations the predominant species is PF_6^-. At higher concentrations ion pairing causes a significant dipolar shift for the Co compound.

Two further experiments provide additional evidence for the above equilibria. In the first, chemical shifts were measured for mixtures of the Co and Zn complexes of the same total concentration. In all cases only a single doublet is observed and its position varies linearly with the fraction of cobalt complex. Rapid exchange between the ion pairs is indicated with the fraction complexed to cobalt, which determines the extent of the shift, varying in the manner expected for dissociative equilibria. In Table 1 results showing the temperature dependence of the ^{19}F shifts for the cobalt compound are also given. The increasing shift at low temperatures arises predominantly from the temperature dependence of the magnetic susceptibility of the cobalt complex and confirms that the shifts arise from interaction with the unpaired electrons on the cobalt.

In order to obtain geometric parameters we require the chemical shift of the undissociated cobalt ion-pair. In view of the extensive dissociation demonstrated by the above results and of the existence of two dissociative equilibria this shift is not easy to obtain. Further, a previous discussion has shown (1) that even given such a shift there are inevitable ambiguities in translating the data into concrete geometric parameters when the complexes involved are labile on the n.m.r. time scale. This latter condition holds in the present case. We shall therefore be content with a very approximate treatment which will however serve to illustrate the structural point we wish to make. Zero dissociation of the complex is expected either at infinite concentration or at zero dielectric constant of the solvent. Extrapolation to the latter limit proves to be the more convenient. The cobalt shifts relative to zinc were therefore measured in mixtures of acetonitrile and carbon tetrachloride, to reduce the dielectric constant, and acetonitrile and water, to enhance the dielectric constant. As anticipated the shifts are larger in the low dielectric constant mixtures. Dielectric constants were obtained by measuring the proportions of the solvents by n.m.r. integration of their peaks and assuming proportionality on a volume basis. The dependence of the shift appears to be linear with dielectric constant as is shown in Fig. 2. Extrapolation gives $\Delta\nu_0$ -1375 ± 75 Hz. More realistically we should perhaps say $\Delta\nu_0$ lies between -1000 and -2000 Hz. It is, however, very clearly negative and of this order of magnitude. The former feature shows immediately that $(3\cos^2\theta - 1)$ is positive and hence that the preferred geometry of the ion pair involves approach of the PF_6^- in a direction more nearly parallel to the axis of the cobalt complex (see Fig. 1) than perpendicular to it. This result is exactly opposite to that obtained for neutral second sphere ligands (1, 2). If it is assumed that the preferred approach is along the symmetry axis and if the formula derived by LaMar (8) for the dipolar shift of a freely tumbling counter ion is used, the observed intercept corresponds to a Co–P separation of 8.1 ± 0.1 Å.[3] A model shows that this is very similar to the closest separation in this orientation allowed by the Van der Waals radii of the ions (~8 Å). Again, we do not wish to stress this numerical agreement, which is probab-

[3]A referee has pointed out that there is an error in LaMar's equation. However, the corrected equation changes the calculated separation by less than 1%. At this large separation the shift is insensitive to the exact model chosen for tumbling of the anion and other sources of error are far more important.

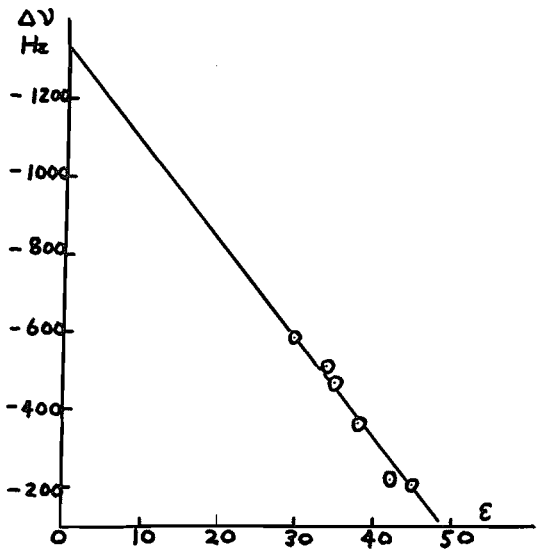

FIG. 2. ^{19}F isotropic shifts of $Co[HCpz_3]_2(PF_6)_2$ as a function of the dielectric constant of the solvent.

ly fortuitous, but do take the result as a clear indication that we are dealing with a contact ion pair, rather than a solvent separated ion pair, with a preferred geometry approximately that shown in Fig. 1.

The significant feature of this result is that the preferred geometry of the ionic second sphere complex is indeed different from that of a neutral second sphere complex. The favored positions, corresponding to closest approach to the central metal atom, may be taken up by dipolar solvent molecules interacting with the negatively charged primary ligands. The counter ion must then be fitted into the resulting structure by taking up the next best position. Bearing in mind that ion–ion interactions fall off less rapidly with distance than ion–dipole or ion-induced dipole interactions this is perhaps not unreasonable from an electrostatic point of view. It is also reminiscent of the much more familiar situation in which solution of a simple salt in water leads to an aquated cation with the anion relegated to the second coordination sphere. It is apparent that the detailed second coordination sphere structure could be changed dramatically by the presence of charge bearing substituents at positions comparatively remote from the central ligand bearing metal atom.

Experimental

^{19}F n.m.r. spectra were obtained at 56.4 Mc/s using a Varian DP instrument. Freon 112 was used as an internal calibrant. There is some dependence of the shifts on the concentration of Freon 112 so that calibrant concentrations were kept as low as possible. Integrated proton spectra of the solvents were obtained on a Varian A60 instrument.

We are indebted to the National Research Council of Canada for financial support of this research and to Dr. S. Trofimenko of the Central Research Dept., E. I. Du Pont Company for kindly donating the complexes.

Methyl 2,3-*O*-Isopropylidene-β-D-*ribo*-pentodialdofuranoside: a Useful Intermediate in Chain Extension Reactions[1]

ROGER F. BUTTERWORTH[2] AND STEPHEN HANESSIAN
Department of Chemistry, University of Montreal, Montreal, Quebec.

Received March 17, 1971

Oxidation of methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside with the "Pfitzner–Moffatt" reagent (methyl sulfoxide – dicyclohexylcarbodiimide) provides an efficient route to the corresponding 5-aldehydo derivative. Oxidation with methyl sulfoxide – acetic anhydride mixtures affords low yields of the aldehyde, the 5-acetate and 5-*O*-methylthiomethyl ether derivatives being the principal products.

L'oxydation du méthyl 2,3-*O*-isopropylidene-β-D-ribofuranoside avec le réactif de Pftizner et Moffatt (diméthyl sulfoxide – dicyclohexylcarbodiimide) introduit une méthode efficace d'obtention du dérivé 5-aldehydo correspondant. D'autre part, l'oxydation avec le couple diméthyl sulfoxide – anhydride acétique fournit un rendement faible en aldéhyde, les dérivés secondaires 5-*O*-acétyl et l'éther 5-*O*-méthylthiomethyl étant les produits principaux.

Canadian Journal of Chemistry, 49, 2755 (1971)

The discovery and application of mild and efficient oxidants for the conversion in high yield of isolated hydroxyl groups to the corresponding aldehydes or ketones (1) in carbohydrate chemistry, has brought about a renewed interest in the chemistry of carbonyl sugars (2). Uloses and aldehydo sugars are now commonly used as reactive intermediates in the synthesis of deoxy, amino, and branched-chain sugars, frequently found in many antibiotics (3).

In view of the biological importance of derivatives of D-ribofuranose and the ready availability (4, 5) of methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside (**1**), the synthesis of the aldehydo sugar **2** was undertaken. Application of recently developed chain-extension reactions would then offer a useful route to modified derivatives of D-ribofuranose.[3]

Methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside (**1**) is now readily obtainable (4, 5) directly from D-ribose in yields of over 70%. In the present investigation, we note that n.m.r. studies of the product **1**, even prior to purification, reveal the absence of measurable quantities of either ribopyranosides or the α-furanoside.[4]

Treatment of the pure **1** with methyl sulfoxide – dicyclohexylcarbodiimide (6) afforded the crude aldehyde **2** in 76% yield (see Scheme 1). Attempts to purify the product by multiple distillation were unsuccessful, affording low yields of pure product. Chromatographic separation, followed by distillation, afforded the pure aldehyde **2** in 48% yield as a colorless syrup. The n.m.r. spectrum of **2** in CCl_4 (Fig. 1) was consistent with the assigned structure, showing an aldehydo proton singlet at τ 0.3. In D_2O, however, the n.m.r. spectrum showed the presence of the hydrate **3** in solution, the H-5 proton appearing as a doublet at τ 6.0 ($J_{4,5}$ = 7.7 Hz). A crystalline *p*-nitrophenylhydrazone **4** was prepared in the usual manner.

Treatment of **1** with methyl sulfoxide and acetic anhydride (7) gave only low yields of the aldehyde **2**, the two major products being methyl 5-*O*-acetyl-2,3-*O*-isopropylidene-β-D-ribofuranoside (**5**) and the methylthiomethyl ether derivative **6**. Removal of excess reagents by lyophilization (8), followed by de-esterification of the mixture and final chromatographic separation afforded methyl 2,3-*O*-isopropylidene-5-*O*-methylthiomethyl-β-D-ribofuranoside (**6**) as a syrup,

[1]Presented in part at the 161st Meeting of the American Chemical Society, April 1971, Los Angeles, California, CARB 15.

[2]Postdoctoral Fellow, 1969–1971.

[3]The reaction of **1** with various Wittig-type reagents affords the expected chain-extended and branched products in high yields. Results to be reported from this laboratory.

[4]The β anomeric configuration for **1** has previously been assigned on the basis of n.m.r. spectral studies (5).

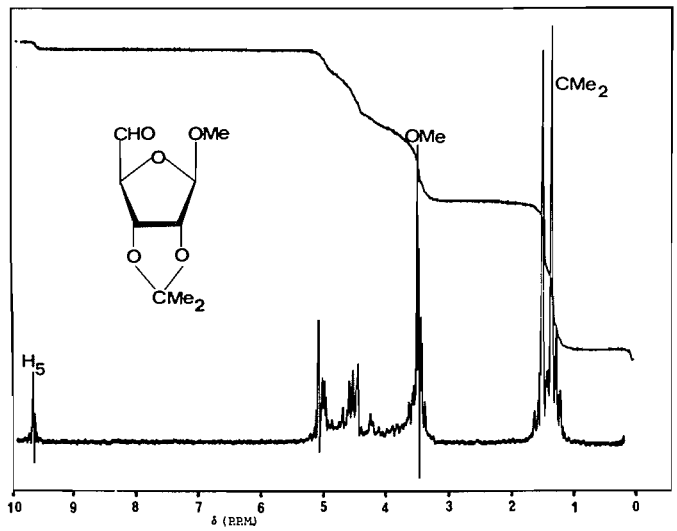

FIG. 1. The 100 MHz n.m.r. spectrum of methyl 2,3-*O*-isopropylidene-β-D-*ribo*-pentodialdofuranoside (**2**) (CCl_4 solution).

which was the major product present in the initial reaction mixture. The structure of **6** was established by n.m.r. spectroscopy and by desulfurization to the 5-*O*-methyl ether derivative **7**. The n.m.r. spectra of compounds **5** and **6** are shown in Fig. 2. Due to the proximity of peaks due to the acetyl and thiomethyl protons, caution should be exercized in assigning structures based on the appearances of such resonances in the n.m.r. spectra of the products of oxidation using DMSO/acetic anhydride.

The relative distribution of acetate and methylthiomethyl ether by-products obtained upon attempted oxidation of isolated hydroxyl groups of carbohydrates using DMSO and acetic anhydride is worthy of comment. From a consideration of published data (1), the extent of thioether formation appears to be dependent upon the nature of the hydroxyl group to be oxidized, as well as its steric and electronic environment. Thus, thioether formation appears to decrease in the order: OH(primary) > OH(secondary equatorial) > OH(secondary axial). In some cases (9), for example, when the secondary alcohol to be oxidized has an azido group on the adjacent carbon atom, the major product of oxidation using DMSO/acetic anhydride has been shown to be corresponding acetate. In the presence of a vicinal phenylthio substituent, the corresponding enol acetate can be formed (10) indicating the possible importance of electronic effects.

Attempts to prepare the aldehyde **2** by treatment of **1** with ruthenium tetroxide (11) met with little success, affording extensive decomposition and very low yields of oxidized product. This result is surprising in view of the report by Berkowitz and Rylander (12) that ruthenium tetroxide converts primary alcohols to the corresponding aldehydes or carboxylic acids. Similarly, attempts to effect a "Kornblum-type" oxidation (13) of the type recently reported (14) from this laboratory, by treatment of the 5-*O*-*p*-tolylsulfonyl ester of **1** with DMSO in the presence of sodium bicarbonate led to partial detosylation with no detectable quantity of aldehyde, even at elevated temperatures.

Experimental

General

Melting points are uncorrected. The i.r. spectra were recorded with a Beckmann IR-8 instrument. The t.l.c. was performed on plates coated with silica gel GF_{250} (Merck) and the spots were detected with a solution of 10% v/v sulfuric acid in ethanol, after the plates were heated at 110°. Sulfur-containing compounds were also detected using a 0.05 *M* sulfuric acid solution containing 1% of potassium permanganate. Column chromatography was performed using silica gel (Baker) 60–200 mesh. The developing system used both for column and t.l.c. was benzene – ethyl acetate, 3.5:1. The n.m.r. spectra were measured with a JEOL-4H-100 100 MHz

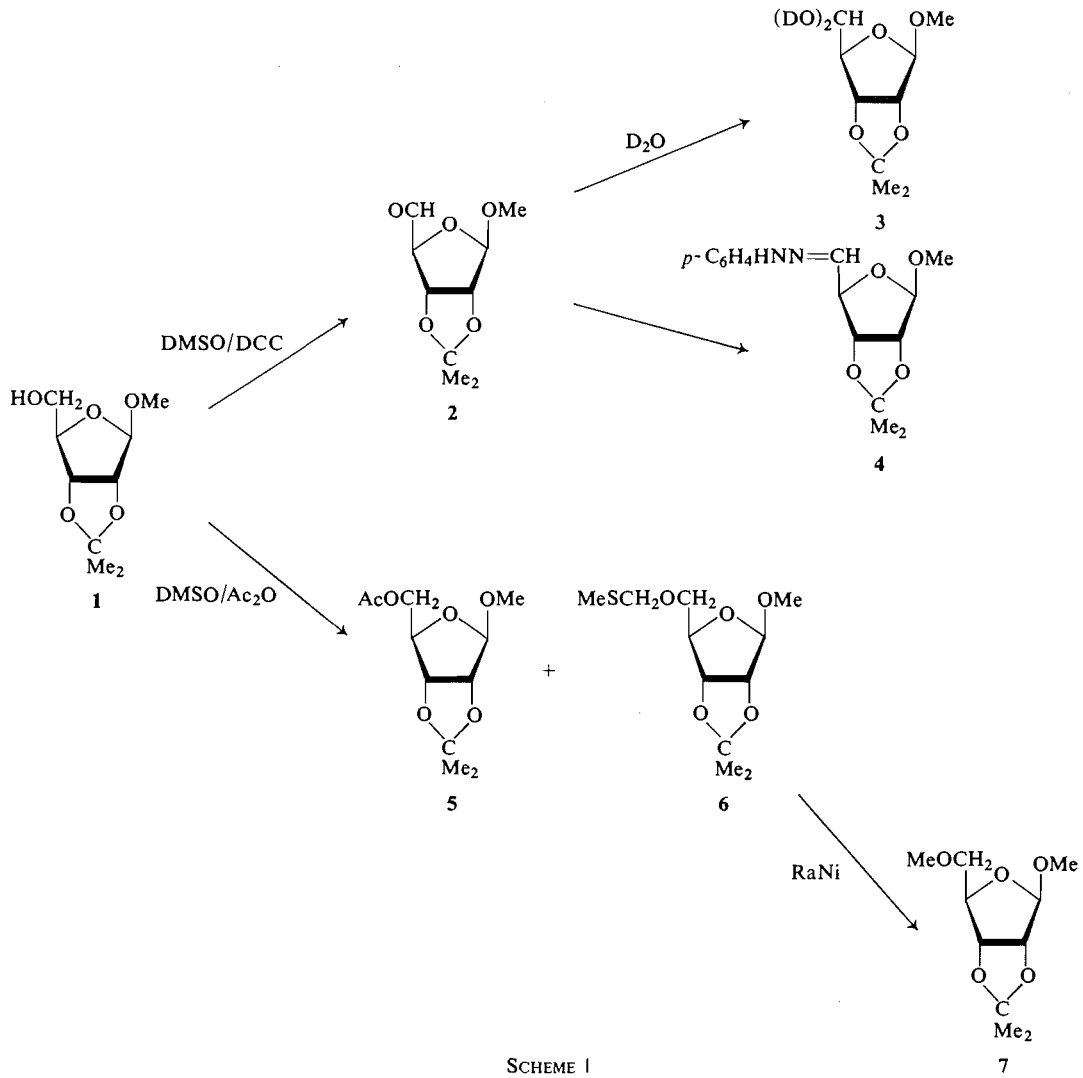

SCHEME I

instrument with an operating temperature of 30°; internal standards were, in the case of CCl_4 solutions, tetramethylsilane, and for D_2O solutions, sodium 4,4-dimethyl-4-silapentane-1-sulfonate. Optical rotations were measured with a Rudolph Model 80 photoelectric polarimeter (Caldwell, New Jersey).

Methyl 2,3-O-Isopropylidene-β-D-ribo-pentodialdofuranoside (2)

Freshly distilled methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside (**1**, 8.0 g) in dry methyl sulfoxide (25 ml) was added to a mixture of methyl sulfoxide (40 ml), dry benzene (50 ml), and pyridine (3.2 ml) containing trifluoroacetic acid (1.6 ml). To the stirred solution was added dicyclohexylcarbodiimide (25 g) and the reaction mixture was stirred at 5 °C for 2 h, then at room temperature overnight. After this time, t.l.c. indicated that reaction had terminated. The mixture was filtered and a solution of oxalic acid (20 g) in methanol (50 ml) was added to the filtrate in small portions, with stirring. The resulting suspension was stirred 1 h at room temperature then filtered, the filtrate was washed with saturated sodium hydrogen carbonate solution (3 × 100 ml), the aqueous layer was extracted with ethyl acetate (150 ml) and the organic extracts were combined and dried (Na_2SO_4). Removal of solvent afforded a syrup which was dissolved in a little acetone and insoluble dicyclohexylurea was removed by filtration. Repetition of this treatment several times, followed by removal of solvent afforded a mobile syrup (6.14 g, 76%). Attempts to purify the product by repeated distillation were unsuccessful. A portion (2.5 g) was

Treatment of Methyl 2,3-O-Isopropylidene-β-D-ribofuranoside with Methyl Sulfoxide – Acetic Anhydride

Methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside (4, 5), (**1**, 2.5 g) in dry methyl sulfoxide (35 ml) was treated with acetic anhydride (20 ml) and the reaction mixture was stored 36 h at room temperature. The t.l.c. showed the presence of three products, of which, the minor component having an R_f identical to that of the authentic aldehyde **2**. Removal of solvent and excess reagents by lyophilization afforded a pale yellow syrup (2.9 g) which was partitioned between water (75 ml) and petroleum ether (b.p. 30–60°), (50 ml). The organic layer was washed with a saturated solution of sodium hydrogen carbonate (2 × 15 ml), then with water (2 × 15 ml) and dried (Na_2SO_4). Removal of solvent yielded a colorless syrup (1.39 g), shown by t.l.c. to be a mixture of two products, the minor component having an R_f identical to that of an authentic sample of methyl 5-*O*-acetyl-2,3-*O*-isopropylidene-β-D-ribofuranoside (**5**); n.m.r. data (see Fig. 2): τ 5.0 (1-proton singlet, H-1), 5.4 (2-proton AB quartet, $J_{2,3}$ = 3.5 Hz, H-2,3), 5.6–6.0 (3-proton multiplet, H-4, -5, -5′), 6.6 (3-proton singlet OCH_3), 7.9 (3-proton singlet, —O—C(=O)—CH_3), 8.6, 8.8 (3-proton singlets $C(CH_3)_2$). Treatment of the mixture with 20 ml of a solution of methanol, saturated with ammonia at 0°, for 24 h, followed by removal of reagents by evaporation gave a syrupy product, shown by comparative t.l.c. studies to contain **1** and a major product of higher chromatographic mobility. Separation of the mixture (1.06 g) by chromatography on a column containing 125 g of silica gel afforded the major product (0.64 g) as a colorless syrup, $[\alpha]_D^{24}$ −60(*c* 2, $CHCl_3$). The n.m.r. spectrum of this product in CCl_4 (see Fig. 2) was consistent with the assignment of its structure as methyl 2,3-*O*-isopropylidene-5-*O*-methylthiomethyl-β-D-ribofuranoside (**6**); n.m.r. data (see Fig. 2); τ 5.1 (1-proton singlet, H-1), 5.3 (2-proton singlet —CH_2S—), 5.4 (2-proton AB quartet, $J_{2,3}$ = 3.5 Hz, H-2,3), 5.8, (1-proton multiplet, H-4), 6.6 (2-proton multiplet, H-5, -5′), 6.75 (3-proton singlet, OCH_3), 7.9 (3-proton singlet, —SCH_3), 8.6, 8.76 (3-proton singlets, $C(CH_3)_2$). Treatment of a solution of **6**, (0.25 g) in methanol (5 ml), with Raney nickel (1.25 g) at reflux for 8 h, gave, after filtration and removal of solvent a product (0.13 g), chromatographically and spectroscopically indistinguishable from an authentic sample of methyl 2,3-*O*-isopropylidene-5-*O*-methyl-β-D-ribofuranoside **7**, prepared by methylation (Ag_2O, MeI) of **1**.

Photochemistry of Metal Olefin Complexes. Isomerization and Stereospecific Cyclodimerization of Silver Cycloalkene Complexes

F. LEH, S. K. WONG, AND J. K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ontario

Received May 17, 1971

Photolysis of $AgClO_4$ – 1-methylene cyclohexane complex in pure polycrystalline state or in methanol solution leads to isomerization of the complex to $AgClO_4$ – 1-methylcyclohexene. The isomerized complex undergoes further photochemical cyclodimerization giving the stereospecific *exo-trans-exo* dimer of the 1-methylcyclohexene and colloidal silver. Similar photoisomerization and a less stereospecific photodimerization were observed in the photolysis of the polycyclic $AgClO_4$ – β-pinene complex.

La photolyse du complexe méthylène-1 cyclohexane – $AgClO_4$ soit sous forme polycristalline soit en solution dans le méthanol conduit à une isomérisation du complexe en méthyl-1 cyclohexène – $AgClO_4$. Le complexe isomérisé subit une cyclodimérisation photochimique ultérieure pour donner d'une façon stéréospécifique le dimère *exo-trans-exo* du méthyl-1 cyclohexène et de l'argent colloïdal. De la même façon, une photoisomérisation et une photodimérisation moins stéréospécifique sont observées dans la photolyse du complexe polycyclique β-pinène – $AgClO_4$.

Canadian Journal of Chemistry, 49, 2760 (1971)

Although recent interests in the Ag^+-catalyzed rearrangements of strain polycyclic alkanes are developing rapidly (1–6), surprisingly little effort has been devoted to explore the photochemical reactivity of the well-known silver–olefin complexes. We report here the photoisomerization and the stereospecific photocyclodimerization of $AgClO_4$ complexes of 1-methylene cyclohexane and 1-methylcyclohexene. Similar photochemical reactions of the silver – β-pinene complex are also observed. These results indicate that the photochemical reactivity of these silver–olefin complexes are distinctly different from those of the free ligands and may be of general interest to synthetic and mechanistic organic photochemistry.

The complexes were prepared by addition of the corresponding olefins to an acetone solution of $AgClO_4$ at 0 °C. The white crystalline products were filtered, washed, and dried over P_2O_5. Silver analyses of these solid complexes indicated a 2:1 olefin to Ag ratio. Since the i.r. and n.m.r. data characterizing these complexes are not available in the literature, they are presented here in Table 1.

The $AgClO_4$ – 1-methylene cyclohexane complex was found to be stable in the dark at 0 °C for several weeks. Irradiation of a methanol solution of this complex (0.1 *M*) with u.v. (2537 Å) effects firstly an isomerization to silver – 1-methylcyclohexene. The photoisomerization can be readily followed by n.m.r. and/or i.r. analyses showing the conversion of a complexed exocyclic olefin to a complexed endocycloalkene. The rate of the photoisomerization process is apparently independent of temperature within the range 10–30 °C. However, photolysis of the complex in the pure solid state leads to a tenfold increase in the rate of conversion. Prolonged irradiation of the complex either in solution or in the solid state for several hours results in secondary photochemical reaction of the isomer product giving the sole *exo-trans-exo* cyclic dimer of the 1-methylcyclohexene and colloidal silver via a stereospecific photocyclodimerization. It was confirmed by further experiments involving separate photolyses of $AgClO_4$ – 1-methylene cyclohexane and $AgClO_4$ – 1-methylcyclohexene alone that the photoisomerization is a nonreversible process, in that the endocyclic olefin complex is photostable. However, it was also demonstrated that only the endocyclic olefin complex undergoes photodimerization by stereospecific cycloaddition with a yield up to 20%

TABLE 1. The i.r. and n.m.r. characterization of the silver olefin complexes

Compound	$\nu_{C=C}(cm^{-1})$	Proton chemical shifts* (c.p.s.)		
		CH_3	CH_2(olefinic)	CH(olefinic)
1-Methylene cyclohexane	1644	—	271.1	—
$AgClO_4$ – 1-methylene cyclohexane	1584	—	292.0	—

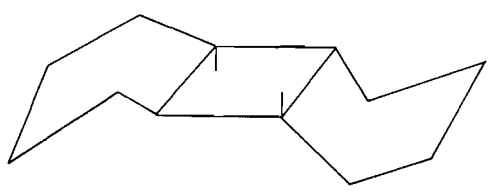
*Recorded with a Bruker HX60 spectrometer using TMS as reference.

after several hours irradiation. Dimerization was, in fact, the only photochemical reaction for silver – 1-methylcyclohexene. In all cases, no other products resulting from addition of solvent to the olefin complexes were observed.

There are at least six possible stereoisomers which can be formed via cyclodimerization of the 1-methylcyclohexene ligand. However, only one stereospecific photodimer was obtained which was separated by g.l.c. using an 8 ft column packed with nitrile silicon gum XE60 (10%) on Chromosorb P. The molecular weight of the dimer was confirmed by mass spectrometric analysis which shows that the base peak is in fact the dimer parent ion (*m/e* 192). The i.r. spectrum of the dimer shows absorption maxima at 1576, 1466, 1451, 1020, 926, and 841 cm^{-1} which are consistent with the spectra due to cyclohexane and cyclobutane derivatives. The p.m.r. spectrum of the photodimer recorded with a Bruker HX60 high resolution spectrometer, displays a complex absorption pattern centered at 2.15 p.p.m. which is probably due to the cyclobutane protons and the cyclohexane methylene protons having similar chemical shifts. The methyl protons on the cyclobutane ring are associated with the absorption centered at 1.68 p.p.m. Since the protons of the cyclobutane ring in the *trans* configuration are likely to have resonance at higher field (7), we tentatively assign the photodimer to the *exo-trans-exo* configuration **1**. Absolute assignment will have to await further study.



1

It is apparent that the photochemical behavior of the above silver–olefin complexes is in marked contrast to that of the free olefins. For example, Kropp and Krauss (8) have studied the xylene-photosensitized reaction of 1-methylcyclohexene in both methanol and hydrocarbon solvents. In protic media, photoisomerization to the exocyclic 1-methylene cyclohexane as well as conversion to ether by addition of a solvent molecule to the olefin, were the principal courses of reaction. These authors also found that the exocyclic isomer is photo-stable, thus the photoisomerization is non-reversible. This is exactly opposite to the photochemical behavior of the corresponding silver complexes. Furthermore, photosensitized reaction of 1-methylcyclohexene in hydrocarbon solvent also leads to dimerization yielding a mixture of at least six different dimers (8). This again is distinctly different from the stereospecific photocyclodimerization of the corresponding silver complex. On the other hand, Herling and co-workers (9) have found that thermal isomerization of 1-methylene cyclohexane to 1-methylcyclohexene can be effected by using sodium–alumina as the catalyst at 25 °C. However, thermal isomerization of silver–1-methylene cyclohexane at room temperature in the dark has not been observed.

The mechanistic implications of these results are being investigated by flash photolysis and by low temperature e.s.r. spectroscopy. Our preliminary e.s.r. results suggest that photochemical reactions may involve radical intermediates such as the Ag^+–cyclohexenyl radical and trapped H atoms. Silver – cycloalkenyl radicals have been observed in γ-radiolysis of solid silver cycloalkene complexes (10, 11).

Similar photochemical behavior was observed for the polycyclic silver – β-pinene and silver – α-pinene complexes. Only silver – β-pinene was found to photoisomerize to the more stable

silver – α-pinene complex. However, photodimerization via less stereospecific routes was found to occur in both α- and β-complexes.

Oxidation of Hydrocarbons. III. Kinetics and Mechanism of the Oxidation of Arenes by Aqueous Sodium Dichromate[1]

DONALD G. LEE AND UDO A. SPITZER[2]

Department of Chemistry, University of Saskatchewan, Regina Campus, Regina, Saskatchewan

Received April 26, 1971

The kinetics of the oxidation of several sodium *p*-alkylbenzenesulfonates by aqueous dichromate have been studied under slightly acidic conditions (pH = 7.0 to 5.4). The results indicate that the only active oxidant under these conditions is the acid chromate ion, $HCrO_4^-$, and that the reaction probably involves a free radical process.

Les cinétiques de l'oxydation de quelques *p*-alkylbenzènesulfonates de sodium par le dichromate aqueux ont été étudiées sous des conditions légèrement acide (pH = 7.0 à 5.4). Les résultats indiquent que dans ces conditions, la seule espèce oxydante active est l'ion chromate acide, $HCrO_4^-$, et que la réaction fait probablement intervenir un processus par radicaux libres.

Canadian Journal of Chemistry, 49, 2763 (1971)

Introduction

The oxidation of arenes by aqueous sodium dichromate is a reaction of considerable synthetic potential since it results in selective oxidation of side chains with little or no ring degradation (1, 2). For example, using this procedure, 2-methylnaphthalene can be converted to 2-naphthoic acid in almost quantitative yields whereas the use of most other oxidants, including acidic chromium(VI), results in the formation of a considerable amount of 2-methylnaphthoquinone (3). Other attractive features of this procedure include the ease with which products can be recovered, and the reaction has consequently found several synthetic applications (4–6).

Despite its apparent synthetic utility only one study dealing with the mechanism of the reaction has been reported (7). In this investigation, Bixel and Drayer found that the oxidation of *o*-toluic acid using a 30% aqueous solution of $Na_2Cr_2O_7$ followed the rate law expressed in eq. 1, and they suggested that the reaction was initiated by the abstraction of a hydrogen atom in the rate determining step. However, these authors noted that their data could also be successfully accommodated by other mechanisms as well.

$$[1] \quad v = k[Cr_2O_7^{2-}][o\text{-Toluic Acid}][H^+]$$

Other workers reported that oxidations of arenes with side chains two or more carbon atoms in length underwent reaction at the terminal carbon (8). However, this report was later shown to be erroneous; oxidation occurs only at the α-position (9).

In the present work we have attempted to increase our understanding of the mechanism of the reaction by studying the oxidation of arenes with different types of side chains. Because of the low solubility of hydrocarbons in aqueous media it was found that reproducible rate constants could be obtained only if the arenes contained an additional group which increased their solubility in water. The *p*-sulfonate group functions admirably in this respect since it increases the solubility of the arene, but is itself inert to oxidation. Furthermore, judging from its small σ-value (10), it should not have a large electronic effect on the rate of reaction.

Experimental

Apparatus

The reaction vessel was a Parr #4501 stirrer type Pressure Reaction Vessel with the following specifications: capacity, 2000 ml; bomb material, T-316 stainless steel; pressure gauge range, 0 to 2000 p.s.i.; heater, W1OM auto transformer 1500 W; circuitry, 60 cycles, 115 V a.c.; stirrer, mechanical, 520 r.p.m. The temperature was monitored by a custom dial thermometer with a range of 0–250°. This range was verified from 100–250° by a chromel–alumel thermocouple. The accuracy (±0.5°) was limited by the temperature control apparatus. Samples for kinetic analysis were withdrawn through the liquid sampling valve by means of a simple glass apparatus which prevented loss of water vapor.

Preparation of Sodium p-Sulfonates of Toluene, Toluene-α-d_3, Ethylbenzene, Isopropylbenzene, and t-Butylbenzene

These salts were prepared according to the general procedure described by Fieser (11) after the arenes had been purified by repeated treatments with cold concentrated H_2SO_4 to remove thiophene derivatives and then distilled. The following ratios were observed although the quantities of each arene varied. To 0.3 mol of arene at 100° were added 19 ml of 97% H_2SO_4 with stirring at such a rate that the temperature did not exceed 120°. The resulting solution was kept at 110° until the organic layer disappeared (usually 1 h). This mixture was allowed to cool to 50° and then poured into 100 ml of water. The organic layer was removed using a separatory funnel. The aqueous solution was partially neutralized by the careful addition of 15 g of sodium bicarbonate. Sodium chloride (40 g) was then added, the mixture was heated to boiling and just enough water was added to bring all the salt into solution. The mixture was cooled in ice and the crystals were collected. The recovered crystals were redissolved in hot water and treated with 40 g NaCl and the product was again recovered. The product was recrystallized once more in this manner and then once from water. The yield at this point was only 30% but the purity was 98% or better as determined from carbon–hydrogen analysis. The impurities were in all cases resistant to oxidation (as judged from the fact that compounds at different stages of purification gave the same rate constants). The analysis for these compounds are listed below.

Anal. Calcd. for sodium *p*-toluenesulfonate: C, 43.29; H, 3.63. Found: C, 43.10; H, 3.51.

Anal. Calcd. for sodium *p*-(α-d_3)-toluenesulfonate: C, 42.60. Found: C, 40.38.

Anal. Calcd. for sodium *p*-ethylbenzenesulfonate: C, 46.15; H, 4.36. Found: C, 45.98; H, 4.38.

Anal. Calcd. for sodium *p*-isopropylbenzenesulfonate: C, 48.64; H, 4.99. Found: C, 49.08; H, 4.91.

Anal. Calcd. for sodium *p*-*t*-butylbenzenesulfonate: C, 50.83; H, 5.55. Found: C, 46.61; H, 5.35.

Although the purity of sodium *p*-*t*-butylbenzenesulfonate was not high according to the analysis it was found that this compound was resistant to oxidation under our conditions, thus supporting the conclusion that the impurities which contaminated these compounds are not oxidizable. Similarly the deuterated compound, because of the excessive cost of starting material, was recrystallized only twice to give a yield of 50% and a purity of 95%. In the preparation of solutions for kinetic experiments the substrate concentration was always corrected for purity.

Kinetic Method

The rate of oxidation was followed by spectrophotometrically observing the decrease of [Cr^{VI}] with respect to time. Since the reaction temperatures were all too high for direct spectrophotometric observation samples were withdrawn at known time intervals. These samples were quenched by quickly cooling to room temperature using a Dry Ice – ethanol slurry. After centrifuging to remove suspended Cr_2O_3 the samples were analyzed at 364 nm for Cr^{VI} using a Unicam Model SP-500 Series 2 spectrophotometer. At this wavelength Cr^{VI} has an absorption peak in the phosphate buffer solutions that was found to obey Beer's Law (12).

The reactants were first mixed together in an aqueous phosphate buffer at room temperature. (The ionic strength of the buffers was maintained at 1.2.) The reactor was then sealed, purged with purified nitrogen, charged with 320 p.s.i. of nitrogen, and heated to and stabilized at the desired temperature. This usually required ½ to 1 h of heating, but since the reaction half lives were always long in comparison, this warm up time could be neglected.

Good pseudo first order rate plots, all with correlation coefficients of 0.993 or greater, were obtained for that portion of the reaction taking place after the warm up time. Two typical plots for the oxidation of *p*-ethylbenzenesulfonate are reproduced in Fig. 1. The data were processed by the method of least squares utilizing an IBM #360 computer.

Results

Initially, attempts were made to investigate the rate law for the oxidation of ethylbenzene by using unsubstituted arenes as substrates, but it soon became apparent that the investigation was severely hampered by poor reproducibility. This was attributed to the low solubility of arenes in aqueous media. However, it was observed that the arene oxidation proceeded at a rate that was approximately equal to that of the corresponding arene sulfonate, and in order to obtain precise rate constants, it was necessary to use these more soluble derivatives. The data obtained are summarized in Table 1.

Discussion

From the data presented in Table 1, it is possible to define the rate law for the oxidation of sodium *p*-ethylbenzenesulfonate.

The good straight line plots obtained in Fig. 1, where ln (absorbance) is plotted against time indicates that the reaction is first order in Cr^{VI}.

The order with respect to arene was then obtained by maintaining the acidity constant and

varying the arene concentration. The pseudo first order rate constants were found to be directly dependent on the concentration of arene when the oxidation of sodium *p*-ethylbenzenesulfonate was studied at a p*H* of 5.45 and 200 °C. This is indicated by the constancy of the k_2 values for the first nine experiments in Table 1.

When attempts were made to evaluate the order with respect to acidity in a similar manner by varying the p*H*, it was found that a plot of log k_2 *vs.* p*H* gave a curve rather than a straight line (see Fig. 2). However, this apparently complex dependence upon acidity is really a result of the analytical method used which measures the concentration of all chromium(VI) species present in solution. Under neutral conditions the primary chromium(VI) species present in dilute solutions are CrO_4^{2-} and $HCrO_4^-$ (1*a*). If it is assumed that $HCrO_4^-$ is the only active oxidant, it can be concluded from the derivation presented in the Appendix that the rate of reaction should be dependent on a complex function of acidity, $[H^+]/([H^+] + K)$, where K is the acid dissociation constant of $HCrO_4^-$. In accordance with this derivation, it was found that a plot of log k_2 against log $([H^+]/([H^+] + K))$ gave a straight line with slope of 1.05 ± 0.09 (see Fig. 3). Hence, the reaction apparently depends only upon p*H* in so far as it controls the equilibrium between $HCrO_4^-$ and CrO_4^{2-}.

From these considerations the rate law for the oxidation of arenes under neutral conditions is of the form,

$$v = k[\text{arene}][Cr^{VI}]([H^+]/[H^+] + 3.0 \times 10^{-7})$$

or

$$v = k[\text{arene}][HCrO_4^-]$$

At this point it is of value to consider the differences observed between acidic and neutral chromium(VI) oxidations. Wiberg and Evans (15) thoroughly studied the acidic chromium(VI) oxidation of diphenylmethane and found the rate law,

$$v = k[\text{Total } Cr^{VI}][\text{diphenylmethane}]h_0$$

where h_0 is the Hammett acidity function. But under these conditions, chromium(VI) exists primarily as H_2CrO_4 and $HCrO_4^-$ and it is noteworthy that ring degradation becomes extensive, particularly when polycyclic aromatic hydrocarbons are used as the substrates (13). However, neutral chromium(VI) oxidations, where $HCrO_4^-$ is the major oxidant, do not attack aromatic (9) or polyaromatic ring systems

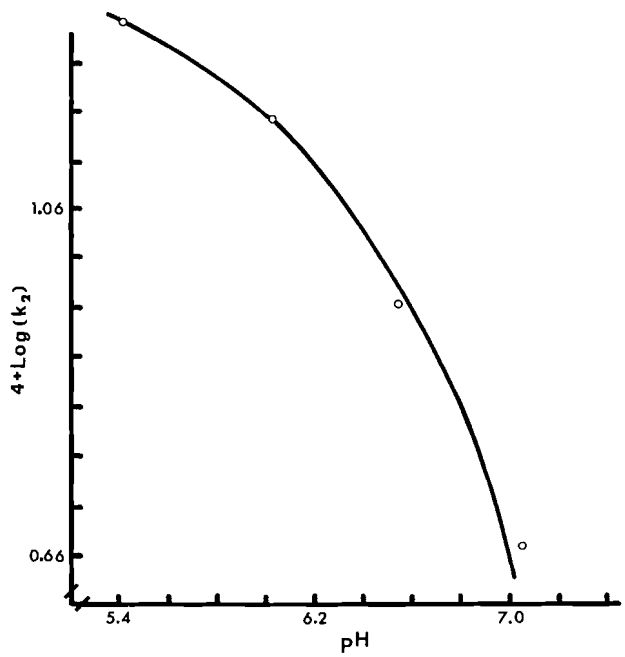

FIG. 2. Plot of log k_2 against p*H* for the oxidation of sodium *p*-ethylbenzenesulfonate.

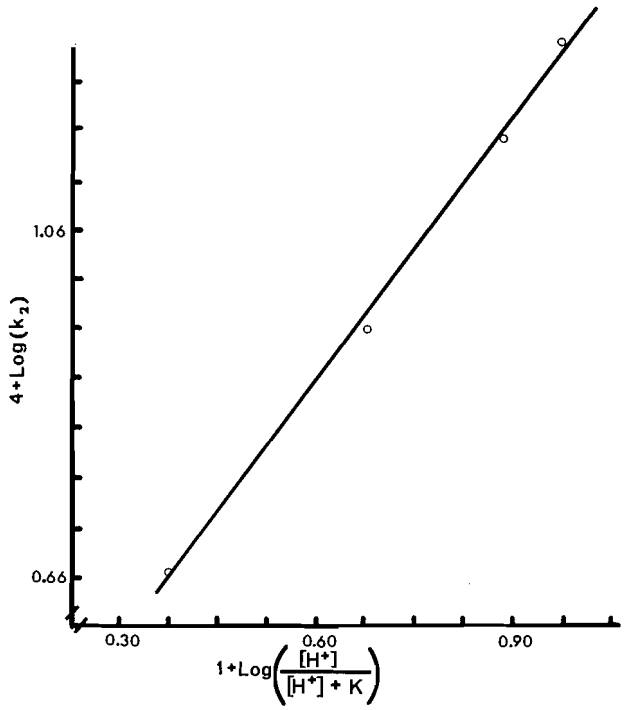

FIG. 3. Dependence of k_2 upon acidity for the oxidation of sodium *p*-ethylbenzenesulfonate. K is the acid dissociation constant of $HCrO_4^-$. Slope = 1.0, correlation coefficient = 0.975.

(3). It thus becomes attractive to propose that H_2CrO_4 (or $H_3CrO_4^+$) is responsible for the ring degradation. An alternative explanation could be that at higher acidities the ring systems become protonated and are thus rendered more susceptible to oxidation.

From the rate law, it can be concluded that the transition state for neutral chromium(VI) oxidations is composed of one molecule of arene and one of acid chromate anion. The observation of a primary deuterium isotope effect, k_H/k_D = 4.6, when the rates of reaction of sodium *p*-toluenesulfonate and its α,α,α-d_3 analogue are compared indicates that the cleavage of the carbon–hydrogen bond is the rate determining step.

The thermodynamic parameters (see Fig. 4) are close to those obtained for the acidic chromium(VI) oxidations of alcohols, $\Delta S^{\neq}$ (arene) = −22.8 e.u., $\Delta S^{\neq}$ (2-propanol) ≐ −35 e.u., $\Delta H^{\neq}$ (arene) = 21.0 kcal/mol, $\Delta H^{\neq}$ (2-propanol ≐ 12 kcal/mol, thus suggesting the possibility that a similar mechanism may be operating (14).

By comparing the relative rates of 1°:2°:3° carbon–hydrogen bond cleavage, it is also possible to distinguish between homolytic cleavage (radical abstraction) or heterolytic cleavage (hydride ion abstraction). Table 2 illustrates

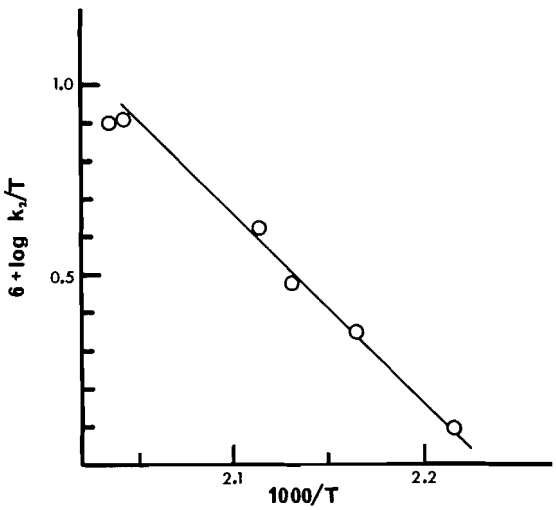

FIG. 4. Thermodynamic parameters for the oxidation of sodium *p*-ethylbenzenesulfonate. $\Delta H^{\neq}$ = 21.0 kcal/mol, $\Delta S^{\neq}$ = −22.8 e.u., slope = −4.59, correlation coefficient = 0.996.

TABLE 2. Comparative rates for different types of side chains*

Arene	$k_2 \times 10^4 (M^{-1}s^{-1})$†	Ratio	Free radical formation‡	Carbonium ion formation§
Sodium *p*-toluenesulfonate	4.06	1	1	1
Sodium *p*-ethylbenzenesulfonate	20.0	5	4	10^2
Sodium *p*-isopropylbenzenesulfonate	28.5	7	13	10^5

*pH = 5.42, temperature = 200°.
†The k_2 values are the averages of two or more experiments.
‡Hydrogen abstraction by methyl radicals from toluene, ethylbenzene, and isopropylbenzene (18).
§Solvolysis rates for the chlorides of toluene, ethylbenzene, and isopropylbenzene (19).

that the comparative rates are very similar to those observed for reactions known to proceed by a radical mechanism. Hydrogen abstraction has also been suggested for the acidic chromium-(VI) oxidation of toluene, ethylbenzene, and triphenylmethane where the ratio of 1°:2°:3° was found to be 1:3:8 (15). It is likely that this abstraction does not result in a completely free radical since the oxidation of styrene under similar conditions yielded no polymers (12). The radical can rather be visualized as being trapped in a solvent cage with Cr^V, a more powerful oxidant than Cr^{VI} (16). This would lead to further rapid oxidation.

Appendix

In the particular pH region where these experiments were performed two chromium species are present (CrO_4^{2-} and $HCrO_4^-$), both of which are detected spectrophotometrically (1*a*). Since the spectrophotometric analytical technique used at 364 nm does not distinguish between the two species the absorbance recorded is really due to $[Cr^{VI}]_{total} = [HCrO_4^-] + [CrO_4^{2-}]$. It is known that CrO_4^{2-} is oxidatively inactive since at p$H \geq 9$ no oxidation occurs, so it can be assumed that the only effective oxidant is the acid chromate anion, *i.e.* $v = k[\text{substrate}]\,[HCrO_4^-]$. However, as a result of the analytical technique, the rate is measured as $-d[Cr^{VI}]_{total}/dt$. These two parts of the rate equation can be equated using the equilibrium constant for the acid chromate anion–chromate dianion system which is known to be 3.0×10^{-7} at 25° (1*a*). After the following calculations are performed, the rate equation can be expressed in terms of $[Cr^{VI}]_{total}$.

$$\frac{[CrO_4^{2-}][H^+]}{[HCrO_4^-]} = 3.0 \times 10^{-7} = K = \frac{[CrO_4^{2-}][H^+]}{[Cr^{VI}]_T - [CrO_4^{2-}]}$$

$$K[Cr^{VI}]_T - K[CrO_4^{2-}] = [CrO_4^{2-}][H^+]$$

$$K[Cr^{VI}]_T = [CrO_4^{2-}]([H^+] + K)$$

$$[2] \qquad [CrO_4^{2-}] = [Cr^{VI}]_T\left(\frac{K}{[H^+] + K}\right)$$

$$-d[Cr^{VI}]/dt = k[\text{substrate}][HCrO_4^-]$$

$$[3] \qquad = k[\text{substrate}]([Cr^{VI}]_T - [CrO_4^{2-}])$$

substituting eq. 2 into eq. 3,

$$-d[Cr^{VI}]_T/dt = k[\text{substrate}]\left([Cr^{VI}]_T - [Cr^{VI}]_T\left(\frac{K}{[H^+] + K}\right)\right)$$

$$= k[\text{substrate}][Cr^{VI}]_T\left(1 - \frac{K}{[H^+] + K}\right)$$

$$= k[\text{substrate}][Cr^{VI}]_T\left(\frac{H^+}{[H^+] + K}\right)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The rates of oxidation were found to be linearly dependent on this somewhat unusual acidity function, thus indicating that the basic assumption was correct, *i.e.* $v = k[\text{substrate}]\ [HCrO_4^-]$. It should be noted that the equilibrium constant used was determined at 25° whereas the kinetic investigations were at about 200°. Similarly the p*H* measurements were all made at 25° and although it is not at present known how *K* responds to temperature changes it is known that the changes in p*H* are small in the phosphate buffer system used (17). The derivation thus rests on the assumption that changes in *K* as the temperature increases are either small or parallel to changes in the p*H* of the phosphate buffer system.

Novel Chemical Shift Changes of Carbohydrates Induced by Lanthanide Shift Reagents: Some Experimental Optimizations[1]

IAN ARMITAGE AND L. D. HALL

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received March 15, 1971

The ^{1}H n.m.r. spectra of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**), of 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose (**5**), and of their 3-*O*-acetyl derivatives **6** and **7**, respectively have been separately measured in the presence of varying concentrations of the tris{dipivaloylmethane} derivatives of europium (**1**), thulium (**2**), and praseodymium (**3**). For these derivatives, both europium (**1**) and thulium (**2**) induce shifts to low field whereas praseodymium (**3**) produces high field shifts; for any individual proton the magnitude of the induced shift is shown to be linearly proportional to the amount of added reagent and is best followed by addition of volume aliquots of a dilute solution of the lanthanide. It is shown that simplistic rationales concerning the relationship between the magnitudes of induced shifts and the geometry of the substrate system can be entirely misleading; the D-*gluco*-derivative **4** is particularly noteworthy in this regard. Since the magnitudes of the induced shifts are temperature dependent it is important to report the temperature at which experiments are performed. For **1** the induced shifts are *ca.* 2.2 times larger for carbon tetrachloride solutions than for deuterochloroform solutions when operating under otherwise identical conditions.

Les spectres de r.m.n. de ^{1}H du 1,2:5,6-di-*O*-isopropylidène-α-D glucofuranose (**4**), du 1,2:5,6-di-*O*-isopropylidène-α-D-allofuranose (**5**) et de leurs dérivés respectifs 3-*O*-acétylés **6** et **7** ont été séparement mesurés en présence des dérivés tris (dipivaloylméthane), en concentrations variables, de l'europium (**1**), du thulium (**2**), et du praseodymium (**3**). Pour ces dérivés, à la fois ceux de l'europium (**1**) et du thulium (**2**) provoquent des déplacements à champ faible tandis que celui du praseodymium (**3**) donne des déplacements à champ fort; pour chaque proton, l'importance du déplacement induit est proportionnellement linéaire à la quantité de réactif ajouté. Cette variation est mieux appréciée par addition de volumes d'une solution diluée de lanthanide. On montre que des raisonnements trop simples concernant la relation qui lie l'importance des déplacements induits et la géométrie du substrat peuvent être entièrement erronés. L'exemple du dérivé D-glucosidique **4** est particulièrement significatif à cet égard. Puisque l'importance des déplacements induits dépend de la température, il est important de noter la température à laquelle les expériences sont faites. Pour le composé **1**, les déplacements induits sont 2.2 fois plus importants pour des solutions de tétrachlorure de carbone que pour des solutions de deutero chloroforme lorsqu'on opère dans des conditions par ailleurs identiques.

Canadian Journal of Chemistry, **49**, 2770 (1971)

Introduction

One of the principle shortcomings of ^{1}H n.m.r. spectroscopy as a method for studying the structures of complex organic substances is associated with the intrinsically low sensitivity of ^{1}H chemical shifts to changes in chemical and stereochemical environment. As a result, it often happens that a resonance of particular interest is obscured by the fortuitous overlap of other resonances. Although the spectra of monosaccharide derivatives are not commonly complicated by this hazard, it remains that direct spectral assignments are occasionally precluded by a small chemical shift between a pair of protons; for example, the resonances of C-6 methylene protons are often difficult to observe.

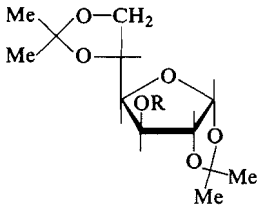
Over the years this laboratory has been concerned with the development and evaluation of methods for simplifying the proton spectra of carbohydrate derivatives and in this regard we have variously described the use of spin-decoupling (2), solvent shifts (3), high-magnetic fields (4), and ^{1}H–{^{1}H} INDOR spectroscopy (5). In the present paper we shall discuss several lanthanide, tris{dipivaloylmethane} derivatives which appear to have considerable potential as reagents for inducing large chemical shift changes in the ^{1}H n.m.r. spectra of carbohydrate substances dissolved in organic solvents.

The potential of lanthanide complexes as "chemical-shift" reagents was first recognised by Hinckley (6) in 1969 and since then we (1) and a large number of other workers have out-

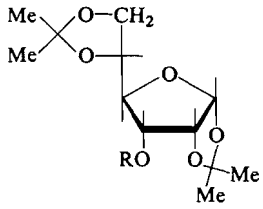
[1]For a preliminary communication of some of these data, see ref. 1. The present paper is Part 1 of a series "Nuclear Magnetic Resonance Studies of Paramagnetic Systems".

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

lined a variety of europium (7) and other lanthanide (8) systems which respond favorably. Most of these studies have been concerned with organic systems having a single "chelating" substituent, usually a hydroxyl group, and our initial concern was to demonstrate that monosaccharide derivatives, which are potentially polyfunctional can also give useful results. We shall also be concerned here with details of what we regard to be the most useful way of using these lanthanide reagents, with particular emphasis on the tris{dipivaloylmethane} derivatives of europium (**1**), thulium (**2**) and praseodymium (**3**). For convenience, four derivatives of the 1,2:5,6-di-*O*-isopropylidene-α-D-hexofuranose system (**4**–**7**), which were available from other studies in our laboratory were chosen as the substrate molecules. Other merits of these derivatives are that they all have reasonably well



4 R = H
6 R = $\overset{\overset{O}{\|}}{C}CH_3$



5 R = H
7 R = $\overset{\overset{O}{\|}}{C}CH_3$

defined geometries and each has one group, either an hydroxyl or acetoxyl group, likely to provide the major association site for the lanthanide reagent, together with many additional functionalities likely to provide weaker "donor-bonds."

Results and Discussion

The syntheses of tris{dipivaloylmethane} derivatives of europium (**1**), thulium (**2**), and of praseodymium (**3**) following the standard literature procedures (9), present no difficulties. During preliminary experiments no particular attempts were made to perform the measurements with rigorously dried reagents or solvents and the spectra which were obtained showed considerable line-broadening, even with **1**. The experiments described here used freshly sublimed lanthanide reagents (**1**, **2**, or **3**) and carefully dried solvents and substrates, and for **1** no significant line-broadening was observed up to 0.15 mol equiv added reagent. The effect of deliberately adding a small amount of water to a solution is shown in Fig. 1. A comparison between the spectra shown in Figs. 1A and B indicates the effect which the added europium reagent, **1**, has had on the ^1H spectrum of **4**. The outcome of adding water to this system is shown in Fig. 1C. Clearly the added water has almost entirely eliminated the induced shift; from Fig. 1A, $\tau_{H\text{-}1} = 4.080$, $\tau_{H\text{-}2} = 5.489$ and from Fig. 1C $\tau_{H\text{-}1} = 4.060$, and $\tau_{H\text{-}2} = 5.463$. This implies that the water associates more strongly with **1** than does the carbohydrate derivative **4**; a practical outcome of this phenomenon is given later in this paper.

Preliminary experiments also established that the rather small[2] quantities (<0.15 mol equiv; <25 mg; $<3.5 \times 10^{-5}$ mol) of lanthanide reagent needed to produce interesting chemical shift changes, were most conveniently obtained by the addition of volume aliquots of a freshly prepared stock solution of the reagent. This procedure also provided an automatic access to two important sets of data: (*i*), plots of the magnitude of induced shifts as a function of the amount of added reagent and (*ii*), the spectrum of the compound having the optimal dispersion of chemical shifts and hence the maximal number of measurable coupling constants. This latter aspect is clearly illustrated in Fig. 1, which shows spectra of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**). The spectrum in Fig. 1B shows the effect of 9.84×10^{-2} mol equiv of added europium (**1**); all seven ring-proton resonances are clearly resolved.

Following preliminary evaluations, a routine series of spectra were measured in which aliquots of each of the lanthanide reagents **1**, **2**, and **3** were added to each of the four sugars **4**, **5**, **6**, and **7**, using deuterochloroform solutions throughout. For brevity, we shall center our discussion on the behavior of the D-*gluco*-derivative, **4**.

The plots shown in Figs. 2, 3, and 4 are typical and indicate that there is a linear relationship between the magnitude of an induced shift and the amount of added lanthanide reagent, at

[2]It will be noted that throughout this work we have intentionally kept the amount of added lanthanide to a minimum. It is possible to add far larger quantities but for carbohydrate derivatives this is not generally necessary.

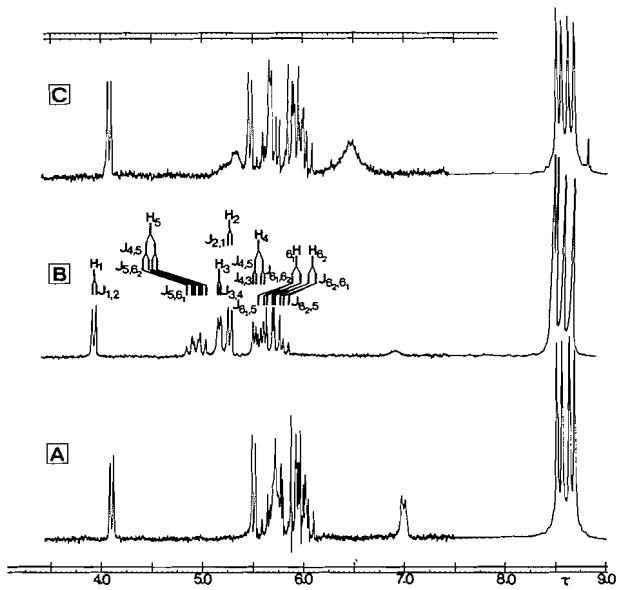


FIG. 1. The ^{1}H n.m.r. spectra (100 MHz) of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**, 0.0842 g) in deuterochloroform (0.5 ml). [A] The normal spectrum. [B] The spectrum after the addition of europium tris {dipivaloylmethane} (**4**, 9.84×10^{-2} mol equiv). [C] As for [B] but with the further addition of water (0.01 ml, 1.55 mol equiv per mol of **4**). A diagrammatic representation of the first-order assignment is given above the spectrum shown in [B].

least up to *ca.* 0.15 mol equiv. The linearity of these plots implies that on the n.m.r. time scale the exchange between the "free" and "complexed" lanthanide reagent must be in the fast exchange limit. Besides providing a convenient means for indicating the progress of an experiment and for obtaining the spectrum having the optimal dispersion of chemical shifts, this linear relationship provides for the recovery of the chemical shift data which would otherwise be lost; thus, extrapolation of a shift–concentration plot back to zero concentration of the added lanthanide gives the "normal" shift of that particular proton. However, it must be emphasized that this useful procedure can be subject to a sizeable experimental error. A notable illustration of this point is given in Fig. 3 for the thulium reagent (**2**). It can be seen that there is a "lag" during the addition of the first 0.01 mol equiv of **2**; furthermore, the lag is identical for all observable protons. These observations are consistent with the presence of a small amount of water in the carbohydrate sample, which complexes preferentially with the thulium reagent; in accord with this suggestion the lag was decreased by further drying of the carbohydrate **4**.

Similar results were obtained with the same sample of the D-*gluco*-derivative **4** in conjunction with the europium (**1**) and praseodymium (**3**) reagents; these data are summarized in Table 1. It is of interest to note that the final magnitude of the error induced by this effect is dependent on the slope of the shift–concentration plot for that particular resonance; the greater the slope the greater will be the error. Fortunately this potential hazard need not be troublesome since it is only necessary for the normal chemical shift of *one* proton to be directly measurable; this then provides a correction factor which can be applied to the other measurements.

The excellent results which can be obtained by extrapolations of shift–concentration plots

TABLE 1. Chemical shifts (τ-values) for 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**) in "chloroform" solution obtained by direct measurement and by extrapolation of the plots shown in Figs. 2, 3, and 4 back to zero concentration of lanthanide reagent

Proton	Extrapolated chemical shift values			Values by direct observation

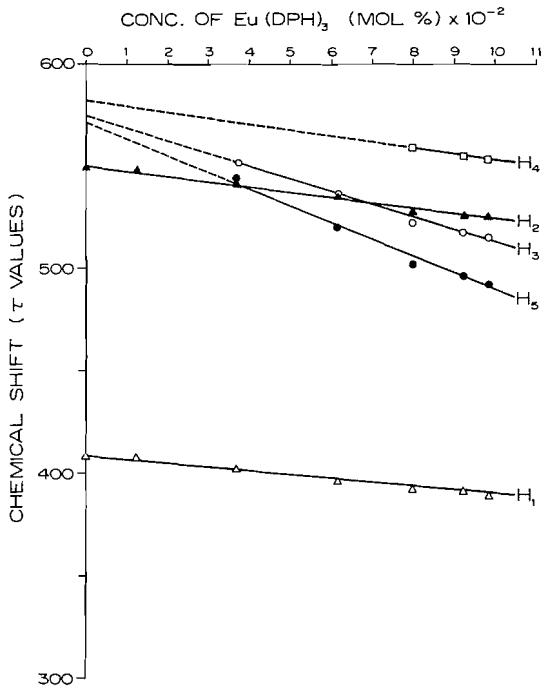

FIG. 2. Chemical shifts observed for a solution of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**, 0.0842 g) in deuterochloroform (0.6 ml) following the dropwise addition of a solution of europium tris{dipivaloylmethane} (**1**, 0.3115 g) in deuterochloroform (1 ml). The dotted sections of the plots shown for the H-4, -3, and -5 resonances apply over the region where assignments were considered to be insufficiently accurate to be included here.

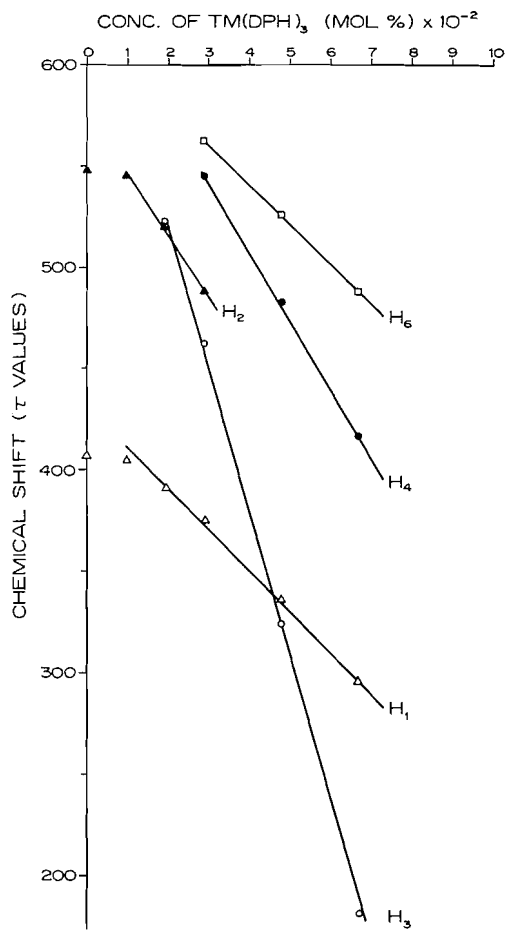

FIG. 3. Plot of the chemical shift changes observed for a solution of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**, 0.0897 g) in deuterochloroform (0.6 ml) induced by thulium tris{dipivaloylmethane} (**2**). The chemical shifts of the two H-6 resonances remained essentially the same throughout the experiment. The chemical shift of the H-5 resonance ran roughly parallel with that of H-4; it could not be measured with sufficient accuracy to justify its inclusion here.

when no water impurity is present are typified in the data listed in Table 2 for 3-*O*-acetyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**6**); with care, even better agreement can be obtained.

It is interesting to note that for the compounds we have studied the thulium reagent **2** generally produces larger changes in chemical shifts than an equivalent amount of the europium reagent **1**. Insofar that the shifts induced by europium (**1**) are already very large, there seems to be at this time little advantage in using the thulium reagent **2** except possibly for conformationally mobile systems. Furthermore, the fact that for any particular amount of induced shift, **2** appears to cause significantly more line broadening[3] than **1**, also dictates in favor of **1**. Although there may

TABLE 2. Chemical shifts (τ-values) for 3-*O*-acetyl 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**6**) in deuterochloroform solution, showing values obtained by direct measurements and by extrapolation to zero concentration of a shift–concentration plot for the addition of lanthanide reagents **1**, **2**, and **3**

	Chemical shifts			
	Extrapolated values			
Proton	τ_0(Eu)	τ_0(Tm)	τ_0(Pr)	Direct values
H-1	4.165	4.160	4.113	4.152
H-2	5.550	5.555	5.470	5.522
H-3	4.825	4.835	4.710	4.765

[3]This point is being further investigated.

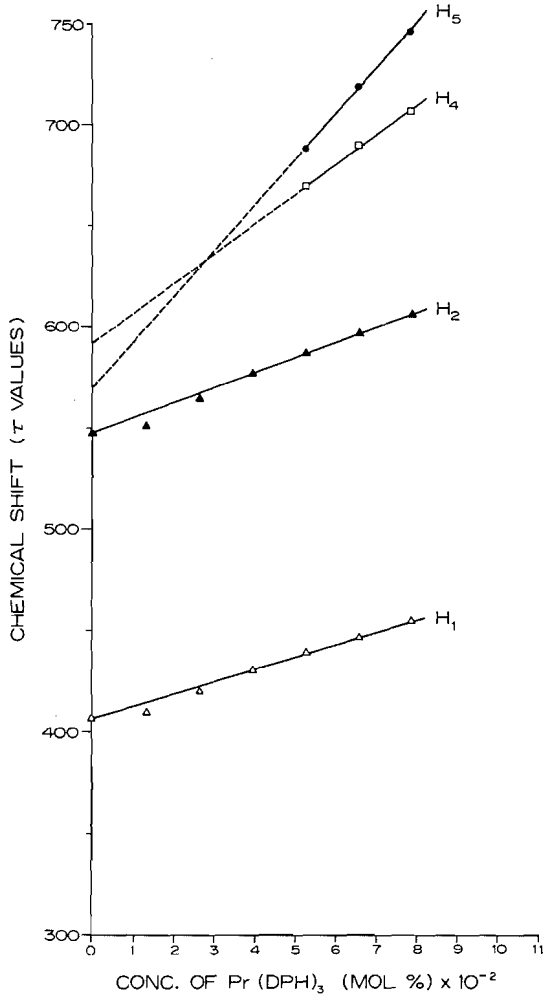

FIG. 4. Plot of the chemical shift changes induced by praseodymium tris{dipivaloylmethane} (**3**) in the proton spectra of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**, 0.0964 g) in chloroform (0.6 ml). The H-3 resonance moves at approximately the same rate as the H-4 resonance, that is at a rate less than that of H-5.

be occasions when it is advantageous to use the shifts to high field induced by the praseodymium reagent **3** this is certainly not the case for derivatives **4**–**7**; virtually no additional data could be obtained for these substances.

Several serendipitous observations made during the course of this study provide some interesting insights and may serve as cautions against some of the simplistic rationalizations which have been implied elsewhere, and which we consider to be either incorrect or misleading.

For simple aliphatic derivatives it is often found that the protons which are nearest in terms of bond separation to the functional group predominantly engaged in complexing with the lanthanide, are the ones which undergo the largest induced shifts. However, it would be totally naive to anticipate that this same situation should necessarily pertain to more complex molecules, particularly cyclic systems, although in principle it can. Instead, it must be emphasized that *if the shifts induced by lanthanide reagents arise via the pseudo-contact mechanism, as has generally been assumed (10), then an angular dependence must also be included in calculations of induced shift-changes.*

An indication of the complications which can arise for cyclic systems is afforded by the results for 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**4**). According to results from aliphatic derivatives, one might have assumed that the C-3 hydroxyl group would be the principle donor group and hence that the H-3 resonance should undergo the largest shift. As can be seen from the Fig. 1 this is not so, and H-5 shifts 1.35 times as fast as the H-3 resonance. Interestingly, the other three compounds **5**, **6**, **7** do behave in a "normal" fashion with **1**, with H-3 undergoing the largest shift. The "anomalous" behavior of **4** is further compounded by the observation that with the thulium reagent **2**, H-3 does shift the most.

There are several possible reasons for the unusual behavior of **4** with europium (**1**). It could be that the geometry of this compound is uniquely suitable for forming a second donor bond with the europium reagent **1**, but not with the thulium reagent **2**. An alternative rationale is that the angle factor implicit in the $\cos^2 \phi$ term of the formulation of the pseudo-contact interaction is different for europium (**1**) than it is for thulium (**2**). We prefer to wait for additional mechanistic insight before commenting further. It is, however, interesting to note that the large value of $J_{4,5}$ 7.8 Hz for **4** implies that H-5 is *transoid* with respect to H-4 and is hence located quite near to the C-3 hydroxyl group. For the present it suffices to note that this behavior would certainly not have been expected on the basis of simplistic arguments.

A further chance observation, which we have not yet had the opportunity to pursue is that the

magnitudes of induced shifts appear to be significantly solvent dependent. For example we have measured the shift-changes of the D-*gluco* derivative **4**, induced by europium (**1**), for both chloroform (or deuterochloroform) and carbon tetrachloride solutions. For H-1, -3, and -5, the shift induced by a certain amount of europium (**1**) is 2.2 times larger in a carbon tetrachloride solution than it is for a chloroform solution. Should this observation have any generality it will provide the basis for some interesting chemical speculations.

To the best of our knowledge our preliminary communication (1) contains the only reference to date of the temperature dependence of lanthanide induced chemical shift changes; as the temperature is decreased so the magnitude of the shift increases. This has a number of important implications which we shall discuss elsewhere. Suffice for the present comment that it is possible to increase the "effectiveness" of a lanthanide reagent by decreasing the temperature at which the measurements are made. For example, as part of a separate series of experiments (11) we made the measurements summarized in Table 3. For H-5 the shift induced at *ca.* −47 °C by 9.4×10^{-2} mol equiv of **1** is 2.5 times that produced by the same amount of reagent at 33°C.

In a preliminary communication Crump and coworkers (8*b*) have suggested that the absolute concentration of a solution is important in determining the magnitude of an induced shift. We have repeated on several occasions the measurements discussed in this paper and do find discrepancies between individual determinations; however, we have detected no systematic regularity in these deviations and feel that it is quite likely that they represent the large experimental errors associated with this type of measurement. It is noteworthy, however, that in our experiments the *molar* concentrations of both lanthanide and substrate (*ca.* 0.6 *M*) are varied simultaneously. Other experiments which involve only changes in lanthanide do indeed show a substrate dependence (11). The same workers (8*b*) have also commented that "... the shift ratios of protons in any given substrate remain the same whichever lanthanide is used". That our chemical shift changes appear to be in very poor accord with this suggestion is demonstrated by the data summarized in Table 4.

In summary then, we have shown that lanthanide tris{dipivaloylmethane} derivatives do indeed produce useful chemical shift changes in the ^{1}H n.m.r. spectra of carbohydrates and that the reagents are used most effectively by dropwise addition of aliquots of a dilute solution. Even for potentially polyfunctional derivatives of the sort described in this paper, the induced chemical shift changes are proportional to the amount of reagent added; extrapolation of chemical shifts back to zero lanthanide concentration then affords the basic chemical shift data of the substrate system, providing that the substrate has been rigorously dried. Insofar as the induced shifts are very dependent on the temperature at which the measurements are made, it is obvious that it may prove difficult to intercompare data obtained in different laboratories, indeed it is often very difficult to obtain reproducible data. Finally, we have shown that assumptions as to which particular proton is likely to undergo the largest change in shift may lead to erroneous assignments.

Further studies on lanthanide shift reagents are clearly of interest; for example, the stoichiometry of the lanthanide-substrate equilibrium is not yet known. In particular it seems necessary to develop a fuller model for the relationship between the magnitudes of induced shifts and the conformations of both the free and associated substrates.

Experimental

Europium tris{dipivaloylmethane} (**1**) was prepared from europium oxide[4] following the method of Eisentraut and Sievers (9). The thulium reagent **2** and the praseodymium reagent **3** were prepared by the same route, but starting from the corresponding nitrate salt.[4] 2,2,6,6-Tetramethyl-3,5-heptanedione was purchased from Eastman Organic Chemicals, a division of Eastman Kodak Co.

The carbohydrate derivatives **4**–**7** were stock samples and had m.p. and n.m.r. parameters in entire accord with the assigned structures.

A sample of the lanthanide reagent and of the carbohydrate were vacuum sublimed immediately prior to an experiment. The lanthanide was dissolved in either deuterochloroform, chloroform, or carbon tetrachloride (*ca.* 0.4 g/ml). Aliquots of this standard solution were added via a 0.10 ml syringe to a solution of the carbohydrate (*ca.* 0.18 g/ml).

All n.m.r. measurements were made with a modified Varian HA-100 spectrometer, operating in the frequency-swept mode with a probe temperature of 35.0 °C. For experiments using the europium and thulium reagents (**1**, **2**) deuterochloroform solutions were used, with internal tetramethylsilane as the reference signal for the field-frequency lock. Experiments with the praseodymium reagent **3** were made with chloroform [5] solutions and the chloroform resonance was used to provide a lock signal; some tetramethylsilane was added to provide a chemical shift reference.

This work was supported by grants from the National Research Council of Canada. It is a pleasure to thank Dr. Peter Legzdins of this Department for many helpful discussions concerning the synthesis and handling of lanthanide derivatives.

Kinetics and Mechanism of Hydrogen Exchange in the 2,4,6-Trihydroxybenzenonium Ion[1]

A. J. KRESGE,[2] Y. CHIANG,[2] AND S. A. SHAPIRO

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received May 17, 1971

The n.m.r. line-broadening method was used to measure rates of hydrogen exchange in the 2,4,6-trihydroxybenzenonium ion (carbon-protonated phloroglucinol) in a series of concentrated sulfuric and perchloric acid solutions. Comparison of separately determined rates of exchange of protons in the methylene and vinyl groups of this ion allows a concerted mechanism for the exchange reaction to be excluded and shows that exchange must occur through intermediate formation of completely deprotonated 1,3,5-trihydroxybenzene. This assignment of reaction mechanism allows transformation of the data into deprotonation rate constants, which, together with previously measured positions of equilibrium, permit estimation of specific rates of protonation of 1,3,5-trihydroxybenzene, k_+; the latter are in good agreement with the rate of aromatic hydrogen exchange of 1,3,5-trihydroxybenzene measured by an isotopic tracer method at lower acidities. The kinetic acidity dependence of k_+ is unusually shallow; this, coupled with the much steeper acidity dependences of other aromatic protonation reactions, serves to reinforce the growing realization that there is no unique relationship between kinetic acidity dependence and reaction mechanism.

La méthode d'élargissement de raies en r.m.n. a été utilisée pour mesurer les vitesses d'échange d'hydrogène dans l'ion trihydroxy-2,4,6 benzenonium (phloroglucinol protoné sur un carbone) dans une série de solutions d'acide sulfurique et d'acide perchlorique concentré. La comparaison des vitesses d'échange des protons des groupes méthylènes et vinyles de cet ion déterminées séparément, permet d'exclure un mécanisme concerté pour la réaction d'échange et montre que cet échange doit se faire par l'intermédiaire du trihydroxy-1,3,5 benzène entièrement déprotoné. L'attribution de ce mécanisme réactionnel permet de traduire ces résultats en constantes de vitesses de déprotonation, lesquelles, en liaison avec les positions d'équilibre, préalablement mesurées, permettent une estimation des vitesses spécifiques k_+, de protonation du trihydroxy-1,3,5 benzène. Ces dernières sont en bon accord avec la vitesse d'échange d'hydrogène aromatique du trihydroxy-1,3,5 benzène mesurée par une méthode de traceur isotopique à plus faible acidité. L'influence de l'acidité sur la constante cinétique k_+ est inhabituellement faible; ceci, relié à l'influence beaucoup plus forte de l'acidité sur d'autres réactions de protonation de composés aromatiques permet de renforcer l'idée qu'il n'y a pas de relation unique entre l'influence de l'acidité sur la cinétique et le mécanisme de la réaction.

Canadian Journal of Chemistry, 49, 2777 (1971)

Introduction

Comparison of the acidity dependence of the rate of aromatic hydrogen exchange (eq. 1) in concentrated acid solutions with the acidity dependence of the position of equilibrium between the aromatic substrate and its benzenonium ion conjugate acid (eq. 2) has, within recent years, afforded new insight into the nature of concentrated acid solutions (1–6). These conclusions rest upon the assumption that acid-catalyzed exchange occurs only through successive protonation and deprotonation of the aromatic substrate, and that the kinetic and equilibrium measurements therefore refer to the same chemical reaction. Should exchange take place by some other reaction path which circumvents proton addition or removal, such as, for example, a concerted mechanism which exchanges protons in the benzenonium ion while avoiding deprotonation (eq. 3), these conclusions would be upset.

[1] 
[2] 
Fortunately, it is possible to test for the presence of such a concerted reaction, for that mechanism and the deprotonation–reprotonation reaction scheme lead to different ratios of rates of exchange at different sites in the benzenonium

[1]Aromatic Protonation X. For Part IX, see ref. 6.

[3] 
[4] 
ion. Consider, for example, the case of phloroglucinol, the molecule used in the present study. When hydrogen exchange in the conjugate acid of this substance, the 2,4,6-trihydroxybenzenonium ion (**1**), occurs by the deprotonation–reprotonation mechanism, free 1,3,5-trihydroxybenzene is formed, and this then reaccepts a proton with equal probability at any one of its three equivalent basic sites (eq. 4). The specific rates of these three reprotonation reactions must be the same, but it is useful to distinguish them as k_1, k_2, and k_3 because the consequences of the three reactions on the lifetimes of the methylene group hydrogens and the vinyl group hydrogens of the 2,4,6-trihydroxybenzenonium ion, τ_m and τ_v respectively, are different. Reprotonation at the same site replaces one of the methylene group hydrogens but restores the other to its original state; the coefficient of k_1 in the rate law for methylene group exchange is therefore 0.5 (eq. 5).

$$[5] \quad -d[{=}CH_2]/dt = (0.5k_1 + k_2 + k_3)[THB] = 2.5k[THB]$$

Reprotonation at a different site, on the other hand, removes the original methylene group completely, and the coefficients of k_2 and k_3 in this rate law are therefore each unity. Exchange of vinyl group hydrogens is not effected at all by reprotonation at the same site, and only half of the original vinyl group is lost by reprotonation at either one of the other sites; this leads to the rate law for vinyl group exchange given as eq. 6.

$$[6] \quad -d[{=}CH{-}]/dt = (0.0k_1 + 0.5k_2 + 0.5k_3)[THB] = 1.0k[THB]$$

Comparison of eqs. 5 and 6 shows that exchange of methylene group hydrogens will occur 2.5 times as fast as exchange of vinyl group hydrogens ($\tau_v = 2.5\tau_m$) provided that the deprotonation–reprotonation mechanism is operating.

The concerted mechanism requires proton removal and proton addition to occur at different sites, and it therefore necessarily leads to formation of a new benzenonium ion at each act of exchange (eq. 7). This has the effect of blocking one of the reactions which occur in the deprotona-

tion–reprotonation reaction scheme, and that leads to the rate laws shown in eqs. 8 and 9. The

$$[8] \quad -d[{=}CH_2]/dt = (k_2' + k_3')[THBH^+] = 2.0k'[THBH^+]$$

$$[9] \quad -d[{=}CH{-}]/dt = (0.5k_2' + 0.5k_3')[THBH^+] = 1.0k'[THBH^+]$$

concerted mechanism, therefore, gives a rate of exchange of methylene group hydrogens which is only twice that of the vinyl group hydrogens ($\tau_v = 2.0\tau_m$), a prediction different from that for the deprotonation–reprotonation mechanism.

It is difficult, if not impossible, to compare rates of methylene and vinyl group hydrogen exchange in benzenonium ions using the conventional tracer method of monitoring aromatic hydrogen exchange. Benzenonium ions, however, generally give well-separated methylene and vinyl group n.m.r. signals, which, under certain conditions, experience lifetime broadening and can therefore be used to determine rates of hydrogen exchange (7). The 2,4,6-trihydroxybenzenonium ion is particularly well suited for this purpose, for its spectrum contains only two lines at τ 3.7 (vinyl group) and 5.9 p.p.m. (methylene group) which broaden appreciably in moderately concentrated aqueous sulfuric and perchloric acids (8). This substance was therefore chosen for the present test of the concerted mechanism.

Experimental

Materials

The water of hydration was removed from phloroglucinol dihydrate (Fisher Scientific Co., Reagent Grade) by drying in an oven at 110° for 24 h. Acetone was Mallinckrodt ANALAR grade and was used without further treatment. Reagent grade 95% sulfuric acid and 70% perchloric acid were diluted with distilled water to approximately desired strengths, and exact concentrations were then determined by titration (by weight) with standard base.

Solutions for kinetic measurement were prepared by combining weighed amounts of anhydrous phloroglucinol and acid solution, adding a trace of acetone and shaking (and sometimes heating gently) to complete solution. Since the effect of added phloroglucinol on H_0 values and other measures of the acid strength of concentrated solutions is not known, phloroglucinol concentrations were kept as low as possible (2–4 weight % = 0.3–0.5 *M*) without impairing the quality of the n.m.r. signals, and acid strengths were evaluated on the basis of the acid concentration before phloroglucinol was added. Molarities and acidity function values were calculated from weight % using recently provided interpolation functions (9*a*, 10).

Kinetics

Spectra were taken with a Varian A-60 spectrometer operating at an r.f. field no greater than 0.05 mG and a sweep rate of 0.1–0.2 Hz/s; the fact that all lines were accurately Lorentzian in shape indicates that these conditions ensured slow passage and avoided saturation. The methylene and vinyl group portions of the spectra were recorded on ordinary chart paper using a convenient horizontal scale (0.5–2 Hz/cm) and a spectral amplitude sufficient to give a large vertical deflection; each line was scanned 3–4 times in order to average out noise. The sample (probe) temperature was determined by measuring the separation between hydroxyl and methyl group signals from a sample of methanol and using relationships between this parameter and temperature provided in the literature (11). During the course of a day's operations, temperature fluctuations never exceeded 0.2°, but variations from day to day sometimes were of the order of 1°. The experiments in H_2SO_4 were done at 33.1–33.8° and those in $HClO_4$ at 32.7–34.0°.

Full line widths at half-heights, $\delta\nu$, were determined from these traces by reading off intensities, I_l, at 15–25 frequencies, ν_l, spaced regularly throughout each line, and then fitting these data by the method of least squares to the Lorentzian line-shape function given as eq. 10.

$$[10] \quad \frac{I_l - I_0}{I_{max} - I_0} = \frac{1}{1 + [(2/\delta\nu)(\nu_l - \nu_0)]^2}$$

In this expression, I_0 is the base line and I_{max} is the maximum intensity, *i.e.* the peak height at the mid-point of the spectral line, ν_0. This function falls off only very gradually at distances far removed from ν_0, and it is significant, therefore, that base lines obtained by least squares fit were usually lower by appreciable amounts (as much as 50%) than base lines drawn by eye through the bottoms of the spectral lines; this indicates that the scans seldom covered a frequency range large enough for accurate visual analysis. Compliance to eq. 10 containing the least squares parameters was invariably well within the experimental uncertainty of the data; on the other hand, when visually-determined parameters were used in the equation, the fit was usually poor, especially in the spectral tails.

Average lifetimes, τ, of methylene or vinyl group hydrogens were calculated from line-widths using eq. 11.

$$[11] \quad \pi\delta\nu = \tau^{-1} + T_2^{-1}$$

The natural line-width in the absence of hydrogen exchange, T_2^{-1}, was approximated as the width at half-height of the signal from a trace of acetone dissolved in each kinetic sample. This signal proved to be wider for H_2SO_4 solutions than for $HClO_4$ solutions, but in each acid it was approximately independent of acid concentration; constant values of 0.6 Hz for H_2SO_4 and 0.4 Hz for $HClO_4$ were therefore adopted.

The data obtained in this way are summarized in Tables 1 and 2.

Results and Discussion

These kinetic experiments allow a particularly straightforward choice between the two mechanisms for hydrogen exchange in the 2,4,6-trihy-

droxybenzenonium ion, represented as eqs. 4 and 7. The data presented in Table 1 show that the average value of τ_v/τ_m measured in 11 separate experiments at four different sulfuric acid concentrations is 2.56 ± 0.07; this is within experimental error of the value 2.50 demanded by the kinetic analysis for a deprotonation–reprotonation scheme (eqs.4–6), but is clearly incompatible with $\tau_v/\tau_m = 2.00$ required for a concerted reaction mechanism (eqs. 7–9). The results for perchloric acid are in complete accord with this: $\tau_v/\tau_m = 2.50 \pm 0.06$ for 12 experiments at eight different acid concentrations.

These results show that the mechanism favored by hydrogen exchange in the 2,4,6-trihydroxybenzenonium ion is the deprotonation–reprotonation scheme shown as eq. 4, and that, at the very most, only a few per cent of the reaction can occur through the concerted mechanism of eq. 7. It would seem reasonably safe, therefore, to com-

[12] 
pare rates of aromatic hydrogen exchange with equilibria of benzenonium ion formation under the assumption that these are two different manifestations of the same chemical process.

With this mechanistic assignment in hand, it is possible to transform the data of Tables 1 and 2 into specific rates of deprotonation of the conjugate acid of phloroglucinol, k_- (eq. 12). The constant k_+ of eq. 12 is the specific rate of reprotonation at all basic sites, and it is therefore equal to the sum of the three individual rate constants k_1, k_2, and k_3 used in eq. 4. The rate law of eq. 5 can then be transformed into that shown as eq. 13, which, since the system is at equilibrium and

$$[13] \qquad \frac{-\mathrm{d}[{=}\mathrm{CH_2}]}{\mathrm{d}t} = \frac{2.5}{3.0}k_+[\mathrm{THB}]$$

$k_+[\mathrm{THB}] = k_-[\mathrm{THBH^+}]$ is equivalent to eq. 14. This shows that the specific rate of deprotona-

$$[14] \qquad \frac{-\mathrm{d}[{=}\mathrm{CH_2}]}{[\mathrm{THBH^+}]\,\mathrm{d}t} = \tau_m^{-1} = \frac{2.5}{3.0}k_-$$

tion, k_-, may be obtained by multiplying τ_m^{-1} by the factor 3.0/2.5. A similar treatment of the rate of exchange of vinyl group protons (eqs. 15 and 16) shows that k_- is also available from τ_v^{-1} but here the multiplicative constant is 3.0.

$$[15] \qquad \frac{-\mathrm{d}[{=}\mathrm{CH}{-}]}{\mathrm{d}t} = \tfrac{1}{3}k_+[\mathrm{THB}]$$

$$[16] \qquad \frac{-\mathrm{d}[{=}\mathrm{CH}{-}]}{[\mathrm{THBH^+}]\,\mathrm{d}t} = \tau_v^{-1} = \tfrac{1}{3}k_-$$

The results of this analysis are presented in Tables 3 and 4 together with some conventional measures of the acid strength of the concentrated acid solutions in which these experiments were performed. It may be seen, first of all, that k_- decreases with increasing acidity, as is appropriate for a deprotonation and therefore base-catalyzed reaction. This decrease, however, is considerably more precipitous than expected were the basic strength of these solutions just the inverse of acid concentration, and it would seem that here, as with many acid-catalyzed reactions in concentrated acid solutions, an indicator acidity function is a more appropriate measure of acid-base strength. Figure 1 shows that the H_0 function does in fact correlate the data reasonably well, giving slopes $\mathrm{d}(\log k)/\mathrm{d}(H_0)$ of 0.52 ± 0.02 in sulfuric acid and 0.42 ± 0.01 in perchloric acid.

The fact that this correlation shows essentially no difference in deprotonation rate between sulfuric and perchloric acid solutions of the same

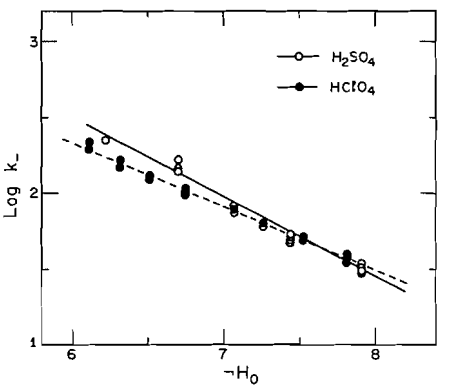

FIG. 1. Relationship between the specific rate of deprotonation of 2,4,6-trihydroxybenzenonium ion and the H_0 acidity function.

H_0 value, however, is disturbing. An indicator acidity function such as H_0 is based on equilibrium measurements, and it thus presumably reflects the equilibrium acidity of the medium. This may well be different from the kinetic acidity, and, in particular, a sulfuric acid solution, with its additional general acid-general base pair, HSO_4^-–SO_4^{2-}, available to protonate and/or deprotonate a substrate, might be expected to have a greater kinetic acidity than a perchloric acid solution of the same H_0. Such differences in kinetic and equilibrium acidity are in fact not uncommon; a particularly relevant case is the increase in the rate of detritiation of 1,3-dimethoxybenzene-4-*t* observed in going from perchloric acid solutions to sulfuric acid solutions at constant H_0 (5).

This work on 1,3-dimethoxybenzene suggests, moreover, that the H_0 scale, based as it is on primary aniline indicators, is not altogether appropriate for correlating rates of aromatic hydrogen exchange, and that an acidity function which uses indicator bases more similar in structure to the carbonium ions generated in aromatic hydrogen exchange, might be more suitable; this conclusion is reinforced by more recent investigations of equilibrium aromatic protonation (10). It is significant, therefore, that correlations of the present rate data with H_c, a recently constructed acidity function which uses only conjugate bases of carbonium ions as indicators (12), does show the present reaction to be more rapid in sulfuric acid than in perchloric acid. Perhaps even more appropriate for this purpose than the H_c function would be an acidity scale based upon phloroglucinol itself. The extent of protonation of phloroglucinol has recently been measured in sulfuric and in perchloric acids (10), and extrapolation of these data to the regions for which k_- is available gives the values of $[THBH^+]/[THB]$ listed in Tables 3 and 4. Figure 2 shows the correlation of the present rate data using this measure of acid strength; it may be seen that, at constant extent of protonation of 1,3,5-trihydroxybenzene, the 2,4,6-trihydroxybenzenonium ion loses protons to sulfuric acid *ca.* four times more rapidly than to perchloric acid.

The availability of these values of $[THBH^+]/[THB]$ makes it possible to estimate specific rates of protonation of phloroglucinol, k_+, by using the equilibrium relationship $k_+[THB] =$

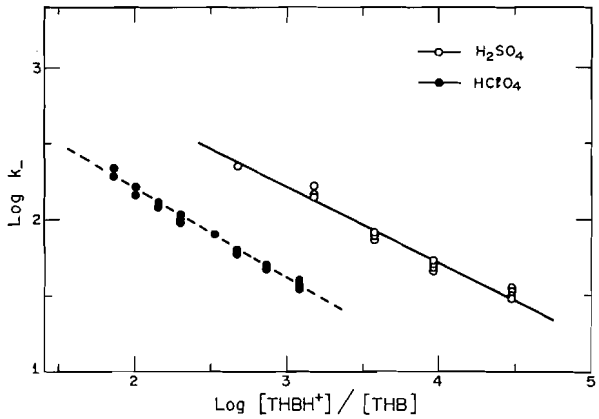

FIG. 2. Relationship between the specific rate of deprotonation of 2,4,6-trihydroxybenzenonium ion and an acidity function based upon the equilibrium protonation of 1,3,5-trihydroxybenzene.

$k_-[THBH^+]$; values of k_+ obtained in this way are listed in Tables 3 and 4. These rate constants are composed of $[THBH^+]/[THB]$ measured at 25° (10) and k_- determined at 33–34°, but the uncertainty in k_+ introduced by this difference in temperature is likely to be well under a factor of two, for extents of protonation of weak bases in concentrated acids usually do not change very rapidly with temperature (13–16). The effect of temperature, moreover, will be much the same on all of the values of $[THBH^+]/[THB]$ involved, and the uncertainty in relative values of k_+ should thus be an order of magnitude less than that in their absolute magnitude. Any conclusions drawn from the manner in which k_+ changes as a function of some other variable, *e.g.* acidity of the medium, should therefore be quite reliable.

The acidity dependence of k_+ is in fact unusually shallow; for example, in sulfuric acid $-d(\log k_+)/d(H_0) = 0.54 \pm 0.02$ and the Bunnett–Olsen parameter ϕ (17) has the value 0.49 ± 0.02, while in perchloric acid $-d(\log k_+)/d(H_0) = 0.30 \pm 0.01$ and $\phi = 0.73 \pm 0.01$. Though uncommon, this behavior is nevertheless readily understandable in terms of the two factors which control kinetic acidity dependence: (*1*) substrate structure and (*2*) transition state structure (6). The substrate here, phloroglucinol, shows a relatively shallow acidity dependence even in its equilibrium protonation, principally because its conjugate acid interacts strongly with solvent water by forming hydrogen bonds through its positively charged hydroxyl groups (10, 18). The rate of proton addition to phloroglucinol cannot show an acidity dependence any steeper than this, and, in fact, the kinetic acidity dependence should be somewhat more shallow than the equilibrium acidity dependence because this reaction, being quite rapid, will have an early transition state in which only a fraction of the equilibrium acidity dependence can be realized. In support of this is the fact that the data of Table 4 give an acidity exponent, α_A (4, 6), of 0.38 ± 0.01, which can be taken to mean that the protonation transition state lies about four-tenths of the way along the reaction coordinate between 1,3,5-trihydroxybenzene and the 2,4,6-trihydroxybenzenonium ion.

This unusually low kinetic acidity dependence, when coupled with the considerably steeper ones shown by some other aromatic protonation reactions proceeding by the same mechanism (3, 6, 16), adds to the growing realization that kinetic acidity dependence is not a sharply defined characteristic of reaction mechanism and points up the danger of drawing mechanistic conclusions from kinetic acidity dependence alone. In particular, the value of ϕ for the present reaction occurring in perchloric acid, 0.73, and that evaluated by Bunnett and Olsen (17) for the protonation of azulene using the data of ref. 16, −0.42, cover almost all of the range available to this parameter.

These relationships between k_+ and the acidity of the medium make it possible to compare the present results with the rate of aromatic hydrogen exchange in phloroglucinol measured by the tracer method at lower acidities (6). Perhaps the best function down which to make the necessary extrapolation is $\log([THBH^+]/[THB])$, and use of the relationship $\log k_+ = 3.366 + 0.415 \log([THBH^+]/[THB])$ gives a value of 2.7×10^2

s^{-1} for k_+ in 28.1 weight % $HClO_4$, the most concentrated acid in which the tracer measurements were done. These tracer experiments determined the rate of loss of tritium from one position of 1,3,5-trihydroxybenzene, and the rate constant measured, k_{-t}, therefore differs from k_+ of the present work by a statistical factor of three plus an isotope effect: $k_{-t} = (k_+/3)/(1 + k_H/k_T)$; in addition, the tracer work was done at 1.4° whereas the present measurements refer to 33–34°. Neither the temperature coefficient of k_{-t} nor the isotope effect k_H/k_T is known for 1,3,5-trihydroxybenzene, but these quantities are available for the same reaction of 1,3,5-trimethoxybenzene; since these two substrates are quite similar both in structure and in reactivity, it would seem not unreasonable to apply the trimethoxybenzene data to the present case. In the interval 1.4–33.5°, k_{-t} for 1,3,5-trimethoxybenzene increases by a factor of 22 (19) and k_H/k_T for this substrate is 20 (20); combination of these numbers with the measured value of k_{-t} for 1,3,5-trihydroxybenzene at 1.4° in 28.1 weight % $HClO_4$, 1.3×10^{-1} s^{-1} (6), gives $k_+(33.5°) = 1.8 \times 10^2$ s^{-1}. This is only 30% less than the value extrapolated from the present experiments, which, in view of the approximations made, must be considered to be very good agreement.

The authors are indebted to the National Research Council of Canada for a grant which made this research possible; to Professor W. F. Reynolds, Professor J. C. Thompson, and Mrs. A. E. Lemire for help with the nmr method of measuring reaction rates; and to Professor K. Yates, in whose laboratory this work was performed, for his most generous hospitality.

Isocarbostyrils. I. Electrophilic Substitution Reactions

D. E. HORNING, G. LACASSE, AND J. M. MUCHOWSKI[1]

Bristol Laboratories of Canada, Candiac, Quebec

Received April 19, 1971

The electrophilic substitution of *N*-alkylated isocarbostyrils was examined in considerable detail. Bromination, acylation, nitration, and acid-catalyzed condensation with formaldehyde occurred exclusively at C-4 under relatively mild conditions. The acylation of isocarbostyrils has heretofore not been reported.

The bromination of 2-methyl-5-nitroisocarbostyril in aqueous acetic acid gave 2-methyl-3,4-dihydro-3-hydroxy-4-bromo-5-nitroisocarbostyril (7) of unknown stereochemistry, as the sole product. When heated above its melting point, 7 lost the elements of water to give the "normal" product of bromination **8**.

In aqueous acetic acid, excess bromine was shown to convert isocarbostyrils to the corresponding 3,4-dihydro-3-hydroxy-4,4-dibromo derivatives whose structures were supported by spectral and degradative evidence.

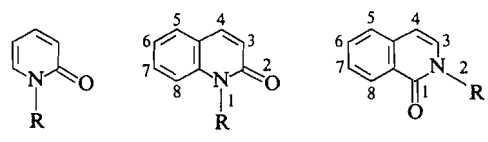
La substitution électrophile d'isocarbostyriles *N*-alkylés a été examinée avec beaucoup de soin. Sous des conditions relativement douces, la bromation, l'acylation, la nitration, et la condensation acido-catalysée avec le formaldéhyde, se fait exclusivement sur C-4. L'acylation des isocarbostyriles n'a jusqu'a présent jamais été rapportée.

La bromation du méthyl-2 nitro-5 isocarbostyrile dans l'acide acétique aqueux conduit au seul méthyl-2 dihydro-3,4 hydroxy-3 bromo-4 nitro-5 isocarbostyrile (7) de stéréochimie inconnue. Lorsque le composé 7 est chauffé au-dessus de son point de fusion, il y a élimination d'eau et formation du produit "normal" de bromation **8**.

Dans l'acide acétique aqueux, un excès de brome transforme les isocarbostyriles en dérivés dihydro-3,4 hydroxy-3 dibromo-4,4 correspondants, dont les structures sont confirmées par des preuves spectrales et de dégradation.

Canadian Journal of Chemistry, **49**, 2785 (1971)

2-Pyridone (**1**; R = H) and its *N*-alkylated derivatives are electron-rich heterocyclic systems which are generally considered to possess a substantial degree of aromatic character (1–3). These compounds undergo electrophilic substitution with ease at the 3- and the 5-positions, with substitution often, but by no means always, occurring preferentially at C-3 (4–7; see also ref. 2, pp. 659–671). Quinolin-2-one (**2**, R = H; carbostyril), isoquinolin-1-one (**3**, R = H; isocarbostyril), and the *N*-alkylated derivatives thereof, are expected to have properties somewhat similar to 2-pyridones, but with the obvious difference that electrophilic attack of the hetero ring would be confined to one carbon atom (C-3 in **2** and C-4 in **3**).



1 **2** **3**

[1]To whom enquiries concerning this paper should be addressed.

In connection with several synthetic objectives, it was necessary to examine the behavior of various electrophilic reagents toward selected members of the isocarbostyril family. When this investigation was initiated (1963), only a few examples of electrophilic substitution in the isocarbostyril[2] series had been described (8–12). These, and studies which have appeared since then, are described in the main body of this paper.

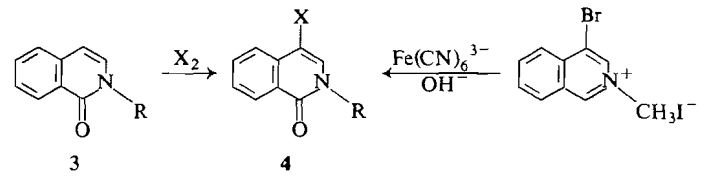
The great majority of this work was restricted to *N*-substituted isocarbostyrils because of the ease with which they were prepared from isoquinolines (see Experimental), and because an *N*-substituent was expected to ensure that the lactam form[3] was the species undergoing reaction.

Halogenation

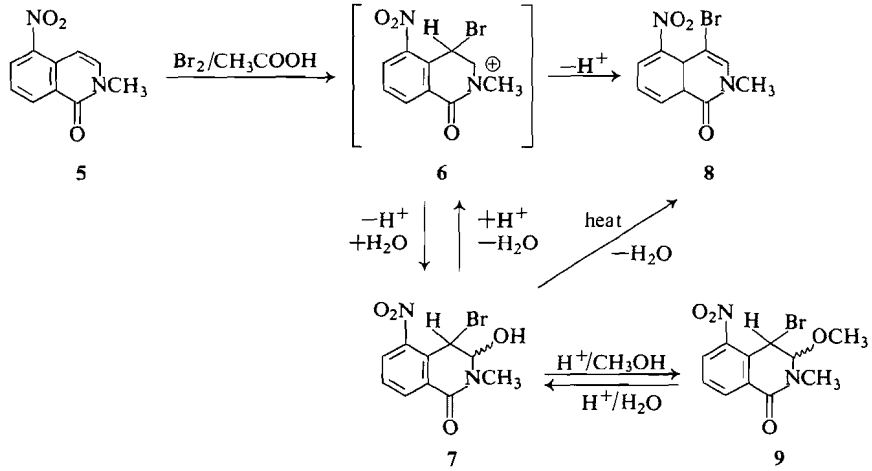
The bromination of 2-methylisocarbostyril (**3**, R = CH_3) was first described by Bamberger and Frew in 1894 (9). A monobromo compound

[2]The carbostyril series will not be considered further in this paper. References 13 and 14 should be consulted for pertinent data in this area.

[3]Electrophilic substitution of isocarbostyril (**3**, R = H) could occur via the lactam form, the enol form, or a mixture of both forms. See section on nitration, below.



SCHEME 1



SCHEME 2

of unspecified structure was obtained in high yield. In 1958, Robison and Robison (10) reported that the oxidative chlorination or bromination ($HX + H_2O_2$) of isocarbostyril produced 4-chloro- or 4-bromoisocarbostyril (**4**, X = Cl, Br; R = H: see Scheme 1) respectively. Very shortly thereafter, Ochiai and Kawazoe (12) showed that the bromination of isocarbostyril in acetic acid gave 4-bromoisocarbostyril, the structure of which was confirmed by conversion to the known 1-chloro-4-bromoisoquinoline.

In this study the addition of a molecular equivalent of bromine in acetic acid to a solution of 2-methylisocarbostyril in the same solvent, gave a monobromo compound with properties in agreement with those previously reported (9). This compound was shown to be 2-methyl-4-bromoisocarbostyril (**4**, X = Br; R = CH_3) by direct comparison with a specimen synthesized by the alkaline ferricyanide oxidation of 4-bromoisoquinoline methiodide. The bromination of several other isocarbostyrils under the same conditions gave the corresponding 4-monobromo derivatives (see Table 1) in every case but one (see below). The structures of these compounds were assigned by analogy to the examples cited above, and were supported by their characteristic n.m.r. spectral properties (see Table 2).

The bromination of 2-methyl-5-nitroisocarbostyril (**5**, see Scheme 2) under the usual conditions (*i.e.* bromine in acetic acid followed by an aqueous work-up), gave a 1:1 mixture of two monobromo compounds. One of these, a lemon yellow solid, was clearly 2-methyl-4-bromo-5-nitroisocarbostyril (**8**) as deduced from its elemental analysis and spectral properties. The other, a pale yellow solid, analyzed for $C_{10}H_9BrN_2O_4$ (*i.e.* **8** + 1 H_2O), and had a broad i.r. absorption (Nujol mull) at 3262 cm^{-1}. The n.m.r. spectrum (see Table 2) confirmed the presence of an intact 1,2,3-trisubstituted benzene system (for typical ABC spectra see ref. 17*b*), the absence of other absorptions in the aromatic region, and in addition, showed three single proton absorptions at δ 5.32 (J = 2.3 Hz), 5.79 (J = 2.3 Hz) and 6.85 ($w/2$ = 13 Hz, exchanged with D_2O). These data when viewed together left little doubt that the light yellow compound possessed the bromohydrin structure **7**. Finally, it is of interest to note that the bromination of **5** in 10% aqueous acetic acid gave **7** as the sole product, and that **7** was converted to **8** when heated to its melting point.

The formation of **7** was interpreted as occurring via the relatively stable cationic species **6** which, when produced, did not readily lose a proton because of the severe non-bonded bromine–nitro group interaction expected in the product. Instead, the carbonium ion could revert to the starting material by the expulsion of Br^+, or be trapped by a suitable nucleophile.[4] The stability of **6** was shown to be appreciable, since acid-catalyzed methanolysis of **7** gave the methyl ether **9** as the major product. It would be of considerable mechanistic interest to undertake a kinetic investigation of the bromination of **3** and its 4-deuterio derivative, to determine if the formation of **4** also occurred with rate limiting proton loss from an intermediate analogous to **6**.

The question of the stereochemistry of the bromohydrin **7** and its methyl ether **9** must now be considered. The dihedral angles between the protons on C-3 and -4 for the most stable conformers[5] of the *cis*- and the *trans*-isomers of **7** and **9**, as measured from Dreiding models, were *ca.* 50 and 70° respectively. These values corresponded to coupling constants of 3.1 Hz for the *cis*- and 0.6 Hz for the *trans*-isomers as calculated from the Karplus equation (17*a*). The measured *J* values of 2.3 and 2.8 Hz respectively, for **7** and **9**, would therefore be indicative of a *cis* disposition of the substituents in these compounds. This conclusion must, however, be regarded with circumspection on at least two counts. Firstly, it is not known whether the so called less favored conformer of the *trans*-isomer can in reality be disregarded completely. As little as 20–25% of this conformer would make the calculated *J* values agree with those observed. Secondly, the known (18) effect of electronegative substituents on vicinal H–H coupling constants makes a stereochemical assignment especially hazardous when both isomers are not available.

In view of the likelihood that **9** (and probably **7** on the basis of the similar *J* value) was the product of thermodynamic control, an unambiguous assignment of its geometry would clearly be of interest.[6]

In connection with other synthetic studies, it was necessary to determine if the polybromination of isocarbostyrils could be effected. The addition of a molecular equivalent of bromine to 2-methyl-4-bromoisocarbostyril (**12**, R = CH_3; R′ = H; see Scheme 3) resulted in the relatively slow formation of a dibromo alcohol **11** (R = CH_3; R′ = H), which could also be obtained directly from 2-methylisocarbostyril (**10**, R = CH_3; R′ = H) and an excess of bromine.[7] The structure of this compound was established on the basis of analytical, spectral, and degradative evidence. For example, oxidation of the above dibromo carbinolamide with sodium dichromate in sulfuric acid gave the known (19) dibromo imide **13**, which was reduced with potassium iodide in aqueous acetic acid to *N*-methylhomophthalimide (**14**).

The bromination of isocarbostyril (**10**, R = R′ = H) and 2,3-dimethylisocarbostyril (**10**, R = R′ = CH_3) gave dibromo carbinolamides analogous to that derived from 2-methylisocarbostyril. In no case was there any evidence (i.r., n.m.r.) for the existence of the open chain tautomer **15** of **11**. Similar conclusions can be drawn from the published spectral data for cyclic carbinolamides in the 2-azaphenalone series (20).

Acylation

The acylation of isocarbostyrils does not appear to have heretofore been reported (see note added in revision at end of discussion).

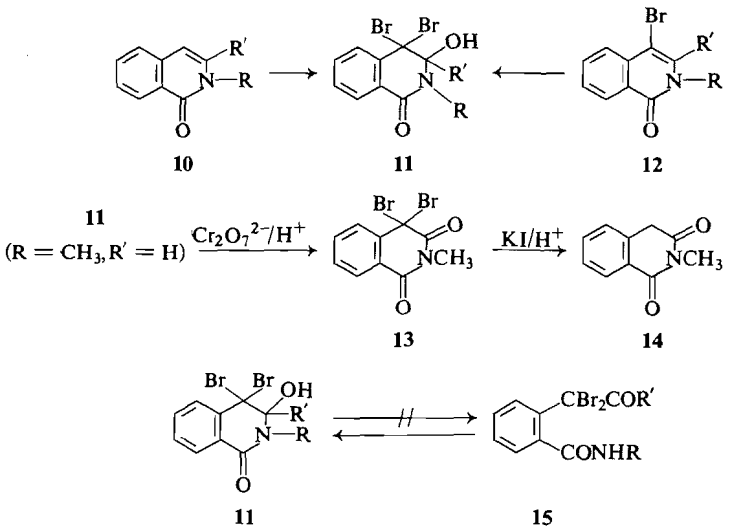
Vilsmeier–Haack formylation of 2-methylisocarbostyril (Scheme 4) gave a mono aldehyde

[4]Examples of steric retardation of product formation in the bromination of certain aromatic systems are known; *e.g.* see refs. 15 and 16.

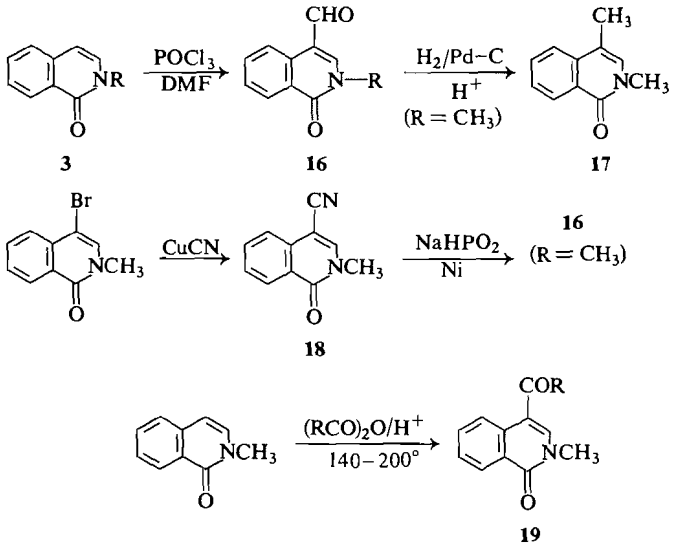
[5]There were two possible conformers for each isomer, but in both cases, one conformer was considered as less likely because of a large non-bonded repulsion between the 4-bromo and the 5-nitro groups. The dihedral angle for both conformers of the *cis*-isomer was the same (*ca.* 50°); for the less favored (?) conformer of the *trans*-isomer, the measured angle was *ca.* 175° (*J* = 9.2 Hz).

[6]A referee has suggested that some information concerning the stereochemistry of **7** and **9** might be derived from a study of the behavior of **7** towards base. This possibility had already been examined by us in a cursory way, but the results obtained were not interpretable in a clear cut manner. For example, **7** did react with sodium hydride in dimethylformamide, but a complex mixture of products (six by t.l.c.), at least some of the components of which still contained halogen (strong positive Beilstein test), was obtained.

[7]Normally these brominations were effected in 10% aqueous acetic acid, but the same products were obtained if the reaction was performed in glacial acetic acid. This would tend to indicate that in the absence of water, the product was either a tribromide, a dibromo acetate, or a mixture of both, and that the carbinolamide was produced during the aqueous work-up.



SCHEME 3



SCHEME 4

(**16**, R = CH_3; see Tables 3 and 4) which was catalytically reduced to a dimethylisocarbostyril **17** different from 2,3-dimethylisocarbostyril. That the formyl group had occupied the 4-position was proved unequivocally by the synthesis of **16** (R = CH_3) from 2-methyl-4-cyanoisocarbostyril (**18**).

2-Benzylisocarbostyril (**3**, R = $C_6H_5CH_2$) furnished a product analogous to **16** (R = CH_3), but isocarbostyril itself reacted very slowly under the same conditions to produce 1-chloroisoquinoline.

Other acyl groups could be incorporated into the isocarbostyril system by the sulfuric acid catalyzed acylation with carboxylic acid anhydrides. For example, a solution of 2-methylisocarbostyril in acetic anhydride containing the catalyst gave the 4-acetyl derivative **19** (R = CH_3) in 72% yield, after 1 h at reflux temperature. The 4-benzoyl analogue **19** (R = C_6H_5) was obtained under somewhat more vigorous conditions from benzoic anhydride (40% yield from isoquinoline methiodide). Sainsbury *et al.* (21) have prepared this compound in poor yield

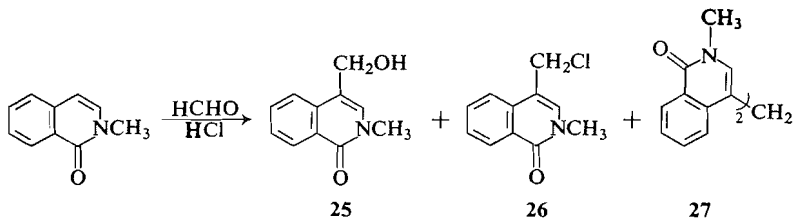

SCHEME 6

(12% from isoquinoline methiodide) by the aerial oxidation of the product of benzoylation of 2-methyl-1,2-dihydroisoquinoline.

Nitration

In 1886, Gabriel (8) reported that treatment of 3-phenylisocarbostyril (**20**, R = H; R′ = C_6H_5; see Scheme 5) with dinitrogen tetroxide in acetic acid gave the 4-nitro derivative **21** (R = H; R′ = C_6H_5), but no evidence was given in support of this structure. The nitration of isocarbostyril with potassium nitrate in sulfuric acid has been said (11) to produce 6- and 8-nitroisocarbostyril, but this disclosure was undoubtedly erroneous since Kawazoe and Yoshioka (13) have recently shown that the n.m.r. spectra of the two major products were fully consistent with 5- (**22**) and 7-nitroisocarbostyril (**23**) respectively. These authors also described the formation of a third mono nitro compound (trace amounts) to which they tentatively assigned the 4-nitro structure **24**.

We have studied the nitration of 2-methylisocarbostyril (**20**, R = CH_3; R′ = H) with nitrous acid in acetic acid (22) and with nitric acid in acetic anhydride (acetyl nitrate). The same mono nitro compound was obtained in both cases. The n.m.r. spectrum (Table 4) of this compound was fully compatible with that expected for 2-methyl-4-nitroisocarbostyril (**21**, R = CH_3; R′ = H). Since we have never observed electrophilic substitution at any position other than C-4, even when conditions were such that disubstitution could have taken place, it is tempting to suggest that the major nitration products observed by Kawazoe and Yoshioka were those derived from the *N*-protonated hydroxy tautomer of isocarbostyril.[8] This proposal is not consistent, however, with the results of the sulfuric acid promoted deuteration experiments[9] which showed that the proton at C-4 is most readily exchanged.

Condensation with Formaldehyde

Tomisawa *et al.* (23) recently reported that 2-methylisocarbostyril condensed with formaldehyde to give mixtures of products, the composition of which depended on the reaction conditions. For example, in the presence of hydrochloric acid, acetic anhydride, and sodium acetate (100°), a 1:1 mixture of the alcohol **25** (see Scheme 6) and the bis-isocarbostyrilmethane **27** was obtained. In the absence of sodium acetate and at room temperature, a 1:3 mixture of the chloro-

[8]Indeed, this proposal has been made by Kawazoe and Yoshioka (13) to account for the above results.

[9]In 61% D_2SO_4, H-4 of isocarbostyril was completely exchanged after 4 h at 140°; H-5 and -7 were totally exchanged after 4 h at 180° (13).

methyl compound **26** and the bis-isocarbostyrilmethane **27** was produced.

Our interest in the above condensation stemmed from an attempt to effect an acid-catalyzed (hydrochloric acid) Mannich reaction between 2-methylisocarbostyril, paraformaldehyde, and dimethylamine hydrochloride (refluxing ethanol). The only product, formed in low yield, was the bis-isocarbostyrilmethane (**27**). This compound was produced in significantly better yield when the reaction time was lengthened and when dimethylamine hydrochloride was omitted from the reaction mixture. The same compound was obtained as a by-product during the acid-catalyzed hydrogenolysis of 2-methylisocarbostyril-4-aldehyde (**16**, R = CH_3).

In summary, isocarbostyrils undergo electrophilic substitution with an ease approaching that observed for indoles, although the substitution pattern of the latter group of compounds bears only a superficial resemblance to that described for isocarbostyrils (24). The accessibility of 4-substituted isocarbostyrils opens up an area with a substantial synthetic potential. The following paper (25) describes one application of some of the data described herein.

Note Added in Revision

After this manuscript had been submitted to the referees, Professor H. Tomisawa (Tohoku College of Pharmacy, Sendai, Japan) informed us that he also had successfully acylated *N*-substituted isocarbostyrils, and that these results were presented at the annual meeting of the Japanese Pharmaceutical Society in the summer of 1970. We thank Professor Tomisawa for providing us with this information.

Experimental

The melting points were determined in a Gallenkamp m.p. apparatus and are not corrected.

Preparation of the 2-Alkylisoquinolinium Iodides

2-Methylisoquinolinium iodide was prepared according to the method of Freund and Bode (26). The other 2-alkylisoquinolinium salts were prepared as follows.

A solution of the isoquinoline in acetonitrile (30 ml/g of the base) containing a 10 mol % excess of the alkyl iodide (benzyl iodide was prepared *in situ* from equimolar amounts of benzyl chloride and anhydrous sodium iodide (15 min in boiling acetonitrile followed by filtration to remove sodium chloride)) was heated at reflux temperature for 1–17 h. If the salt did not crystallize on cooling, the acetonitrile was removed *in vacuo* and the residue was crystallized from a suitable solvent. The yields of the pure salts ranged from 70–90%. All of the salts but one (see below) were known compounds and had physical constants in agreement with those given in the literature.

2-Methyl-4-cyanoisoquinolinium iodide was obtained in 88% yield. After crystallization from alcohol it had m.p. 255–256°.

Anal. Calcd. for $C_{10}H_6N_2$:CH_3I: C, 44.62; H, 3.06. Found: C, 44.74; H, 3.34.

Preparation of the Isocarbostyrils

Isocarbostyril was prepared either by the method of Chichibabin and Kursanova (27) or by the method of Robison and Robison (28).

All of the *N*-substituted isocarbostyrils but two (see below) were prepared by the alkaline ferricyanide oxidation of the corresponding 2-alkylisoquinolinium iodides. The method was in essence that described by Haworth and Perkin (29). The general procedure is given below.

To a stirred solution of the isoquinolinium salt (0.05 mol) in water (250 ml) was added a solution of 85% potassium hydroxide (11.22 g) in water (110 ml). This was followed immediately by the addition of a solution of potassium ferricyanide (49.4 g) in water (300 ml). The mixture was stirred for 1 h at room temperature, the product was extracted into a suitable solvent, and then purified by distillation or by crystallization from an appropriate solvent. The yields ranged from 45–95%.

2,3-Dimethylisocarbostyril (**10**, R = R′ = CH_3) was obtained in very low yield by the above method. It was, however, preparable in satisfactory yield as follows:

2,3-Dimethylisoquinolinium iodide (37.0 g, 130 mmol) was added all at once to a solution of 85% potassium hydroxide (34.3 g) in water (650 ml). The mixture was stirred at room temperature under a slight positive pressure of oxygen for 2.5 h. The mixture was then stirred with dichloromethane (100 ml) and benzene (150 ml) until the solids were dissolved. The organic phase was separated and combined with a benzene extract of the aqueous phase. The aqueous phase was stirred under oxygen for an additional 24 h and then extracted as above. The combined extracts were washed with 10% hydrochloric acid (to remove the 1,2-dihydroisoquinoline), and then with water. The extract was dried over sodium sulfate, the solvent was removed *in vacuo*, and the solid residue was recrystallized from cyclohexane (charcoal) to give 8.7 g (39%) of a solid m.p. 100–102° (lit. (30) m.p. 101–102°).

Monobromination of the Isocarbostyrils

The following procedure was typical. To a stirred solution of the isocarbostyril in glacial acetic acid (10–20 ml/g) was added an equimolar amount of bromine in acetic acid (5–10 ml/g of bromine) at a rate such that the reaction temperature did not exceed 30°. After an additional 0.5 to 1.5 h at room temperature the reaction mixture was poured into a large volume of ice-water, the mixture was stirred for *ca.* 10 min, and the product was extracted into dichloromethane or collected by filtration. The physical constants and spectral data for these compounds are recorded in Tables 1 and 2.

When 2-methyl-5-nitroisocarbostyril (**5**) was brominated in the above manner a 1:1 mixture of compounds **7** and **8** was obtained. After crystallization of the mixture from benzene the two products were separated mechanically and crystallized to constant m.p. Compounds **7** and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

8 were more conveniently prepared in the manner described below.

2-Methyl-3,4-dihydro-3-hydroxy-4-bromo-5-nitroisocarbostyril (7)

To a solution of 2-methyl-5-nitroisocarbostyril (4.09 g, 20.1 mmol) in 10% aqueous acetic acid (200 ml) was added a solution of bromine (6.42 g, 40.2 mmol) in the same solvent system (50 ml). After 5 h at room temperature the reaction was poured into a large volume of ice-water and the product was extracted into dichloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was slurried with 1,2-dichloroethane and the insoluble material (4.54 g, 79%) was collected by filtration. It was identical to the bromohydrin obtained as one component of the mixture described above.

2-Methyl-4-bromo-5-nitroisocarbostyril (8)

The above bromohydrin (602 mg, 2 mmol) was heated at 150°/10 mm for 10 min. The residual solid was crystallized from 1,2-dichloroethane to give a lemon yellow solid (461 mg, 81%) m.p. 225–230° (dec). Three further crystallizations gave material m.p. 231–233° (dec.) identical to the sample obtained as part of the mixture described above.

2-Methyl-3,4-dihydro-3-methoxy-4-bromo-5-nitroisocarbostyril (9)

A solution of the bromohydrin **7** (2.00 g, 6.65 mmol) and *p*-toluenesulfonic acid monohydrate (20 mg) in methanol (35 ml) was heated under reflux for 3 h. When the solution was cooled in ice, a solid (1.81 g, 86%), m.p. 138–143°, crystallized from solution. Three further crystallizations of the methoxy compound raised its m.p. to 146–148°. Evaporation of the original mother liquor and crystallization of the residue from 1,2-dichloroethane gave a solid (108 mg, 6%), m.p. 226–228° identical to the bromoisocarbostyril (**8**) described above.

Dibromination of the Isocarbostyrils

A solution of the isocarbostyril in 10% aqueous acetic acid (20–30 ml/g) was treated in the usual manner with 3 mol equiv of bromine in the same solvent system (5 ml/g of bromine). When the addition was completed stirring was continued for 2–3 h at room temperature and then the mixture was poured with stirring into a large volume of ice-water. After *ca.* ½ h the product was collected by filtration or extracted into a suitable solvent. Further purification of these materials was effected by crystallization from a suitable solvent. See Tables 1 and 2.

N-Methyl-4,4-dibromohomophthalimide (13)

A stirred solution of the dibromocarbinolamide (**11**, R = CH_3 = R′= H; 3.35 g, 10 mmol) in acetic acid which was 2.5 *M* in sulfuric acid (200 ml) was treated with 0.694 *M* sodium dichromate solution in 2.5 *M* sulfuric acid (5.64 ml, 3.66 mmol) at a rate such that the reaction temperature did not exceed 35°. When the addition was completed, stirring at room temperature was continued for 1 h, the mixture was then poured into a large volume of ice-water and the product was extracted into dichloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. Crystallization of the residue from benzene–cyclohexane (1:2) gave the product in two crops, m.p. 151–154 (2.943 g) and 145–150° (0.411 g) (lit. (19) m.p. 140°).

N-Methylhomophthalimide (14)

Pulverized potassium iodide (1.332 g, 8 mmol) was added to a solution of the dibromohomophthalimide (0.333 g, 1 mmol) in 30% aqueous acetic acid (20 ml). The liberated iodine was destroyed by the addition of solid sodium bisulfite. The clear solution was poured into a large volume of ice-water, the product was extracted into dichloromethane, the extract was washed with water, and then dried over sodium sulfate. The solvent was removed *in vacuo* and the residue was sublimed at 70°/0.001 mm to give *N*-methylhomophthalimide (0.161 g, 92%) m.p. 120–122°. A mixed melting point with an authentic specimen of *N*-methylhomophthalimide (34) was undepressed.

Vilsmeier–Haack Formylation of the Isocarbostyrils

The formylating agent was prepared in the usual manner at 0° from dry dimethyl formamide (39.2 g, 440 mmol) and phosphorous oxychloride (16.9 g, 110 mmol). A solution of the isocarbostyril (100 mmol) in dry dimethylformamide (13 g) was added dropwise at 0° with stirring over a 0.5 h period, and then the reaction was heated on a steam bath for 2.5–4 h. The hot solution was poured into ice-water and the product was isolated by filtration, or by extraction into a suitable solvent. Further purification was effected by crystallization from an appropriate solvent system (see Table 3).

Preparation of 2-Methyl-4-formylisocarbostyril (16, R = CH_3) from 2-Methyl-4-cyanoisocarbostyril (18)

The nitrile **18** was prepared from 2-methyl-4-bromoisocarbostyril and cuprous cyanide in *N*-methyl-2-pyrrolidone (31); *e.g.*, a mixture of the bromoisocarbostyril (0.900 g, 3.78 mmol) and cuprous cyanide (0.610 g, 6.82 mmol) in *N*-methyl-2-pyrrolidone (10 ml) was heated at reflux temperature for 2.5 h. The hot solution was poured into aqueous sodium cyanide solution (50 ml, 25% (weight)), the mixture was shaken vigorously and then filtered through Celite. The filter cake was washed with dichloromethane, the organic phase was separated and combined with a dichloromethane extract of the aqueous phase. The solvent was removed *in vacuo*, the residue was dissolved in toluene, and the resulting solution was washed with 10% (weight) sodium cyanide solution and then with water. The dried solution (sodium sulfate) was evaporated *in vacuo* and the residue was crystallized from benzene to give the nitrile (0.451 g, 65%) m.p. 195–197°. One recrystallization of this solid gave material with m.p. 197–199° identical in all respects to the nitrile obtained by the alkaline ferricyanide oxidation of 2-methyl-4-cyanoisoquinolinium iodide. Thuillier *et al.* (32) reported m.p. 198° for this compound.

A suspension of the nitrile (0.802 g) and sodium hypophosphite (1.6 g) in 1:1:2 water – acetic acid – pyridine (28 ml) containing Raney nickel (0.5 g) was stirred at 40–45° for 4 h (see ref. 33). The solution was poured into water and extracted with dichloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was crystallized from 1:1 benzene:cyclohexane to give the aldehyde

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(0.360 g) m.p. 151–153°. Several crystallizations gave material m.p. 155–156° identical in all respects with that prepared by the Vilsmeier–Haack method.

*2,4-Dimethylisocarbostyril (**17**)*

A solution of the above aldehyde (7.48 g, 40 mmol) in glacial acetic acid (200 ml) containing perchloric acid (8 ml, 60–62%) and 10% palladium-on-charcoal (750 mg) was hydrogenated at room temperature and an initial hydrogen pressure of 46 p.s.i.g. After 13 h the catalyst was removed by filtration through Celite. The filtrate was concentrated to a small volume *in vacuo*, the residue was diluted with water and extracted with dichloromethane. The extract was washed with sodium carbonate solution (50 g/l), then with water, and finally it was dried over sodium sulfate and evaporated *in vacuo*. The residue was separated into a benzene soluble oil and a benzene insoluble solid. The solid (1.10 g, 17%) had m.p. 290–298°. On crystallization from acetonitrile, material with m.p. 297–302°, with an i.r. spectrum indistinguishable from the bis-isocarbostyril methane **27**, was obtained.

The benzene solution from above was evaporated *in vacuo* and the residue was evaporatively distilled at 140°/0.01 mm to give an oil (4.57 g, 66%) which solidified spontaneously. After crystallization from cyclohexane and sublimation *in vacuo* at 70°/0.001 mm, a white solid m.p. 80–82° was obtained. Admixture of this material with 2,3-dimethylisocarbostyril caused a depression of the m.p. to 55–65°.

*2-Methyl-4-acetylisocarbostyril (**19**, $R = CH_3$)*

A solution of 2-methylisocarbostyril (4.78 g, 30 mmol) in acetic anhydride (10 ml) containing concentrated sulfuric acid (10 drops) was heated at reflux temperature for 1 h. The hot solution was poured into water (150 ml) and after 1 h the product was extracted into dichloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The solid residue was chromatographed on neutral alumina (Fluka, Activity II; 300 g) using 10% chloroform in benzene as the eluant. The first 200 ml of the eluate was discarded, the next 3.2 l contained the product which was crystallized from 1:1 benzene cyclohexane. The ketone (4.35 g, 72%) had m.p. 142–144°.

*2-Methyl-4-benzoylisocarbostyril (**19**, $R = C_6H_5$)*

A mixture of 2-methylisocarbostyril (15.9 g, 100 mmol), benzoic anhydride (67.9 g, 300 mmol) and concentrated sulfuric acid (30 drops) was heated in an oil bath at 200° under a slight positive pressure of nitrogen for 40 h. To the melt was cautiously added methanol (300 ml) and 2 *N* sodium hydroxide (300 ml) and the resultant was heated at reflux temperature for 1 h. The methanol was removed *in vacuo*, the residue was diluted with water and extracted with ethyl acetate. The extract was washed well with water, dried over sodium sulfate, and evaporated *in vacuo*. The solid residue was crystallized from benzene–cyclohexane (1:3) to give the product in two crops, m.p. 131–132 (15.1 g) and 128–131° (1.7 g).

*2-Methyl-4-nitroisocarbostyril (**21**, $R = CH_3$; $R' = H$)*

(a) Nitration with Acetyl Nitrate

To a stirred and cooled solution of 2-methylisocarbostyril (1.59 g, 10 mmol) in acetic anhydride (6.0 ml) was added a solution of concentrated nitric acid (0.71 ml) in acetic acid (3.0 ml) at a rate such that the reaction temperature did not exceed 5°. The cooling bath was removed, but the temperature was not allowed to exceed 25° (periodic cooling was necessary). After 0.5 h the reaction had ceased, the solution was poured into ice-water and the product was extracted into dichloromethane. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on neutral alumina (Fluka, Activity II; 50 g) using benzene as the eluant (50 ml fractions). The product was present in fractions 3–7. Evaporation of the solvent and crystallization of the residue from 1:1 benzene cyclohexane gave a pale yellow crystalline solid (0.745 g, 36.5%) m.p. 163–165°.

(b) Nitration with Nitrous Acid

To a stirred, cooled solution of 2-methylisocarbostyril (7.96 g, 50 mmol) in glacial acetic acid, which was 2.5 *M* in sulfuric acid (100 ml), and water (10 ml), was added a solution of sodium nitrite (10.35 g, 150 mmol) in water (30 ml) at a rate such that the reaction temperature did not exceed 10°. After 4 h at 10–15°, the reaction was diluted with water and the product was extracted into benzene. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was chromatographed on neutral alumina (Activity II, 320 g) as before (100 ml fractions). The product was contained in fractions 4–16. Crystallization of this material gave a product, m.p. 163–165° (1.59 g, 18%) identical in all respects to the nitration product obtained as described above.

Acid-catalyzed Condensation of 2-Methylisocarbostyril with Formaldehyde

2-Methylisocarbostyril (1.59 g, 10 mmol), paraformaldehyde (0.396 g, 4.4 mmol) in 95% ethanol (5 ml), containing concentrated hydrochloric acid (0.05 ml), was heated under reflux for 18.5 h. The reaction mixture was cooled to room temperature and the bis-isocarbostyrilmethane **27** (0.500 g, 66% based on recovered starting material), m.p. 297–300° was collected by filtration. The filtrate was diluted with water, and extracted with benzene. Evaporation of the dried extract *in vacuo* gave 0.862 g of starting material. Three crystallizations of crude **27** from acetonitrile gave a solid with m.p. 302–305°. (lit. (23), m.p. 302–304°).

Isocarbostyrils. II.[1] The Conversion of 2-Methyl-4-acyl-5-nitroisocarbostyrils to 2-Substituted Indole-4-carboxylic Acids

D. E. HORNING, G. LACASSE, AND J. M. MUCHOWSKI[2]
Bristol Laboratories of Canada, Candiac, Quebec

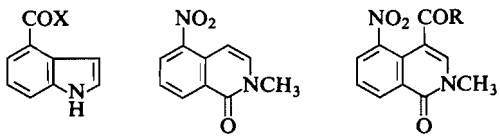
Received April 19, 1971

The sulfuric acid catalyzed acylation of 2-methyl-5-nitroisocarbostyril with carboxylic acid anhydrides gave the corresponding 4-acylated derivatives **3**, which underwent reductive cyclization to 2-substituted derivatives of 4-methyl-1,3,4,5-tetrahydropyrrolo[4.3.2.*de*]isoquinolin-5-one (**4**). Alkaline hydrolysis of the six-membered lactam in **4** was accompanied by a retro-Mannich reaction to produce 2-substituted indole-4-carboxylic acids in about 40% overall yield from **3**.

L'acylation catalysée par l'acide sulfurique du méthyl-2 nitro-5 isocarbostyrile par les anhydrides des acides carboxyliques conduit aux dérivés **3** acylés en-4 correspondants. Ces derniers subissent une cyclisation pour donner les dérivés substitués en-2 du méthyl-4 tétrahydro-1,3,4,5 pyrrolo[4.3.2.*de*]-isoquinolinone-5 (**4**). L'hydrolyse alcaline de la lactane à six chainons dans **4** est accompagnée d'une réaction rétro-Mannich pour donner les acides indole carboxyliques-4 substitués en position-2, et cela avec un rendement global d'environ 40% à partir de **3**.

Canadian Journal of Chemistry, 49, 2797 (1971)

The synthesis of indoles bearing a 4-carbonyl function (**1**, X = H, OR, NH_2, etc.), or a substituent at that position which could be readily transformed to a carbonyl group (*e.g.*, CH_2OH, CN, etc.) has been the subject of extensive investigation during the past three decades (1–8). An appreciable number of these studies stemmed from the need to prepare suitable precursors for the synthesis of lysergic acid and closely related compounds (see refs. 1–3, for example). In the preceding paper (9), it was reported that *N*-alkylisocarbostyrils were readily acylated at the 4-position. This was an important observation, since it was apparent to us that 2-methyl-5-nitroisocarbostyril (**2**) was a potential source of 4-carbonyl indoles if acylation could be effected at C-4. There would then remain only the problem of devising an appropriate ring closing – ring opening reaction sequence, which, when applied to **3**, would provide a 4-carbonyl indole. This paper describes a successful three-step transformation of 2-methyl-5-nitroisocarbostyril to some 2-substituted indole-4-carboxylic acids.



1 **2** **3**

When 2-methyl-5-nitroisocarbostyril and carboxylic acid anhydrides were heated together (95–150°) in the presence of a catalytic amount of sulfuric acid, the 4-acylated compounds **3** (R = CH_3, C_2H_5, C_6H_5) were formed in satisfactory yields. It is noteworthy that these conditions were milder than those required for the acylation of 2-methylisocarbostyril (9). For example, acetylation and benzoylation of 2-methylisocarbostyril required reaction temperatures of 140 and 200° respectively, whereas the corresponding reactions on 2-methyl-5-nitroisocarbostyril occurred readily at 95 and 150°. This observation is quite remarkable in view of the anticipated adverse steric effect of the *peri* nitro group in **2** on an entering acylium ion. Whereas the acylation of **2** was accomplished with surprising ease, it was equally unexpected that formylation could not be effected under conditions which were successful for 2-methylisocarbostyril, or under a large number of other variants of the Vilsmeier–Haack reaction.[3]

The structures of the 4-acylated-5-nitroiso-

[1]For Part 1, see ref. 9.

[2]To whom inquiries concerning this paper should be addressed.

[3]A referee has suggested that one explanation for this observation is that Vilsmeier–Haack complexes may have greater steric requirements than solvated acylium ions.

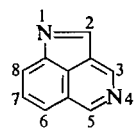
SCHEME 1

carbostyrils were supported by their elemental analyses (Table 1), characteristic n.m.r. spectra (Table 2), and by the chemical transformations described below. For instance, catalytic hydrogenation of the nitroacetyl derivative **3** (R = CH_3) resulted not only in the expected ring closure, but also was accompanied by migration of the isocarbostyril double bond into the newly formed five-membered ring. The tricyclic compound thus produced **4** (R = CH_3) is the first member of the hitherto unknown pyrrolo-[4.3.2-*de*]isoquinoline ring system.[4] Although this compound was indefinitely stable in the solid state, solutions of it were rapidly oxidized to tarry substances on exposure to air. The phenyl substituted analogue **4** (R = C_6H_5)[5] was, however, sufficiently air insensitive to be handled without special precautions. The tricyclic nature of these compounds was substantiated by their n.m.r. spectra, elemental analysis (see Tables 1 and 2), and the transformation described below and shown in Scheme 1.

On the basis of previous observations (11, 12), it was concluded that the cleavage of **4** to an indole-4-carboxylic acid would be most readily accomplished under alkaline conditions. At that time, it was not known whether the product would be an amino acid **5**, or if a retro-Mannich reaction would occur to give a desmethyl-

[4]Proposed numbering for this ring system. For the numbering of the related quinoline analogue see ref. 10.



[5]The cyclization of **3** (R = C_2H_5) was not attempted.

aminomethyl acid **6** (R′ = H). An indication that the latter reaction might occur was to be found in the observations of Powers (13), which showed that indoles bearing a 3-substituent at the aldehyde level of oxidation underwent loss of that substituent in strongly alkaline media.[6] In any event, heating an aqueous dimethyl sulfoxide solution of **4** (R = C_6H_5) containing an excess of potassium hydroxide, under reflux, effected its direct conversion to 2-phenylindole-4-carboxylic acid (**6**, R = C_6H_5, R′ = H) in 77% yield.[7] The same reaction could be accomplished on **4** (R = CH_3), but in this case, because of its sensitivity toward aerial oxidation, the tricyclic indole was used without purification. In this way, 2-methylindole-4-carboxylic acid (**6**, R = CH_3, R′ = H) was obtained in 39–46% overall yield from **3** (R = CH_3).

The gross structure of 2-phenylindole-4-carboxylic acid was corroborated by an elemental analysis, and by the u.v., i.r. (Table 3), and n.m.r. spectra of the methyl ester. Furthermore, cupric ion catalyzed decarboxylation of the carboxylic acid gave the known 2-phenylindole (**7**, R = C_6H_5). 2-Methylindole-4-carboxylic acid did not decarboxylate under the same conditions, but the spectral data (Tables 2 and 3) measured for the methyl ester strongly supported the assigned structure. The n.m.r. spectrum of the aromatic protons of **6** (R = R′ = CH_3) was especially definitive. The quartet at δ 7.87 was assigned to H-5 which was deshielded by the methoxycarbonyl group at C-4, while the broad absorption at δ 8.14 was due to the NH proton. The finely structured apparent doublet centered at δ 7.42 and the narrow multiplet at δ 6.86 were attributed, respectively, to H-7 and -3, which were weakly long range (< 1 Hz) coupled. The remaining, partially obscured quartet centered at δ 7.14, was ascribed to H-6. Acid-catalyzed deuterium exchange caused the disappearance of the signals due to H-1 and -3 with concurrent simplification of the H-6 resonance to a clean quartet. A small (0.6–1 Hz) long range coupling between H-3 and -7 in indoles has been observed previously (17, 18).

Experimental

The melting points were determined in a Gallenkamp m.p. apparatus and are not corrected.

2-Methyl-5-nitroisocarbostyril (m.p. 115–116°, lit. (19) m.p. 120°) was prepared in 85–95% yield by the alkaline ferricyanide oxidation of 2-methyl-5-nitroisoquinolinium iodide (see ref. 9).

Methyl indole-4-carboxylate (m.p. 67–69°, lit. (*1b*) m.p. 69.5–70.5°; after crystallization from cyclohexane and sublimation at 60°/0.001 mm) was obtained from the carboxylic acid (*1a*) and ethereal diazomethane.

[6]Certain 5-hydroxy-4-dialkylaminomethylindoles have recently been shown to undergo a base-catalyzed reverse Mannich reaction (14).

[7]When the hydrolysis was carried out in aqueous ethanol or aqueous ethylene glycol a mixture of two carboxylic acids was obtained. The major (60% yield), less soluble, product was shown to be **6** (R = C_6H_5) by direct comparison with the product obtained in the absence of alcoholic solvents. The minor (20% yield), more soluble, acid (m.p. 214–216°) was considered to be 2-phenyl-3-methylindole-4-carboxylic acid on the basis of its elemental analysis (Found: C, 76.36; H, 4.94; N, 5.75), spectral data (i.r. (Nujol), 3365, 2655, 2570, 1680 cm^{-1}; n.m.r. (DMSO-d_6), δ 2.57 (s, 3H), 7.14–8.14 (m, 8H), 11.72 (s, 1H), 12.08 (s, 1H)), and decarboxylation (see above) to 2-phenyl-3-methylindole (15). The minor product must have been formed via reduction of the intermediate **5** (R = C_6H_5) by the alcoholic solvent. Primary alcohols are known (16) to function as reducing agents in aqueous alkaline media, but the conditions (320–380°, sealed tube) are rather more vigorous than those described herein.

2-Methyl-4-acetyl-5-nitroisocarbostyril (3, R = CH_3)

2-Methyl-5-nitroisocarbostyril (8.16 g, 40 mmol), acetic anhydride (18 ml), and concentrated sulfuric acid (5 drops) were heated on a steam bath for 4 h. The dark colored solution was cooled to room temperature, water (25 ml) was added, and the mixture was heated on a steam bath until a single phase was produced (*ca.* 10 min). The solution was poured into a large volume of water, the product was extracted into dichloromethane, the extract was washed well with water, dried over sodium sulfate, and then evaporated *in vacuo*. The residue was crystallized from benzene to give the product in two crops, m.p. 197–200 (5.70 g) and 194–197° (1.17 g). Upon recrystallization from 2-propanol the m.p. was raised to 200–202°.

2-Methyl-4-propionyl-5-nitroisocarbostyril (3, R = C_2H_5)

This compound was prepared in the same manner as the above acetyl compound, with the exception that propionic anhydride was used and the reaction time was lengthened to 6 h. The product (m.p. 175–176°, 42% yield) was crystallized from benzene: cyclohexane (2:1).

2-Methyl-4-benzoyl-5-nitroisocarbostyril (3, R = C_6H_5)

Benzoic anhydride (13.6 g, 60 mmol), 2-methyl-5-nitroisocarbostyril (4.08 g, 20 mmol), and concentrated sulfuric acid (8 drops) were heated together at 150° (oil bath) under a slight positive pressure of nitrogen for 17 h. To the hot melt was added acetonitrile (20 ml), pyridine (10 ml), and water (10 ml) and the solution was heated at reflux temperature for 1 h. The solution was poured into ice-water, sodium carbonate solution (200 g/l) was added until alkalinity was achieved, the product was extracted into dichloromethane and the extract was dried over sodium sulfate, and evaporated *in vacuo*. The oily solid was taken up in chloroform and placed on a column of Florisil (100 g, 100–200 mesh, packed in benzene). The column was developed with chloroform; the first 350 ml of the eluate was discarded, the product was contained in the next 2.4 l. The product was crystallized from benzene:cyclohexane (4:1). The first crop had m.p. 165–167°, subsequent crops had a lower m.p. (153–157°) but on crystallization from 1:1 benzene cyclohexane material with m.p. 165–167° was obtained. The total yield of product with m.p. 165–167° ranged from 3.08–4.00 g (50–65%).

2,4-Dimethyl-1,3,4,5-tetrahydropyrrolo-[4,3,2-de]isoquinolin-5-one (4, R = CH_3)

2-Methyl-4-acetyl-5-nitroisocarbostyril (1.64 g, 6 mmol) and 10% palladium-on-charcoal (200 mg) in ethanol (100 ml) were hydrogenated at room temperature and an initial hydrogen pressure of 60 p.s.i.g. The theoretical amount of hydrogen was absorbed in 1 h. Some of the product had separated from solution; it was collected (680 mg of product and catalyst) by filtration in an atmosphere of nitrogen. It was sufficiently pure to be purified by crystallization in the manner described below. The filtrate was evaporated *in vacuo* at 30°; the residue was slurried with toluene, and the insoluble material (693 mg) was collected by filtration and sublimed at 190–195°/0.001 mm. A yellow solid (381 mg) m.p. 311–312° (evacuated capillary) was obtained. The sublimate was dissolved in boiling acetonitrile (through which a slow stream of nitrogen was bubbled) and on cooling in ice, the product crystallized. The m.p. remained unchanged.

2-Phenyl-4-methyl-1,3,4,5-tetrahydropyrrolo-[4,3,2-de]isoquinolin-5-one (4, R = C_6H_5)

2-Methyl-4-benzoyl-5-nitroisocarbostyril was catalytically reduced in the same manner as described above (1.5 h). The product was sufficiently stable in solution to be handled without special precautions. The catalyst was removed by filtration through Celite, the filtrate was evaporated *in vacuo* and the residue was crystallized from ethanol. The product, m.p. 270–274° (evacuated capillary), was obtained in 55% yield. Further crystallization raised the m.p. to 276–278°.

2-Methylindole-4-carboxylic Acid (6, R = CH_3, R′ = H)

2-Methyl-4-acetyl-5-nitroisocarbostyril (1.64 g, 6 mmol) and 10% palladium-on-charcoal (200 mg) in absolute ethanol (100 ml) was hydrogenated as before. The contents of the hydrogenation vessel were transferred in an atmosphere of nitrogen to a 500 ml round-bottomed flask. The solvent was removed *in vacuo* at 30° and a solution of 85% potassium hydroxide (8.4 g) in 50% aqueous dimethylsulfoxide (120 ml) was added to the residue. The mixture was stirred magnetically under reflux for 17 h while a gentle flow of nitrogen was maintained through the apparatus. Concentrated hydrochloric acid was carefully added to the cooled solution until the dissolved silica precipitated from solution (still weakly basic). The mixture was filtered, the filter cake was washed well with water, and the filtrate was made acidic with concentrated hydrochloric acid. The product was extracted into ethyl acetate, the extract was shaken with sodium carbonate (100 g/l), the basic solution thus obtained was acidified with concentrated hydrochloric acid, and the product was extracted into ethyl acetate. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue (1.06–1.24 g) was taken up in methanol, silica gel (5 g, Merck, activity II–III) was added, and the mixture was evaporated to dryness *in vacuo*. This mixture was placed on top of a dry packed column of silica gel (100 g) and the column was developed with ethyl acetate. The product was contained in the first 250 ml of the eluate. It was crystallized from aqueous ethanol (2:3) to give the carboxylic acid in two crops, m.p. 225–229 (356–368 mg) and 219–223° (49–96 mg). The yield of the combined crops ranged from 39–46% based on the starting nitro ketone.

The methyl ester was prepared by adding an excess of ethereal diazomethane to an ice cold methanolic solution of the carboxylic acid. The ester was crystallized from cyclohexane:benzene (4:1) to give material m.p. 130–131°.

2-Phenylindole-4-carboxylic Acid (6, R = C_6H_5, R′ = H)

The tricyclic indole (524 mg, 2 mmol) and 85% potassium hydroxide (2.5 g) in 50% aqueous dimethylsulfoxide (30 ml) was heated at reflux temperature for 20 h. The reaction was processed as before, the sodium carbonate soluble fraction being crystallized from 3:2 aqueous ethanol (chromatography was unnecessary). The product (385 mg, 77%) had m.p. 265–267°.

The methyl ester was prepared in the usual manner using ethereal diazomethane. It had m.p. 124.5–126°, after crystallization from cyclohexane:benzene (10:1).

Decarboxylation of 2-Phenylindole-4-carboxylic Acid

An intimate mixture of the carboxylic acid (40.2 mg) and basic cupric carbonate (1.8 mg), contained in a 10 ml flask equipped with a water cooled condenser, was heated under a slight vacuum at 270° until gas evolution had ceased. Full water pump vacuum (10 mm) was then applied and the bath temperature was increased to 320° during a ½ h period. The sublimate was taken up in dichloromethane and the solution was extracted with aqueous sodium carbonate (100 g/l). The aqueous phase was made acidic with concentrated hydrochloric acid and the mixture was extracted with ethyl acetate. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo* to give recovered carboxylic acid (14.8 mg).

The dichloromethane phase from above was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was sublimed at 140–145°/0.005 mm to give 2-phenyl indole (9.2 mg) m.p. 185–186°; mixed m.p. with authentic 2-phenyl indole, 186–188°. The solution i.r. spectrum ($CHCl_3$) was identical to that of an authentic specimen (20).

Thermodynamic Analysis of the Hammett Equation, the Temperature Dependence of ρ, and the Isoequilibrium (Isokinetic) Relationship[1]

LOREN G. HEPLER

Department of Chemistry, The University of Lethbridge, Lethbridge, Alberta

Exact thermodynamic analysis of the Hammett equation has led to four differential equations relating $\delta\Delta H^0$, $\delta\Delta S^0$, $\delta\Delta C_p^0$, $d\rho/dT$, and $d^2\rho/dT^2$. Similar equations can be obtained in terms of activation parameters $\Delta H^{\ddagger}$, etc. For temperature independent $\delta\Delta H^0$ and $\delta\Delta S^0$ and therefore $\delta\Delta C_p^0 = 0$, two of these differential equations lead to $\rho = \rho_\infty[1 - (\beta_i/T)]$ and the familiar isoequilibrium (isokinetic) equation $\delta\Delta H^0 = \beta_i\delta\Delta S^0$. The "isoequilibrium (isokinetic) temperature" represented here by β_i is a temperature independent constant of integration. For constant non-zero $\delta\Delta C_p^0$ we similarly obtain more complicated expressions for ρ and the "isoequilibrium (isokinetic) temperature." These findings are considered in relation to a model in which environmental contributions (due to solute–solvent interactions) to $\delta\Delta H^0$ and $\delta\Delta S^0$ are related by a parameter β_e. The relationship between β_i and β_e is established, and it is shown that in general $\beta_i \neq \beta_e$.

L'analyse thermodynamique exacte de l'équation de Hammett a conduit à quatre équations différentielles se rapportant à $\delta\Delta H^0$, $\delta\Delta S^0$, $\delta\Delta C_p^0$, $d\rho/dT$ et $d^2\rho/dT^2$. Des équations semblables peuvent être obtenues en termes de paramètres d'activation $\Delta H^{\ddagger}$, etc. Lorsque $\delta\Delta H^0$ et $\delta\Delta S^0$ sont indépendants de la température et que, par conséquent, $\delta\Delta C_p^0 = 0$, deux de ces équations différentielles amènent à $\rho = \rho_\infty[1 - (\beta_i/T)]$ et à l'équation habituelle d'isoéquilibre (isocinétique) $\delta\Delta H^0 = \beta_i\delta\Delta S^0$. La "température d'isoéquilibre (isocinétique)" représentée ici par β_i est une constante d'intégration indépendante de la température. Pour une valeur $\delta\Delta C_p^0$ constante et non nulle, nous obtenons de la même manière des expressions plus compliquées pour ρ et la "température d'isoéquilibre (isocinétique)". Ces données sont envisagées en fonction d'un modèle dans lequel les contributions de l'environnement à $\delta\Delta H^0$ et $\delta\Delta S^0$ dues aux intéractions soluté-solvant) sont évaluées par un paramètre β_e. La relation entre β_i et β_e est établie et on montre que, en général $\beta_i \neq \beta_e$.

Canadian Journal of Chemistry, 49, 2803 (1971)

Introduction

The empirical successes of the Hammett equation in correlating a wide variety of equilibrium and rate data are well known. Considerable progress has been made (1–6) in gaining some understanding of why the Hammett equation works as well as it does, and also elucidating its thermodynamic consequences. Among problems that remain partly unresolved are those involving the temperature dependence of the Hammett ρ parameter and the relationships between the Hammett ρ and two different β parameters that have been widely used. This paper is devoted first to detailed thermodynamic analysis of the Hammett equation and then to the relationship of this analysis to an extrathermodynamic model for substituent and solvent effects.

Thermodynamic Consequences of the Hammett Equation

The Hammett equation can be applied to the effect of substituents on acid ionizations as represented by the equation

$$[1]\quad HA^z(S) + R^{z-1}(S) = A^{z-1}(S) + HR^z(S)$$

in which HA^z is a substituted acid, HR^z is a reference acid, and (S) is used to denote that the preceding substance is in solution. We denote the equilibrium constant for reaction 1 by K, which is equal to K_{HA}/K_{HR}, and write the Hammett equation as

$$[2]\quad \log K \simeq \rho\sigma$$

Thus we also have

$$[3]\quad \delta\Delta G^0 = -2.3RT\rho\sigma$$

in which $\delta\Delta G^0 = \Delta G_{HA}^0 - \Delta G_{HR}^0$. The Hammett equation has also been applied similarly to substituent effects on equilibrium constants and rate constants for a wide variety of other reactions.

All of the following derivations are carried out in terms of standard state thermodynamic functions indicated by the superscript zero, but could equally well be done in terms of a ratio of rate constants such as $k_{subst.}/k_{ref.}$ and

[1]Presented in part at the Nobel Workshop in Biochemical Thermochemistry at the Chemical Center University of Lund, Lund, Sweden, 1971.

For personal use only.

the related activation parameters commonly represented by $\Delta G^{\ddagger}$, etc.

It is a general empirical observation that the Hammett equation "works" about as well at one temperature as another. We shall therefore begin our thermodynamic analysis on the basis that eq. 2 is exactly valid over the entire temperature range of interest. According to the original and still used definitions of the parameters in the Hammett eq. 2, the substituent parameter σ is independent of temperature ($d\sigma/dT = 0$), while the reaction–solvent parameter ρ may depend on temperature.

Differentiation of eq. 2 with respect to temperature and combination of the resulting equations with well known thermodynamic equations leads to a number of further equations, of which the following are of immediate interest

$$[4] \quad \delta\Delta H^0 = 2.3RT^2(d\rho/dT)\sigma$$

$$[5] \quad \delta\Delta S^0 = 2.3R[\rho + T(d\rho/dT)]\sigma$$

$$[6] \quad \delta\Delta H^0 = \left[\frac{T^2(d\rho/dT)}{\rho + T(d\rho/dT)}\right]\delta\Delta S^0$$

$$[7] \quad \delta\Delta C_p{}^0 = 2.3R\sigma[T^2(d^2\rho/dT^2) + 2T(d\rho/dT)]$$

In these equations $\delta\Delta H^0 = \Delta H_{HA}{}^0 - \Delta H_{HR}{}^0$, and similarly for both $\delta\Delta S^0$ and $\delta\Delta C_p{}^0$.

Accuracy of most experimental data is such that we are limited to consideration of both $\delta\Delta H^0$ and $\delta\Delta S^0$ (and maybe more especially $\delta\Delta H^{\ddagger}$ and $\delta\Delta S^{\ddagger}$) as temperature independent constants. It therefore follows from $d\delta\Delta H^0/dT = \delta\Delta C_p{}^0$ and $d\delta\Delta S^0/dT = \delta\Delta C_p{}^0/T$ that in these common cases we must take $\delta\Delta C_p{}^0 = 0$. From eq. 7 we therefore have

$$[8] \quad T^2(d^2\rho/dT^2) + 2T(d\rho/dT) = 0$$

The general solution of the differential eq. 8 is a two constant equation of the form

$$[9] \quad \rho = C_1 + C_2/T$$

It is more convenient for us to use symbols similar to those introduced by Leffler and Grunwald (2). Thus we write this general equation with its two constants of integration as

$$[10] \quad \rho = \rho_\infty(1 - \beta_i/T)$$

in which the subscript *i* on β is used to emphasize that we are here concerned with the quantity called the *i*sokinetic or *i*soequilibrium temperature by Leffler and Grunwald (2) and others. It is a necessary requirement of differential eq. 8 that this β_i be independent of temperature. To show that this β_i is indeed the same as the isokinetic or isoequilibrium temperature used by Leffler and Grunwald (2), we substitute ρ and $d\rho/dT = \rho_\infty\beta_i/T^2$ from eq. 10 into eq. 6 to obtain

$$[11] \quad \delta\Delta H^0 = \beta_i\delta\Delta S^0$$

It should now be emphasized that $\log K = \rho\sigma$ and $\delta\Delta C_p{}^0 = 0$, both valid over a range of temperature, necessarily lead by exact thermodynamics and the solution of differential eq. 8 to the temperature dependence of ρ given in eqs. 9 and 10 and to the isoequilibrium (isokinetic) relationship of eq. 11 in which β_i is independent of temperature.

For a reaction series with $\delta\Delta S^0 = 0$ at all temperatures, eq. 5 requires that

$$[12] \quad \rho + T(d\rho/dT) = 0$$

The solution of this differential equation is

$$[13] \quad \rho = C_2/T \quad (\text{for } \delta\Delta S^0 = 0)$$

in which we have a special case corresponding to $C_1 = 0$ in eq. 9. For a reaction series with $\delta\Delta H^0 = 0$ at all temperatures, eq. 4 requires that

$$[14] \quad d\rho/dT = 0$$

Thus in this special case we have a temperature independent ρ as in

$$[15] \quad \rho = C_1 \quad \text{or } \rho = \rho_\infty \quad (\text{for } \delta\Delta H^0 = 0)$$

Now we turn to consideration of reaction series for which both $\delta\Delta H^0$ and $\delta\Delta S^0$ vary with temperature and for which we therefore have $\delta\Delta C_p{}^0 \neq 0$. The simplest case is that in which non-zero $\delta\Delta C_p{}^0$ is independent of temperature, which now requires that we find the appropriate solution for the differential eq. 7. This solution may be written in the form

$$[16] \quad \rho = \rho^*\left[1 - \frac{\beta^*}{T} + \frac{\delta\Delta C_p{}^0}{2.3R\sigma\rho^*}\ln T\right]$$

First we note that for the special case of $\delta\Delta C_p{}^0 = 0$, eq. 16 reduces to eq. 10 with $\rho_\infty = \rho^*$ and $\beta_i = \beta^*$.

Substitution of ρ, $d\rho/dT$, and $d^2\rho/dT^2$ from eq. 16 into eq. 6 gives us

$$[17]\quad \delta\Delta H^0 = \left[\frac{\beta^* + \frac{T\delta\Delta C_p^0}{2.3R\rho^*\sigma}}{1 + \frac{\delta\Delta C_p^0}{2.3R\rho^*\sigma}(1 + \ln T)}\right]\delta\Delta S^0$$

Again we note that for $\delta\Delta C_p^0 = 0$ we obtain a simplification to $\delta\Delta H^0 = \beta^*\delta\Delta S^0$, which is the same as eq. 11 already obtained for this special case.

Leffler was apparently the first to observe and express the now common linear relationship between $\delta\Delta H^0$ and $\delta\Delta S^0$ (or $\delta\Delta H^{\ddagger}$ and $\delta\Delta S^{\ddagger}$) in terms of the isoequilibrium (isokinetic) eq. 11. Although some published examples of linear enthalpy–entropy relationships have been justly criticized as spurious because of experimental errors or large uncertainties, particularly when enthalpies and entropies are derived from $d \ln K/dT$ or $d \ln k/dT$, there is now considerable empirical support for the applicability of eq. 11 to a variety of reaction series. Leffler and Grunwald (2) and Hammett (1) have shown in different ways that the isoequilibrium (isokinetic) temperature here denoted by β_i is a temperature independent constant when $\delta\Delta C_p^0 = 0$ in agreement with the present identification of β_i as one of the constants of integration obtained from differential eq. 8. It is worth emphasizing that the isoequilibrium (isokinetic) relationship of eq. 11 with constant β_i is a rigorous thermodynamic consequence of the Hammett equation and $\delta\Delta C_p^0 = 0$.

Leffler and Grunwald (2) have cited a number of empirical β_i values and have noted that many of these values are close to the experimental temperature under consideration. They have presented some theoretical explanation for this observation and also the generalization that β_i is expected to be positive. The purely thermodynamic treatment given here, in which β_i appears as a constant of integration, requires no particular numerical value or even sign for β_i. As shown later in this paper, a reaction model that is consistent with the present thermodynamic analysis can give further information about the magnitude of β_i.

Since we have few data to justify consideration of temperature dependent $\delta\Delta H^0$ and $\delta\Delta S^0$ values with $\delta\Delta C_p^0 \neq 0$, the treatment given in eqs. 8–15 is all that is appropriate for most reaction series. But because there is a slow accumulation of more accurate data applicable over wider ranges of temperature to justify taking $\delta\Delta C_p^0 \neq 0$, and because it is of value to ascertain the limits of applicability of such useful empirical relationships as the Hammett equation, we now give careful consideration to eqs. 16 and 17.

In eq. 16 we have ρ expressed partly in terms of $\delta\Delta C_p^0/\sigma$. This is directly contrary to the definitions of ρ and σ, which require that these two parameters be independent of each other. It is therefore a thermodynamic requirement of the Hammett equation that $\delta\Delta C_p^0/\sigma$ be a constant so that the right hand side of eq. 16 becomes effectively independent of σ. Because of the $\ln T$ term in eq. 16 we expect to observe a slight curvature in graphs of ρ *vs.* $1/T$ when $\delta\Delta C_p^0 \neq 0$.

The term in brackets in eq. 17 also involves $\delta\Delta C_p^0/\sigma$, but it was shown above that the independence of ρ and σ in the Hammett equation requires that this ratio be constant in any reaction series. Thus it is still appropriate to describe eq. 17 as an isoequilibrium (isokinetic) relationship. The isoequilibrium (isokinetic) "temperature" previously denoted by β_i is now a function of temperature rather than a constant.

There are a number of reaction series that do exhibit the various proportionalities that have been derived by thermodynamic analysis of the Hammett equation. On the other hand, it is becoming well known that the Hammett equation often provides a good approximate correlation of both equilibrium and rate constants even when enthalpies and entropies vary in apparently erratic fashion and there is no good isoequilibrium (isokinetic) relationship. In the next section of this paper, in which a particular reaction model is described, it is shown that "compensation" of contributions of solute–solvent interactions to enthalpies and entropies can account for the approximate success of the Hammett equation even when its derivative thermodynamic consequences are far from being satisfied.

A Model for Thermodynamics of Substituent and Solvent Effects

It has been shown previously (3–7) that it is useful to express thermodynamic functions for reactions of type represented by eq. 1 in terms of "*int*ernal" and "*env*ironmental" contributions as in the following

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[18] $$\delta\Delta H^0 = \delta\Delta H_{int} + \delta\Delta H_{env}$$

[19] $$\delta\Delta S^0 = \delta\Delta S_{int} + \delta\Delta S_{env}$$

King (8) has clearly described these contributions as follows: "*Internal effects* are those intrinsic to the molecules of the acid and base. *Environmental effects* are those which result from interaction of the molecules of the acid and base with the solvent." Similar definitions apply to other solute species in other reaction series.

A useful and reasonable expression of the proportional relationship between $\delta\Delta H_{env}$ and $\delta\Delta S_{env}$ is (5, 6)

[20] $$\delta\Delta H_{env} = \beta_e\delta\Delta S_{env} + \gamma\delta\Delta H_{int}$$

in which β_e is an "environmental" parameter (*not* the same as β_i) and γ is a parameter that depends on the solvent and the temperature. Because $\delta\Delta S_{int} \simeq 0$ (7) for many symmetrical reactions of type represented by eq. 1, we can write eq. 20 as

[21] $$\delta\Delta H_{env} = \beta_e\delta\Delta S^0 + \gamma\delta\Delta H_{int}$$

A wide variety of evidence (4–11) shows that the environmental parameter β_e is approximately equal to the temperature of the solution so that we henceforth take

[22] $$\beta_e = T$$

It has been shown (5, 6) that eqs. 18–22 lead to

[23] $$\delta\Delta G^0 = \delta\Delta H_{int}(1 + \gamma)$$

and thence

[24] $$\rho\sigma = [C(1 + \gamma)/2.3RT][-\delta\Delta H_{int}/C]$$

in which C is an arbitrary proportionality constant. We identify $C(1 + \gamma)/2.3RT$ with ρ and $-\delta\Delta H_{int}/C$ with σ. Thus this reaction model correctly leads to a linear free energy relationship with ρ that is dependent on solvent and temperature and to σ that is dependent only on the substituent. It is "compensation" of $\delta\Delta H_{env}$ and $\delta\Delta S_{env}$ that is responsible for the simple form of eqs. 23 and 24, which permit us to understand substituent effects largely in terms of "internal" enthalpy or energy. Furthermore, it is this partial compensation of $\delta\Delta H_{env}$ and $\delta\Delta S_{env}$ that accounts for the observation that the Hammett equation gives a good approximate correlation of equilibrium and rate constants even when enthalpies and entropies are not in accord with the thermodynamic requirements of the Hammett equation.

Differentiation of eq. 23 with respect to temperature (taking $\delta\Delta H_{int}$ to be independent of temperature as done previously for σ) leads to the following

[25] $$\delta\Delta H^0 = C[T(d\gamma/dT) - (1 + \gamma)]\sigma$$

[26] $$\delta\Delta S^0 = -\delta\Delta H_{int}(d\gamma/dT) = C(d\gamma/dT)\sigma$$

In eqs. 25 and 26 we have $\delta\Delta H^0$ and $\delta\Delta S^0$ both proportional to σ, as in eqs. 4 and 5 obtained directly from the Hammett equation.

Further combination of equations leads to the isoequilibrium (isokinetic) relationship

[27] $$\delta\Delta H^0 = \left[T - \frac{1 + \gamma}{d\gamma/dT}\right]\delta\Delta S^0 = \left[\beta_e - \frac{1 + \gamma}{d\gamma/dT}\right]\delta\Delta S^0$$

Since the terms in brackets in eq. 27 correspond to the isoequilibrium (isokinetic) temperature denoted in this paper by β_i, we have

[28] $$\beta_i = \beta_e - \frac{1 + \gamma}{d\gamma/dT} = T - \frac{1 + \gamma}{d\gamma/dT}$$

Although β parameters without subscripts have incorrectly been taken to be the same, eq. 28 clearly shows that β_i is not equal to β_e. When $(1 + \gamma)/(d\gamma/dT)$ is small compared to T, we find that $\beta_i \simeq T$ as commonly observed. On the other hand, there is no requirement that $(1 + \gamma)/(d\gamma/dT)$ be small, in which case β_i may be much larger than T or even negative. It should be noted, however, that negative β_i values are rare and that several of these are quite uncertain.

Differentiation of either eq. 25 or 26 with respect to temperature and combination with either $d\delta\Delta H^0/dT = \delta\Delta C_p^0$ or $d\delta\Delta S^0/dT = \delta\Delta C_p^0/T$ leads to

[29] $$\delta\Delta C_p^0 = CT(d^2\gamma/dT^2)\sigma$$

Thus this reaction model leads to $\delta\Delta C_p^0$ proportional to σ, as required by the Hammett equation.

When $\delta\Delta C_p^0 = 0$, eq. 29 leads to

[30] $$d^2\gamma/dT^2 = 0$$

A general solution of this differential equation is

[31] $$\gamma = a + bT \quad (\delta\Delta C_p^0 = 0)$$

and we therefore also have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

[32] $\beta_i = -(1 + a)/b$

Again, β_i is independent of temperature because we take $\delta\Delta C_p^0 = 0$.

Conclusions and Summary

Because some of the thermodynamic consequences of the Hammett equation and the dichotomized enthalpy–entropy model for substituent and solvent effects may be obscured by mathematical details, a verbal summary may be useful. It should also be emphasized that some of the present conclusions concerning the temperature dependence of ρ and the isoequilibrium (isokinetic) relationship have been deduced previously (1, 2) in other ways.

The assumed validity of the Hammett equation over a range of temperature *requires* by thermodynamics that $\delta\Delta H^0$ and $\delta\Delta S^0$ be proportional to σ and therefore that $\delta\Delta H^0$ be proportional to $\delta\Delta S^0$. The exact validity of the Hammett equation with independent ρ and σ values also requires that $\delta\Delta C_p^0$ be proportional to σ or equal to zero. When $\delta\Delta C_p^0 = 0$ we find that $\rho = \rho_\infty[1 - (\beta_i/T)]$ and that $\delta\Delta H^0 = \beta_i\delta\Delta S^0$ with β_i independent of T. When $\delta\Delta C_p^0 \neq 0$, we have $\beta_i = f(T)$. If $\delta\Delta C_p^0$ is neither proportional to σ nor equal to zero, then ρ is a function of σ and we can no longer have an exactly linear relationship between $\delta\Delta H^0$ and $\delta\Delta S^0$. These statements are totally independent of all reaction models. Similar statements about $\delta\Delta H^{\ddagger}$, $\delta\Delta S^{\ddagger}$, and $\delta\Delta C_p^{\ddagger}$ are dependent on the applicability of thermodynamics to the transition state theory and the various activation parameters.

A useful model for substituent and solvent effects is one in which thermodynamic functions are taken to be sums of environmental and internal contributions. This model can account for the general form of the Hammett equation and the temperature dependence of ρ. It also leads to $\delta\Delta H^0$, $\delta\Delta S^0$, and $\delta\Delta C_p^0$ proportional to σ and thence to an isoequilibrium (isokinetic) relationship, all similar to the thermodynamic requirements of the Hammett equation. The environmental parameter β_e that occurs in this model is not the same as the isoequilibrium (isokinetic) temperature β_i, but is instead (approximately) equal to the experimental temperature. A relationship between β_i and β_e or T is derived in terms of the solvent parameter γ.

The solvent parameter γ is related to the solvent-reaction parameter ρ of the Hammett equation. It remains to be seen whether it is possible to obtain more useful information from γ values than from ρ values.

An important but inexact consequence which follows from $\beta_e \simeq T$ is that there is substantial "compensation" of $\delta\Delta H_{env}$ by $\delta\Delta S_{env}$ so that the Hammett equation is approximately satisfied even when $\delta\Delta H^0$ and $\delta\Delta S^0$ vary in erratic ways contrary to the exact thermodynamic requirements of proportionality to σ.

I am grateful to Douglas Dolman for many helpful discussions and to the authors of refs. 1 and 2, whose writings have provided the background and much of the impetus for the work reported here. I also thank the National Research Council of Canada and the Research Corporation for their support of experimental research that has led to some of this paper.

^{121}Sb Mössbauer: Antimony–Fluorine Systems

T. BIRCHALL AND B. DELLAVALLE
Department of Chemistry, McMaster University, Hamilton, Ontario

Received March 12, 1971

^{121}Sb Mössbauer data are presented for $NaSbF_4$, $KSbF_4$, KSb_2F_7, K_2SbF_5, $KSbF_6$, $CsSb_2F_{11}$, and $(NH_4)_2SbCl_5$. Attempts are made to rationalize the data in terms of known structural parameters.

Les données Mössbauer relatives à ^{121}Sb sont présentées pour $NaSbF_4$, $KSbF_4$, KSb_2F_7, K_2SbF_5, $KSbF_6$, $CsSb_2F_{11}$, et $(NH_4)_2SbCl_5$. On essaye de rationaliser les données en termes de paramètres structuraux connus.

Canadian Journal of Chemistry, 49, 2808 (1971)

Introduction

Mössbauer spectroscopy is being increasingly used in structural investigations of inorganic systems. We have become interested in applying the technique to a study of compounds of antimony, and although a number of papers have been published in this area (1–5), the interpretation of data has often been hampered by a lack of reliable structural information. A catalogue of Mössbauer parameters for compounds of known structure is necessary before the technique can be reliably used in obtaining structural imformation about compounds of unknown structure. To this end we decided to study the much quoted fluoro-anions of antimony(III) (6). These antimony–fluorine compounds were reported (7–10) to have structures in which the antimony was coordinated to 3 to 5 fluorines, and such a variation in environment would be expected to produce significant changes in Mössbauer parameters. Recently some of these compounds have been reinvestigated and shown to have structures which differed considerably from those previously reported. For example, SbF_3 has recently been shown to be polymeric (11), with six fluorine neighbors, rather than molecular (7), and KSb_2F_7 to consist of chains of SbF_4^- and SbF_3 units (12) rather than the simple $Sb_2F_7^-$ ion (8).

We here report the Mössbauer parameters for a number of these fluoro-antimony anions and attempt to rationalize the data in terms of the structural data available. In addition we also include our data on $KSbF_6$, and $CsSb_2F_{11}$.

Experimental

Preparation of Compounds

Attempts were made to prepare all of the compounds reported by Bystrom *et al.* according to their procedures (8–10). However, these were not always successful. For example all attempts to prepare KSb_4F_{13} resulted in KSb_2F_7 and it is extremely unlikely that the former compound exists. It is interesting to note that Bystrom and Wilhelmi (8) provide no analytical data for this compound.

KSb_2F_7

Several procedures yielded samples of this compound. Dissolution of Sb_2O_3 and K_2CO_3 in a 2:1 mole ratio in aqueous HF and allowing the solution to cool produced crystals of KSb_2F_7. KSb_2F_7 was also obtained from the attempted preparation of KSb_4F_{13}, and from Bystrom and Wilhelmi's (8) procedure for obtaining K_2SbF_5, except that the residue was recrystallized at room temperature from aqueous HF. Analysis: Sb found 59.0% theoretical 58.7%.

$NaSbF_4$

This was prepared by dissolving Sb_2O_3 and Na_2CO_3 in a 1:1 molar ratio in excess aqueous HF, evaporating to dryness and recrystallizing from water at room temperature. Clear colorless crystals were obtained. Analysis: Sb found 54.3% theoretical 55.1%.

$KSbF_4$

This was prepared in an analogous manner to the sodium salt, to yield a white powdery compound. Analysis: Sb found 52.1% theoretical 51.4%.

K_2SbF_5

This compound was obtained while attempting to prepare K_3SbF_6 by dissolving Sb_2O_3 and K_2CO_3 in a 1:3 mole ratio in excess aqueous HF. The solution was evaporated to dryness and the residue recrystallized twice from water at room temperature to give clear colorless crystals. Analysis: Sb found 41.0% theoretical 41.3%.

$KSbF_6$ was obtained from Ozark-Mahoning Co. and used without further purification. $CsSb_2F_{11}$ was kindly supplied by Dr. P. A. W. Dean formerly of this department.

Mössbauer Spectra

The Mössbauer spectra were recorded on apparatus previously described (13) except that a Xe–CO_2 proportional counter was used instead of a scintillation counter. The source was a 0.5 mCi $Ba^{121}Sn(Sb)O_3$ obtained from New England Nuclear and the single

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

channel analyzer was set on the escape peak of the 37.2 keV γ ray. The source was at room temperature while all samples were cooled to liquid nitrogen temperatures. The Sb(III) samples contained ~25 mg Sb/cm while those of Sb(V) contained ~40 mg Sb/cm. All of the spectra were obtained from finely powdered samples. The drive system was calibrated, before and after each spectrum, using Pd.^{57}Co and a standard iron foil. All spectra were computer fitted to an eight line quadrupole split pattern using a modification of Gabriel and Ruby's (14) program kindly supplied by G. J. Long, University of Missouri. All isomer shifts are with respect to InSb at liquid nitrogen temperature as zero isomer shift.

Results and Discussion

The Mössbauer isomer shift may be written simply as δ = constant $(\Delta R/R)\ \Delta|\psi s(0)|^2$ where $\Delta R/R$ is the change in nuclear radius on going from the ground to excited state and $\Delta|\psi s(0)|^2$ represents the difference in s electron density between the source and absorber. For ^{121}Sb, $\Delta R/R$ has been established as having a negative sign (15), hence the more negative the isomer shift the higher the s electron density at the nucleus. For ^{121}Sb, I = 7/2 and 5/2, the presence of an electric field gradient results in a splitting of the absorption into an eight line pattern which cannot be completely resolved due to the relatively large natural line width. The intensities of these lines are governed by the Clebsch–Gordan coefficients, and their relative positions by the magnitudes of the quadrupole moments for the ground and excited states, the size of the electric field gradient and upon the asymmetry parameter. The broad asymmetric resonance absorption which results when an electric field gradient is present must therefore be computer fitted in order to arrive at accurate Mössbauer parameters. In this work we have taken the ratio of quadrupole moments (Q 7/2/Q 5/2) to be 1.34 (15). Because of the unequal intensities of all transitions, the shape of the absorption envelope immediately yields the sign of the quadrupole splitting and hence the sign of the electric field gradient. Since Q for ^{121}Sb is negative, a positive quadrupole splitting means a negative electric field gradient and a concentration of charge along the symmetry axis. Such additional information is not normally obtained from ^{57}Fe or ^{119}Sn spectra.

The Mössbauer data obtained are summarized in Table 1 and representative spectra are shown in Fig. 1. The data has been arranged in order of increasing isomer shift or decreasing s electron density, with the Sb(III) compounds having much more negative shifts than those of Sb(V). This is to be expected since the higher oxidation state has no 5s electron pair. Also included in Table 1, for the purposes of comparison, are data for $(NH_4)_2SbCl_5$ and SbF_3. The data for SbF_3 are that of Ruby *et al.* (16) while that for $(NH_4)_2SbCl_5$ is the result of a more accurate analysis of a spectrum which we have already reported elsewhere (5).

Of the Sb(III) compounds examined the SbF_4^- and $Sb_2F_7^-$ ions have been reported as having novel structures: the $KSbF_4$ salt having a tetrameric anion $[Sb_4F_{16}]^{4-}$ with a square pyramidal arrangement about each antimony and a lone pair occupying the sixth coordination position (9), while $CsSb_2F_7$ contained discrete $Sb_2F_7^-$ ions with a trigonal bipyramidal arrangement about each antimony with one of the equatorial positions being occupied by the lone pair (8). These structures have been accepted and widely referred to for many years (6). The structure of SbF_3 had been reported as consisting of discrete molecules with a pyramidal arrangement of fluorines about antimony (7). There appeared, then, to be a considerable variation in coordination about Sb(III) in these Sb—F systems and large variation in Mössbauer parameters might have been expected. Careful reading of Bystrom *et al.* later papers (9, 10) reveals that he regarded the apparent changes in coordination number

with some suspicion, and suggested that the structures of SbF_3, KSb_4F_{13}, and $CsSb_2F_7$ should be reinvestigated.

Recently Edwards (11) has shown that SbF_3 is not molecular, but polymeric with bridging fluorines to give an arrangement in which there are six fluorines about each antimony in a distorted octahedral arrangement. The distortion being due to the stereochemically active 5s electron pair. We have been unable to obtain any compound with an analysis corresponding to KSb_4F_{13}: the data reported by Bystrom and Wilhelmi (8) for this stoichiometry may well have been that of a mixture of SbF_3 and KF. Further evidence on the $Sb_2F_7^-$ anion has very recently (12) shown the previously accepted structure (8) to be incorrect. Again there are no discrete ions and this structure should be regarded as made up of SbF_4^- and SbF_3 units with interaction between units via fluorine bridges so that the whole structure resembles a chain. This results in two antimony environments, one six coordinate (5 fluorines and a lone pair), and the other five coordinate (4 fluorines and a lone pair). Mastin (12) has also reexamined the data for $NaSbF_4$ and finds this to be essentially as reported (10), but he was unable to prepare suitable crystals of the corresponding potassium salt to verify its structure. The sodium salt has each SbF_4^- ion sharing two fluorines with two other SbF_4^- units, so that each Sb has five fluorines and a lone pair to give a distorted octahedral arrangement about the antimony. The ion should be written as $[SbF_4]_n^{n-}$. A similarly distorted octahedral geometry is observed in the SbF_5^{2-} ion (8) as well as in the analogous chloro salt $(NH_4)_2SbCl_5$ (17).

Thus, apart from SbF_3 and one site in KSb_2F_7, the environments about Sb(III) all appear to be distorted octahedra and the Mössbauer data in Table 1 can be explained on this basis. One can describe the bonding in terms of sp^3d^2 hybridization with an electron pair occupying one position of the octahedron. A comparison of the data for the $SbCl_5^{2-}$ and SbF_5^{2-} salts shows that the former has the higher s electron density at the Sb nucleus: the less electronegative chlorine being less efficient at removing electron density from the central antimony than is fluorine. There is also a more marked difference in quadrupole splitting between these two salts which can again be attributed to electronegativity differences in the halogens. Since the quadrupole coupling constants are all positive this means that there is a negative electric field gradient and an excess of electron density along the symmetry axis as compared to the equatorial plane. The four equatorial fluorines by virtue of their greater electron withdrawing power would therefore create more asymmetry than four chlorines and a greater quadrupole splitting results as is observed.

Since $NaSbF_4$ has been shown to have a chain structure *i.e.*, $(SbF_4)_n^{n-}$ by two independent groups (10, 12), as described above, it seems reasonable to suppose that the potassium salt with identical Mössbauer parameters will also have the same structure. Thus the tetrameric structure for $KSbF_4$, originally proposed by Bystrom *et al.* (9), may be incorrect. The lower isomer shift and smaller quadrupole splitting compared to K_2SbF_5 indicate that the bridging fluorines are less effective at removing electron density from the antimony than are terminal fluorines.

Examination of the crystallographic data for KSb_2F_7 indicates that there are two antimony sites, one with five near fluorine neighbors and the other with four near fluorines. Both sites are very distorted due to the stereochemically active lone pair. We have been unable to resolve the Mössbauer spectrum for this compound into components due to each site, and the data reported are the result of fitting one eight line pattern to the absorption envelope. The site having 5 fluorines might be expected to have an isomer shift close to that for SbF_5^{2-}, while that having only 4 fluorines would be expected to have a higher s electron density and a lower shift, since four fluorines will withdraw less electron density than five fluorines. We note that the "average" shift for KSb_2F_7 is indeed more negative than K_2SbF_5. The value for the quadrupole coupling constant for this compound cannot be interpreted though we feel that the positive value is realistic. If $Sb_2F_7^-$ had had a structure in which each antimony was surrounded by four fluorines and a lone pair of electrons in a distorted trigonal bipyramidal arrangement, then the lone pair in the equatorial plane would have resulted in a positive electric field gradient at the Sb and hence a negative value for the quadrupole coupling constant. This is not observed and is added support for the polymeric structure (12).

The Mössbauer data for SbF_3 also fall into place as a result of the recent structure redetermination (11). Because of the significant interactions between the SbF_3 units, all fluorines can be regarded as bridging, and since a bridging fluorine appears to be less efficient at removing electron density than a terminal fluorine, a relatively high s electron density remains on the antimony. Alternatively one might regard the antimony as seven coordinate (six fluorines and a lone pair) with the lone pair in a hybrid orbital having considerable s character, giving a relatively high s electron density at Sb and hence a lower isomer shift. In cases where the 5s pair is stereochemically inactive, as in $[Co(NH_3)_6][SbCl_6]$, isomer shifts as low as -11.2 mm/s are observed (5). The large quadrupole coupling is evidence that the 5s electron pair is not completely inactive and is clearly consistent with the distorted structure (11).

Two salts of Sb(V) have been examined and the relevant data are given in Table 1. Mössbauer data on SbF_6^- salts have been reported previously by Ruby *et al.* (16) and Bryukhanov *et al.* (18). The isomer shift of the sodium salt is 10.4 ± 0.2 mm/s (18) while that for the potassium salt is given as 12.3 ± 0.4 mm/s (16), both with respect to InSb. We find an isomer shift of $+11.42$ mm/s for $KSbF_6$, but a direct comparison between our data and that of Ruby *et al.* (16) may not be valid since they recorded their spectra at 4.2 °K. However, since our data and that of the Russian workers (18) both refer to InSb at liquid nitrogen temperature, a comparison is allowable. The sodium salt has a lower isomer shift than the potassium salt by 1 mm/s. Part of this difference may be experimental error but it is interesting to note that these salts do have different crystal structures. Sodium hexafluoroantimonate(V) (19) has the same structure as $LiSbF_6$ (20), with a perfect octahedron of fluorines about each antimony. However, in $KSbF_6$ this octahedron is distorted (21). It is also noted that the Sb—F bond length is 1.877 Å in $LiSbF_6$ but 1.77 Å in $KSbF_6$. Such differences are significant and if the sodium salt has a similar Sb—F bond length to that found in $LiSbF_6$ then the difference in isomer between $NaSbF_6$ and $KSbF_6$ are accounted for. However, only the data for $LiSbF_6$ can be considered accurate and the others should probably be reinvestigated.

Bryukhanov *et al.* (18) found no quadrupole splitting in the sodium hexafluoroantimonate(V) as would have been expected for the regular octahedral arrangement discussed above. A splitting was reported for the $KSbF_6$ (16) which we confirm, although our value is considerably less (+3.1 mm/s) than that previously reported (+8.0 mm/s) (16). Both results confirm that this salt indeed has a distorted anion. We feel that our lower value is the more realistic in view of the crystallographic evidence.

The data for the $Sb_2F_{11}^-$ salt can be rationalized on terms of the known structural information. Although the structure of the Cs^+ salt is

unknown, it seems reasonable that the anion will resemble that in $XeF.Sb_2F_{11}$ (22) where two SbF_5 units are linked by a fluorine bridge. Since a bridging fluorine will remove less electron density from the central atom than a terminal fluorine, one would expect the Sb in $Sb_2F_{11}^-$ to have a higher s electron density than in SbF_6^-, and hence a lower isomer shift. This is indeed observed. One also notes a larger quadrupole splitting in $Sb_2F_{11}^-$ than in SbF_6^-. In the Sb_2F_{11} fragment of $XeF.Sb_2F_{11}$ there are three Sb—F distances 1.78–1.80 Å and 1.90–1.93 Å for the two kinds of terminal fluorine, and a longer bond 2.05 Å to the bridging fluorine. The quadrupole splitting found for $CsSb_2F_{11}$ is clearly in accord with a similarly distorted antimony environment.

We hope to make use of the data presented here in a Mössbauer analysis of more complex antimony–fluorine systems.

We wish to thank the National Research Council of Canada for supporting this work and for a fellowship for B.D.V.

Studies on Metal Hydroxy Compounds. XIII. Thermal Analyses and Decomposition Kinetics of Hydroxystannates of Bivalent Metals

P. RAMAMURTHY AND E. A. SECCO

Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received March 8, 1971

The thermal analyses of hexahydroxystannates of bivalent metals of the type $Me[Sn(OH)_6]$, where Me = Zn, Co, Cu, Ni, Mn, Ca, Mg, Cd, Sr, reveal that the primary mode of decomposition occurs by dehydroxylation and subsequent decomposition of the metastannate residue occurs in the Zn, Cu, Mn, Ca, and Mg compounds. Calorimetric measurements along with related enthalpic values for the decomposition reaction are given. The kinetics of thermal decomposition of all compounds studied, except the Cd and Mg analogues, follow first order reaction kinetics up to $\alpha \sim 0.9$.

Les analyses thermiques d'hexahydroxystannates de métaux divalents du type $Me[Sn(OH)_6]$, avec Me = Zn, Co, Cu, Ni, Mn, Ca, Mg, Cd, Sr, indiquent que le premier mode de décomposition se fait par déshydroxylation, et que la décomposition subséquente du métastannate résiduel se fait dans les composés du Zn, Cu, Mn, Ca et Mg. Des mesures calorimétriques, de pair avec les valeurs d'enthalpies, sont rapportées pour la décomposition.

Les cinétiques de la décomposition thermique de tous les composés étudiés, à l'exception des analogues du Cd et Mg, obéissent aux réactions cinétiques de premier ordre jusqu'à $\alpha \sim 0.9$.

Canadian Journal of Chemistry, 49, 2813 (1971)

Introduction

Hexahydroxystannates of the general formula $Me[Sn(OH)_6]$, where Me is a bivalent metal, have been known for some time (1, 2) but hitherto no detailed work has been reported on their mode of decomposition and decomposition kinetics.

The existence of $Me[Sn(OH)_6]$ type compounds was thought to provide an opportunity to probe the effect of the metal species Me on the $-Sn(OH)_6$ portion of the molecule. Any effect arising from the Me species might be expected to manifest itself indirectly on the thermal stability, mode of decomposition, and decomposition kinetics of the compound.

The purpose of this paper is to report on a physico-chemical study involving thermal analyses and decomposition kinetics of $Me[Sn(OH)_6]$ compounds where Me represents a bivalent transition metal or Group II*a* metal.

Experimental

All compounds used in this study were prepared in this laboratory by following procedure described in the literature (2, 3). In each preparation, the precipitate was filtered, washed thoroughly with distilled water, and dried at 110 °C overnight.

The identities of the reactant compounds were confirmed by the available X-ray diffraction patterns (3). Those compounds for which X-ray patterns were not available were confirmed in an indirect manner by correlating the thermogravimetric analysis with the X-ray patterns of the solid residues; furthermore, the unknown X-ray patterns had to resemble the known patterns in their essential features.

The heating curves, calorimetric measurements, and isothermal kinetic traces were obtained as previously described (4–6). The heating rate used was 20 °C/min and an ambient atmosphere of dry N_2 (Matheson Prepurified Grade with a stated impurity of 0.003% O_2) at a flow rate of 2SCFH was maintained during all experiments.

Results and Discussion

Thermogravimetry

The results of thermogravimetry are presented in Table 1; the proposed reaction for each compound is that which best fits the observed weight loss. The only step observed in the decomposition reaction is via dehydroxylation which is represented by the general equation

$$[1] \quad Me[Sn(OH)_6]_{(s)} \rightarrow MeSnO_{3(s)} + 3H_2O_{(g)}$$

The products of decomposition were identified by X-ray diffraction and correlated with DTA curves.

Differential Thermal Analysis

The DTA results are given in Table 2 with two thermal effects in evidence. The first effect is endothermic observed in all compounds and corresponds to dehydroxylation according to [1]. The second effect is an exotherm observed

*Exotherms.

with Zn, Cu, Mn, Ca, and Mg and assigned to the decomposition of the metastannate according to the general equations (7),

[2] $$2MeSnO_3 \rightarrow Me_2SnO_4 + SnO_2$$

or

[2*a*] $$MeSnO_3 \rightarrow MeO + SnO_2$$

These latter modes of decomposition, [2] and [2*a*], do not involve any weight change and therefore are not observable in thermogravimetry; the reaction products were, however, identified by X-ray diffraction patterns.

Calorimetric Measurements

The calorimetric results along with the related enthalpic values for the decomposition of the compounds according to reaction 1 with the onset–terminal temperature limits are presented in Table 3; the literature value of decomposition of $Sn(OH)_4$ is included for comparison. The ΔH^0_f of the various hydroxystannates could not be calculated since the heats of formation of the products, $MeSnO_3$, are not reported in the literature.

Reaction Kinetics Data

The experimental α, t data for the decomposition reactions were processed through a large number of kinetic rate expressions. The best linear relations between the experimental data and the known rate expressions over the maximum reaction fraction ($\alpha \sim 0.9$) for all compounds, excepting $Cd[Sn(OH)_6]$, and over the temperature range studied are given in Table 4. All the compounds studied, except the Cd and Mg compounds, obey first order reaction kinetics up to $\alpha \sim 0.9$.

The rate data for $Cd[Sn(OH)_6]$ fit a power law relationship in the initial accelerating stage up to $\alpha = 0.4$, *i.e.*

$$\alpha = kt^n$$

where n is found to be in the range 1.5–1.8. The non-integral and temperature dependent nature of "n" have been interpreted by Thomas and Tompkins (8).

The $Mg[Sn(OH)_6]$ decomposition reaction follows a phase boundary control reaction mechanism as shown by the fitting of its kinetic data to the three-dimensional contracting sphere model equation, *viz*

$$1 - (1 - \alpha)^{1/3} = kt$$

The column of $\log_{10} A$ shows that all compounds, except $Cd[Sn(OH)_6]$, possess a value of $A < 10^{13}$. From the Arrhenius rate equation, in the form derived from activated complex theory (6)

$$k_r = \left[10^{13}\frac{Q^*}{Q}\right] e^{-E_a/RT} = A\, e^{-E_a/RT}$$

A values of 10^6–10^{12} are interpreted in terms of a complex restricted in its modes of rotation to varied degrees as discussed by Cordes (9). A linear relationship is evident for the activation energy E_a and heat of decomposition ΔH as displayed in Fig. 1. The intercept value of *ca.* 3 kcal/mol might represent the net activation energy E_n for decomposition. The relationship is expressed in equation form, $E_a = E_n + \Delta H$, where the dependence of E_a could be ascribed

TABLE 3

Compound	Temperature range (°C)	Heat of decomposition* ΔH/mol of H_2O formed (kcal)	Heat of decomposition* ΔH/mol of compound decomposed (kcal)

$Cd[Sn(OH)_6]$	210–250	4	$\alpha = kt^n (\alpha < 0.4)$ First order ($\alpha > 0.4$)	39.36±2.1 48.9 ±2.8	13.48 23.25
$Mg[Sn(OH)_6]$	250–310	4	$[1 - (1 - \alpha)^{1/3}] = kt$	27.17±1.25	9.16

directly to ΔH. A more meaningful relationship would be, therefore, between ΔH and a fundamental property, such as the ionization potential, of the Me species (Fig. 2). The plot approximates a linear dependence for the bivalent metals of the "first transition" series and Mg; Cd and Sr, apparent exceptions to the linear relationship, belong to the "second transition" series.

The structure of $Me[Sn(OH)_6]$ compounds is reported to consist of discrete $Sn(OH)_6^{2-}$ groups as determined from spectroscopic studies (2). Crystal structure studies of $Me[Sn(OH)_6]$, however, (*i*) report ReO_3 type structures (3*a*) with Me, and Sn species alternating on Re sites and (*ii*) show the metallic species bound to 6OH groups in a pseudo-octahedral coordination (3). Whatever the exact structure of $Me[Sn(OH)_6]$, two types of reactive bound OH groups may be assumed to be present, that is, Me—OH and Sn—OH bonded groups. It is expected the OH bound to Sn to be essentially of constant character in all compounds and also the character of OH bonded to Me is expected to be a function of the nature of Me. Furthermore, if first-order rate kinetics in dehydroxylation reactions of hydroxy compounds (10) is due to the high mobility of free H and bearing in mind the amphoteric nature of stannic hydroxide, then it is suggested that mobile H arises from the [—Sn—O...H] site. Any effect due to the nature of Me is expected therefore to reflect itself on the [—Me—OH] portion.

A simple interpretation for the inverse dependence of ΔH with ionization potential, assuming all other factors to remain constant, might be given in terms of —Me—OH character. As the ionization potential of Me increases, the contribution of negative charge by Me to the electronegative O is minimal so that the OH is covalently bonded to Me resulting in a relatively

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

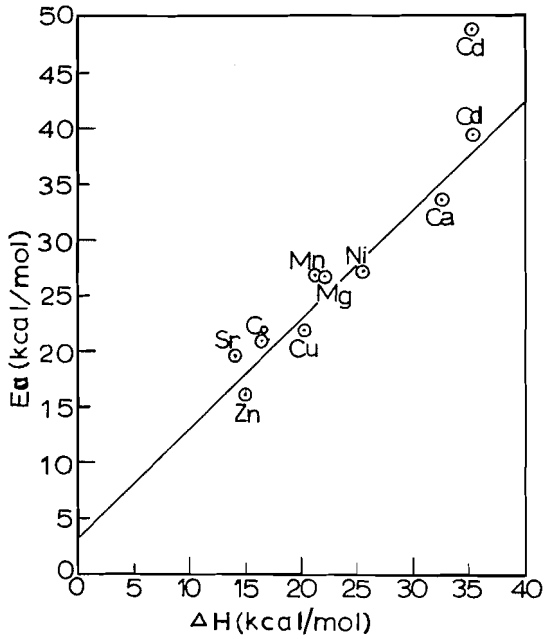

FIG. 1. Plot of activation energy E_a *vs.* heat of decomposition ΔH.

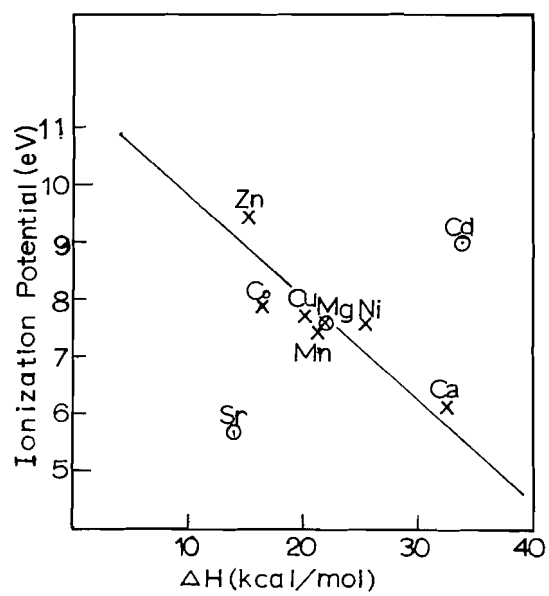

FIG. 2. Plot of ionization potential of the metal species *vs.* heat of decomposition ΔH.

weak [—Me...OH] bond. Conversely, for Me of low ionization potential the contribution of negative charge to O is much greater so OH becomes negatively charged with [—Me^+—OH^-] assuming an ionic character with increased strength. However, a more realistic interpretation must involve an interplay of the effect of the ionization potential of Me on OH groups bonded to both Me and Sn.

The Influence of Sulfoxides and Sulfones on the Temperature of Maximum Density of Water

DIGBY D. MACDONALD,[1] M. D. SMITH, AND J. B. HYNE
Department of Chemistry, University of Calgary, Calgary, Alberta

Received March 11, 1971

The influence of dimethyl sulfoxide (DMSO), diethyl sulfoxide (DESO), tetramethylene sulfoxide (TMSO), and tetramethylene sulfone ($TMSO_2$) on the temperature of maximum density of water has been investigated. It is concluded that in dilute solution DESO stabilizes the characteristic three-dimensional structure of water. The other solutes, however, destabilize the structure of water over the entire concentration range studied (0–1.3 $\times$ 10^{-2} mole fraction solute).

L'influence du diméthyl sulfoxyde (DMSO), diéthyl sulfoxyde (DESO), tétraméthylène sulfoxyde (TMSO) et tétraméthylène sulfone ($TMSO_2$) sur la température du maximum de densité de l'eau, a été étudiée. Il en a été déduit qu'en solution diluée, le DESO stabilise la structure caractéristique à trois dimensions de l'eau. Les autres solutés, par contre, déstabilisent la structure de l'eau sur toute l'échelle de concentration étudiée (0–1.3 $\times$ 10^{-2} fraction molaire de soluté).

Canadian Journal of Chemistry, **49**, 2817 (1971)

Introduction

The influence of various solutes on the temperature of maximum density (TMD) of water has been used in a number of investigations (1–5) to determine the effect of dissolved substances on the structural properties of water. This method is particularly useful since the observed effects are readily interpreted in terms of changes in concentration of the "structured" and "unstructured" components of liquid water (3). Previous studies by Wada and Umeda (1, 2) and by Franks and Watson (3) have demonstrated that certain organic solutes (*e.g.* alcohols, amines) shift the "structured–unstructured" equilibrium in liquid water in the direction of the "structured" component. Other solutes (*e.g.* acetonitrile, propionitrile, acetamide, and 1,4-dioxane) have the reverse effect (2). These two classes of solutes are commonly referred to as "water-structure makers" and "water-structure breakers", respectively.

In view of the growing importance of sulfoxides and sulfones as solutes in biochemical and physico-chemical investigations involving water as solvent, the present study was undertaken to determine their influence on the structure of liquid water. The compounds chosen for this study were dimethyl sulfoxide (DMSO), diethyl sulfoxide (DESO), tetramethylene sulfoxide (TMSO), and tetramethylene sulfone ($TMSO_2$). This series permitted us to examine various relationships between the structural properties of the solutes and their abilities to perturb the structure of liquid water.

[1]Present address: Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba.

Experimental

Apparatus and Method

Temperatures of maximum density were determined by observing the temperature of minimum volume using a 100 ml dilatometer of conventional design (3). The dilatometer was filled with solution and cooled slowly to approximately 5 °C. Air bubbles were carefully excluded. The dilatometer was then thermostated in an oil bath controlled to better than $\pm$0.02 °C. The position of the meniscus was determined with a cathetometer at eight temperatures within $\pm$1.5 °C of the TMD of each solution. After each temperature setting thermal equilibration was indicated by time independence of the solvent meniscus in the capillary. This required about 15 min and a further 15 min were allowed to elapse before reading the meniscus position. All temperature measurements were made with a 6° Beckman thermometer which was calibrated against a platinum resistance thermometer.

Molar volumes of the various solutes were measured at several temperatures using a mercury displacement dilatometer (6). The measurements were made in a 30 °C range extending from about 5 °C above the melting point. The dilatometer was periodically calibrated using degassed conductivity grade water.

Materials

All four compounds were dried over freshly cut calcium hydride and distilled under reduced pressure (~0.1 mm Hg). The middle 70% cuts were collected and stored in tightly stoppered flasks. Chromatographic analysis showed no impurities greater than 0.5% by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

weight. The melting points of the various compounds agreed well with published values (Table 1). We could find no reliable melting point for TMSO in the literature. In this case we have used density as a criterion of purity and find excellent agreement between the density measured in this study and that quoted by Jeffery, Parker, and Vogel (9).

All solutions were prepared by weight using doubly-distilled conductivity grade water. The water was degassed by boiling prior to preparation of the solutions.

Results

The TMDs were determined graphically from the parabolic meniscus position *vs.* temperature plots. It was found that the observed TMD of water in our apparatus occurred at 4.40 °C, 0.42 °C higher than the accepted value of 3.98 °C. This type of discrepancy has been noted previously (1, 4) and has been attributed to expansion of the dilatometer. Accordingly, all observed TMDs were corrected by subtracting 0.42 °C.

Numerical values for $\Delta\theta$, the shift in the TMD from 3.98 °C (*i.e.* TMD − 3.98), for various concentrations of the four compounds in water are listed in Table 2. In order to check the accuracy of the experimental method the TMDs of three potassium chloride solutions were measured and compared with data taken from the literature. The comparison is presented in Fig. 1. The $\Delta\theta$ values illustrated in Fig. 1 were reproducible to ± 0.1 °C and clearly lie on the same line as that generated by literature values to within this limit of error. All other $\Delta\theta$ values reported in this work have the same uncertainty limits.

The numerical values for $(\partial V^0/\partial T)_p$ listed in Table 1 were calculated directly from plots of V^0 *vs.* T. These plots were found to be linear, within experimental error, demonstrating that the $(\partial V^0/\partial T)_p$ values are not strongly dependent on temperature. Accordingly, these values are used in calculating ideal solute induced shifts in the TMD of water (see the following section). The $(\partial V^0/\partial T)_p$ values are considered accurate to better than $\pm 2\%$ as determined by inspection of the V^0 *vs.* T plots.

Discussion

The shifts in the TMD of water produced by the four compounds studied in this work are shown in Fig. 2. In all cases $\Delta\theta$ becomes more negative with increasing concentration of the solute species. This behavior is commonly found (1–5) and was recognized as early as 1839 by Despretz (10, 11).

Wada and Umeda (1, 2) and later Franks and Watson (3) have shown that the observed shift in the TMD can be divided into an ideal contribution ($\Delta\theta_i$) and a non-ideal contribution ($\Delta\theta_s$). Thermodynamic reasoning shows that this relationship may be written as eq. 1.

$$[1]\quad \Delta\theta = -\left(\frac{\chi}{1-\chi}\cdot\frac{(\partial V^0/\partial T)_p}{2\alpha_1 V_1^*}\right) - \left(\frac{(\partial \Delta V_x^M/\partial T)}{2(1-\chi)\alpha_1 V_1^*}\right) = \Delta\theta_i + \Delta\theta_s$$

where V^0 is the molar volume of the solute, V_1^* is the molar volume of water at 3.98 °C (*i.e.* 18.016 ml mol^{-1}), ΔV_x^M is the excess volume of mixing, χ is the mole fraction of solute, and α_1 is a constant which defines the parabolic variation of the molar volume of water with temperature about the TMD (1, 3). This constant has a numerical value of 7.80×10^{-6} deg^{-2} (1). For an ideal solution ΔV_x^M is zero at all temperatures so the shift in the TMD becomes numerically equal to the first term on the right hand side of eq. 1, $\Delta\theta_i$. For dilute real systems $\chi/(1-\chi) \rightarrow \chi$ and $(1-\chi) \rightarrow 1$ so eq. 1 can be reduced to eq. 2.

$$[2]\quad \Delta\theta = -\frac{(\partial V^0/\partial T)_p}{2\alpha_1 V_1^*}\cdot\chi - \frac{(\partial \Delta V_x^M/\partial T)}{2\alpha_1 V_1^*}$$

Equation 2 predicts that if $(\partial \Delta V_x^M/\partial T)$ is a linear function of χ then $\Delta\theta$ will vary linearly with composition thus obeying the Depretz rule (10, 11). The data plotted in Figs. 1 and 2 reveal that potassium chloride and $TMSO_2$ obey the Depretz rule whereas the other compounds examined do not. This observation shows that for potassium chloride and $TMSO_2$ $(\partial \Delta V_x^M/\partial T)$ is a linear function of χ. For the three less dipolar sulfoxides, however, $(\partial \Delta V_x^M/\partial T)$ must vary non-linearly with χ over the composition range considered resulting in the observed non-linear dependence of $\Delta\theta$ on χ. Unfortunately no direct measurements of $(\partial \Delta V_x^M/\partial T)$ as a function of χ have been made for these systems with sufficient accuracy to test the above predictions.

Numerical data contained in Table 1 permit calculation of $\Delta\theta_i$ for the various sulfoxide and sulfone solutions employed in this study. The results of these calculations are illustrated in Fig. 3. Two points should be noted. First, $\Delta\theta_i$ is always negative and varies linearly with χ (see eq. 2). Second, the relative abilities of the compounds to depress $\Delta\theta$ (Fig. 2) and $\Delta\theta_i$ (Fig. 3) are not the same. This clearly demonstrates that the non-ideal term ($\Delta\theta_s$) makes a significant contribution to the behavior of $\Delta\theta$ for the compounds studied.

The non-ideal contribution to the solute-induced shifts in the TMD of water have also been calculated (eq. 1) and are plotted in Fig. 4. Previous investigations (1–3) suggest that *non-electrolytes* which stabilize the characteristic three-dimensional structure of water against thermal destruction, *i.e.*, "water – structure makers", exhibit positive values for $\Delta\theta_s$.[2] Ac-

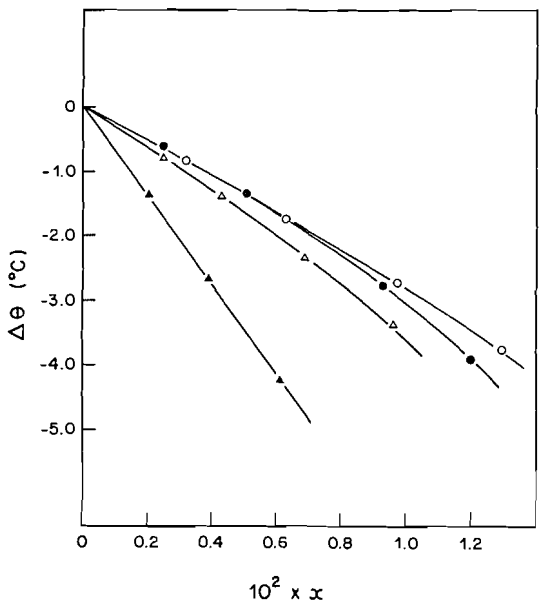

FIG. 2. The overall influence ($\Delta\theta$) of sulfoxides and sulfone mole fraction on the TMD of water. ○, DMSO; ●, DESO; △, TMSO; ▲, $TMSO_2$.

[2]Recent work by Wada and Miura (12) and Sarma and Ahluwalia (13) suggests that this generalization may not hold true for "structure-making" ionic solutes such as the tetra-alkyl ammonium halides. The reader is referred to these papers for a detailed discussion of this apparent anomaly.

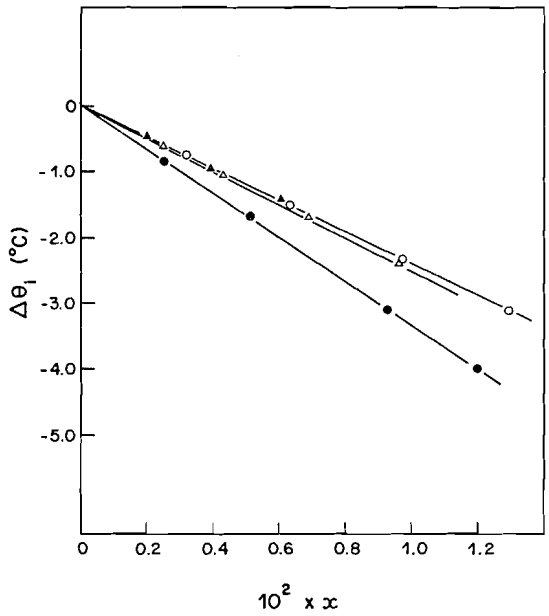

FIG. 3. Ideal component of the shift ($\Delta\theta_i$) in the TMD of water as a function of mole fraction. ○, DMSO; ●, DESO; △, TMSO; ▲, $TMSO_2$.

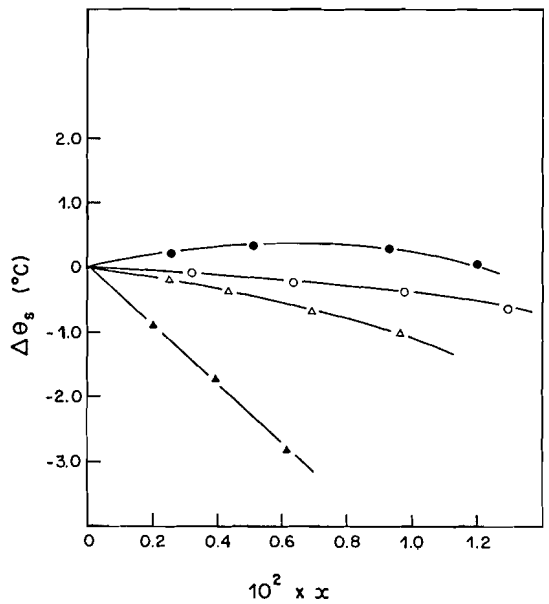

FIG. 4. Non-ideal component of the shift ($\Delta\theta_s$) in the TMD of water as a function of mole fraction. ○, DMSO; ●, DESO; △, TMSO; ▲, $TMSO_2$.

cording to the above interpretation of the four solutes investigated here only DESO can be considered as a "water-structure maker" and then only in dilute solution ($<1.2 \times 10^{-2}$ mol fraction). The other three solutes appear to destabilize or break-down the characteristic three-dimensional structure of liquid water apparently in the increasing order of effectiveness DMSO < TMSO < $TMSO_2$. A recent study by Safford *et al.* (14) showed that small additions of DMSO to water sharpen the peaks in the radial distribution function derived from X-ray diffraction and also the intermolecular frequency spectrum of water derived from neutron inelastic scattering. These data indicate that DMSO increases the molecular order in water. On the other hand, a more recent study by Brink and Falk (15) has shown that addition of a few mol% of DMSO to water does not change the average value or the width of distribution of hydrogen bond energies derived from infrared spectroscopy. These latter data indicate that small additions of DMSO have little effect on the structure of water. In the present study, however, we find that DMSO produces a small negative $\Delta\theta_s$ suggesting that this compound destabilizes or breaks down the characteristic three-dimensional structure of liquid water. This contrasts with the findings of both Safford *et al.* and Brink and Falk. It is possible, though not considered likely, that the different conclusions reflect different experimental temperatures, *i.e.* 4 °C for the present study but 25 °C for the other two. It is more likely, however, that the three experimental techniques respond to different phenomena.

If the ability of a solute to perturb the structure of water can be regarded as a sum of group effects, as proposed by Wada and Umeda (2), then the data plotted in Fig. 4 provide a means of determining the effect of varying the hydrophobic nature and the hydrophilic nature of the solute on its ability to "make" or "break" the structure of liquid water. In the sulfoxide series the structure making tendencies fall in the order DESO > DMSO > TMSO. Since the sulfoxide group is common to all three compounds then this order reflects the relative abilities of the diethyl, dimethyl, and tetramethylene groups to stabilize water structure. The observation that a diethyl configuration has a greater structure making ability than a dimethyl configuration is expected since previous investigations (1–3) have shown that hydrophobic structure making ability increases with carbon

chain length. On the other hand, comparison of the behavior of DESO and TMSO (Fig. 4) shows that the open chain configuration (DESO) has a much greater ability to stabilize water structure than the closed ring configuration (TMSO), even though both compounds possess four carbon atoms. This difference is too large to reflect merely the different number of hydrogen atoms. Instead, it is likely that the greater degree of conformational freedom possessed by DESO allows this compound to adopt a more efficient structure making configuration in the open three-dimensional structure which is characteristic of liquid water.

The effect of varying the hydrophilic nature of the solute may be examined by comparing the $\Delta\theta_s$ *vs.* χ curves for TMSO and $TMSO_2$ plotted in Fig. 4. These curves clearly show that a sulfone group ($>SO_2$) is much more efficient at destabilizing water structure than a sulfoxide group ($>SO$). Wada and Umeda (2) have demonstrated that the water-structure breaking ability of a hydrophilic group increases with its group dipole moment. Since sulfones have larger dipole moments than sulfoxides (16) the relationship found above is expected.

Finally, the $\Delta\theta_s$ *vs.* χ curve for DESO plotted in Fig. 4 passes through a maximum at about 0.7×10^{-2} mole fraction solute, indicating that the structure making ability of DESO is optimized at this composition. This observation suggests that at this concentration the structure making ability of DESO is counterbalanced by the structure breaking effect of its sulfoxide dipole, and further additions of DESO to the system result in the destruction of the stabilized water clusters by a bulk effect, *i.e.* the water molecules become too dilute to maintain co-operative hydrogen bonding. This explanation can also account for the curved $\Delta\theta_s$ *vs.* χ curves (Fig. 4) for DMSO and TMSO, both of which are water-structure destabilizers. At low concentrations solute–water dipole–dipole interaction or hydrogen bonding are the dominant mechanisms in destabilizing water clusters. At higher concentrations, however, the water-structure destabilizing bulk effect of the solute is superimposed on the above mechanism resulting in $(\partial\Delta\theta_s/\partial\chi)$ becoming more negative with increasing solute concentration.

The Decomposition of Aqueous Sodium Bromite

C. L. Lee and M. W. Lister
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received March 24, 1971

An investigation of the rate of decomposition of aqueous sodium bromite is described. The main reactions are: $2BrO_2^- \rightarrow BrO^- + BrO_3^-$ and $Br^- + BrO_2^- \rightarrow 2BrO^-$, followed by $BrO^- + BrO_2^- \rightarrow Br^- + BrO_3^-$. The rate constants and activation parameters of the decomposition reactions are reported. As the second reaction is the reverse of that previously studied in the decomposition of sodium hypobromite, its equilibrium constant (at various temperatures) can be obtained, and hence the thermodynamic properties of aqueous bromite ions. These are briefly compared with the properties of similar ions containing bromine or chlorine.

On décrit les recherches entreprises en vue de déterminer la vitesse de décomposition d'une solution aqueuse de bromite de sodium. Les réactions principales sont: $2BrO_2^- \rightarrow BrO^- + BrO_3^-$ et $Br^- + BrO_2^- \rightarrow 2BrO^-$ puis $BrO^- + BrO_2^- \rightarrow Br^- + BrO_3^-$. On rapporte les constantes de vitesse et les paramètres d'activation pour ces réactions de décomposition. Puisque la deuxième réaction est l'inverse de celle étudiée précédemment pour la décomposition de l'hypobromite de sodium, sa constante d'équilibre (à différente température) peut être obtenue et par conséquent les propriétés thermodynamique des ions bromites en solution aqueuse. Celles-ci sont brièvement comparées avec les propriétés d'ions similaires contenant du brome ou du chlore.

Canadian Journal of Chemistry, 49, 2822 (1971)

This paper is concerned with the kinetic and, to a lesser extent, thermodynamic stability of bromite ions in aqueous solution. The results permit some comparisons to be made amongst the series of bromine oxyions, and these in turn are briefly compared with the analogous chlorine compounds. Bromite ions have been relatively little investigated, but a study of their kinetic stability was made by Engel, Oplatka, and Perlmutter-Hayman (1) as part of their research on hypobromite ions. We have examined their decomposition under somewhat different conditions and over a range of temperature, and a comparison with their results will be made later in this paper. A fairly extensive investigation of the conditions of formation of bromite from hypobromite ions, and of the preparation of sodium bromite, has been made by Breiss (2). The present work was done at sufficiently high p*H*, so that protonated species (particularly HOBr) would be present only at very low concentrations. Acidified sodium bromite decomposes rapidly, so presumably other reactions, not investigated in the present work, are then important.

Experimental

Sodium Bromite

Several sources were used for the reagent. Firstly, it was prepared by the method of Breiss (2), which gave crystals of the trihydrate, $NaBrO_2.3H_2O$. Secondly, crystals of the same composition were made available by La Société d'Études Chimiques pour l'Industrie et l'Agriculture, of Argenteuil, France, to whom we are much indebted. Thirdly, a solution of the compound was obtained from the Olin Mathieson Chemical Corporation of New York, and this solution was evaporated and the sodium bromite recrystallized. Most of the experiments used material from the first two sources. Since the solid showed a tendency to decompose, the crystals were dissolved in dilute sodium hydroxide solution to give a stock solution that was reasonably stable, and which was diluted as required for the experiments.

Sodium hydroxide and bromine, used in the preparation of sodium bromite, were of analytical reagent grade, as were the sodium bromide and sodium perchlorate which were added to the solutions in the kinetic experiments.

Apparatus

In the kinetic runs, samples of the appropriate solution were sealed in Pyrex glass ampoules, and immersed in a thermostat for known lengths of time. The thermostat contained silicone oil, controlled to ± 0.02 °C. The solutions contained sodium bromite, sodium hydroxide, sodium bromide (not added in some runs), and sodium perchlorate to adjust the ionic strength to a value of 0.50. At suitable times the ampoules were removed, rapidly cooled, and the contents analyzed.

Analysis of Solutions

The solutions in general contained sodium bromide, hypobromite, bromite, and bromate, sodium hydroxide and possibly a little carbonate. The sodium perchlorate present was assumed not to react, so its concentration was known from the amount added initially. The sodium bromide concentration was also known from the amount put in initially, plus the amount formed in the reaction (see below).

The sodium bromite and hypobromite were estimated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

spectrophotometrically with a Beckmann DU Spectrophotometer. Their extinction coefficients were measured from the absorbances of freshly prepared alkaline solutions; in the case of sodium hypobromite this was made in the usual way by adding bromine to cold sodium hydroxide solution. It was checked by polarography that these solutions did not contain appreciable amounts of the other ion (*e.g.* hypobromite in the bromite solution). The polarographic experiments would have detected 0.5% of the other ion as impurity. The extinction coefficients found were as follows:

	Extinction coefficient	
Wavelength (nm)	NaBrO	$NaBrO_2$
296	113.2	114.6
300	140.5	112.4
310	220.2	100.0
320	284.5	90.0
330	303.2	83.6
340	278.1	73.7
350	220.8	60.4
360	155.0	44.6
370	94.9	30.8
380	56.6	20.5

The solutions used to obtain these extinction coefficients were standardized by titration with arsenious oxide at a p*H* regulated by excess sodium bicarbonate (3). The arsenious oxide reacts with both sodium hypobromite and bromite. In the kinetic runs measurements were made at 296 and 380 mμ, and it was checked that the other species present did not contribute appreciably to the absorbances at these wavelengths.

It was found that the total oxidizing normality, measured by the iodine liberated on adding excess potassium iodide and sulfuric acid, did not change during a run, so presumably oxygen is not evolved. Consequently changes in bromide and bromate concentrations could be calculated from the mass balance of bromine and oxygen atoms. The absence of oxygen evolution was confirmed (within moderate limits) by the fact that the ampoules did not develop increased pressure during a run.

The concentration of sodium hydroxide was found by adding excess hydrogen peroxide to a sample, boiling to destroy the excess, followed by titration with standard acid. The hydrogen peroxide reacts with both sodium bromite and hypobromite.

Mechanism and Calculation of Rate Constants

Engel, Oplatka, and Perlmutter-Hayman (1) proposed a mechanism for the decomposition of sodium bromite. Our results fit their mechanism, though with some difference in the relative contributions of the various reactions. They found a dependence of the rate on p*H*,while under the conditions of the present experiments (0.06 to 0.18 *M* sodium hydroxide), no change in rate constant was found with varying $[OH^-]$. They interpreted their results as showing that at the lower p*H* of most of their experiments protonated species are reacting. Presumably these species are present in such low concentrations under the conditions of our experiments as to have no effect. However, it should be mentioned that in the somewhat analogous decomposition of hyperbromite ions, the rate increases with $[OH^-]$, and the rate in fact passes through a minimum at about the p*H* values we have used (3, 4). It is possible, therefore, that a similar minimum occurs for bromite ions, and that the apparent lack of p*H* dependence arises because our experiments fall in the region of this minimum.

We can therefore re-write their mechanism, and propose that the following reactions occur:

$$[1] \qquad 2BrO_2^- \xrightarrow{k_1} BrO_3^- + BrO^-$$

$$[2] \qquad BrO^- + BrO_2^- \xrightarrow{k_2} BrO_3^- + Br^-$$

$$[3] \qquad Br^- + BrO_2^- \xrightarrow{k_3} 2BrO^-$$

$$[4] \qquad 2BrO^- \xrightarrow{k_4} Br^- + BrO_2^-$$

Reaction 4 is the reverse of reaction 3, and is the initial step in the decomposition of hypobromite ions. Engel, Oplatka, and Perlmutter-Hayman found that, at 25 °C and at the concentrations they used, reaction 3 was more important than reaction 1. However, in our experiments, both reaction paths made appreciable contributions, with reaction 1 predominating.

The mechanism above gives rate equations which could not be integrated, but since k_2 is relatively high, the steady state approximation was made that $d[BrO^-]/dt = 0$. From this, putting $[Br^-] = x$, $[BrO^-] = y$, and $[BrO_2^-] = z$, we get

$$2k_4y^2 + k_2yz - k_1z^2 - 2k_3xz = 0$$

Values of k_4 are known (1, 4, 5), and also of k_2 (5), and these combined with the values of k_1 and k_3 obtained below show that the term $2k_4y^2$ is small enough to be neglected. Hence $y = (k_1z + 2k_3x)/k_2$. With this approximation, the rate equations can be integrated to give (with $\beta = x_0/z_0$)

$$\frac{1}{z} = \frac{k_3 - 3k_1 + 3(k_3\beta + k_1)\, e^{k_3(3\beta+1)z_0t}}{k_3(3\beta + 1)z_0}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

A plot of $1/z$ against t should give an exponential curve of increasing slope, but it was found that our experimental results were such that the curvature was very slight during the decomposition of the first 20–25% of the sodium bromite. The slope $d(1/z)/dt$ is

$$3(k_3\beta + k_1)e^{k_3(3\beta + 1)z_0 t}$$

and the initial slope is $3(k_3\beta + k_1)$. In practice, we took an average slope, $(1/z - 1/z_0)/t$, over the first part of the reaction. This average slope can be shown to be $S_0\,(e^{ct} - 1)/ct$, where S_0 is the initial slope, and $c = k_3(3\beta + 1)z_0$. The average slope was therefore corrected to give the initial slope by this expression. This involves a knowledge of k_3, which was obtained as described below. The process of correction was repeated until the value of k_3 used to obtain S_0 was the same as the final value of k_3. Finally S_0 was plotted against β, which gave a linear plot, though with some scatter. The best line through the points was obtained by least mean squares, and k_1 and k_3 were obtained from this line, since $S_0 = 3(k_3\beta + k_1)$. The corrections from the average to the initial slopes were mostly under 5%, and in only one run above 10%.

After the rate constants had been obtained, the validity of the steady state approximation was checked as follows. Firstly, the concentrations of hypobromite ion, which are also obtainable from the measured absorbances, were compared with the steady state values given by $(k_1z + 2k_3x)/k_2$. However, $[BrO^-]$ was always so low, that the most that can be said is that the values were of the right order of magnitude. In a typical run $[BrO_2^-] = 0.05\ M$, and the calculated $[BrO^-] = 0.0004\ M$. As the extinction coefficients are not very different, it follows that a very small error in absorbance gives a large error in $[BrO^-]$. Secondly, the differential equations were integrated numerically, with the assumption that initially $[BrO^-] = 0$. It was found that the steady state concentration of hypobromite had developed rapidly compared with the rate of decomposition of the bromite. 95% of the steady state $[BrO^-]$ was reached during the first 1 to 2½% of the bromite decomposition, the exact amount depending chiefly on the concentration of bromide ions. At the same time the slope, which starts low if $[BrO^-]$ is initially zero, had risen to 97 to 98% of its steady state value. The first sample was taken after a time that was long enough to ensure firstly that temperature equilibrium had been reached and secondly that steady state conditions had been virtually established.

Results

Table 1 gives the results for the main series of runs at 76.6 °C. The slopes are corrected on the assumption that $k_3 = 3.925 \times 10^{-7}\ M^{-1}\ s^{-1}$, and the least mean squares line drawn through S_0 plotted against β gives $k_3 = 3.917 \times 10^{-7} M^{-1}\ s^{-1}$. The best value for k_3 is therefore $3.92 \times 10^{-7}\ M^{-1}\ s^{-1}$. The value derived for k_1 is $3.04 \times 10^{-6}\ M^{-1}\ s^{-1}$.

Similar data for 86.0 °C are given in Table 2. Here the slopes are corrected on the assumption that $k_3 = 6.90 \times 10^{-7}\ M^{-1}\ s^{-1}$, and the resulting plot of S_0 against β makes $k_3 = 6.896 \times 10^{-7}\ M^{-1}\ s^{-1}$. Hence the best value for k_3 is $6.90 \times 10^{-7}\ M^{-1}\ s^{-1}$, and the value for k_1 is found to be $8.10 \times 10^{-6}\ M^{-1}\ s^{-1}$. Table 2 also contains data for 96.7 °C. The slopes are corrected with $k_3 = 12.08 \times 10^{-7}\ M^{-1}\ s^{-1}$, and these in turn give $k_3 = 12.06 \times 10^{-7}\ M^{-1}\ s^{-1}$. The best value for k_3 is taken to be $12.07 \times 10^{-7}\ M^{-1}\ s^{-1}$, and the value of k_1 is found to be $24.79 \times 10^{-6}\ M^{-1}\ s^{-1}$.

A plot of $\log k_1$ or $\log k_3$ against $1/T$ is reasonably linear in both cases. For k_1, the activation energy is 26.8_5 kcal/mol. If we assume that $\Delta H^{\ddagger}$ is independent of temperature, then $\Delta H^{\ddagger} = 26.2_5$ kcal/mol (at 25 °C) and $\Delta S^{\ddagger} = -7.3$ cal/deg mol; $\log k_1$ extrapolated to 25 °C is −8.43. For k_3, the activation energy is 13.7 kcal/mol. From this, $\Delta H^{\ddagger} = 13.1$ kcal/mol (at 25 °C) and $\Delta S^{\ddagger}$ is −47 cal/deg mol; $\log k_3$ extrapolated to 25 °C is −7.96.

The slope, S_0, and hence the rate constants do not appear to depend on the concentration of hydroxide ions present. Neither k_1 nor k_3 gave any systematic trend with $[OH^-]$ over the range 0.06 to 0.18 M.

Discussion

The results of the present work differ somewhat from those of Engel, Oplatka, and Perlmutter-Hayman (1), but the differences can be attributed to different experimental conditions. Firstly, these workers find the rate decreases with increasing pH, by a factor of 3 for every pH unit. However, their results are only for pH values of 8.5, 9.7, and 13.0, and they did not investigate whether there is any change around pH 13. Our

results indicate that at high pH, the rate does not change with pH; this is presumably because protonated species (such as HOBr), which could offer alternative routes for the reaction, are effectively absent in 0.1 M sodium hydroxide. Hence we have written the reactions as occurring between ions.

Secondly, the earlier workers found that at 25 °C the reaction $Br^- + BrO_2^- \rightarrow 2BrO^-$ predominated under their experimental conditions. However, the rate constants they quote are not very different: in our nomenclature, they give $k_1 = 1.3 \times 10^{-4}$ M^{-1} s^{-1}, and $k_3 = 1.43 \times 10^{-4}$ M^{-1} s^{-1}. At high temperatures, we find k_1 greater than k_3, but the activation parameters are such that this order reverses at low temperatures, and the rate constants extrapolated to 25 °C are $k_1 = 3.7 \times 10^{-9}$, $k_3 = 1.1 \times 10^{-8}$ M^{-1} s^{-1}. This is a long extrapolation, but at least it agrees with Engel, Oplatka, and Perlmutter-Hayman's result that k_3 is more important at low temperatures. Their rate constants quoted above are for a pH of 8.5, which is presumably why they are much larger than ours. However, the discrepancy is larger than would be expected from their observations on the effect of pH, and cannot at present be explained.

The results allow some calculations to be made on the thermodynamic properties of bromite ions. Reactions 3 and 4 above lead to an equilibrium

$$Br^- + BrO_2^- \underset{k_4}{\overset{k_3}{\rightleftharpoons}} 2BrO^-$$

with the activation parameters: reaction 3 has $\Delta H^{\ddagger} = 13.1$ kcal/mol, $\Delta S^{\ddagger} = -47$ cal/deg mol;

TABLE 3. Conventional thermodynamic quantities for aqueous ions at 25 °C

Ion	ΔH^0_f	ΔG^0_f	S^0	Ion	ΔH^0_f	ΔG^0_f	S^0
Cl^-	−40.0	−31.35	13.2	Br^-	−28.9	−24.6	19.3
ClO^-	−25.4	−8.9	10.0	BrO^-	−21.9	−8.0	12.0
ClO_2^-	−16.6	2.7	24.1	BrO_2^-	−8.9	6.5	30.5
ClO_3^-	−25.15	−2.15	38.8	BrO_3^-	-16.2_5	4.3	38.6
ClO_4^-	−31.0	−2.1	43.5	BrO_4^-	2.9	28.9	44.7
$Cl_2O_2^{2-\ddagger}$	−26.3	10.1	8.7	$Br_2O_2^{2-\ddagger}$	−25.0	9.1	3.0

and reaction 4 has $\Delta H^{\ddagger} = 18.8$ kcal/mol, $\Delta S^{\ddagger} = -21$ cal/deg mol (5). Hence ΔH for the reaction in the k_3 direction is −5.7 kcal/mol, and ΔS is −26 cal/deg mol. Thermodynamic data on dilute aqueous solutions are for sodium bromide: $\Delta H^0_f = -86.2$, $\Delta G^0_f = -87.2$ kcal/mol, $S^0 = 33.7$ cal/deg mol; and for sodium hypobromite: $\Delta H^0_f = -79.1$, $\Delta G^0_f = -70.6$ kcal/mol, $S^0 = 26.4$ cal/deg mol (6, 7). Hence calculated values for sodium bromite (aq) are: $\Delta H_f^0 = -66.3$ kcal/mol, and $S^0 = 45$ cal/deg mol. These results, combined with data for the elements in sodium bromite, make the value for its $\Delta G^0_f = -56.1$ kcal/mol. Some confirmation of this is provided by the value for ΔH^0_f of −66.0 kcal/mol from calorimetric measurements on the reaction of aqueous sodium bromite and sodium sulfite (8). Table 3 summarizes values for chlorine and bromine oxyions, in order to show that the values deduced above for sodium bromite (aq) are reasonable. The data come from refs. 6, 7, and 9. Values are included for the activated species $X_2O_2^{2-\ddagger}$ (for $Cl_2O_2^{2-\ddagger}$, see ref. 10). The values in Table 3 are conventional values, relative to H^+ (aq) as zero.

The general trends of these quantities are similar, apart from the well-known low stability of perbromates. As regards bromite ions, their ΔH^0_f, relative to the other bromine ions, is somewhat more positive compared to the chlorine series. This is somewhat offset by their higher entropy, so that there is less contrast in ΔG^0_f. Thus the equilibrium constant for $X^- + XO_2^- \rightleftharpoons 2XO^-$ is calculated to be 1.4×10^{-3} for the bromine compounds, and 1.4×10^{-11} for chlorine. The activated species $X_2O_2^{2-\ddagger}$ are also not very different in the two series, although here the entropy of the bromine species is somewhat lower. At present, it does not seem to be possible to explain these differences in detail.

In a recent paper (11), Massagli, Indelli, and Pergola report results of the decomposition of bromite at pH of 8.5 and below. Their results follow a rate equation

$$\text{Rate} = [HBrO_2][Br^-]\{k_1 + k_2[H^+]\}$$

which is evidently a different mechanism from ours, the difference being presumably attributable to the much lower pH of their experiments.

The Decomposition of Perchloric Acid on Metal Oxide Catalysts

R. GILBERT[1] AND P. W. M. JACOBS

Department of Chemistry, The University of Western Ontario, London 72, Ontario

Received February 9, 1971

The thermal decomposition of perchloric acid has been investigated on five Harshaw catalysts: copper chromite, alumina, iron(III) oxide, copper(II) oxide, and manganese(IV) oxide (the last three being supported on alumina). Manganese(IV) oxide gave complex kinetics which were not fully analyzed but on the other four catalysts the reaction was first order. Activation energies were: copper chromite, 54 kcal/mol; alumina, 28.8 kcal/mol; iron(III) oxide, 28.6 kcal/mol; copper(II) oxide, 39.0 kcal/mol. A mechanism is proposed for the decomposition which involves proton transfer to an acceptor (typically an O^{2-} ion) in the catalyst surface followed by decomposition of the ClO_4^- anion formed in this process. Some observations on the catalyzed thermal decomposition of ammonium perchlorate are presented.

L'étude de la décomposition thermique de l'acide perchlorique a été faite à partir de cinq catalyseurs de Harshaw: le chromite de cuivre, l'alumine, les oxydes de fer(III), de cuivre(II) et de manganèse(IV) (les trois derniers ayant comme support l'alumine). L'oxyde de manganèse(IV) donne des cinétiques complexes qui n'ont pas été complètement élucidées mais pour les quatre autres catalyseurs, la réaction est du premier ordre. Les énergies d'activation sont de 54 kcal/mol pour le chromite de cuivre, de 28.8 kcal/mol pour l'alumine, de 28.6 kcal/mol pour l'oxyde de fer(III) et de 39.0 kcal/mol pour l'oxyde de cuivre(II). Un mécanisme est proposé pour la décomposition: il y a transfert de proton sur un accepteur (un ion O^{2-} typique) à la surface du catalyseur puis décomposition de l'anion ClO_4^- formé dans ce processus. Quelques observations sur la décomposition thermique catalysée du perchlorate d'ammonium sont aussi présentées.

Canadian Journal of Chemistry, 49, 2827 (1971)

In the course of their study of the thermal decomposition and ignition of ammonium perchlorate, Jacobs and Russell-Jones (1) suggested that the catalytic activity of copper chromite might be due to its ability to catalyze the thermal decomposition of perchloric acid which is produced in the initial step of the decomposition of ammonium perchlorate by proton transfer (2, 3). At that time only the uncatalyzed thermal decomposition of perchloric acid had been studied (4). This reaction appears to be heterogeneous in Pyrex glass reaction vessels at low temperatures (4–6) but homogeneous at high temperatures (4, 6). Further studies of the perchloric acid decomposition and particularly the effect on this of metal oxide catalysts, which are the traditional catalysts for the ammonium perchlorate decomposition, clearly were required. While this work was in progress Solymosi *et al.* published a preliminary report (7) of the effect of a number of oxide catalysts on the decomposition of perchloric acid and later a detailed account (8) of the decomposition on chromium oxide catalysts. In this paper we describe the decomposition of perchloric acid on copper chromite, on alumina, and on iron(III) oxide, copper(II) oxide, and manganese(IV) oxide supported on alumina.

Experimental

The catalysts were supplied by the Harshaw Chemical Co. and are identified by their catalogue numbers. They were in the form of small pellets 1/8 in. long and 1/8 in. in diameter. The surface areas of the catalysts are given in Table 1. The decomposition was studied by a flow method using nitrogen as the carrier gas. The diameter of the catalyst bed was 22 mm. The effluent gases from the

reactor were passed through a trap containing standard NaOH. Analysis of the contents of this trap, after time t, for Cl^-, OCl^-, and OH^- gave the amount of decomposition of $HClO_4$. The residence time, t_r, was calculated from the flow rate and the volume of the reactor. Further details of experimental technique have been given elsewhere (6).

Results

Kinetics

Iron(III) Oxide

A 30 g sample of the catalyst Fe-0301 with a surface area of 1.23×10^3 m^2 was studied at five temperatures in the range 177 to 238 °C. The initial perchloric acid concentration was varied from 2×10^{-4} to 1×10^{-3} mol/l and residence times t_r of 0.05 to 0.7 min were employed. After an initial conditioning period in which the activity increased, reproducible results were obtained. The reaction was of first order, as shown by the plots of $\log (a/a_0)$ *vs.* t_r, a_0 being the initial acid concentration and a the concentration of acid after a residence time t_r (Fig. 1). Points corresponding to different values of a_0 are not distinguished because the fractional decomposition in a given t_r is insensitive to a_0 in the range covered. The catalyst showed no visible signs of attack by the perchloric acid.

Alumina

A 30 g sample of Al-0104 having a surface area of 2.36×10^3 m^2 was studied at five temperatures in the range 176 to 251 °C. The initial acid concentration was in the range 3.2 to 4.0 $\times$ 10^{-4} mol/l and residence times from 0.06 to 1.0 min were employed. No conditioning period was required and the activity of the catalyst remained constant. The reaction was first order at all temperatures studied.

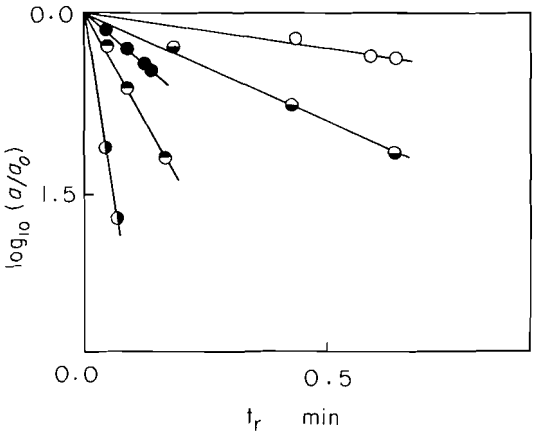

FIG. 1. First order plots for the decomposition of perchloric acid on iron(III) oxide. ○, 176.7 °C; ◒, 196.1 °C; ●, 206.5 °C; ◓, 216.7 °C; ◑, 238.5 °C.

Copper(II) Oxide

A 10 g sample of Cu-0803 having a surface area of 1.37×10^3 m^2 was studied at six temperatures in the range 196 to 250 °C. The initial acid concentration was varied from 2×10^{-4} to 1.5×10^{-3} mol/l and residence times of 0.05 to 0.2 min were used. The activity decreased initially until a relatively constant value was reached. The decomposition was then first order in the above temperature range. At the conclusion of the experiments it was noted that the cupric oxide had partly changed in color from black to green.

Copper Chromite

Two 30 g samples of Cu-0203, each having surface areas of 3.45×10^2 m^2 were used. Both samples were studied at 261 °C and the second sample was also studied at five other temperatures before non-reproducible results were obtained. The initial perchloric acid concentration was varied in the range 3.5 to 9.9 $\times$ 10^{-4} mol/l; residence times were between 0.05 and 0.26 min. Preliminary work showed that initially all the perchloric acid which was passed over the catalyst was consumed but that after a few runs, the catalytic decomposition could be observed. The activity of the catalyst then increased to more than ten times its original value. A second sample showed the same sequence. After this initial conditioning, results were fairly reproducible for about 15 runs but then they gradually became less reproducible and the activity generally decreased. In the reproducible region the decomposition obeyed first order kinetics. Both catalyst samples were visibly attacked by the perchloric acid producing a ginger colored product.

Manganese(IV) Oxide

A 30 g sample of Mn-0201 with a surface area of 2.06×10^3 m^2 was studied at five temperatures in the range 142 to 207 °C. Reproducibility was excellent but the kinetics were not first order. Plots of fractional decomposition α against residence time in Fig. 2 show an initial acceleratory period. Attempts were made to fit these data to a number of Langmuir–Hinshelwood type models but without success. At

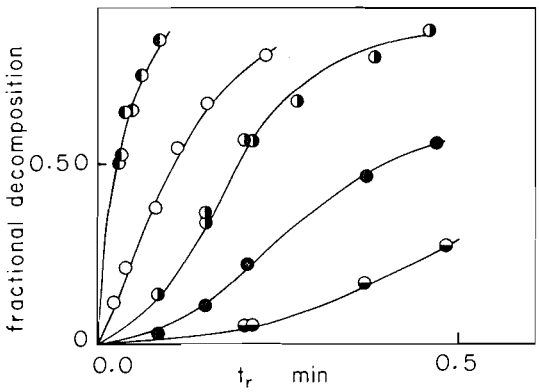

FIG. 2. Decomposition of perchloric acid on manganese(IV) oxide. The plots show the fraction decomposed in a residence time t_r. ◐, 207.2 °C; ○, 197.3 °C; ◑, 177.6 °C; ●, 159.0 °C; ◒, 142.2 °C.

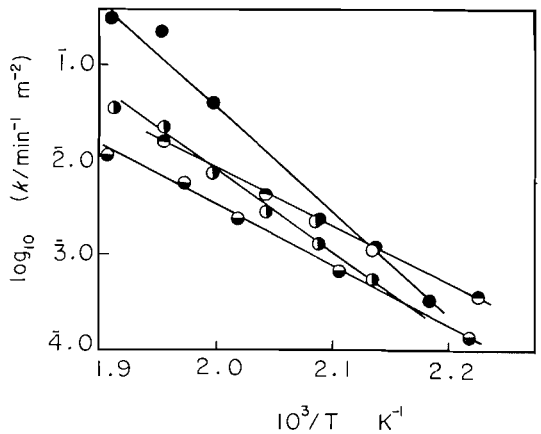

FIG. 3. Arrhenius plots showing the relative activity of four Harshaw catalysts for the decomposition of perchloric acid. ◒, Al-0104; ◑, Cu-0803; ◓, Fe-0301; ●, Cu-0203. Physical characteristics of the catalysts are given in Table 1.

177 °C the fractional decomposition was observed to decrease slightly with increasing acid concentration, suggesting an apparent order of less than unity. Manganese(IV) oxide is an excellent catalyst and highly reproducible results can be obtained with it, but the results were not analyzed in detail because it was felt that self-heating was probably the cause of the acceleratory reaction.

Arrhenius Parameters

The decomposition of perchloric acid is first order on all the catalysts tried apart from Mn-0201. A composite Arrhenius plot is shown in Fig. 3, and the Arrhenius parameters are summarized in Table 2.

TABLE 2. Arrhenius parameters

Catalyst	Apparent activation energy (kcal/mol)	Specific preexponential factor (min^{-1} m^{-2})
Cu-0203	54.0	2.5×10^{22}
Fe-0301	28.6	2.5×10^{10}
Al-0104	28.8	1.3×10^{10}
Cu-0803	39.0	8.0×10^{14}

Discussion

All five of the Harshaw catalysts used catalyzed the decomposition of perchloric acid. Cu-0203 is a pelleted form of Cu-0202 which is used extensively in solid propellant compositions. Its composition corresponds (9) to $CuCr_2O_4$.7CuO; no thermal changes in the catalyst are expected in the temperature range in which it was used. Pearson (9) has shown that alternate exposures of Harshaw Cu-0202 to fuels (ethylene, isobutene or ammonia) and to oxygen resulted in reduction and oxidation of the catalyst and that this was a bulk effect. With these reactants the weight of the catalyst never exceeded 100% of the initial weight, *i.e.* oxygen did not oxidize the Cr(III) present. Alternate exposures to isobutene and perchloric acid induced a similar redox cycle but in this instance the catalyst did show a net weight gain after exposure to perchloric acid. At the same time catalyst samples changed color from black to reddish brown and chromate ion was detected in an alkaline extract, confirming oxidation to Cr(VI). Similar changes were observed in our Cu-0203 catalyst. Initially, all the perchloric acid is consumed so that it must be reacting with the catalyst; then the activity gradually increases until a stable catalyst results. The initial conditioning must correspond to the formation of surface chromate which then functioned as the actual catalyst in this work. It should be noted that cupric chromate, with the empirical formula $CuCrO_4$.1.75Cu$(OH)_2$, is also used in propellant compositions and the same redox cycles as are observed on copper chromite can be induced in copper chromate (9).

Solymosi and Börcsök (8) found that the activity of chromium oxide catalysts lay in the order Cr(III) > Cr(IV) ≫ Cr(VI) and that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

activity of chromium(III) oxide declined due to surface oxidation. The activation energy for decomposition of perchloric acid on Cr(III) oxide (fresh) is 31 kcal/mol (8) and on copper chromite (pre-treated) is 54 kcal/mol while that on cupric oxide is 39 kcal/mol (Table 2). Furthermore the activities of the chromite and cupric oxide catalysts are different. The measured activity of the conditioned chromite must be due, therefore, to the Cr(VI) formed.

Perchloric acid was also observed to react with cupric oxide probably forming the chloride and the oxychloride (9). Since the decomposition kinetics were only studied in the reproducible region the activation parameters (Table 2) correspond to perchloric acid decomposition on the reacted surface containing Cl^- and OCl^- as well as O^{2-} and Cu^{2+} ions.

No visible changes were observed following decomposition on ferric oxide, alumina, or manganese(IV) oxide although there was a conditioning period on ferric oxide. This could have corresponded to oxidation of some iron(II) present but this was not tested for specifically.

Mechanism

Solymosi and Börcsök (8) have suggested that the activity of perchloric acid catalysts is connected with the stability of the corresponding metal perchlorate. We now propose a mechanism for the catalyzed decomposition of perchloric acid that is consistent with this proposal. The requirements for decomposition in this model are (*i*) adsorption of $HClO_4$ molecules on the catalyst, (*ii*) the presence of a proton acceptor in the surface, (*iii*) thermal instability of the metal perchlorate complex formed. The process is depicted in Fig. 4 for an alumina catalyst. The adsorbed perchloric acid (*i*) loses a proton to a surface oxide ion (*ii*). Repetition of this process gives two adjacent OH^- ions from which water can be eliminated. Metallic perchlorates decompose to yield either the chloride or the oxide (10) or, in the case of cupric perchlorate, the oxychloride. In Fig. 4 we presume the oxide is formed. The mechanism (10) in the case of barium and magnesium perchlorates is successive removal of O atoms from ClO_4^- until ClO^- is formed; the ClO^- ions can then either lose a further oxygen atom or decompose bimolecularly to $O^{2-} + Cl_2$. The key step determining the activity of the catalyst is clearly

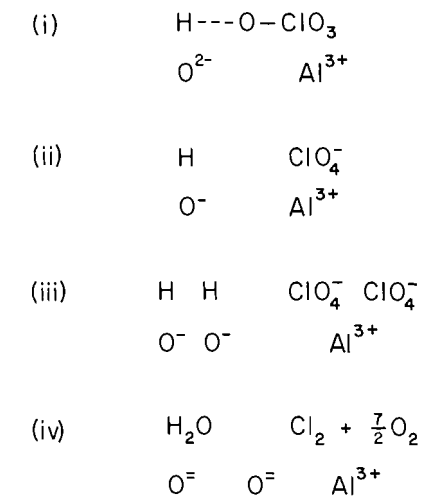

FIG. 4. Schematic representation of the proposed mechanism of decomposition of perchloric acid on metal oxide catalysts. Alumina is used as an example. The essential feature is proton transfer to an acceptor in the catalyst surface followed by decomposition of the resulting ClO_4^- anion.

the (unimolecular) decomposition of ClO_4^- and this will be influenced by the properties of the cation: presumably small cations of high charge will exert the greatest perturbing effect on the $O—ClO_3^-$ bond.

On chromium(III) oxide Solymosi and Börcsök (8) observed ClO_2 to be formed at low temperatures and this would imply a bimolecular decomposition of ClO_4^- ions rather than the unimolecular decomposition discussed above. If further work shows ClO_2 formation to occur quite generally, then the bimolecular decomposition of ClO_4^- will be established as the preferred route. In metallic perchlorates the ClO_4^- decomposes unimolecularly in barium and magnesium perchlorates (10, 11) but bimolecularly in the group I perchlorates (12).

Implications for Ammonium Perchlorate Decomposition

There have been no previously recorded investigations of the catalytic effect of Cu-0803, Fe-0301, and Mn-0201 on the decomposition of ammonium perchlorate although the metal oxides contained in these catalysts are known to be positive catalysts for the ammonium perchlorate decomposition. The catalytic activity of these Harshaw catalysts towards ammonium perchlorate was therefore confirmed in a number

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of experiments using a Perkin–Elmer Differential Scanning Calorimeter. In a previous summary of the activity of catalysts for the high-temperature decomposition of ammonium perchlorate (*i.e.* at temperatures at which the ammonia and perchloric acid desorb into the gas phase) Jacobs and Whitehead (13) classified catalysts into two groups: (*A*) those like magnesium oxide which react with ammonium perchlorate to form the corresponding metallic perchlorate and then form a molten phase, and (*B*) those like copper(II) oxide which do not form a melt and in which any reaction is limited to the catalyst surface. The mechanism of decomposition for group *B* was believed to involve the catalyzed decomposition of perchloric acid (1) while that for group *A* to consist essentially (11, 14) of proton transfer from NH_4^+ to O^{2-} ions, with decomposition of ClO_4^- to regenerate oxide ions. If the views on the mechanism of decomposition of perchloric acid expressed above (Fig. 4) are basically correct, then we see how similar the two catalytic mechanisms really are. For group *A* proton transfer from NH_4^+ to O^{2-} occurs directly while for group *B* proton transfer from NH_4^+ to ClO_4^- is followed by proton transfer from $HClO_4$ to the O^{2-} (or Cl^- or other proton acceptor) in the catalyst. Evidence supporting this view comes from the work of Boldyreva, Bezrukov, and Boldyrev (15) who showed that copper(II) oxide (and several other oxides from group *B*) can catalyze the decomposition of ammonium perchlorate even when separated physically from it so that it is the perchloric acid diffusing to the catalyst through the vapor phase whose decomposition is being facilitated. The work of Solymosi and Börcsök (8) also supports these mechanisms: these authors observe that while ZnO, CdO, and MgO all form perchlorates only ZnO is an active catalyst for the perchloric acid decomposition at ~350 °C and they attribute this (quite correctly in our view) to the greater thermal stability of magnesium and cadmium perchlorates compared to that of zinc perchlorate. It follows that in catalyzing the thermal decomposition of ammonium perchlorate CdO and MgO (group *A*) are not acting by catalyzing the decomposition of perchloric acid.

The explanation of the generally close parallel between catalytic activity for perchloric acid decomposition and ammonium perchlorate decomposition (7, 16) would thus seem to have a sufficient basis in the mechanisms presented and discussed in this paper.

Low Surface Coverage Interactions of Sulfur Dioxide on Selected Transition Metal Catalysts from 273 to 423 °K

R. W. GLASS AND R. A. ROSS
Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received April 13, 1971

Calorimetric heats of adsorption for sulfur dioxide at low surface coverages from 0.004 to 0.600 μmol m^{-2} on a number of supported transition metal catalysts have been measured between 273 and 423 °K mainly by an adiabatic technique. The catalysts included Fe_2O_3, Mn_2O_3, V_2O_5, $MnSO_4$, and "NiS" all supported on silica gel.

Sulfur dioxide adsorption/desorption isotherms, nitrogen adsorption data, and chemical and infrared analyses were also determined to provide further ancillary information.

Heats of adsorption at 423 °K for adsorbed amounts of 0.004 μmol m^{-2} varied with the adsorbent from nearly 39.0 for Mn_2O_3 on silica gel to 23.0 kcal mol^{-1} for the silica gel support medium. With increase in surface coverage to 0.600 μmol m^{-2} the heat values begin to steady at 6 to 7, 7 to 8, and 8 to 9 kcal mol^{-1} at 423, 373, and 323 °K, respectively, and less discrimination is observed among the various materials. Preadsorption of small amounts of sulfur dioxide on the supported oxides followed by oxygen admission caused sharp initial falls of as much as 7 to 8 kcal mol^{-1} in the heat values whereas preadsorption of oxygen followed by sulfur dioxide gave only slight heat increases of around 1 kcal mol^{-1}.

It is proposed that sulfur dioxide is chemisorbed on all surfaces with the strongest interactions occurring at the lowest coverages. Sulfates are formed on the oxides as confirmed by chemical analysis, and it is postulated that multiple hydrogen bond formation occurs on silica gel through the interaction of sulfur dioxide oxygen atoms with surface hydroxy groups.

Les chaleurs calorimétriques d'adsorption du dioxyde de soufre (à faible surface couverte; de 0.004 à 0.600 μmol m^{-2}) sur un certain nombre de catalyseurs de métaux de transition fixés sur un support, ont été étudiées entre 273 et 423 °K au moyen d'une technique adiabatique. Sur un support commun en gel de silice, les catalyseurs incluent Fe_2O_3, Mn_2O_3, V_2O_5, $MnSO_4$ et "NiS".

Les isothermes adsorption/désorption pour le dioxyde de soufre, les données relatives à l'adsorption de l'azote ainsi que les analyses chimiques et infrarouges ont été déterminées dans le but d'informations secondaires ultérieures.

Les chaleurs d'adsorption à 423 °K pour des quantités adsorbées de 0.004 μmol m^{-2} varient avec l'adsorbant entre 39.0 pour Mn_2O_3 fixé sur du gel de silice, à 23.0 kcal mol^{-1} pour le support en gel de silice. Lorsque la surface couverte augmente jusqu'à 0.600 μmol m^{-2}, les valeurs des chaleurs d'adsorption s'étalent entre 6 et 7 à 423 °K, 7 et 8 à 373 °K, 8 et 9 à 323 °K. Dans ce cas, les différences observées entre les divers produits sont nettement plus faibles. Une préadsorption de dioxyde de soufre en petite quantité sur les oxydes fixés sur un support, suivie d'une admission d'oxygène provoque une chute initiale brutale de 7 à 8 kcal mol^{-1} des valeurs de chaleur d'adsorption; au contraire, une préadsorption d'oxygène suivie de dioxyde de soufre n'augmente que de 1 kcal mol^{-1} les chaleurs d'adsorption.

Il est suggéré que le dioxyde de soufre est chemisorbé sur toutes les surfaces mais que les interactions les plus fortes ont lieu sur des surfaces faiblement couvertes. La formation de sulfates sur les oxydes est confirmée par des analyses chimiques; il est postulé que la formation de liaisons hydrogène multiples se produit sur le gel de silice par suite de l'interaction des atomes d'oxygène du dioxyde de soufre avec les groupes hydroxyles de surface.

Canadian Journal of Chemistry, 49, 2832 (1971)

Introduction

This investigation contributes to a series of studies of the adsorption of sulfur-containing gases on various solids. The studies are largely motivated by the possibility of using adsorption or adsorption with catalysis as effective processes for the removal of deleterious sulfur compounds from industrial stack gases.

Although considerable work has been reported on the mechanism and kinetics of the heterogeneous oxidation of sulfur dioxide on catalytic solids (1, 2), comparatively little adsorption data have been determined for the gas. In particular, thermodynamic information is extremely sparse; most noticeably for systems where chemical adsorption is likely to occur.

Earlier, results were described (3) for the adsorption of sulfur dioxide on silica gels in the temperature range 263 to 323 °K when both adsorption–desorption isotherms and isosteric

For personal use only.

heats for surface coverages above one-tenth of a monolayer were determined. These data showed that physisorption was the dominant process although some chemical interaction with surface hydroxy groups appeared to take place.

In the present work calorimetric heats of adsorption of sulfur dioxide have been determined between 273 and 423 °K for silica gel and a range of catalytic solids, namely Mn_2O_3, V_2O_5, Fe_2O_3, $MnSO_4$, and "NiS", supported on silica gels. Further, several experiments have been carried out at 423 °K in which small amounts of either oxygen or sulfur dioxide were preadsorbed by the catalysts and the heats of adsorption on stepwise addition of the other gas measured. Complete sulfur dioxide adsorption–desorption isotherms have been determined for each supported catalyst at several temperatures from 273 to 423 °K and chemical and infrared analyses used to identify the products of the adsorption reactions.

Experimental

Materials

Supported metal oxides were prepared by impregnating Davison '923' grade silica gel (surface area 630 m^2/g; particle size, 75–150 μ) with an approximately 1 *M* solution of the appropriate metal nitrate for 6 h. After filtering and washing, the material was heated in air at 550 °C for 12 h to decompose the nitrate. Supported manganese(II) sulfate adsorbent was prepared by impregnating the gel with a 1 *M* solution of manganese(II) sulfate for 6 h and then heat-treating in air at 550 °C for 12 h. Nickel sulfide on silica gel was prepared by impregnating the gel with a 1 *M* solution of nickel nitrate for 6 h and then adding directly a 0.05 *M* solution of ammonium sulfide. The material was then filtered and washed before heat-treatment in air at 550 °C for 12 h.

Particles of the various adsorbents were examined by optical microscopy before and after use in the adsorption experiments. Photomicrographs (×70) were taken for record purposes. Except for the supported nickel sulfide all adsorbents showed evidence of aggregation after heat treatment at 550 °C. The particle size range increased to 75–225 μ with a very small proportion, <1%, of fine particles <75 μ present which indicated a small amount of disintegration. The manganese(III), iron(III), and vanadium(V) oxides were uniformly dispersed into the individual gel particles as indicated by the uniformity of color throughout the samples examined. The dispersion of nickel(II) sulfide and manganese(II) sulfate was not as uniform, which might be anticipated. With the former, the gel particles had a fairly uniform grey color but fine black 'dots' of material, presumably "NiS", were observed sticking to practically all particles while with the latter a very small amount of fine crystals (~1–10 μ) of manganese(II) sulfate was present in addition to the impregnated gel particles. Observations in color changes which resulted from the adsorption experiments are referred to later.

The following properties were determined for the finished adsorbents: (*a*) silica gel (surface area 590 m^2/g), (*b*) 2.50% Mn (as Mn_2O_3 *w/w*; 475 m^2/g), (*c*) 9.50% V (as V_2O_5 *w/w*; 450 m^2/g), (*d*) 3.20% Mn (as $MnSO_4$ *w/w*; 460 m^2/g), (*e*) 9.20% Fe (as Fe_2O_3 *w/w*; 555 m^2/g), and (*f*) 2.80% Ni (as "NiS" *w/w*; 390 m^2/g).

The supported nickel sulfide adsorbent (*f*) was assumed to have a one-to-one nickel/sulfur ratio and because of the complex nature of the supported catalysts no attempt was made to measure possible nonstoichiometric compositions. Surface areas were determined by low-temperature nitrogen adsorption at 77 °K.

Immediately before making adsorption measurements all adsorbents were activated at 240 °C for 2 h in air, transferred to the appropriate apparatus and then outgassed at 100 °C for 30 min at $<10^{-5}$ mm.

Sulfur dioxide (Matheson Co.) was anhydrous quality and was drawn directly from the cylinder after line-flushing to a trap attached to the apparatus. It was then outgassed at 10^{-4} mm and vacuum distilled over trays of phosphorous pentoxide. Middle portions only were used and g.l.c. analysis showed these to be >99.99% pure. Helium (Canadian Liquid Air Ltd.) was 99.995% pure and oxygen (Canadian Liquid Air Ltd.) 99.6% minimum prior to drying in desiccant columns.

Apparatus

Adsorption–desorption isotherms were determined in an all-glass vacuum system using a quartz spring microbalance (4). The quartz spring had a sensitivity of 403 mm g^{-1} at room temperature. At 273 °K the adsorption chamber was placed in an ice-bath controlled to ±0.01°. For higher temperatures a noninductively wound metal furnace was used. The furnace was insulated with asbestos rope and placed in a vacuum jacket. Tests showed that the temperature could be held to better than ±0.1° at 423 °K.

Heats of adsorption were determined calorimetrically in a vessel similar to that described (5). At 273 °K the outer jacket was air filled and the adsorption heats determined isothermally. At temperatures above 273 °K it was not possible to obtain temperature control of the required accuracy for the minimum 45 min necessary for isothermal determinations. Hence, the calorimeter was then operated adiabatically with its outer jacket evacuated, giving control to ±0.01°. In all experiments helium at 6 to 7 mm pressure was introduced to maximize the thermal conductivity prior to admission of the other gases.

The heats quoted were measured for the conditions $(dT/dt) = 0$ which normally occurred about 1 min after admission of the gas to the calorimeter. A cooling correction was applied to the observed temperature rise by extrapolating the linear portion of the cooling curve immediately after the maximum to a point midway between 't_{max}' and 't_0'. Four to five electrical calibrations were carried out in each run, prior to, during, and after adsorption. These were accurate to ±1% with no significant trends while the shapes of the temperature/time calibration traces were identical to those for the gas additions. The measurement technique was adapted from that used by Smith and Ford (6).

At 20 to 30 cm, well above the experimental pressure range, the heat of compression was measured with helium and instantaneous and maximum temperature

rises of 0.005° were observed. These values were well within the limits of experimental error when compared with the temperature rises of about 1° observed in the normal adsorption experiments at much lower pressures.

Results

Heats of Adsorption

The values were determined for a range of sulfur dioxide surface coverages from 0.004 to 0.200 μmol m^{-2} on all six adsorbents and normally at three temperatures for each adsorbent between 273 and 423 °K. Table 1 summarizes the heat values obtained at 423 °K.

A useful approximate figure for the degree of surface coverage can be calculated assuming close-packing and a cross-sectional area (7) of 22.9 $Å^2$ for an adsorbed sulfur dioxide molecule at 423 °K. With these assumptions, 0.700 μmol m^{-2} can be shown to be approximately equivalent to one-tenth of a monolayer at that temperature.

Heats of adsorption on several of the catalysts were measured to higher values of surface coverage at 323, 373, and 423 °K. There was a marked tendency for the value to appear to level out at amounts adsorbed between 0.200 and 0.300 μmol m^{-2}, particularly at the higher temperatures when fairly steady values of the heats of adsorption seemed to be approached. These data are shown for silica gel in Fig. 1. The results obtained with supported manganese(II) sulfate showed different characteristics to those of silica gel and the other supported catalysts. The differences were most marked at 323 °K where a comparatively sluggish fall from *ca.* 30 kcal mol^{-1} at 0.004 μmol m^{-2} to a value of 9 to 10 kcal mol^{-1} at 0.400 μmol m^{-2} was observed, Fig. 2.

Additional experiments were carried out with silica gel to test the possibility of surface dehydration occurring during adsorption of sulfur dioxide at 423 °K. The heat curve was measured up to a coverage of 0.100 μmol m^{-2} and the gas then desorbed at the same temperature at 10^{-5} mm. Samples of the desorbed gas were analyzed with a Beckman IR-12 infrared spectrophotometer. No trace of water could be detected in the samples while sulfur dioxide was easily identified by the strong asymmetric stretching frequency at 1362 cm^{-1}. After desorption, sulfur dioxide was readmitted to the gel and the whole procedure repeated thrice. Each time the heat curves obtained were identical with that in Fig. 1 within the limits of experimental error. For example, at a coverage of 0.004 μmol m^{-2} the

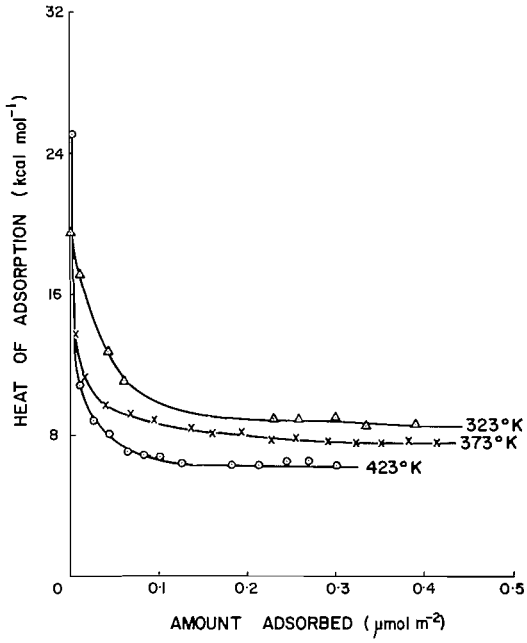

FIG. 1. Variation of heat of adsorption of sulfur dioxide with amount adsorbed on silica gel.

TABLE 1. Heats of adsorption (kcal mol^{-1}) at 423 °K for low surface coverages of sulfur dioxide on silica gel and catalysts supported on silica gel*

Surface coverage (μmol m^{-2})	Heat of adsorption (kcal mol^{-1})					
	Silica gel	Mn_2O_3	V_2O_5	Fe_2O_3	$MnSO_4$	"NiS"
0.004	23.0	38.8	24.0	32.0	28.0	28.0
0.010	11.1	17.4	17.6	18.0	17.5	18.0

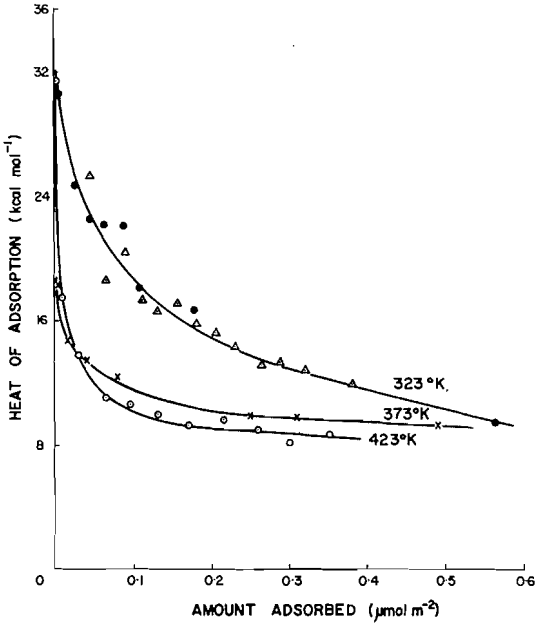

FIG. 2. Variation of heat of adsorption of sulfur dioxide with amount adsorbed on $MnSO_4$/silica gel.

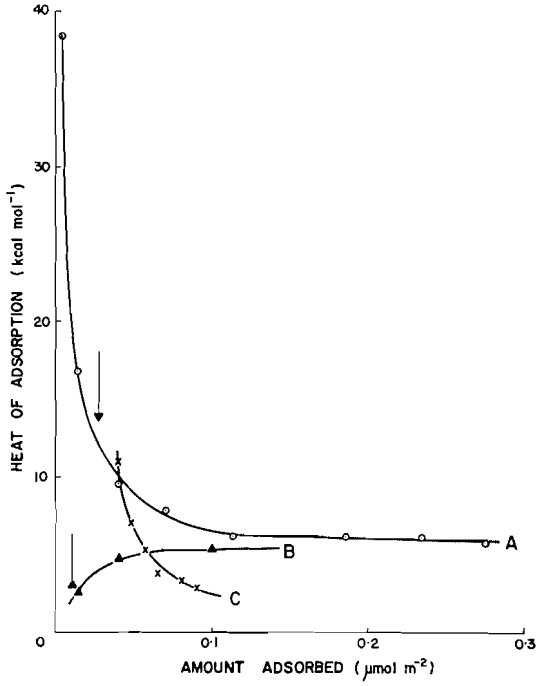

FIG. 3. Adsorptions on Mn_2O_3/silica gel at 423 °K.

heat of adsorption in each case was 24 ± 1 kcal mol^{-1}. Separate experiments in which 'massive' samples, *ca.* 5g, of silica gel were equilibrated with sulfur dioxide at 423 °K also failed to show the presence of water in the desorbed gas samples when examined in the spectrophotometer.

Sulfur Dioxide/Oxygen Interactions

Several experiments were carried out in which either oxygen or sulfur dioxide was preadsorbed by the catalytic solids prior to exposure to the other gas. Thus at 423 °K, 0.028 μmol m^{-2} of sulfur dioxide was preadsorbed in one dose on Mn_2O_3/silica gel. Oxygen was then admitted to the system in small quotas and heats of adsorption measured for amounts adsorbed up to 0.100 μmol m^{-2}. For the first three additions maximum increases of 1.58, 1.18, and 0.78 mm pressure were observed at system equilibrium which was achieved at each stage in about 45 min. With the fourth and subsequent oxygen additions no such pressure increases occurred. The measured heats, curve *C*, are shown in Fig. 3 along with the heat curves for sulfur dioxide on Mn_2O_3/silica gel, *A*, and sulfur dioxide on the same adsorbent after preadsorption of 0.011 μmol m^{-2} of oxygen, *B*.

Very similar results to those in Fig. 3 were obtained when the oxygen experiments with preadsorbed sulfur dioxide were repeated at the same temperature using silica gel and supported V_2O_5 and Fe_2O_3 as adsorbents.

When oxygen was preadsorbed in quantities from 0.011 to 0.015 μmol m^{-2} at pressures from 65 to 80 mm on the supported Mn_2O_3, V_2O_5, and Fe_2O_3 adsorbents, small heats of adsorption were recorded on subsequent admission of quotas of sulfur dioxide. For Mn_2O_3/silica gel the heat increased with each addition to the final measured value of 5.3 kcal mol^{-1} at 0.100 μmol m^{-2}, Fig. 3. The time taken to reach equilibrium in these experiments was from 3 to 4 h.

Analytical Examinations

Studies were made of both desorbed gas fractions and solid residues after adsorption of sulfur dioxide and the sulfur dioxide/oxygen compositions on the supported oxides to investigate the possibility of the formation of sulfur trioxide either in the gas phase or as an adsorbed complex or both. Further, particular experiments were designed in which oxygen was adsorbed at 423 °K on a 'massive' sample, *ca.* 7 g, of Fe_2O_3/silica gel containing preadsorbed sulfur dioxide using similar relative quantities of the gases as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

those in the calorimeter experiments. After desorption, solid samples were examined by the potassium bromide disc technique. However, the SO_3 asymmetric stretching vibration (8) at 1391 cm^{-1} lay within a very broad and diffuse Si—O band which occurred from about 1150 to 1450 cm^{-1}. Hence no conclusion could be made.

The spectra of desorbed gas samples were carefully examined using the optimum working conditions of the spectrophotometer and a slight perturbation was detected at 1391 cm^{-1} in three out of five experiments with the 'massive' sample. Hence the presence of extremely small quantities of sulfur trioxide could not be ruled out.

More significantly, qualitative chemical analysis (see, for example, ref. 9) of the oxide sample residues after the sulfur dioxide calorimeter experiments gave clear evidence that sulfate formation had occurred. Careful comparative tests with the original adsorbents showed that very small amounts of sulfate were formed on both Mn_2O_3 and V_2O_5 while a larger quantity was evident in the Fe_2O_3 residue. Quantitative analysis was not attempted.

Adsorption–Desorption Isotherms

Sulfur dioxide isotherms were determined at 273, 323, 373, 423, and 473 °K. The isotherm shapes were very similar for each adsorbent at a given temperature.

Figure 4(*a*) shows the adsorption–desorption isotherms obtained with Mn_2O_3/silica gel. Adsorption equilibrium times varied with the temperature and pressure. At 273 °K the times increased with increase in pressure from not more than 30 min at pressures up to 250 mm to approximately 2 h at 700 mm.

Hysteresis was present at 273, 323, and 373 °K, negligibly so at 423 °K and not at all at 473 °K. The shape of the hysteresis loop at 273 °K was completely different from those obtained at the higher temperatures. Hysteresis was observed over a limited range from 450 to 700 mm while at 323 and 373 °K it extended over the complete pressure range. On pumping out, the sulfur dioxide was removed within 30 min for experiments at 273, 323, and 373 °K, but at 423 and 473 °K about 0.015 μmol m^{-1} remained.

Figures 4(*b*), (*c*), and (*d*) show similar characteristics at each temperature for supported V_2O_5, Fe_2O_3, and $MnSO_4$, respectively. Adsorption equilibrium times were of the same order of magnitude as for Mn_2O_3/silica gel and all the sulfur dioxide could be removed on pumping out, except at 423 and 473 °K when again approximately 0.015 μmol m^{-2}, as sulfur dioxide, was retained by the adsorbent.

Discussion

The high heats of adsorption shown in Table 1 for 0.004 μmol m^{-2} refer to an extremely small amount of adsorbed gas when compared with that required to complete a monolayer although in molecular terms the figure represents between 10^{14} and 10^{15} molecules adsorbed per m^2 of surface. When the surface concentration of adsorbed sulfur dioxide is increased fifty times to 0.200 μmol m^{-2} the measured heats fall by factors of three to six which indicates significantly that the strongest gas/solid interactions are located within a surface occupancy of less than one-hundredth of a monolayer. This conclusion is confirmed by the isotherm measurements where similar quantities of sulfur dioxide appeared to be irreversibly adsorbed at 423 and 473 °K.

At the lowest coverage measured the heat of adsorption of sulfur dioxide on Mn_2O_3/silica gel was 38.8 kcal mol^{-1} at 423 °K. At this temperature the heat of formation of manganese(II) sulfate as calculated from published tables (10) is −43.2 kcal mol^{-1} according to the reaction

$$Mn_2O_3(s)+SO_2(g) \rightarrow MnO(s)+MnSO_4(s)$$

Formation of manganese(II) sulfite and manganese(IV) oxide from the same reactants (10) has a $\Delta H_f = -19.0$ kcal mol^{-1} and hence sulfate formation seems likely. Chemical tests on the residues from both 423 and 473 °K confirmed the presence of small amounts of sulfate.

Similarly, sulfate was detected in used V_2O_5/silica gel samples after sulfur dioxide adsorptions at 423 °K and also a distinct color change in this material was observed from the original pale yellow to pale brown when it was removed from the reaction chamber. This observation is also indicative of sulfate formation (10). At this temperature the heat of formation calculated for $VOSO_4$ from the two reactants is −40.5 kcal mol^{-1}, almost twice the measured heat of adsorption at 0.004 μmol m^{-2}. However, it is stressed that the formation of these traces of

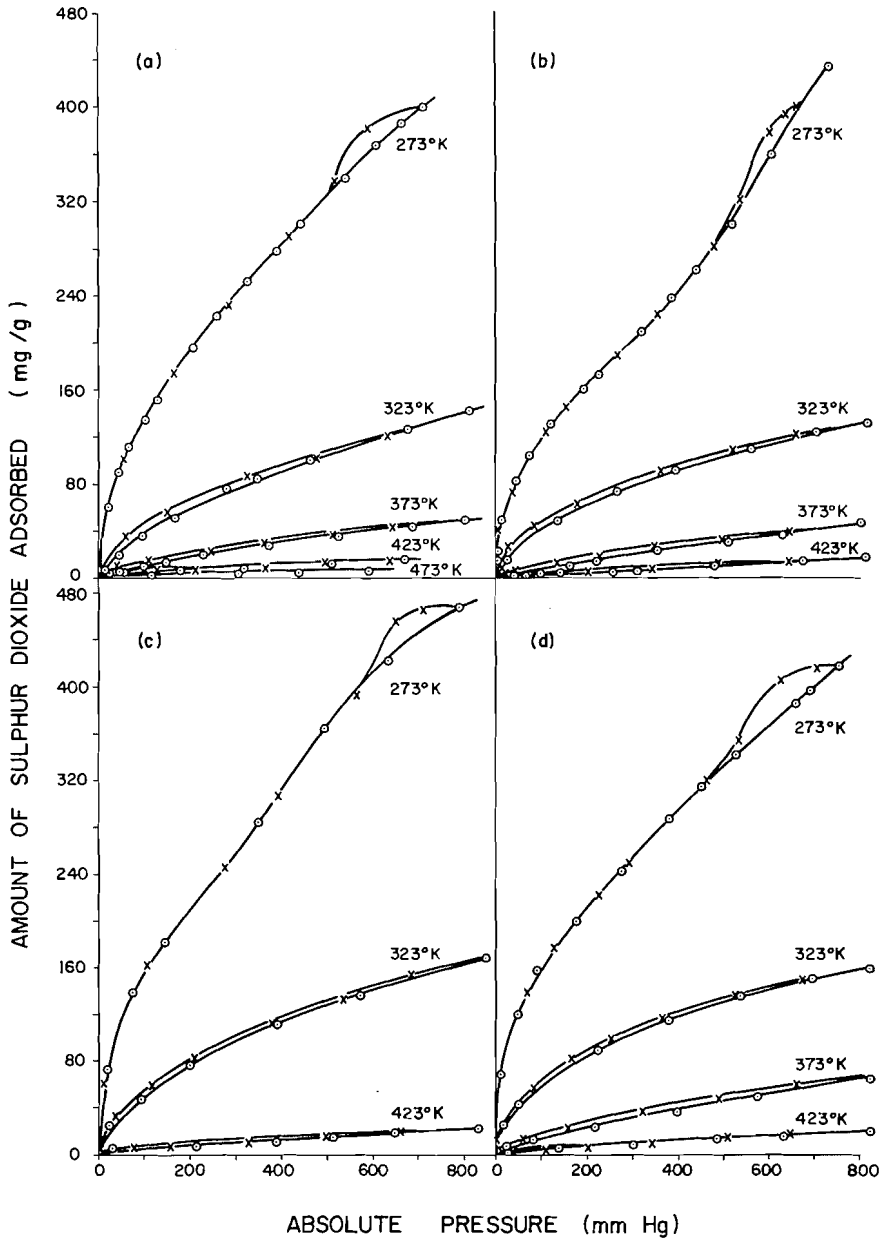

FIG. 4. Adsorption/desorption isotherms for sulfur dioxide on (*a*) Mn_2O_3/silica gel, (*b*) V_2O_5/silica gel, (*c*) Fe_2O_3/silica gel, and (*d*) $MnSO_4$/silica gel. To convert the ordinates (mg/g) to μmol/m^2, multiply the plotted values by (*a*) 0.0329, (*b*) 0.0347, (*c*) 0.0340, and (*d*) 0.0282, respectively.

sulfates on the oxide catalysts is not interpreted as excluding strong chemisorptive but reversible interactions from contributing to the measured heat values at 0.004 μmol m^{-2} since the sulfur dioxide molecules are adsorbed on an essentially heterogeneous surface matrix. Rather it is suggested that the largest contribution to the heat of adsorption arises at a few surface loci where the supported oxides are endowed with favorable geometric and chemical properties for sulfate formation. It is not possible to identify these loci with the present techniques.

Continued dosing of all of the supported oxide catalysts with sulfur dioxide up to 0.300 μmol m^{-2} at 423 °K results in a smooth decrease in the adsorption heat values which begin to steady at between 6.0 and 8.0 kcal mol^{-1}. Hence the gas/solid interactions become progressively weaker as the surface coverage increases. Probably little or no significant adsorbate/adsorbate interactions occur (see, for example, ref. 11) in agreement also with the very low degrees of surface coverage in these experiments.

Further information on the state of the adsorbed sulfur dioxide molecules can be deduced from the preadsorption experiments, Fig. 3. Thus preadsorption of sulfur dioxide on all of the adsorbents and subsequent addition of small oxygen quotas causes increases in the pressure of the system and the surface equilibrium is slow to settle on each addition. The adsorption heats fall fairly sharply from 11.3 to 3.5 kcal mol^{-1} over the first four oxygen additions indicating that oxygen is weakly adsorbed in comparison with sulfur dioxide.

The catalytic reaction between SO_2 and O_2 to give SO_3 does not proceed readily on any of these oxides until around 600 °K and while the reaction mechanism has been variously interpreted (12–14), there is general agreement that sulfur dioxide is chemisorbed and reacts with either gas phase oxygen species (12) or adsorbed oxygen atoms (13) or ions (14). Whichever way, the formation of sulfur trioxide requires dissociation of some oxygen which would cause a pressure increase in the system if occurring in the gas phase prior to either reaction or adsorption followed by reaction. Only small pressure rises were detected consistent with the very small amount of sulfur trioxide likely to be present. Electrical resistance measurements of the adsorption of (SO_2 + O_2) mixtures on evaporated carbon films (15) at 473 and 523 °K have been interpreted as indicating that oxygen is weakly adsorbed also on those surfaces and that an (SO_3) adsorbed complex may be present. Any sulfur trioxide formed on the adsorbents and subsequently desorbed should be perfectly stable in the gas phase at 423 °K since $\log_{10} K_p$ for $SO_3(g) \rightleftharpoons SO_2(g) + \frac{1}{2}O_2(g)$ is -7.94 and -5.33, respectively (16) at 400 and 500 °K.

Adsorption of sulfur dioxide on all solids with oxygen preadsorbed causes an increase in the heat to a value approaching that for the normal surfaces which is again compatible with a stronger surface interaction with sulfur dioxide. The abnormal length of time required to achieve system equilibrium in these experiments may be due simply to the slowness of diffusion of the sulfur dioxide molecules to the surface in the presence of the large quantities of gas-phase oxygen that were required to produce 0.011 to 0.015 μmol m^{-2} of the adsorbed gas.

The heats of adsorption on silica gels of sulfur dioxide at 263 °K, boiling point, approach the value of the heat of liquefaction as the monolayer coverage nears completion (3). At the higher temperatures studied here the heats of liquefaction (16) are 5.07 (8.44), 3.96 (27.40), and 1.73 kcal mol^{-1} (68.67 atm) at 323, 373, and 423 °K, respectively. At these three temperatures the heats of adsorption are 9.0, 8.0, and 6.3 kcal mol^{-1} for 0.200 μmol m^{-2} surface coverage at pressures very much less than 1 atm. Hence, even at the highest coverages studied the gas/solid interactions still seem likely to involve chemical adsorption.

After heat treatment at 550 °C there are about 3 to 4 μmol m^{-2} of hydroxy groups present on the silica gel surface (17). Some of these groups are still bonded to adjacent silicon atoms about 3 Å apart (18). Since the normal ⟨O—S—O in sulfur dioxide (10) is 119.54° the O—O distance will be about 2.5 Å, which allows the possibility of orbital interactions between sulfur dioxide oxygen atoms and hydroxy hydrogens on the gel surface. For adsorbed water on silica gel it is now accepted (19) that the molecules are linked via their oxygen atoms to two adjacent hydroxy groups by hydrogen bonds (20). Adsorption of sulfur dioxide presents a more complex situation since the geometry of the interaction as well as the bonding possibilities indicates that the sulfur atom could be linked to the surface by four, two, one or even three hydrogen bonds formed through its oxygen atoms interacting with suitably spaced hydroxy groups. High adsorption heats of 23.0 to 25.0 kcal mol^{-1} at 423 °K for 0.004 μmol m^{-2} adsorbed in the absence of surface dehydration reactions suggests that several bridge linkages of the O—H···O type may be formed since one such arrangement normally involves from 3 to 6 kcal mol^{-1} of energy (21). The fall in the heat values with surface coverage, Fig. 1, could then be due to a progressive increase in the contributions of single and dual modes of attachment to the surface.

The results obtained with supported man-

ganese(II) sulfate and 'nickel sulfide' at 423 °K are very similar. Again the values at the lowest coverages in particular indicate chemisorption which has already been postulated (22) to explain the sorption of sulfur dioxide on nickel(IV) sulfide at 393 °K.

Clear differences are apparent in the heat curves for silica gel and manganese(II) sulfate on silica gel, Figs. 1 and 2; noticeably so at 323 °K where the sulfate heats are from 2 to 10 kcal mol^{-1} higher than those for the gel with the greatest differences observed at low coverages. Contributions to the heat of adsorption on manganese(II) sulfate from complex interactions between surface sulfate species and the initially adsorbed sulfur dioxide molecules may account for these effects.

Differences in the adsorption/desorption isotherms for sulfur dioxide on the various supported catalysts are only obvious for those measured at 273 °K. At 323 °K and higher both the amounts adsorbed and the isotherm pattern are almost entirely independent of the chemical nature of the adsorbent. Equilibrium amounts adsorbed fall sharply with increase in temperature in each case and at 423 and 473 °K pressure increase has little effect on the incremental adsorbed amounts. At 473 °K adsorption is confined to a small area of the external surface and there is little or no pore contribution as is evident from the absence of hysteresis. The critical temperature for sulfur dioxide (16) is 430 °K and observations on other systems particularly for carbon dioxide on silica gel (23), have also shown that hysteresis disappears at temperatures above or close to the critical temperature of the adsorbate.

The shapes of the 273 °K hysteresis loops were analyzed as previously outlined (24). The only significant feature was with respect to the supported manganese(II) sulfate where the width of loop separation was nearly twice that of the oxides indicating a greater difference in the chemical potential of the adsorbed sulfur dioxide molecules on the sulfate surface between the two extreme adsorbed states (25).

Theoretical Studies of Nonbenzenoid Hydrocarbons: 16 π-Electron Systems

F. W. Birss and N. K. Das Gupta[1]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 29, 1970[2]

Hückel and self-consistent-field semi-empirical π-electron molecular orbital calculations on pentalenoheptalene are reported and the results compared to those of pyrene, acepleiadylene, napth[*cde*]azulene, and cyclohept[*bc*]acenaphthylene which contain the same number of π electrons. Resonance energies of all molecules calculated by the methods of Dewar and Whitehead are reported. It is suggested that pentalenoheptalene can be treated as two fused azulene nuclei.

Utilisant la méthode de Hückel et la méthode semi-empirique s.c.f., on a effectué des calculs d'orbitales moléculaires pour les électrons π du pentalénoheptaléne; on compare ces résultats avec ceux du pyrène, de l'acépléiadylène, du naphto[*cde*]azulène et du cyclohepta[*bc*]acénaphtylène qui contient le même nombre d'électrons π. On a calculé les énergies de résonance de toutes les molécules par les méthodes de Dewar et de Whitehead. Il apparaîtrait que le pentalénoheptalène peut être considéré comme deux noyaux d'azulène qui ont été attachés ensemble.

Canadian Journal of Chemistry, 49, 2840 (1971)

Introduction

Recently Hafner *et al.* (1) have reported the synthesis of 4-methyl-pentaleno[6,6*a*,1,2-*def*]-heptalene. This molecule belongs to a relatively small class of compounds with fused five- and seven-membered rings with planar structure. As such it is amenable to theoretical treatment within the π-electron approximation. Other molecules in this class, notably azulene, pentalene, heptalene, pentenoazulene, and pentenoheptalene have been studied by various authors (2–4) with particular interest in the aromatic nature of such molecules. In this paper we report calculations on pentalenoheptalene along with the π-isoelectronic molecules acepleiadylene, napth-[*cde*]azulene, and cyclohept[*bc*]acenaphthylene within the π-electron approximation using Hückel and self-consistent-field molecular orbital methods. Heilbronner and co-workers (5) have reported calculations on these molecules by a modified Pariser–Parr–Pople method which involves neglect of many of the two-electron repulsion integrals included in the present work.

Method and Parameters

The Hückel calculations were of the simplest type, assuming equal one-center and neighboring two-center coulomb integrals throughout the molecule. Self-consistent-field molecular orbitals were obtained by a linear combination of atomic orbitals-molecular orbitals (l.c.a.o.-m.o.) method similar to that introduced by Pariser and Parr (6) and Pople (7). The orbitals are expressed as eigenvectors of the matrix representation of the closed-shell Hartree–Fock operator (8).

$$F = H + \sum_{i=1}^{8} (2J_i - K_i)$$

within the zero-differential overlap approximation. Assuming one $2p_\pi$ atomic orbital, represented as χ, on each center, the matrix elements are

$$F_{kk} = \langle\chi_k|F|\chi_k\rangle = \alpha_k + \sum_{m=1}^{16} q_m\gamma_{km} - \tfrac{1}{2}q_k\gamma_{kk}$$

$$F_{kl} = \beta_{kl} - \tfrac{1}{2}p_{kl}\gamma_{kl}$$

for neighboring k and l. For non-neighboring centers β_{kl} is assumed to be zero. The one-center one-electron integrals, α_k, are given by

$$\alpha_k = \langle\chi_k|H_1|\chi_k\rangle = -I - \sum_{\substack{m\neq k\\=1}}^{16} \gamma_{km}$$

with I the ionization energy of the carbon atom in its sp^2 valence state (9), 11.16 eV. The two-electron integrals, γ_{kl}, were calculated by the method of Ohno (10)

$$\gamma_{kl} = \langle\chi_k(1)\chi_k(1)|1/r_{12}|\chi_l(2)\chi_l(2)\rangle$$
$$= e^2/(a^2 + R_{kl}^2)^{1/2}$$
$$= 14.397/(1.328^2 + R_{kl}^2)^{1/2}\ \text{eV}$$

For personal use only.

with R_{kl} the internuclear distance in Å. The parameter a is chosen such that the one-center two-electron integral has the value 11.134 eV, the difference between the ionization energy and electron affinity of carbon in its sp^2 valence state (9).

The one-electron integrals between neighboring centers, β_{kl}, were the source of two types of calculation reported below. In one a constant value, -1.7901 eV, was used. This was obtained by the method of Chung and Dewar (11) using the value of γ_{kk} given above, assuming an average neighboring internuclear distance of 1.40 Å. In the other type β_{kl}, dependent upon the internuclear distance, was obtained by the method of Lo and Whitehead (12).The designations s.c.f.(*a*) and s.c.f.(*b*) are used to denote the type of β integral used, the former indicating β dependent on internuclear distance, the latter indicating the constant value.

The charge density at a center

$$q_k = 2 \sum_{i=1}^{8} C_{ki}^2$$

and bond order

$$p_{kl} = 2 \sum_{i=1}^{8} C_{ki} C_{li}$$

are obtained from the eigenvector components C_{ki}. For the first s.c.f. iteration the eigenvectors produced by the Hückel calculation were used for calculation of the contributions of the J_i and K_i operators to the **F** matrix elements. Self-consistency was declared when all components for occupied orbitals agreed within five figures after the decimal in a comparison of vector components of successive iterations.

Molecular Geometry

The structures of 4-methyl-pentaleno[6,6*a*,1,2-*def*]heptalene (13) and acepleiadylene (14) are known; they are planar. The structures of the other molecules were not found in the literature. For naphth[*cde*]azulene, a planar structure assuming all bond lengths equal to 1.40 Å which gave reasonable bond angles was obtained. For cyclohept[*bc*]acenaphthylene a planar structure with reasonable bond angles could not be obtained with all bond lengths equal to 1.40 Å. Therefore a compromise structure was used, with bond lengths varying from 1.36 to 1.46 Å, similar to the range for the molecules of known structure. The geometries used in the present calculation are given in Fig. 1, with labels *I*: pentaleno[*def*]-heptalene, *II*: acepleiadylene, *III*: naphth[*cde*]-azulene, *IV*: cyclohept[*bc*]acenaphthylene. Henceforth these molecules will be referred to as pentalenoheptalene, acepleiadylene, napthazulene, and cycloheptacenaphthylene.

Bond Orders and Bond Lengths

The calculated bond orders and available experimental bond lengths are given in Tables 1 to 4 along with empirical bond lengths obtained from the relation of Dewar and Gleicher (15)

$$R_{kl} = 1.504 - 0.166 p_{kl}$$

The agreement of any set of theoretical bond lengths with the experimental is somewhat erratic as experience with similar compounds would lead one to anticipate. Nevertheless we suggest that the similarity of bond length and bond order for the 9–10 bond of azulene and the 11–15 and 13–16 bonds of pentalenoheptalene indicates that the latter may be treated as two fused azulene structures as against fused pentalene and heptalene.

Taking the highest bond orders together indicates that the Kekule structure *A*, shown with others in Fig. 2, is dominant in the description of pentalenoheptalene. Structures *B* and *C* are perhaps more strongly contributing than *D*. The situation is similar for the other molecules with structure *A* less dominant. The Kekule structures which contribute to each bond are given in Tables 1 to 4.

The relatively high bond orders of the 6–7 and 8–9 bonds of pentalenoheptalene, the 5–6 and 7–8 bonds of acepleiadylene, the 8–9 and 10–14 bonds of naphthazulene, and the 5–6 and 7–8 bonds of cycloheptacenaphthylene suggest that these molecules may exhibit dienophilic activity in these regions.

Charge Densities and Dipole Moments

The charge densities for the molecules are given in Table 5. As in azulene, the π-electron density of the five-membered rings is increased at the expense of the seven-membered rings, with a tendency to establish a local sextet in all rings. This is also reflected by the theoretical π dipole moments given in Table 6 with the angles shown in Fig. 1, labelling the s.c.f. result as *1* (the angles given by the two methods of β determination being indistinguishable) and the Hückel result as *2*.

The dipole moment of acepleiadylene has been

determined experimentally at 0.49 D (16). Theoretical values for the π dipole moment have been obtained (17) by Pullman, 1.0 D, and by Julg, 0.9 D, compared with 1.2 and 2.0 D in the present work.

Spectra, Ionization Energies, Electron Affinities

The experimental spectra of the molecules studied here have a large number of peak maxima, many of which are not clearly resolved. Therefore, the best that one can expect in a comparison of the theoretical and observed transition energies is a general correlation over quite wide spectral regions. Tables 7 to 10 display this comparison. Except for pentalenoheptalene, the reported experimental values were measured from published curves (18), taking only clearly pronounced maxima. For pentalenoheptalene, the same criterion was used, based upon the peak maxima reported by Hafner *et al.* (1) and the spectra given by Heilbronner and co-workers (5).

In addition to the observed peak maxima in-

cluded in the tables there is in every case a number of observed maxima at low transition energies for which no theoretical counterpart was found. Dinghra and Poole (19) have discussed these transitions in the case of pentalenoheptalene. Aside from these bands the agreement between experiment and theory is good. It is encouraging to note that the orbital transitions occurring in each grouping shown in Tables 7 to 10 remain almost constant as the style of β integral evaluation is changed.

The last columns in Tables 7 to 10 show the results obtained by Heilbronner and co-workers (5) using a modified form of the Pariser–Parr–Pople method. The agreement of these results with experiment and with those obtained in this work is also good.

According to Koopmans' theorem (20), the ionization energy should be well approximated by the highest occupied orbital energy. It has commonly been observed (21) that values obtained by this method are 1 to 2 eV too high. Hoyland and

Goodman (22) have shown that the discrepancy can be accounted for by σ-core contraction and π-orbital deformation in the ionized molecule.

In the context of constant-β calculations, Bloor (2) has proposed a general corrected ionization energy for hydrocarbons as $-(\varepsilon_h + 1.33)$ eV, where ε_h is the highest occupied orbital energy. He also proposes that the half-wave reduction potential, measured in 95% aqueous dioxane, can be fitted by the form $-(\varepsilon_l + 4.77)$ eV, where ε_l is the lowest unoccupied orbital energy.

Values for the uncorrected ionization energy, based upon Koopmans' theorem, the ionization energy corrected by Bloor's method and for the lowest unoccupied orbital energy and the corresponding half wave potential, $\varepsilon_{1/2}$, obtained by Bloor's method are given in Table 11.

Also included in Table 11 are ionization energies and electron affinities calculated as the difference in total calculated energy of the neutral molecule and the total energy obtained in an open shell calculation on the positive or negative ion. Since identical basic integrals were used in all cases, these values should reflect the correction due to π-orbital deformation, neglecting σ-core contraction.

Resonance Stabilization

Delocalization energies (d.e.) per electron (d.e./e), based upon Hückel calculations, for the series naphthalene, phenanthrene, and pyrene are (23) 0.37, 0.39, and 0.41, respectively, indicating that this quantity increases with the size of the molecule. A similar increase occurs (23) in the series azulene, 1,2-benzazulene and cycloheptacenaphthylene (naptho(1,9,8,7-*aji*)azulene) with values 0.34, 0.36, and 0.39, respectively. Comparison between these series indicates a lowering in d.e./e with the replacement of a naphthalene by an azulene unit while maintaining the number of electrons and rings constant. This feature is also shown by the series pyrene, napthazulene, and pentalenoheptalene in which the naphthalene units of pyrene are successively replaced by azulene units. The d.e./e values are 0.41, 0.39, and 0.37, respectively, indicating that the molecules with successively greater numbers of azulene nuclei are successively somewhat less resonance stabilized.

Chung and Dewar (11) have proposed that the resonance stabilization may be expressed as

$$E_R^{(b)} = n(A_0 + a_1 A_1) + E_{\pi b}$$

where $A_0 = -1.0871$ eV, determined from the empirical resonance stabilization of benzene, $A_1 = -0.1627$ eV, the difference in the bond energies of "aromatic" and single carbon–carbon σ bonds,

$$a_1 = \frac{1}{n}(n' - n/2)$$

with n the number of π-electrons and n' the number of carbon–carbon single bonds in a reference valence bond structure. $E_{\pi b}$ is the π-bonding energy determined by

$$-E_{\pi b} = 2\beta \sum_{i<j} p_{ij} + \tfrac{1}{4}\sum_i q_i^2\gamma_{ii} + \sum_{i<j}[(q_i - 1)(q_j - 1) - \tfrac{1}{2}p_{ij}^2]\gamma_{ij}$$

Lo and Whitehead (12) give the resonance energy as

$$E_R^{(a)} = E_{\sigma b} + E_{\pi b} - (n' E_{C-C} + n'' E_{C=C})$$

with $E_{\pi b}$ and n' defined as above, n'' the number of double bonds in a reference valence bond structure, $E_{\sigma b}$ the σ-bonding energy determined by the method given by those authors, $E_{C-C} = 3.9115$ eV is the single bond energy at 1.505 Å C—C distance and $E_{C=C} = 5.6033$ eV is the double bond energy at 1.334 Å C—C distance. They also maintain that the stabilization energy per carbon–carbon bond, rather than the delocalization

energy per electron, is of prime significance in a comparison of π-bonding in conjugated systems.

Table 12 contains values of the quantities described above. For comparison we have included values for naphthalene, azulene, and pyrene as given by Chung and Dewar (11) and Lo and Whitehead (12). The two methods give good agreement for the molecules discussed in this paper but inconsistencies appear in the case of naphthalene and pyrene. We believe that this is due to the smaller value of γ_{11} chosen by Chung and Dewar in evaluating β, since recalculation of naphthalene with integral values consistent with the methods described in this paper leads to good agreement of the resonance energies calculated by the two methods.

The resonance stabilization per carbon–carbon bond can be used to arrange the ground states of the molecules in order of stability

pyrene > acepleiadylene > cycloheptacenaphthylene > napthazulene > pentalenoheptalene

although the three molecules in the middle of the sequence have so similar resonance energies that the order may be interchanged by minor variations in the choice of integral values.

The stabilization energy per carbon–carbon bond may also be used in a discussion of the aromaticity of the molecules. For that purpose, the aromatic molecules naphthalene and azulene, with stabilization energies per carbon–carbon bond of 0.34 and 0.23, respectively, serve as useful reference points. All the molecules fall in this range, pyrene with the value 0.34 and pentalenoheptalene with the value 0.26, suggesting that all are aromatic but that this character decreases with the number of benzenoid rings.

Like pentalene, heptalene, acenaphthylene, and pentenoazulene, pentalenoheptalene has $4n\pi$ electrons as well as being representable by more than one Kekule structure. Within Hückel's rule, such molecules should not exhibit aromatic character. Pentalene and heptalene are in fact typically olefinic, pentenoazulene is pseudoaromatic whereas acenaphthylene is aromatic. As for pentalenoheptalene, its stability, as expressed by the stabilization energy per carbon–carbon bond, resistance to electrophilic attack, and increase of electron density in the five-membered rings at the expense of that in the seven-membered rings, suggest that it may be effectively classified as an aromatic compound.

We are grateful to the National Research Council of Canada for financial support and to the Computing Center of The University of Alberta for making available facilities for the computations involved.

Base-induced Rearrangement of γ-Diketones. I. The Rearrangement of 1,2,2-Triphenyl-1,4-pentanedione to 1,3,3-Triphenyl-1,4-pentanedione[1]

PETER YATES, G. D. ABRAMS, MICHAEL J. BETTS, AND S. GOLDSTEIN
Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario

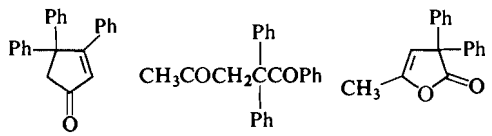
Received March 18, 1971

Treatment of 4-hydroxy-2,2-diphenyl-3-pentenoic acid lactone (**3**) with phenyllithium gives 1,2,2-triphenyl-1,4-pentanedione (**2**), 1,3,3-triphenyl-1,4-pentanedione (**7**), and 3,3-diphenylpropiophenone (**16**). The γ-diketone **7** is shown to arise via rearrangement of an anion of the γ-diketone **2**. The formation of 1,2,3-triphenyl-1,4-pentanedione (**27**) is not observed, nor is **27** converted to **7** on treatment with base. It is concluded that the rearrangement proceeds via two homoenolate anion intermediates rather than via two 1,2 phenyl shifts.

Le traitement de la lactone de l'acide hydroxy-4 diphényl-2,2 pentène-3 oique (**3**) avec le phényllithium conduit aux triphényl-1,2,2 pentanedione-1,4 (**2**), triphényl-1,3,3 pentanedione-1,4 (**7**), et diphényl-3,3 propiophénone (**16**). Il est montré que la γ-dicétone **7** provient d'une transposition de l'anion de la γ-dicétone **2**. La formation de la triphényl-1,2,3 pentanedione-1,4 (**27**) n'est pas observée; par traitement basique **27** n'est pas non plus transformé en **7**. On en déduit que la transposition procède par l'intermédiaire de deux anions homoénolates plutôt que par deux migrations 1,2 de phényle.

Canadian Journal of Chemistry, 49, 2850 (1971)

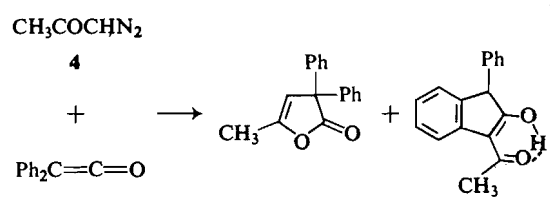
In connection with studies of the i.r. spectra of cyclopentenones (2), the synthesis of 3,4,4-triphenyl-2-cyclopentenone (**1**) was undertaken. It was anticipated that this could be prepared from 1,2,2-triphenyl-1,4-pentanedione (**2**), which could be obtained by the reaction of the lactone **3** with phenyllithium. Previous work (3) suggested that **3** could be prepared by the reaction of diazoacetone (**4**) with diphenylketene (**5**).



1 **2** **3**

In the event (Scheme 1), the reaction of **4** with **5** gave a mixture of products from which two compounds, $C_{17}H_{14}O_2$, were isolated. One of these, obtained in 11% yield, is identified as the desired lactone **3** by its i.r. and p.m.r. spectra.[2] The other, major product is assigned structure **6** (or the alternative enol) on the basis of its spectra[2] and the fact that it gives a positive test for a chelated enol on treatment with anhydrous methanolic ferric chloride; the formation of this type of product finds analogy in the reaction of diphenylketene with ethyl diazoacetate reported by Kende (4).

When the lactone **3** was treated with phenyllithium in ether for 20 min followed by work-up in aqueous acid, three products were obtained (Scheme 2). Two of these are isomers, $C_{23}H_{20}O_2$, and on the basis of their spectra (Table 1) are considered to be **2** and 1,3,3-triphenyl-1,4-pentanedione (**7**). The relationship of the u.v. spectra of the two isomers led to the assignment of structure **2** to the compound m.p. 154.5–155.5° (42%) and of structure **7** to the compound m.p. 152.5–154° (4%), in that the hypsochromic and hypochromic shifts of the high intensity maximum in the spectrum of the former relative to the latter can be attributed to a departure from coplanarity of the benzoyl phenyl and carbonyl groups of **2** due to the adjacent *gem*-diphenyl grouping. These assignments were corroborated by conversion of



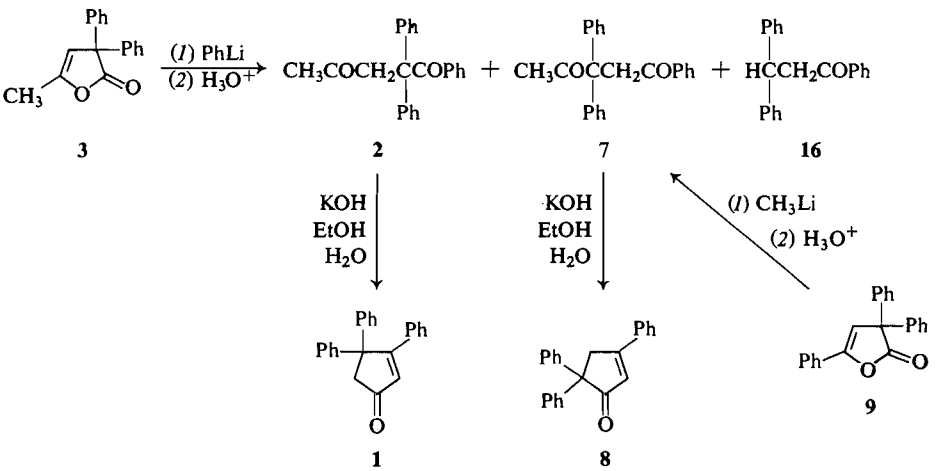
SCHEME 1

[1]Preliminary reports on part of this work have appeared (1).

[2]See Experimental.

TABLE 1. Spectra of 1,2,2- and 1,3,3-triphenyl-1,4-pentanediones

Compound	2	7
Melting point (°C)	154.5–155.5	152.5–154
λ_{max} (CCl_4) (μ)	5.79, 5.96, 7.36 (m)	5.85 (sh), 5.90, 7.40 (m)
λ_{max} (EtOH) [mμ(ε)]	239 (9800), 316 (sh, 310)	242.5 (13 800), 276.5 (sh, 1580)
δ ($CDCl_3$)	1.91 (s, 3H), 3.71 (s, 2H), 7.0–7.6 (m, 15H)	2.17 (s, 3H), 4.14 (s, 2H), 7.1–7.5 (m, 13H), 7.7–7.9 (m, 2H)



SCHEME 2

2 and **7** with aqueous ethanolic base to the cyclopentenones **1** and **8**, respectively. These products are readily distinguishable on the basis of their p.m.r. spectra;[2] as discussed elsewhere (2), the carbonyl-stretching band in the i.r. spectrum of **1** (unsubstituted at C-5) is split while that in the spectrum of **8** (substituted at C-5) is unsplit. Confirmation for the structural assignment for **7** was provided by its independent synthesis by treatment of the lactone **9** with methyllithium. In contrast to **3**, **9** was obtained in 77% yield by reaction of diphenylketene (**5**) with 2-diazoacetophenone (**10**) (3): two minor products, assigned structures **11** and **12**, were also isolated from the reaction mixture (Scheme 3). The i.r. and u.v. spectra of **11** closely resemble those of **13** (5); its formation again finds analogy in the reaction of diphenylketene with ethyl diazoacetate (4). The yellow compound **12** has a u.v. spectrum similar to that of **14** (6) and gives diphenylacetic acid on hydrolysis; its formation can readily be envisaged as proceeding via reaction of **15**, the analogue of **6**, with diphenylketene.

The third product formed on treatment of lactone **3** with phenyllithium was shown to be 3,3-diphenylpropiophenone (**16**) by direct comparison with an authentic sample.[3]

The most probable pathway for the formation of the diketone **7** from **3** appeared to be via rearrangement of the anion **17**, formed by reaction of **3** with phenyllithium, to the anion **18**. That this is the case was indicated by the observation that the yield of **7** relative to **2** increased with longer reaction times. Further, when **2** was treated with sodium methoxide in ether it was converted to a mixture of the cyclopentenones **1** and **8**; under these conditions **1** was not converted to **8**, and thus it may be concluded that **2** undergoes partial base-induced conversion to an anion of **7**, which then gives **8**.

Two general types of pathway may be envisaged as accounting for the rearrangement of the anion

[3]We thank Professor R. E. Lutz, University of Virginia, for his kindness in providing this sample (7).

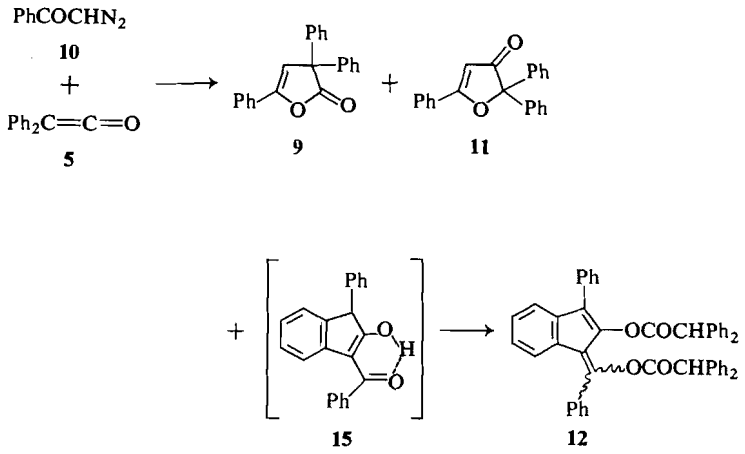
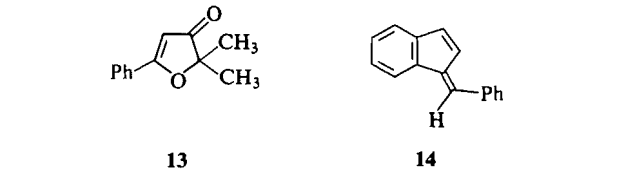
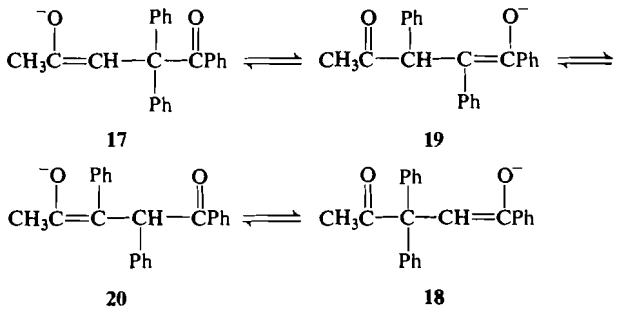


SCHEME 3





SCHEME 4

17 to the anion **18**.[4] In the first (Scheme 4), migration of a phenyl group could occur to give **19**, followed by hydrogen migration to give **20**, which would give **18** upon migration of the second phenyl group.

Such 1,2 migrations of phenyl groups to anionic centers find ample precedent in the work of Zimmerman, Grovenstein, and their coworkers (8). However, the postulate of a step involving hydrogen migration is less attractive. Consideration of a suprafacial [1,2] sigmatropic shift of hydrogen to an anionic center in terms of conservation of orbital symmetry (9, 10) shows that it is symmetry-forbidden, and no concerted intramolecular pathway is available for such a transformation. The same considerations apply to the more extended π-system of **19**. This restriction does not apply to phenyl migration, where a p-orbital at the migrating carbon atom can be utilized for simultaneous bonding to the atoms between which migration is occurring (9, 11). These considerations do not exclude the possibility that the conversion of **19** to **20** could occur by a non-concerted intramolecular process involving a radical anion – radical pair, as in the case of certain Stevens and Wittig rearrangements (11, 12), or by an intermolecular process involving

[4]Consideration of the reaction in terms of free anions is, of course, an approximation, since it neglects the presence of the cationoid species. Also neglected are any effects due to the presence of inorganic salts in the organolithium reagents.

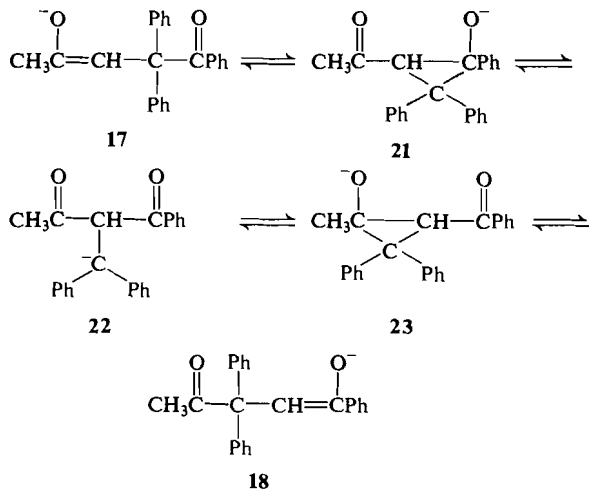
protonation followed by deprotonation. However, the first process seems energetically most unfavorable (12*a*) in the case of hydrogen migration since a hydrogen atom would be one member of the radical pair, while the second process is likely to be unfavorable since it would require abstraction of a proton from an anionic species.[5]

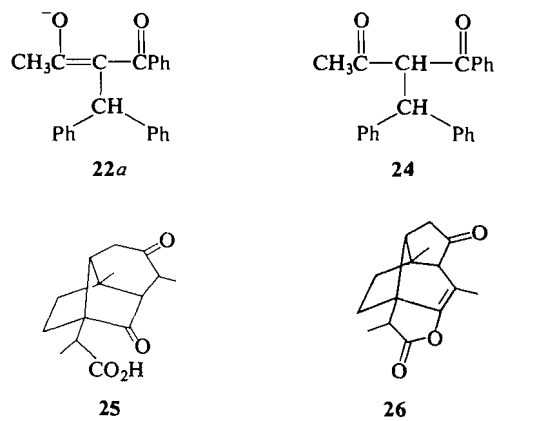
In the second type of mechanism (Scheme 5), the anion **17** could give the homoenolate anion **21**, followed consecutively by formation of the anion **22** and a second homoenolate anion, **23**, which would give rise to the anion **18**. The intermediacy of homoenolate ions in several base-induced reactions of ketones has been demonstrated by Nickon and others (13), and Freeman and Plonka (14) have proposed the intermediacy of a homoenolate ion in a closely related case. A point of importance relating to Scheme 5 concerns the anion **22**; this is expected to be considerably less stable than the ion **22***a* that would be derived from it by 1,2 hydrogen migration. Indeed, should **22***a*, the enolate ion of the β-diketone **24**, be formed, it would be anticipated that the reaction would terminate at this stage. However, the suprafacial hydrogen migration required to effect the intramolecular conversion of **22** to **22***a* is symmetry-forbidden as discussed above, and thus formation of **22***a* would not be expected to occur readily.



SCHEME 5

A more concerted version of Scheme 5 is possible and in this connection it is of interest to note its relationship to the mechanism proposed by Woodward and Kovach (15) many years ago for the acid-catalyzed rearrangement of santonic acid (**25**) to parasantonide (**26**). This was postulated to proceed via a concerted process involving (quasi) cyclopropanols analogous to the homoenolate ions **21** and **23**.

Scheme 5 is preferred to Scheme 4 because of the inclusion in the latter of a symmetry-forbidden step. Furthermore, experimental evidence confirms that the rearrangement does not proceed via Scheme 4. Were this scheme operative, it would be expected that significant amounts of the anions **19** and **20** would be present in the reaction mixture prior to quenching and that upon quenching the products would include the corresponding protonated species, 1,2,3-triphenyl-1,4-pentanedione (**27**). However, examination of the spectra of the total crude reaction product obtained from the treatment of **3** with phenyllithium failed to reveal the presence of any **27**.

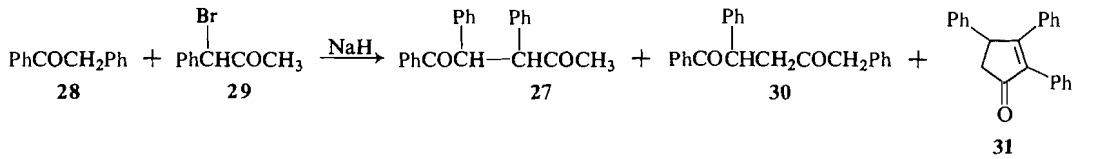


In order to test further the possibility of the intermediacy of **19** and **20** in the rearrangement, the synthesis of the diketone **27** was undertaken. Treatment of deoxybenzoin (**28**) in tetrahydrofuran with sodium hydride followed by 1-bromo-1-phenyl-2-propanone (**29**) gave a mixture of the diastereomers of **27** in low yield (Scheme 6). These were separated by fractional crystallization and identified on the basis of their elemental analyses and spectra (Table 2). Formed in addition were an isomeric compound, considered to

[5]The fact that increase in the reaction time beyond that required for the complete consumption of **3** leads to an increased yield of **7** shows that if an intermolecular proton transfer step is involved it must be able to proceed in the presence of anionic species alone.

TABLE 2. Spectra of the diastereomers of 1,2,3-triphenyl-1,4-pentanedione

Compound	*27a*	*27b*
Melting point (°C)	155–155.5	187–188
λ_{max} (CCl_4) (μ)	5.85, 5.96, 7.41 (m), 7.79 (w), 8.02 (w), 14.32	5.85, 5.96, 7.41 (m), 7.83, 14.35
λ_{max} (EtOH) [mμ(ε)]	247 (14 800)	248 (13 200)
δ ($CDCl_3$)	2.15 (s, 3H), 4.60 (d, J = 11 Hz, 1H), 5.20 (d, J = 11 Hz, 1H), 7.3 (m, 13H), 8.05 (m, 2H)	1.92 (s, 3H), 4.84 (d, J = 11 Hz, 1H), 5.60 (d, J = 11 Hz, 1H), 7.4 (m, 13 H), 7.9 (m, 2H)



SCHEME 6

be 1,2,5-triphenyl-1,4-pentanedione (**30**) on spectroscopic grounds,[2] and 2,3,4-triphenyl-2-cyclopentenone (**31**), identified by comparison with an authentic sample (16) (Scheme 6). The relationship between **30** and **31** was confirmed by the observation that the former was converted to the latter by treatment with methanolic sodium methoxide. The pathway for the formation of **30** has not been established; possibilities include (*i*) isomerization of **29** to 1-bromo-3-phenyl-2-propanone followed by reaction with the anion of **28** and (*ii*) isomerization of the enol ether formed by *O*-alkylation of **28** by **29**.

When **27***a*, the lower-melting diastereomer of **27**, was treated with sodium methoxide in ether under conditions that led to the conversion of **2** to a mixture of the cyclopentenones **1** and **8**, neither of these products nor their precursors, **2** and **7**, could be detected in the reaction mixture. Much of compound **27***a* was recovered unchanged, together with several products formed in small amount; one of these was identified as the diastereomer **27***b* on the basis of its R_f value, and another is tentatively considered to be 3,4,5-triphenyl-2-cyclopentenone, the cyclization product from **27**, but was not fully characterized. The fact that **27** is not converted to either **2** or **7** nor to their cyclization products, **1** and **8**, under these conditions excludes it as an intermediate in the conversion of **2** to **7** and thus eliminates a mechanism of the type depicted in Scheme 4.

A mechanism of the type shown in Scheme 5 is therefore considered to be the best representation of the rearrangement pathway. The third product, 3,3-diphenylpropiophenone (**16**), from the reaction of phenyllithium with **3** is formed in variable yield and may result from the adventitious entry of water into the reaction mixture after consumption of the phenyllithium. It might also arise via attack of phenyllithium on **18**, **21**, or **22**. It is not formed by cleavage of **24** during the aqueous work-up, since **24** is stable under these conditions.

Each of the steps in Scheme 5 should be reversible as depicted. However, when the diketone **7** was treated with sodium methoxide in ether, only the cyclopentenone **8** was formed. This suggests that **7** does not undergo significant rearrangement to **2**, although it does not establish this unambiguously since it is possible that cyclization to **8** occurred more rapidly than rearrangement to **2**. Decisive evidence for the failure of the rearrangement to occur in the reverse direction to any significant extent was supplied by the observation that treatment of the lactone **9** with methyllithium gave only **7** and that no trace of **2** could be detected in the p.m.r. spectrum of the crude reaction product after several hours of reaction. It may be concluded that the equilibrium between the anions **17** and **18** very highly favors the latter.[6]

Full acceptance of the type of mechanism shown in Scheme 5 requires the demonstration that the geminal phenyl groups remain attached to the same carbon atom, since this represents a decisive distinction between mechanisms involv-

[6]In related cases, it has been established that the rearrangement is reversible; the position of equilibrium in the present case will be discussed in relation to these cases (17).

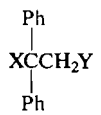
ing homoenolate ions and those involving 1,2 phenyl migrations. In order to test this, methods were sought for the preparation of **2** with an isotopic label at C-3. Its synthesis via **3** was unsatisfactory for this purpose because of the low yield obtained in the preparation of **3**. In spite of a variety of approaches, no success was achieved. Some of the observations made in the course of this search are not without intrinsic interest and they will be discussed here briefly.

Alkylation of diphenylacetonitrile with ethyl bromoacetate in the presence of aqueous sodium hydroxide and benzyltriethylammonium chloride gave the ester **32** in excellent yield.[7] The ester was hydrolyzed to the acid **33**, which was treated with 2 equiv of phenylmagnesium bromide in the expectation that it would be converted to the keto acid **34**. However, elimination of cyanide ion occurred to give the unsaturated acid **35**; a similar result was obtained when phenyllithium was used. When excess Grignard reagent was used the unsaturated alcohol **36** was obtained. The dinitrile



32 X = CN; Y = CO_2Et

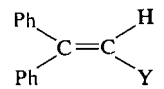
34 X = COPh; Y = CO_2H
37 X = Y = CN



35 Y = CO_2H
36 Y = CPh_2OH
38 Y = CN

37, prepared by alkylation of diphenylacetonitrile with chloroacetonitrile (18), on treatment with methylmagnesium iodide or methyllithium gave the unsaturated nitrile **38** in similar fashion.

Alkylation of diphenylacetonitrile with 2,3,3-triphenylallyl bromide and with methallyl chloride in the presence of 50% aqueous sodium hydroxide and benzyltriethylammonium chloride gave the nitriles **39** and **40**, respectively. It was hoped that treatment of these with methyllithium would convert the nitrile groups to acetyl groups. However, cleavage of a carbon–carbon bond occurred in each case to give the hydrocarbons **41** and **42**, respectively. Such cleavage has been observed in related cases (19) and presumably involves elimination of acetonitrile from the lithium derivative of the imine formed as an intermediate in the attack of the methyllithium on the nitrile group. The preference for elimination in these cases and those referred to above presumably stems from the severe steric crowding at the carbon atom bearing the geminal phenyl groups. A similar cause must underlie the failure of another approach involving attempts to protect the carbonyl group of the keto nitrile **43**, prepared by benzoylation of diphenylacetonitrile.

Although these attempts to find an efficient route for the synthesis of labeled **2** failed, success attended the synthesis of a related labeled γ-diketone, and the study of its rearrangement has corroborated the mechanistic conclusions reached here (*1b*).

Experimental

Reaction of Diazoacetone and Diphenylketene. Formation of 4-Hydroxy-2,2-diphenyl-3-pentenoic Acid Lactone (3) and 3-Acetyl-2-hydroxy-1-phenylindene (6)

A solution of diazoacetone (**4**) was prepared by addition during 2.25 h of acetyl chloride (32.3 g, 412 mmol) in petroleum ether (80 ml) with stirring to 0.704 *M* ethereal diazomethane (1385 ml; 975 mmol) in an ice-water bath. The volume of the solution was reduced to *ca.* 100 ml by evaporation under reduced pressure at room temperature, and the remaining solution was diluted with benzene (800 ml).

This solution was added dropwise to a stirred solution of diphenylketene (**5**)[8] (47.1 g, 242 mmol) in benzene (1 l) at room temperature under nitrogen, and the mixture was stirred under these conditions overnight. The reaction mixture was concentrated to *ca.* 750 ml by distillation under reduced pressure under nitrogen. It was then washed three times with aqueous 5% sodium bicarbonate and once with saturated aqueous sodium chloride, and dried. Removal of the solvent gave a brown oil (57.6 g) from which some **6** (8.49 g) was separated by repeated solution in boiling ether, cooling, scratching, and filtering,

[7]This method of alkylation, that of Lange and Makosza (18), is preferable to methods involving alkoxides as the basic condensing agent because of its simplicity.

[8]Prepared by the method of Smith and Hoehn (20); to avoid severe bumping and frothing it was found necessary to distil the reaction mixture under nitrogen at water aspirator pressure to remove benzene prior to distillation of the diphenylketene at 3–4 mm.

followed by evaporation of the mother liquor. The residue was dissolved in petroleum ether – benzene (3:2) and chromatographed on silica gel (Davison; 800 g) with the same solvent mixture as eluent; 100-ml fractions were collected. Evaporation of fractions 42–76 gave crude **3** as a yellowish solid (6.05 g). A further quantity of crude **3** was obtained by evaporation of fractions 35–41 and heating of the combined residues at *ca.* 75° (0.025 mm) to volatilize the major contaminant, which was shown to be phenyl benzoate by spectral comparison with an authentic sample.

The total crude **3** (6.87 g) was rechromatographed on silica gel (100 g), packed and eluted with petroleum ether – benzene (3:2); 25-ml fractions were collected. Combination of fractions shown by their i.r. spectra to be rich in **3** and evaporation of the solvent yielded **3** as a colorless solid (6.33 g, 11% based on diphenylketene), m.p. 49–52°; λ_{max} (CCl_4) 5.54, 5.92 μ(m); δ (CCl_4) 2.10 (d, J = 1.5 Hz, 3H), 5.63 (q, J = 1.5 Hz, 1H), 7.26 (s, 10 H). Several sublimations at 70° (0.005 mm) failed to improve the m.p.

Anal. Calcd. for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64. Found: C, 81.40; H, 5.59.

Further elution of the original chromatographic column with petroleum ether – benzene (3:2) gave **6** which was combined with the material obtained by treatment of the crude reaction product with ether. Eight recrystallizations from hexane gave **6** as colorless crystals, m.p. 125–126°; λ_{max} (CCl_4) 6.03, 6.22 μ(br); λ_{max} (MeOH) 254.5 (ε 9300), 278 (ε 7100), 287.5 (ε 7400), 340 mμ (ε 6000); δ ($CDCl_3$) 2.43 (s, 3H), 4.59 (s, 1H), 7.0–7.5 (m, 9H), *ca.* 14.1 (br s, 1H); blue-green coloration with anhydrous methanolic ferric chloride.

Anal. Calcd. for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64. Found: C, 81.37; H, 5.69.

*Reaction of **3** with Phenyllithium. Formation of 1,2,2-Triphenyl-1,4-pentanedione (**2**), 1,3,3-Triphenyl-1,4-pentanedione (**7**), and 3,3-Diphenylpropiophenone (**16**)*

To a solution of **3** (294 mg, 1.18 mmol) in ether (25 ml) was added a 0.291 *M* ethereal solution of phenyllithium (8.0 ml; 2.33 mmol). The mixture was stirred under nitrogen at room temperature for 20 min and then acidified with 1.1 *N* hydrochloric acid. The ethereal phase was washed twice with aqueous 5% sodium bicarbonate and three times with water, and dried. Evaporation of the ether gave an oily solid (400 mg), which was triturated with hexane to give **2** (140 mg). Recrystallization from hexane gave **2** as colorless crystals, m.p. 154.5–155.5°.[9]

Anal. Calcd. for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14. Found: C, 84.13; H, 6.34.

The mother liquors were stripped of solvent, and the residue was taken up in chloroform and separated into three major solid fractions by preparative t.l.c. on silica gel plates (with phosphor) with elution with 5% ethyl acetate – carbon tetrachloride. The solid fraction with the lowest R_f value consisted of **2** (55 mg; total yield of pure product: 163 mg, 42%). The next fraction (40 mg) had a closely similar R_f value and was recrystallized from isopropyl alcohol to give **7** (16 mg, 4%) m.p. 146–147°. Three recrystallizations from cyclohexane gave **7** as colorless crystals, m.p. 152.5–154°.[9]

[9]For spectra, see Table 1.

Anal. Calcd. for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14. Found: C, 83.99; H, 6.15.

The third solid fraction (28 mg) was recrystallized from methanol to give **16** (19 mg, 6%), m.p. 94–95° (lit. (7) m.p. 94°), undepressed on admixture with an authentic sample;[3] λ_{max} ($CHCl_3$) 5.93 μ; λ_{max} (EtOH) 241.5 mμ (log ε 13 200); δ ($CDCl_3$) 3.68 (d, J = 7.3 Hz, 2H), 4.83 (t, J = 7.3 Hz, 1H), 7.0–7.5 (m, 13H), 7.8–8.0 (m, 2H).

Anal. Calcd. for $C_{21}H_{18}O$: C, 88.08; H, 6.34. Found: C, 88.13; H, 6.32.

When the reaction time was extended to 2.5 h and the product mixture was again resolved by preparative t.l.c. and crystallization, there was obtained **2** (18%) and **7** (27%) together with the corresponding cyclopentenones **1** (3%) and **8** (5%) (*vide infra*) (total yields of unrearranged and rearranged products: 21 and 32%, respectively).

*Reaction of **2** with Aqueous Ethanolic Potassium Hydroxide. Formation of 3,4,4-Triphenyl-2-cyclopentenone (**1**)*

A solution of **2** (248 mg, 0.756 mmol) in a 5% solution of potassium hydroxide in ethanol–water (4:1, 15 ml) was boiled under reflux for 30 min. The mixture was neutralized with 2 *N* hydrochloric acid and diluted with water, and solvent was distilled until the vapor temperature reached 98°. The residue was extracted four times with dichloromethane, and the extracts were washed twice with water and dried. Evaporation of the solvent gave a solid, which was crystallized from ethanol to yield **1** (117 mg, 50%), m.p. 173–179°. Further recrystallization from several solvents did not give a sharp-melting solid; the product consisted of two types of crystals, long needles and irregular globular forms, that were separated by hand picking and shown to have identical i.r. spectra in solution; λ_{max} (CCl_4) 5.80 (sh), 5.87 μ; λ_{max} (EtOH) 290 mμ (ε 17 000); δ ($CDCl_3$) 3.30 (s, 2H), 6.84 (s, 1H), 7.0–7.5 (m, 15H).

Anal. Calcd. for $C_{23}H_{18}O$: C, 89.00; H, 5.85. Found: C, 88.86; H, 5.83.

*Reaction of **7** with Aqueous Ethanolic Potassium Hydroxide. Formation of 3,5,5-Triphenyl-2-cyclopentenone (**8**)*

A solution of **7** (64 mg, 0.20 mmol) in a 5% solution of potassium hydroxide in ethanol–water (4:1) was boiled for 30 min. Work-up as in the case of **2** above gave a solid, which was crystallized from methanol to yield **8** (38 mg, 63%), m.p. 152–154°. This product was also obtained, together with **1**, when a mixture of **2** and **7** was chromatographed on neutral alumina; one recrystallization from hexane and two from methanol gave an analytical sample, m.p. 155–156.5°; λ_{max} (CCl_4) 5.87 μ; λ_{max} (EtOH) 288.5 mμ (ε 22 900); δ ($CDCl_3$) 3.83 (d, J= 1.5 Hz, 2H), 6.63 (t, J = 1.5 Hz, 1H), 7.0–7.9 (m, 15H).

Anal. Calcd. for $C_{23}H_{18}O$: C, 89.00; H, 5.85. Found: C, 88.77; H, 5.93.

*Reaction of 2-Diazoacetophenone and Diphenylketene. Formation of 4-Hydroxy-2,2,4-triphenyl-3-butenoic Acid Lactone (**9**), 2,2,5-Triphenyl-3(2H)-furanone (**11**), and **12**[10]*

To a solution of 2-diazoacetophenone (**10**) (21) (4.25 g, 29 mmol) in ether (30 ml) was added diphenylketene (**5**)

[10]*Cf.* ref. 3.

(22) (6.25 g, 32 mmol) in a nitrogen atmosphere. Brisk evolution of nitrogen occurred and the mixture was stirred under nitrogen at room temperature for 2 h, and then heated under nitrogen on the steam bath for a further 2 h after removal of most of the ether. The resulting oil (10.75 g) was dissolved in hot petroleum ether (b.p. 60–70°) and chromatographed on a silica gel column (Davison; 800 g) packed in the same solvent. The column was eluted with petroleum ether containing increasing amounts of ether (2% increments). Elution with 8% ether – petroleum ether gave **9** (7.00 g, 77% based on **10**), which was obtained after recrystallization from ethanol as colorless needles, m.p. 117.5–118.5° (lit. (3) m.p. 121–121.5°, 120°); λ_{max} 5.55, 6.03 μ(w); δ ($CDCl_3$) 6.33 (s, 1H); 7.2–7.5 (m, 13H), 7.6–7.8 (m, 2H).

The fractions eluted with 20% ether–petroleum gave **12** (2.17 g, 11%), which was obtained after recrystallization from ethanol as yellow needles, m.p. 183–184°; λ_{max} 5.71, 6.15 μ(m); λ_{max} (EtOH) 253 (ε 20 100), 259 (ε 19 400), 283.5 (ε 16 700), 333.5 mμ (ε 14 300); δ ($CDCl_3$) 3.90 (s, 1H), 5.34 (s, 1H), 6.8–7.6 (m, 34H).

Anal. Calcd. for $C_{50}H_{36}O_4$: C, 85.70; H, 5.18. Found: C, 85.21, 85.13; H, 5.09, 5.03.

Hydrolysis of **12** in 2-methoxyethanol with aqueous sodium hydroxide on the steam bath followed by recrystallization of the acid fraction from petroleum ether gave diphenylacetic acid, m.p. 146–147°, undepressed on admixture with an authentic sample; the i.r. spectra of the two samples were identical.

The fractions eluted with 26–28% ether – petroleum ether gave **11** (0.76 g, 8%), which was obtained after recrystallization from ethanol as colorless needles, m.p. 175–175.5°; λ_{max} (CCl_4) 5.89 μ; λ_{max} (EtOH) 247 (ε 6100), 309 mμ (ε 16 900); δ ($CDCl_3$) 6.11 (s, 1H), 7.35–7.6 (m, 13H), 8.0 (m, 2H); *m/e* (relative abundance) 312 (43), 283 (16), 207 (98), 179 (100), 105 (47).

Anal. Calcd. for $C_{22}H_{16}O_2$: C, 84.59; H, 5.16. Found: C, 84.36; H, 5.25.

Reaction of ***9*** *with Methyllithium. Formation of* ***7***

To a solution of **9** (500 mg, 1.60 mmol) in ether (40 ml) under nitrogen was added 1.75 *M* ethereal methyllithium (1.5 ml, 2.6 mmol). The mixture was stirred at room temperature for 25 min and then treated with 2 *N* sulfuric acid (15 ml). The ethereal layer was separated, washed with aqueous sodium bicarbonate and saturated aqueous sodium chloride, and dried. Evaporation of the ether gave a white solid that was crystallized from methanol to give **7** (470 mg, 89%), m.p. 148–148.5°. The p.m.r. spectrum of the crude product gave no evidence for the presence of **2**. When the reaction was allowed to proceed for 5 h, the yield of **7** was reduced to 77%, but again the p.m.r. spectrum of the crude product failed to show the presence of **2**.

Reaction of ***2*** *with Sodium Methoxide in Ether*

Sodium hydride (22 mg of a 54% dispersion in mineral oil; 0.49 mmol) was washed twice with petroleum ether and once with ether to remove mineral oil, and suspended in ether (25 ml) with stirring under nitrogen. To the stirred suspension was added a solution of **2** (127 mg, 0.39 mmol) in ether (35 ml) followed by two drops of methanol. After 3 days the mixture was treated with 1.2 *N* hydrochloric acid (25 ml). The ethereal layer was separated, and the aqueous layer was extracted twice with ether. The combined ethereal solutions were washed with aqueous 5% sodium bicarbonate and dried. The solvent was evaporated to give a solid residue (110 mg), which was resolved into two major components by preparative t.l.c. on silica gel (with phosphor) with elution with 5% ethyl acetate – carbon tetrachloride. The faster-moving major component (32 mg) was recrystallized from hexane–methanol to give **8** as colorless needles (25 mg, 21%), m.p. 150.5–152.5°. The slower-moving major component (43 mg) was crystallized from cyclohexane to give **1** as colorless crystals (35 mg, 29%), m.p. 168–173°.

When a solution of **1** in ether was treated with sodium hydride and methanol for 3 days and the mixture was worked-up as above, **1** was recovered quantitatively.

When a solution of **7** (61 mg) in ether was treated similarly, it was converted to **8** (43 mg, 75%), m.p. 148–150°; the p.m.r. spectrum of the total crude reaction product failed to show the presence of **1**.

*Reaction of the Sodium Derivative of Deoxybenzoin with 1-Bromo-1-phenylacetone. Formation of the Diastereomers of 1,2,3-Triphenyl-1,4-pentanedione (****27****), 1,2,5-Triphenyl-1,4-pentanedione (****30****), and 2,3,4-Triphenyl-2-cyclopentenone (****31****)*

Sodium hydride (460 mg of 54% dispersion in mineral oil; 10.3 mmol) was suspended in tetrahydrofuran (15 ml) in a nitrogen atmosphere. Deoxybenzoin (1.96, 10.0 mmol) dissolved in a little tetrahydrofuran was added. The mixture was warmed for 15 min, after which time hydrogen evolution had ceased. 1-Bromo-1-phenylacetone (23) (2.13 g, 10 mmol) was added and the mixture was boiled under reflux for 5 h. It was then poured into water and extracted with benzene. The extract was dried and stripped of solvent to give an orange gum, which was chromatographed on silica gel (150 g) packed in benzene–petroleum ether (2:3). Elution was commenced with mixtures of these solvents, the proportion of benzene being progressively increased. With benzene as eluent, deoxybenzoin (1.42 g, 72% recovery) was eluted. Elution was continued with benzene containing increasing amounts of ether. With 10% ether an oil (1.37 g) was eluted that was fractionated by preparative t.l.c. on silica with multiple gradient elution with 2–6% ether in petroleum ether to give a mixture of the diastereomers **27** (259 mg, 8%), together with **30** (409 mg, 12.5%) and **31** (233 mg, 7.5%) as the major components in order of decreasing R_f values.

Crystallization of the mixture of diastereomers **27** from methanol (20 ml) gave **27***b* as colorless needles (55 mg), m.p. 187–188° after recrystallization from methanol.[11]

Anal. Calcd. for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14. Found: C, 83.94; H, 6.11.

On slow evaporation of the mother liquors a mixture of fine needles (**27***b*) and large prisms (**27***a*) crystallized. On dilution with methanol and heating, the needles dissolved more rapidly than the prisms, which were separated by filtration of the hot solution. Recrystallization from methanol gave **27***a*, m.p. 155–155.5°.[11]

Anal. Calcd. for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14. Found: C, 83.87, 84.58; H, 6.54, 6.18.

Concentration of the mother liquors followed by

[11]For spectra, see Table 2.

For personal use only.

repetition of the above separation processes together with hand-picking of crystals gave further **27***b* (total yield: 80 mg), m.p. 187–188°, and **27***a* (total yield; 137 mg), m.p. 154–155°.

Several recrystallizations of **30** from methanol gave crystals, m.p. 112.5–113°; λ_{max} (CCl_4) 5.86, 5.97 μ; λ_{max} (EtOH) 246 mμ (ε 13 600); δ ($CDCl_3$) 2.76 (dd, J = 4, 18 Hz, 1H), 3.62 (dd, J = 10, 18 Hz, 1H), 3.74 (s, 2H), 5.13 (dd, J = 4, 10 Hz, 1H), 7.26 (m, 13H), 8.0 (m, 2H); *m/e* (relative abundance) 328 (0.8), 237 (47), 105 (100).

Anal. Calcd. for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14. Found: C, 84.24; H, 6.09.

Compound **31** was purified by preparative t.l.c. on silica with multiple elution with 5% ether – petroleum ether followed by recrystallization from methanol with treatment with Norit. It was obtained as pale yellow prisms, m.p. 139.5–140.5°, undepressed on admixture with an authentic sample prepared by the method of Koelsch and Geissman (16*a*); the i.r. spectra of the two samples were identical.

Reaction of 30 with Aqueous Ethanolic Sodium Hydroxide

A solution of **30** (59 mg) in ethanol (2 ml) was treated with 1 *N* aqueous sodium hydroxide (0.4 ml), and the resulting yellow solution was warmed briefly on the steam bath, acidified by the addition of 1 *N* hydrochloric acid (0.45 ml), and evaporated to dryness. The organic material was extracted from the residue with methanol, and the extract was concentrated to small volume. On standing, the concentrate deposited yellow crystals, which were recrystallized from methanol to give **31** (35 mg, 63%) as very pale yellow prisms, m.p. 140–140.5°, undepressed on admixture with an authentic sample (16*a*).

Reaction of 27a with Sodium Methoxide in Ether

Compound **27***a* (27 mg, 0.082 mmol) in ether (15 ml) was treated with sodium hydride (7.4 mg of a 54% dispersion in mineral oil; 0.17 mmol) and methanol (one drop) as in the case of **2**. Preparative t.l.c. on silica gel (with phosphor) with multiple elution with 50 and 80% benzene – petroleum ether gave **27***a* (18 mg, 67%) and several minor fractions, which did not include **1**, **2**, **7**, or **8**. One of these fractions (2.5 mg) had an R_f value identical with that of **27***b*. A second (4 mg) was tentatively identified as 3,4,5-triphenyl-2-cyclopentenone: λ_{max} (CCl_4) 5.85 μ; λ_{max} (EtOH) 286.5 mμ (ε ~ 14 000); δ ($CDCl_3$) 3.53, 4.60, 6.85, 7.3.

2-Benzhydryl-1-phenyl-1,3-butanedione (24)

The β-diketone **24** was prepared from benzhydrol and benzoylacetone by the method of Fosse (24) in 95% yield; m.p. 149.5–150.5° (lit. (24) m.p. 148–150°); λ_{max} 5.78, 5.96 μ; λ_{max} (EtOH) 252 (ε 16 100), 274 mμ (sh, ε 3000); λ_{max} (EtOH–NaOH) 315 mμ (ε 9500); δ ($CDCl_3$) 2.02 (s, 3H), 5.12 (d, J = 12 Hz, 1H), 5.63 (d, J = 12 Hz, 1H), 7.0–7.5 (m, 13H), 7.9–8.1 (m, 2H).

Anal. Calcd. for $C_{23}H_{20}O_2$: C, 84.12; H, 6.14. Found: C, 83.90; H, 6.22.

Compound **24** gave a negative test with anhydrous methanolic ferric chloride and was recovered unchanged after its ethereal solution was stirred for 1 h with either 5% aqueous sodium bicarbonate or 1.2 *N* hydrochloric acid.

Ethyl 3-Cyano-3,3-diphenylpropionate (32)

A mixture of diphenylacetonitrile (1.93 g, 10.0 mmol), 50% aqueous sodium hydroxide (5 ml), and benzene (5 ml) was vigorously stirred to give an emulsion. Benzyltriethylammonium chloride (20 mg) was added, producing an intense red coloration, and the reaction flask was flushed with nitrogen. Ethyl bromoacetate (1.67 g, 10.0 mmol) was added from a dropping funnel. The mixture became warm, and the red color was discharged within 10 min. After 1 h the mixture was poured into water, and extracted with benzene. The extract was washed with dilute hydrochloric acid and saturated aqueous sodium chloride, and dried. Evaporation of the solvent gave a colorless crystalline residue (2.68 g) that was twice recrystallized from ethanol to give **32** (2.10 g, 75%) as colorless prisms, m.p. 103.5–105° (lit. (25) m.p. 103–105°); λ_{max} (CCl_4) 4.49 (w), 5.71, 5.75 μ; δ ($CDCl_3$) 1.10 (t, J = 7 Hz, 3H), 3.42 (s, 2H), 4.07 (q, J = 7 Hz, 2H), 7.37 (s, 10H).

3-Cyano-3,3-diphenylpropionic Acid (33)

The ester **32** (2.01 g, 7.20 mmol) was dissolved in 70% aqueous ethanol (20 ml) containing potassium hydroxide (4 g), and the solution was heated on the steam bath for 30 min. Acidification with dilute hydrochloric acid gave a copious precipitate, which was filtered and crystallized from aqueous ethanol to give **33** (1.71 g, 95%) as colorless prisms, m.p. 182–183° (lit. (25) m.p. 183–184°); λ_{max} ($CHCl_3$) 3–4, 4.50 (w), 5.79 μ; δ ($CDCl_3$–Me_2CO) 3.48 (s), 7.37 (m), 8.33 (br s).

Reaction of 33 with Phenylmagnesium Bromide or Phenyllithium. Formation of 3,3-Diphenylacrylic Acid (35) and 1,1,3,3-Tetraphenyl-2-propen-1-ol (36)

(*A*) A solution of phenylmagnesium bromide was prepared from magnesium (26 mg, 1.1 mg-at.) and bromobenzene (173 mg, 1.1 mmol) in boiling, dry tetrahydrofuran (5 ml) under nitrogen. The solution was cooled to room temperature, and to it was added a solution of **33** (126 mg, 0.50 mmol) in dry tetrahydrofuran (5 ml). The mixture was stirred overnight, and then treated with 2 *N* sulfuric acid (10 ml). The resulting mixture was boiled under reflux for 45 min, cooled, and extracted with chloroform. The chloroform extract was extracted twice with aqueous 10% sodium carbonate. The combined basic extracts were acidified, and the mixture was extracted with chloroform. This chloroform extract was dried and stripped of solvent to give **35** (95 mg, 85%), which was obtained as long needles, m.p. 160–161° (lit. (26) m.p. 162°) after several crystallizations from aqueous methanol; λ_{max} (CCl_4) 3–4, 5.95 μ; λ_{max} (EtOH) 275 mμ (ε 12 900); *m/e* (relative abundance) 224 (100), 207 (18), 179 (42), 178 (37), 123 (13).

(*B*) Compound **33** (500 mg, 1.99 mmol) was treated with phenylmagnesium bromide (23 mmol) in tetrahydrofuran (40 ml) as in section *A*. The mixture was boiled under reflux for 2 h, cooled, and treated with 2 *N* sulfuric acid (25 ml). The resulting mixture was boiled under reflux for 1 h, cooled and extracted with ether. The extract was dried and stripped of solvent to give an orange gum (1.48 g), which was dissolved in 20% benzene – petroleum ether and chromatographed on silica (50 g). Elution was conducted with petroleum ether containing increasing amounts of benzene, followed by benzene. The latter eluted crude **36** (470 mg, 65%), which was crystallized several times from heptane to give prisms, m.p. 137–137.5° (lit. (27) m.p. 138–139°); λ_{max} (CCl_4) 2.80 (m),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

6.15 μ (w); δ ($CDCl_3$) 2.44 (s, 1H, absent after D_2O treatment), 6.88 (s, 1H), 7.1–7.6 (m, 20H); *m/e* (relative abundance) 362 (1), 168 (16), 167 (100), 105 (20).

(*C*) A solution of **33** (126 mg, 0.50 mmol) in tetrahydrofuran (6 ml) was treated with a solution of phenyllithium (1.54 mmol) in ether (2 ml). The mixture was boiled under reflux for 5 h and worked-up as in section *A* to give **35** (69 mg, 62%), m.p. 159–160°.

2,2-Diphenylsuccinonitrile (37) (18)

A mixture of diphenylacetonitrile (2.50 g, 13.0 mmol), 50% aqueous sodium hydroxide (10 ml), and benzyltriethylammonium chloride (50 mg) was stirred to give an emulsion. A solution of chloroacetonitrile (0.755 g, 10.0 mmol) in benzene (5 ml) was added at such a rate that the temperature of the mixture was maintained at 30–35° (20 min). After 30 min of stirring, more chloroacetonitrile (0.378 g, 5.0 mmol) was added in benzene. After a further 30 min of stirring, the mixture was poured into water. The benzene layer was separated, washed once with water, twice with 2 *N* sulfuric acid, and once with saturated aqueous sodium chloride, dried, and stripped of solvent. The residual solid was twice crystallized from methanol (once with Norit treatment) to give **37** (2.26 g, 75%), m.p. 110–111° (lit. (18) m.p. 111°); λ_{max} ($CHCl_3$) 4.50 μ (m); δ ($CDCl_3$) 3.40 (s, 2H), 7.40 (s, 10H).

Reaction of 37 with Methylmagnesium Iodide or Methyllithium. Formation of 3,3-Diphenylacrylonitrile (38)

A solution of methylmagnesium iodide was prepared from magnesium (27 mg, 1.1 mg-at.) and methyl iodide (156 mg, 1.1 mmol) in ether (3 ml) under nitrogen. To it was added a solution of **37** (116 mg, 0.50 mmol) in ether (15 ml). The mixture was boiled under reflux for 2 h, cooled, and treated with 2 *N* sulfuric acid (5 ml). The resulting mixture was boiled under reflux for 2 h, cooled, and extracted with ether. The extract was washed twice with aqueous 10% sodium carbonate and once with saturated aqueous sodium chloride, dried, and stripped of solvent. The residue was subjected to preparative t.l.c. on silica with five elutions with 25% benzene – petroleum ether. The major fraction was a yellow gum, which on treatment with chloroform gave a small amount of solid residue. Filtration of the chloroform solution and removal of the solvent gave **38** as an oil (54 mg, 53%); λ_{max} (CCl_4) 4.51 μ; δ ($CDCl_3$) 5.73 (s, 1H); 7.3–7.5 (m, 10H).

Similar treatment of **37** (464 mg, 2.00 mmol) in tetrahydrofuran with methyllithium (2.3 mmol) in ether gave **38** as the major product together with unconsumed **37**.

2,2,4,5,5-Pentaphenyl-4-pentenonitrile (39)

A mixture of diphenylacetonitrile (276 mg, 1.43 mmol), 50% aqueous sodium hydroxide (9 ml), and benzene (10 ml) was stirred vigorously under nitrogen to give an emulsion. Benzyltriethylammonium chloride (40 mg) was added to give a deep red coloration, followed by a solution of 2,3,3-triphenylallyl bromide (28) (500 mg, 1.43 mmol) in benzene (20 ml). The red coloration was rapidly lost,[12] and stirring was continued at room temperature for 22 h. The mixture was diluted with an equal volume of water, the benzene layer was separated, and the aqueous layer was extracted twice with benzene. The combined benzene solutions were washed with water and saturated aqueous sodium chloride, dried, and stripped of solvent. The residue was recrystallized from 2-methoxyethanol to give **39** (496 mg, 75%), m.p. 215–217°. Two recrystallizations from this solvent raised the m.p. to 218.5–219°; λ_{max} (CCl_4) 4.49 μ (w); δ ($CDCl_3$) 3.73 (s, 2H), 6.9–7.3 (m, 25H); *m/e* (relative abundance) 461 (1), 270 (28), 269 (100), 193 (19), 192 (14), 191 (43), 178 (8), 165 (15).

Anal. Calcd. for $C_{35}H_{27}N$: C, 91.07; H, 5.90; N, 3.03. Found: C, 91.40; H, 5.82; N, 3.08.

Reaction of 39 with Methyllithium. Formation of 1,1,2,4,4-Pentaphenyl-1-butene (41)

A solution of **39** (335 mg, 0.73 mmol) in dry tetrahydrofuran (25 ml) under nitrogen was treated with 1.75 *M* methyllithium (1.5 ml, 2.6 mmol) in ether. The mixture was stirred at room temperature for 24 h, cooled in ice, and treated with 2 *N* sulfuric acid (6 ml). The organic layer was separated, and the aqueous layer was extracted twice with ether. The combined organic solutions were washed with aqueous 5% sodium bicarbonate and saturated aqueous sodium chloride, dried, and stripped of solvent to give crystalline **41** (307 mg, 100%), m.p. 152–152.5° after two recrystallizations from heptane; δ 3.22 (d, J = 7.5 Hz, 2H), 3.93 (t, J = 7.5 Hz, 1H), 6.6–7.4 (m, 25H); *m/e* (relative abundance) 436 (5), 269 (100), 191 (32).

Anal. Calcd. for $C_{34}H_{28}$: C, 93.53; H, 6.47. Found: C, 93.64; H, 6.47.

4-Methyl-2,2-diphenyl-4-pentenonitrile (40)

Diphenylacetonitrile (7.00 g, 36.3 mmol) in benzene (50 ml) was alkylated with methallyl chloride (3.5 g, 39 mmol), 50% aqueous sodium hydroxide (25 ml), and benzyltriethylammonium chloride (200 mg) by the procedure described for the preparation of **39** to give **40** (8.5 g, 95%) as a colorless oil, b.p. 126–127° (0.03 mm); λ_{max} (CCl_4) 4.49 (w), 6.05 μ (m); δ (CCl_4) 1.51 (m, 3H), 3.03 (br s, 2H), 4.69 (m, 1H), 4.86 (m, 1H), 7.3 (m, 10H); *m/e* (relative abundance) 247 (18), 193 (22), 192 (100), 165 (46).

Anal. Calcd. for $C_{18}H_{17}N$: C, 87.41; H, 6.93; N, 5.66. Found: C, 87.46; H, 6.93; N, 5.50.

Reaction of 40 with Methyllithium. Formation of 2-Methyl-4,4-diphenyl-1-butene (42)

A solution of **40** (192 mg, 0.78 mmol) in ether (8 ml) under nitrogen was treated with 1.75 *M* methyllithium (1 ml) in ether. The mixture was stirred for 19 h at −8 to −10°, and then treated with 2 *N* sulfuric acid (5 ml). The resulting mixture was worked-up as in the case of the corresponding reaction of **39** to give **42** as an oil (160 mg, 93%), b.p. 78–80° (0.01 mm); λ_{max} (CCl_4) 6.06 μ (m); δ (CCl_4) 1.63 (m, 3H), 2.71 (d, J = 8 Hz, 2H) 4.11 (t, J = 8 Hz, 1H), 4.55 (m, 1H), 4.64 (m, 1H), 7.2 (m, 10H).

Anal. Calcd. for $C_{17}H_{18}$: C, 91.84; H, 8.16. Found: C, 92.07; H, 8.10.

3-Oxo-2,2,3-triphenylpropionitrile (43)

Diphenylacetonitrile (965 mg, 5.00 mmol) in benzene (50 ml) was acylated with benzoyl chloride (1.405 g, 10.00 mmol), 50% aqueous sodium hydroxide (25 ml), and benzyltriethylammonium chloride (125 mg) as above, except that the reaction time was reduced to 10 min.

[12]A run that was terminated at this point showed that the loss of the red color did not signal the completion of the reaction.

Crystallization of the crude product, **43**, from methanol gave colorless prisms (955 mg, 64%), m.p. 125–127°. Recrystallization from methanol raised the m.p. to 128–129°; λ_{max} (CCl_4) 4.48 (w), 5.90 μ; λ_{max} (EtOH) 254.5 mμ (ε 12 500); δ ($CDCl_3$) 7.35 (br s, 13H), 7.8–8.0 (m, 2H); *m/e* (relative abundance) 297 (0.1), 190 (2.5), 165 (13), 106 (8), 105 (100).

Anal. Calcd. for $C_{21}H_{15}NO$: C, 84.82; H, 5.09; N, 4.71. Found: C, 85.03; H, 4.99; N, 4.79.

Attempts to ketalize and thioketalize **43** with ethylene glycol and 1,2-ethanedithiol, respectively, were unsuccessful.

We thank the National Research Council of Canada for generous support of this work. G.D.A. thanks the Province of Ontario for a Graduate Fellowship. Preliminary experiments by Dr. L. L. Williams (29) are gratefully acknowledged.

Temperature Dependence of Disproportionation–Combination Ratios for Alkyl Radicals in Liquid Methane[1,2]

HUGH A. GILLIS

Division of Physics, National Research Council of Canada, Ottawa, Canada[3]

and

Radiation Research Laboratories, Mellon Institute, Carnegie-Mellon University, Pittsburgh, Pa. 15213

Received February 16, 1971

The ratios of rate constants for disproportionation to combination have been measured for ethyl radicals and for *i*-propyl radicals in liquid methane between −181 and −94 °C. The radicals were generated by γ-radiolysis of dilute methane solutions of ethylene-d_4 or propylene-d_6. The activation energy for combination was found to exceed that for disproportionation by 290 ± 30 cal mol^{-1} for ethyl radicals and by 255 ± 25 cal mol^{-1} for *i*-propyl radicals. In both cases the disproportionation–combination ratio in the liquid, extrapolated to room temperature, is greater than that in the gas phase by a factor of about 2.5. These results are interpreted as indicating that disproportionation and combination reactions proceed by way of different transition states.

Les rapports des constantes de vitesse dismutation sur combinaison ont été mesurés pour les radicaux éthyles et *i*-propyles dans le méthane liquide entre −181 et −94 °C. Ces radicaux ont été engendrés par radiolyse-γ de solutions d'éthylène-d_4 ou de propylène-d_6 dans le méthane. L'énergie d'activation pour la combinaison s'est averée dépasser celle de dismutation par 290 ± 30 cal mol^{-1} pour les radicaux éthyles et par 255 ± 25 cal mol^{-1} pour les radicaux *i*-propyles. Dans les deux cas, le rapport dismutation sur combinaison dans le liquide, extrapolé à la température de la pièce, dépasse par un facteur d'environ 2.5 celui obtenu en phase gazeuse. L'interprétation de ces résultats indiquent que les réactions de dismutation et de combinaison se font par passage par des états de transition différents.

Canadian Journal of Chemistry, 49, 2861 (1971)

Introduction

Measurements of ratios of rate constants for disproportionation to combination (k_d/k_c) of alkyl radicals in a liquid at various temperatures are of interest for two principal reasons: (*a*) They are important in photochemical and radiation chemical studies on liquid hydrocarbons at low temperatures in deducing radical yields from final product yields; (*b*) They should give some information about the nature of the transition state(s) involved in these reactions. One of the main reasons for proposals that the same transition state is involved in the two reactions is that several authors concluded that these ratios remain constant within experimental error over a wide temperature range in the gas phase.[4]

In an earlier study (3) liquid methane was γ-irradiated in the pure state and with small amounts of added ethylene or propylene at a single temperature, −161 °C. The effects of these olefins on the major products were interpreted by a simple hydrogen atom scavenging mechanism. The k_d/k_c ratios for both the reaction of two ethyl radicals and the reaction of two isopropyl radicals were found to be much higher than gas phase values. In the present study k_d/k_c ratios for these radical pairs were determined from product yields over almost the whole temperature range at which methane is a liquid with the object of measuring any difference in activation energies. Deuterated olefins were used with the expectation that isotopic analysis would reveal whether there are contributions to the yields of the disproportionation and combination products from other reactions. Also it was hoped that the isotope effect in the disproportionation reaction could be measured.

Experimental

Materials

Matheson research grade methane (minimum purity 99.99 mol %) was treated in an effort to remove traces of water, ethane, and higher hydrocarbons. It was first passed through a trap containing thoroughly degassed silica gel at −120 °C. The last 20% was discarded. It was then passed through a spiral trap at −159 °C

packed with glass wool. Analysis of this purified methane by gas chromatography and mass spectrometry gave the following upper limits: O_2, 7; C_2H_4, 0.02; C_2H_6, 0.02; C_3H_8, 0.01 p.p.m.

Ethylene-d_4 and propylene-d_6 were obtained from Merck, Sharpe and Dohme and used as received except that they were pumped on at −196 °C.

Irradiation Conditions

A sample of 0.29 g in a glass cell was positioned in a Dewar flask in the irradiation chamber of a Co^{60} source. At the highest temperature about 2%, and at lower temperatures somewhat less, of the sample was in the gas phase. Sample temperatures of −94, −129, −161, and −181 °C were achieved by the use of a frozen toluene slush, a frozen *n*-pentane slush, boiling methane, and boiling oxygen (at a pressure about 15 cm above atmospheric), respectively, in the Dewar flask. The temperature was monitored during an irradiation with a thermocouple.

Two different Gammacell Co^{60} sources used provided dose rates of approximately 1.5×10^{18} and 1.0×10^{18} eV g^{-1} min^{-1}. Dose rates were determined by Fricke dosimetry with water in the Dewar flask, and dose rates for the samples were calculated by applying corrections for the electron density of the methane and the refrigerant. Only ratios of yields are of significance in this work so that exact doses are unimportant. Samples were given doses in the range $1.5–3.1 \times 10^{20}$ eV g^{-1}.

Product Analyses

Hydrocarbons were analyzed by gas chromatography in the same manner as in the previous study (3) with an F and M 5750 instrument equipped with a splitter, dual thermal conductivity and dual hydrogen flame detectors. Separated products were often trapped for mass spectrometric analysis at the exit of the thermal conductivity detector.

Isotopic analyses of various deuterated products were made mass spectrometrically. Analyses of products from solutions of C_3D_6 in CH_4 were performed at Mellon Institute on a Consolidated Model 21-101 instrument. Cracking patterns and sensitivities for detection of C_3D_8 and C_3H_8 were obtained by the use of authentic samples. The patterns obtained by Scala *et al.* (4) were used for C_3HD_7 (assumed to be $CD_3CD_2CHD_2$) and $C_3H_2D_6$ (assumed to be $CD_3CHDCHD_2$). Sensitivities for C_3HD_7 and $C_3H_2D_6$ were obtained by interpolation between those for C_3D_8 and C_3H_8.

Isotopic analyses of product ethanes from solutions of C_2D_4 in CH_4 were performed at the National Research Council of Canada, Ottawa, on an Atlas CH_4 mass spectrometer at an ionizing voltage of 14 eV with the use of calibrations obtained by Amenomiya and Pottie (5). The spectra of the propane and *n*-butane products from these solutions were also determined by this method. The percentages of $C_3H_3D_5$ in the propane and *n*-C_4HD_9 in the *n*-butane were calculated from the parent peaks, and the qualitative conclusions about relative contributions of other isotopic species given below in Results and Discussion were deduced.

Results and Discussion

Propylene-d_6 Solutions

The main radical reactions in this system are expected to be:

[1] $CH_4 \rightsquigarrow H, CH_3$

[2] $H + C_3D_6 \rightarrow CHD_2CDCD_3$

[3] $CH_3 + CHD_2CDCD_3 \rightarrow CHD_2CD(CH_3)CD_3$

[4] $\rightarrow CH_3D + C_3HD_5$

[5] $\rightarrow CH_4 + C_3D_6$

[6] $2CHD_2CDCD_3 \rightarrow$ Diisopropyl-d_{12}

[7] $\rightarrow CHD_2CD_2CD_3 + C_3HD_5$

[8] $\rightarrow CHD_2CHDCD_3 + C_3D_6$

The results in Table 1 show that the main isotopic propane species are C_3HD_7 and $C_3H_2D_6$ as expected from the above reactions. The effect of oxygen, added at a concentration such that it should scavenge most free radicals but not react otherwise to a significant extent (6), is to reduce the isobutane, diisopropyl, and propane yields to practically zero.[5] The small residual yields of C_3H_8 and C_3D_8 indicate approximately 30% non-radical contribution to these products. The remainder of the C_3H_8 must come from the reaction of C_2H_5 with CH_3. Independent evidence that there is a small yield of C_2H_5 radicals, in the absence of O_2, came from mass spectrometric analysis of the *i*-pentane from one of the runs at −129.5 °C, which showed that it is at least mainly $CH_3CH_2CD(CHD_2)CD_3$, and presumably results from a combination reaction of C_2H_5 with CHD_2CDCD_3. In the earlier work (3) it was suggested that *i*-pentane could result from the addition of methyl radicals to propylene followed by the reaction of the resulting sec-butyl radicals with methyl radicals. However that would produce $CH_3CD_2CD(CH_3)CD_3$, rather than the species found, and hence cannot be important.[6]

[5]It has been shown (3) that some of the ethane produced in a solution containing oxygen comes from the insertion reactions of methylene radicals into methane, and the rest probably is produced by the combination of methyl radicals in spurs. The possibility that methylene radicals could be complicating the system by preferentially reacting with the added olefin was considered, and rejected because in the experiments with ethylene solutions, the most likely products of such reactions, cyclopropane and propylene, were found to be insignificant.

[6]The API spectrum for undeuterated *i*-pentane gives the peak at mass 43 as the largest, and the peak at mass 57 is the largest in the C_4 region with an intensity of 54.5% of the 43. Therefore $CH_3CD_2CD(CH_3)CD_3$ would be expected to give peaks at masses 60 and 63 of

*Also contained 0.50 mol % O_2.

For the reaction of two *i*-propyl radicals, k_d/k_c should be given by $[0.7\,G(C_3D_8) + G(C_3HD_7) + G(C_3H_2D_6)]/G$(diisopropyl).These ratios are given in Table 1, and the points are shown on an Arrhenius plot in Fig. 1. The slope of the line corresponds to a difference in activation energies, $E_c - E_d = 255 \pm 25$ cal mol^{-1}. The extrapolated k_d/k_c at room temperature is 1.63 ± 0.12, as compared to the gas phase value of 0.69 (7).

The results in Table 1 show that consumption of C_3D_6 is somewhat greater than can be accounted for by the propane, *i*-butane and diisopropyl products, despite the fact that the fraction of energy absorbed directly by the solute must be negligible. Also mass spectrometric analysis of the *i*-butane product showed that although most of it is the expected *i*-butane-d_6, a significant fraction of it is *i*-butane-d_7, which must result from the addition to C_3D_6 of D atoms from decomposition of C_3D_6, followed by reaction of the *i*-C_3D_7 with CH_3. For each experiment the %D (yield of D atoms divided by the total yield of H plus D atoms) was calculated from this *i*-butane data, and these are given in Table 1. Some of the C_3D_8 must come from the disproportionation of *i*-C_3D_7 radicals.

about equal intensity as the largest C_4 peaks, and a large peak at mass 47 and no significant peak at 49. On the other hand $CH_3CH_2CD(CHD_2)CH_3$ should give peaks at 60 and 61 of approximately equal intensity as the largest peaks in the C_4 region and a very large 49 peak. The mass spectrum of the product *i*-pentane shows that the peak at mass 49 is the largest in the spectrum, and peaks at masses 60, 61, and 63 are 31, 28, and 4%, respectively, of the 49 peak. Therefore this *i*-pentane is at least mainly $CH_3CH_2CD(CHD_2)CD_3$.

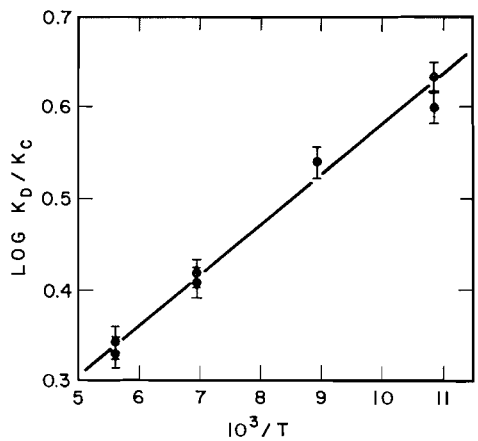

FIG. 1. Arrhenius plot of k_d/k_c ratios for the mutual reaction of *i*-propyl-d_6 radicals in liquid methane.

In the radiolysis of solutions of ethylene-d_4 in liquid ethane it was found that decomposition of the solute to give D_2 and D became increasingly important as the concentration of solute was raised, and this effect was ascribed to a charge transfer reaction (6). In a solution of C_3D_6 in methane a transfer of charge to C_3D_6, followed by neutralization of $C_3D_6^+$ and decomposition of the highly excited C_3D_6, would similarly account for the extra consumption of C_3D_6 and the production of D atoms. The occurrence of such reactions would not change the interpretation that the deuterated propanes and diisopropyl originate only in the disproportionation and combination of *i*-propyl radicals.

Originally it was hoped that both the isotope effect (k_H/k_D) in the disproportionation of two

i-C_3HD_6 radicals, and k_d/k_c for the reaction of CH_3 and i-C_3HD_6 could be measured in these experiments. The former can be calculated to a first approximation from the relationship

$$\frac{k_H}{k_D} = 5\frac{G(C_3H_2D_6)}{G(C_3HD_7)}$$

which is based on the assumption that H or D atoms are transferred only from the methyl groups. The k_d/k_c ratio for the reaction of CH_3 and i-C_3HD_6 would be inferred from the yield of propylene-d_5 after subtracting the amount produced in reaction 7, and the yield of i-butane. However for both calculations corrections have to be made for the following: (*a*) the appreciable yield of D atoms which give i-C_3D_7 radicals; (*b*) the considerable consumption of C_3D_6, and production and consumption of C_3HD_5; (*c*) the isotopic impurity in the C_3D_6. It turns out that these corrections make it impossible to estimate k_d/k_c for the reaction of CH_3 with i-C_3HD_6 radicals. Estimates of k_H/k_D for the disproportionation of two i-C_3HD_6 radicals after the above corrections were made are given in Table 1. Because of the magnitude of the corrections these estimates are possibly quite inaccurate, and in particular the change with temperature may not be significant.

Ethylene-d_4 Solutions

The results obtained by irradiating ethylene-d_4 solutions at various temperatures are shown in Table 2. The main radical reactions in this system are expected to be [1] and

[9] $H + C_2D_4 \rightarrow CHD_2CD_2$

[10] $CH_3 + CHD_2CD_2 \rightarrow CH_3CD_2CHD_2$

[11] $\rightarrow CH_3D + C_2HD_3$

[12] $\rightarrow CH_4 + C_2D_4$

[13] $2CHD_2CD_2 \rightarrow n$-$CHD_2CD_2CD_2CHD_2$

[14] $\rightarrow CHD_2CD_3 + C_2HD_3$

[15] $\rightarrow CHD_2CHD_2 + C_2D_4$

The low-voltage mass spectrum of the n-butane product indicates that the largest component is n-$C_4H_2D_8$, the product of reaction 13, with smaller amounts of n-C_4HD_9 and n-$C_4H_3D_7$ and a maximum of 2% n-C_4H_{10}. Small amounts of other deuterated species would not have been seen. The low-voltage mass spectrum of propane shows that the main component is $C_3H_4D_4$, the product of reaction 10, with smaller amounts of $C_3H_3D_5$ and $C_3H_5D_3$. The maximum C_3H_8 content ranges from 5.0% at −94.4 °C to 8.5% at −181 °C. The n-C_4HD_9 and $C_3H_3D_5$ must result from the sequence of D atoms adding to C_2D_4, and the resulting C_2D_5 radicals combining with either C_2HD_4 or CH_3 radicals. The percentage of D atoms in the total of H + D atoms was calculated for both the propane and n-butane products, and at all temperatures agreement is within 10%. The average values are given in Table 2. As with the CH_4–C_3D_6 solutions, the production of D atoms is accompanied by a greater consumption of C_2D_4 than can be accounted for by reaction 9, and the yield of D atoms is higher at higher temperatures and concentrations. The product $C_3H_5D_3$ and n-$C_4H_3D_7$ must result from addition of H atoms to C_2HD_3, present as an isotopic impurity in the C_2D_4 and also produced by reactions 11 and 14, followed by combination of the $C_2H_2D_3$ radicals with CH_3 and C_2HD_4 radicals. The percent C_2HD_3 calculated on this basis from the product n-$C_4H_3D_7$ agreed well with direct analyses of C_2HD_3 in the C_2D_4 that were done for three of the experiments in Table 2.

Isotope effects in the disproportionation reaction of two ethyl radicals were calculated at different temperatures in an analogous fashion as for two i-C_3HD_6 radicals, from the measured ratios of C_2HD_5 to $C_2H_2D_4$, and the percentages of H and D atoms, and C_2D_4 and C_2HD_3. Values found for k_H/k_D are given in Table 2. Again these are expected to be rather imprecise ($\pm$0.25). These calculations also indicate that about half of the product C_2D_6 can be accounted for by disproportionation of C_2D_5 radicals; the origin of the rest is unknown.

For the reaction of two ethyl radicals, k_d/k_c should be given by $[0.5\,G(C_2D_6) + G(C_2HD_5) + G(C_2H_2D_4) + G(C_2H_3D_3)]/G(n\text{-butanes})$. These ratios are given in Table 2, and the points are shown on an Arrhenius plot in Fig. 2. The slope of the line corresponds to a difference in activation energies, $E_c - E_d = 290 \pm 30$ cal mol^{-1}. The extrapolated k_d/k_c at room temperature is 0.34 ± 0.05, as compared to the gas phase value of 0.13 (7). It is noteworthy that this ($E_c - E_d$) is very similar to that obtained for i-propyl radicals, and also that the extrapolated k_d/k_c for the liquid at room temperature is 2.6 and 2.4 times the gas phase value for i-propyl and ethyl radicals, respectively.

Comparison with Other Work

The conclusion that can be drawn from this work is that k_d/k_c ratios for alkyl radicals depend both on temperature and phase; $E_c - E_d \simeq 270$ cal mol^{-1}, and the extrapolated ratios at room temperature are higher in the liquid than those reported for the gas phase. Similar conclusions have been reached by some of the authors who have reported on these problems. Thus Dixon *et al.* (8) found that k_d/k_c for ethyl radicals reacting in a cage in liquid isooctane is proportional to $T^{-0.86}$, which corresponds to $E_c - E_d \simeq 400$ cal mol^{-1}. For ethyl radicals in liquid methane at −184° they found $k_d/k_c = 0.35$, which is much lower than the value of 1.01 found in this work. For ethyl radicals in liquid isooctane at 65° they reported $k_d/k_c = 0.14$, which is the same as the gas phase value. Sheldon and Kochi (9) found k_d/k_c for ethyl radicals of 0.15 and 0.12 in *n*-pentane and decalin at 30°, which is essentially the same as the gas phase value.[7] For *i*-propyl radicals in decalin at 30° they obtained 1.2, which is almost twice what is probably the best gas phase value (7). Bakale and Gillis (6) found $k_d/k_c = 0.41 \pm 0.06$ for C_2HD_4 radicals in liquid ethane at −78 °C; this point would fit well on Fig. 2. Klein *et al.* (10) measured disproportionation and combination products from the reaction of isopropyl radicals produced in the photolysis of solid and gaseous azoisopropane over the temperature range 77–380 °K. The points for both the gas and solid phase experiments fitted reasonably on the same Arrhenius plot, the slope of which gave $E_c - E_d = 260 \pm 25$ cal mol^{-1}. However the interpretation of these experiments is clouded by the fact that at 77 °K k_d/k_c was 2, in contrast to the value of 9 measured at this temperature by the same authors for an experiment involving hydrogen atom addition to solid propylene (11).

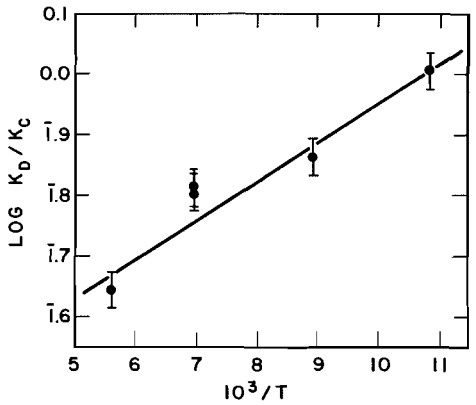

FIG. 2. Arrhenius plot of k_d/k_c ratios for the mutual reaction of ethyl-d_4 radicals in liquid methane.

It has been pointed out by one of the referees that the isotope effect in disproportionation found in this work indicates that k_d/k_c ratios might be quite sensitive to isotopic substitution, and therefore direct comparisons of k_d/k_c ratios for CHD_2CDCD_3 and C_2HD_4 radicals with those found for the corresponding undeuterated species in other laboratories might not be meaningful. Unfortunately the origin of the isotope effect is not known. If the transition states for disproportionation and combination are different, then the isotope effect seen here

[7]It might be expected that the reason for the higher values of k_d/k_c in this study as compared to that of Dixon *et al.* (8) is that reaction took place in a solvent cage in the latter, whereas in the present work the ethyl and *i*-propyl radicals are free in solution. However from their observation that the values of k_d/k_c for a number of alkyl radicals were the same in various solvents in which the percentages of radicals reacting in a cage were different, Sheldon and Kochi (9) concluded that k_d/k_c ratios for alkyl radicals in a cage are essentially the same as for those free in solution.

must be in the disproportionation reaction. If k_H/k_D is taken as 1.3, from Table 1, then k_d/k_c should be at most 24% larger for CH_3CHCH_3 than for CHD_2CDCD_3. However if only one transition state is involved, then the isotope effect could really be an inverse secondary effect on the combination reaction, and k_d/k_c might be larger for CH_3CHCH_3 than for CHD_2CDCD_3 by somewhat more than 24%. The results of the earlier study (3) on the radiolysis of liquid methane have a direct bearing on this question. In that investigation k_d/k_c was measured at -161 °C for CH_3CHCH_2D radicals, produced from solutions of C_3H_6 in CD_4. The average k_d/k_c from three experiments, recalculated on the same basis as used here, was 3.3 as compared to 3.5 in the present study. This strongly indicates that in fact k_d/k_c ratios are not influenced by isotopic substitution to an extent greater than the combined error limits of approximately 25%.

One might expect that there should also be an effect of temperature on k_d/k_c in the gas phase. A recent study by Reid and LeRoy (12) concluded tentatively that $E_c - E_d = -900$ cal mol^{-1} for ethyl radicals in the gas phase, and a paper by James and Suart (13) reported that $E_c - E_d = 250$ cal mol^{-1} for the mutual interaction of tert-butyl radicals. Konar (14) treated literature data by the thermodynamic formulation of reaction rates, and concluded that E_c is probably not equal to E_d for all alkyl radicals. But many experimental studies have concluded that k_d/k_c is independent of temperature within experimental error (1, 2). However the ranges of $\Delta(1/T)$ covered in the gas phase studies were much smaller than in this work, so the small $E_c - E_d$ found here would not have been seen easily. Thus the range 25–225 °C covered in a study by James and Steacie (15) corresponds to $\Delta(1/T) = 1.35 \times 10^{-3}$, as compared to $\Delta(1/T) = 5.26 \times 10^{-3}$ in this study.

Significance of Nonzero $E_c - E_d$

The most straightforward interpretation of a finite $(E_c - E_d)$ and a phase effect on k_d/k_c is simply that disproportionation and combination proceed by way of different transition states and although both activation energies are small, that for combination is about 270 cal mol^{-1} larger. These results are compatible with the proposal by Benson (16) that both reactions involve transition states with considerable ionic character, but the transition states are different, and there could be more contribution from ionic states to the transition state for disproportionation. Solvation in the liquid phase, even in a nonpolar liquid like methane, would therefore be expected to favor disproportionation.

Stefani (17) measured k_d/k_c ratios for ethyl radicals at 65 °C in ten different solvents covering a range of polarities, from isooctane to ethylene glycol. He found that the log of k_d/k_c is a linear function of the square root of the internal pressure of the solvent. He applied equations developed by Hildebrand and Scott (18*a*) to describe thermodynamic properties of regular solutions, and concluded that the solvent polarity effect is due to a larger internal pressure of the transition state for combination as compared to the internal pressure of the transition state for disproportionation. Also he concluded that the dependence of k_d/k_c on temperature in condensed phases is due to the effect of temperature on the internal pressure of the solvent, and not due to a real difference in activation energies. As indicated above, k_d/k_c for ethyl radicals in isooctane at 65 °C is much lower than any of the values reported here, although the internal pressures are comparable. Nevertheless the log of k_d/k_c taken from Fig. 2 was plotted against the square root of internal pressure of methane over the temperature range -168 to -126 °C for which the internal pressures of methane are available (19). The slope obtained, with internal pressure in atmospheres, was 20×10^{-3}, as compared to a slope of 4.76×10^{-3} obtained by Stefani. It must be concluded that the results of this work are not explicable by Stefani's treatment. A more general criticism of Stefani's treatment is that, as Hildebrand and Scott (18*b*) point out, the use of solubility parameters (the solubility parameter, δ, is the square root of the internal pressure) for polar molecules is somewhat questionable, unless the dipole is reasonably well buried within the molecule. Further, they indicate that temperature corrections for δ are of little value because the solubility parameter equations are rather crude approximations. Hence it must be considered that Stefani's explanation of the temperature and phase effects on k_d/k_c is rather dubious.

The author is very grateful to Dr. R. F. Pottie and Mr. R. L. Sander of the National Research Council of Canada for doing mass spectrometric analyses.

Spectroscopic Evidence for the Formation of the Mercurous Ion in Irradiated Acetates

R. S. Eachus and F. G. Herring
Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received February 25, 1971

The Hg(I) center has been produced by γ-irradiation both in Hg(II) doped cadmium acetate trihydrate and pure mercuric acetate. Both electron paramagnetic resonance and optical spectroscopy have been used to identify this species. The results indicate that the Hg(I) ion is produced in a covalent environment.

La formation de Hg(I) est produite par l'irradiation-γ à la fois de Hg(II) additionné d'acétate de cadmium trihydraté et d'acétate mercurique pur. Cette espèce a été identifiée à la fois par résonance paramagnétique électronique et par spectroscopie optique. Les résultats indiquent que l'ion Hg(I) est produit dans un environnement covalent.

Canadian Journal of Chemistry, 49, 2868 (1971)

Introduction

The effect of crystal structure on the production of radicals in irradiated acetates has been the subject of a recent publication (1). At 77 °K, the hydrated metal acetates gave methyl radicals as the primary product, whereas the anhydrous salts gave other species, usually the $CH_2CO_2^-$ radical. The products of C—C bond rupture are stabilized by the hydrogen bond network present in hydrated salts. In this study the effect of the metal ion was ignored. However, recent results (2–4) have indicated that the metal ions can play an important role in the radiolysis of their salts. For example, it was necessary to invoke cation-involvement to account for the unusual electron paramagnetic resonance (e.p.r.) spectra exhibited by polycrystalline Group IB and IIB metal carbonates and nitrates exposed to γ-rays (2). The species $(CdCO_3)^-$, $(Ag_2CO_3)^-$, $(CdNO_3)$, and $(AgNO_3)^-$, essentially covalent entities, were identified. Also, we recently reported that the exposure of the double salt $CaCd(CH_3.CO_2)_4 6H_2O$ to γ-rays at 77 °K resulted in the formation of Cd(I) and the methyl radical; on warming these centers decayed to produce the acetate fragment, $CH_2CO_2^-$ (3, 4). It would appear that the formation of low oxidation states of the metal ion, on irradiation, will occur when the cation present in the undamaged crystal has a high inelastic scattering cross section for electrons. The present investigation forms part of a comprehensive examination of the role of metal ions, which have high electron-capture cross-sections in radiation damage processes.

We wish to report the formation of the Hg(I) ion in single crystals of cadmium acetate dihydrate containing mercuric acetate as a substitutional impurity. Rogers and Kispert (1) reported that the exposure of pure mercuric acetate to high energy radiation gave paramagnetic species which were responsible for a very asymmetric e.p.r. pattern. These radicals were not identified. We have reexamined this e.p.r. spectrum and, in the light of the data obtained from Hg(II) doped in $Cd(CH_3CO_2)_2.2H_2O$, identify the principle products as $CH_2CO_2^-$ and the mercurous ion, no methyl radicals are formed in the anhydrous mercuric acetate.

The mercurous ion was first thought to have been isolated in a γ-irradiated aqueous glass containing a mercuric salt (5). Identification was based upon the observation of a single asymmetric line in the e.p.r. spectrum of the glass. The tail of a weak optical absorption (λ_{max} below 240 nm) has also been observed in a sulfuric acid glass which was tentatively assigned to the Laporte forbidden $^2D_{3/2} \leftarrow {}^2S_{1/2}$ transition in Hg(I). More convincing evidence for the existence of Hg(I) from radiation studies of acidic glasses containing Hg(II) has recently been presented (7). The detection of weak hyperfine features associated with the magnetic ^{199}Hg and ^{201}Hg isotopes established the identity of the species.

We have endeavored to relate optical studies to

For personal use only.

the e.p.r. results to make this first report of the stabilization of the Hg(I) ion as a molecular complex in a crystalline environment. The data derived is used to probe both the electronic structure and the environment of the radical.

Experimental

Single crystals of pure cadmium acetate and cadmium acetate containing the mercuric ion as a substitutional impurity (0.5 wt% of $Hg(CH_3CO_2)_2$) were grown from aqueous solution. Large, colorless, monoclinic crystals were readily obtained. Samples were exposed to ^{60}Co γ-rays at both 77 °K and ambient temperatures, the doses varying from 0.3 to 3.0 Mrads. Electron paramagnetic resonance measurements were made at 77 and 295 °K on a conventional X-band spectrometer. Optical absorption spectra were recorded on a Cary-14 recording spectrophotometer incorporating a single crystal holder and an adjustable reference-beam attenuator. On exposure to γ-rays at room temperature, single crystals of cadmium acetate dihydrate were reduced to powder within 2 h. To reduce this efflorescence selected crystals were irradiated at 77 °K and subsequently annealed to 300 °K for investigation.

In addition to the experiments on doped cadmium acetate dihydrate the radiation damage in mercuric acetate was investigated. In this case however, the experiments were carried out on the polycrystalline material due to the difficulty in growing adequate single crystals.

Results

(a) Radiation Damage in Hg(II) doped Cadmium Acetate Dihydrate

The irradiation of pure $Cd(CH_3CO_2)_2.2H_2O$ at 77 °K with the subsequent annealing to 300 °K led to the well characterized $CH_2CO_2^-$ radical (8), a colorless stable fragment being formed. In contrast, a single-crystal of cadmium acetate dihydrate containing the mercuric ion as a substitutional impurity was rendered deep yellow on exposure to γ-rays. This yellow coloration is associated with a paramagnetic species (A) which also gives rise to the distinctive e.p.r. spectrum displayed in Fig. 1. The weaker triplet of features in the spectrum, centered around 3300 G, arise from $CH_2CO_2^-$. It may be noted here that when the irradiated crystal of Hg(II) doped cadmium acetate was annealed at room temperature for several days, this acetate fragment decayed with the concomitant formation of a second center (labelled B in Fig. 1). Intensive e.p.r. and e.n.do.r. investigations are now in progress in order to identify this species and it will be discussed in detail in a subsequent publication. During this annealing period the concentration of the original center A decreased slowly.

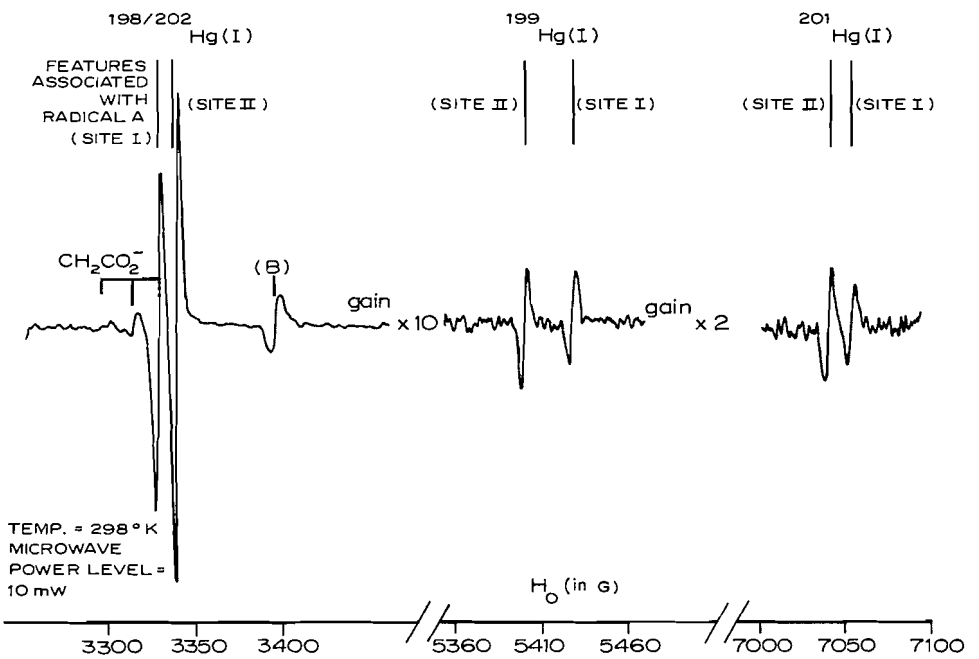

FIG. 1. Electron paramagnetic resonance spectrum of the Hg(I) impurity center in single-crystal $Cd(CH_3CO_2)_2.2H_2O$. $\theta = 40°$ in the bc'-plane.

Cadmium acetate dihydrate grows as large, monoclinic, prismatic crystals from aqueous solution and has the following unit cell parameters $a:b:c = 2.6076:1:2.1473$ and $\beta = 101° 25.5'$ (9). For the present e.p.r. investigation rotations were performed about the *a*- and *b*-axes, and a third orthogonal direction, *c'*, which makes an angle of 11°25.5′ to *c* (Fig. 2*a*). Figure 3 is a plot of the angular dependence of the spectrum of radical (A) with the applied magnetic field (H_0) in the *bc'*-plane; it will be noticed that there are two non-equivalent sites for this radical.

An examination of the e.p.r. spectrum of radical A measured at high incident microwave powers showed that each hyperfine line was accompanied by a weak pair of satellite lines. The intensity of these weaker resonances increased, with respect to the main lines, as the microwave power increased. Their separation was also field dependent, being 10.6 G at $H_0 = 3300$ G and 9.4 G at $H_0 = 5300$ G. This behavior is characteristic of features arising from the sympathetic spin-inversion of neighboring protons (10).

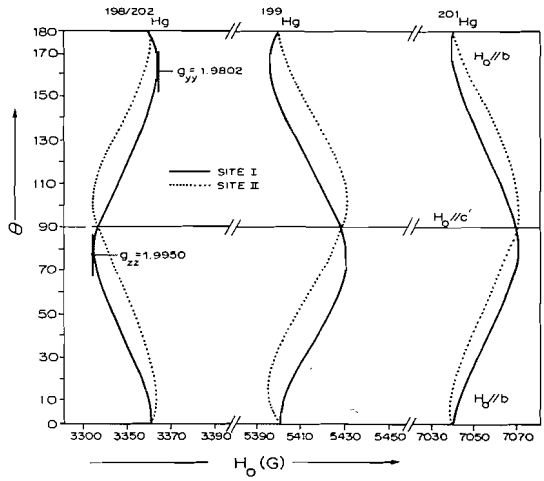

FIG. 3. Angular variation of the Hg(I) hyperfine features in the *bc'*-plane for the two distinguishable sites.

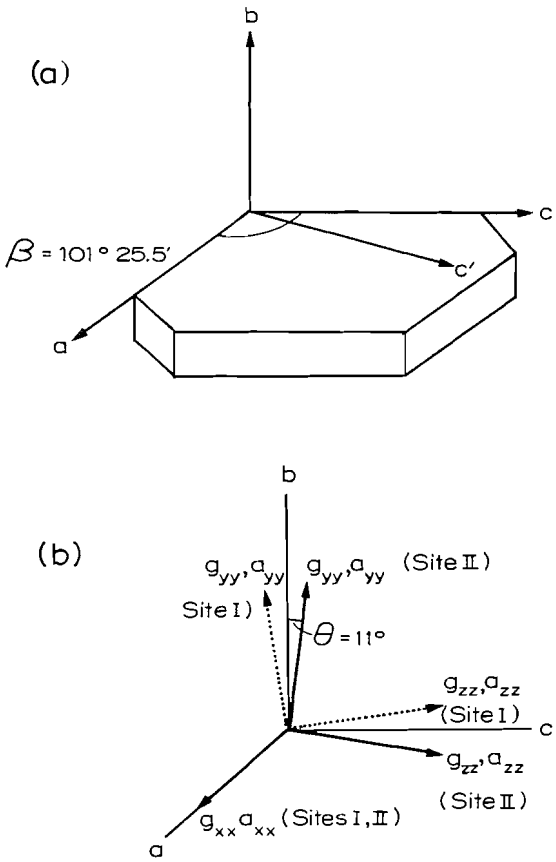

FIG. 2. (*a*) Crystal morphology and chosen axis system for $Cd(CH_3CO_2)_2.2H_2O$; (*b*) orientations of the principle values of the **g**- and hyperfine tensors relative to the chosen axis system.

The optical absorption spectrum of the irradiated crystal was characterized by a broad absorption having a maximum intensity at 305 nm.

(b) Radiation Damage in pure Mercuric Acetate

Irradiation of mercuric acetate at 77 °K resulted in the formation of a species whose electron spin resonance (e.s.r.) spectrum was identical to that of radical (A) in Hg(II) doped cadmium acetate. Although this species was stable indefinitely at this lower temperature, it decayed on warming to room temperature after approximately 2 h. The product of this decay was the $\dot{C}H_2CO_2^-$ radical.

Discussion

The magnetic and optical properties of radical (A) are those expected for the trapped mercurous ion. There are two magnetic isotopes of mercury in natural abundance (^{199}Hg, $I = \frac{1}{2}$, $\mu_N = 0.4979$ nuclear magnetons, 16.86%; ^{201}Hg, $I = \frac{3}{2}$, $\mu_N = -0.5513$ nuclear magnetons, 13.24%). The electronic energy levels expected for the ground state of Hg(I) are shown in Fig. 4. For this ion the isotropic hyperfine coupling constants are very large [$A_{iso}(^{199}Hg) \approx 28.0$ GHz and $A_{iso}(^{201}Hg) \approx 10.0$ GHz] so that the "normal" e.p.r. transitions which occur at lowest field, are not in-

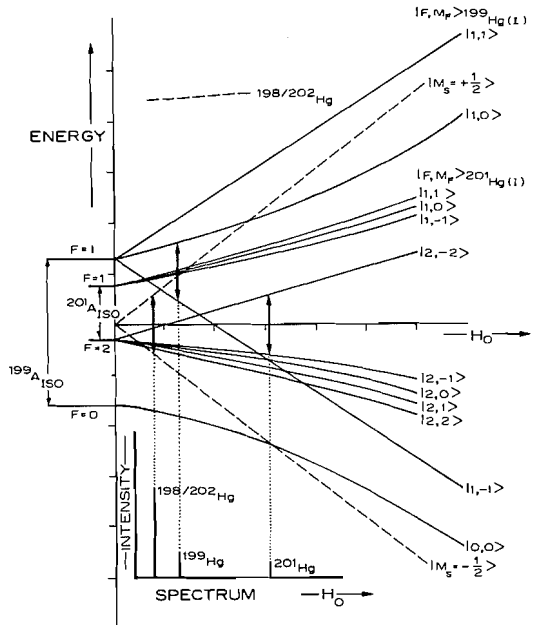

FIG. 4. Energy level diagram for the two magnetic isotopes of Hg(I). Note: $\mu_N(^{199}Hg)$ is positive whereas $\mu_N(^{201}Hg)$ is negative. The observed transitions are indicated on the constructed spectrum.

duced at the X-band operating frequency of 9.3 GHz. Consequently, we only detect the transitions

$$|F = 1, m_F = 0\rangle \leftrightarrow |F = 1, m_F = -1\rangle$$
at 5300 G for ^{199}Hg

$$|F = 2, m_F = -2\rangle \leftrightarrow |F = 2, m_F = -1\rangle$$
at 7000 G for ^{201}Hg

$$|S = \tfrac{1}{2}, m_S = \tfrac{1}{2}\rangle \leftrightarrow |S = \tfrac{1}{2}, m_S = -\tfrac{1}{2}\rangle$$
at 3300 G for $^{198/202}Hg$

where $\boldsymbol{F} = \boldsymbol{I} + \boldsymbol{S}$

The phenomenological spin Hamiltonian parameters given in Table 1 were computed from spectra measured in the *ab*-, *ac'*-, and *bc'*-crystal planes using a program written by Dr. J. A. Hebden based on the general method of Byfleet *et al.* (11). The experimental data were fitted to the general Hamiltonian

$$\beta\, \boldsymbol{H}\cdot\mathbf{g}\cdot\boldsymbol{S} + \boldsymbol{S}\cdot\mathbf{A}\cdot\boldsymbol{I} + Q'[I_z^2 - \tfrac{1}{3}I(I+1)] - \gamma\beta_N\, \boldsymbol{H}\cdot\boldsymbol{I}$$

in the usual notation.

Q', a redundant parameter for the 198/202 and 199-isotopes was calculated to be close to zero for the $^{201}Hg(I)$ ion. g_{xx} and a_{xx} are parallel to the crystallographic *a*-axis whilst g_{yy}, a_{yy}, and g_{zz}, a_{zz} lie in the *bc'*-plane and approximately 11° from *b* and *c'*, respectively (Fig. 2*b*). Included in Table 1 are the e.p.r. parameters, estimated using the Breit–Rabi approximation, for the Hg(I) ion trapped in a rigid, aqueous perchloric acid matrix. Eachus *et al.* (7) attributed the significant discrepancy between the experimental value of A_{iso}^{i} (^{201}Hg) and that calculated from the observed A_{iso}^{i} (^{199}Hg) value, to the effect of a large quadrupole term in the spin Hamiltonian. No such discrepancy has been found in the present work and in fact it appears that Q for $^{201}Hg(I)$ is very small; we feel that the errors incurred in the use of the Breit–Rabi expression led to the apparent discrepancy.

The optical absorption with a maximum at 305 nm is assigned to the Laporte-allowed $^2P_{\frac{1}{2},\frac{1}{2}} \leftarrow {}^2S_{\frac{1}{2}}$ transition of the mercurous ion. The analogous transition occurs at 300 nm for the pseudo-isoelectronic Cd(I) ion in both aqueous solutions (12) and rigid glasses (6). Brown and Dainton (6) observed that there is a significant blue shift of the P ← S transitions for the isoelectronic systems Ag^0, Cd^+, and In^{2+} as the atomic number increases. Consequently, we would expect a similar shift to lower energy on going from Tl^{2+} to Hg^+ in the analogous third row series (optical absorption data for trapped Au^0 are not available for comparison). If our assignment is correct, this is observed (λ_{max} Tl^{2+} = 267 nm (6)). It is surprising that Dainton and co-workers were unable to detect an optical absorption for Hg(I) in a rigid acid matrix. However, they did report that the tail of a band having a λ_{max} below 240 nm was apparent and Treinin (13) has assigned this high-energy absorption to the Laporte-forbidden $^2D_{\frac{1}{2},\frac{1}{2}} \leftarrow {}^2S_{\frac{1}{2}}$ transitions which occur at 198 nm in the gas phase. This band is expected to be intense for mercury in view of the pronounced *jj*-coupling. We feel that the absence of a P ← S transition for Hg(I) in rigid H_2SO_4 reflects the "free-ion" nature of the radical in this matrix. Conversely, the detection of an absorption at 305 nm in cadmium acetate dihydrate would suggest that the mercurous ion is stabilized as a molecular complex in this environment. This conclusion is further substantiated both by the reduction of the Fermi contact term relative to other studies and by the orthorhombic character of the mercury hyperfine tensor in the crystalline environment.

The factors which control the magnitude of the Fermi contact term have been discussed previously (4) in connection with the Cd(I) ion produced by radiation damage in calcium tetraacetate cadmium(II) hexahydrate. The fact that the Fermi contact interaction of the present center is substantially reduced relative to the Hg(I) produced in $CdCO_3$ (2) reflects the increased covalent interaction of the acetate ligands with the Hg(I) relative to the carbonate anion.

The crystal structure of cadmium acetate is, as yet, undetermined, however, the symmetry of the experimental **g**-tensor and the unusual form of the anisotropic hyperfine interaction tensor (-62, -17, $+79$ G for ^{199}Hg(I)) can be understood if the coordinated mercurous ion is assumed to occupy a site of C_2 or lower symmetry. It should be noted here that the values of the anisotropic part of the hyperfine coupling tensor may be in error to some degree since they are obtained by the subtraction of two large numbers.

Similarly the center observed in γ-irradiated mercuric acetate shows a large isotropic hyperfine coupling and a highly anisotropic term, consequently it would appear that the Hg(I) produced has a very low site symmetry similar to that in cadmium acetate. The differences in the magnitude of these parameters to those observed in the cadmium reflect the differences in crystal structure between cadmium and mercuric acetates.

The ground state of a mercurous ion in C_2 symmetry would be a linear combination of those mercury orbitals that transform as the irreducible representation A of C_2 point group. A consideration of these orbitals readily shows that such an orbital could produce the anisotropic hyperfine coupling observed. In addition the transformation properties of L_z, L_x, and L_y indicate that in C_2 symmetry g_{zz} will be close to the free spin value and the Δg_{yy} may be significant. However, without a more complete knowledge of the likely environment of the metal ion in cadmium acetate dihydrate or mercury acetate it is not possible to make a more quantitative interpretation of the data. Crystal structure studies on the Group IIB acetates are at present being undertaken (14) and it is hoped that these investigations and the further radiation damage studies we are undertaking will lead to a better understanding of the processes involved.

The authors wish to thank Professor C. A. McDowell for his interest in this work and the National Research Council of Canada for financial support.

Couplings into Methylene Groups: a New Nuclear Magnetic Resonance Approach to Stereochemistry

K. N. SLESSOR AND A. S. TRACEY
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received December 17, 1970

A method of assigning dihedral angles to hydrogens adjacent to a methylene function by using computer analyzed n.m.r. coupling constants in a modified Karplus equation is presented. The "Dihedral Angle Estimation by the Ratio Method" (DAERM) is based on the assumption that, although the magnitudes of the Karplus constants, k_1 and k_2, vary, the ratio of k_1 to k_2 is a constant. Dihedral angles computed in this way seem not to be influenced by the effects of ring strain and substituent electronegativity. The conformational preferences of several four- to six-membered ring systems, some containing oxygen and sulfur atoms, have been investigated by this method. Molecular features such as ring puckering and flattening are indicated by DAERM as are some subtle electrostatic influences.

Une méthode qui consiste à assigner des angles dièdres aux hydrogènes adjacents à un groupe méthylène est présentée. A cet effet, on utilise les constantes r.m.n. de couplage, que l'on analyse par ordinateur suivant une équation de Karplus modifiée. "L'Estimation d'Angle Dièdre par la Méthode du Rapport" (EADMR) est fondée sur l'hypothèse que si la grandeur des constantes de Karplus (k_1 et k_2) varient, par contre, le rapport k_1 sur k_2 demeure constant. Les angles dièdres calculés de cette manière ne semblent pas influencés par les effets de tension de cycle et par l'électronégativité des substituants. Par cette méthode il a été possible de déterminer les conformations préférentielles de quelques systèmes cycliques de quatre à six chaînons, certains contenant des atomes d'oxygène et de soufre. Certaines particularités moléculaires comme le gauchissement et l'applatissement du noyau apparaissent dans la EADMR; il en est de même de quelques subtiles influences électrostatiques.

Canadian Journal of Chemistry, 49, 2874 (1971)

Introduction

The eq. 1 relating dihedral angle and coupling constant, reported by Karplus in 1959 (1), has maintained its essential features after several years of experimental and theoretical investigations. The limitations of the equation have been stressed by a number of workers (2, 3), including Karplus himself (4). The variation of the theoretically derived constants k_1 and k_2 with molecular and substituent properties, such as ring size and electronegativity have been noted and these have been attributed (3) to changes in magnitude of the electron exchange term, which is the major contributor to the Karplus constants, k_1 and k_2.

This report presents conformational results based on calculation of dihedral angles from a modified Karplus equation. Variations in Karplus constants are accommodated in this method through the assumption that the ratio of the Karplus constants k_1/k_2 is a constant. From the theoretical parameters calculated by Karplus (1), the ratio k_1/k_2 is very nearly equal to 0.9. Using accurate coupling constants, dihedral angles can be calculated for a hydrogen vicinal to a methylene function without prior assignment of Karplus constants and without consideration of the electronic perturbations affecting the system.[1] This process is termed the "Dihedral Angle Estimation by the Ratio Method" (DAERM).

The original form of eq. 1 is used, in which J is the vicinal coupling constant; k, the Karplus constant; Φ, the dihedral angle subtended by the coupled nuclei; and c, a constant.

$$[1a] \quad J_1 = k_1 \cos^2 \Phi_1 - c \qquad 0 \leq \Phi_1 \leq 90°$$

$$[1b] \quad J_2 = k_2 \cos^2 \Phi_2 - c \qquad 90 \leq \Phi_2 \leq 180°$$

The four possible arrangements of a hydrogen adjacent to a methylene group in a saturated system are shown in Fig. 1. Only cases A, B, and C will be discussed as case D is seldom, if ever, found in ring systems. From case A, the two equations describing the system are 1*a* and *b*, where $k_1 = k_1'$ since both Φ_1 and Φ_2 are less than 90°, and therefore [2] is obtained.

$$[2] \quad \frac{J_1 + c}{J_2 + c} = \frac{\cos^2 \Phi_1}{\cos^2 (\omega - \Phi_1)}$$

Assuming a regular tetrahedral system (ω =

[1] An attempt to separate electronic effects from stereochemical influences has been reported (5).

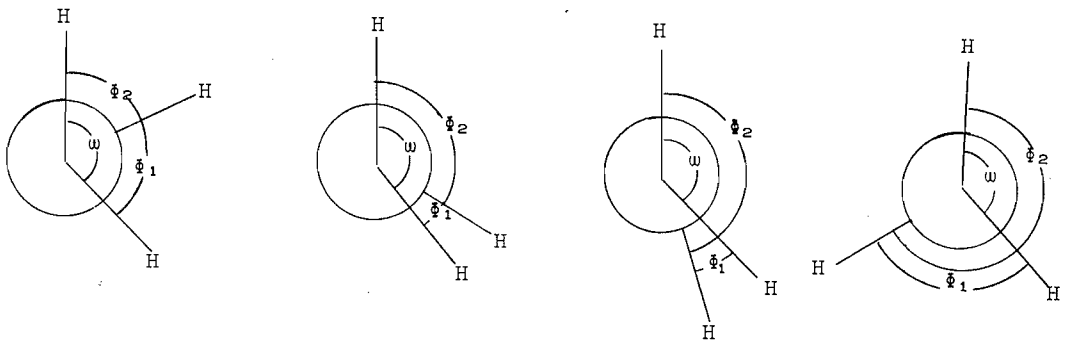

FIG. 1. Four arrangements of the —C—C—H system.
H H

120°) and using the theoretical value (1) of 0.28 for c, a complete solution for the angles Φ_1 and Φ_2 is possible from the coupling constants, J_1 and J_2, without knowledge of the Karplus constant, k_1, for that system. Cases B and C can be resolved in a similar manner, as shown in eqs. 3 (case B) and 4 (case C).

$$[3] \qquad \frac{J_1 + c}{J_2 + c} = \frac{k_1}{k_2} \frac{\cos^2 \Phi_1}{\cos^2 (\omega - \Phi_1)}$$

$$[4] \qquad \frac{J_1 + c}{J_2 + c} = \frac{k_1}{k_2} \frac{\cos^2 \Phi_1}{\cos^2 (\omega + \Phi_1)}$$

Having assumed a value of 0.9 for k_1/k_2, complete solutions for cases B and C are possible. If electronegativity and other substituent effects are reflected solely in the magnitude of the Karplus constants, DAERM should result in a sensitive probe into the angular relationship between vicinally coupled nuclei, as well as the electronic situation prevailing in the system being investigated. Testing of DAERM was undertaken through application of the method to ring systems having four to six atoms for which n.m.r. parameters were available.

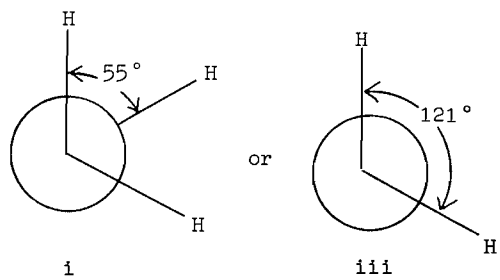
Method

In order to easily evaluate the utility of DAERM, a short Fortran program[2] was written for the IBM 360/50 computer which calculated the possible angle sets for a given set of coupling constants from eqs. 2–4. DAERM provides two solutions for each set of coupling constants, one with both dihedral angles less than 90° (*i.e.* case A), the other with one angle less than, the other greater than 90° (*i.e.* either case B or C).

An example of the application of DAERM is provided by consideration of the computer analyzed low temperature proton n.m.r. parameters of octadeuterocyclohexane obtained by Garbisch and Griffith (6). One signal indicated two couplings of 3.65 and 13.12 Hz and, without prior assignment of their origin, DAERM allows four possible solutions as seen in Table 1.

Sets *ii* and *iv* are equivalent and can be rejected as the required Karplus constants are much too large. Unacceptably large calculated Karplus constants can often be used to rule out possible angular solutions and thus simplify the analysis. The second signal from octadeuterocyclohexane was analyzed as two couplings, 2.96 and 3.65 Hz. Again, without prior assignment, four solutions are seen in Table 2.

It is obvious that sets *vi* and *viii* are equivalent and that one set (*viii*) can be discarded. From Table 1 the coupling of 3.65 Hz is associated with two possible angles (sets *i* and *iii*).



From Table 2 the three solutions for the coupling of 3.65 Hz are *v*, 152; *vi*(*viii*), 58; and *vii*, 23°. Thus, the only compatible set of solutions is *i* and *vi*.

TABLE 1.* DAERM calculations† on 3.65 and 13.12 Hz couplings

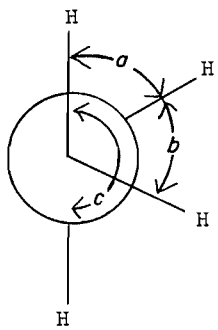
	Observed coupling constants		Calculated dihedral angles		Calculated Karplus constants	
Set	J_1	J_2	Φ_1	Φ_2	k_1	k_2
i	3.65	13.12	55	175	12.14	13.49
ii	3.65	13.12	70	50	32.78	36.43
iii	13.12	3.65	1	121	13.40	14.89
iv	13.12	3.65	50	70	32.78	36.43

*In all Tables and discussion, Φ_1 is the *cis* angle; Φ_2 the *trans* angle; k_1 the calculated Karplus constant for less than 90°; k_2 for greater than 90°.
†$k_1/k_2 = 0.9$, $\omega = 120°$.

TABLE 2. DAERM calculations* on 2.96 and 3.65 Hz couplings

	Observed coupling constants		Calculated dihedral angles		Calculated Karplus constants	
Set	J_1	J_2	Φ_1	Φ_2	k_1	k_2
v	2.96	3.65	32	152	4.52	5.02
vi	2.96	3.65	62	58	14.32	15.91
vii	3.65	2.96	23	143	4.61	5.13
viii	3.65	2.96	58	62	14.32	15.91

*$k_1/k_2 = 0.9$, $\omega = 120°$.



Angle *a*, 55 → 58°, gives rise to the J_{ae} coupling of 3.65 Hz; *b*, 62 → 65°, gives rise to the J_{ee} coupling of 2.96 Hz, and *c*, 175 → 178°, gives rise to the J_{aa} coupling of 13.12 Hz. It is important to note that the assignments were made without prior knowledge of the proton identities and without assigning numerical values of the Karplus constants. DAERM predicts a flattened chair conformation with proton assignments identical to Garbisch and Griffith (6).

Prior to further application of DAERM, an investigation of two main features of this method was carried out. These were: (*1*) distortion of the system from regular tetrahedral geometry ($\omega \neq 120°$), and (*2*) variation of the parameter, k_1/k_2. Using the octadeuterocyclohexane data with a k_1/k_2 constant at 0.9, the effect of distortion from tetrahedral geometry can be evaluated by plotting the calculated angle Φ_2 against values of ω. The value of ω was varied over the range 110 to 130°, which is beyond the range of distortions expected for normal tetrahedral systems. Figure 2 shows the results in which the angles obtained from the two sets of octadeuterocyclohexane couplings, J_{ae}, J_{ee}, and J_{ae}, J_{aa}, give two curves intersecting at a ω value of 115°. Karplus constants calculated for $\omega = 115°$ reassuringly provide identical results, $k_1 = 12.4$ and $k_2 = 13.8$, from the two sets of couplings.

The Φ_2 solutions should be the same from either set of couplings and as this value is influenced by the ratio k_1/k_2, the variation of k_1/k_2 with ω was investigated and the results presented in Fig. 3.

From theory, a ratio of unity or greater for k_1/k_2 cannot be accepted and, thus, Fig. 3 indicates that ω for cyclohexane is less than 120°. This in turn suggests that if constant p character is assumed for the bonding about carbon, the angle subtended by H—C—H at each methylene grouping in cyclohexane is smaller than the expected tetrahedral angle. Eliel *et al.* (7) has calculated an H—C—H angle of 107.3° from the cyclohexane electron diffraction data of Davis and Hassel (8). This value corresponds with an ω value of approximately 116° (9) and is in keeping with a ratio of very nearly 0.9. Figures 2 and 3 emphasize the inter-relationship between ω and the ratio k_1/k_2, and also provide an appreciation of the range permitted in the magnitude of the values.

From computer analyzed n.m.r. parameters, the conformation of a cyclohexane derivative has been determined to a degree where ring flattening and distortion from tetrahedral geometry are apparent. This method is considered to be of significance in assigning conformational properties to cyclic molecules in particular, as we shall describe in the succeeding section.

Discussion

An essential prerequisite of DAERM is the availability of n.m.r. coupling parameters of hydrogen nuclei vicinal to a methylene function. Four cyclohexyl systems for which such data

were available are now considered. A ratio of 0.9 and an ω value of 115° are assigned from which not only Φ_1 and Φ_2 but the Karplus constants, k_1 and k_2, which correspond to these acceptable solutions, are calculated.

Table 3 illustrates an essential point of DAERM. Although large variations exist in the reported coupling constants, all the Φ_1 angles are reasonably constant in the range 46–57°, and the Karplus constants are rather variable. Possibly more striking is the series of six-membered heterocycles shown in Table 4. Angles and constants were calculated using a ratio of 0.9 and tetrahedral geometry, ω = 120°, for the carbon atoms involved in the coupling. As seen in the cyclohexyl derivatives, rather large changes in

*The calculated angles presented in Tables 3 and 4 must be treated with caution, since these are derived from first order couplings which may vary considerably from the actual values. In addition, some of these examples may exhibit errors due to the configurational dependence of electronegative substituents. These errors, combined with possible conformation mobility in these systems, limit the use of the calculated parameters to qualitative comparisons.

the calculated Karplus constants are evident for these heterocyclic derivatives, but these seem to bear little relation to the conformation of the molecule. The overall conformation of these molecules is of interest as the oxygen heterocycles show the expected flattening and the sulfoxides the expected puckering due to the bonding angles of the hetero atoms (15). The conformational mobility of these compounds at room temperature will result in time averaged dihedral angles and a general lowering of the calculated Karplus constants as can be seen in **4***b*, Table 3.

DAERM calculations on four-membered rings were made possible by the recent report of computer analyzed spectra of several thietanes. The results are presented in Table 5 using the proton assignments of the original workers (16, 17).

Four of the five compounds (**9–13**) gave DAERM angles in very good agreement with the reported angles, but the fifth, *trans*-2,4-diphenylthietane-1-oxide (**13**) gave quite different solutions. In contrast to the severely distorted molecule originally proposed (17), DAERM indicates a molecule flattened slightly in a manner which allows the phenyl groups to approach pseudo-equatorial positions. The possibility of incorrect proton assignments was excluded since DAERM predicted an impossibly distorted molecule for the alternate assignment.

Five-membered rings have posed a more complex problem in conformational analysis because of their very low barrier to pseudo-rotation. The bicyclo[2.2.1]heptane system is free from such complexities as the bridge locks the molecule in a single conformer. Table 6 represents the first-order coupling constants obtained by Williamson (18) on the hexachlorobicyclo[2.2.1]-heptenes and the DAERM calculated angles and Karplus constants. Not unexpectedly, the magnitude of the Karplus constants appears to be inversely proportional to the electronegativity of the substituent. This inverse relationship has been predicted on a theoretical basis (4) and a number of examples of the inverse dependence of J with electronegative substituents have been reported (see for example Williamson (18) and Cohen and Schaefer (19)).

As the $C_1—C_2—C_3$ bond angle in these systems is found to be significantly smaller than the tetrahedral angle (100° *vs.* 109.5°) (20), the angle between hydrogens on the methylene group at position 2 can be expected to be greater than the

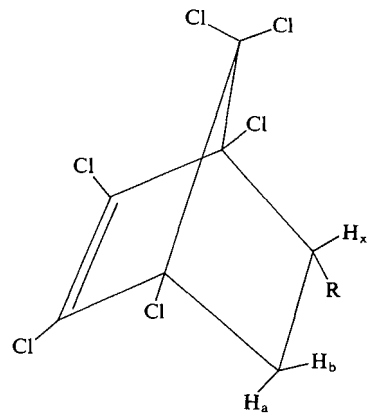
b $R_1 = —H$; $R_2 = —\overset{\overset{O}{\|}}{C}—OCH_3$



14

tetrahedral angle (21). Assuming a distortion of a few degrees ($\omega = 125°$), both the amount of twist about the $C_2—C_3$ bond and the Karplus constants decrease by a small amount (Table 7). These latter results are in better agreement with the magnitude of twists found by X-ray studies (22).

Our studies with DAERM suggest that in certain systems having couplings varying with solvent, the major reason for this may be a change in the Karplus constants rather than the conformation of the molecule (*e.g.* Table 3, compounds **1***b* and **4***a*). It would thus be very unwise to interpret variations in coupling constants on varying the solvent as changes in conformer populations until this point has been clarified.

Two general points are worth mentioning. The

ratio, $k_1/k_2 = 0.9$, has been established only for cyclohexane and although variations in this value only affect the calculated angles by a few degrees, molecular orbital calculations indicate this value decreases with electronegative substituents (24). As far as we are aware, no information for systems expected to show this effect is available. The configurational dependence of electronegative substituents on couplings is only partially compensated for in DAERM through an internal averaging process. Thus, the applicability of DAERM is limited when electronegative substituents are bonded directly to the molecular segment under consideration. The error introduced will be maximal when the electronegative substituent is anti-periplanar to any of the hydrogen nuclei under consideration and minimal in the case of hydrocarbons and rings in which electronegative groups are not aligned in a *trans*-diaxial orientation with the hydrogen atoms. A formal correction could be introduced if such parameters were available, but only at the expense of computational simplicity.

Conclusions

Dihedral Angle Estimation by The Ratio Method (DAERM) is a means of establishing conformational preference without prior assignment of Karplus constants and in some systems without prior assignment of proton identities. The basic requirement of DAERM is a methylene group coupled vicinally to one or more hydrogens for which the n.m.r. parameters have been accurately determined. Using this data, the required angular solutions may be obtained from simple calculations. Such solutions not only allow assignment of conformational properties to the molecule but also allow calculation of the Karplus constants for the system. An advantage of DAERM is the determination of the dihedral angle from two vicinal couplings which improves the reliability of the solutions obtained. In the examples given, DAERM easily provided solutions agreeing well with the known conformational properties of the molecules studied.

Pressure Effect on the Kinetics of Reaction Between Solid NaCl and $ZrCl_4$ or $HfCl_4$ Vapors

P. PINT AND S. N. FLENGAS

Department of Metallurgy and Materials Science, University of Toronto, Toronto 181, Ontario

Received April 30, 1971

The kinetics of reaction between single crystals of sodium chloride and zirconium tetrachloride and hafnium tetrachloride vapors, to form sodium hexachlorozirconate and sodium hexachlorohafnate, respectively, have been investigated as a function of the tetrachloride pressures at a constant temperature of 485 °C. The rate of formation of Na_2ZrCl_6 is kinetically more favorable. The heterogeneous reaction is diffusion controlled, with the rate of diffusion depending on the availability of Cl^- vacancies.

Les cinétiques à température constante (485 °C) des réactions entre des cristaux uniques de chlorure de sodium avec des vapeurs de tétrachlorure de zirconium et d'hafnium, ont été étudiées en fonctions des pressions en tétrachlorure. Ces réactions conduisent respectivement à l'hexachlorozirconate de sodium et à l'hexachlorohafnate de sodium. La vitesse de formation de Na_2ZrCl_6 est cinétiquement plus favorable. Ces réactions hétérogènes sont contrôlées par diffusion et la vitesse de diffusion dépend de la disponibilité des espèces Cl^-.

Canadian Journal of Chemistry, **49**, 2885 (1971)

Introduction

Compounds of the general formula M_2XCl_6 (where M is an alkali metal cation, and X is Zr, Hf, or Ti) have been prepared by the reaction between solid MCl and gaseous XCl_4 (1–5). These compounds are of interest because of their possible uses for the recovery of the metals Zr, Hf, and Ti by fused salt electrolysis (6, 7) and for the purification of $ZrCl_4$ for applications requiring a low Hf content (8).

In a previous investigation (9) the rate of formation of Na_2ZrCl_6 was measured as a function of temperature. In the present work the effect of applied pressure of $ZrCl_4$ and of $HfCl_4$, on the rate of formation of the compounds Na_2ZrCl_6 and Na_2HfCl_6, respectively, was investigated at a constant reaction temperature of 485 °C.

Experimental

The apparatus for measuring the kinetics of the reaction is shown in Fig. 1.

The method involved the measurement of the weight increase of a single crystal of NaCl suspended from a quartz spring balance. The increase in weight was due to the reaction

$$[1] \qquad 2NaCl_{(s)} + XCl_{4\,(v)} \rightarrow Na_2XCl_{6\,(s)}$$

where X is Hf or Zr.

The crystals of sodium chloride were smooth and hexahedral, of approximate size 0.6 × 0.6 × 1.0 cm, and were cleaved from larger crystals. For every pressure run a new sodium chloride crystal was used.

To control the temperature of the $ZrCl_4$ or $HfCl_4$ to within ±1 °C, the ampoule containing the $ZrCl_4$ or $HfCl_4$ was placed into a brass block, into which two controlling chromel–alumel thermocouples had been inserted. This temperature fluctuation corresponds to a change in the $ZrCl_4$ or $HfCl_4$ vapor pressures of only ±15 Torr, at a total applied pressure of 700 Torr (10).

To ensure that the ampoule containing the $ZrCl_4$ or $HfCl_4$ was at the lowest temperature of the total system, a temperature profile of the system was taken prior to each experiment.

The vapor pressures were measured directly using the liquid tin isoteniscope incorporated in the system as shown in Fig. 1.

At the beginning of a run the furnace was heated to the desired temperature, and then wheeled into position over the cell containing the tetrachlorides. This procedure reduced the time-lag required by the system to reach its equilibrium.

The quartz spring balance was calibrated at the reaction temperature of 485 ± 2 °C. The spring constant was about 4.5% higher than that at room temperature.

To establish the pressure dependence of the rate of formation of Na_2ZrCl_2, six applied pressures were investigated, ranging from approximately 70 Torr to 1 atm. In the case of Na_2HfCl_6 formation, four different pressures between 100 Torr and 1 atm were applied.

The decomposition pressures of the compounds at the reaction temperature are of the order of 10 Torr (11, 12). Accordingly, the thermodynamic "drive" for the reaction is the difference between the applied and the decomposition pressures.

The microscopic examination of polished, partially reacted samples indicated the existence of two distinct layers. The definite separation of the two layers is shown in Fig. 2(*a*). It may be seen that the advancing interface is planar and symmetrical with the original shape retained, as expected for an isotropic material such as NaCl. Some rounding of the corners can also be seen (Fig. 2(*b*)). The outer layer represents the compound

FIG. 1. Na_2XCl_6 and the inner, the unreacted core of NaCl. The compositions of the outer layers were verified to be the stoichiometric compounds by considering the initial weight and the final weight of the NaCl crystals, as well as the increase in weight of the sample due to the reaction with the vapors.

The dimensions of the NaCl crystals were measured with a micrometer. The final dimensions and weights of the unreacted NaCl were obtained by mechanically removing the outer layers.

Data Treatment

For any diffusion controlled heterogeneous reaction Fick's first law of diffusion may be written as

$$[2] \qquad \frac{dn}{dt} = -DA\left(\frac{\delta c}{\delta x}\right)_x$$

where D is the diffusion coefficient and the number of moles dn of substance diffusing across a sectional plane of surface area A cm^2 in the time dt is proportional to the concentration gradient $\delta c/\delta x$.

If it is assumed that the concentration gradient of the diffusing species depends only on the pressure of the tetrachloride vapor, it is evident that throughout a reaction the boundary conditions of the diffusing species should remain constant at a constant applied pressure.

Assuming the establishment of a steady state, at any given time, the change in the number of gram moles of reacted substance, dN, (where N is proportional to n), occupying a volume dV, is given by

$$dN = (\rho/M)dV = (\rho/M)\,A\,d(\Delta X)$$

where ρ is the density of the reaction product, M is the molecular weight, A the surface area, and ΔX the thickness of the reacted layer. Accordingly eq. 2 may be written as

$$[3] \qquad \frac{dN}{dt} = \frac{\rho A}{M}\frac{d(\Delta X)}{dt} = -DA\frac{k}{\Delta X}$$

By integrating eq. 3; one has

$$[4] \qquad \Delta X^2 = k^1 t$$

where k^1 and k are constant. This equation defines a parabola and relates ΔX to the time of reaction.

Since the thickness ΔX of the Na_2ZrCl_6 and Na_2HfCl_6 layers cannot be precisely estimated from weight gain measurements due to lack of density data for the compounds at the working temperature, a more suitable parameter for correlating the kinetic data is the decrease in the thickness ΔL of the reacting NaCl crystal. This parameter also corrects for the change in the surface area of the NaCl as the reaction takes place. The quantity ΔL may be calculated from the weight gain measurements by the following method.

For an isotropic crystal such as NaCl, of dimensions X, Y, and Z the decrease ΔL is expected to be equal in all three directions. During reaction the volume of the NaCl crystal decreases according to

$$d(\Delta V)_{NaCl} = (XY + YZ + XZ)\,d(\Delta L)$$

If X_0, Y_0, and Z_0 are the initial dimensions of the crystal, the instantaneous dimensions may be expressed as

$$X = X_0 - \Delta L$$
$$Y = Y_0 - \Delta L$$
$$Z = Z_0 - \Delta L$$

Substituting these relationships and integration from $\Delta L = 0$ at $\Delta V = 0$ to $\Delta L = \Delta L$ at $\Delta V = \Delta V$,

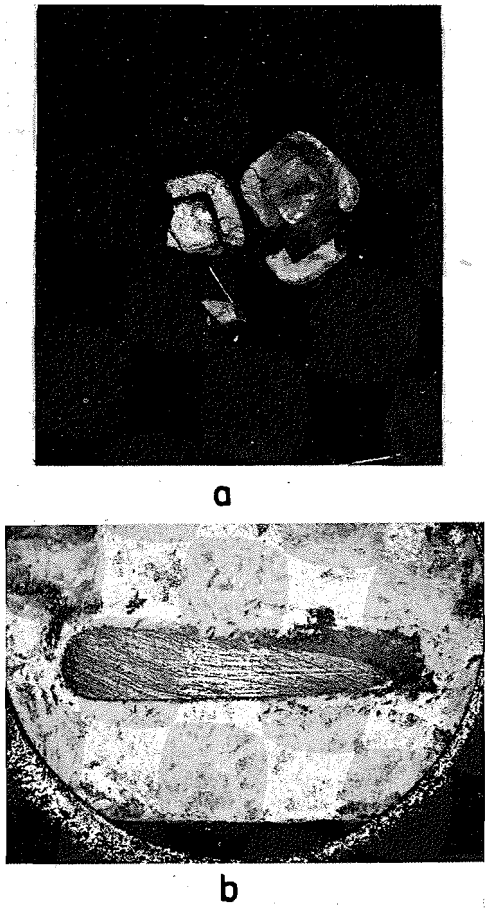

FIG. 2. Macrographs of reacted crystals. (*a*): Approximately 1.5×. Na_2ZrCl_6 and NaCl core. (*b*): Approximately 5×. Na_2ZrCl_6 and NaCl core.

$$[5]\quad (\Delta V)_{NaCl} = (X_0Y_0 + X_0Z_0 + Y_0Z_0)\Delta L - (X_0 + Y_0 + Z_0)\Delta L^2 + \Delta L^3$$

From the stoichiometry of reaction 1,

$$(W)_{NaCl} = \frac{2(W)_{XCl_4}(M)_{NaCl}}{(M)_{XCl_4}}$$

and since $(V)_{NaCl} = (W/\rho)_{NaCl}$ it is readily seen that

$$[6]\quad (\Delta W)_{XCl_4} = \frac{(\Delta V)_{NaCl}(M)_{XCl_4}(\rho)_{NaCl}}{(M)_{NaCl}}$$

where, V, W, M, and ρ represent the volume, weight, molecular weight, and density, respectively. From eqs. 5 and 6 the penetration ΔL can be calculated from the increase in weight due to the reaction with XCl_4 vapor. If a graphical method is used, the change in weight of the various crystals may be plotted as a function of arbitrarily chosen values of ΔL. From these graphs values of ΔL are obtained for the experimentally measured weight changes at the noted times of measurement.

For this calculation the density of the NaCl at 485 °C was obtained from the volumetric coefficient of expansion of NaCl at 20 °C ($\alpha_V = 1.21 \times 10^{-4}$/deg). To correct for the increase in dimensions of the NaCl at the working temperature, the linear coefficient of expansion was estimated from the volumetric coefficient. This correction was insignificant.

Results

Plots of ΔL^2 *vs.* time are shown in Figs. 3 and 4, for various pressures of $ZrCl_4$ and $HfCl_4$. The curves are linear and indicate a diffusion controlled mechanism. The data are summarized in Table 1.

ΔL values were also measured directly from partially reacted crystals from which the reacted layers had been removed. In all cases the measured ΔL agreed to within 5% of the calculated values.

The effect of pressure on the reaction rate is shown in Fig. 5, where the apparent reaction

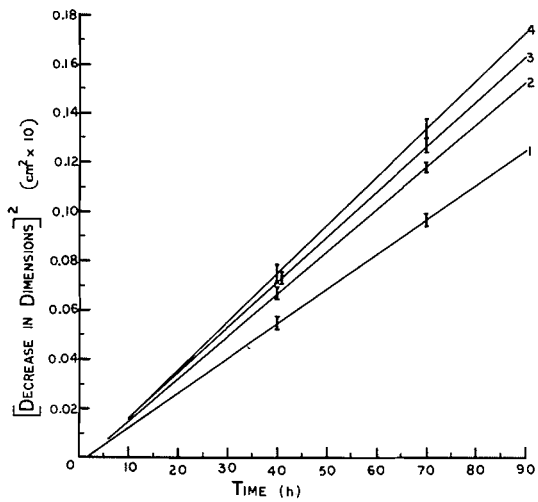

FIG. 4. (Decrease in dimensions of NaCl)² *vs.* time for Na_2HfCl_6 formation. P_{HfCl_4} in Torr for run *1*, 174; *2*, 322; *3*, 526; and *4*, 667.

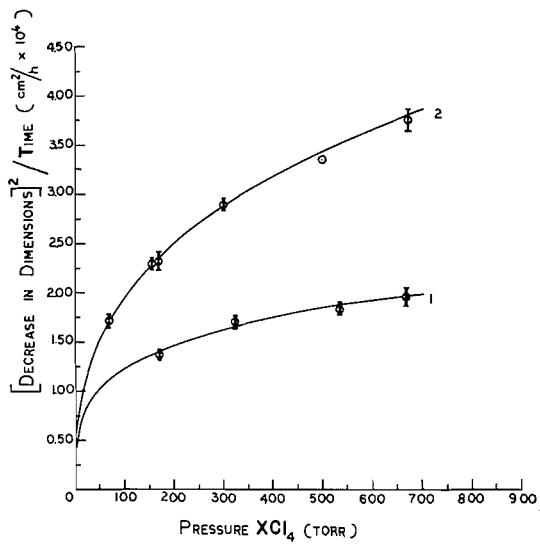

FIG. 5. Apparent reaction rate constant *vs.* pressure of $HfCl_4$ and $ZrCl_4$. *1*, $HfCl_4$ systems. *2*, $ZrCl_4$ systems.

rate constants are plotted *vs.* pressure. The curves in Fig. 5 are represented by the equations

$$[7] \qquad K^1_{Na_2ZrCl_6} = AP_{ZrCl_4}{}^{1/2.8}$$

and

$$[8] \qquad K^1_{Na_2HfCl_6} = BP_{HfCl_4}{}^{1/4.1}$$

which were determined from the least squares plots of log P_{XCl_4} *vs.* log K^1. It is seen that the reaction between NaCl and $ZrCl_4$ is kinetically favored as compared with that of NaCl and $HfCl_4$. Thus, the removal of Hf from Zr by preferential reaction of the $HfCl_4$ vapor with solid NaCl is favored thermodynamically (8) but not kinetically. However, since the proposed method of separation (8) uses powdered NaCl of large surface-to-volume ratio, the kinetic disadvantage is not significant.

Discussion

Generally, parabolic reaction rates indicate that a diffusion process is rate determining. As was seen the effect of pressure on the apparent reaction rate constant differs for the two compounds. Thus, it is probable that the mechanisms of diffusion differ.

Since the $ZrCl_4$ and $HfCl_4$ are relatively large molecules, and as no appreciable porosity was observed at the working temperature, it is unlikely that the molecular vapors are the diffusing species.

Although it is known (13) that alkali halides contain Schottky type defects, there is no information regarding the defect structure of the alkali chlorozirconates or hafnates.

The form of the equation describing the pressure dependence of the rate of reaction for the Na_2HfCl_6 and Na_2ZrCl_6 systems may be explained if the presence of an intermediate compound $NaXCl_5$ is postulated. The existence of $NaZrCl_5$ has been implied in phase diagram studies (14–16), where, depending upon the author, it appears as congruently (16) or incongruently melting (14, 15). No previous indication for the presence of $NaHfCl_5$ can be found in the literature. A complex ion of the type Na_2XCl_6 in an ionic solid can be understood by a configuration characterized by a finite co-ordination number. The strength of the bonds between the central cation X and the Cl^- anions, and also the bond distances should be different from those defining a hypothetical noncomplexed state. The condition of local electrical neutrality makes it necessary for the Na^+ cations to be bonded to the central X cations through bridging Cl^- anions.

Accordingly, the XCl_4 vapor is expected to react with the rigid Na_2XCl_6 lattice by direct bonding with surface Cl^- anions.

The following reaction mechanisms may be postulated depending whether one or two bridging chloride anions are reacting with the XCl_4 vapor to form the intermediate $[XCl_5^-]^*$ species.

[9] $$XCl_6^{2-} + XCl_{4\,(v)} \rightarrow 2[XCl_5^-]^* + [Cl_v^-]$$

where $[Cl_v^-] = \frac{1}{2}[XCl_5^-]^*$ or

[10] $$XCl_6^{2-} + XCl_{4\,(v)} \rightarrow 2[XCl_5^-]^* + 2[Cl_v^-]$$

where $[Cl_v^-] = [XCl_5^-]^*$ and $[Cl_v^-]$ indicates the concentration of chloride anion vacancies.

If the rate of diffusion is proportional to the concentration of vacancies the rate of reaction shall depend on the availability of Cl^- vacancies. The Cl^- ions are expected to diffuse from the NaCl inner layer, through the structure containing the Cl^- vacancies, to the gas–solid interface where the formation of the complex species is completed according to

$$[XCl_5^-]^* + Cl^- \rightarrow XCl_6^{2-}$$

The sodium cations are more mobile than the much larger Cl^- anions and therefore should not contribute to the kinetics of the reaction. The Na^+ cations follow the Cl^- anions through the largely open structure of the ionic lattice because of the electrostatic attractions.

The pressure effect on the kinetics is understood in terms of the concentration of XCl_5^- species at the gas–solid interface in accordance with either reactions 9 or 10.

From reactions 9 and 10, the corresponding forms for the equilibrium constants are written as

[11] $$K_9 = \frac{[XCl_5^-]^{*2}[Cl_v^-]}{P_{XCl_4}}$$

or

[12] $$[Cl_v^-] = K_9{}^1 P_{XCl_4}{}^{1/3}$$

and

[13] $$K_{10} = \frac{[XCl_5^-]^{*2}[Cl_v^-]^2}{P_{XCl_4}}$$

or

[14] $$[Cl_v^-] = K_{10}{}^1 P_{XCl_4}{}^{1/4}$$

For this calculation, the $a_{XCl_6^{2-}}$ in pure Na_2XCl_6 is taken to be unity.

From the experimental results the rates of reaction for the $ZrCl_4$–NaCl system appeár to follow reaction 9, as the pressure dependence approximates the 1/3 law, while the system NaCl–$HfCl_4$ appears to follow reaction 10 as the pressure dependence of the rate of reaction approximates the 1/4 law.

The effect of temperature on the kinetics of the reaction between NaCl and $ZrCl_4$ vapor, at the constant pressure of 600 Torr, has been previously investigated in this laboratory (9) and the apparent activation energy was found to have the low value of 12.3 ± 3 kcal/mol. In agreement with the proposed vacancy model, the increase in temperature is expected to decrease the concentration of Cl^- vacancies, because the effective thermodynamic drive for reaction 9 decreases as the decomposition pressure of the complex Na_2ZrCl_6 increases. This effect, however, is counteracted by the increasing rate of diffusion at higher temperatures.

Hence the overall temperature dependence should represent the combination of those two effects and should yield an apparent activation energy which is less than the activation energy usually observed in diffusion controlled processes.

The authors are indebted to the Defence Research Board for its financial aid.

Photochemistry of Oximes III.[1] The Photochemical Beckmann Rearrangement

M. CUNNINGHAM, L. S. NG LIM, AND G. JUST
Department of Chemistry, McGill University, Montreal 110, Quebec

Received May 13, 1971

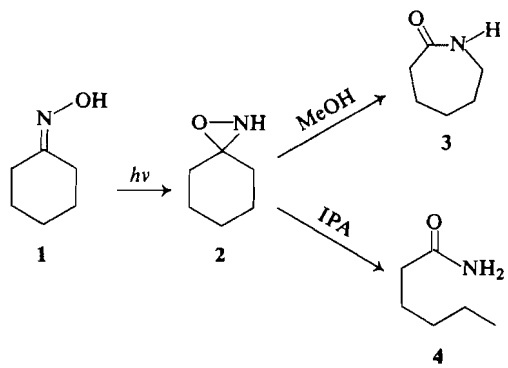
Cycloalkanone oximes of ring-size four to fifteen are shown to yield lactams upon irradiation in methanol solution. Acyclic ketoximes similarly yield Beckmann-type products in methanol solution. Unlike the Beckmann rearrangement, unsymmetrically α-substituted cyclohexanone oximes give mixtures of approximately equal parts of both possible lactam isomers. The photolysis of oximes epimeric at the α-carbon gives products in which the α-center has retained its configuration. The results are interpreted in terms of a concerted breakdown of an oxazirane intermediate.

Par irradiation en solution méthanolique, les oximes de cyclohexanones, dont le cycle comprend entre six et quinze chaînons, conduisent à des lactames. De la même façon, les cétoximes acycliques conduisent en solution méthanolique, à des produits de type Beckmann. Par contre, les oximes de cyclohexanones substituées en α d'une manière dissymétrique conduisent, d'une façon différente à la transposition de Beckmann, aux deux lactames isomères possibles avec environ une égale probabilité. La photolyse d'oximes épimères au carbone α, conduit à des produits où le centre α conserve sa configuration. Les résultats sont interprétés en terme d'une rupture concertée d'une oxazirane intermédiaire.

Canadian Journal of Chemistry, **49**, 2891 (1971)

Introduction

It has been reported (1, 2) that oximes are photosensitive compounds and that the products formed by the photolysis of cyclohexanone oxime (**1**) were solvent dependent, caprolactam (**3**) being formed from the photodecomposition of **1** in methanol and caproamide (**4**) being formed in iso-propanol. The results of further studies (2*d*) of the photoreaction in iso-propanol have been interpreted in terms of an oxazirane (**2**) as the



intermediate. We wish now to report in detail on the photoreaction of cyclic and acyclic ketoximes in methanol which results in the formation of Beckmann-type products.

[1]For part II in this series, see ref. 2*d*.

Results

(a) The Effect of α-Substitution on the Photolysis of Cyclohexanone Oximes

The photolysis of α-methyl cyclohexanone oximes is similar to that of cyclohexanone oxime (**1**). The photo-products were isolated in a pure state by t.l.c. in most cases and shown, where possible, to be identical with authentic samples. New compounds were adequately characterized by spectral and analytical data. The yields of the various photoreactions are summarized in Table 1.

(b) Lactam Ratios Formed in the Photolysis of Unsymmetrically α-Substituted Cyclohexanone Oximes

In a previous paper, (2*d*) we reported that the photolysis of unsymmetrically α-substituted cyclohexanone oximes in iso-propanol solution gave preferential cleavage of the bond to the more highly substituted carbon atom, presumably because the more stable free radical was formed. Photolysis in methanol solution gave no such preference for α-cleavage; approximately equal amounts of both possible lactam isomers were formed. The results of the photolysis of three

TABLE 1. Photolysis yields of α-substituted cyclohexanone oximes in methanol solution*

Starting oxime	% Yield			
	Ketone	Oxime	Amide	Lactam
Cyclohexanone oxime	5	27	4	37

		50/50
		44/56

*All photolyses reported were carried out in a standard manner.

unsymmetrically α-substituted cyclohexanone oximes are summarized in Table 2.

(c) The Photolysis of Medium Sized Ring Ketoximes

The data of Table 2 indicate that free radical intermediates are probably not involved in the photoreaction in methanol solution. To test this hypothesis, the photolysis of a large ring ketoxime, cyclopentadecanone oxime, and of medium ring oximes was studied. If free radical intermediates were involved in the photoreaction a large ring ketoxime would be expected to give little lactam since, once opened, it would close again only to a limited extent. The medium rings should be even more sensitive to radical-type intermediates since ring strain, particularly for nine- and ten-membered rings, would prevent radical recombination. In fact, the lactam yield was little affected by ring size. The results are summarized in Table 3.[2] All compounds described therein were isolated in a pure state by t.l.c. and shown to be identical with authentic

[2]Other cyclic oximes have been included for comparison.

*All photolyses reported were carried out in a standard manner.
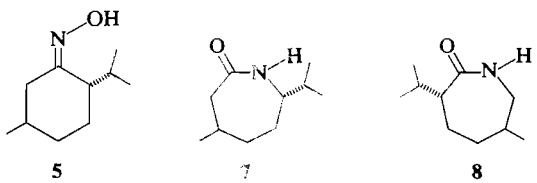
†The limit of detection was of the order of 1–2%.

samples with the exception of the small and common ring ketones which were too volatile to be isolated.

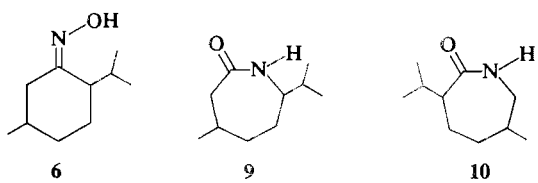
(d) The Photolysis of Menthone and Isomenthone Oxime and of cis-2,6- and trans-2,6-Dimethylcyclohexanone Oxime

The photolysis of menthone oxime (**5**) and isomenthone oxime (**6**) could, in principle, each give four isomeric lactams, **7**–**10**. Only lactams **7** and **8** were found among the photoproducts of **5**. The lactams isolated were identical to those obtained by the Beckmann rearrangement of menthone oxime. Similarly, photolysis and a Beckmann rearrangement of isomenthone oxime (**6**) gave the same lactams, **9** and **10**.

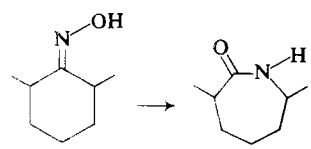
In like manner, photolysis and a Beckmann rearrangement of *cis*-2,6-dimethylcyclohexanone oxime (**11**) and *trans*-2,6-dimethylcyclohexanone oxime (**12**) gave only lactams **8** and **14** respectively. The results are summarized in Table 4.



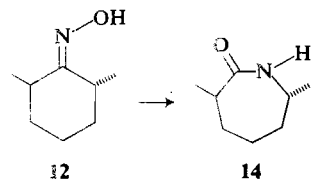
5 **7** **8**



6 **9** **10**



11 **13**



12 **14**

Di-isopropyl ketone oxime	4	28	4	34
Di-*t*-butyl ketone oxime	5	28	5	24

*All photolyses reported were carried out in a standard manner.
†Not determined

It was noted that recovered isomenthone oxime contained small amounts of menthone oxime and that recovered *cis*-2,6-dimethylcyclohexanone oxime contained some *trans*-2,6-dimethylcyclohexanone oxime.

(e) Photolysis of the Acyclic Ketoximes

The photolysis of the acyclic ketoximes was similar to that of cyclohexanone oxime (**1**), giving mainly Beckmann-type products in methanol. The results of the photolysis of a number of acyclic ketoximes are given in Table 5.

Discussion

(a) The Beckmann Rearrangement

The photolysis of the α-substituted cyclohexanone oximes has been shown to yield the corresponding lactams in good yield. This proves interesting since it suggests a method of extending the usefulness of the Beckmann rearrangement, for which the yield decreases sharply as the degree of α-substitution increases (3). In particular, a Beckmann rearrangement on 2,2,6,6-tetramethylcyclohexanone oxime gives only nitrile and no lactam, while the photoreaction gives a 60% lactam yield.

Furthermore, in the case of unsymmetrically substituted cyclohexanone ketoximes, both possible lactam isomers are formed in good yield in a 1:1 ratio by photolysis. A preponderance of one isomer is formed by the normal Beckmann rearrangement.

(b) The Mechanism of the Photoreaction

Although a free radical intermediate is almost certainly involved in the photolysis of oximes in iso-propanol solution (2), the evidence rules against such intermediates in the photoreaction in methanol. Taylor *et al.* (1) have shown the reaction to be only partly quenched by oxygen. In iso-propanol solution, the reaction is strongly quenched. Also, the ratio of lactam isomers formed in the photolysis of unsymmetrically α-substituted cyclohexanone oximes is almost unity. It is of the order of 6–10:1 for the amide isomers resulting from the photolysis in iso-propanol. Should a radical mechanism be involved, a ratio of lactam isomers similar to the amide isomer ratio would be expected. A large ring (cyclopentadecanone) ketoxime photolyzed normally giving a good yield of lactam as do the ketoximes of the medium rings. If these rings opened to form free radical intermediates, they should close again to the lactams only to a limited extent. Finally, menthone oxime and isomenthone oxime rearranged to the same lactams as those resulting from the Beckmann rearrangement, demonstrating that retention of configuration of the migrating group has occurred during the photo-rearrangement.[3] These results are not compatible with a free radical intermediate and are best explained by a mechanism in which the migrating group never becomes kinetically free of the migration terminus. In a subsequent paper, it will be shown that the photolysis of oxazirane **2** does indeed give caprolactam.

Experimental

All melting points were determined in open capillaries on a Gallenkamp melting point apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer 337 grating-type spectrometer as dilute carbon tetrachloride solutions. The n.m.r. spectra were recorded on a Varian A-60 spectrometer operating at 60 MHz (TMS, 0.00 p.p.m.). Merck silica gel HF was used for t.l.c. The photolysis yields were determined by v.p.c. on a Hewlitt–Packard 5751B instrument equipped with dual flame ionization detectors and a disc integrator. Except where noted, the yields were determined on 6 ft × 1/8 in.

[3]A similar finding has recently been reported (11).

stainless steel columns packed with 10% Carbowax 20M on high performance chromosorb W (100/120 mesh). All photolyses were carried out in quartz cells in a Rayonet Photochemical Reactor, model 1061, available from the Southern New England Ultraviolet Company, Middletown, Connecticut. The total energy output of the reactor was 32 W of which about 90% was emitted at the 253.7 nm mercury line. All photolyses were carried out in spectroquality methanol available from Matheson, Coleman and Bell.

General Procedure for the Photolysis of Oximes

A solution of the oxime (1 mmol) in methanol (100 ml) was placed in a quartz cell and nitrogen was bubbled through the solution for 20 min (the nitrogen atmosphere was maintained by a mercury seal). All solutions were photolyzed for 2 h, then concentrated to 10 ml for v.p.c. analysis, and/or to 1 ml for separation by t.l.c.

The required *ketones* were either commercially available or prepared by known methods (4–9).

The required *oximes* were prepared by standard methods (10) and sublimed to literature melting points.

cis- and trans-Dimethylcyclohexanone Oxime

cis-2,6-Dimethylcyclohexanone oxime (**11**) was prepared from commercially available 2,6-dimethylcyclohexanone[4] (90% *cis*). Several recrystallizations from hexane gave the pure *cis* oxime, m.p. 77.0–78.0°.

The *trans* isomer (**12**) was obtained by heating to reflux overnight 2,6-dimethylcyclohexanone[4] with 2 equiv of hydroxylamine hydrochloride and 3 equiv of potassium hydroxide in methanol solution. The oxime was shown by v.p.c. to be a mixture (68% *trans* – 32% *cis*). Several recrystallizations from methanol gave the pure *trans* isomer, m.p. 120.5–121.0°.

2,2,4,4-Tetramethyl-3-pentanone Oxime

2,2,4,4-Tetramethyl-3-pentanone oxime was prepared by heating the ketone to reflux with a concentrated solution of hydroxylamine acetate (0.64 g/cc) in methanol for 2 weeks. The oxime was isolated as a crystalline compound in 22% yield and melted, after sublimation and recrystallization, at 159–161°. The i.r. spectrum showed an absorption (O—H) at 3600 cm^{-1}. The n.m.r. spectrum showed signals at δ 1.25 (9H), 1.40 (9H), and 9.50 p.p.m. (1H).

Anal. Calcd. for $C_9H_{19}NO$: C, 68.74; H, 12.18; N, 8.91. Found: C, 69.08; H, 12.08; N, 8.90.

All *amides* and *lactams* were prepared by known procedures.

Attempts to prepare 2,2,6,6-tetramethylcaprolactam by a Beckmann rearrangement were without success. The crude product remaining after extraction showed no carbonyl band in the i.r. spectrum, but always a strong nitrile band.

trans- and cis-2,6-Dimethylcaprolactam

trans-2,6-Dimethylcaprolactam (**14**) was prepared by treating *trans*-2,6-dimethylcyclohexanone oxime (1 g) with thionyl chloride (1 ml) in methylene chloride solution (25 ml) at 0° for 30 min. The product was shown to be a mixture of *cis* and *trans* isomers by v.p.c. The mixture was enriched to 15% *cis* and 85% *trans* by chromatography on alumina (activity I). Fractional sublimation (40°/1 mm) gave the pure *trans* lactam, m.p. 77.0–78.0°.

cis-2,6-Dimethylcaprolactam (**13**) was prepared in an analogous manner. The crude product obtained in 64% yield was purified by recrystallization (hexane) to m.p. 71.0–72.0°.

All lactams and amides obtained in the photolyses of oximes were compared with authentic samples except for the one reported below, which has not yet been described, and which will serve as a typical example of the photolysis mixture work-up.

The Photolysis of 2,2,6,6-Tetramethylcyclohexanone Oxime

Photolysis of 2,2,6,6-tetramethylcyclohexanone oxime yielded, upon work-up by preparative t.l.c. using a benzene–ether eluant (1:1), unreacted oxime, R_f 0.93 and 2,2,6,6-tetramethylcaprolactam, R_f 0.46. Recrystallization of the lactam from pentane gave platelets, m.p. 113.5–114.5°. The i.r. spectrum showed a strong carbonyl absorption at 1640 and an N—H absorption band at 3380 cm^{-1}. The n.m.r. spectrum (CCl_4 solution) showed two methyl singlets at 1.17 (6H) and 1.30 (6H), the ring protons at 1.70 (6H), and a D_2O exchangeable proton at 7.17 p.p.m. (1H).

Anal. Calcd. for $C_{10}H_{19}NO$: C, 70.96; H, 11.32; N, 8.28. Found: C, 70.82; H, 11.12; N, 8.19.

The Photolysis of Unsymmetrically Substituted Cyclohexanone Oximes

Photolysis of these oximes gave lactam mixtures which could be separated by t.l.c. The relative amounts of isomers were determined by g.l.c. and n.m.r. spectroscopy.

The Photolysis of α-Epimeric Oximes

Photolysis of menthone oxime gave a mixture of lactams. Although it gave a single peak in the gas chromatograph on a polar column (10% Carbowax 20M), it separated into two peaks on a 5% OV-210 column. These peaks had the same retention times as the two lactam isomers resulting from a Beckmann rearrangement on menthone oxime and were different from the retention times of the two lactam isomers resulting from a Beckmann rearrangement on isomenthone oxime.

Photolysis of isomenthone oxime similarly gave a mixture of lactams, which separated into two peaks in the gas chromatograph on a 5% OV-210 column. The two peaks had the same retention times as the two lactam isomers resulting from a Beckmann rearrangement on isomenthone oxime and different retention times from the lactam isomers resulting from a Beckmann rearrangement on menthone oxime.

We would like to thank the National Research Council of Canada for financial support.

Dehydration of Amides to Nitriles Initiated by Hexamethylphosphoric Triamide

RICHARD S. MONSON AND DEGGARY N. PRIEST
Department of Chemistry, California State College, Hayward, California 94542

Received May 4, 1971

Aliphatic and aromatic carboxamides are found to undergo ready dehydration in hexamethylphosphoric triamide at 220–240° affording the corresponding nitriles in good yield.

Les carboxamides aliphatiques et aromatiques subissent une déshydratation facile dans le HMPT à 220–240° et conduisent aux nitriles correspondants avec un bon rendement.

Canadian Journal of Chemistry, 49, 2897 (1971)

Hexamethylphosphoric triamide (HMPT) has found wide use as a reaction medium (1, 2), but has only recently been observed (3) to act as a dehydrating agent in the conversion of alcohols to olefins at elevated temperatures. In the course of our investigations into the chemistry of HMPT (3, 4), we have observed another dehydration reaction initiated by HMPT which is the subject of this report.

When primary aliphatic or aromatic carboxamides were heated to reflux in approximately a three-fold molar excess of HMPT (pot temperatures of 220–240°), a copious evolution of dimethylamine was observed. If the corresponding nitrile is volatile (b.p. <170°), it was then observed to distill from the reaction flask in a good state of purity but for the presence of dimethylamine. A simple work-up affords the pure nitrile. For high boiling products, a 2 h reflux is sufficient to allow conversion of amides to nitriles. The yields of nitriles obtained by these procedures are given in Table 1.

TABLE 1. Nitriles by HMPT dehydration of amides

Amide	Yield of corresponding nitrile (%)	Method
Propionamide	94	Distillation
n-Butyramide	75	Distillation
Hexanoamide	78	Distillation
Benzamide	67	Reflux
Phenylacetamide	75	Reflux
Adipamide	49	Reflux

The rapid evolution of dimethylamine, when considered in the light of the known propensity of HMPT to exchange with hydroxylic compounds (1, 3) suggests that the initial step of the reaction is the formation of a phosphorodiamidate derivative of the enol form of the amide (eq. 1). The basic solvent may then initiate the elimination of this leaving group affording the nitrile (eq. 2).

Conventional reagents for carrying out the dehydration of amides to nitriles are usually extremely reactive towards many functional groups, and the reaction by-products may also be reactive.

[1] $$R{-}CONH_2 \rightleftharpoons R{-}C(=NH){-}OH \xrightarrow{HMPT} R{-}C(=NH){-}O{-}P(=O)(NMe_2)_2 + Me_2NH \uparrow$$

[2] $$R{-}C(=N\text{H})\text{-}O{-}P(=O)(NMe_2)_2 \longrightarrow R{-}C{\equiv}N + {}^{\ominus}O{-}P(=O)(NMe_2)_2$$

$$\ddot{O}{=}P(NMe_2)_3 \qquad HO^{\oplus}{=}P(NMe_2)_3$$

Thionyl chloride, for example, effectively dehydrates amides but generates hydrogen chloride in the process making it an unsuitable reagent for acid-sensitive compounds. On the other hand, neither HMPT or its reaction products are highly reactive offering a possible advantage in the preparation of sensitive nitriles.

Experimental

All amides employed were the commercially available materials. HMPT, technical grade, was used without purification. Products were identified by comparison of their retention times in g.l.p.c. with authentic samples. Analysis by g.l.p.c. was carried out on an Aerograph Model 600 HyFi with flame ionization detector, column 15% SE-30 on acid washed Chromosorb, 1/8 in. × 2 m.

Dehydration of Amides

(a) Distillation Method

The amide (0.1 mol) is added to 65 ml of HMPT in a set-up arranged for distillation. The mixture is brought to reflux (pot, 220–240°) and dimethylamine and the nitrile distill from the reaction vessel over a period of about 2 h. The distillate is taken up in ether, the ethereal solution is washed three times with brine, and the dried (sodium sulfate) solution concentrated under reduced pressure. Distillation of the residue affords the desired nitrile.

(b) Reflux Method

The same proportions of amide and HMPT are refluxed together for 2 h. The cooled reaction mixture is diluted with 100 ml of brine and extracted with ether. (Disubstituted nitriles may require extraction into chloroform due to their limited solubility in ether.) The organic phase is washed, dried, concentrated, and distilled as above.

An Attempted Synthesis of 4,5-Bis(dimethylamino)-1,2,3-thiadiazole

JAMES E. OLIVER AND JERRY B. STOKES

Entomology Research Division, Agricultural Research Center, USDA, Beltsville, Maryland 20705

Received April 26, 1971

Oxidation of 2-hydrazono-*N,N,N',N'*-tetramethylthiooxamide (**8**) by various reagents did not provide the expected thiadiazole **4**, but rather gave azines **11** and **12**. It is postulated that the hydrazone derived from **8** lost nitrogen to give carbene **14** which in turn produced **11** and **12**.

L'oxydation du l'hydrazono-2 tétraméthyl-*N,N,N',N'* thiooxamide (**8**) par différents réactifs ne conduit pas au thiadiazole **4** attendu, mais plutôt aux azines **11** et **12**. Il est suggéré que l'hydrazone qui dérive de **8**, perd l'azote et conduit au carbène **14** qui à son tour produit **11** et **12**.

Canadian Journal of Chemistry, 49, 2898 (1971)

3,5 - Bis(dimethylamino) - 1,2,4 - dithiazolium chloride (**1**) (1), hexamethylphosphoric triamide (**2**) (2), and hexamethylmelamine (**3**) (3) are all chemosterilants (4) against house flies (*Musca domestica* L.) and certain other insects. In at least the latter two cases, replacement of dimethylamino substituents by other groups tends to result in reduction of male-sterilizing activity (2, 3). In the hope of discovering new insect sterilants and defining requirements for activity in dimethylamino-substituted compounds, we decided to synthesize a series of bis(dimethylamino) heterocyclic compounds including 4,5-bis-(dimethylamino)-1,2,3-thiadiazole (**4**).

4

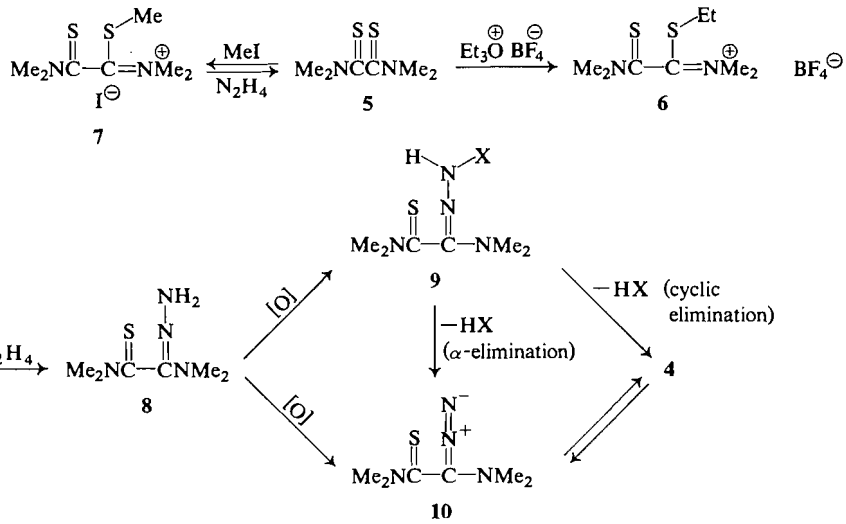
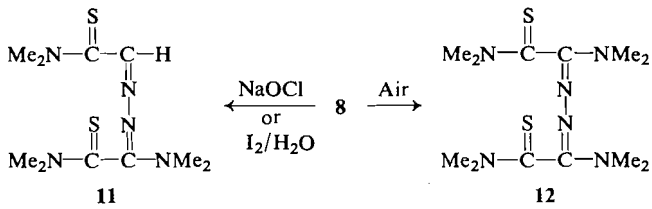


SCHEME 1



SCHEME 2

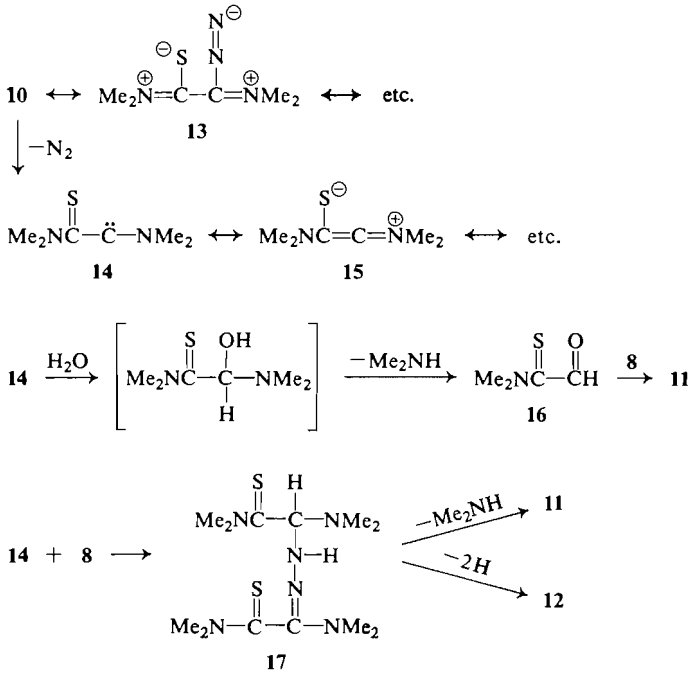
A few amino-substituted 1,2,3-thiadiazoles have been reported (5–7), but none of the synthetic methods seemed readily adaptable to synthesis of bis(dialkylamino)-1,2,3-thiadiazoles. For example, the reactions of diazoalkanes with isothiocyanates (7) necessarily provide monosubstituted amines, and the most general synthesis of the ring system involves the direct introduction of a diazo function into an activated methylene position and thus invariably produces carboxyl or acyl substituted thiadiazoles.

We therefore undertook a new synthesis of the ring system wherein the diazo function or its equivalent would be created by oxidation of the corresponding hydrazone. The required hydrazonothiooxamide **8** was synthesized as shown in Scheme 1. *N,N,N′,N′*-Tetramethyldithiooxamide (**5**)(8) was alkylated with triethyloxonium tetrafluoroborate to provide the *S*-ethyl salt **6** which reacted smoothly with hydrazine to give **8**. Methyl iodide also alkylated **5** to give the *S*-methyl salt **7**; however **7** reacted with hydrazine to regenerate **5**, presumably because of attack by hydrazine on the *S*-methyl.

Pross and Sternhell (9) and Barton, *et al* (10) have reported that hydrazones are oxidized to diazo compounds by iodine in the presence of base and have postulated that an *N*-iodohydrazone is formed that loses HI to give the diazo compound. We reasoned that hydrazone **8** should react analogously with iodine, and that loss of HI from the *N*-iodohydrazone **9** should occur by one of two pathways, either of which would provide the thiadiazole **4**; α-elimination would give the diazothioamide **10** which could spontaneously cyclize to **4** (5, 11) whereas cyclic elimination involving displacement of iodide by the thiocarbonyl would provide **4** directly.

When **8** was reacted with iodine in aqueous sodium carbonate at 0–5°, the only product isolated (75%) was a yellow solid identified as the azine **11** (see Scheme 2). The same azine was obtained in about 50% yield from the oxidation of **8** with aqueous sodium hypochlorite.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



SCHEME 3

Hydrazone **8** was also slowly oxidized by air; a neat sample that had remained at room temperature for two weeks was found to contain a yellow solid different from that isolated from the iodine and hypochlorite oxidations. The material has been identified as the symmetrical azine **12**.

Mercuric oxide and silver oxide have also been reported (12) to oxidize hydrazones to diazo compounds; however **8** was recovered unchanged after attempted reaction with each of these reagents. 1-Chlorobenzotriazole (13) in methylene chloride oxidized **8** to a mixture of **11** and **12** plus a small amount of unidentified material. We were unable to separate the mixture but its n.m.r. and i.r. spectra indicated a ratio of **11** to **12** of about 2:3.

Thus we have oxidized **8** under conditions reported to convert hydrazones to diazo compounds, but in spite of the proximity of the thioamide function, the expected cyclization (11) did not occur. Although there are a variety of mechanisms by which azines can be formed from hydrazones (9, 10) and diazo compounds (12,14, 15), we feel that the formation of **11** and **12** is best explained by loss of N_2 from **10** to give carbene **14**, and subsequent conversion (depending on the reaction medium) of **14** to **11** and **12** as indicated in Scheme 3. Resonance form **13** of the diazothioamide **10** indicates that both the terminal nitrogen and sulfur atoms, between which bond formation must occur for ring-closure, bear partial negative charges. Thus electron donation into the diazo function by the dimethylamino group[1] may promote carbene formation instead of ring formation.

Experimental[2]

Melting points were obtained on a Thomas Hoover Capillary Melting Point Apparatus and are uncorrected. The n.m.r. spectra were recorded on a Varian Model T-60 spectrophotometer and i.r. spectra were obtained on a Perkin–Elmer Model 137 sodium chloride prism spectrophotometer. Magnesium sulfate was employed as a drying agent. Microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, Tennessee.

[(Dimethylthiocarbamoyl)(ethylthio)methylene]-dimethylammonium Tetrafluoroborate (6)

A solution of triethyloxonium tetrafluoroborate (30.3 g, 0.161 mol) in methylene chloride (160 ml) was

[1]A closely related phenomenon has recently been reported (16*a*, *b*) in the equilibration of dialkylamino substituted 1,2,3-triazoles with diazoamidines.

added dropwise to a stirred solution of *N,N,N',N'*-tetramethyldithiooxamide (**5**, (8), 28.4 g, 0.161 mol) in methylene chloride (160 ml) under nitrogen. The solution was allowed to stand overnight at room temperature, then the solvent was removed *in vacuo* to yield an oil that crystallized on standing. Recrystallization from tetrahydrofuran–acetonitrile afforded 43.2 g (92%) of **6**, m.p. 92–93.5°; i.r. ν ($CHCl_3$) 1607, 1545, 1405, 1060 cm^{-1}; n.m.r. δ ($CDCl_3$) 1.47 (t, 3), 3.22 (q, 2), 3.46 (s, 3), 3.57 (s, 3), 3.60 (s, 3), 3.63 (s, 3).

Anal. Calcd. for $C_8H_{17}BF_4N_2S_2$: C, 32.89; H, 5.86; N, 9.59; S, 21.95. Found: C, 32.69; H, 5.89; N, 9.54; S, 21.97.

[(Dimethylthiocarbamoyl)(methylthio)methylene]-dimethylammonium Iodide (7)

Methyl iodide (11.0 g, 0.077 mol) in methylene chloride (50 ml) was slowly added to a solution of **5** (13.2 g, 0.075 mol) in methylene chloride (200 ml). After addition, the solution was refluxed 4 h. Evaporation of the solvent and recrystallization of the residue from absolute ethanol gave 19.9 g (84%) of **7** m.p. 142–143°; i.r. ν, ($CHCl_3$) 1603, 1525, 1395, 1210, 1150, 1125 cm^{-1}; n.m.r. δ ($CDCl_3$) 2.87 (s, 3), 3.68 (s, 3), 3.78 (s, 3), 3.87 (s, 3), 3.90 (s, 3).

Anal. Calcd. for $C_7H_{15}IN_2S_2$: C, 26.42; H, 4.75; I, 39.88. Found: C, 26.37; H, 4.59; I, 39.68.

N,N,N',N'-Tetramethyl-1-thiooxamide 2-Hydrazone (8)

A solution of anhydrous hydrazine (4.8 g, 0.15 mol) in methylene chloride (100 ml) was added dropwise to a stirred solution of **6** (21.9 g, 0.075 mol) in methylene chloride (400 ml) under nitrogen at room temperature. The mixture was stirred overnight, filtered, and the filtrate was evaporated. The resulting orange oil was extracted with ether (150 ml) and the ether solution was dried, filtered and evaporated. Distillation of the residue yielded 11.1 g (85%) of **8**, b.p. 92–93° (0.08 mm), i.r. ν ($CHCl_3$) 1615, 1512, 1385, 1144, 934, 867 cm^{-1}; n.m.r. δ ($CDCl_3$) 2.83 (s, 6), 3.28 (s, 3), 3.50 (s, 3), 4.30 (s, 2).

Anal. Calcd. for $C_6H_{14}N_4S$: C, 41.35; H, 8.10; N, 32.15. Found: C, 41.17; H, 8.24; N, 32.23.

Recrystallization (benzene–hexane) of the pot residue from the distillation gave a small amount of **12** identical to that isolated from the air oxidation of **8** (*vide infra*).

Reaction of 7 with Hydrazine

Anhydrous hydrazine (0.150 g, 4.7 mmol) in absolute ethanol (5 ml) was added dropwise to a stirred solution of **7** (0.636 g, 2.0 mmol) in absolute ethanol (20 ml) at room temperature under nitrogen. The mixture was stirred overnight then the solvent was evaporated *in vacuo*. Extraction of the residue with benzene followed by recrystallization from benzene–hexane gave 0.290 g (83%) of **5**, m.p. 136–138°, whose i.r. spectrum was identical to that of the authentic material.

Oxidation of 8 with Iodine. N,N,N',N'-Tetramethyl-1-thiooxamide 2-Azine with N,N-Dimethyl-1-thioglyoxaldehyde (11)

A solution of iodine (0.254 g, 1.0 mmol) and potassium iodide (0.498 g, 3.0 mmol) in water (20 ml) was added dropwise to a cold (0–5°), stirred solution of **8** (0.174 g, 1.0 mmol) and sodium carbonate (0.106 g, 1.0 mmol) in water (10 ml). The mixture was stirred for 2 h during which time a yellow solid separated (0.103 g, 75%, m.p. 170–176°). Recrystallization from benzene gave pure **11**, m.p. 179.5–180°, i.r. ν ($CHCl_3$) 1590, 1530, 1398, 914, 873 cm^{-1}; n.m.r. δ ($CDCl_3$) 3.10 (s, 6), 3.19 (s, 3), 3.46 (s, 3), 3.48 (s, 3), 3.53 (s, 3), 8.23 (s, 1).[3]

Anal. Calcd. for $C_{10}H_{19}N_2S$: C, 43.93; H, 7.00; N, 25.61; S, 23.45. Found: C, 43.82; H, 6.95; N, 25.45; S, 23.31.

Oxidation of 8 with Sodium Hypochlorite

Aqueous sodium hypochlorite (3.45 ml, 5.25%) was added dropwise to a cold (0–5°) solution of **8** (0.523 g, 3.0 mmol) in water (10 ml). A yellow–orange solid gradually precipitated that was collected and recrystallized from benzene to give pure **11**, m.p. 179.5–180°, identical to that obtained from the iodine oxidation.

Air Oxidation of 8. N,N,N',N'-Tetramethyl-1-thiooxamide 2-Azine (12)

A sample of pure **8** was exposed to air at room temperature for 2 weeks. A yellow solid (**12**) slowly separated (*ca.* 5% conversion in this time); it was purified by recrystallization from benzene–hexane, m.p. 186.5–187.5°, i.r. ν ($CHCl_3$) 1567, 1520, 1372, 1148, 1050, 941, 868 cm^{-1}; n.m.r. δ ($CDCl_3$) 2.88 (s, 12), 3.23 (s, 6), 3.47 (s, 6) (17).

Anal. Calcd. for $C_{12}H_{24}N_6S_2$: C, 45.54; H, 7.64; N, 26.55; S, 20.26. Found: C, 45.47; H, 7.56; N, 26.26; S, 20.12.

Oxidation of 8 with 1-Chlorobenzotriazole (13)

A solution of 1-chlorobenzotriazole (0.766 g, 5.0 mmol) in methylene chloride (50 ml) was added dropwise to a cold (0–5°), stirred solution of **8** (0.87 g, 5.0 mmol) in methylene chloride (25 ml) under nitrogen. After stirring at room temperature overnight the solution was washed with 1 *N* sodium hydroxide (2 × 10 ml), then with water (10 ml), and finally with brine (10 ml). The organic layer was dried, filtered, and evaporated to yield 0.705 g of brown residue that was chromatographed on silica gel. Elution with 1:1 benzene–chloroform gave 0.439 g of a yellow semi-solid. The n.m.r. spectrum indicated a 60:40 ratio of **12** to **11** plus a small amount of unidentified material (n.m.r. δ ($CDCl_3$) 3.00 and 3.30). Further attempts at purification were unsuccessful.

Optically Active Amines. Part XIII.[1] Circular Dichroism of the *N*-Salicylidene Derivatives of Alkylamines

HOWARD E. SMITH AND HARRY E. ENSLEY[2]
Department of Chemistry, Vanderbilt University, Nashville, Tennessee 37203

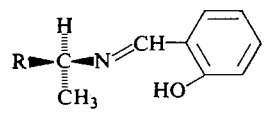
Received April 6, 1971

Comparison of the c.d. spectra of (*S*)-(+)-*N*-salicylidene-α-phenylethylamine with those of (*S*)-(+)-*N*-salicylidene-sec-butylamine and (*R*)-(−)-*N*-salicylidene-2,2-dimethyl-3-aminobutane confirms the conclusion that the strong rotational strength shown by *N*-salicylidene-α- and β-phenylalkylamines is due to an interaction of the π-electron system of the phenyl group and the salicylidenimino chromophore. The sign of the Cotton effects near 255 and 315 nm shown by the *N*-salicylidenes of alkylamines and cycloalkylamines, when these are conformationally defined, can be correlated with their absolute configurations using a planar sector rule, similar to that used for the interpretation of the c.d. and o.r.d. spectra of *N*-salicylidene-α- and β-phenylalkylamines.

La comparaison des spectres de d.c. du *S*-(+)-*N*-salicylidène α-phényléthylamine avec ceux du *S*-(+)-*N*-salicylidène sec-butylamine et R-(−)-*N*-salicylidène diméthyl-2,2 amino-3 butane confirme le fait que l'importance de la force de rotation qui se manifeste dans les *N*-salicylidène α et β-phénylalkylamines, est due à une interaction des électrons π du groupe phényle avec le chromophore salicylidenimino. Les signes des effets Cotton entre 255 et 315 nm dans les *N*-salicylidènes d'alkylamines, dans une conformation définie, peuvent être reliés aux configurations absolues en utilisant le même genre de règle que celle utilisée dans l'interprétation des spectres de d.c. et d.o.r. des *N*-salicylidène α et β-phénylalkylamines.

Canadian Journal of Chemistry, 49, 2902 (1971)

In an earlier paper (2), the optical rotatory dispersion (o.r.d.) curves of the *N*-salicylidenes [(*S*)-**1***b* and (*S*)-**2***b*] of (*S*)-(−)-α-phenylethylamine[3] [(*S*)-**1***a*] and (*S*)-(+)-α-benzylethylamine [(*S*)-**2***a*] were compared with that of the *N*-salicylidene [(*S*)-**3***b*] of (*S*)-(+)-sec-butylamine [(*S*)-**3***a*]. Both (*S*)-**1***b* and (*S*)-**2***b* in ethanol show



(*S*)-**1***b* R = C_6H_5
(*S*)-**2***b* R = $C_6H_5CH_2$
(*S*)-**3***b* R = C_2H_5

positive Cotton effects near 315 and 410 nm. In contrast, (*S*)-**3***b* is much weaker in rotatory power, and in ethanol only one weak peak at 437 nm could be observed. It was concluded that the strong rotational strength shown by *N*-salicylidene-α- and β-phenylalkylamines is due to an interaction of the π-electron system of the

phenyl group and the salicylidenimino chromophore, the chirality of which gives the sign to the observed Cotton effects. This conclusion has been confirmed by subsequent o.r.d. and circular dichroism (c.d.) measurements with a substantial number of *N*-salicylidenes of α- and β-phenylalkylamines (3–5) and comparison of these measurements with similar ones made with the *N*-salicylidenes of steroidal amines (6–8) and of amino sugars (9). However, direct comparison of c.d. measurements with open-chain α- and β-phenylalkylamine derivatives with those of open-chain alkylamine derivatives has been lacking.

We now report the comparison of the electronic absorption (e.a.) and c.d. spectra of (*S*)-**1***b* with those of (*S*)-**3***b* as well as the *N*-salicylidene [(*R*)-**4***b*] of (*R*)-(−)-2,2-dimethyl-3-aminobutane (10) [(*R*)-(−)-pinacolylamine] [(*R*)-**4***a*]. (*S*)-**4***a* has been prepared earlier with a low rotatory power from (*R*)-tert-leucine (10). The complete resolution of (±)-**4***a* is now reported. In addition, the e.a. and c.d. spectra for the *N*-salicylidene [(*S*)-**5***b* and (*R*)-**6***b*] of (*S*)-(+)-2-amino-1-propanol (11) [(*S*)-**5***a*] and (*R*)-(−)-2-amino-1-butanol (12) [(*R*)-**6***a*] are also reported. The c.d. measurements with these latter two *N*-salicylidenes are pertinent to the interpretation of the c.d. spectra of salicylidenimino sugars (9).

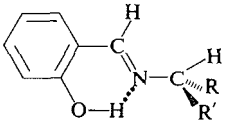
(*R*)-**4***a* (*S*)-**5***a* (*R*)-**6***a*

Results and Discussion

As seen in Table 1, the e.a. spectra of (*S*)-(+)-*N*-salicylidene-α-phenylethylamine [(*S*)-**1***b*], (*S*)-(+)-*N*-salicylidene-sec-butylamine [(*S*)-**3***b*], and (*R*)-(−)-*N*-salicylidene-2,2-dimethyl-3-aminobutane [(*R*)-**4***b*] in a particular solvent are the same. The absorption bands near 255 and 315 nm are assigned to electronic transitions of the intramolecularly hydrogen-bonded salicylidenimino group. The absorption band near 400 nm has been assigned, for the alkylamine *N*-salicylidenes in ethanol, to hydrogen-bonded complexes with the solvent (13) or to a tautomeric form (14). At high concentration, however, an absorption band near 400 nm is observed in the spectrum of *N*-salicylideneisopropylamine in carbon tetrachloride (13). This band disappears on dilution, and it is attributed to a small concentration of a dimeric species (13).

In the c.d. spectrum of (*S*)-**1***b*, the sign of the Cotton effects near 255 and 315 nm is correlated with the absolute configuration of (*S*)-**1***b* using a planar sector rule (5). Thus, in the preferred conformation of (*S*)-**1***b* (**7***a*), the phenyl group is behind the plane of the salicylidenimino chromophore, and in the spectrum, the two Cotton effects are positive. The c.d. maximum at 274 nm, not seen in the spectra of *N*-salicylidene-β-phenylalkylamines (3–5), has been assigned to a $\pi \rightarrow \pi^*$ transition of the phenyl ring of the amine moiety (4).



7

a R = C_6H_5; R′ = CH_3
b R = C_2H_5; R′ = CH_3
c R = CH_3; R′ = $C(CH_3)_3$
d R = CH_2OH; R′ = CH_3

For (*S*)-(+)-*N*-salicylidene-sec-butylamine [(*S*)-**3***b*] and (*R*)-(−)-*N*-salicylidene-2,2-dimethyl-3-aminobutane [(*R*)-**4***b*] corresponding c.d. maxima near 255 and 315 nm are observed. The intensities of these maxima are reduced since the interaction of a phenyl group with the salicylidenimino chromophore is no longer present. Both (*S*)-**3***b* and (*R*)-**4***b* have a preferred conformation (**7***b* and *c*) similar to that of (*S*)-**1***b*. As has been shown for alkyl-substituted cyclohexanones, the rotatory perturbation of the carbonyl chromophore by a tert-butyl group is larger than that by a methyl group (15). The rotatory perturbation of the salicylidenimino chromophore by an ethyl group may also be taken as larger than that by a methyl group. Using the same sector rule, (*S*)-**3***b* and (*R*)-**4***b* are predicted to show Cotton effects near 255 and 315 nm with signs as shown in Table 1.

Assuming a similar preferred conformation for the salicylidenimino group about its attachment bond and this sector rule, the sign of the Cotton effect near 315 nm shown by the *N*-salicylidenes of a number of 20-aminopregnanes can be predicted (6, 7). Much the same is true for the *N*-salicylidenes of cyclic amines, especially 17α-, 17β-, and 3α-amino steroids (8). For other cyclic amines, including other amino steroids, contributions from other salicylidenimino conformations may be important and perturbations by several remote groups may be significant (8). In these latter cases, predictions are sometimes unreliable.

The e.a. spectra of (*S*)-(+)-*N*-salicylidene-2-amino-1-propanol [(*S*)-**5***b*] and (*R*)-(+)-*N*-salicylidene-2-amino-1-butanol [(*R*)-**6***b*] in methanol are essentially the same as those of the others. In hexane, however, a weak absorption band near 400 nm is detected in each spectrum. The molecular absorptivity of the band decreases on dilution. The band may be due to a small concentration of the intermolecularly hydrogen-bonded dimer (13) in *n*-hexane.

The c.d. spectra of (*S*)-**5***b* and (*R*)-**6***b* also show an additional maximum near 268 nm. A maximum near this same wavelength is frequently present in the c.d. spectra of the *N*-salicylidene derivatives of α-hydroxy steroidal amines (8).

The rotatory perturbation of the salicylidenimino chromophore by a hydroxymethylene group is taken as greater than that by a methyl group. Application of the sector rule to a conformation of (*S*)-**5***b* (**7***d*) similar to the preferred conformation of (*R*)-**4***b* (**7***c*), predicts, as are observed, positive maxima near 255 and 315 nm

For personal use only.

in the c.d. spectrum of (*S*)-**5***b*. The rotatory perturbation by a hydroxymethylene group is taken to be about the same as that by an ethyl group, and unusually low molecular ellipticities are found for the maxima near 255 and 315 nm in the c.d. spectrum of (*R*)-**6***b*. Also the sign of the maximum near 315 nm is different in the two solvents used.

Experimental

General

Boiling points are not corrected. The *N*-salicylidenes were prepared as previously reported (2). They had n.m.r. spectra compatible with their assigned structures. Optical rotations at the sodium D-line were obtained using a 1-dm sample tube. Elemental analyses were done by Galbraith Laboratories, Inc., Knoxville, Tennessee. The e.a. spectra were measured with a Cary Model 14 spectrophotometer using 1-cm sample cells. The c.d. spectra were measured at 25–28° with a Cary Model 60 spectropolarimeter with a Model 6001 accessory. The slit was programmed for a spectral band width of 1.5 nm, and a path length of 1 cm was used. Cut-off was indicated when the dynode voltage reached 400 V.

(S)-(+)-N-Salicylidene-sec-butylamine [(S)-3b][4]

This compound had $[\alpha]_D^{25}$ +73° (*c* 1.15, MeOH).

Resolution of (±)-2,2-Dimethyl-3-aminobutane [(±)-4a]

To 113.0 g (0.753 mol) of (+)-tartaric acid in 1000 ml of boiling 95% EtOH was added 75.0 g (0.741 mol) of (±)-**4***a*. On cooling the mixture to room temperature, there was deposited 141.2 g (152%) of solid, $[\alpha]_D^{23}$ +16° (*c* 2.78, H_2O). Four recrystallizations of this solid from 95% EtOH gave 59.1 g (63%) of the acid tartrate salt of (*R*)-**4***a*, $[\alpha]_D^{26}$ +16° (*c* 2.64, H_2O). Fifty grams of this salt was decomposed with 25% KOH, and the amine extracted into ether. The ethereal solution was dried (KOH), and the ether evaporated. Distillation of the residue gave 15.5 g (49%) of (*R*)-**4***a*, b.p. 100–103°, d_4^{20} 0.758, $[\alpha]_D^{23}$ −5.6° (neat), $[\alpha]_D^{25}$ −2.6° (*c* 5.10, MeOH) (lit. (10) $[\alpha]_D^{24}$ +0.70° (neat, *l* = 0.2 dm) for (*S*)-**4***a*).

The mother liquors from the above resolution were combined, and the solvent was removed. Decomposition of the residual salt gave 36.6 g (0.362 mol) of the partially racemic amine, $[\alpha]_D^{23}$ +2.02° (neat), which was combined with 54.4 g (0.362 mol) of (−)-tartaric acid in 500 ml of boiling 95% EtOH. On cooling this solution to room temperature, there was deposited 54.4 g (58%) of solid, $[\alpha]_D^{26}$ −16° (*c* 5.70, H_2O). After three recrystallizations of this solid from 95% EtOH, there was obtained 10.5 g (11%) of the acid tartrate salt of (*S*)-**4***a*, $[\alpha]_D^{25}$ −16° (*c* 4.69, H_2O).

The salt was decomposed and the amine purified as before. There was thus obtained 2.40 g (6.4%) of (*S*)-**4***a*, b.p. 100–103°, d_4^{20} 0.760, $[\alpha]_D^{24}$ +5.4° (neat), $[\alpha]_D^{24}$ +2.5° (*c* 5.10, MeOH).

[4]The preparation and characterization of this sample were reported earlier (2).

(±)-N-Salicylidene-2,2-dimethyl-3-aminobutane [(±)-4b]

From 5.06 g (50.0 mmol) of (±)-2,2-dimethyl-3-aminobutane [(±)-**4***a*] and 5.50 g (45.0 mmol) of salicylaldehyde in 15 ml of MeOH there was obtained 3.03 g (33%) of (±)-**4***b*, yellow oil, b.p. 82–84° (0.1 mm), n_D^{25} 1.5323, d_4^{20} 0.965.

Anal. Calcd. for $C_{13}H_{19}NO$: C, 76.05; H, 9.33; N, 6.82. Found: C, 76.21; H, 9.39; N, 7.05.

(R)-(−)-N-Salicylidene-2,2-dimethyl-3-aminobutane [(R)-4b]

From 4.10 g (40.5 mmol) of (*R*)-(−)-2,2-dimethyl-3-aminobutane [(*R*)-**4***a*] and 4.45 g (36.4 mmol) of salicylaldehyde in 50 ml of benzene there was obtained 3.54 g (47%) of (*R*)-**4***b*, yellow oil, b.p. 89–90° (0.2 mm), which on standing crystallized as yellow needles, m.p. *ca.* 30°, $[\alpha]_D^{24}$ −133° (*c* 2.04, MeOH).

Anal. Calcd. for $C_{13}H_{19}NO$: C, 76.05; H, 9.33; N, 6.82. Found: C, 76.21; H, 9.30; N, 7.04.

(S)-(+)-N-Salicylidene-2-amino-1-propanol [(S)-5b]

From 1.90 g (25.3 mmol) of (*S*)-(+)-2-amino-1-propanol [(*S*)-**5***a*], d_4^{20} 0.955, $[\alpha]_D^{24}$ +15.1° (neat), $[\alpha]_D^{24}$ +16° (*c* 4.99, MeOH) (lit. (16) $[\alpha]_D^{20}$ +15.8° (neat)), and 3.20 g (26.2 mmol) of salicylaldehyde in 10 ml of MeOH, there was obtained 3.67 g (81%) of (*S*)-**5***b*, yellow oil, b.p. 114–115° (0.3 mm), n_D^{25} 1.5815, $[\alpha]_D^{24}$ +76.2° (*c* 2.23, MeOH).

Anal. Calcd. for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31; N, 7.82. Found: C, 66.86; H, 7.15; N, 7.80.

(R)-(+)-N-Salicylidene-2-amino-1-butanol [(R)-6b]

From 4.68 g (52.5 mmol) of (*R*)-(−)-2-amino-1-butanol [(*R*)-**6***a*], d_4^{20} 0.936, $[\alpha]_D^{25}$ −10.2° (neat), $[\alpha]_D^{24}$ −10° (*c* 5.00, MeOH) (lit. (17, 18) $[\alpha]_D^{26}$ −9.92° (neat), $[\alpha]_D^{22}$ −10.00° (*c* 2, EtOH)), and 6.70 g (54.9 mmol) of salicylaldehyde in 20 ml of MeOH, there was obtained 7.15 g (70%) of (*R*)-**6***b*, recrystallized from *n*-hexane, yellow needles, m.p. 55–56° (corrected), $[\alpha]_D^{24}$ +8.1° (*c* 3.50, MeOH).

Anal. Calcd. for $C_{11}H_{15}NO_2$: C, 68.37; H, 7.82; N, 7.25. Found: C, 68.53; H, 7.67; N, 7.25.

A Differential Scanning Calorimeter Study of Phase Transitions in Alkali Metal Stearates

J. A. RIPMEESTER[1] AND B. A. DUNELL
Chemistry Department, The University of British Columbia, Vancouver 8, British Columbia

Received September 22, 1970[2]

Differential scanning calorimeter thermograms have been obtained for the alkali metal stearates from 25 to 200 °C. Four different samples of different thermal history were studied for each soap, and differences in temperature and relative enthalpy of transitions were found to depend on the various sample histories. For lithium stearate good correlation is found between DSC and nuclear magnetic resonance (n.m.r.) results. Rubidium and caesium stearates seem to be less sensitive to thermal history than the sodium and potassium salts.

Des thermogrammes par calorimétrie différentielle de précision ont été obtenus pour des stéarates de métaux alcalins de 25 à 200 °C. Quatre échantillons différents avec une histoire thermique différente ont été étudiés pour chaque savon et les différences trouvées dans la température et l'enthalpie relative de transitions dépendent des différentes histoires. Pour le stéarate de lithium, il existe une bonne corrélation entre les résultats en DSC et en r.m.n. Les stéarates de rubidium et de caesium paraissent moins sensibles à l'histoire thermique que les sels de sodium et potassium.

Canadian Journal of Chemistry, **49**, 2906 (1971)

In the course of a broad line nuclear magnetic resonance study of alkali metal oleates and stearates (1), we examined a number of these soaps by the differential scanning calorimeter technique, using a Perkin–Elmer DSC 1-B instrument. In particular, DSC curves were run on different samples of the same substance of which the various samples had different thermal histories. As might be expected from previous work (2, 3), the thermal history had significant influence on the thermogram obtained for the sample. The temperatures of the various phase transitions as observed from the thermograms are also compared with transition temperatures observed by other techniques.

It may be worth noting at this point that in differential thermal analysis (DTA) the difference in temperature between the sample and a standard reference substance is measured, whereas in the differential scanning calorimeter (DSC) the difference in the energy required to keep sample and reference at the same temperature under constant rate of heating is recorded. In the DTA method, peaks are normally observed for both first and second order transitions, but in the DSC method peaks should accompany only first order transitions; the second order transitions should cause only a shift in the baseline of the thermogram. In this report only distinct peaks in the DSC thermograms are considered, so that all transitions listed for the DSC method should be first order.

Samples of alkali metal stearates were prepared from Eastman Kodak white label grade stearic acid and reagent grade alkali metal hydroxide by precipitation from hot ethanol and aqueous

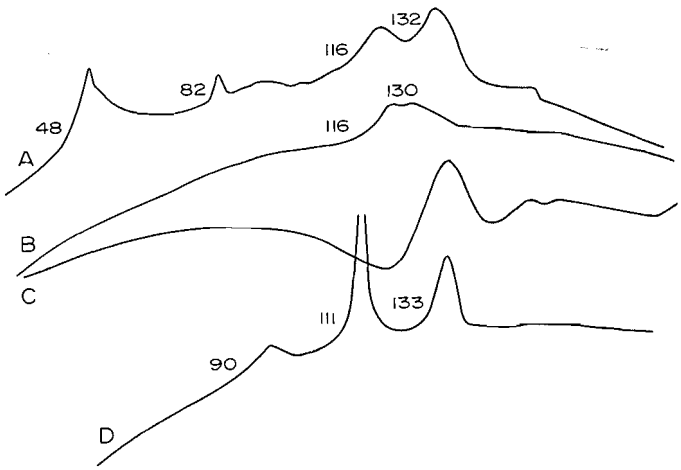

FIG. 1. Differential scanning calorimeter thermograms for four samples of sodium stearate of different thermal history. See text for details.

ethanol solutions (1). After the precipitated soap had been dried and recrystallized once from ethanol, four samples of each soap were prepared by the following treatment: samples *A* were kept under vacuum for one day at room temperature, samples *B* were kept under vacuum for 14 h at 110–120 °C and were run 24 h later, samples *C* were kept under vacuum for 28 h at 110–120 °C and were run 24 h later, and samples *D* were fused under vacuum and run about a week later. The samples were covered after preparation, but no special precautions were taken to keep them out of contact with the atmosphere when they were transferred to the DSC. Tank nitrogen passed around the sample during the DSC run. The thermogram was always run at a heating rate of 10 °C/min from room temperature to 200 °C.

The question has arisen as to whether this rate of heating is too rapid for substances in which some of the transitions occur sluggishly. In running DSC thermograms one must compromise between using a fast heating rate, thereby obtaining very well defined peaks, and using a slow heating rate in order to work at conditions closer to equilibrium, but thereby obtaining relatively small, poorly defined peaks. Pacor and Spier (4) report that with a DTA instrument they observed only little dependence of transition temperature upon heating rate for sodium salts of fatty acids containing from 10 to 19 carbon atoms for heating rates in the range of 1 to 16° per min. Using a sodium stearate sample and our DSC instrument, we find that there is a tendency for transition temperatures to be displaced to higher values as the rate of heating is increased. Differences of 1 to 3° in the temperatures of the major transitions up to 150 °C were observed between the thermograms for sodium stearate, one run at a rate of 2.5 °C/min and the other at 10 °C/min. It is felt that such differences are about equal to the experimental uncertainty of the method. Transition temperatures for heating rates of 2.5 °C/min and 40 °C/min were observed to differ by at most 10°, at least 2°, and on the average 5°, in the range up to 150 °C, the higher transition temperatures being obtained with the fast heating rate. A heating rate of 10 °C/min appears to be a satisfactory compromise in which systematic errors in transition temperatures are comparable with random errors and peaks in the thermogram are still well defined.

The thermograms for the four samples of sodium stearate are reproduced in Fig. 1 as examples of the type of behavior observed. The dependence of behavior on thermal history is clear, and the difficulty of determining transition temperatures is greater here than in any of the other soaps because of the long leading edges and general breadth of the peaks. The thermogram for sample *C* is especially difficult. In all cases the assignment of transition temperatures should be considered approximate. The transition temperature is taken to be that of the point at which the peak starts to break away from the base line. Transition temperatures are listed in Table 1 along with values obtained by X-ray methods (5,

§Reference 7, except where marked otherwise.

6), DTA (3), dilatometry (7, 8), and n.m.r. (2, 9, 10). The list of values obtained from other studies is intended to be representative rather than complete. Other results and a more extensive range of temperature than approximately 50 to 200 °C may be found in the references cited for Table 1 as well as in papers by Vold (11, 12), Ravich and Nechitaylo (13), Pace and Spier (4), and Puddington and co-workers (14).

In lithium stearate the higher temperature transition is shifted to lower temperature after the sample has been fused. The same behavior was observed (2) in an n.m.r. study of lithium stearate, and one may now conclude that the motional process which is manifested in this phase change involves a rate of reorientation of hydrocarbon chains which is great enough to be thermodynamically significant, and therefore much greater than the mere 10^4 or 10^5 s^{-1} which would be necessary to narrow the n.m.r. line.

In potassium stearate it is remarkable that no DSC transition was observed near 170 °C, where a transition is found by other techniques. We have no explanation for this. One may also note that in the rubidium and caesium stearates the effect of thermal history of the sample is less marked than in the other salts, and appears more in the variation in size of corresponding peaks than in significant shifts in the temperature at which peaks appear.

For sodium stearate Trzebowski (3) has reported three different DTA thermograms corresponding to an α form obtained by air drying at room temperature the precipitate from an aqueous alcohol solution, a β form obtained by heating to 55–60 °C and drying at this temperature, and a σ form obtained by heating above 110–135 °C. Trzebowski reports that DTA peaks occur for these three modifications, of which the α- and σ-forms should correspond to our samples *A* and

The Vapor Phase Radiolysis of Isopropanol and Water–Isopropanol Mixtures. II. Nitrous Oxide as Electron Scavenger[1,2]

M. G. BAILEY AND R. S. DIXON

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Manitoba

Received March 25, 1971

Nitrous oxide reduces the hydrogen yield from water–isopropanol vapor mixtures by complete scavenging of electrons. Nitrogen is produced over the whole concentration range but the yield at higher isopropanol concentrations is much greater than the electron yield. The results indicate a competition between water and isopropanol for a secondary species resulting from electron attachment to N_2O. Reaction of this species with isopropanol leads to further N_2 whereas reaction with water does not. The reactive intermediate is most probably N_2O^- or $N_2O_2^-$.

Le protoxyde d'azote réduit le rendement en hydrogène de mélanges vapeurs eau–isopropanol en piégeant complètement les électrons. L'azote est produit pendant tout l'intervalle de concentration mais le rendement à concentration plus élevée en isopropanol est beaucoup plus grand que le rendement électronique. Les résultats indiquent qu'il y a compétition entre l'eau et l'isopropanol envers une deuxième espèce provenant de la fixation d'un électron sur N_2O. La réaction de cette espèce avec l'isopropanol fournit encore de l'azote alors que la réaction avec l'eau n'en fournit pas. L'intermédiaire réactif est probablement N_2O^- ou $N_2O_2^-$.

scavenging reaction. Nitrous oxide has been used extensively as an electron scavenger in gas phase radiolysis, and correlations made between the decrease in hydrogen yield and the production of nitrogen. Here we have extended our study of water–isopropanol mixtures by measuring yields of hydrogen and the production of nitrogen from mixtures containing nitrous oxide, and have found that the yield of N_2 is much higher than the yield of electrons in the system. Possible mechanisms are discussed.

The experimental details have been described previously (1). Irradiations were carried out at ~700 Torr pressure and 125 °C. The dose rate was $\sim 1.9 \times 10^{18}$ eV g^{-1} min^{-1} (estimated by the ethylene dosimeter (2) using $G(H_2) = 1.31$) and total doses were in the range 10^{19}–10^{20} eV g^{-1}. G-values were based on the total energy absorbed by both water and isopropanol. The energy absorbed by each component in the mixture was calculated, assuming it to be proportional to the electron density.

The hydrogen yields from water–isopropanol mixtures over the complete concentration range, with and without 2 mol% N_2O, are shown in Fig. 1. $G(H_2)$ shows a linear dependence on the fraction of energy absorbed by each component, in the presence and absence of N_2O. The effect of N_2O is due to electron capture by N_2O completely suppressing the neutralization reaction

$$[1] \quad e^- + H^+(H_2O)_x(C_3H_7OH)_y \rightarrow H + xH_2O + yC_3H_7OH$$

By extrapolating the straight lines in Fig. 1 to zero isopropanol and zero water concentrations, we obtain the yields of H atoms which arise from electrons in pure water and pure isopropanol. The values are $g(H)_w^e = 2.5 \pm 0.5$ and $g(H)_p^e = 3.5 \pm 0.5$, respectively. The hydrogen which remains in the presence of nitrous oxide represents the sum of the "residual" H atom yield plus the molecular hydrogen yield, designated $g(H)$ and $g(H_2)$, respectively. Figure 1 shows $g(H)_w + g(H_2)_w = 5.5 \pm 0.3$ and $g(H)_p + g(H_2)_p = 5.6 \pm 0.3$. These values in the presence of N_2O are in good agreement with our earlier results using other electron scavengers (1). Concentrations of N_2O higher than 2 mol% did not reduce $G(H_2)$ further showing that this quantity is sufficient to capture all the electrons. The effect of N_2O concentrations on $G(H_2)$ from pure isopropanol is shown in Fig. 2.

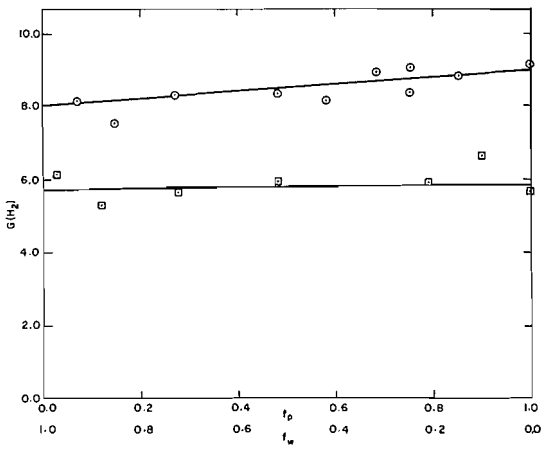

FIG. 1. Hydrogen yields from γ-irradiated water–isopropanol vapor mixtures at 125 °C and ~700 Torr. f_w and f_p are the fractions of energy absorbed by water and isopropanol, respectively. ○, No additive; □, with 2 mol% N_2O.

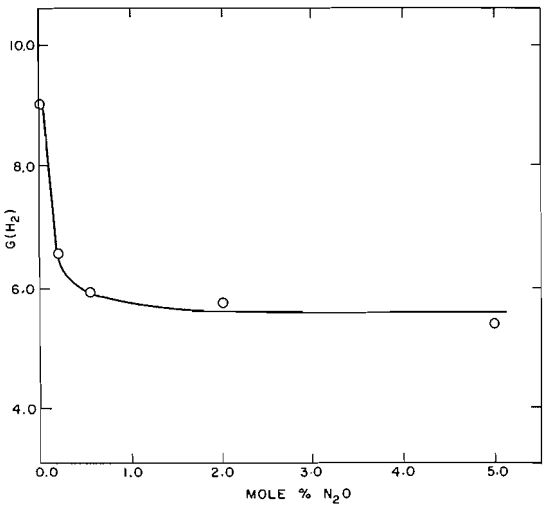

FIG. 2. Effect of N_2O concentration on $G(H_2)$ from isopropanol vapor at 125 °C and ~700 Torr.

The nitrogen yields from water–isopropanol mixtures containing various concentrations of N_2O are shown in Fig. 3. In all mixtures $G(N_2)$ increased rapidly up to a plateau value at ~2 mol% N_2O. However, the plateau values of $G(N_2)$ also increased with increasing fraction of isopropanol in the mixture, from 2.8 ± 0.3 at 0.2 mol% isopropanol to 12.5 ± 1.0 in pure isopropanol.

Figure 4 shows a plot of these plateau values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

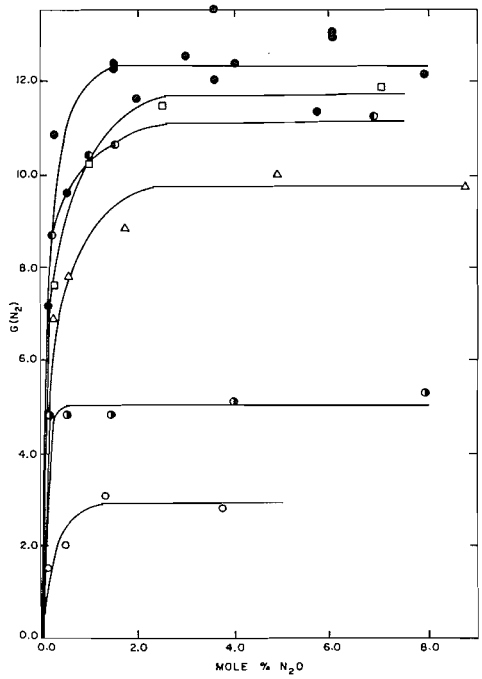

FIG. 3. Effect of N_2O concentration on $G(N_2)$ from water–isopropanol vapor mixtures at 125 °C and ~700 Torr. Isopropanol concentrations: ○, 0.2 mol%; ◑, 2.3 mol%; △, 10 mol%; ◐, 28 mol%; □, 51 mol%; ●, pure isopropanol.

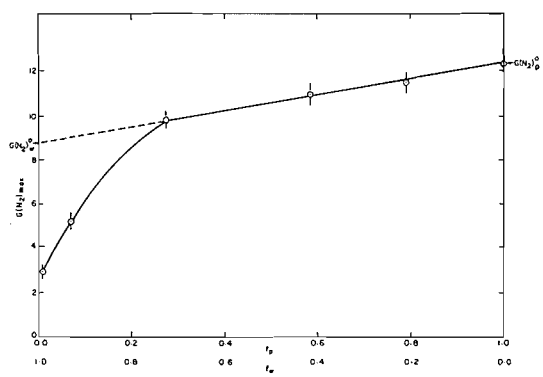

FIG. 4. Plot of $G(N_2)_{max}$ values from Fig. 3 against fraction of energy absorbed by water (f_w) and isopropanol (f_p).

$G(N_2)_{max}$ against the fraction of energy absorbed by the two components. $G(N_2)_{max}$ is seen to rise sharply up to $f_p \simeq 0.3$ and then increase more slowly and linearly up to $f_p = 1$. Extrapolation of the linear portion of the curve to $f_p = 0$ and $f_p = 1$ gives $G(N_2)_w^0 = 8.7 \pm 0.5$ and $G(N_2)_p^0 = 12.5 \pm 1.0$, respectively, as shown in Fig. 4.

Assuming electron capture to be a three-body process at the pressures used (3, 4)

[2] $$e^- + N_2O + M \rightarrow N_2O^- + M$$

the ion N_2O^- may react in several ways to produce N_2. If each N_2O^- yields one molecule of N_2 only, and no secondary reactions produce N_2, then $G(N_2)$ should equal $g(e)$. However, the N_2 yields are clearly much higher than the value of $g(e)$ and depend markedly on the fraction of isopropanol in the mixture. Despite this, the effect of SF_6, which suppresses virtually all the N_2 yield in both isopropanol and water–isopropanol mixtures, shows that most (possibly all) of the N_2 has the electron as precursor.

It is evident from Fig. 4 that a competition is occurring between water and isopropanol for some species X. Reaction of X with water leads to an overall yield of N_2 which equals $g(e)$, whereas reaction with isopropanol leads to a yield of N_2 which is greater than $g(e)$, the latter presumably by some short chain mechanism. The maximum yield of N_2 will therefore be obtained when all X reacts with isopropanol and Fig. 4 shows that this occurs at concentrations above ~10 mol% isopropanol ($f_p \sim 0.3$). The chain length may thus be calculated from the values of $G(N_2)_w^0$ and $G(N_2)_p^0$. Assuming that our values of $g(H)_w^e$ and $g(H)_p^e$ are equal to the respective electron yields, then $G(N_2)_w^0 \simeq 3.5\ g(e)_w$ and $G(N_2)_p^0 \simeq 3.6\ g(e)_p$, showing good agreement between the two estimates. These values would be slightly high if a small fraction of the electrons did not form H atoms on neutralization via reaction 1, since $g(H)^e$ would be slightly less than $g(e)$. The latter has been suggested in hydrocarbons (5, 6) but the evidence for it in water vapor (7) or alcohols (8) is sparse and inconclusive.

In hydrocarbon gases containing N_2O (6, 9–12), high nitrogen yields were explained mainly by a mechanism involving reaction of O^- with N_2O, the substrate or an additive. However, mass spectrometric (13), drift tube (14) and ion cyclotron resonance (15) experiments now show that O^- does not form N_2 on reaction with N_2O, at least at low kinetic energies (16). Recent results in the propane–HCl system (17) also indicate that O^- is not a precursor of N_2. Although the probability of forming O^- will be higher at 125 °C than at room temperature (18), we conclude that O^- is not responsible for the high N_2 yield in the present

system. The most probable identity of X is therefore N_2O^- or $N_2O_2^-$, the latter being formed by the reaction

[3] $$N_2O^- + N_2O \rightarrow N_2 + N_2O_2^-$$

Complete reaction of either N_2O^- or $N_2O_2^-$ with water

[4] $$N_2O^- + H_2O \rightarrow N_2 + OH + OH^-$$

[5] $$N_2O_2^- + H_2O \rightarrow N_2O + OH + OH^-$$

would lead to an overall yield of $G(N_2) = g(e)$, which corresponds to our experimental $G(N_2)$ at very low isopropanol concentrations.

The mode of attack of N_2O^- or $N_2O_2^-$ on the alcohol and the intermediates in the chain reaction are difficult to define specifically. Results in alkanes (10) indicate that the α-hydrogen of the alcohol is involved and, in our system, H-atom or proton abstraction at the α-H would result in the formation of $(CH_3)_2\dot{C}OH$ or $(CH_3)_2\bar{C}OH$. $(CH_3)_2\dot{C}OH$ is also formed in large yield, even at < 1 mol% isopropanol, by the reactions

[6] $$H + (CH_3)_2CHOH \rightarrow H_2 + (CH_3)_2\dot{C}OH$$

[7] $$OH + (CH_3)_2CHOH \rightarrow H_2O + (CH_3)_2\dot{C}OH$$

which appears to rule out H atom abstraction by N_2O^- or $N_2O_2^-$ as a major step in the chain reaction, unless some other product is important. The latter cannot be OH^-, as suggested in methylcyclohexane vapor (11), since in our system OH^- is also produced by reactions 4 and 5. Further, we see no reason why proton abstraction should occur at the α-H rather than from the —OH group or why the anion should not be protonated by H_2O. The latter also appears to rule out the radical ion $(CH_3)_2\dot{C}O^-$ which was proposed as chain carrier in aqueous alkaline isopropanol solutions (19) and alkaline liquid isopropanol (20).

It is clear that the intermediates in these chain reactions are not well identified in any gas phase system, but the necessity of an α-H in the alcohol does indicate a product resulting from attack at this α-H as one intermediate in the mechanism. However, despite the limited modes of attack, none of the possible products suggests itself immediately as the reaction intermediate.

The authors would like to thank Drs. P. J. Dyne, N. H. Sagert, K. W. Chambers, and F. P. Sargent for stimulating discussions and comments on the manuscript.

The Effect of Counter Ion and Crosslinking on the Bulk Volume Magnetic Susceptibility of Dowex 50W

PAUL H. WEINER

Department of Chemistry and Chemical Engineering, Stevens Institute of Technology, Hoboken, N.J. 07030

AND

DARRYL G. HOWERY[1]

Department of Chemistry, Brooklyn College of the City University of New York, Brooklyn, N.Y. 11210

Received February 15, 1971

The bulk volume magnetic susceptibility $\chi_{v,p}$ of packed beds of ten ionic forms of Dowex 50W having a crosslinking of 4, 8, and 12% divinylbenzene are measured using a spinning coaxial cell technique. Proton chemical shifts are referenced relative to external hexamethyldisiloxane (HMD). The measured values of $\chi_{v,p}$ range from -0.730 to -0.795 c.g.s. units. The absolute value of $\chi_{v,p}$ generally increases with an increase in atomic mass of the counter ion. For a given counter ion $|\chi_{v,p}|$ increases as the crosslinking increases. Chemical shifts for water external to and internal to the ion-exchange bead phase are corrected for bulk susceptibility differences between the reference and the packed bed. The widths at half height of the external water peak increase with an increase in $|\chi_{v,p}|$.

La susceptibilité magnétique volumique $\chi_{v,p}$ de couches tassées de dix formes ioniques de Dowex 50W ayant des liaisons transversales avec le divinylbenzène de 4, 8 et 12% est mesurée en utilisant la technique de la cellule coaxiale rotative.

Les déplacements chimiques des protons sont donnés par rapport à l'hexaméthyl disiloxane (HMD) pris comme référence externe. Les valeurs mesurées de $\chi_{v,p}$ vont de -0.730 à -0.795 unités c.g.s. La valeur absolue de $\chi_{v,p}$ croit généralement lorsque la masse atomique de l'ion opposé augmente.

Pour un ion opposé donné, $|\chi_{v,p}|$ augmente de la méme façon que le nombre de liaisons transversales. Les déplacements chimiques de l'eau extérieure et intérieure à la phase échangeuse d'ions en perles, sont corrigés à cause des différences de susceptibilité volumique qui existent entre la référence et la couche tassée. Les largeurs à mi-hauteur du pic de l'eau extérieure augmentent avec un accroissement de $|\chi_{v,p}|$.

Canadian Journal of Chemistry, 49, 2913 (1971)

Introduction

High resolution proton magnetic resonance (p.m.r.) studies of ion-exchange resins (1–7) are furnishing valuable information concerning the structure of water internal to the ion-exchange resin. For spherical ion-exchange beads suspended in water, the chemical shift of the resin-phase internal water is usually reported relative to the interstitial external water in the packed bed. Gordon (1) pointed out that changes in the bulk volume magnetic susceptibility of the packed bed alter line positions relative to an external standard but that the measured difference between the chemical shift of external water and that of internal water requires no correction for differences in bulk susceptibility of water and bead. We report here the application of a method for determining the bulk susceptibility of packed beds containing spherical ion-exchange resin beads. A knowledge of bulk susceptibilities then allows the calculation of corrected chemical shifts using external standards to measure chemical shifts.

The equation which must be used to obtain corrected chemical shift values when a coaxial sample cell is utilized is

$$[1]\quad \delta_{cor}^{HMD} = \delta_{obs}^{HMD} - (2\pi/3)(\chi_{v,s} - \chi_{v,p})$$

Here δ_{cor}^{HMD} is the corrected chemical shift in p.p.m. relative to the external reference standard (hexamethyldisiloxane in this study); δ_{obs}^{HMD} is the observed chemical shift; and $\chi_{v,s}$ and $\chi_{v,p}$ are the bulk volume magnetic susceptibilities of the reference solution and the packed bed, respectively. Resonance shifts which occur to the low-field side of the reference are positive.

The bulk susceptibility of an aqueous suspension of ion-exchange beads, needed for eq. 1, is determined by using the method of Malinowski and Weiner (8). It was shown that the bulk volume susceptibility of material contained in the central region of a spinning coaxial sample cell

could be determined from

$$[2]\quad \chi_{v,center} = \frac{[\nu_s^{(1)} - \nu_s^{(3)}]kr^2}{(a^2 + b^2)\pi\nu_0} = \frac{\nu_s^{(1)} - \nu_s^{(3)}}{72.65}$$

Here $\nu_s^{(1)}$ is the spinning frequency in Hz necessary to make the intensity of the first spinning sideband of the material in the annular region of the coaxial cell equal in intensity to the main band of that region (under the experimental conditions of reference annular and packed bed central); $\nu_s^{(3)}$ is the spinning frequency which produces equal intensities when the reference is annular and nitrogen gas at 1 atm pressure is central; k is the argument of a Bessel function; r is the mean radius of the annular region of the coaxial cell; a and b are the inner and outer radii of the central tube; and ν_0 is the spectrometer frequency in MHz. The spinning frequencies, $\nu_s^{(1)}$ and $\nu_s^{(3)}$, are determined by plotting relative peak height differences between main band and first sideband *vs.* the splitting between the two bands, and interpolating to find the spinning frequency when the relative peak height difference is zero. Because of the geometry of the coaxial cell, the first sideband appears at twice the sample spinning frequency. The right hand side of eq. 2 results when the constants are evaluated for the coaxial cell used in this work. Under the condition of equal peak height of main band and first sideband, the argument of the Bessel function takes the value of 1.4347.

The absolute signs of all $\nu_s^{(i)}$ (where $i = 1$ and 3) are determined by the field-gradient method proposed by Malinowski and Pierpaoli (9). In their method, if a change in the z-gradient produces asymmetric intermediate sidebands to the right (left) hand side of the main peak of the material in the annular region, then $\nu_s^{(i)}$ is positive (negative). Similarly, changing the x-gradient when $\nu_s^{(i)}$ is positive (negative) will produce asymmetric sidebands to the left (right) of the main peak of the annular region. The magnitude of $\nu_s^{(i)}$ should be determined only after all intermediate sidebands have been eliminated.

Since the packed bed – reference interface is cylindrical in a coaxial cell, corrections for differences in bulk susceptibility between reference and packed beds have to be made as indicated in eq. 1. Bernstein and Frei (10) pointed out that no additional susceptibility corrections need be made if the interface between two sample regions is spherical. For packed beds of spherical resin beads suspended in water, the interface between the external and internal water phases is spherical. Therefore, both regions of the packed beds experience the same magnetic field strength and no corrections have to be made for differences in bulk susceptibilities of the external and internal water phases.

Experimental

The ion exchange resins employed were Dowex AG 50W, 20–50 mesh, purchased from BioRad Laboratories. Details of resin pretreatment and of sample preparation have been reported (4). The exchange capacities of the sodium-form resin were found to be 4.62, 4.51, and 4.33 meq/g dry resin for crosslinkings of × 4, × 8, and × 12, respectively; the water contents determined by the centrifugation method for the three sodium-form resins were 0.62, 0.45, and 0.36 g/g wet resin, respectively. Spectra were taken at a probe temperature of 39 ± 1 °C on a Varian A-60A p.m.r. spectrometer utilizing a Hewlett–Packard Model 200AB wide range oscillator and a Hewlett–Packard Model 523DR frequency counter. The coaxial cell was a Wilmad Glass model number 516 of 5 mm outer diameter. The precision of the bulk susceptibilities is better than ±0.01 p.p.m.; the precision of uncorrected chemical shifts is better than ±1 Hz.

Results and Discussion

Results of studies on 10 ionic forms of Dowex 50W of crosslinkings × 4, × 8, and × 12 are summarized in Table 1.

The values of $\chi_{v,p}$ are all fairly similar to $\chi_{v,polystyrene}$ (= −0.690) (1) and to χ_{v,H_2O} (= −0.720). For ions in a given group the absolute value of $\chi_{v,p}$ increases with an increase in counter ion mass, as expected (11). For a given counter ion $|\chi_{v,p}|$ increases slightly with a decrease in water content of the ion-exchanger phase. The bulk susceptibility of the ion-exchanger bead, $\chi_{v,b}$, can be estimated by assuming additivity of the volumetric susceptibilities (12) of the two phases in the packed bed. For resin beads suspended in water, $\chi_{v,b}$ can be calculated from

$$[3]\quad \chi_{v,p} = 0.40\chi_{v,H_2O} + 0.60\chi_{v,b}$$

where the coefficients represent the approximate volume fractions of the two phases.

The constancy of the corrected chemical shifts for the external water calculated from eqs. 1 and 2 substantiates the method since the uncorrected chemical shifts for the external water (see Table 1) varied over the range 5.02–5.15 p.p.m. Chemical shifts for internal resin water referred to external tetramethylsilane–chloroform which were not corrected for susceptibility differences

are generally in good agreement with the corrected chemical shifts since in chloroform, $\chi_{v,TMS}$ ($= -0.727$) differs in most cases so slightly from $\chi_{v,p}$ that the susceptibility correction in eq. 1 is insignificant.

Since the dependence of $\chi_{v,p}$ upon counter ion mass and crosslinking is established fairly completely in Table 1, values of $\chi_{v,p}$ for other resin forms of various crosslinkings can be estimated and the corresponding corrected chemical shifts can be calculated using eq. 1. Bulk susceptibility corrections become extremely important in studies of ion exchanger – mixed solvent systems (6, 7) where for many solvent pairs $\chi_{v,p}$ varies considerably with solvent composition. The method utilized in this work is applicable to any system containing spherical particles suspended in a fluid phase.

The widths at half height of the external water peak, w_e, increase with an increase in the absolute value of $\chi_{v,b}$, as predicted by Gordon (1). The correspondence between $\chi_{v,b}$ and w_e shown in Table 1 indicates that values of $\chi_{v,b}$ can be estimated to better than ± 0.02 from a determination of the width at half height of the external water peak.

The Norrish Type II Photodecomposition of Di-*n*-Butyl Terephthalate[1]

M. DAY AND D. M. WILES
Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received May 11, 1971

The liquid phase photolysis of undiluted di-*n*-butyl terephthalate yields 1-butene and carboxylic acid end groups as a result of a Norrish Type II photochemical rearrangement reaction. Quantum yields for the production of these two products have been determined and found to be $\phi_{1-\text{butene}} = 0.017$ and $\phi_{\text{COOH}} = 0.022$ in vacuum and $\phi_{1-\text{butene}} = 0.0050$ and $\phi_{\text{COOH}} = 0.0056$ in air.

La photolyse en phase liquide du téréphtalate de di-*n*-butyl non dilué conduit au butène-1 et à des terminaisons carboxyliques. Ceci est le résultat de la transposition photochimique du type "Norrish II". Les rendements quantiques de la formation de ces deux produits ont été déterminés et sont de $\phi_{\text{Butène-1}} = 0.017$ et $\phi_{\text{COOH}} = 0.022$ dans le vide et $\phi_{\text{Butène-1}} = 0.0050$ et $\phi_{\text{COOH}} = 0.0056$ dans l'air.

Canadian Journal of Chemistry, 49, 2916 (1971)

The photolyses of aliphatic and aromatic esters in which a β hydrogen atom occurs in the alcohol portion of the ester are known to yield an olefin and an acid as a result of an intramolecular process analogous to the Norrish Type II split of aldehydes and ketones (1–7). As a part of our studies of the photochemical decomposition of poly(ethylene terephthalate) (PET) in vacuum and air, we have examined the liquid phase photolysis of di-*n*-butyl terephthalate (DBT). Our objective was to determine the extent of Norrish Type II cleavage occurring in the photolysis of an aromatic di-ester similar in structure to the polymer, PET.

Degassed or air saturated undiluted DBT (4.5 ml) was sealed off after filling in a quartz cell (1 cm path). The ester was irradiated with the light from an Osram super pressure mercury lamp (HBO 200 W), filtered through a Corning filter CS 7-54 (range 225–420 nm) with 140 nm half band width and a 10 cm path water filter. After irradiation, volatile products were removed via a break seal and analyzed on a gas chromatograph equipped with a flame ionization detector. Quantitative analysis of the photolysis products indicated 1-butene was the main product. The concentrations of carboxylic acid end groups formed in the irradiated liquid as a result of photolysis were determined either by titrimetric analysis, or more conveniently by differential i.r. spectroscopy of the irradiated ester in comparison with the original liquid. The optical

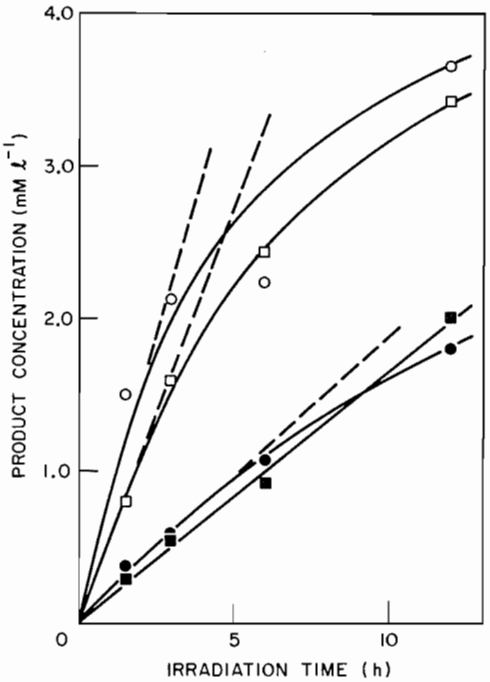

FIG. 1. Rate of formation of 1-butene in vacuum (□) and air (■) and —COOH in vacuum (○) and air (●) as a function of irradiation time.

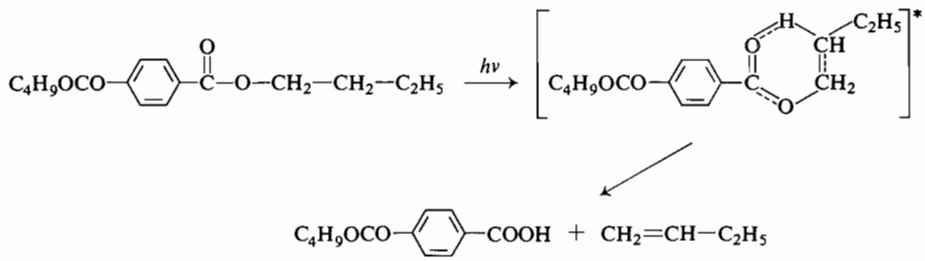
density changes of the band centered at 3290 cm^{-1} was used to calculate the —COOH concentration. A molar extinction coefficient of $\varepsilon = 450 \pm 30$ was obtained from a comparison of the $o.d._{3290}$ and acid equivalence of several samples by non-aqueous potentiometric titrations.

The rates of formation of 1-butene and —COOH end groups as a function of irradiation time in air and vacuum are illustrated in Fig. 1. From these results, together with the light intensities on the cells (calibrated with an Eppley thermopile), the known spectral distribution of the lamp and the extinction coefficient for the undiluted DBT as a function of wavelength, calculations were made of the initial quantum yields for these two products. The photolysis of DBT under vacuum conditions gave acid end groups and 1-butene with initial quantum efficiencies of $\phi_{COOH} = 0.022$ and $\phi_{1-butene} = 0.017$. When the photolysis was carried out in air the initial quantum yields were reduced, ($\phi_{COOH} = 0.0056$; $\phi_{1-butene} = 0.0050$).

These results indicate that the following Norrish Type II intramolecular processes occur on photolysis



This process is consistent with the observations that 1-butene and carboxylic acid are the main products, and that the rates of formation of 1-butene and carboxylic acid end groups are comparable. The quantum yields obtained are also comparable to those reported for other esters of aromatic carboxylic acids photolyzed in solution (6, 7). The lower quantum yields obtained in air may be due to the influence of oxygen, in reducing the efficiency of reaction of the triplet-derived intermediate as suggested by Ausloos (5).

Thus the importance of the Norrish Type II cleavage in the photolysis of an aromatic diester has been established under our experimental conditions. This concludes our model compound investigation by establishing a possible mechanism which PET (the polymeric counterpart of DBT) may be expected to undergo. The actual photolysis of the polymer PET will be reported in a future publication.

Electron Affinities from Thermal Proton-Transfer Reactions: C_6H_5 and $C_6H_5CH_2$

D. K. BOHME
Department of Chemistry, York University, Toronto, Ontario
AND
L. BREWSTER YOUNG
Mobil Chemical Company, Edison, New Jersey 08817

Received June 4, 1971

The observation of the preferred direction of proton transfer reactions in the gas phase at 300 °K has been employed to bracket the electron affinity, e.a., of the radicals C_6H_5 and $C_6H_5CH_2$ using well-established values for electron affinities and bond energies. The results indicate that 1.2 eV ≤ e.a.(C_6H_5) ≤ 1.6 eV and that 0.4 eV ≤ e.a.($C_6H_5CH_2$) ≤ 0.9 eV.

Les observations relatives à la direction préférentielle dans les réactions de transfert de proton en phase gazeuse et à 300 °K, ont été utilisées pour encadrer la valeur e.a. d'électron affinité pour les radicaux C_6H_5 et $C_6H_5CH_2$; à cet effet, des valeurs d'électron affinité et d'énergie de liaison bien établies, ont été utilisées. Les résultats indiquent que 1.2 eV ≤ e.a.(C_6H_5) ≤ 1.6 eV et que 0.4 eV ≤ e.a.($C_6H_5CH_2$) ≤ 0.9 eV.

Canadian Journal of Chemistry, 49, 2918 (1971)

Chemically useful values for the electron affinity of small molecules have recently become accessible through gas-phase investigations of the kinetics of negative ion – molecule reactions. For example, exothermic and endothermic negative-ion charge-transfer reactions have been employed to bracket unknown electron affinities between well-established electron affinities (1, 2). Electron affinities of molecules have also been determined from the translational energy thresholds for endothermic charge transfer reactions involving atomic halogen anions (3).

We report here the determination of electron affinities of selected radicals from bracketing experiments involving proton transfer reactions of the type

$$[1] \qquad X^- + YH \leftrightarrows Y^- + XH$$

proceeding in the gas phase at 300 °K. Although bracketing experiments can surpass the precision of other earlier techniques, they lack the precision of photodetachment (4) and electron impact (5) methods which, however, are often limited to the study of the electron affinity of atoms and small molecules.

The determination of the preferred direction of proton transfer in reaction 1 identifies the sign of the standard free energy change which, in turn, identifies the sign of the standard enthalpy change if the change in standard entropy can be neglected. The standard enthalpy change, $\Delta H°$, for reaction 1, is related to bond dissociation energy, D, and electron affinity, e.a., parameters in the following manner

$$[2] \quad \Delta H° = D(YH) - D(XH) + \text{e.a.}(X) - \text{e.a.}(Y)$$

Thus a knowledge of the sign of $\Delta H°$ and three of the four energy parameters allows the determination of a limiting value for the fourth parameter. The parameter of interest in these studies was the electron affinity of either X or Y.

The experiments were performed in a flowing afterglow system at the National Oceanic and Atmospheric Administration, Environmental Research Laboratories, in Boulder, Colorado. Details of the method of operation and data analysis have been thoroughly described elsewhere (6, 7). Helium was used as the buffer gas at a pressure *ca.* 0.4 Torr. H^- ions were generated by 25 eV electron impact on NH_3. The production of OH^- and $C_3H_5^-$ has been described previously (7) as has the generation of $C_6H_5^-$ and $C_6H_5CH_2^-$ (8). The concen-

*Units in cm^3 molecule^{-1} s^{-1}, (-11) denotes 10^{-11}.

trations of water, benzene, ethanol, and toluene in the reaction region were measured by monitoring the increase in total pressure in the reaction region as the vapors were introduced. As a result of the insensitivity of the capacitance manometer (with a 10 Torr sensing head) used in these experiments, the rate determinations for fast reactions using this technique led only to limiting values for rate constants.

A summary of the rate constant data obtained is given in Table 1. The last reaction listed has been reported previously (7). The ratio of the forward to the reverse rate constant was taken to be equal to the thermodynamic equilibrium constant since the energy distribution of both the ions, which undergo many thousand collisions with helium atoms before entering the reaction region, and the neutral reactants, which are added in thermal equilibrium at the operating temperature, is expected to be Boltzmann in all the forward and reverse reactions investigated. For each of the reactions listed in Table 1, the thermodynamic equilibrium constant was found to be greater than 1. Hence the standard free energy change is negative for all these reactions as written. We now make the assumption that the transfer of a proton is not accompanied by a significant change in entropy, *i.e.*, $T\Delta S^\circ \ll \Delta H^\circ$. Consequently, the five reactions listed in Table 1 are taken to be exothermic or thermoneutral at 300 °K. Relation 2 then leads to the limiting values 1.2 eV $\leq$ e.a.(C_6H_5) $\leq$ 1.6 eV and 0.4 eV $\leq$ e.a.($C_6H_5CH_2$) $\leq$ 0.9 eV. The electron affinities of H, OH, and C_2H_5O are taken to be well established at 0.754 eV (9), 1.83 eV (10), and 1.68 eV (11), respectively. The bond energies for H—H, HO—H, C_2H_5O—H, C_6H_5—H, and $C_6H_5CH_2$—H were taken to be 4.477 (12), 5.11 (12), 4.43 (13), 4.86 (14), and 3.69 (13), respectively.

The authors are aware of only one previous experimental determination of the electron affinity of these radicals. Page and Goode, who employ the magnetron technique they developed (15), report values ranging from 2.15 to 2.46 eV for e.a.(C_6H_5) and values ranging from 0.76 to 0.84 eV (with one value of 2.5 eV) for e.a. ($C_6H_5CH_2$). An early molecular orbital theory calculation by Hush and Pople (16) yielded e.a.($C_6H_5CH_2$) = 0.69 eV. The limiting values for e.a.($C_6H_5CH_2$) determined in these studies are in good agreement with the values (0.76 to 0.84 eV) determined by the magnetron technique and the value obtained from theoretical calculations. However, the limiting values determined in this study suggest a value for e.a.(C_6H_5) considerably lower than that obtained from the magnetron technique. An electron affinity e.a.-(C_6H_5) > 2.0 eV would make the first reaction in Table 1 endothermic (and $\Delta G^\circ > 0$) for ground-state reactants at 300 °K by more than 0.3 eV. We expect that our kinetic measurements deal with ground-state $C_6H_5^-$ ions and not $C_6H_5^-$ excited. Hence our result should represent a more accurate value for the electron affinity of C_6H_5.

Infrared Spectra of Some Alkyl Platinum Compounds. Part II. Assignment of the CH Stretching Modes of a Methyl Group

B. A. MORROW[1] AND Y. BEAUCHAMP

Department of Chemistry, University of Ottawa, Ottawa, Canada

Received May 5, 1971

Several isotopically substituted triphenylphosphine stabilized dimethyl platinum compounds of the type $(Ph_3P)_2PtMe_2$ where Me = CH_3, CH_2D, CD_2H, and CD_3 have been prepared and their infrared spectra in the CH and CD stretching regions have been examined. The assignments of the stretching vibrations of the methyl group have been confirmed by means of an application of the Average Rule for isotopically substituted species. The possible application of the Average Rule as a general method for assigning CH stretching modes is discussed and it is suggested that the method could be used to confirm some recently proposed reassignments of the traditional Fox and Martin assignments. The method may also be used by surface chemists as a means of determining the number of hydrogen atoms in an adsorbed XH_n species.

Les composés diméthylés du platine du type $(Ph_3P)_2PtMe$, dans lesquels Me = CH_3, CH_2D, CD_2H et CD_3 ont été préparés et leurs spectres infrarouges dans les régions de vibrations d'élongation de CH et CD ont été examinés. Les attributions des vibrations d'élongation du groupe méthyle ont été confirmées grâce à l'application de la Règle de la Moyenne pour des espèces substituées par des isotopes. L'application possible de la Règle de la Moyenne comme une méthode générale pour l'attribution des modes de vibration CH est discutée et on suggère que la méthode pourrait être utilisée pour confirmer quelques réattributions récemment proposées des attributions traditionnelles de Fox et Martin. La méthode pourrait être aussi utilisée dans la chimie des surfaces comme un moyen de déterminer le nombre d'atomes d'hydrogène dans une espèce adsorbée XH_n.

Canadian Journal of Chemistry, **49**, 2921 (1971)

Introduction

The surface chemist who wishes to use infrared spectroscopy in order to study the nature of a surface–adsorbate species is severely hampered in making a complete vibrational analysis because the adsorbent is usually totally absorbing in-part of the infrared region (1). This problem is particularly critical in studying the spectra of hydrocarbons adsorbed on silica or alumina supported metal catalysts since the spectral regions below about 1200 cm^{-1} will be totally masked by the strong infrared absorptions of silica. Further, since it is usually only possible to utilize metal loadings of the order of 10–15% by weight, the deformation bands in 1400 cm^{-1} spectral region are often so weak so as to be undetectable (2). As a result, surface chemists often have to base any interpretation on a limited spectral region, which for hydrocarbons is usually the CH stretching region. In Part 1 of this series (3), the infrared spectra of some alkyl platinum compounds were discussed in relation to the spectra of chemisorbed hydrocarbons. In the present paper, the spectra of some partially deuterated methyl–platinum compounds are discussed. Because of the limited spectral region, the surface chemist often has to resort to isotopic substitution in order to confirm a spectral assignment, and it is important that the effects of such substitutions be well understood with reference to the spectra of model compounds.

A second point of interest is a current concern over the exact assignments of the CH stretching modes of a methyl group. Organic chemists have for years used the Fox and Martin assignments as an aid to identify this functional group (4, 5) and several interesting papers have recently

appeared in the literature in which these assignments are questioned (6, 7). This aspect will be discussed further later, but suffice it to say that it was anticipated in Part I (3) that the spectra of the partially deuterated methyl compounds should throw some light on the assignment problem. In this paper, the compounds $(Ph_3P)_2PtMe_3$ have been synthesized (Ph = phenyl, and Me = CH_3, CH_2D, CHD_2 or CD_3) and their infrared spectra in the CH and CD stretching regions have been analyzed.

Experimental

The *cis*-bis(triphenylphosphine)dimethylplatinum derivatives were prepared as in Part I (3). The CD_3Br, CH_2DBr, and CHD_2Br were obtained from Merck, Sharp and Dohme Ltd. of Montreal and were claimed to be of 98% isotopic purity (99.5% for CD_3Br). All spectra were run as saturated solutions in CCl_4 (about 10 mg/ml) on a Perkin–Elmer model 13G infrared spectrometer using a spectral slit width of about 3 cm^{-1}. The cell path length was 0.992 mm.

Results

Spectra in the CH and CD stretching regions are shown in Fig. 1, and the wavenumbers of the observed band of the methyl group ($< 3000\ cm^{-1}$ in the CH stretching region) are listed in Table 1.

Assignments

A methyl group is expected to give rise to three valence stretching modes in the infrared near 2800–3000 cm^{-1} for a CH_3 group, or near 2200–2000 cm^{-1} for a CD_3 group (5). When the 3-fold axis of symmetry is preserved, as for example in the methyl halides, one vibration is classified as being symmetric (ν_s) and two are asymmetric (ν_a) with respect to this axis, and the two asymmetric modes are degenerate. However, in most molecules which possess a methyl group, the 3-fold axis of symmetry is destroyed; but the

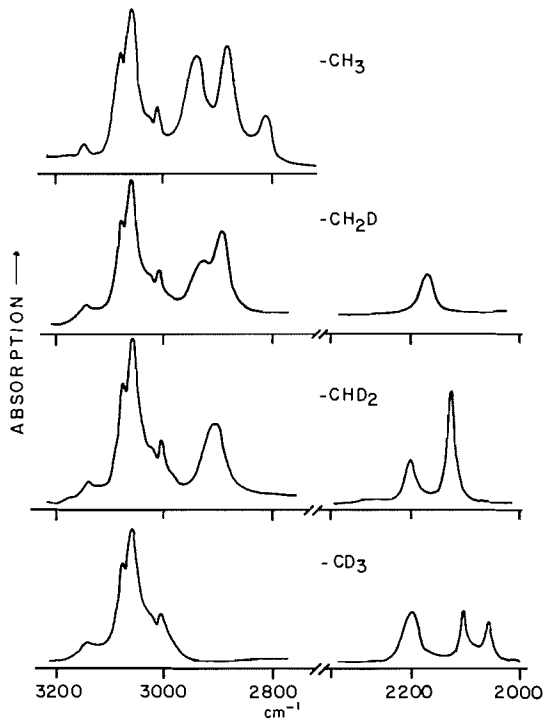

FIG. 1. Infrared spectra in the ν_{CH} and ν_{CD} region of $(Ph_3P)_2PtMe_2$ where Me = CH_3, CH_2D, CHD_2, and CD_3. All spectra were run as approximately 10^{-2} *M* solutions in CCl_4.

CH stretching vibrations are still commonly classified as being symmetric or asymmetric with respect to the localized 3-fold axis of the methyl group. In this case, the degeneracy of the two ν_a modes should be removed, but in practice, the vibrations of a methyl group are rather insensitive to its surroundings and the degeneracy is often preserved.

In a partially deuterated methyl group, CH_2D or CHD_2, the 3-fold symmetry is always destroyed and three distinct bands are to be expected. Therefore, a CH_2D group will give rise to one CD stretching mode and two CH_2 stretching modes, classified as ν_s and ν_a depending on whether the two CH bonds are vibrating in phase (symmetric) or out of phase (asymmetric).

In the present work, the infrared bands of the partially deuterated methyl derivatives, CH_2D and CHD_2 clearly show the predicted number of bands (Table 1) and where two bands are observed, the higher frequency mode can be assigned to ν_a for that species. These assignments can be further checked since the Average Rule (8) predicts that the XH and XD stretching frequencies of an XHD species should be the average of ν_a and ν_s of the corresponding XH_2 and XD_2 species, respectively. In the present case this rule is closely obeyed for CH_2D and CD_2H (Table 1), as it always is in other cases (8–10) although to be strictly correct this rule is an approximation which when valid should apply only to the root-mean-square values of the harmonic frequencies.

The spectrum of the CH_3 and CD_3 derivatives both exhibit three bands in the respective CH or CD stretching regions. This 3-band spectrum is commonly observed for the methyl group in a variety of environments although the band positions may be shifted to slightly higher or lower wavenumber depending on the nature of the atom to which the methyl carbon is attached (9, 11–15). The traditional Fox and Martin assignments (4) for a methyl group in a hydrocarbon place the "degenerate" ν_a modes near 2962 ± 10 cm^{-1}, and ν_s near 2872 ± 10 cm^{-1}, and accompanying these, a weaker band is often observed near 2810 cm^{-1} which is assigned to an overtone of a CH_3 deformation mode near 1450 cm^{-1}. Using this type of assignment scheme for the methyl platinum derivative, ν_a would occur at 2934 cm^{-1}, ν_s at 2878, and the band 2806 would be an overtone enhanced in intensity by Fermi resonance interaction with ν_s. It is also possible that the three bands could be assigned to the three anticipated CH stretching fundamentals since the 3-fold axis of symmetry is strictly speaking non-existent, or it is possible that the order of assignments suggested above are incorrect. The latter might particularly be the case for the CD_3 derivative where all three bands are of comparable intensity. There is no reason to assume that a Fermi resonance enhanced overtone should not be more intense than a fundamental; this situation has been invoked in a recent reassignment of the CH stretching bands of the Group IV tetramethyl derivatives (7).

There are numerous examples in the literature where assignments other than the Fox and Martin assignments are made (9); it is particularly common to ascribe the weaker low wavenumber band near 2810 cm^{-1} to ν_a. Indeed Adams (12) has examined the spectrum of $[(CH_3)_3P]_2Pt(CH_3)_2$ and $[(CH_3)_3P]_2Pt(CD_3)_2$ and although the spectrum of the $Pt–CH_3$ portion in the CH stretching region is partly obscured by the strong absorptions of the methyl phosphines, the CH stretching bands of $Pt–CH_3$ appear to be close to ours. On the basis of isotope shifts, Adams assigned a low wavenumber band at 2815 to ν_s, and was unable to decide which of the two "shoulders" near 2930 and 2885 was due to ν_a. Other examples are discussed below.

The correct assignments in the present case can be deduced from the wavenumbers of the bands of the partially deuterated species. Thus, using the Average Rule (8) again, the mean value of the three stretching modes of a methyl group should be very nearly equal to the single CH stretching mode of CHD_2, or to the average of two CH stretching modes of CH_2D. For the CH_3 derivative, if we assign the band at highest wavenumber to the doubly degenerate ν_a, and that at intermediate wavenumber to ν_s of CH_3, the calculated mean shown in Table 1 is somewhat higher than the mean of the two CH stretching vibrations of CH_2D, or of the single ν(CH) of CHD_2. A similar result is found for the CD_3 vibrations (Table 1). However, if, as assumed, ν_s is perturbed by Fermi resonance interaction with the band at 2806 (2050), then using the method of Hansen and Dennison (16, 17) to correct ν_s for this interaction, the predicted mean of the CH_3 and CD_3 vibrations is almost exactly equal to the "experimental" mean from CH_2D and CD_2H. This agreement is in fact far better than to be expected considering the approxima-

TABLE 2. Application of the Average Rule to the XH stretching vibrations of some pyramidal XH_3 species

Molecule	Wavenumbers (cm^{-1})	Average of ν_a and ν_s (cm^{-1})	Reference number

CH_2DI	3057 (ν_a) 3002 (ν_s)	3030	17
CHD_2I	3030		17

tions of the Average Rule, and of the Fermi resonance correction. However, it should be pointed out that using literature data, similar excellent agreement between predicted and "experimental" wavenumbers of the NH stretching modes of the partially deuterated ammonias (18) and for the partially deuterated methyl halides (9, 17) is also obtained (Table 2). Therefore, this technique clearly demonstrates the correctness of this assignment for the methyl stretching vibrations in both the CH and CD stretching regions, since no other assignment is compatible with the experimental results.

Further, since the wavenumbers of the bands observed by Adams for the Pt methyl group in $[(CH_3)_3P]_2Pt(CH_3)_2$ are very close to those observed in this work (12), it is clear that Adams' original assignments must be incorrect.

Discussion

The main conclusion to be reached from the present investigation is that caution must be exercised in assigning the CH stretching modes of a methyl group. As stated above, there are many examples in the literature where three bands have been observed from a methyl group in the CH stretching region and where the two higher wavenumber bands have been assigned to the two ν_a modes for which the degeneracy is assumed to be removed, and the low wavenumber band is assigned to ν_s. Some cases are listed in Table 3 and this work throws some doubt on the correctness of these assignments. Winther and Hummel (6) have recently re-examined the spectra of some ethyl containing compounds and have challenged the Fox and Martin assignments for the CH stretching modes in hydrocarbons, suggesting instead that ν_a is to be expected near 2962 cm^{-1}, but that ν_s should lie between 2940–2910 cm^{-1} and that the band near 2872 cm^{-1} which has formerly been assigned to ν_s is in fact an overtone of the methyl deformation mode. Apart from a shift in the absolute wavenumber, the difference in wavenumber between each of the three bands in this and other work is more compatible with Winther and Hummel's re-assignment. Therefore, the three bands listed in Table 3 for the stretching vibrations of a methyl

	2939	Combination band	
	2873	ν_s	

group should possibly be re-assigned in order of decreasing wavenumber to ν_a, ν_s, and a Fermi resonance enhanced overtone of a methyl deformation mode. Graham (7) has independently proposed this type of re-assignment for the Group IV tetramethyl compounds, and has suggested that a study of the temperature dependence of the half widths of these bands would confirm the correctness of these assignments. We would suggest that a study of the partially deuterated species, which is intrinsically simpler, could also be used as a check.

Conclusions

The essential correctness of the Average Rule has been demonstrated for the CH stretching modes of a methyl group of $(Ph_3P)_2Pt(CH_3)_2$ and its validity was also verified using literature data for some of the methyl halides, and for the NH stretching modes of ammonia. Surface chemists may reasonably safely use this rule as a means of determining the number of hydrogen atoms in an adsorbed terminal X—H_n group when studying the appropriate infrared spectra of the partially deuterated species. The method of partial deuteration also offers a method of checking the assignments of the CH stretching modes of compounds which contain methyl groups.

Complexes of Tungsten Halides with Group VI Donors: Adducts with Triphenylphosphine Chalcogenides

P. M. BOORMAN AND K. J. REIMER

Department of Chemistry, The University of Calgary, Calgary 44, Alberta

Received February 15, 1971

The preparation of complexes with the empirical formula WCl_5L (L = Ph_3PS, Ph_3PSe) and $WBr_4.Ph_3PS$ is reported. The tungsten chloride adducts have been formulated as $[W_2Cl_8L_2]2Cl$ on the basis of infrared spectra, molecular weight, and conductance measurements. The complex WBr_4Ph_3PS is probably a non-ionic dimer, but solubility problems make this suggestion tentative. No corresponding complex with Ph_3PSe could be isolated.

The shifts in ν(P—X) (X = S, Se) upon coordination are amongst the largest ever reported, and are indicative of bridging behavior by these ligands.

La préparation de complexes ayant pour formule empirique WCl_5L (L = Ph_3PS, Ph_3PSe) et $WBr_4.Ph_3PS$ est rapportée. Les produits d'addition avec le chlorure de tungstène ont pour formule $[W_2Cl_8L_2]2Cl$; ceci d'après les spectres infrarouges et les mesures de masse moléculaire et de conductance. Le complexe WBr_4Ph_3PS est probablement un dimère non ionique; des problèmes de solubilité rendent cependant cette suggestion hypothétique. Aucun complexe correspondant avec Ph_3PSe n'a été isolé.

Les déplacements de ν(P—X)(X = S, Se) d'après la coordination sont parmi les plus grands jamais rapportés et sont significatifs du phénomène de formation de ponts par ces ligands.

Canadian Journal of Chemistry, 49, 2926 (1971)

Introduction

Our interest in the chemistry of tungsten halides (1, 2) has led us to investigate their reactions with a wide variety of ligands with group VI donor atoms. We report here the reactions of triphenylphosphine chalcogenides with tungsten(VI) chloride and tungsten(V) chloride and bromide.

Although phosphine oxides in general, and Ph_3PO in particular, are known to form a wide variety of complexes with transition metal halides (3–7) and carbonyls (8) much less is known of comparable reactions with phosphine sulfides, selenides, and tellurides. Since reactions of tungsten halides with phosphine oxides had been reported previously (9) as yielding materials such as $WO_2Cl_2.2Ph_3PO$, which contained W=O bonds, we have confined our attention in the first instance to reactions with Ph_3PS and Ph_3PSe.[1]

Experimental

All preparative and handling procedures were carried out in a dry, nitrogen-filled glove-box.

[1]Extension to the telluride analogue was not possible since the latter compound is not stable (10).

Materials

Ph_3PS was obtained from Aldrich Chemicals and used after drying *in vacuo*. Ph_3PSe was prepared by the published methods (11, 12). Tungsten hexachloride and pentabromide were obtained from Alfa Inorganics, Beverley, Mass., and were carefully resublimed in sealed, evacuated tubes several times before use. WCl_5 was prepared by disproportionation of WCl_4 (13). Solvents were purified as before (1) and were thoroughly degassed before use.

Microanalyses were carried out by Alfred Bernhardt Microanalytical Laboratories. Halide determinations were also carried out independently in our laboratories by a standard potentiometric method.

Preparations

Two general synthetic methods were employed. Method II is preferable for reactions involving the more insoluble tungsten(V) halides.

Method I

Approximately 6 g of WCl_6 was dissolved in 500 ml of dry CCl_4 by magnetic stirring *in vacuo* and then the solution was filtered to remove any insoluble material. To the filtrate a 1.5:1 molar excess of the ligand was added via a filter stick. Precipitation of the product was immediate; it was filtered off on the stick and thoroughly washed with CCl_4 then dried *in vacuo*.

Method II

To a reaction flask containing a magnetic stirring bar and a suspension of the halide (*ca.* 1.5 g) in 150 ml of CCl_4 a slight molar excess of the ligand in 200 ml of CCl_4 was added. The reaction flask was evacuated and the mixture stirred for a period of 4 days to ensure com-

plete reaction. The product was then filtered off, washed with CCl_4 then dried *in vacuo*.

WCl_5Ph_3Ps and WCl_5Ph_3PSe

These compounds were prepared in almost quantitative yield from WCl_6 and the ligands by Method I. WCl_5Ph_3PS was also prepared from WCl_5 by Method II. Its properties were identical when prepared by either route. Analytical data for the new compounds are presented in Table 1.

WBr_4Ph_3PS

This compound was prepared from WBr_5 by Method II. Reaction of WBr_5 and Ph_3PS using Method I yielded insignificant quantities of a green powder. It was impracticable to investigate these further although the identity of this product could well be WBr_5Ph_3PS.

$WBr_5 + Ph_3PSe$

This reaction was attempted by Method II but the product proved to be non-stoichiometric regardless of slight variations in the synthetic procedure.

Attempted Preparations of W(IV) Complexes

A standard technique for synthesis of compounds of the general formula WX_4L_2 is to displace RCN from the complexes $WX_4.2RCN$ with the appropriate ligand (14). In spite of numerous attempts using a variety of conditions we were unsuccessful in preparing W(IV) complexes with Ph_3PS or Ph_3PSe by this technique. Products obtained invariably contained some alkyl cyanide and free phosphine chalcogenide.

Physical Measurements

Conductance measurements were performed on *ca.* 10^{-3} *M* solutions in nitrobenzene at 25 °C, using an Industrial Instruments Model RC-18 Conductance Bridge.

Infrared spectra were recorded with a Perkin–Elmer Model 621 spectrophotometer, using Nujol mulls between CsI plates. Attempts to measure spectra in solution in the ν(PS) stretching frequency region were not successful, due either to instability of solutions or strong absorption of the solvent.

Electronic spectra (200–750 mμ) of dilute solutions of the complexes in acetonitrile were obtained using a Perkin–Elmer Model 202 spectrophotometer. Diffuse reflectance spectra were recorded over the range 270–700 mμ using a Cary 15 spectrophotometer with a standard attachment.

Magnetic susceptibility measurements were made at 22 °C by the Gouy Method. The susceptibilities were corrected for diamagnetism using Pascal's constants (15).

Molecular weight measurements were made cryoscopically in nitrobenzene. Temperatures were measured using an iron–constantan thermocouple connected to a Leeds and Northrup 7554 Model K4 potentiometer.

Results

The complexes with empirical formula WCl_5Ph_3PS (**1**) and WCl_5Ph_3PSe (**2**) were isolated as air sensitive yellow-green powders. All attempts at isolating crystalline samples using a wide variety of solvents and techniques were unsuccessful. The compounds decompose below their melting points. They were insoluble in non-polar solvents but moderately soluble in $PhNO_2$, $MeNO_2$, and MeCN.[2]

Addition of both complexes to benzene resulted in the formation of dark brown oil, and attempted preparation of **1** in benzene as solvent also gave rise to an oil of indefinite composition.

The compound of empirical formula WBr_4Ph_3PS (**3**) was isolated as an exceptionally air-sensitive brown solid. The analogous compound WBr_4Ph_3PSe could not be isolated in a pure form, although there was evidence from infrared spectral data of complex formation between WBr_5 and Ph_3PSe. **3** exhibited only slight solubility in $PhNO_2$ and $MeNO_2$ and was also insoluble in non-polar organic solvents.

Solution Measurements

Data are presented in Table 2. For compounds **1** and **2** the apparent molecular weights correspond best with values expected for dimers yielding 3 ions, *i.e.* $[W_2Cl_8L_2]^{2+}2Cl^-$. It will be noted that even allowing for the errors of such measurements the other likely formulations would have to be excluded. Furthermore when the conductance data are evaluated on this basis they show excellent agreement with molar conductance values expected for 2:1 electrolytes

[2]After standing for a few minutes solutions of **2** in $MeNO_2$ and MeCN deposited selenium, however.

Compound	Λ_m ohm^{-1} cm^2 (10^{-3} M)	Apparent molecular weight			
		Found*	Calculated		
			$[W_2Cl_8L_2]2Cl$	$[WCl_5L]$	$[WCl_4L_2][WCl_6]$
WCl_5Ph_3PS	40.2	465 ± 15	437	655	655
WCl_5Ph_3PSe	42.2	475 ± 15	468	702	702

*Molecular weight measurements were made at concentrations ranging from 10^{-3}–10^{-2} M.

(16). Allowing for some slight association of $[W_2Cl_8L_2]2Cl$ at the concentrations used for the molecular weight measurements, these data are very strong evidence for a binuclear structure.

The compound $WBr_4.Ph_3PS$ was insufficiently soluble to enable us to make molecular weight measurements, but the molar conductance of a 10^{-3} M solution in $PhNO_2$ was well below the value expected for a 1:1 electrolyte, when the solution was initially prepared. On standing the conductance increased and a white precipitate appeared.

Infrared Spectra

The spectra were recorded over the range 1400–200 cm^{-1} and pertinent frequencies are presented in Table 3. Assignments were made for ligand vibrations on the basis of those suggested by Jensen and Nielsen (17). The ligand spectra change remarkably little upon coordination, so that the most interesting feature is the change in the P—X stretching frequency. King and McQuillan (18) reported decreases in ν(P—S) as 40–50 cm^{-1} and in ν(P—Se) as 18–20 cm^{-1} for metal halide complexes of these ligands. Different authors have attributed this shift to lower frequencies to two possible reasons. Firstly (18) the pπ → dπ bond (X → P) could be weakened upon forming a M ← X bond as is observed for phosphine oxide (8, 19) and arsine oxide (20) complexes. Alternatively the decrease in frequency could be attributed to a mass effect, considering the M—X unit as a point mass (21).

TABLE 3. Infrared frequencies for triphenyl phosphine sulfide and triphenyl phosphine selenide complexes

Complex	Frequencies* (cm^{-1})	
	P—X	W—Cl
Ph_3PS	632 vs	
WCl_5Ph_3PS	536 s	329 sh, 324 sh, 319 vs
WBr_4Ph_3PS	536 s	
Ph_3PSe	555 vs	
WCl_5Ph_3PSe	532 sh	331 sh, 329 sh, 320 vs

*v = very, s = strong, sh = shoulder.

For the tungsten halide complexes we observe ν(P—S) and ν(P—Se) to decrease by 96 and 23 cm^{-1}, respectively. This could therefore be attributed to one of three factors.

Firstly the large value we observe might possibly be ascribed to a mass effect. However, since complexes of Au(I), Au(III), and Hg(II) halides with Ph_3PS exhibit much smaller shifts, in spite of the higher mass of the metals concerned, this argument is discounted.

Secondly the importance of electronic effects and their possible influence on the P—S π-bond might be considered. Since in the tungsten compounds only one (W(V)) or two (W(IV)) d electrons would be available for back donation to the sulfur it might be argued that this could result in localization of charge from the pπ–dπ P—S bond on to the sulfur. Even if this were possible the argument is no longer plausible when the (P—S) stretching frequencies for complexes of Nb(V) and Ta(V) chlorides are observed to be "normal" (22).

Thus the only logical explanation lies in assuming that the ligands are in fact bridging between two tungsten atoms, thus supporting the binuclear structure discussed above.

The argument is supported by three further observations. Firstly the possibility of structures involving W=S and W—P bonds (for the Ph_3PS products) is excluded, since on allowing a sample of WCl_5Ph_3PS to stand in moist air for a few minutes the free ligand Ph_3PS is regenerated (as evidenced by the introduction of a strong band attributable to ν(PS) for uncoordinated Ph_3PS). Secondly some impure samples exhibited bands which could be attributed to free ligand, bridging ligand, and to normally bonded ligand.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

One such sample was obtained by dissolving WCl_5Ph_3PS in dichloromethane, and then removing the solvent.

Thirdly if the complex is binuclear there would be a strong possibility of chloride ions acting as the bridging groups. This situation is invariably accompanied by the observation of strong bands in the infrared spectrum at about 250 cm^{-1} (2, 23). Such bands are entirely absent.

While the above arguments have been directed specifically towards the compound $WCl_5.Ph_3PS$, all of our evidence supports the assignment of an identical structure for $WCl_5.Ph_3PSe$. In the latter case shifts in ν(P—Se) are much smaller. This has been attributed (18) to the less extensive P—Se π-character, and to the decreased sensitivity of ν(P—Se) owing to the larger mass of Se with respect to S.

We have not attempted to assign the bands in the region 300–340 cm^{-1} to individual ν(W—Cl) modes. However, assuming the local symmetry to be C_{2v} for the tungsten atoms, four W—Cl stretching modes would be predicted, whereas three are observed. Vibrational spectroscopy is frequently unreliable, however, for deducing the stereochemistry of complexes containing a heavy central atom (24).

For the compound $WBr_4.Ph_3PS$ ν(PS) is at the same frequency as for WCl_5Ph_3PS, hence again we suggest that the ligand is bridging. Little else can be derived from the spectrum of this compound, however.

Magnetic Moments and Electronic Spectra

The room temperature magnetic moments of the tungsten(V) complexes (Table 4) are within the range of values previously reported for tungsten in this oxidation state (25). We were unable to study the temperature dependence of the susceptibilities due to lack of facilities. The value of μ_{eff} for compound **3** is slightly lower than those often observed for W(IV). A variable temperature study of this compound would probably indicate antiferromagnetic behavior.

The electronic spectra (Table 5) suffer from the usual problems (1, 2) of interpretation in that the d–d bands are hidden by intense charge transfer bands with tails in the visible. However, it is notable that the reflectance spectra of **1** and **2** are extremely similar, again indicating that their structures are the same.

TABLE 4. Magnetic moment measurements

Compound	$\chi_m(\times 10^6)$	$\chi_m'(\times 10^6)$*	μ_{eff}(B.M.)
WCl_5Ph_3PS	55.7	361.9	0.925

WCl_5Ph_3PS	MeCN	235(39.4), 272(26.2), 297(32.8), 345(22.2), 370(6.96)
	Reflectance	305sh, 335sh, 370, 445sh
WCl_5Ph_3PSe†	Reflectance	285, 335sh, 370, 445sh

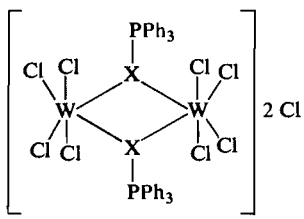
*$\varepsilon_{max} \times 10^{-3}$ l mol^{-1} cm^{-1} in parentheses.
†Solution measurement not possible due to decomposition of complex.

We were unable to obtain solution spectra of compound **3** due to its insolubility, and attempts to obtain reflectance spectra were also unsuccessful even when the sample was diluted with $MgCO_3$.

Conclusion

The first complexes of tungsten halides with Group V chalcogenides have been prepared. The solution properties of the WCl_5 adducts indicate that they should be formulated as $[W_2Cl_8L_2]2Cl$ (L = Ph_3PS, Ph_3PSe).

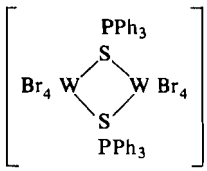
The decrease in (P—X) (X = S, Se) upon coordination suggests bridging behavior by the chalcogen, giving the structural formulation



Such behavior has not previously been reported for these ligands although it is known in the case of Ph_3AsO (26).

The compound $WBr_4.Ph_3PS$ also appears to contain bridging Ph_3PS ligands, although in this

case solubility problems precluded some solution measurements necessary for a more complete characterization. Since the compound is probably a non-electrolyte, and polymeric structures would require tungsten to have a coordination number greater than 6, the most likely structure is



This structure is consistent with all of our data, but must remain speculative in the absence of molecular weight, and X-ray data.

Extensive attempts to isolate crystals suitable for X-ray structural studies have proved unsuccessful. However, both of the chloride complexes exhibit weak powder diffraction patterns.

We thank the National Research Council of Canada for financial support and for a Scholarship (to K.J.R.). The experimental assistance of Mrs. Monica Reimer and Mr. N. D. Cowie is gratefully acknowledged. We also thank Dr. K. A. Kerr and Mr. Brian Smith for help in acquiring X-ray powder diffraction measurements.

The Vibrational Spectra of Silane and Germane Derivatives. Part IV. The Infrared and Raman Spectra of the Iodo(methyl)germanes

J. W. ANDERSON, G. K. BARKER, J. E. DRAKE,[1] AND R. T. HEMMINGS
Department of Chemistry, University of Windsor, Windsor, Ontario

Received April 19, 1971

The infrared and Raman spectra of the series of iodo(methyl)germanes, CH_3GeI_3, $(CH_3)_2GeI_2$, and $(CH_3)_3GeI$ have been recorded. A normal coordinate analysis based on a modified valence force field confirms the *a priori* assignments for all of the fundamental frequencies except the torsional modes.

Les spectres infrarouges et Raman des séries de iodo (méthyl) germanes, CH_3GeI_3, $(CH_3)_2GeI_2$ et $(CH_3)_3GeI$ ont été enregistrés. Une analyse normale de coordination, fondée sur un champ de force valentiel modifié, confirme les attributions *a priori* de toutes les fréquences fondamentales à l'exception des modes de torsion.

Canadian Journal of Chemistry, 49, 2931 (1971)

Introduction

The vibrational spectra of the chloro- and bromo(methyl)germanes, $(CH_3)_nGeX_{4-n}$ (X = Cl, Br; n = 1, 2, and 3) have been studied by several workers (1–7). The work reported here is part of a continuing program on the vibrational analyses of various methylated and halogenated derivatives of germane. We investigated the vibrational spectra of the three iodo(methyl)-germanes, $(CH_3)_nGeI_{4-n}$ (n = 1, 2, and 3) to assist the interpretation of the spectra of other halogeno(methyl)germanes with lower symmetry elements and to confirm the assignments of previous authors. A full normal coordinate analysis was carried out to yield the best set of harmonic force constants, the eigenvectors, and the potential energy distributions for the molecules. Near the completion of this work, a vibrational analysis of tri-iodo(methyl)germane and its deuterated analogue was reported (8) which is in excellent agreement with our studies.

Experimental

The iodo(methyl)germanes were all prepared in high yield by the reaction of hydrogen iodide on the appropriate chloro(methyl)germanes, a method which has been used successfully for almost quantitative iodination in germane chemistry (9, 10). The compounds were purified by trap-to-trap distillation or fractional sublimation on a conventional Pyrex-glass, greaseless vacuum line. All samples for spectral analysis were estimated to be > 98% pure from their ^1H nuclear magnetic resonance (n.m.r.) spectra recorded on a Jeol C-60 HL high resolution spectrometer. Thus, tri-iodo(methyl)germane, CH_3GeI_3, was prepared by condensing trichloro(methyl)germane (*ca.* 1.1 mmol) (commercial sample, Alfa Inorganics) and excess of hydrogen iodide (*ca.* 4 mmol into a 50 ml reaction vessel at −196° and allowing the mixture to warm to room temperature. Reaction was complete after 1 h when infrared analysis showed the only volatiles to be hydrogen chloride (*ca.* 3.3 mmol), in a trap at −196°, and hydrogen iodide (*ca.* 0.7 mmol) in a trap at −78°. A pale yellow solid remained in the reaction vessel which was purified by sublimation and subsequently shown from its m.p. (45°) and ^1H n.m.r. spectrum to be CH_3GeI_3. Similarly, di-iodo(dimethyl)germane, $(CH_3)_2GeI_2$, and iodo(trimethyl)germane, $(CH_3)_3GeI$, were prepared by the reaction of excess hydrogen iodide on dichloro-(dimethyl)germane and chloro(trimethyl)germane, respectively (both available commercially, Alfa Inorganics).

The Raman spectra were recorded at room temperature on a Spectra-Physics 700 laser–Raman spectrometer using a helium–neon source. The sealed Pyrex glass tubes (*ca.* 1 mm o.d.) contained *ca.* 3 cm column length of neat liquid (for the volatile $(CH_3)_2GeI_2$ and $(CH_3)_3GeI$) or solid (for the involatile CH_3GeI_3). To permit Raman polarization data the tri-iodide was also run in CS_2 solution.

Infrared spectra were recorded at room temperature in the range 4000–200 cm^{-1} on a Beckman IR-12 infrared spectrometer using CsI plates for the liquid-film spectra of $(CH_3)_2GeI_2$ and $(CH_3)_3GeI$, or the CS_2 "smear" spectrum of CH_3GeI_3. A gas cell (10 cm path length) fitted with KBr windows was used for the gas phase spectrum of $(CH_3)_3GeI$. Scale expansion facilities on both instruments enabled strong sharp bands to be estimated to ± 1 cm^{-1} in the infrared spectrum and ± 2 cm^{-1} in the Raman effect.

An IBM s/360-50 computer was used for the normal coordinate calculations with the program SOTONVIB, a modified version of that described by Schachtschneider as GMAT and FPERT (11). A SVFF calculation was first attempted followed by modification of the inter-

five non-degenerate a_1 vibrations; six doubly degenerate e vibrations; and a single a_2 vibration. The a_1 and e modes should all be infrared active with the former polarized and the latter depolarized in the Raman effect. The a_2 mode is inactive. All eleven active fundamentals are observed and their description is given in Table 3 along with the potential energy distribution amongst the force constants. We make no further comment in view of the recent work by Durig *et al.* (8).

Di-iodo(dimethyl)germane, $(CH_3)_2GeI_2$

As with the corresponding chloride (3) the molecule $(CH_3)_2GeI_2$ is conveniently considered as having C_{2v} symmetry. The twenty-seven fundamental modes can be divided into nine, infrared active, a_1 modes which should appear as polarized bands in the Raman effect; five, infrared inactive, a_2 modes which, however, are Raman active leading to depolarized bands; and six b_1 and seven b_2 modes, all of which are infrared active and should give depolarized

Raman bands. A full description of these is presented in Table 5 along with the potential energy distributions amongst the force constants. There is no evidence in the spectra that permits reasonable assignments for the methyl torsional modes, ν_{14} and ν_{20}, but all of the remaining fundamentals are assigned (Table 4).

Iodo(trimethyl)germane, $(CH_3)_3GeI$

The molecule is assumed to have C_{3v} symmetry where the CH_3 groups are in their most symmetric positions. Twenty-four fundamental vibrations can be expected of which eight are a_1-type, four are a_2-type, and twelve are e-type. A description of these is presented in Table 7 along with the potential energy distributions amongst the force constants. The symmetric and asymmetric GeC_3 stretches ν_6 and ν_{21}, are assigned to polarized and depolarized bands at 580 and 625 cm^{-1}, respectively. The splitting of these asymmetric and symmetric modes is comparable to that in $(CH_3)_2GeI_2$. The GeI stretching mode, ν_7, appears as a polarized band at 224 cm^{-1} in the Raman spectrum.

The GeC_3 symmetric and asymmetric deformations ν_8 and ν_{22} are not resolved and are apparently contained in the broad band centered at 179 cm^{-1} in the Raman effect. This accidental degeneracy has been observed in other systems (4, 5) but it is interesting to note that the polarization data give no indication of the near coincidence of the symmetric and asymmetric deformations.

The two symmetric CH_3 rocking modes, ν_5 and ν_{19}, are assigned to a broad band at 840 cm^{-1} in the infrared. The results of the normal coordinate analysis confirm the assignment of the other CH_3 rocking mode, ν_{20} to a band at 730 cm^{-1} in the infrared. The a_2 mode, ν_{11}, is inactive in the infrared and too weak to be seen in the Raman spectrum but calculations give a frequency of 723 cm^{-1} for this vibration. These results are consistent with those currently accepted for the analysis of other methyl–germanium compounds (3, 4). A depolarized band at 132 cm^{-1} is attributable to the remaining GeC_3 rock, ν_{23}. Again, no indication appeared in any spectra for the CH_3 torsional modes, ν_{12} and ν_{24}, so no information could be obtained on the barrier hindering rotation around the carbon–germanium bond.

Force Constant Listings

The force constants listed in Table 1 are those calculated for the individual molecules. A very reasonable "fit" is found when average values of the stretching force constants are used although the bending modes do not exhibit such a high

degree of transferability, possibly due to the complex mixing we have observed amongst these modes.

Potential Energy Distributions

The potential energy distributions amongst the force constants are presented in Tables 3, 5, and 7. The symmetric and asymmetric CH_3 and GeC stretching modes in all three systems show almost total dependence on force constants one and two, respectively, consistent with their being essentially "pure stretches". By contrast, the GeI stretching modes are much less solely dependent on force constant three. The symmetric GeI stretches exhibit strong dependence on GeI/GeI stretch–stretch interactions and the CGeI and CGeC bending force constants as well as that of GeI stretching.

The asymmetric CH_3 deformation shows almost total dependence on force constant four but the symmetric CH_3 deformations show strong interaction with HCGe bending, and GeC stretching. The appearance of the GeC stretching force constant in the p.e.d. of the symmetrical deformations is noted in other methyl-germane derivatives that we are studying at this time. It is interesting to speculate that Fermi resonance between the first overtone of the symmetrical GeC stretch and the symmetrical CH_3 deformations might well be expected. However, complete splitting of bands is not observed although a shoulder is apparent on the low frequency side in each case.

The asymmetric GeC_3 deformation and GeC_3 rocking mode in $(CH_3)_3GeI$, the asymmetric GeI_3 deformation in CH_3GeI_3, and the CH_3 rocking vibrations in all molecules are essentially pure modes with little contribution from other force constants. The remaining modes are only approximately described by the conventional terminology. Thus, the GeC_2 (scissors) deformation in $(CH_3)_2GeI_2$ and symmetric GeC_3 deformation in $(CH_3)_3GeI$ have *ca.* 32 and 44% contribution from GeC stretching and GeI stretching, respectively, as well as significant contributions from CGeI bending. By contrast the symmetric GeI_2 (scissors) deformation in $(CH_3)_2GeI_2$ only has a small contribution from CGeI bending, but the remaining bending modes, the GeI_3 rock in CH_3GeI_3 and the GeI_2 wag and rock in $(CH_3)_2GeI_2$ all contain appreciable mixing among the force constants.

We wish to thank the National Research Council of Canada for financial support and express our great debt to Dr. D. E. Rogers of the University of Southampton for all his help on the programs SOTONVIB and FPERT.

The Trifluoroacetic Acid Solvent System. Part II. Acids

M. G. HARRISS AND J. B. MILNE[1]

Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received April 21, 1971

^{19}F nuclear magnetic resonance (n.m.r.) studies show that SbF_5 forms $HSbF_5(OOCCF_3)$ in trifluoroacetic acid. This complex acid does not react with $(CF_3CO)_2O$ which must be added to carry out conductimetric studies in anhydrous $HOOCCF_3$. However, $HClO_4$, HSO_3F, and HNO_3 all react with $(CF_3CO)_2O$ to yield mixed anhydrides CF_3COClO_4, CF_3COSO_3F, and NO_2OOCCF_3. HBF_4 reacts with the anhydride to give CF_3COF while H_2SO_4 appears to be simply dehydrated to polysulfuric acids.

Les études de résonance magnétique nucléaire du fluor-19 indiquent que SbF_5 dans l'acide trifluoroacétique conduit à $HSbF_5(OOCCF_3)$. Ce complexe acide ne réagit pas avec $(CF_3CO)_2O$ qui doit être ajouté à $HOOCCF_3$ anhydre pour mener à bien des études conductimétriques. Cependant, $HClO_4$, HSO_3F et HNO_3 réagissent avec $(CF_3CO)_2O$ pour donner des anhydrides mixtes CF_3COClO_4, CF_3COSO_3F et NO_2OOCF_3. HBF_4 réagit avec l'anhydride pour donner CF_3COF alors que H_2SO_4 semble être déshydraté en acides polysulfuriques.

Canadian Journal of Chemistry, **49**, 2937 (1971)

Introduction

Trifluoroacetic acid is a very weak base (1) and, considering its good solvent properties (2), is of interest as a solvent for the titration of weakly basic substances. Some studies have already been carried out using perchloric acid as a titrant (3, 4). However, very few studies of acids in this solvent have been reported. According to electrical conductivity measurements, sulfuric acid is a non-electrolyte in trifluoroacetic acid (5). However, other authors, using indicator methods, report that sulfuric acid has a pK_a of 6.3 in the solvent (6). Pyrosulfuric (5), methanesulfonic and perchloric acids (6) are reported to behave as acids in trifluoroacetic acid. In view of the assumptions implicit in the indicator method for determining acid dissociation constants (6, 7) and the discrepancy in the behavior reported for sulfuric acid, it was considered of interest to study some strong acids in trifluoroacetic acid. The work reported here relies principally on nuclear magnetic resonance studies; the results of conductivity measurements are reported elsewhere (8).

Experimental

Materials

The trifluoroacetic acid was purified by distillation as described elsewhere (9).

Trifluoroacetic acid anhydride was prepared by refluxing the acid over P_2O_5 and then, distilling the product (b.p. 40.0 °C). Analar grade 71% perchloric acid, 98% sulfuric acid, 69% nitric acid, and 40% hydrofluoric acid were standardized by titration against sodium carbonate. Tetrafluoroboric acid was prepared from analytical grade boric acid and 40% hydrofluoric acid. Fluorosulfuric acid from Allied Chemical was doubly distilled before use (b.p. 160 °C). Antimony pentafluoride from Ozark-Mahoning was purified by distillation (b.p. 142 °C). Samples for n.m.r. spectra were made up by weight in precision n.m.r. tubes. All transfers were made in a dry box. Reaction was prevented by cooling the sample in liquid air until the tube was drawn off. Inserts made from Kel-F tubing supplied by Chemplast Co. Inc., Wayne, N.J. were used for the HBF_4 solutions initially, but no attack on glass was apparent in the n.m.r. spectra of solutions containing excess trifluoroacetic acid anhydride.

Fluorine n.m.r. spectra were taken on a Varian Associates HA-100 spectrometer. Except for the SbF_5 solutions all spectra were recorded at 25 °C.

Results and Discussion

The low dielectric constant of trifluoroacetic acid ($\varepsilon = 8.4$) requires that conductivity measurements be made at concentrations below $1.9 \times 10^{-4}\ M$ to observe ion-pairing without interference from higher ion aggregates (10). For this reason difficulties, arising from impurities in the solvent, water in particular, are greatly magnified. Acid containing as little as 0.00023% water has a water concentration equal to that of the limiting concentration at which simple ion-pair equilibria for an ionophore may be studied. For a very deliquescent solvent like trifluoroacetic acid sufficiently accurate removal of water to avoid interference with solute equilibria,

[1]To whom all correspondence should be addressed.

TABLE 1. Chemical shifts and peak areas for perchloric acid in trifluoroacetic acid anhydride*

Product	Chemical shift (p.p.m.)	Observed peak area	Calculated peak area (reaction 2)
$HOOCCF_3$	0.00	1.00	1.00
$(CF_3CO)_2O$	−0.54	0.483	0.485
CF_3COClO_4	−2.95	0.184	0.184

*Mole fractions $H_2O/(CF_3CO)_2O/HClO_4$; 0.286/0.585/0.129.

especially for acid solutes, is virtually impossible. For this reason a small amount of trifluoroacetic acid anhydride (0.5% by weight), which is a non-electrolyte in trifluoroacetic acid, was added for conductivity experiments (9). Nuclear magnetic resonance studies were made to establish whether the anhydride was inert towards acid solutes.

Perchloric Acid

Bessiere found perchloric acid to be an electrolyte in trifluoroacetic acid (6). Since the solvent used contained up to 36 p.p.m. water (0.002 *M*), the conductivity observed could be due to $H_3O^+ClO_4^-$ rather than $H_2OOCCF_3^+$-ClO_4^-. We have found that perchloric acid is a non-electrolyte in the presence of trifluoroacetic acid anhydride. This might suggest that perchloric acid exists in molecular form in the solvent, since any ion-pair that was formed would be expected to be dissociated to some degree. However, there is also the possibility of the dehydration reactions

[1] $2HClO_4 + (CF_3CO)_2O \rightarrow Cl_2O_7 + 2HOOCCF_3$

[2] $HClO_4 + (CF_3CO)_2O \rightarrow CF_3COClO_4 + HOOCCF_3$

The anhydrides formed in reactions 1 and 2 are expected to be non-electrolytes. Ionization of the mixed anhydride to give a trifluoroacetylium cation would be unlikely in view of the instability of this cation (11). Moreover, the isoelectronic CF_3COSO_3F behaves like a covalent compound (12). Fluorine n.m.r. was used to study the possibility of these reactions. The spectrum of a solution containing insufficient anhydride for complete removal of water consists of only one signal, indicating stoichiometric removal of water by anhydride. However, the addition of excess anhydride results in a spectrum with three peaks. This is consistent with reaction 2. The chemical shifts and peak areas for a solution with the composition in mole fraction units; $H_2O/(CF_3CO)_2O/HClO_4$; 0.286/0.585/0.129, are given in Table 1.

The observed peak areas are in good agreement with those required for reaction 2. A more extensive study of this reaction was not made because the solutions were of variable stability, turning yellow after a period of time varying from a few hours to a few days. When the solutions were frozen they turned a red color. The colors suggest the presence of chlorine dioxide or chlorine hexoxide.

Since perchloric acid reacts with trifluoroacetic acid anhydride and almost certainly reacts with water, further conductivity studies were considered unprofitable.

Fluorosulfuric Acid

The nuclear magnetic resonance spectrum of fluorosulfuric acid (0.38 mole fraction) in trifluoroacetic acid consists of two absorptions only, one in the F on S region, 116.3 p.p.m. to low field of the F on C peak. The areas correspond to the stoichiometry of the mixture and this shows that dehydration of trifluoroacetic acid does not take place. The spectra of solutions of fluorosulfuric acid in trifluoroacetic acid anhydride consist of 5 absorptions, 3 in the F on C region and 2 in the F on S region. No changes in the spectra were observed when the tubes were left standing for several weeks or heated to 100 °C for several days. The chemical shifts and peak areas are given in Table 2.

The spectra are consistent with the equilibrium

[3] $HSO_3F + (CF_3CO)_2O \rightleftarrows CF_3COSO_3F + HOOCCF_3$

The peaks *A*, *B*, and *C* are assigned to $HOOCCF_3$, $(CF_3CO)_2O$, and F on C in CF_3COSO_3F, respectively. The peaks *D* and *E* arise from F on S in HSO_3F and CF_3COSO_3F, respectively. The ratio of the area of peak *C* to peak *E* is 3:1

*$HOOCCF_3/(CF_3CO)_2O$.

within the error of the measurement for peaks so far apart. The chemical shifts of *C* and *E* and their separation are in good agreement with literature values for CF_3COSO_3F (12, 13), considering changes in solvent. The absence of coupling is consistent with the spectrum for CF_3COSO_3F (13); also it eliminates other possible products such as CF_3SO_3F (14) and CF_3SO_2F with fewer bonds between different fluorines which would show coupling. A small amount of water present causes peak *A* to be greater than peak *C* (although equilibrium 3 requires them to be equal). From the peak areas the equilibrium constant, *K*, for reaction 3 may be calculated and this is also given in Table 2. Considering the changing nature of the mixture, *K* is reasonably constant.

Because of the complication of mixed anhydride formation the conductivity of HSO_3F in $HOOCCF_3$ was not measured but the n.m.r. spectra suggest that the solvent is protonated by HSO_3F. In solutions of $(CF_3CO)_2O$ in $HOOCCF_3$, the acid peak lies 0.5 p.p.m. above the anhydride peak, varying slightly with changing concentration. In solutions containing HSO_3F the $HOOCCF_3$ peak shifts to lower field relative to $(CF_3CO)_2O$ with increasing HSO_3F mole fraction as would be expected if $H_2OOCCF_3^+$ were formed.

Sulfuric Acid

Solutions of concentrated H_2SO_4 in $(CF_3CO)_2O$ in the concentration range studied gave only 2 fluorine n.m.r. signals, one for anhydride and the other, displaced slightly to low field, for $HOOCCF_3$. The peak area ratios, chemical shifts and compositions are given in Table 3. The hypothetical area ratios for water removal to give H_2SO_4 and for complete dehydration to SO_3 are also given.

The high field peak increases in intensity relative to the other with increasing $(CF_3CO)_2O$ mole fraction and is assigned to anhydride. The low field peak is assigned to $HOOCCF_3$. The ratios of the areas of acid to anhydride show that anhydride removes the water and dehydrates H_2SO_4 as well. Three reactions may be considered

[4] $$nH_2SO_4 + (n-1)(CF_3CO)_2O \rightarrow H_2S_nO_{2n+1} + 2(n-1)HOOCCF_3$$

and

[5] $$H_2SO_4 + (CF_3CO)_2O \rightleftarrows (CF_3CO)HSO_4 + HOOCCF_3$$

[6] $$H_2SO_4 + 2(CF_3CO)_2O \rightleftarrows (CF_3CO)_2SO_4 + 2HOOCCF_3$$

However, for the equilibria 5 and 6 a third absorption for the mixed anhydride would be expected in the spectrum as for solutions of HSO_3F. Exchange with $HOOCCF_3$ or $(CF_3CO)_2O$, which would result in two peaks being observed, is unlikely. The compound $(CF_3CO)HSO_4$ has been prepared (15) by distillation of an equimolar mixture of SO_3 and $HOOCCF_3$ but it is said to undergo reaction with $HOOCCF_3$

TABLE 4. Chemical shifts and peak areas for the solution, $H_2O/(CF_3CO)_2O/HBF_4$; 0.380/0.560/0.060

Peak	Chemical shift (p.p.m.)	Observed area	Calculated area	Product
A	−90.6 (quartet)	~0.02	0.024	$CF_3CO\mathit{F}$
B	−1.25 (doublet)	0.069	0.073	$C\mathit{F}_3COF$
C	−0.50	0.304	0.293	$(CF_3CO)_2O$
D	0.00	1.00	1.00	$HOOCCF_3$
E	+53.1	~0.07	0.073	BF_3

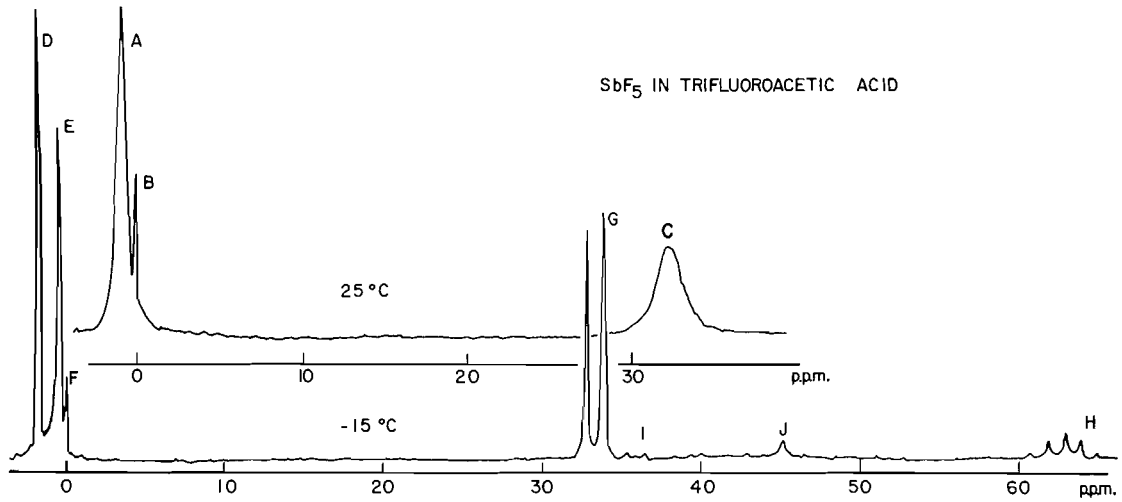

FIG. 1. ^{19}F nuclear magnetic resonance spectrum of a solution of composition $HOOCCF_3/(CF_3CO)_2O/SbF_5$ mole fraction, 0.639/0.023/0.338.

to give $(CF_3CO)_2O$. In the solutions studied here excess $HOOCCF_3$ is always present. The appearance of the $HOOCCF_3$ resonance to low field of $(CF_3CO)_2O$ suggests that the polysulfuric acids protonate $HOOCCF_3$.

Trifluoroacetic acid anhydride is a very strong dehydrating agent and, in terms of reaction 4, solution 1 corresponds to $n > 2$ (for $n = 2$, acid/anhydride area ratio is 5.7) and in solutions 3 and 4 the dehydration proceeds almost completely to SO_3.

Tetrafluoroboric Acid

The n.m.r. spectrum of a solution of $H_2O/(CF_3CO)_2O/HBF_4$, 0.474/0.450/0.076 mole fractions, consists of two resonances, that for $HOOCCF_3$ (area 1.000) and that for BF_4^- (area 0.116), shifted 70 p.p.m. to high field. Both the position and area of the high field peak are consistent with the presence of BF_4^-, which, from the stoichiometry of the mixture, should have an area of 0.113. Details of the spectrum of a solution, containing $(CF_3CO)_2O$ in excess of the sum of the moles of H_2O and HBF_4 together are given in Table 4. The spectrum is consistent with the reaction

[7] $(CF_3CO)_2O + HBF_4 \rightarrow$

$$CF_3COF + BF_3 + HOOCCF_3$$

The calculated areas in Table 4 are based upon the known stoichiometry of the solution assuming reaction 7 takes place. The chemical shift for BF_3 is comparable with the known value (14) and the shifts assigned to CF_3COF compare favorably with those of CF_3— and —COF groups (14). The coupling constant for CF_3COF was found to be 6.2 c.p.s. in the doublet and 5.6 c.p.s. in the quartet. Apparently CF_3CO^+-BF_4^- is not stable at room temperature similar to the corresponding hexafluorophosphate and arsenate (11).

Nitric Acid

The ^{19}F n.m.r. spectrum of a solution with the composition, $H_2O/(CF_3CO)_2O/HNO_3$; 0.337/0.446/0.217 mole fraction showed only one signal. Apparently H_2O is removed and the anhydride remaining reacts further with the HNO_3 according to one of two reactions

[8] $2HNO_3 + (CF_3CO)_2O \rightarrow 2HOOCCF_3 + N_2O_5$

[9] $HNO_3 + (CF_3CO)_2O \rightarrow NO_2OOCCF_3 + HOOCCF_3$

The spectrum of a solution containing anhydride in excess of that required for completion of reaction 9 ($H_2O/(CF_3CO)_2O/HNO_3$; 0.264/0.566/0.170) consists of two signals, with the weaker of the two 10.4 c.p.s. to low field of the other. This weaker peak is assigned to the excess anhydride. If reaction 8 is occurring, the peak area ratio ($HOOCCF_3/(CF_3CO)_2O$) would be 1.61. If reaction 9 takes place and the mixed anhydride exchanges with $HOOCCF_3$ the peak area ratio should be 3.31. The observed ratio is 3.42, indicating the formation of mixed anhydride. Exchange of NO_2OOCCF_3 with $HOOCCF_3$ is not unlikely in view of the feasibility of ionization to $NO_2^+OOCCF_3^-$.

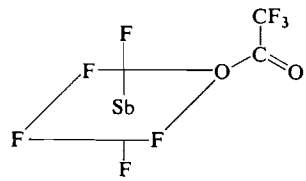
Decomposition to form NO_2 was apparent in these solutions after several days.

Antimony Pentafluoride

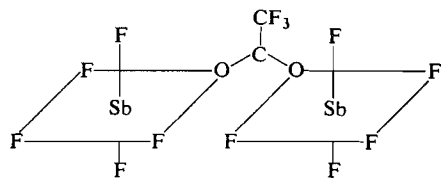
The fluorine-n.m.r. spectra at 25 and -15 °C of a solution of SbF_5 in $HOOCCF_3$ with a small amount of $(CF_3CO)_2O$ added to ensure anhydrous conditions ($HOOCCF_3/(CF_3CO)_2O/SbF_5$, 0.639/0.023/0.338 mole fraction) are given in Fig. 1. The spectra of a more dilute solution (0.885/0.038/0.077 mole fractions) were similar except that the doublet *I* and the peak *J* were missing. The spectra bear close resemblance to those reported for SbF_5 dissolved in other solvents (16, 17) and are consistent with the reaction

[10] $HOOCCF_3 + SbF_5 \rightarrow HSbF_5(OOCCF_3)$

In the spectrum at 25 °C the peak *A* is assigned to $HOOCCF_3$ exchanging with $HSbF_5(OOCCF_3)$, the peak *B*, $(CF_3CO)_2O$, and the peak *C*, F on Sb in $HSbF_5(OOCCF_3)$. The peaks *A* and *C* are broadened by exchange processes. At -15 °C these processes have been slowed sufficiently and the spectrum of the F on Sb region consists of an AX_4 spectrum (peaks *G* and *H*) and the small peaks *I* and *J*. In addition, the peak *A* has split into two sharp peaks, *D* and *E*. The chemical shifts and areas of *D*, *G*, and *H* are those expected for the complex anion



or its parent acid. The coupling constant for the fluorines *cis* and *trans* to the trifluoroacetate group is 98.0 c.p.s. which is comparable to that in other species (16, 17). The doublet *I* may arise from the dimer ion



which also gives an AX_4 spectrum (16).

The other components of the spectra for these ions would be too weak to be observed. The single broad resonance *J* is assigned to SbF_6^- which has a chemical shift similar to that observed here (17, 18). The peak is broadened by quadrapole relaxation processes associated with the ^{121}Sb and ^{123}Sb species. The SbF_6^- could arise from a ligand redistribution reaction

$$2SbF_5(OOCCF_3)^- \rightleftarrows SbF_6^- + SbF_4(OOCCF_3)_2^-$$

which has been observed in other solutions with SbF_5 (17). The second species is expected to have a *cis* structure by analogy with other known $SbF_4X_2^-$ species (16, 17) and the intensity of the two triplets expected for this ion would be too weak for observation.

The addition of $KOOCCF_3$ to solutions of SbF_5 in $HOOCCF_3$ results in the precipitation of $KSbF_6$ which was identified by its X-ray powder diffraction pattern. The potassium analysis of the precipitate was slightly low for $KSbF_6$ (%K observed, 13.20; calculated for $KSbF_6$, 14.2; calculated for $KSbF_5(OOCCF_3)$, 10.6). The fluorine n.m.r. spectrum of the supernatant liquid from this reaction had no absorption in the F on Sb region but several peaks were observed in the F on C region. Further work is being carried out on this system.

Conclusion

To study acid behavior in $HOOCCF_3$, to which $(CF_3CO)_2O$ is added to ensure anhydrous conditions, an acid which does not react with anhydride is needed. The strong acids, $HClO_4$, HSO_3F, H_2SO_4, HNO_3, and HBF_4 all react with the anhydride. Antimony pentafluoride can be used for conductivity studies (8), although slight interference arises from side reactions. It is interesting that perchloric acid reacts completely to form the mixed anhydride while fluorosulfuric acid does not. It is known that fluorosulfuric acid is a considerably stronger acid than perchloric acid (19) and the protonation of $HOOCCF_3$ by HSO_3F could prevent complete reaction to the mixed anhydride. The preferential formation of the mixed anhydride to that of the symmetric anhydride has been previously reported (20) and may be a result of increased ionic contribution to the bonding in the mixed anhydride.

We thank the National Research Council of Canada for generous support and a bursary (M.G.H.).

Ion Pairing and the Reaction of Alkali Metal Ferrocyanides and Persulfates

R. W. Chlebek and M. W. Lister

Received April 29, 1971

Osmometric measurements have been made on the alkali metal persulfates, and these are interpreted in terms of formation of ion pairs, $MS_2O_8^-$, by means of the method of Masterton and Berka (5). Equilibrium constants, and the derived thermodynamic quantities are deduced for the reactions $M^+ + S_2O_8^{2-} \rightleftharpoons MS_2O_8^-$. These results are applied to the interpretation of the kinetics of the reactions

$$2M_4Fe(CN)_6 + M_2S_2O_8 \rightarrow 2M_3Fe(CN)_6 + 2M_2SO_4$$

With M = K^+, Rb^+, and Cs^+, the reacting species are $MFe(CN)_6^{3-} + MS_2O_8^-$, with very similar rate constants; with M = Li^+, Na^+ the species are $MFe(CN)_6^{3-} + S_2O_8^{2-}$; and for lithium the reaction of $Fe(CN)_6^{4-} + S_2O_8^{2-}$ is also important. Rate constants and activation parameters are deduced.

Les mesures osmométriques ont été effectuées sur les persulfates d'un métal alcalin; les résultats sont interprétés en fonction de la formation d'une paire d'ions, $MS_2O_8^-$, suivant la méthode de Masterton et Berka (5). Les constantes d'équilibre et les quantités thermodynamiques qui en dérivent sont déduites des réactions $M^+ + S_2O_8^{2-} \rightleftharpoons MS_2O_8^-$. Ces résultats sont utilisés en vue de l'interprétation des cinétiques des réactions

$$2M_4Fe(CN)_6 + M_2S_2O_8 \rightarrow 2M_3Fe(CN)_6 + 2M_2SO_4$$

avec M = K^+, Rb^+ et Cs^+, les espèces réactionnelles sont $MFe(CN)_6^{3-} + MS_2O_8^-$, avec des constantes de vitesse très semblables; avec M = Li^+ et Na^+ les espèces réactionnelles sont $MFe(CN)_6^{3-} + S_2O_8^{2-}$; pour le lithium la réaction $Fe(CN)_6^{4-} + S_2O_8^{2-}$ est également importante. Les constantes de vitesse ainsi que les paramètres d'activation sont déduits.

Canadian Journal of Chemistry, 49, 2943 (1971)

In two earlier papers (1, 2), we reported measurements on the rates of the reactions

$$2M_4Fe(CN)_6 + M_2S_2O_8 \rightarrow 2M_3Fe(CN)_6 + 2M_2SO_4$$

where M is an alkali metal. These were interpreted in terms of ion pairs, such as $KFe(CN)_6^{3-}$, as the actual reacting species, and the criterion used was to discover which reaction path best followed the predictions of Brönsted's equation (3). This required a knowledge of the equilibrium constants of the reactions

$$M^+ + Fe(CN)_6^{4-} \rightleftharpoons MFe(CN)_6^{3-}$$

$$M^+ + S_2O_8^{2-} \rightleftharpoons MS_2O_8^-$$

Values of these constants are available in the literature for ferrocyanides (4), and we had made measurements (1) with a glass electrode on $KFe(CN)_6^{3-}$ and $KS_2O_8^-$, and also on the product ion pairs $KFe(CN)_6^{2-}$ and KSO_4^-. Values were not available for other persulfates, but since Masterton and Berka (5) had found fairly similar values for all alkali metal sulfates, it was assumed that the values of the equilibrium constants for all alkali metal persulfates were the same as the known value for $KS_2O_8^-$. The present paper reports values for these constants obtained by the method of Masterton and Berka (5), who used osmometric measurements and these values are in turn used to interpret the kinetic data. Water was the solvent throughout.

Experimental

Alkali Metal Persulfates

These were obtained by the methods already described (1, 2). Freshly prepared solutions were always used, and the concentrations were known, firstly from the weights of salt used, and secondly by titration. Two titrations were used: (*i*) excess ferrous ammonium sulfate solution was added and the excess was titrated with ceric ammonium sulfate, and (*ii*) potassium iodide was added and the resulting iodine was titrated with sodium thiosulfate.

Osmometric Measurements

These were done with a Mechrolab 301 A Vapor Pressure Osmometer. Potassium chloride solutions were used as the comparison solutions, and their osmotic coefficients were taken to be as given by Robinson and Stokes (6). The British Drug House AnalaR reagent grade of potassium chloride was used, the solution being made up by weight from the salt dried at 110 °C. Osmometric measurements were made at 25 and 37 °C.

Results

Table 1 gives the results of the osmometric measurements. The table gives the osmotic coefficient, ϕ_{12}, for various salt molalities *m*.

TABLE 1. Osmotic coefficients and equilibrium constants for ion pairing of alkali metal persulfates

From these are calculated the fractions of the ion pair dissociated, α, the ionic strength, I, and the equilibrium constant, defined as

$$K^c = \frac{[MS_2O_8^-]}{[M^+][S_2O_8^{2-}]}$$

at the particular ionic strength. The calculations followed Masterton and Berka's method (5). It was assumed that their osmotic coefficients for completely dissociated electrolytes held at both 25 and 37 °C. Table 1 also gives values of the equilibrium constant extrapolated to zero ionic strength. This extrapolation was made by the usual equation for single ion activity coefficients, f,

$$[1] \quad -\log f = Az^2\left(\frac{\sqrt{I}}{1 + Ba\sqrt{I}} - CI\right)$$

for an ion of charge z. Kielland found a value of $a = 4$ Å for persulfate ions (7), and an average value of 0.25 was used for C, (8), so that the equation used was

$$[2] \quad -\log f = Az^2\left(\frac{\sqrt{I}}{1 + 1.33\sqrt{I}} - 0.25I\right)$$

It may be noted that Masterton and Berka quote mean values of activity coefficients which approximately fit an equation

$$[3] \quad -\log f = Az^2\left(\frac{\sqrt{I}}{1 + 1.5\sqrt{I}} - 0.1I\right)$$

and use of this would increase K° to about 8% above the values given in Table 1.

In addition to the results given in Table 1, measurements were also made on lithium persulfate. The values of the osmotic coefficients were close to those given by Masterton and Berka for completely dissociated salts, so that we obtained no evidence of ion pairing in this case. As will be seen later, the kinetic measurements of lithium ferrocyanide and persulfate can be interpreted without invoking the participation of $LiS_2O_8^-$. Measurements were also made on potassium persulfate which gave equilibrium constants somewhat higher (about 20%) than those obtained by use of a glass electrode (1). Attempts to obtain constants by use of a glass electrode for the other alkali metals were unsuccessful, as the glass electrode readings were not steady enough, and a small change in cell voltage can give a large change in equilibrium constant.

Table 2 summarizes the results in the form of the average equilibrium constants, including those obtained earlier (1) for potassium persulfate. The derived thermodynamic quantities, ΔG^0, ΔH^0, and ΔS^0 are included. It may be

TABLE 2. Values of thermodynamic functions for $M^+ + S_2O_8^{2-} \rightleftharpoons MS_2O_8$

M^+	K^0 (M) 25 °C	K^0 (M) 37 °C	ΔG^0 (25 °C) (kcal/mol)	ΔH^0 (kcal/mol)	ΔS^0 (cal/deg mol)
Na^+	3.8	5.0	−0.79	4.3	17.0
K^+	8.2	9.4	−1.25	1.6	9.6
Rb^+	14.7	16.0	−1.59	1.3	9.8
Cs^+	26.0	24.4	−1.93	−1.0	3.2

noted that ΔG^0 changes much less than ΔH^0, since ΔH^0 and ΔS^0 in effect oppose each other.

Discussion

The original object of this research was to investigate the effect of ion pairing on the reaction of persulfate and ferrocyanide ions. Kinetic measurements on this reaction have already been reported (1, 2). In the case of the lithium, sodium, rubidium, and cesium salts, the conclusions reached were tentative, because equilibrium constants for the formation of alkali metal – persulfate ion pairs were not known. It is now possible to make a more quantitative comparison of the reactions.

The general method of treating the kinetic data, which appeared in Tables I to IV in ref. 2, was as follows. The concentrations of all the species present in a reacting mixture were calculated from the gross concentrations of the solutions, and from the equilibrium constants for ion pairing. These constants were those appropriate to the actual ionic strengths of the solutions, and were adjusted by means of activity coefficients calculated by eq. 2 above. Since the true ionic strength could only be found when the appropriate equilibrium constants were known, an iterative procedure was used, until the finally calculated ionic strength differed by less than 0.1% from that used in finding the equilibrium constants. Since the kinetic data were for 25 and 40 °C, the equilibrium constants for $MS_2O_8^-$ formation (obtained at 25 and 37 °C) were extrapolated to 40 °C, with the usual assumption that $\log K$ was linear in T^{-1}. A more serious assumption was necessitated by the fact that Shvedov and Nichugovskii's data on ferrocyanides (4) only applied to 25 °C, and data are not available for the other alkali metals. It was assumed that the temperature coefficients of all these equilibrium constants were the same as for the potassium ion pair, which was known from glass electrode measurements. As ΔH^0 for formation of the ion pair $KFe(CN)_6^{3-}$ is only 3.86 kcal, and as fairly small values are also found for the other potassium ion pairs involved (1), it was felt that this assumption would not introduce much error. Small corrections were made for ion pairing of rubidium and cesium with chloride, from data of Davies (ref. 8, p. 169), and also for alkali metal ferricyanide ion pair formation. The only known appropriate equilibrium constant is that for $KFe(CN)_6^{2-}$; this is close to one tenth of the value for $KFe(CN)_6^{3-}$, and it was assumed that this value of one tenth held for other alkali metals.

When all the concentrations were known, it was assumed that some particular pair of ions were the main reacting species, as follows:

Reacting species	Rate constant	Path
$Fe(CN)_6^{4-} + S_2O_8^{2-}$	k_1	4/2
$MFe(CN)_6^{3-} + S_2O_8^{2-}$	k_2	3/2
$Fe(CN)_6^{4-} + MS_2O_8^-$	k_3	4/1
$MFe(CN)_6^{3-} + MS_2O_8^-$	k_4	3/1

Values of k_1, etc., were calculated, and it was then seen which rate constant most closely followed the Brönsted equation. This rate constant was then supposed to belong to the correct mechanism of the reaction.

Some comments should be made on this procedure. Firstly, Brönsted's equation is

$$\log k = \log k^0 + 2Az_az_bF(I)$$

for reaction of ions of charge z_a, z_b, and $F(I)$ is the function of the ionic strength appearing in the extended Debye–Hückel equation, [1] above. $F(I)$ contains two constants Ba and C which vary somewhat from ion to ion, and it is not obvious which values should be used. Indeed, as we are dealing with various reacting species, and also a transition state species, it is not certain that the

		40	1.0	0.3	3.07	−1.087
Cs^+	3/1	25	1.0	0.1	3.02	−1.423
		40	1.0	0.1	3.05	−1.038

same constants apply throughout. The values in eq. 2 were used in adjusting the equilibrium constants, and various combinations of *Ba* and *C* were investigated in obtaining a fit with Brönsted's equation. The range of *Ba* investigated was 1.0 to 1.65, and the range of *C* was 0.1 to 0.3, in accordance with the values found to fit observed activity coefficients. Except with lithium, it was found that these ranges never allowed any ambiguity about the mechanism; for lithium (as will be seen) it is probable that two paths are important. Table 3, which contains results for the rubidium salts, shows the extent of the variation. This table gives the slopes of plots of log k against $F(I)$, which at 25 °C should have the value 1.018 $z_a z_b$. It can be seen that only k_4 gives agreement of observed and calculated slopes, which happens when $Ba = 1.0$, $C = 0.3$ approximately. Hence the reacting species are $RbFe(CN)_6^{3-}$ and $RbS_2O_8^-$. Similar calculations were made with Li^+, Na^+, and Cs^+.

Secondly, the equilibrium constants were taken to be those applying to the ionic strength at the start of the run. This ionic strength falls gradually, and calculations were made for the potassium salts at the mid point of the run, as well as at the beginning. The change in slope was always less than 1%, so that calculations at the initial ionic strength were taken to be sufficient.

Thirdly, with lithium a fit of the calculated and observed shapes was possible for both k_1 and k_2. The method cannot distinguish between k_2 and k_3, for both of which mechanisms the composition of the transition state species is $MFe(CN)_6$-$S_2O_8^{5-}$, so that the k_2 path only was arbitrarily chosen. It was therefore assumed that for lithium, both the k_1 and k_2 paths simultaneously contributed to the rate, and values were thus obtained for both constants. There was no evidence of this sort of behavior for sodium.

Table 4 gives the results of these calculations. The reaction path is indicated by the charges on the reacting species; *i.e.* $Fe(CN)_6^{4-} + S_2O_8^{2-}$ is 4/2. The values of *Ba* and *C* are those that give observed slopes most closely fitting Brönsted's equation (within the ranges of *Ba* and *C* quoted above). k^0 is the value of the rate constant extrapolated to zero ionic strength; k^0 is in units of M^{-1} s^{-1}. The usual activation parameters, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, can be calculated from these results, and these are given in Table 5. Since the extrapolation to zero ionic strength follows slightly different equations for different M^+, Table 5 also contains values at $I = 0.1$. In the actual kinetic runs, the ionic strengths were varied from about 0.02 to 0.3 so $I = 0.1$ may be considered a typical value. Results reported earlier (1) on the 3/1 path for the potassium salts made $\Delta H^{\ddagger} = 9.0$ kcal/mol, and $\Delta S^{\ddagger} =$

Rb^+	3/1	9.4	−32	9.65	−30
Cs^+	3/1	10.4	−28.5	10.55	−26.5

*$\Delta H^{\ddagger}$ in kcal/mol; $\Delta S^{\ddagger}$ in cal/deg mol.

−34.7 cal/deg mol at zero ionic strength; at $I = 0.1$, $\Delta H^{\ddagger} = 9.5$, and $\Delta S^{\ddagger} = -31$.

A few comments may be made on the quantities in Tables 4 and 5. It is found that the 3/1 paths for cesium, rubidium, and potassium (for which $\log k^0 = -1.402$ at 25 °C, and -1.085 at 40 °C) have fairly similar rate constants. Thus the ions do not seem to play a very specific role, and their behavior is perhaps merely a reflection of identical charge and not very different size (especially if hydrated). $\Delta H^{\ddagger}$ rises slightly from potassium to cesium, but this is offset by a rise in $\Delta S^{\ddagger}$. Possibly the somewhat smaller potassium ion permits a closer approach of the reacting ions in the activated complex leading to a smaller $\Delta H^{\ddagger}$ for electron transfer in the reaction, and also to a somewhat more tightly bound complex with a more negative $\Delta S^{\ddagger}$. Sodium salts behave differently, and this is not just a reflection of a lower degree of ion pairing. In fact if the 3/1 path for the sodium system had the same rate constant as for the potassium system, it would be the main route of the reaction, in spite of the lower concentrations of ion pairs. The reason for this change of behavior, which is evidently carried further in the lithium system, is not clear. $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for all the reactions show some signs of a linear relation at $I = 0.1$, but this is almost totally obscured at $I = 0$. It may be noted that $\Delta H^{\ddagger}$ is on the average larger for reactions of ions with larger charges, though only by a small amount, as is to be expected for aqueous solutions.

Finally it may be noted that the 4/2 reaction will presumably be occurring in all reaction mixtures. However, it can be calculated from the rate constants and concentrations of various species, that in all the runs using an alkali metal other than lithium, it contributes only a small fraction to the total rate, and consequently went undetected.

The Structure of Derivatives of $[SCH_3Fe(CO)_3]_2$

J. P. Crow and W. R. Cullen
Chemistry Department, The University of British Columbia, Vancouver 8, British Columbia

Received May 12, 1971

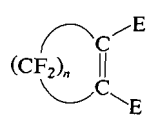
$[SCH_3Fe(CO)_3]_2$ when separated into its two known isomers reacts with tertiary phosphines with retention of the sulfur-methyl group configuration. The reaction of the mixture of isomers of $[SCH_3Fe(CO)_3]_2$ with ditertiary phosphines and arsines has been studied. Some ligands give bridged complexes, and others chelates: one ligand gives both. The p.m.r. and Mössbauer spectra of these complexes are discussed.

Le composé $[SCH_3Fe(CO)_3]_2$, lorsqu'il est séparé en ses deux isomères connus, réagit avec les phosphines tertiaires avec rétention de la configuration du groupe méthyle-soufre. La réaction du mélange d'isomères de $[SCH_3Fe(CO)_3]_2$ avec les phosphines di-tertiaires et les arsines a été étudiée. Certains ligands donnent des complexes pontés et d'autres des chélates: un ligand donne les deux. Les spectres r.m.p. et Mössbauer de ces complexes sont discutés.

Canadian Journal of Chemistry, 2948 (1971)

Introduction

King has shown that $[SCH_3Fe(CO)_3]_2$ exists as two isomers **A** and **B** which can be separated chromatographically (1). The p.m.r. spectra of these compounds showed that isomer **A** contained inequivalent or *anti* sulfur-methyl groups and isomer **B** contained equivalent or *syn* sulfur-methyl groups. Later an X-ray crystallographic study of the *anti* isomer of $[SC_2H_5Fe(CO)_3]_2$ provided more details of the structure of these compounds (2). We have investigated the reactions of $[SCH_3Fe(CO)_3]_2$ with tertiary and ditertiary phosphines and assigned structures to the products on the basis of their infrared, proton magnetic resonance (p.m.r.), and Mössbauer spectra. Of particular interest are the reactions of fluorocarbon-bridged ditertiary phosphines and arsines such as **1** which are known to give bridged complexes with dicobalt octacarbonyl (3, 4), and triiron dodecacarbonyl (5, 6).



1*a* E = $As(CH_3)_2$, $n = 2$; $f_4$fars
1*b* E = $P(C_6H_5)_2$, $n = 2$; $f_4$fos
1*c* E = $P(C_6H_5)_2$, $n = 4$; $f_8$fos

Some related complexes have been previously prepared by other investigators (7) but little was said about their possible structures. A recent communication (8) describes the spectroscopic properties of a number of complexes of the sort $[SRFe(CO)_2P(C_6H_5)_3]_2$ and $[SRFe(CO)_2]_2$diphos (diphos = $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$) and comments on some interesting structural features. Some of these have been found in the present investigation and in addition this paper describes, for the first time, separate reactions of the *syn* and *anti* isomers of the parent compound.

Experimental

Nuclear magnetic resonance (n.m.r.) spectra were run on a Varian T.60 spectrometer. Chemical shifts are reported in p.p.m. downfield from internal T.M.S. Mössbauer spectra were recorded at 80 °K and were processed as described in ref. 9. Infrared spectra were recorded on a Perkin–Elmer model 457 instrument. Microanalyses were done by Mr. P. Borda of this department. Ligands were prepared by literature methods (5, 9, 10) or were commercial samples.

Bis(methylthioirontricarbonyl) was prepared as in ref. 11 and separated into isomers by chromatography on alumina in pentane. $[C_6H_5SFe(CO)_3]_2$ and $S_2Fe_3(CO)_9$ and derivatives of these were made by the methods described in the literature (7, 12), purity was checked by melting points and infrared spectra. All other reactions were done under nitrogen by stirring equimolar amounts (2:1 for $[SCH_3Fe(CO)_2P(CH_3)_2C_6H_5]_2$) of the ligand and metal carbonyl in an aromatic solvent. Purification was effected by filtration of the solution followed by recrystallization from benzene/hexane to yield about 75% of the product. Reaction conditions and analyses for new compounds are shown in Table 1. Spectroscopic data are listed in Tables 2 and 3.

Results and Discussion

The **A** and **B** isomers of $[SCH_3Fe(CO)_3]_2$, henceforth called *anti-* and *syn-*, were separated by chromatography and were found to react

with equimolar amounts of triphenyl- and dimethylphenylphosphine at room temperature, in benzene, to give complexes $(SCH_3)_2Fe_2(CO)_5$(ligand). The p.m.r. spectra of these complexes (Table 2) show that substitution occurs with retention of the sulfur-methyl configuration. Thus the tertiary phosphine complexes obtained from *syn*-$[SCH_3Fe(CO)_3]_2$ show one sulfur-methyl resonance in their p.m.r. spectra, whereas the complexes obtained from *anti*-$[SCH_3Fe(CO)_3]_2$ show two sulfur-methyl p.m.r. resonances separated by 0.70 p.p.m. The only significant change in the p.m.r. spectrum of $[SCH_3Fe(CO)_3]_2$ on substitution is a shift of the methyl resonances to higher field, and an increase of about 50% in the chemical shift between inequivalent methyl groups of the *anti* isomer. In these complexes, and in the other phosphorus complexes described later, a coupling P—Fe—S—C—H of about 1 Hz was also observed irrespective of the orientation of the S-methyl group.

Only one phosphorus-methyl resonance was observed in the p.m.r. spectrum of *syn*-$(SCH_3)_2Fe_2(CO)_5(CH_3)_2PC_6H_5$. This probably indicates that substitution by dimethylphenylphosphine occurs in the axial position (*cis* to both sulfur atoms), for only by substitution in this position is the molecule symmetrical enough to allow magnetic equivalence of the phosphorus-methyl groups.

The suggested structure of this molecule is shown in Fig. 1*a*. The isomer of this compound *anti*-$(SCH_3)_2Fe(CO)_5P(CH_3)_2C_6H_5$ which almost certainly is also substituted in the axial position does not have sufficient symmetry for equivalence of its P-methyl groups and hence shows two resonances attributable to these groups separated by 2 Hz (J_{P-C-H} = 8 Hz). Infrared and Mössbauer parameters (Table 3) of the complexes $(SCH_3)_2Fe_2(CO)_5L$ also show differences between the isomers. In the carbonyl stretching region of the infrared spectrum the *anti* isomers have five bands whereas the *syn* isomers show four bands. In addition the dimethylphenylphosphine com-

*In C_6H_{12} solution, relative intensities in parentheses.
†Isomer shift and quadrupole splitting values (at 80 °K) are in mm $s.^{-1}$ Shifts are quoted relative to sodium nitropruside.

plexes also show slight splitting of some of the carbonyl infrared bands which may be due to the presence of rotamers in solution. A related phenomenon has been noted by Jetz and Graham (13).

The Mössbauer spectra of $(SCH_3)_2Fe_2(CO)_5L$ complexes show quite large differences in the quadrupole splitting of the iron atoms in the *syn* and *anti* isomers (Table 3). In accordance with previous results (5, 9 and references therein), the isomer shift and quadrupole splitting parameter with the higher isomer shift value is assigned to the phosphine substituted iron atom. Thus complex formation decreases the quadrupole splitting of the substituted iron atom and increases the quadrupole splitting of the other iron atom. This effect is slightly more pronounced in the *syn* than in the *anti* isomers. $[SCH_3Fe(CO)_3]_2$ also shows quadrupole splitting differences between *anti* and *syn* isomers, perhaps an indication that in these complexes a change in the basic skeleton of the molecule accompanies *syn–anti* isomerism.

Attempts were also made to separate possible isomers of $[C_6H_5SFe(CO)_3]_2$ without success. The mono-triphenylphosphine derivative is certainly axially substituted as judged by its infrared spectrum.

With 2 mol of dimethylphenylphosphine and 1 mol of the bidentate ligands f_4fars, f_4fos, and f_8fos, (**1**), $[SCH_3Fe(CO)_3]_2$ (not separated into isomers) forms complexes which have carbonyl infrared spectra characteristic of disubstituted compounds. The complex $[SCH_3Fe(CO)_2P(CH_3)_2C_6H_5]_2$ has two equivalent iron atoms in its Mössbauer spectrum, and equivalent S-methyl groups in its p.m.r. spectrum, so the molecule has a *syn* configuration with both axial carbonyl groups displaced by the ligands. The p.m.r. spectrum also indicates that weak virtual coupling between the two phosphines is taking place in spite of the spatial separation between them. The number of bands in the CO stretching region of the infrared spectrum and their position is similar to that reported for $[SCH_3Fe(CO)_2P(C_6H_5)_3]$ (8) (the S-methyl orientation is not stated) which has also been assigned a structure in which the axial carbonyl groups are replaced.

With the cyclic phosphine ligand **1***b* and **1***c* complexes $(SCH_3)_2Fe_2(CO)_4(L—L)$ are formed under mild conditions. These have two Mössbauer environments, and two well separated S-methyl proton magnetic resonances. A structure with the ligand chelating and the S-methyl groups in the *anti* position (Fig. 1*b*) explains

For personal use only.

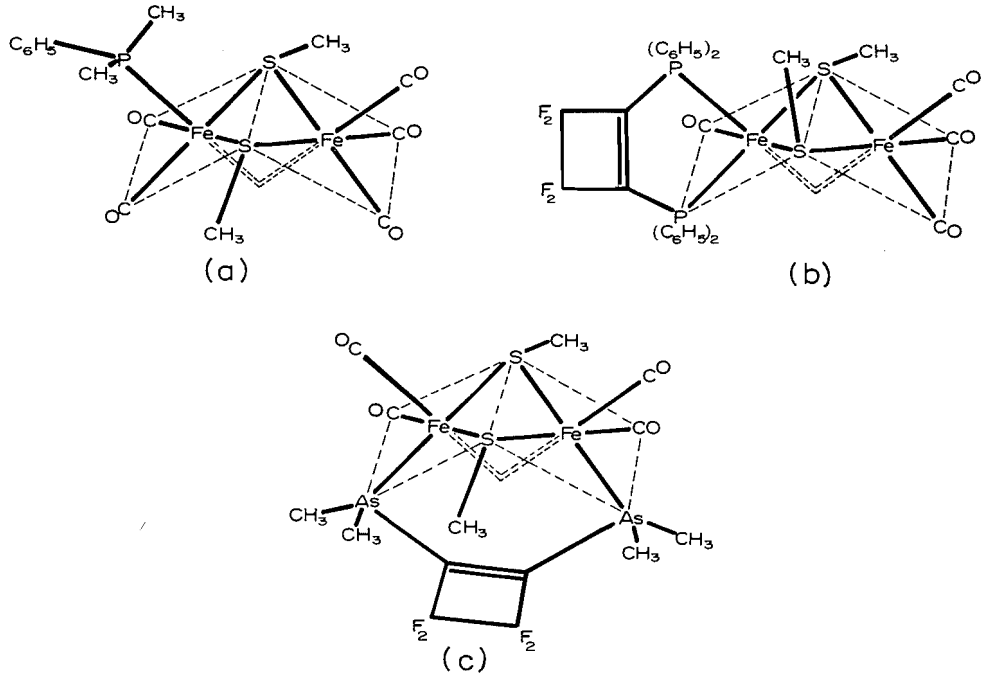

FIG. 1. Proposed structures of (*a*) *syn*-$(SCH_3Fe)_2(CO)_5P(CH_3)_2C_6H_5$, (*b*) $(SCH_3Fe)_2(CO)_4f_4fos$, (*c*) $(SCH_3Fe)_2(CO)_4f_4fars$.

these observations. Thus the chelated iron atom is the one with the greater isomer shift. The shifts are consistent with replacement of two carbonyl groups on one iron atom and none on the other. The infrared spectrum is similar to that of the diphos complex $(SCH_3)_2Fe(CO)_3Fe(CO)$diphos which is also believed to be chelated (7, 8). In Fig. 1*b* the ligand is shown occupying an axial and equatorial position. We believe that this is more likely than the equatorial–equatorial isomer because, as seen above, the axial carbonyl groups seem to be the more easily displaced.

The complexes $[SCH_3Fe(CO)_2]_2$(L—L) formed at higher temperatures with $f_4$fars and $f_4$fos have infrared and Mössbauer spectra which would result from the ligand bridging the two iron atoms. The Mössbauer spectra show that the iron atoms are equivalent and are mono-substituted. The p.m.r. spectrum of the $f_4$fars complex shows that while the As- and S-methyl groups are non-equivalent, the chemical shift values of the S-methyl groups are characteristic of the *syn* isomers. This spectrum would result when the ligand has displaced an equatorial carbonyl group (*i.e.* in the plane of Fe, S, S) from each iron atom (Fig. 1*c*). The infrared spectra of both $f_4$fars and $f_4$fos complexes are similar to that reported for the complex $[SCH_3Fe(CO)_2]_2(C_6H_5)_2PCH_2P(C_6H_5)_2$ which is also believed to be bridged (8).

The ability of fluorocarbon-bridged ligands such as **1** to yield bridged metal carbonyl complexes is well known (*e.g.* 3–6, 14). Indeed the proposed structure in Fig. 1*c* is very similar to that known for $f_4farsCo_2(CO)_6$ which contains the "folded book" skeleton with the ligand bridging two corners (3). These ligands, especially the phosphines, are also known to form chelate complexes with iron and Group VI carbonyls (9, 15), however, the isomers of $(SCH_3)_2Fe_2(CO)_4f_4fos$ are unusual because the ligand is either bridged or chelated.

The cluster compound $S_2Fe_3(CO)_9$ has a structure (16) which can be described in terms of two 6-coordinate iron atoms and one 7-coordinate one, and thus would be expected to have a Mössbauer spectrum of two quadrupole doublets. In fact the spectrum consists of one doublet. The derivatives $S_2Fe_3(CO)_8PR_3$ (R = C_6H_5, *n*-C_4H_9) also have a very similar Mössbauer spectrum

For personal use only.

which seems to suggest that phosphine substitution at one iron atom alters its Mössbauer environment very little.

We thank the National Research Council of Canada for financial assistance and Dr. J. R. Sams for help in obtaining the Mössbauer spectra.

Reçu le 22 avril 1971

Le perfluorométhylcyclohexane a été étudié par diffraction de rayons X, r.m.n. et r.p.e. Les deux premières méthodes confirment l'existence de plusieurs phases thermodynamiquement stables entre 77 °K et le point de fusion (234 °K): phase I ($227 < T < 234$ °K), phase II ($173 < T < 227$ °K), phase III ($T < 173$ °K), ainsi que celle d'une phase métastable (II′) au-dessous de 130 °K. Lorsqu'on élève la température, la r.m.n. indique successivement la rotation de CF_3 (phases II′ et III), la réorientation de toute la molécule autour de l'axe pseudoternaire du cycle (phase II) puis sa réorientation isotrope (phase I). La r.p.e. fournit des renseignements analogues sur les mouvements des radicaux  piégés dans le PFMCH. La comparaison entre l'anisotropie de g mesurée d'après la position des bandes des spectres r.p.e. et celle déduite de leur second moment suggère une large distribution des temps de corrélation de réorientation des radicaux dans la phase métastable.

Solid perfluoromethylcyclohexane has been studied by X-ray diffraction, n.m.r., and e.s.r. The two former methods confirm the existence of several thermodynamically stable crystalline phases between 77 °K and the melting point (234 °K): phase I ($227 < T < 234$ °K), phase II ($173 < T < 227$ °K), phase III ($T < 173$ °K) and that of a metastable phase (II′) below 130 °K. When the temperature is raised, the n.m.r. indicates successively the rotation of CF_3 (phases II′ and III), the reorientation of the molecule about the pseudothreefold axis of the ring (phase II), then its isotropic reorientation (phase I). Similar information is obtained from e.s.r. concerning the motions of  radicals trapped in PFMCH. The comparison between g anisotropy, measured from the position of the peaks of e.s.r. spectra and that deduced from their second moments suggests a wide distribution of reorientation correlation times for radicals in the metastable phase.

Canadian Journal of Chemistry, **49**, 2953 (1971)

I. Introduction

Les spectres de résonance paramagnétique électronique (r.p.e.) des radicaux piégés dans le perfluorométhylcyclohexane (PFMCH) irradié présentent d'importantes variations entre 77 °K et le point de fusion de ce composé (234 °K) (1). Ces variations ont été attribuées à des mouvements moleculaires associés aux transitions de phase qui ont été mises en évidence par des mesures de chaleur spécifique (2). Ces mesures ont permis de détecter deux points de transition entre 77 °K et le point de fusion (234 °K), l'un à 173 °K, l'autre à 226.6 °K. Nous désignerons respectivement par I, II et III les phases comprises dans les domaines de température $226\ °K < T < 234\ °K$, $173\ °K < T < 226\ °K$, $T < 173\ °K$. Dworkin (2) a également mentionné l'existence d'une phase métastable, que nous appellerons provisoirement phase IV, qui se transforme vers 120–140 °K en la phase III, avec dégagement de chaleur.

Nous nous sommes proposés de déterminer par r.p.e. les mouvements de réorientation des radicaux piégés dans le PFMCH en relation avec les mouvements des molécules de la matrice, que l'on étudie par résonance magnétique nucléaire

large bande (r.m.n.). Pour compléter et confirmer les résultats des expériences de résonance magnétique, les différentes phases du PFMCH solide ont été identifiées par diffraction de rayons X.

II. Techniques Expérimentales

Le PFMCH était un produit "Imperial Smelting" que nous avons utilisé tel quel après vérification de sa pureté par spectrométrie de masse (> 99.5%).[1]

(1) Diffraction de rayons X

L'étude des différentes phases cristallographiques du perfluorométhylcyclohexane (PFMCH) a été réalisée par la méthode des poudres, à l'aide d'une chambre de Weissenberg Stoe équipée d'un dispositif réfrigérant à jet d'azote gazeux (3). Un système de régulation stabilise la température du gaz à ± 0.5 degré autour du point choisi. Un étalonnage préalable à partir de substances connues permet de corriger les indications du thermocouple situé au voisinage de la sortie du Dewar dirigeant le jet gazeux et d'obtenir ainsi la température réelle de l'échantillon enformé dans un capillaire (ϕ 0.2 mm) en verre de Lindemann.

L'utilisation d'une chambre photographique (ϕ 57.8 mm) constituée de deux demi-cylindres rend aisé le chargement et le déchargement du film, sans perturber pour autant la température de la substance. En écartant les écrans de la chambre de Weissenberg de 2.5 mm de part et d'autre de son plan équatorial, le rayonnement diffracté par l'échantillon impressionne ce film sur une bande de 6 mm de largeur. Par translation manuelle de 10 mm du support de la chambre photographique entre chaque pose, il est ainsi possible d'enregistrer consécutivement, sur le même film, dix diagrammes Debye–Scherrer.

Tous les clichés ont été obtenus dans les mêmes conditions (Cu Kα, 26 kV, 20mA, 2 h d'exposition). Pour préciser les conditions nécessaires à l'obtention d'enregistrements de bonne qualité, nous avons refroidi l'échantillon de deux manières différentes: (*a*) un refroidissement lent a été effectué jusqu'à 230 °K. Après un premier diagramme, la température a été abaissée de 20° en 30 min, puis un nouveau diagramme a été recueilli, et le processus répété jusqu'à 90 °K; (*b*) le PFMCH a été trempé à 77 °K par un jet d'azote liquide, puis sa température a été ramenée de 90 à 230 °K à raison de 20° en 30 min, des clichés étant enregistrés à intervalles réguliers au cours du réchauffement.

L'examen des deux séries d'enregistrements montre que: (*a*) le refroidissement lent à partir de la phase liquide conduit à des diagrammes caractéristiques d'un solide constitué de quelques cristallites. En effet, le PFMCH dans sa forme I est pratiquement monocristallin; à 210 °K, les cristaux observés après la transition I–II sont encore assez gros et leur état de division ne se modifie guère par abaissement de la température; (*b*) la trempe à 77 °K, suivie d'un réchauffement lent, permet d'obtenir des diagrammes d'excellente qualité en raison de l'extrême division de la poudre cristalline. Pourtant, vers 230 °K, l'échantillon redevient spontanément quasiment monocristallin.

[1]Ces mesures ont été faites au C.E.A., dans le laboratoire de M. Botter que nous tenons à remercier ici.

Après avoir vérifié que la trempe par jet gazeux ou par projection d'azote liquide conduit aux mêmes résultats, nous avons décidé de commencer tout traitement thermique par une trempe gazeuse, la température de la substance pouvant ensuite être variée entre 90 et 210 °K.

(2) Résonance magnétique

Les expériences de résonance magnétique ont été effectuées à l'aide d'un spectromètre r.p.e. Varian V 4501 A convertible en spectromètre r.m.n. large bande par adjonction d'une unité radiofréquence V 4210 A. Les spectres étaient enregistrés en plaçant les échantillons dans un cryostat à circulation d'azote gazeux refroidi, situé dans la cavité r.p.e. ou la sonde r.m.n. La plupart des mesures ont été réalisées à des fréquences de l'ordre de 9250 MHz pour la r.p.e. et de 15 MHz pour la r.m.n. Au voisinage de 100 °K, le temps de relaxation spin-réseau T_1 des fluors, que nous n'avons pas mesuré, est suffisamment long pour provoquer une distorsion des spectres r.m.n. par passage rapide, même pour des vitesses de balayage aussi faibles que 0.5 G/min. Cette difficulté a été évitée en utilisant des échantillons non dégazés ou préalablement irradiés à 77 °K pour créer des centres paramagnétiques de façon à réduire T_1 (4). Nous avons vérifié que ces deux méthodes n'influaient pas sur la largeur et le second moment des spectres.

Le facteur g des radicaux du PFMCH a été mesuré en enregistrant simultanément les spectres r.p.e. des échantillons à étudier et celui d'un échantillon de goudron dispersé dans KCl dont la résonance se situe à $g = 2.0028$. Nous avons utilisé pour cela une cavité double V 4532 en tenant compte du gradient de champ magnétique entre les deux échantillons. Le champ était mesuré à l'aide d'un magnétomètre à résonance protonique Varian F8 relié à un fréquencemètre.

III. Résultats

(1) Diffraction de rayons X

(*a*) Après la trempe, nous avons enregistré des diagrammes Debye–Scherrer de 90 à 170 °K, puis de 170 à 90 °K et enfin de 90 à 170 °K, en faisant varier la température de 20° en 30 min entre deux clichés consécutifs: (*i*) au cours du premier réchauffement, les diagrammes obtenus à 90 et 110 °K sont caractéristiques d'une forme cristalline que nous avons appelée provisoirement "forme IV"; (*ii*) à 130 °K, on observe une autre variété que l'on conserve ensuite durant tout le traitement thermique. Cette forme est stable dans le domaine de température 90–170 °K et s'identifie avec la forme III observée par calorimétrie (2).

(*b*) Partant d'un échantillon trempé puis recuit à 170 °K afin d'obtenir la variété III, nous procédons à des enregistrements à 170 et 190 °K, puis de 190 à 90 °K et enfin de 90 à 170 °K, la température variant entre chaque exposition comme précédemment: (*i*) comme prévu, à 170 °K, nous avons la phase III; (*ii*) à 190 °K, nous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

observons la forme II thermodynamiquement stable entre 173 et 226 °K; (*iii*), par refroidissement de 190 à 130 °K, la phase II se conserve, bien qu'en dessous de 173 °K on soit dans le domaine de la variété III; elle est alors thermodynamiquement instable. Il y a donc un retard à la transformation II–III; (*iv*), à 110 °K, une nouvelle forme II′ apparaît et est également observée aux températures successives de 90 et 110 °K; (*v*) enfin, entre 130 et 170 °K réapparaît la variété III.

On serait donc tenté de conclure que, selon le traitement thermique, le PFMCH présente trois formes cristallines stables (I, II et III) et deux formes métastables (II′ et IV). La superposition des clichés II et II′ montre qu'en fait la variété IV est un mélange de la forme II et de la forme II′, la première étant prédominante aux basses températures.

Une succession de clichés effectués à des intervalles de température plus petits a ensuite permis de préciser les domaines d'existence de ces différentes variétés. Entre 226 et 234 °K existe la forme I; de 226 à 173 °K, on trouve la phase II; au-dessous de 173 °K, la forme III est stable. La variété IV (mélange par trempe de la phase piégée II et de la phase II′) se transforme irréversiblement par réchauffement en III aux environs de 115 °K.

Quant à la phase II′, son domaine d'existence est essentiellement lié au traitement thermique que subit l'échantillon. Un refroidissement progressif rend II métastable et II′ apparaît vers 123–124 °K. Si l'abaissement de la température est poursuivi dans les mêmes conditions, II′ se conserve au-dessous de 123 °K, et ce n'est qu'au réchauffement que cette variété redonne III à 120–121 °K. Par contre, si l'on stabilise la température du PFMCH à 123–124 °K durant plusieurs heures, II′ se transforme spontanément en III.

Il résulte de toutes ces expériences que, quel que soit le mode de refroidissement appliqué à un échantillon polycristallin, la forme stable III ne peut être obtenue à partir de II qu'après passage, durant une période plus ou moins longue par la variété métastable II′. On peut rapprocher ces résultats de ceux établis par la r.m.n. (Fig. 1) et la calorimétrie.

Un abaissement lent de la température à partir de la phase liquide conduit spontanément, comme signalé plus haut, à un monocristal I; il nous a également été possible d'obtenir une tel monocristal par fusion de zone directement réalisée sur la tête goniométrique (5). La même technique permet aussi la fabrication d'un monocristal II. Ces échantillons ont été étudiés par la méthode du cristal tournant et les résultats obtenus sont mentionnés plus loin dans l'interprétation des données recueillies par la r.m.n.

(2) Résonance magnétique nucléaire

Les échantillons de PFMCH ont été solidifiés soit par trempe dans l'azote liquide ou par un courant d'azote gazeux (méthode A), soit par refroidissement par paliers de quinze à vingt minutes tous les cinq ou dix degrés (méthode B). Dans cette seconde méthode, les spectres sont enregistrés au cours du refroidissement progressif.

La Fig. 1 représente les largeurs ΔH et les seconds moments $\langle \Delta H^2 \rangle$ des spectres r.m.n. du PFMCH, en fonction de la température. Les courbes *a* et *a′*, *b* et *b′* correspondent respectivement aux méthodes A et B.

Quelle que soit la méthode de refroidissement initial des échantillons, lorsqu'on les réchauffe à partir de 100 °K, le second moment décroît tout d'abord de 9.5 G^2 à 7.2 G^2 puis augmente rapidement et d'une manière irréversible à 8–8.5 G^2 vers 130 °K. $\langle \Delta H^2 \rangle$ varie ensuite réversiblement entre 9.8 G^2 à 100 °K et 7.5 G^2 à 170 °K. Au-delà de 170–175 °K le second moment tombe à 1.1 ± 0.1 G^2 et demeure sensiblement constant jusqu'à 220 °K. Il décroît de nouveau au-delà de cette température et devient égal à 0.1 G^2 entre 225 et 234 °K. L'évolution de la largeur des spectres est tout à fait parallèle à celle du second moment (Fig. 1*a* et *b*).

Compte-tenu des résultats de calorimétrie (2) et de diffraction de rayons X, on peut admettre qu'une phase métastable est piégée par refroidissement direct des échantillons à 77 ou 90 °K. Il est probable qu'il s'agit de la phase II′, car l'inertie thermique des échantillons de r.m.n. ($\approx$ 1 ml) est très supérieure à celle des échantillons examinés aux rayons X ($\approx$ 1 mm^3) de sorte que la transformation II $\rightarrow$ II′ a le temps de s'effectuer au cours du refroidissement.

L'augmentation de ΔH et de $\langle \Delta H^2 \rangle$ au voisinage de 130 °K nous semble attribuable à la transformation de la phase II′ en phase III, stable au-dessous de 173 °K. Notons que cette transformation est irréversible, que nous ne l'avons

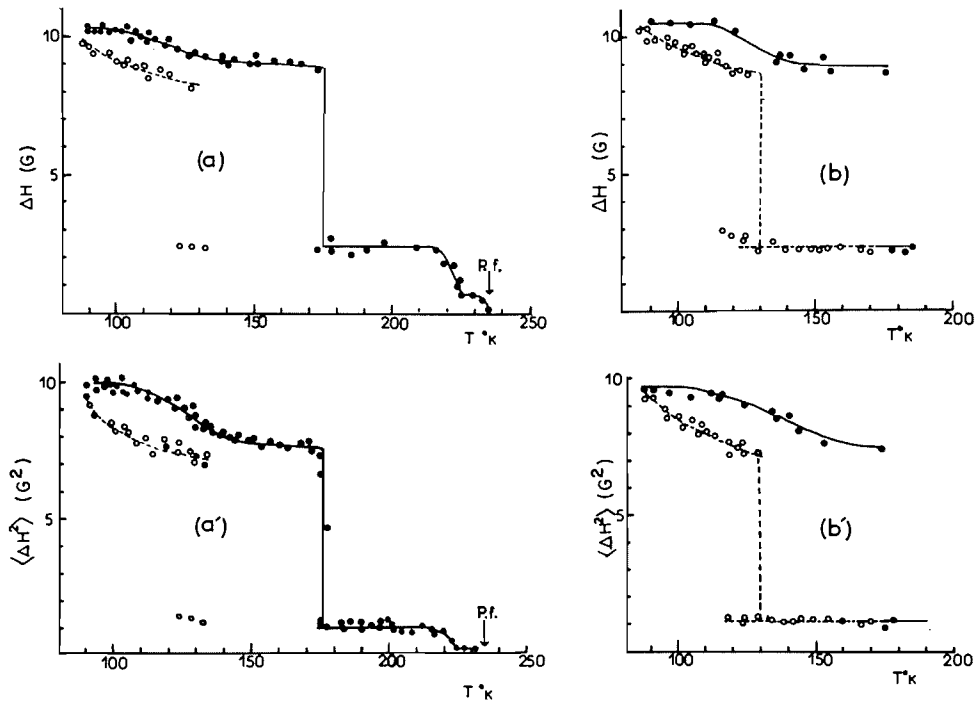

FIG. 1. Largeurs et seconds moments des spectres r.m.n. du PFMCH solide. Les figures *a* et *a'*, *b* et *b'* correspondent respectivement aux traitements thermiques A et B (voir paragraphe III, 2). En pointillés: courbes relatives aux phases métastables.

observée en r.m.n. que par réchauffement et que l'on enregistre transitoirement des spectres mixtes dont la composante étroite est semblable aux spectres obtenus entre 175 et 200 °K (Fig. 2*b* et *c*). Il nous paraît de même tout à fait probable que les paliers de 1.1 G^2 et de 0.1 G^2 correspondent aux phases II et I mentionnées précédemment.

Si l'on refroidit progressivement l'échantillon en partant de la phase II (méthode B) on constate que le palier de 1.1 G^2 caractéristique de cette phase persiste au-dessous de 173 °K, $\langle \Delta H^2 \rangle$ augmentant dans un intervalle de quelques degrés au voisinage de 130 °K pour rejoindre la courbe attribuée à la phase II' (Fig. 1*b'*).

Pour interpréter cet ensemble de résultats nous avons comparé les seconds moments des spectres de r.m.n. à des valeurs théoriques calculées à partir de différentes hypothèses sur la nature des mouvements moléculaires.

Pour un échantillon polycristallin en phase rigide l'expression du second moment d'un spectre de r.m.n. est (6, 7):

$$[1] \quad \langle \Delta H^2 \rangle = \tfrac{6}{5} I(I+1) g_N^2 \beta_N^2 N^{-1} \sum_{i>j} r_{ij}^{-6}$$

où I est le spin des noyaux dont on observe la résonance g_N le facteur de décomposition spectroscopique nucléaire, β_N le magnéton nucléaire, N est le nombre de noyaux en résonance dont on considère les interactions dipolaires et r_{ij} la distance qui sépare deux noyaux i et j. Dans le cas de fluors, l'expression [1] nous donne:

$$[2] \quad \langle \Delta H^2 \rangle (G^2) = 633.6 N^{-1} \times \sum_{i>j} r_{ij}^{-6}$$

La contribution intramoléculaire S_1 au second moment a été calculée pour différentes configurations du PFMCH en prenant r(C—C) = 1.54 Å, r(C—F) = 1.38 Å, $\angle$FCF = 109°28', valeurs indiquées dans la réf. 8. En supposant que CF_3 est bloqué en l'un des deux positions symétriques par rapport au cycle, qui sont sensiblement équivalentes, on trouve pour S_1: configuration chaise du cycle avec CF_3 équatorial: S_1 = 6.61 G^2; chaise avec CF_3 axial: S_1 = 9.89 G^2; bateau

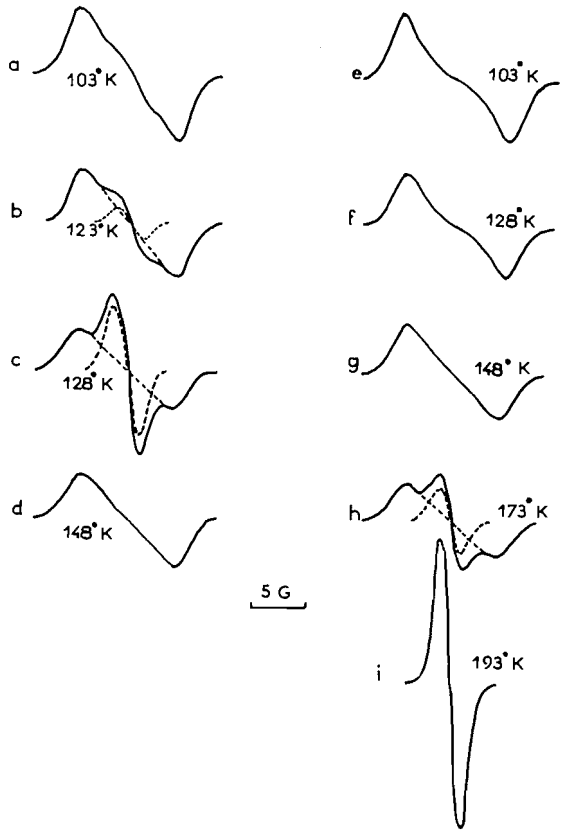

FIG. 2. Spectres r.m.n. du PFMCH solide. Les spectres *a* à *d* sont obtenus par trempe des échantillons (méthode A) et réchauffement continu. Les spectres *e*, *f*, *g* sont relatifs à la phase III, le spectre *h* à la transition III → II et le spectre *i* à la phase II.

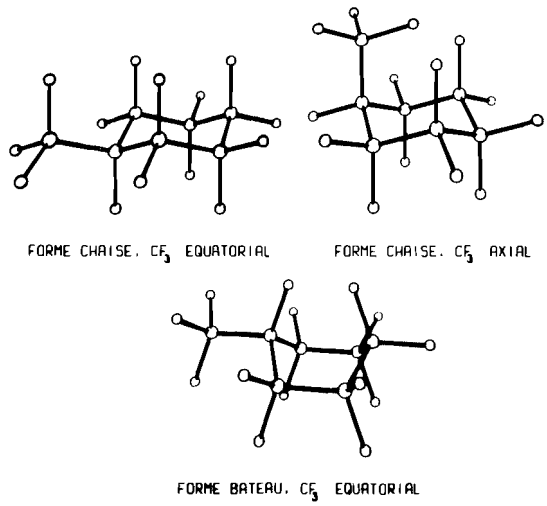

FIG. 3. Représentations moléculaires du PFMCH dessinées à l'aide du programme ORTEP (20) employé sur ordinateur UNIVAC 1108 et traceur de courbes Benson.

avec CF_3 équatorial: $S_1 = 9.87$ G^2. Ces trois configurations sont représentées sur la Fig. 3.

La configuration bateau avec CF_3 axial n'a pas été envisagée car elle amène presque en contact un fluor de CF_3 et un fluor du cycle. Il en est de même pour les formes bateaux asymétriques qui sont energétiquement défavorables (9). La valeur expérimentale maximum du second moment étant de 9.8 G^2, dont une fraction notable provient certainement de la contribution intermoléculaire S_2, nous ne retiendrons que la valeur $S_I = 6.6$ G^2 correspondant à la forme chaise avec CF_3 équatorial. Cette configuration est d'ailleurs celle du PFMCH en phase liquide (10).

Le calcul rigoureux du terme intermoléculaire S_2 n'a pu être effectué pour une phase rigide, faute de connaître la structure cristalline des phases III et II'. Nous avons cependant essayé d'évaluer S_2 à partir de deux approximations qui ont été utilisées dans le cas des molécules globulaires. L'approximation de Fratiello et Douglass (8) utilisée dans le cas du perfluorocyclohexane consiste à assimiler les molécules à des sphères à la surface desquelles les moments magnétiques sont uniformément répartis. Pour le PFMCH nous avons pris un rayon de sphère de 2.76 Å, déterminé d'après un modèle de Dreiding (11). La distance entre les centres de deux sphères voisines est alors: $R_i = 2 \times 2.76$ Å $+ 2 \times 1.35$ Å (rayon V. der Waals de F) $= 8.22$ Å. Cela nous donne une contribution à S_2 de 0.07 G^2 pour l'interaction entre les fluors de deux molécules voisines. Si l'on admet qu'une molécule est au maximum en contact avec douze voisines, on obtient $S_2 = 0.84$ G^2 au lieu de 9 8 G^2 − 6.6 G^2 = 3.2 G^2 (valeur expérimentale pour la phase III à 100 °K).

Dans l'autre approximation, proposée par Smith (12) on suppose une distribution des moments magnétiques continue au-delà d'une distance R du centre d'une molécule ce qui nous donne:

$$[3] \qquad S_2 \approx \tfrac{3}{5} I(I+1) g_N^2 \beta_N^2 \frac{4\pi}{3} \cdot \frac{N}{V} R^{-3}$$

où N est le nombre de fluors par maille de volume

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

V. La diffraction de rayons X indique pour la phase I un réseau cubique à 8 molécules par maille de volume $(13.2\ \text{Å})^3 = 2.3 \times 10^3\ \text{Å}^3$ et pour la phase II, un réseau quadratique à 24 molécules par maille de volume $13.2 \times (22.5)^2\ \text{Å}^3 = 6.67 \times 10^3\ \text{Å}^3$. Cela nous donne $N/V = 0.0487$ en phase I et $N/V = 0.0504$ en phase II. On peut admettre que pour les phases II′ et III le rapport N/V n'est pas très différent de celui des phases I et II, donc voisin de 0.05. En utilisant cette valeur dans la relation 3 avec $R = 2.76$ Å (rayon de la molécule), on obtient $S_2 = 3.15\ \text{G}^2$ en bon accord avec les valeurs expérimentales de $3.2 \pm 0.2\ \text{G}^2$ et de $3.0 \pm 0.2\ \text{G}^2$ déterminées pour les phases III et II′ au voisinage de 100 °K.

Nous allons maintenant calculer l'influence sur le second moment, de différents mouvements moléculaires. Quand un groupement ou une molécule dans son ensemble est en rotation autour d'un axe, l'expression du second moment devient (13):

$$[4]\quad \langle \Delta H^2 \rangle = \tfrac{6}{5} I(I+1) g_N^2 \beta_N^2 N^{-1} \times \sum_{i>j} \tfrac{1}{4}(3\cos^2 \gamma_{ij} - 1)^2 r_{ij}^{-6}$$

γ_{ij} étant l'angle entre un vecteur internucléaire r_{ij} et l'axe de rotation.

La contribution intramoléculaire de la forme chaise avec CF_3 équatorial ($S_1 = 6.61\ \text{G}^2$) comporte trois termes: interactions mutuelles des fluors de CF_3 bloqué $A_1 = 1.04\ \text{G}^2$, interaction CF_3—cycle $A_2 = 1.14\ \text{G}^2$, interactions mutuelles des fluors du cycle $A_3 = 4.43\ \text{G}^2$. La relation 4 permet de calculer que la rotation rapide de CF_3 autour de son axe ternaire réduit les deux premiers termes à $A_1' = 0.26\ \text{G}^2$ et $A_2' = 0.90\ \text{G}^2$, ce qui nous donne $S_1' = 5.59\ \text{G}^2$, A_3 demeurant inchangé. Le terme intermoléculaire S_2' a été calculé en admettant qu'il devient approximativement égal à

$$S_2 \times A_2'/A_2 = 3.2 \times 0.79\ \text{G}^2 = 2.53\ \text{G}^2$$

Le second moment théorique correspondant à la rotation de CF_3 est donc $\langle \Delta H^2 \rangle_{\text{calc}} = S_1' + S_2' = 8.12\ \text{G}^2$. Cette rotation rend compte en grande partie de la réduction du second moment expérimental qui décroît de $9.6 \pm 0.2\ \text{G}^2$ (100 °K) à $7.2 \pm 0.2\ \text{G}^2$ au voisinage des transitions II′ → III et III → II. La différence de $0.9 \pm 0.2\ \text{G}^2$ entre $\langle \Delta H^2 \rangle_{\text{calc}}$ et les valeurs expérimentales minima obtenues pour les phases III et II′ pourrait provenir de mouvements limités de rotation des molécules ou de la réorientation d'une partie d'entre elles, comme le laisse supposer l'existence de spectres mixtes au voisinage des points de transition (Fig. 2*b*, *c*, *h*).

Pour expliquer la diminution de 7 5 G^2 à 1.1 G^2 à la transition III → II (173 °K) nous avons envisagé la réorientation du PFMCH autour de l'axe pseudoternaire du cycle. Le terme intramoléculaire calculé est alors $S_1 = 0.92\ \text{G}^2$. Le terme intermoléculaire est évalué en supposant qu'il provient essentiellement de l'interaction entre molécules distantes de 8.22 Å de leurs deux plus proches voisines, suivant le même axe de rotation, les fluors étant "projetés" sur cet axe. Cette approximation nous donne $S_2 = 0.63\ \text{G}^2$ et donc $\langle \Delta H^2 \rangle_{\text{calc}} = 1.55\ \text{G}^2$. Pour une rotation du PFMCH selon son plus grand axe, on calcule $S_1 = 1.25\ \text{G}^2$ qui à elle seule dépasse la valeur expérimentale de $1.1\ \text{G}^2$ obtenue pour la phase II. La première de ces hypothèses paraît donc la plus vraisemblable.

Enfin dans le cas de la réorientation quasi-isotrope d'une molécule, le terme intramoléculaire s'annule, la contribution intermoléculaire pouvant être calculée en supposant les fluors groupés au centre de la molécule assimilée à une sphère (8):

$$[5]\quad \langle \Delta H^2 \rangle = S_2 = \tfrac{3}{5} I(I+1) g_N^2 \beta_N^2 N_0 \sum_i N_i R_i^{-6}$$

Nous avons vu qu'en phase I la maille est cubique ($a = 13.2$ Å) et contient huit molécules. En tenant compte par conséquent de l'interaction d'une molécule avec huit voisines et en prenant $R_i = 8.22$ Å comme précédemment on obtient $S_2 = 0.106\ \text{G}^2$ en accord avec la valeur expérimentale de $0.1 \pm 0.02\ \text{G}^2$ trouvée pour le second moment de la phase I. L'ensemble de nos valeurs expérimentales de $\langle \Delta H^2 \rangle$, comparées aux valeurs calculées (Tableau I) nous a donc permis de mettre en évidence trois mouvements moléculaires du PFMCH: la rotation de CF_3 en phases III et II′, la réorientation de l'ensemble de la molécule autour de l'axe pseudoternaire en phase II et la réorientation quasi isotrope en phase I.

La décroissance progressive de la largeur des spectres en phase III et II′ nous permet par ailleurs d'évaluer les fréquences de corrélation des mouvements moléculaires à partir de la relation (14, 15):

TABLEAU 1. Seconds moments des spectres r.m.n. du PFMCH

	Valeurs théoriques (G^2)			Valeurs expérimentales		
	S_1	S_2	$\langle \Delta H^2 \rangle$	T °K	Phase	$\langle \Delta H^2 \rangle$
Réseau rigide	6.61	3.18	9.79	100	III	9.8±0.2
				100	II′	9.6±0.2
Rotation CF_3	5.60	2.60	8.20	130	II′	7.2±0.2
				170	III	7.5±0.2
Réorientation autour de l'axe pseudoternaire du cycle	0.92	0.63	1.55	175–220	II	1.1±0.1
Réorientation quasi isotrope	0	0.10	0.10	225–232	I	0.1±0.02

$$[6] \quad \nu_c = \frac{\gamma}{16 \log_e 2} \Delta H \left[\tan \frac{\Delta H^2 - B^2}{C^2 - B^2} \cdot \frac{\pi}{2} \right]^{-1}$$

où ΔH est la largeur du spectre mesurée entre la maximum et le minimum de la dérivée d'absorption, B et C étant les valeurs limites de ΔH ($C > B$). Pour la phase II′ nous avons pris C = 9.8 G, B = 8.9 G et pour la phase III, C = 10.2 G, B = 9 G (*cf.* Fig. 1*a* et *b*). Le diagramme d'Arrhenius de ν_c donne respectivement pour les phases III et II′ les énergies d'activation E_1 = 5.5 kcal/mol et E_2 = 3.4 kcal/mol. Des mesures par écho de spin du temps de relaxation T_1, effectuées dans des conditions assez proches des nôtres (16) ont donné les énergies d'activation E_1' = 3.2 kcal/mol (phase III) et E_2' = 2.75 kcal/mol (phase métastable), de sorte que la valeur que nous avons trouvée pour E_1 paraît sujette à cautions.

(3) Résonance paramagnétique électronique

La structure hyperfine du spectre de  formé par irradiation γ du PFMCH est trop complexe pour permettre une étude détaillée des mouvements moléculaires de ce radical. Il a donc semblé préférable d'étudier le radical  formé par irradiation du PFMCH en présence d'oxygène et dont le spectre ne dépend que de l'anisotropie de g. La peroxydation complète des radicaux  formés initialement à 77 °K est assurée par réchauffement progressif à 175–180 °K (phase II) et refroidissement rapide à 100 °K, dans le cryostat du spectromètre. On augmente ensuite la température de cinq en cinq degrés par paliers d'environ dix minutes en enregistrant les spectres. La recombinaison des radicaux devient rapide à partir de 160 °K ce qui exclut des mesures prolongées au-delà de cette température et donc l'usage de la méthode B utilisée pour les mesures de r.m.n.

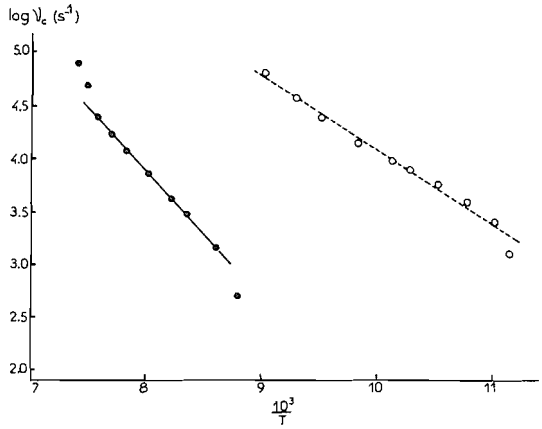

FIG. 4. Diagramme d'Arrhenius de la fréquence de corrélation de réorientation du PFMCH. En pointillés: phase II′, en traits pleins: phase III.

En phase II le spectre du radical peroxyle est une raie symétrique, centrée à g_{iso} = 2.0164 ± 0.0001 (Fig. 5*i*). Cette raie correspond soit à la réorientation isotrope du radical, soit comme on le verra plus loin, à la rotation simultanée du groupe C—O autour de la liaison C—O en position équatoriale, et du radical tout entier autour de l'axe pseudoternaire du cycle. A 77 °K par contre, en phase II′ ou III, le spectre de  est caractéristique d'un tenseur g à symétrie axiale (17) avec $g_{\parallel}$ = 2.0395 ± 0.0001 (maximum du pic à champ faible) et $g_{\perp}$ = 2.00485 ± 0.0001 (minimum de la dérivée d'absorption du côté des champs élevés).

Au cours du réchauffement, le maximum du pic correspondant à $g_{\parallel}$ se déplace dans la direction

des champs élevés. La théorie de Kneubühl (17) permet d'attribuer ce déplacement aux mouvements de réorientation du radical. La valeur principale *apparente* $g_{\parallel}'$ est donnée en fonction du temps de corrélation de réorientation τ_c par la relation 7 que l'on peut déduire des relations 2 et 19 de la réf. 17:

$$[7] \quad g_{\parallel}'^2 = s + (g_{\parallel}^2 - s)\frac{2}{\pi}\arctan\left(\frac{\tau_c}{T_2}\right)$$

avec $s = (1/3)\,(g_{\parallel}^2 + 2g_{\perp}^2)$; s, a été calculé en prenant les valeurs principales du tenseur g déterminées d'après le spectre obtenu à 77 °K, en admettant que le radical soit bloqué à cette température. Le temps de relaxation dipolaire T_2 a été évalué à 10^{-8} s,[2] d'après la largeur de 13 G des gaussiennes élémentaires, qui donne le meilleur accord entre les spectres expérimentaux et les spectres reconstitués par calcul électronique en utilisant le programme de Lefebvre et Maruani (18) (Fig. 5*a* et *d*). $g_{\perp}'$ est donné en fonction de τ_c par une relation analogue à [7] mais sa variation est moins aisée à mesurer que celle de $g_{\parallel}'$.

$g_{\parallel}'$ et $g_{\perp}'$ convergent vers g_{iso} si le mouvement de réorientation du radical est isotrope. Si le mouvement se limite à la rotation de O—O autour de C—O, $g_{\parallel}'$ et $g_{\perp}'$ tendent respectivement vers

$$[8] \quad \begin{aligned} g_{\parallel}^{rot} &= g_{\parallel} - (g_{\parallel} - g_{\perp})\sin^2\alpha \\ g_{\perp}^{rot} &= \tfrac{1}{2}(3g_{iso} - g_{\parallel}^{rot}) \end{aligned}$$

α étant l'angle C—O—O. Pour $\alpha = 120°$ on obtient ainsi $g_{\parallel}^{rot} = 2.0135$ et $g_{\perp}^{rot} = 2.0178$.

Si enfin la rotation de O—O autour de C—O et la réorientation de tout le radical autour de l'axe pseudoternaire du cycle se produisent simultanément, $g_{\parallel}^{rot}$ et $g_{\perp}^{rot}$ demeurent inchangés pour une liaison C—O en position axiale ou deviennent respectivement égaux à 2.0167 et à 2.0162 si C—O est équatorial. Dans ce second cas, le spectre se confond pratiquement, étant donné la largeur de raie, avec le spectre de 
[2]Cette valeur de T_2 n'est donnée qu'à titre indicatif, la valeur exacte aurait pu être déterminée par des mesures de saturation progressive qu'il n'a pas été possible d'effectuer étant donné que le signal des radicaux peroxyles ne se sature pas à 77 °K, même à la puissance hyperfréquence maximum que nous pouvons utiliser (250 mW à la cavité).

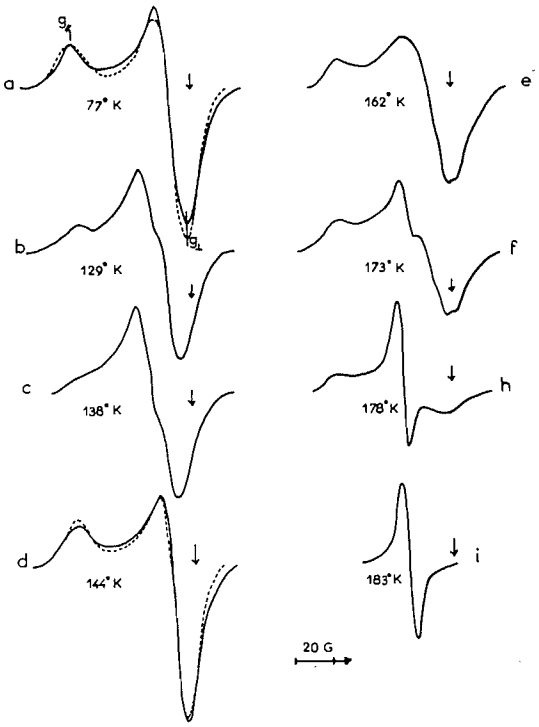

FIG. 5. Spectres r.p.e. des radicaux 
piégés dans le PFMCH. Les spectres *a* à *d* sont obtenus par trempe des échantillons après recuit en phase II et réchauffement continu. Les spectres *a* et *d* sont superposés aux spectres calculés (en pointillés) en prenant respectivement $g_{\parallel} = 2.03950$, $g_{\perp} = 2.00485$, $\lambda = 13.5$ G et $g_{\parallel} = 2.0380$, $g_{\perp} = 2.0056$, $\lambda = 13$ G. Les flèches verticales correspondent à $g_0 = 2.0028$, $H_0 = 3300$ G.

en réorientation isotrope. Il n'est pas exclu que cela se produise en phase II.

On peut constater sur la Fig. 6 que pour des échantillons trempés á 100 °K après recuit en phase II, $g_{\parallel}'$ décroît continuellement entre 100 et 130 °K et augmente dans un intervalle de quelques degrés au voisinage de 130 °K (courbe en pointillés). La relation 7 indique que cette augmentation est liée à un ralentissement des mouvements moléculaires. Si l'on refroidit de nouveau l'échantillon à 100 °K et qu'on le réchauffe ensuite à 160–170 °K, la décroissance de $g_{\parallel}'$ est continue et réversible (Fig. 6, courbe en trait plein). La comparaison des résultats de r.p.e. avec ceux de r.m.n. permet d'attribuer la première de ces courbes à la phase métastable II′, l'augmentation abrupte de $g_{\parallel}'$ à la transition II′ → III et la courbe en trait plein à la phase stable III.

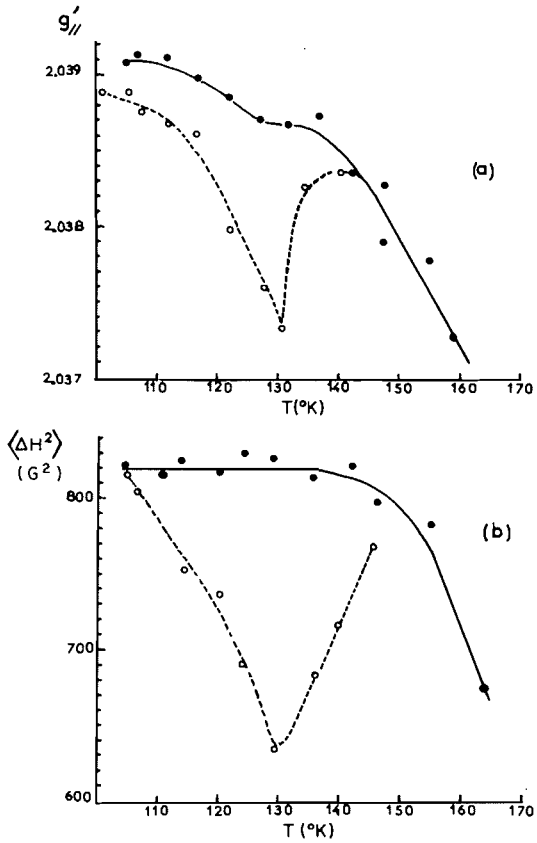

FIG. 6. Variation avec la température de $g_{\parallel}'$ (diagramme *a*) et du second moment des spectres r.p.e. de  (diagramme *b*). En pointillés: phase II′ et transition II′ → III.

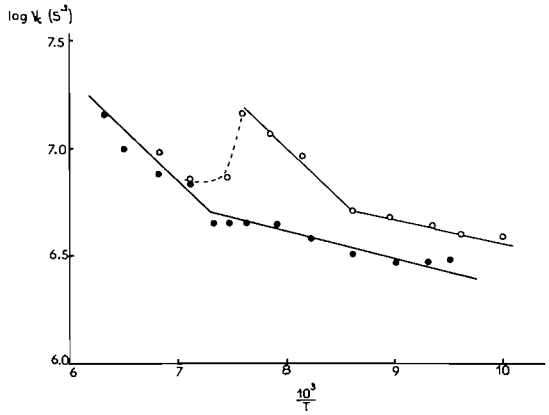

FIG. 7. Diagramme d'Arrhenius de la fréquence de corrélation de réorientation des radicaux peroxyles. ○ réchauffement continu après trempe à 77 °K des échantillons recuits en phase II. ●, phase III. En pointillés: transition II′ → III.

La relation 7 permet par ailleurs d'évaluer les temps de corrélation de réorientation et les énergies d'activation correspondantes pour les phases III et II′. Le diagramme d'Arrhenius de ν_c donne pour chacune de ces phases deux énergies d'activation $E_1 = 0.5 \pm 0.1$ kcal/mol et $E_2 = 2.5 \pm 0.2$ kcal/mol.

Dans le domaine de température étudié, la variation de $g_{\parallel}'$ est trop restreinte pour permettre de caractériser les mouvements moléculaires auxquels correspondent ces énergies d'activation. On peut noter cependant que E_1 est du même ordre de grandeur que celle trouvée par Sohma (19) pour la rotation de O—O autour de C—O dans le cas du radical ~~CF_2—$\underset{\displaystyle O_2^{\cdot}}{\overset{|}{CF}}$—$CF_2$~~ du téflon. L'énergie d'activation E_2 nous semble attribuable à la réorientation globale du radical  puisqu'elle se manifeste au voisinage des transitions II′ → III et III → II qui sont accompagnées d'une réorganisation du réseau. Le spectre "isotrope" de ce radical est effectivement observable en phase III à partir de 165 °K (Fig. 5) et parfois vers 130 °K à la transition II′ → III.

Nous avons également étudié la variation du deuxième moment $\langle \Delta H^2 \rangle$ des spectres de  en fonction de la température. Pour un radical peroxyle, le second moment dépend essentiellement de l'anisotropie de g et a pour expression (18):

$$[9] \quad \langle \Delta H^2 \rangle \approx \frac{H_0^2}{5}(\varepsilon_{\parallel}^2 + \tfrac{8}{3}\varepsilon_{\perp}^2 + \tfrac{4}{3}\varepsilon_{\parallel}\varepsilon_{\perp}) + \frac{\lambda^2}{4}$$

où H_0 est la valeur du champ magnétique par rapport à laquelle on mesure $\langle \Delta H^2 \rangle$ soit dans le cas présent 3320 G pour $g_0 = 2.0028$. $\varepsilon_{\parallel}$ et $\varepsilon_{\perp}$ sont respectivement égaux à $g_{\parallel}'/g_0 - 1$ et à $g_{\perp}'/g_0 - 1$. Le terme $\lambda^2/4$ représente la contribution de la largeur de raie soit 42 G^2 pour $\lambda = 13$ G. Le premier terme de la relation 9 est largement prédominant puisqu'il peut varier de 800 G^2 pour un radical bloqué à 508 G^2 ou 511 G^2 pour la réorientation isotrope du radical et la seule rotation du groupe peroxyle.

Comme on peut le prévoir la variation de $\langle \Delta H^2 \rangle$ avec la température présente quelque

*Valeurs calculées par la relation 9 avec $\lambda^2/4 = 42$ G².

analogie avec celle de $g_{\parallel}'$ (Fig. 6) en particulier pour la transition entre les phases II′ et III qui se traduit par un accroissement de $\langle\Delta H^2\rangle$. Le Tableau 2 donne quelques valeurs des seconds moments des spectres r.p.e. et les valeurs moyennes $\langle g_{\parallel}'\rangle$ que l'on peut en déduire par la relation 9.

Bien que les mesures de $\langle\Delta H^2\rangle$ ne soient pas très précises (reproductibilité de 3 à 5%), on peut noter dans la Fig. 6 et le Tableau 1 que pour la phase III les valeurs de $\langle g_{\parallel}'\rangle$ sont proches de celles de $g_{\parallel}'$ déduites directement des spectres. Pour la phase II′ et au voisinage de la transition III → II par contre, les valeurs de $\langle g_{\parallel}'\rangle$ sont systématiquement inférieures à celles de $g_{\parallel}'$. Nous attribuons cette différence à une large distribution des temps de corrélation dont le maximum correspond vraisemblablement à $g_{\parallel}'$. Il n'est effectivement pas possible, en prenant une seule valeur pour $g_{\parallel}'$ et pour $g_{\perp}'$ de reproduire par calcul électronique les spectres de la phase II′, entre 115 et 130 °K.

La dispersion des temps de corrélation est vraisemblablement liée à l'existence d'un spectre d'énergies d'activation de réorientation. En supposant que ce spectre soit une gaussienne de demi largeur σ:

$$[10]\quad N(E) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(E-E_0)^2}{2\sigma^2}\right]$$

On obtient pour $\tau = \tau_1 \exp(E/RT)$, la fonction de distribution:

$$[11]\quad N(\tau) = \frac{RT}{\sigma\sqrt{2\pi}} \exp\left[-\frac{R^2T^2}{2\sigma^2}\left(\log_e \frac{\tau}{\tau_0}\right)^2\right]$$

Soit $M_2(\tau)$ le second moment du spectre r.p.e. correspondant à une valeur unique de $g_{\parallel}'$ et de $g_{\perp}'$ donc de τ, la valeur du second moment correspondant à la distribution $N(\tau)$ est:

$$[12]\quad \langle\Delta H^2\rangle = \int_0^{\infty} M_2(\tau)N(\tau)\,d\tau$$

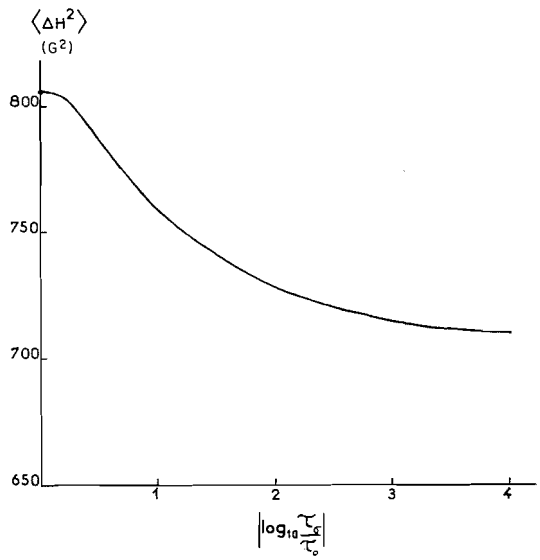

FIG. 8. $\langle\Delta H^2\rangle$ en fonction de la largeur de distribution des temps de corrélation $|\log_{10}\tau/\tau_0| = 0.43\,\sigma/RT$, pour $g_{\parallel}' = 2.0380$ ($\tau_0 = 10^{-7}$ s).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$M_2(\tau)$ pouvant être calculé à partir des relations 7 et 9 (Fig. 8).

A titre d'exemple, nous avons trouvé pour la phase II′ à 122 °K: $g_{\parallel}' = 2.0380$, $\tau_0 = 10^{-7}$ s ($M_2(\tau_0) = 806$ G^2). Le second moment expérimental est $\langle \Delta H^2 \rangle = 715$ G^2, ce qui nous donne $\sigma = 1.7$ kcal/mol ($E_0 = 2.5$ kcal/mol) et $\sigma/RT = 7$. Cette dernière valeur correspond à des temps de corrélation répartis entre 10^{-10} et 10^{-4} s.

IV. Conclusions

Les expériences de r.m.n. et de diffraction de rayons X confirment l'existence de trois phases thermodynamiquement stables entre 77 °K et le point de fusion, ainsi que celle d'une phase métastable que l'on peut piéger au dessous de 130 °K.

La comparaison des résultats de r.m.n. et de r.p.e. indique l'existence d'une corrélation entre les mouvements des radicaux et ceux des molécules de la matrice. Nous avons ainsi montré qu'en phase I les molécules de PFMCH sont en réorientation quasi-isotrope et il en est de même pour les radicaux  piégés dans cette phase (1). En phase II les molécules sont en rotation autour de l'axe pseudo-ternaire du cycle et l'on a vu que le spectre r.p.e. des radicaux peroxyles est interprétable par la composition de ce mouvement avec la rotation du groupe en position equatoriale. Enfin dans les phases II′ (métastable) et III on peut admettre que l'on observe en cours de réchauffement, d'abord les rotations intramoléculaires (de CF_3 ou de COO), puis la réorientation, probablement limitée, des molécules ou des radicaux, au voisinage des transitions II′ → III et III → II.

On peut noter sur les Figs. 4 et 7 que pour une même phase et une même température, les temps de corrélation de réorientation sont très différents pour les molécules de la matrice et pour les radicaux qui y sont piégés. Il est possible que les radicaux soient formés préférentiellement dans les défauts du réseau et possèdent de ce fait une plus grande liberté de réorientation que les molécules de la matrice. Plus vraisemblablement, cette différence apparente entre les temps de corrélation est inhérente aux méthodes de mesures, la r.m.n. étant utilisable dans le domaine $10^{-6} < \tau_c < 10^{-4}$ s et la r.p.e. dans le domaine $10^{-9} < \tau_c < 10^{-6}$ s. La possibilité de mesurer τ_c par ces deux méthodes, dans des conditions expérimentales indentiques, nous paraît la conséquence d'une très large distribution des temps de corrélation de réorientation, dans la phase métastable ainsi qu'au voisinage des points de transition.

L'un des auteurs (C.C.) remercie M. Sohma Professeur à l'Université d'Hokkaido pour lui avoir communiqué le prétirage d'un article (19) ainsi que M. Rigny, ingénieur au C.E.A., qui lui a fait connaître les résultats de mesures de relaxation effectuées dans son laboratoire (16).

Synthesis and Novel Rearrangement of 1,1,1-Trichloro-2-alken-4-ones

EBERHARD KIEHLMANN, PUI-WAH LOO, B. C. MENON, AND NORA MCGILLIVRAY
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received March 31, 1971

Strong mineral acids convert 1,1,1-trichloro-2-hydroxy-4-alkanones to 1,1,1-trichloro-2-alken-4-ones and 1,1,5-trichloro-1-alken-4-ones via an intramolecular chlorine shift from C-1 to -5 of an enol allylic system. Alternatively, 1,1,1-trichloro-2-alken-4-ones may be synthesized from 1,1,1-trichloro-2-hydroxy-4-alkanones by acetylation and elimination of acetic acid or by nucleophilic substitution with thionyl chloride followed by dehydrohalogenation. The two diastereomeric 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanones do not epimerize during acetylation, and the *erythro*-acetate resists elimination of acetic acid. Pyrolysis of 2-(1-hydroxy-2,2,2-trichloroethyl-)cyclohexanone yields 2-(2,2-dichlorovinyl)-2-cyclohexenone while treatment of 1,1,1,7,7,7-hexachloro-2,6-dihydroxy-4-heptanone with strong acid leads to the formation of 1,1,1,7,7,7-hexachloro-2,5-heptadien-4-one.

Des acides minéraux forts transforment les trichloro-1,1,1 hydroxy-2 alcanones-4 en trichloro-1,1,1 alcène-2 ones-4 et en trichloro-1,1,5 alcène-1 ones-4 par déplacement intramoléculaire du chlore du carbone en position 1 sur le carbone en position 5 d'un système énol allylique. Alternativement, les trichloro-1,1,1 alcène-2 ones-4 peuvent être synthétisés à partir des trichloro-1,1,1 hydroxy-2 alcanones-4 soit par acétylation et élimination de l'acide acétique soit par substitution nucléophile avec le chlorure de thionyle suivie d'une déshydrohalogénation. Il n'y a pas épimérisation au cours de l'acétylation des deux trichloro-1,1,1 hydroxy-2 méthyl-3 hexanones-4 diastéréoisomères et l'acétate érythro résiste à l'élimination de l'acide acétique. Le pyrolyse de la (hydroxy-1 trichloroéthyl-2,2,2)-2 cyclohexanone conduit à la (dichloro-2,2 vinyl)-2 cyclohexène-2 one tandis que le traitement de la hexachloro-1,1,1,-7,7,7 dihydroxy-2,6 heptanone-4 avec un acide fort n'amène pas la formation d'hexachloro-1,1,1,7,7,7 heptadiène-2,5 one-4.

Canadian Journal of Chemistry, 49, 2964 (1971)

In the course of our studies of the acetate-catalyzed crossed aldol condensation of chloral with aliphatic ketones in acetic anhydride (1) or glacial acetic acid (2) we observed that this reaction is not accompanied by dehydration of the resulting 1,1,1-trichloro-2-hydroxy-4-alkanones. The low tendency of trichloromethyl-substituted β-ketols to eliminate water (3) parallels the inertness of trichloromethylcarbinols in substitution reactions (4, 5) which has been attributed to the strengthening of the O-alkyl bond by the inductive electron-withdrawing effect of the three chlorine atoms attached to the adjacent carbon (6, 7). Since our attempts to effect the desired elimination reaction under mild neutral conditions using the recently recommended dicyclohexylcarbodiimide (8) in ether solution were not successful and since trichloromethylcarbinols are sensitive to strong base (9), we investigated the synthesis of the title compounds in neutral or acidic solution by three methods involving the conversion of the hydroxy group of the corresponding β-ketols to a better leaving group: protonation, acetylation, and replacement by chlorine.

Results and Discussion

1,1,1-Trichloro-2-penten-4-one has been prepared as early as 1893 (10) by heating acetone and chloral in a sealed tube, and a few years later (11) by treatment of 1,1,1-trichloro-2-hydroxy-4-pentanone with cold concentrated sulfuric acid. However, attempts by Auwers and Schmid (3) to prepare trichlorocrotonic acid from 4,4,4-trichloro-2-hydroxybutanoic acid under similar reaction conditions were unsuccessful. Baluja and coworkers (12, 13) have reported the synthesis of four 1,1,1-trichloro-2-alken-4-ones by pyrolysis of the corresponding β-ketols in molten potassium bisulfate and pointed out that prolonged thermal treatment leads to isomerization and fragmentation reactions.

Adopting a procedure previously described (14) for the dehydration of 1,1,1-trichloro-2-hydroxy-6-phenyl-5-hexen-4-one, we selected initially benzene (or toluene) and *p*-toluenesulfonic acid (TsOH) as solvent and catalyst, respectively. Although the expected 1,1,1-trichloro-4-phenyl-2-buten-4-one was formed in high yield from the corresponding phenyl-substituted ketol, application of this procedure to

purely aliphatic 1,1,1-trichloro-2-hydroxy-4-alkanones of the general structure RCH_2COCHR'-$CHOHCCl_3$ (*a*) yielded discolored reaction mixtures containing in each case two isomeric olefins and a substantial quantity of unreacted starting material. Separation and spectroscopic analysis showed these two products to be the desired 1,1,1-trichloro-2-alken-4-one (*b*) and the corresponding isomeric 1,1,5-trichloro-1-alken-4-one (*c*, eq. 1). Treatment of *a* with molten potassium bisulfate (13) or with refluxing acetic acid containing a trace of sulfuric acid as catalyst gave similar results (Table 1). In the latter case, *c* was found to be the major product after prolonged reflux of the reaction mixture while flash pyrolysis over $KHSO_4$ yielded predominantly *b*. Starting from pure 1,1,1-trichloro-6-methyl-2-hepten-4-one (**2***b*), glacial acetic acid and sulfuric acid, isomerization to 1,1,5-trichloro-6-methyl-1-hepten-4-one (**2***c*) was observed after 6 h at 100°. These observations indicate that *c* is formed by a stepwise dehydration–rearrangement sequence. Close examination of the n.m.r. spectra of several crude product mixtures obtained from the crossed aldol condensation of chloral with dialkyl ketones in glacial acetic acid without added base catalyst (2) revealed that 1,1,5-trichloro-1-alken-4-ones (*c*) constitute the main by-product (<10%) formed under these conditions. All attempts to prepare 1,1,5-trichloro-1-penten-4-one by acid-catalyzed dehydration of 1,1,1-trichloro-2-hydroxy-4-pentanone or rearrangement of 1,1,1-trichloro-2-penten-4-one failed.

The structure assignments for the rearrangement products are based on their n.m.r. spectroscopic analysis. The olefinic protons of **1***c*, **2***c*, and **3***c* appeared at τ 3.93 (triplet), 3.89 (triplet), and 4.17 (two overlapping doublets, due to the existence of two diastereomeric structures), respectively, and were coupled to the protons of the adjacent carbon (**1***c*: τ 6.45, doublet, 2H; **2***c*: 6.43, doublet 2H; **3***c*: 6.01, multiplet, 1H). The protons attached to the chloro-substituted carbon atoms absorbed at τ 5.83 (triplet, **1***c*), 5.93 (doublet, **2***c*) and 5.60 (quartet, **3***c*) and were coupled to their respective vicinal protons (**1***c*: τ 8.10, multiplet, 2H; **2***c*: 7.62, multiplet, 1H; **3***c*: 8.40, doublet, 3H) with a coupling constant of 6.5 Hz. Although the fine-splitting of several peaks due to the non-equivalence of methylene protons near the asymmetric centers of **1***c* and **2***c* has not been taken into account in this simple first-order analysis, these chemical shifts and peak multiplicities are clearly inconsistent with the spectral parameters observed for **1***b*, **2***b*, and **3***b* (see Table 3) or with the pattern expected for the products of an allylic shift of chlorine (15) from C-1 of *b* to C-3 (see below).

To verify our structure assignments, we subjected several 1,1,1-trichloro-2-alken-4-ones (*b*) to those reaction conditions which have recently been reported (15) to lead to allylic rearrangements. These experiments confirmed the results obtained by Takeda for the silica-catalyzed rearrangment of methyl and phenyl 3,3,3-trichloro-1-propenyl ketone and showed that the corresponding tert-butyl alkenone **4***b* undergoes an analogous reaction (eq. 2). The co-product of acid-catalyzed dehydration of **4***a* described by Baluja (13) as the *cis*-isomer on the basis of i.r. absorption at 670 to 690 cm^{-1} (no n.m.r. or u.v. data reported) was actually found to be identical with the allylic isomer **4***d*. On the other hand, pyrolysis of **2***b* and **7***b* on silica did not lead to an analogous allylic shift but gave the 1,5-rearrangement products **2***c* and **7***c* shown in eq. 3 (see also eq. 1). The spectroscopic data observed for the previously described (16) 1,1-dichloro-6-methyl-1-hepten-4-one (n.m.r. τ 3.82 triplet for $—CH=CCl_2$ and 6.60 doublet for $—COCH_2$-$CH=CCl_2$; i.r. bands at 1625 and 1720 cm^{-1}; u.v. absorption maxima at 206 (ε 4700) and 273 nm (ε 150)) are very similar to those found for **2***c* thus providing further support for our structure assignment.

Although thermal allylic rearrangements of

1,1,1-trichloro-2-alkenes in the presence or absence of metal or metal oxide catalysts have been described by other authors (17–19), the shift of a chlorine atom from the γ- to the α′-position of an α,β-unsaturated ketone has to our knowledge not been reported before. Ohse *et al.* (20) observed thermal isomerization of trichlorocrotonic acid to 2,4,4-trichloro-3-butenoic acid in 90% yield while LeCoq (21) did not detect any 2,4,4-trichloro-3-butenal after prolonged heating of trichlorocrotonaldehyde in the presence of Lewis acids. We believe that acid-catalyzed enolization of *b* to form an enol allylic chloride (22) and the close proximity of the bulky trichloromethyl group to the α′-methylene carbon in certain conformations of this molecule are the major driving forces for a [1,5] sigmatropic transfer of chlorine which is presumed to be a thermally allowed suprafacial process (23) if orbital symmetry is to be conserved during the reaction (eq. 4).

The formation of 2-(2,2-dichlorovinyl)-2-cyclohexenone (eq. 5) by thermal decomposition of 2-(1-hydroxy-2,2,2-trichloroethyl)-cyclohexanone (**8***a*) during distillation appears to confirm this view. Since in this case the trichloromethyl group of the originally formed dehydration product cannot adopt a position favorable for a chlorine shift to the α′-carbon via a six-membered ring transition state, normal allylic rearrangement and elimination of hydrogen chloride lead to the observed product.

The acid-catalyzed dehydration of 1,1,1,7,7,7-hexachloro-2,6-dihydroxy-4-heptanone (**9***a*) in refluxing toluene was found to proceed without allylic rearrangement giving the highly conjugated, yellow 1,1,1,7,7,7-hexachloro-2,5-heptadien-4-one (**9***b*) in good yield (eq. 6).

Confirming and supplementing recently published data by Bowman and Williamson (24) we wish to report that **9***a* exists in two diastereomeric forms, and that both diastereomers (m.p. 119–121°, crystallized from chloroform; m.p. 157–158°, crystallized from ethanol) rather than the previously claimed (25) tetrahydro-2,5-bis(trichloromethyl)-4*H*-pyran-4-one are formed in the

condensation of chloral hydrate with acetonedicarboxylic acid.

A more satisfactory method for the preparation of 1,1,1-trichloro-2-alken-4-ones consists of the acetylation-elimination sequence shown in eq. 7. Auwers (3) used this procedure for the preparation of trichlorocrotonic acid from 4,4,4-trichloro-3-hydroxybutanoic acid. Our results of several acetylation experiments are summarized in Table 2. Although acetylation proceeds smoothly in refluxing acetic anhydride, only traces of ketol acetates *e* were detected in the crude product mixtures obtained from the acetate-catalyzed condensation of chloral hydrate with aliphatic ketones in acetic anhydride as solvent (1). In the absence of a catalyst or in the presence of catalytic amounts of glacial acetic acid, 1,1,1-trichloro-2-acetoxy-4-alkanones (*e*) were formed in high yields (Table 2) together with small quantities of the corresponding elimination products (*b*). When the reaction of **2***a* with acetic anhydride was monitored by v.p.c., the concentration of **2***e* was found to increase rapidly during the first 2 h (50% conversion after 2.5 h) and to reach a maximum at 70% conversion (10 h). After 24 h, the starting material had disappeared, and the product mixture contained ketol acetate (**2***e*), elimination product (**2***b*), and unidentified by-products in the approximate ratio 3.7:1:1. It is noteworthy that the two diastereomeric 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanones (*erythro-* and *threo-***3***a*) were converted to the corresponding acetates without detectable epimerization of starting material or product.[1] The *erythro*-isomer of 2-(1-hydroxy-2,2,2-trichloroethyl)-cyclohexanone (**8***a*), on the other hand, gave the corresponding acetate (*erythro-***8***e*) as major product together with small amounts of epimerized starting material and product (after 22 h at 100°).

By comparison of the carbonyl stretching

frequencies of the two diastereomeric 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanones (**3***a*) and their acetates (**3***e*) we were able to verify the presence of strong intramolecular hydrogen bonding in the *threo*-isomer of **3***a* (1). The carbonyl absorption bands of *threo*-**3***a* and *threo*-**3***e* were observed at 1700 and 1720 cm^{-1}, respectively. This blue-shift of 20 cm^{-1} on acetylation of the hydroxy group is of the same order of magnitude (13–24 cm^{-1}) reported by Stiles *et al.* (26) for a series of aromatic β-hydroxy ketones and can be attributed to the breaking of the hydrogen bond. The carbonyl peaks of both the *erythro*-ketol **3***a* and the *erythro*-acetate **3***e* appeared at 1720 cm^{-1}.

In the presence of sodium acetate, the reaction of 1,1,1-trichloro-2-hydroxy-4-alkanones (*a*) with acetic anhydride gives predominantly 1,1,1-trichloro-2-alken-4-ones (*b*) (Table 2). When a mixture of equimolar amounts of *threo*-ketol **3***a* and *threo*-acetate **3***e* was subjected to these reaction conditions and the progress of the reaction was monitored by v.p.c., the acetate was found to react more rapidly than the ketol. This result, in conjunction with the observed rapid and quantitative conversion of pure *threo*-acetate **3***e* to the corresponding alkenone **3***b* after only 45 min at 100° indicates that acetic acid is eliminated more readily from *threo*-**3***e* than water from *threo*-**3***a*, and that the dehydration reactions may proceed via acetylated intermediates.

It is interesting to note that even in the presence of sodium acetate the epimerization rate of diastereomeric acetates **3***e* is very slow relative to the rate of elimination, and that only traces of **3***b* were formed from *erythro*-**3***e*. Examination of space-filling molecular models indicates that this marked reactivity difference is probably due to destabilization of the transition state for *trans*-elimination of acetic acid from *erythro*-**3***e* caused by unfavorable non-bonding interactions between the bulky trichloromethyl group on the β-carbon and the methyl group on the α-carbon. In the most favorable conformation for *trans*-elimination of acetic acid from *threo*-**3***e*, on the other hand, the trichloromethyl and the methyl group reside in *anti*-position, and steric interactions between the trichloromethyl group and the alkyl-substituted carbonyl group can be minimized by free rotation about the R—CO—R′ single bonds (eq. 8). On this basis we have assigned structure **3***b* to the olefinic product.[2] This interpretation presumes that the most favored pathway for elimination involves a *trans*-concerted process.[3]

Since both the acid-catalyzed dehydration of

[2]Experiments to synthesize the other geometric isomer of **3***b* for a comparison of spectral and chemical properties are presently in progress.

[3]Cristol (32) and Truce (33) have used similar arguments and explained the low tendency of certain *threo*-β-chloro- and β-hydroxysulfones to undergo elimination reactions by repulsive steric interactions between the α-substituent (alkyl or phenyl) and the large sulfonyl group. In our case, the *erythro*-compound is less reactive because of the considerably larger steric requirements of the trichloromethyl group (compared to a methyl or phenyl group) and the smaller size of the carbonyl group (compared to a sulfonyl group).

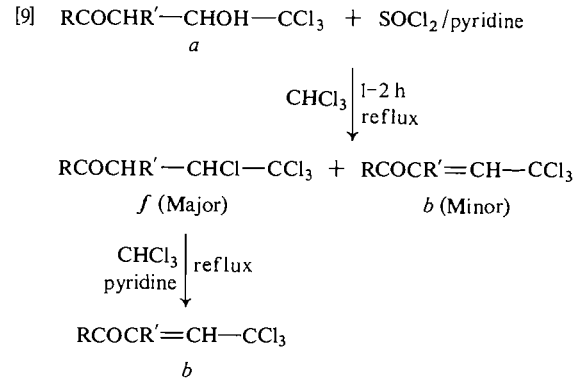
1,1,1-trichloro-2-hydroxy-4-alkanones (eq. 1) and the preparation of 1,1,1-trichloro-2-alken-4-ones via ketol acetates (see eq. 7 and last column of Table 2) are accompanied by undesirable side reactions and the separation of isomeric products proved to be difficult, we investigated the synthesis and dehydrohalogenation of 1,1,1,2-tetrachloro-4-alkanones (*f*) as an alternative route. Although Lucas reagent (5), aluminum chloride (27), and phosphorus pentachloride (19, 28) have been successfully used to replace the hydroxy group of trichloromethylcarbinols by chlorine, these substitution reactions are generally slow due to the electron-withdrawing effect and the steric bulk of the trichloromethyl group (4, 6, 7) and may lead to undesirable rearrangements or product decomposition (19, 29) under the drastic reaction conditions required. Thionyl chloride, on the other hand, has been reported (30) to react smoothly with aryl-substituted 1,1,1-trichloro-2-hydroxy-4-alkanones in the presence of pyridine to yield 1,1,1,2-tetrachloro-4-alkanones at low temperature and the corresponding dehydrohalogenation products at reflux temperature in chloroform.

Following this procedure, we obtained in high yield mixtures of 1,1,1,2-tetrachloro-4-alkanones (*f*) and 1,1,1-trichloro-2-alken-4-ones (*b*) with the substitution product generally predominating (eq. 9). Even at $-10°$ some *b* was formed, while in the absence of pyridine the starting material was quantitatively recovered. However, the *f*/*b* ratio was always found to be considerably higher when the reaction was carried out at lower temperatures (25 or 0° instead of reflux). This result together with the observation that **2***f* and **6***f* are readily dehydrohalogenated by pyridine in refluxing chloroform indicates that tetrachloro-



1 R = *n*-Pr; R′ = H

6 R = C_6H_5; R′ = H
7 R = *t*-$BuCH_2$; R′ = H
10 R = Et; R′ = H
11 R = C_6H_5CH:CH, R′ = H

alkanones (*f*) may be involved as intermediates in the formation of the corresponding 1,1,1-trichloro-2-alken-4-ones (*b*). The conversion of the starting ketols *a* to the products shown in eq. 9 was generally 80–90% complete after 90 min reflux, and further extension of the reaction time led to extensive product decomposition (except for **6***a* and **11***a*). Similar results were obtained on treatment of **2***f* with sodium acetate in glacial acetic acid as dehydrohalogenating agent.

The two diastereomeric ketols *erythro*-**3***a* and *threo*-**3***a* were found to equilibrate rapidly under these reaction conditions to give a mixture of epimers which underwent normal substitution and dehydration. However, they reacted at a much slower rate (40–60% recovery of starting material after 90 min reflux time) than the other ketols which appears to be a consequence of the lower acidity of the hydrogen atom at the methyl-substituted α-carbon adjacent to the —CHOH— group. The two aryl-substituted 1,1,1-trichloro-2-hydroxy-4-alkanones **6***a* and **11***a* exhibited the highest reactivity of the 10 ketols studied and were quantitatively converted to their respective substitution (*f*, major) and dehydration (*b*, minor) products after 1 h at 60°. This result is in agreement with the observation by Roedig and Klappert (30) that **11***a* but not the corresponding diol C_6H_5CH=CH—CHOH—CH_2—CHOH—CCl_3 undergoes chlorine substitution at the trichloromethyl-substituted car-

[10] 
bon when treated with thionyl chloride and pyridine. Enolization to form a highly conjugated enol allylic system (22) appears to facilitate substitution, and the reaction of both aryl- and alkyl-substituted 1,1,1-trichloro-2-hydroxy-4-alkanones with thionyl chloride may well proceed by the S_Ni' mechanism which has been postulated by Pilgram and Ohse (31) and Steckel (19) for the analogous rearrangement of certain alkenyltrichloromethylcarbinols (eq. 10). However, the enol-stabilizing resonance effect involving the phenyl substituent of **11***a* does not render the trichloromethyl-substituted carbon so reactive as to permit solvolytic displacement of its hydroxy group. Thus, n.m.r. spectral analysis has shown that **11***a* can be recrystallized from methanol without structural change, and the reported (30) formation of 1,1,1-trichloro-2-methoxy-6-phenyl-5-hexen-4-one (or any other methoxy-substituted compound) under these conditions has been found to be in error.

Experimental

Elemental analyses were performed by A. Bernhardt Microanalytical Laboratory, Elbach, Germany. The u.v. spectra were run in 95% ethanol using a Unicam SP-200 spectrometer. The n.m.r. spectra were recorded on a Varian A 56/60 spectrometer using TMS as internal standard and $CDCl_3$ as solvent, and i.r. spectra on a Beckman IR-12 or a Perkin–Elmer 457 spectrometer using a dilute CCl_4 solution or a thin film of neat liquid (or melt) between sodium chloride plates.

The v.p.c. analyses were carried out on a Varian Aerograph Model 1200-1 HY-FI III gas chromatograph using a 5 ft × 1/8 in. column packed with 5% SE-30, 5% SE-52, or 2% OV-17 on Aeropak 30 (column temperature 110–140°) and nitrogen as carrier gas.

All 1,1,1-trichloro-2-hydroxy-4-alkanones were prepared from chloral and the respective ketones as previously described (1, 2). Thionyl chloride was distilled before use, while other chemicals were used without further purification (commercially available reagent grade quality).

Acid-catalyzed Dehydration of 1 1,1-Trichloro-2-hydroxy-4-alkanones

Method 1

Using a modified version of the procedure described before (14) for the preparation of **12***b*, a solution of 24.8 g (0.10 mol) of 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**2***a*) and 6.0 g (0.03 mol) of *p*-toluenesulfonic acid in 160 ml benzene was vigorously refluxed for 24 h. Washing with water, drying over magnesium sulfate, and evaporation of the solvent under reduced pressure gave 20 g of a black oil which was found by v.p.c. analysis to contain 1,1,1-trichloro-6-methyl-2-hepten-4-one (**2***b*), 1,1,5-trichloro-6-methyl-1-hepten-4-one (**2***c*), and starting material in the ratio 39:31:30. Recrystallization from petroleum ether (60–100°) yielded 6 g of the starting ketol (**2***a*). Evaporation of the solvent from the mother liquor and vacuum distillation of the residue gave 8 g of a mixture of **2***b* and **2***c* boiling at 57–64°/0.01 mm. Small samples of pure **2***b* and **2***c* were obtained by repeated liquid partition chromatography of the distillate on silica using 20% (by volume) petroleum ether (60–100°) in benzene as eluent.

Compound **2***b*: m p. 17.5–18°, b.p. 57–60°/0.01 mm; i.r. (neat) 962 (H—C=), 1628 (C=C), 1678 and 1703 cm^{-1} (C=O); u.v. (95% EtOH) λ_{max} 223 (ε 12 000) and 336 nm (ε 38).

Anal. Calcd. for $C_8H_{11}OCl_3$: C, 41.86; H, 4.83; Cl, 46.37. Found: C, 41.69; H, 5.02; Cl, 46.41.

Compound **2***c*: b.p. 60–64°/0.01 mm.

Anal. Calcd. for $C_8H_{11}OCl_3$: C, 41.86; H, 4.83; Cl, 46.37. Found: C, 41.98; H, 4.72; Cl, 46.26.

The i.r. (neat) 1720 (C=C) and 1620 (C=C) cm^{-1}; u.v. (95% EtOH) λ_{max} 206 (ε 3500) and 270 nm (ε 1200).

Application of the same procedure to 1,1,1-trichloro-2-hydroxy-4-heptanone (**1***a*) yielded 1,1,1-trichloro-2-hepten-4-one (**1***b*), b.p. 48–49°/0.01 mm, and 1,1,5-tri-

chloro-1-hepten-4-one (**1***c*), b.p. 55–60°/0.01 mm (see Tables 1 and 3).

Anal. Calcd. for $C_7H_9OCl_3$ (**1***c*): C, 39.01; H, 4.20; Cl, 49.35. Found: C, 38.88; H, 4.35; Cl, 49.30.

Reflux of a solution of 26.8 g (0.10 mol) of 1,1,1-trichloro-2-hydroxy-4-phenyl-4-butanone (**6***a*) and 2.0 g (0.01 mol) of *p*-toluenesulfonic acid in 160 ml toluene for 9.5 h and the usual work-up gave 24 g of a yellow, crude product from which 20 g (80% yield) of 1,1,1-trichloro-4-phenyl-2-buten-4-one (**6***b*), m.p. 99–100° (lit. (15) 98–99°) was obtained by recrystallization from petroleum ether (65–110°). The carbonyl and olefinic stretching vibrations of **6***b* were observed at 1680 and 1625 cm^{-1}, respectively, and u.v. absorption maxima (EtOH) at 233 (ε 7400) and 350 nm (ε 95).

Method 2

A solution of 12.4 g (0.05 mol) of **2***a* in 30 g of glacial acetic acid containing five drops of 10% sulfuric acid was heated at 100° for 24 h. After evaporation of the solvent the black reaction mixture was dissolved in ether, washed with water and 10% sodium bicarbonate solution, and dried over magnesium sulfate. Removal of the solvent left a dark oil (9.6 g) containing **2***c* (major product), unreacted starting material and a small amount of **2***b* (ratio of v.p.c. peak areas 11:6:1). Vacuum distillation furnished 5.5 g of distillate (b.p. 66–70°/0.025 mm) from which a pure sample of **2***c* was isolated by liquid partition chromatography as described before.

1,1,5-Trichloro-1-hepten-4-one (**1***c*) and 1,1,5-trichloro-1-hexen-3-methyl-4-one (**3***c*) were prepared by the same procedure from 1,1,1-trichloro-2-hydroxy-4-heptanone (**1***a*) and 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanone (**3***a*), respectively (see Table 1).

Method 3

According to the procedure described by Baluja and coworkers (12, 13) for the preparation of several 1,1,1-trichloro-2-alken-4-ones, 27 g (0.2 mol) of potassium bisulfate was dried at 100° and placed in a 100-ml three-necked flask equipped with thermometer and distillation assembly. After preheating the potassium bisulfate to 230°, 24.8 g (0.10 mol) of **2***a* was rapidly added over a 5-min period and the mixture was immediately distilled at aspirator vacuum (b.p. 115°/15 mm). Addition of ether to the distillate, washing with water, drying, and solvent evaporation gave 8.78 g (38% yield) of a yellow liquid which was found by v.p.c. and n.m.r. analysis to contain **2***b*, **2***c*, and **2***a* in the approximate ratio 70:23:7. When the original mixture of **2***a* and potassium bisulfate was refluxed for 2 h at 130° before distillation, n.m.r. and v.p.c. analysis of the crude distillate (18.6 g = 81% yield) revealed the formation of small amounts of several unidentified byproducts and an increase in the **2***c*/**2***b* ratio from 23/70 to 52/30 (Table 1).

Catalytic Rearrangement of 1,1,1-Trichloro-2-alken-4-ones

Adopting the procedure described in the literature (15) for the rearrangement of **5***b* and **6***b*, 6.38 g of silica gel (0.106 mol) was added to 6.38 g (0.028 mol) of 1,1,1-trichloro-5,5-dimethyl-2-hexen-4-one (**4***b*), and the mixture was heated for 17 h at 130° in a round-bottom flask equipped with reflux condenser. Vacuum distillation of the black semi-solid product mixture yielded 3.10 g (49% yield) of a clear yellow liquid, b.p. 36–38°/10 mm, which was found by n.m.r. and v.p.c. analysis to be pure 1,1,3-trichloro-5,5-dimethyl-1-hexen-4-one (**4***d*).

Spectroscopic Identification

Compound **4***d*: n.m.r. ($CDCl_3$) τ 3.69 (doublet, 1H, $—CH_A=CCl_2$), 4.50 (doublet, 1H, $—CH_BCl—$), and 8.76 (singlet, 9H, $(CH_3)_3C—$), J_{AB} = 10.0 Hz; i.r. (neat) 1625 (C=C) and 1725 cm^{-1} (C=O); u.v. (EtOH) λ_{max} 222 (ε 7700) and 297 nm (ε 130).

Subjecting 1,1,1-trichloro-2-penten-4-one (**5***b*) and 1,1,1-trichloro-4-phenyl-2-buten-4-one (**6***b*), respectively, to the same reaction conditions (15) gave the corresponding allylic rearrangement products **5***d* (27% yield of crude distillate b.p. 40–42°/0.2 mm, containing 8% unidentified byproduct) and **6***d* (20% yield of crude distillate, b.p. 120–125°/3.5 mm, containing 17% unidentified byproduct) with the following spectroscopic characteristics.

Compound **5***d*: n.m.r. ($CDCl_3$) τ 3.89 (doublet, 1H, $—CH_A=CCl_2$), 5.04 (doublet, 1H, $—CH_BCl—$), and 7.70 (singlet, 3H, CH_3), J_{AB} = 10 Hz (lit. (15) τ 3.96, 5.08, and 7.68, J_{AB} = 9 Hz); i.r. (neat) 1733 (C=O, lit. (15) 1730) and 1623 cm^{-1} (C=C); u.v. (EtOH) λ_{max} 221 (ε 8900) and 270 nm (ε 340).

Compound **6***d*: n.m.r. ($CDCl_3$) τ 1.95 and 2.50 (aromatic multiplet, 5H), 3.48 (doublet, 1H, $—CH_A=CCl_2$), and 4.06 (doublet, 1H, $—CH_BCl—$), J_{AB} = 9.5 Hz; i.r. (neat) 1620 (C=C) and 1700 cm^{-1} (C=O) (lit. (15) 1618 and 1690 cm^{-1}); u.v. (EtOH) λ_{max} 254 nm (ε 10 700).

Treatment of 1,1,1-trichloro-6-methyl-2-hepten-4-one (**2***b*) with silica at 130° resulted in the formation of 1,1,5-trichloro-6-methyl-1-hepten-4-one (**2***c*) (low yield), as identified by comparison of the n.m.r. spectrum of the distillate with that of an authentic sample of **2***c*, and one unidentified by-product. No absorption peaks were observed in the τ 4.0–5.1 range characteristic of the —CHCl— proton of 1,1,3-trichloro-1-alken-4-ones (see **4***d* and **5***d*).

Similarly, 1,1,1-trichloro-6,6-dimethyl-2-hepten-4-one (**7***b*) was found to rearrange on silica to 1,1,5-trichloro-6,6-dimethyl-1-hepten-4-one (**7***c*) rather than to 1,1,3-trichloro-6,6-dimethyl-1-hepten-4-one. In this experiment, 7.0 g (0.030 mol) of **7***b* yielded 1.16 g (20% yield) of **7***c* after 17 h heating at 130° on 7.0 g of silica and vacuum distillation (b.p. 109–114°/1.8 mm).

Compound **7***c*: n.m.r. ($CDCl_3$) τ 3.90 (triplet, 1H, $—CH=CCl_2$), 5.94 (singlet, 1H, —CHCl—), 6.45 (doublet, 2H, $—CH_2—$) and 8.91 (singlet, 9H, *t*-Bu); i.r. (neat) 1730 (C=O) and 1625 cm^{-1} (C=C).

Pyrolysis of 2-(1-Hydroxy-2,2,2-trichloroethyl)-cyclohexanone (8a)

It has been reported previously (2) that the condensation of chloral with cyclohexanone in glacial acetic acid results in complete product decomposition when carried out in the absence of a base catalyst; excessively high reaction temperatures and/or long reaction times had the same effect even in the presence of sodium acetate. Since decomposition, once it had started, proceeded rapidly and with evolution of hydrochloric acid, the following experiment was carried out with the sole intent to isolate and identify the major organic decomposition product.

Using the standard condensation procedure (2), a mixture of 30.7 g (0.31 mol) of cyclohexanone, 36.9 g (0.25 mol) of chloral, 5.1 g (0.063 mol) of anhydrous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sodium acetate, and 0.50 mol of glacial acetic acid was heated at 100° for 58 h at which time the evolution of hydrochloric acid fumes and black coloration of the reaction mixture indicated decomposition of the original condensation product (**8***a*). After another 6 h of reaction time, solvent and unreacted starting materials were evaporated, the residue was taken up in ether, washed with water and sodium bicarbonate solution, and dried over magnesium sulfate. Evaporation of the ether gave 48 g of a black viscous oil which was found by v.p.c. analysis to contain **8***a* and two more volatile products in the approximate ratio 8:35:7. The latter two compounds were separated from **8***a* by two high-vacuum distillations (b.p. 85–95°/0.025 mm), and the major component, 2-(2,2-dichlorovinyl)-2-cyclohexanone, was obtained in pure form by preparative gas chromatography on a 20 ft × 3/8 in. 30% SE-52 column at 250°. The originally colorless condensate in the collection tube turned blue-green on standing, the same color which was observed during distillation. The identity of the collected sample (> 96% pure) with the major component of the original crude product mixture was confirmed by re-injection into two analytical v.p.c. columns (OV-17 at 115° and SE-30 at 160°) and comparison of retention times. The structure assignment rests on the analytical and spectroscopic evidence listed below.

Anal. Calcd. for $C_8H_8Cl_2O$: C, 50.29; H, 4.22. Found: C, 50.00; H, 4.00.

Mass spectrometry (80 eV): peaks at *m/e* 190 (P), 192 (P + 2), and 194 (P + 4) in the relative intensity ratio 100:67:16 expected for a compound containing two chlorine atoms (theoretical ratio = 100:65:11), isotopic fragment peaks at *m/e* 162 (100%), 164 (61%), and 166 (13%) due to loss of CO, and base peak (P-chlorine) at *m/e* 155 (100%) with isotopic satellite at *m/e* 157 (34%, expected P/(P + 2) intensity ratio 100:33). The n.m.r. ($CDCl_3$): τ 2.55 (triplet, 1H, $=CH—CH_2—$), 3.28 (singlet, 1H, $—CH=CCl_2$), 7.52 (multiplet, 4H, $—CO—CH_2—$ and $=CH—CH_2—$), and 7.93 (multiplet, 2H, $—CH_2—CH_2—CH_2—$). The i.r. (neat): absorption maxima at 1676 ($>C=C—CO—$) and 1602 cm^{-1} (C=C, *s-cis*). The u.v./visible (95% EtOH): 215 (ε 33 000), 260 (ε 16 000), and 374 nm (ε 180); weak absorption at 642 nm due to colored impurity.

*Preparation of 1,1,1,7,7,7-Hexachloro-2,5-heptadien-4-one (**9b**)*

1,1,1,7,7,7 - Hexachloro - 2,6 - dihydroxy - 4 - heptanone (**9***a*), the precursor of **9***b*, was prepared according to the procedure described by Caujolle and coworkers (25). The crude product (light brown solid) obtained in 65% yield from chloral hydrate and acetonedicarboxylic acid in aqueous solution was recrystallized several times from chloroform to give **a white solid** (**9***a*-1) melting at 119–121°. Evaporation of the solvent from the mother liquors and several successive recrystallizations from ethanol yielded an isomeric white solid (**9***a*-2) melting at 157–158°. Spectroscopic characterization of these two compounds proved to be difficult due to their low solubility in water and most organic solvents (except dioxane, DMSO and trifluoroacetic acid).

Anal. Calcd. for $C_7H_8Cl_6O_3$ (**9***a*-1): C, 23.83; H, 2.29; Cl, 60.28. Found: C, 23.72; H, 2.44; Cl, 60.39.

Compound **9***a*-1: n.m.r. ($CDCl_3$, 57°) τ 5.33 (broad multiplet, 2H, $>CH—CCl_3$), 6.52 (broad singlet, 2H, —OH), and 6.90 (unsymmetrical triplet, 4H, $—CH_2—$); i.r. (KBr pellet, Beckman IR-12) 3450 (strong and broad, OH) and 1721 cm^{-1} (strong, with shoulder at 1708 cm^{-1}, C=O); i.r. (0.5 *M* solution in $CHCl_3$, Beckman IR-12) 3594 (sharp, with shoulder near 3500) and 1726 cm^{-1} (C=O).

Anal. Calcd. for $C_7H_8Cl_6O_3$ (**9***a*-2): C, 23.83; H, 2.29; Cl, 60.28. Found: C, 23.70; H, 2.43; Cl, 60.17.

Compound **9***a*-2: n.m.r. ($CDCl_3$, 57°) τ 5.32 (sharp 1:1:1:1 quartet, 2H, $>CH—CCl_3$), 6.63 (broad singlet, 2H, OH), and 6.90 (unsymmetrical triplet, 4H, $—CH_2—$); i.r. (KBr pellet) 3490 (strong and broad, OH) and 1725 cm^{-1} (C=O); i.r. (0.5 *M* solution in $CHCl_3$) 3594 (sharp, with shoulder near 3500) and 1726 cm^{-1} (C=O); lit. (23): i.r. (Nujol) of **9***a* (m.p. 124–126°) 3448 (OH) and 1710 cm^{-1} (C=O).

Dehydration was accomplished by refluxing (17 h) a solution of 5 g of **9***a*-2 in 40 ml of benzene in the presence of 0.4 g of *p*-toluenesulfonic acid using a Dean-Stark trap for removal of the water from the azeotrope. The resulting black solution was washed with water and aqueous sodium bicarbonate, and dried to give 1.5 g of *trans,trans*-1,1,1,7,7,7-hexachloro-2,5-dien-4-one (**9***b*), m.p. 70–72° (yellow), after several recrystallizations from cyclohexane and chloroform. The i.r. (KBr pellet, Beckman IR-12) 1628, 1640 (C=C), 1680 and 1698 cm^{-1} (C=O). The appearance of two absorption maxima for the carbonyl and the olefinic stretching vibrations, respectively, and the low C=O/C=C intensity ratio (approximately 1.0) of these peaks indicate the presence of both *s-cis* (1698 and 1628 cm^{-1}) and *s-trans* (1680 and 1640 cm^{-1}) conformers with the former predominating. The u.v. (EtOH) of **9***b*: λ_{max} 232 (ε 7300) and 325 nm (ε 63).

Acetylation of 1,1,1-Trichloro-2-hydroxy-4-alkanones

A solution of 11.7 g (0.05 mol) of 1,1,1-trichloro-2-hydroxy-3-methyl-4-hexanone (*erythro*-**3***a*) in 20.4 g (0.20 mol) of acetic anhydride was heated at 100° for 72 h. The pale yellow oil (13.6 g = 99% yield) obtained after removal of the solvent was distilled under high vacuum to give 11.85 g (86% yield) of 1,1,1-trichloro-2-acetoxy-3-methyl-4-hexanone (*erythro*-**3***e*), b.p. 76°/0.01 mm. The i.r. (solution in CCl_4) 1720 (ketone C=O) and 1760 cm^{-1} (ester C=O).

Anal. Calcd. for $C_9H_{13}O_3Cl_3$: C, 39.23; H, 4.76; Cl, 38.60. Found: C, 39.40; H, 4.90; Cl, 38.67.

The ketol acetates listed below were prepared by a similar procedure (data on reaction time, crude product yield, and product composition are summarized in Table 2, n.m.r. chemical shifts in Table 3).

1,1,1-Trichloro-2-acetoxy-3-methyl-4-hexanone (*threo*-**3***e*): b.p. 69–70°/0.01 mm; i.r. (solution in CCl_4) 1720 (ketone C=O) and 1761 cm^{-1} (ester C=O).

Anal. Calcd. for $C_9H_{13}O_3Cl_3$: C, 39.23; H, 4.76; Cl, 38.60. Found: C, 39.13; H, 4.19; Cl, 38.72.

1,1,1-Trichloro-2-acetoxy-6-methyl-4-heptanone (**2***e*): b.p. 88–89°/0.01 mm; i.r. (neat) 1720 (ketone C=O) and 1767 cm^{-1} (ester C=O).

Anal. Calcd. for $C_{10}H_{15}O_3Cl_3$: C, 41.47; H, 5.22; Cl, 36.73. Found: C, 41.33; H, 5.40; Cl, 36.89.

1,1,1-Trichloro-2-acetoxy-4-pentanone (**5***e*): b.p. 76–

For personal use only.

77°/0.01 mm; i.r. (neat) 1725 (ketone C=O) and 1765 cm^{-1} (ester C=O). 2-(1-Acetoxy-2,2,2-trichloroethyl)-cyclohexanone (**8***e*): m.p. 110–111.5°; i.r. (Nujol) 1708 (ketone C=O) and 1754 cm^{-1} (ester C=O).

Preparation of 1,1,1-Trichloro-2-alken-4-ones from 1,1,1-Trichloro-2-acetoxy-4-alkanones

A solution of 82.5 g (0.33 mol) of 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**2***a*) in 170 g (1.67 mol) of acetic anhydride was heated at 115° for 14 h to give a crude product mixture which was found by v.p.c. analysis to contain 1,1,1-trichloro-2-acetoxy-6-methyl-4-heptanone (**2***e*, 70%), 1,1,1-trichloro-6-methyl-2-hepten-4-one (**2***b*, 20%), unreacted starting material (6%), and one unidentified by-product (3%). Addition of 3 g of anhydrous sodium acetate at this point and continuation of the reaction for another hour changed the **2***b*/**2***e* product ratio from 20/70 to 80/5 and also resulted in an appreciable increase of the relative amount of undesirable by-products (from 3 to 10% of the total product mixture) which are believed to be isomers of **2***b*. The usual work-up procedure gave 73 g of crude product (brown liquid) from which 52.5 g (68% yield) of 95% pure **2***b* was obtained by vacuum distillation (b.p. 61–67°/0.1 mm).

When solutions of pure 1,1,1-trichloro-2-acetoxy-4-pentanone (**5***e*) and *threo*-1,1,1-trichloro-2-acetoxy-3-methyl-4-hexanone (*threo*-**3***e*), respectively, in acetic anhydride were heated at 100° for 45 min in the presence of anhydrous sodium acetate, the corresponding α,β-unsaturated ketones **5***b* and **3***b* could be isolated in nearly quantitative yield. The *erythro*-isomer of **3***e*, on the other hand, did not react under these conditions (85% recovery).

Characterization of 1,1,1-trichloro-2-penten-4-one (**5***b*): m.p. 20–20.5° (lit. (15) 25–26°).

Anal. Calcd. for $C_5H_5OCl_3$: C, 32.03; H, 2.68; Cl, 56.74. Found: C, 32.16; H, 2.82; Cl, 56.60.

The i.r. (neat) 1623 (C=C), 1678 and 1704 cm^{-1} (C=O, *transoid* and *cisoid*) (lit. (15) 1630, 1676, and 1700 cm^{-1}).

Acetate-catalyzed Dehydration of 1,1,1-Trichloro-2-hydroxy-4-alkanones

To a solution of 10.3 g (0.05 mol) of 1,1,1-trichloro-2-hydroxy-4-pentanone (**5***a*) in 20.5 g (0.20 mol) of acetic anhydride was added 1 g of anhydrous sodium acetate. The mixture was heated at 100° for 90 min. After evaporation of the solvent under vacuum, the residue was dissolved in 100 ml of ether and washed with water. The organic layer was dried with magnesium sulfate and the ether was evaporated to give 8.4 g of a yellow liquid from which 7.1 g (75% yield) of pure 1,1,1-trichloro-2-penten-4-one (**5***b*), was obtained by high-vacuum distillation (b.p. 41–42°/0.01 mm). 1,1,1-Trichloro-2-hepten-4-one (**1***b*), 1,1,1-trichloro-6-methyl-2-hepten-4-one (**2***b*), 1,1,1-trichloro-5,5-dimethyl-2-hexen-4-one (**4***b*), and 1,1,1-trichloro-6,6-dimethyl-2-hepten-4-one (**7***b*) were prepared from their respective ketols by the same procedure (see Table 2).

Reaction of Aliphatic 1,1,1-Trichloro-2-hydroxy-4-alkanones with Thionyl Chloride

Adopting the procedure described in the literature (30) for the preparation of aryl-substituted 1,1,1-trichloro-2-alken-4-ones, 0.022 mol of thionyl chloride and 100 ml of pyridine were added to a solution of 0.02 mol of 1,1,1-trichloro-2-hydroxy-4-alkanone (*a*) in 12 ml of chloroform, and the mixture was refluxed (60°) for 90 min. After washing with water and drying over magnesium sulfate, the solvent was removed by vacuum distillation and the crude product mixture was analyzed by n.m.r. spectroscopy for 1,1,1-trichloro-2-alken-4-one (*b*), 1,1,1,4-tetrachloro-4-alkanone (*f*), and starting material (*a*); v.p.c. analysis confirmed that no other compounds were present. Pure samples of *b* and *c* were obtained by fractional crystallization from petroleum ether (60–100°) or by partition chromatography on silicic acid using 80% (v/v) benzene/petroleum ether (30–60°) as eluent. When this procedure was applied to the 1,1,1-trichloro-2-hydroxy-4-alkanones listed below, the results specified in parentheses (weight of crude product mixture, product composition, product separation by vacuum distillation (v.d.), fractional crystallization (f.c.), or partition chromatography (p.c.)) were obtained.

1,1,1-Trichloro-2-hydroxy-4-hexanone (**10***a*) (4.5 g, 27% **10***b*/57% **10***f*, p.c.); i.r. of **10***f* (neat) 1724 cm^{-1} (C=O).

Reaction of Aryl-substituted 1,1,1-Trichloro-2-hydroxy-4-alkanones with Thionyl Chloride

Following the procedure described in the literature (30) for the preparation of aryl-substituted 1,1,1,2-tetrachloro-4-alkanones, a solution of 0.11 mol of thionyl chloride in 8 ml of chloroform was added drop-wise at 0–5° to a magnetically stirred solution of 26.8 g (0.10 mol) of 1,1,1-trichloro-2-hydroxy-4-phenyl-4-butanone (**6***a*) and 1.0 ml pyridine in 36 ml chloroform. After the addition was complete (approximately 1 h), stirring was continued for another hour at 0–5°, and then for 20 h at room temperature. Washing with water, drying and solvent evaporation gave 28 g of a yellow solid containing 1,1,1-trichloro-4-phenyl-2-buten-4-one (**6***b*) and 1,1,1,2-tetrachloro-4-phenyl-4-butanone (**6***f*) in the approximate ratio 1:2. The n.m.r. spectrum of the crude product mixture did not reveal the presence of any starting material.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Fractional crystallization from petroleum ether (60–100°) afforded pure **6***f* (less soluble), m.p. 62.5–63.5° (lit. (30) 63°) and **6***b* (from the mother liquor), m.p. 99–100° (lit. (15) 98–99°). The same two products were obtained in the approximate ratio **6***b*/**6***f* 2:3 when the reaction was carried out at reflux temperature (see preceding experiment).

Application of the reflux procedure (90 min at 60°, see before) to the pyridine-catalyzed reaction of 1,1,1-trichloro-2-hydroxy-6-phenyl-5-hexen-4-one (**11***a*) with thionyl chloride resulted in the quantitative conversion of starting material to a mixture containing 45% 1,1,1-trichloro-6-phenyl-2,5-hexadien-4-one (**11***b*) and 55% 1,1,1,2-tetrachloro-6-phenyl-5-hexen-4-one (**11***f*). Fractional crystallization from petroleum ether (60–100°) yielded samples of pure **11***b*, m.p. 93.5–95° (lit. (14, 30) 94–95°), and **11***f*, m.p. 79–80° (lit. (30) 83°). The starting ketol (**11***a*) did not undergo any chemical change when recrystallized from methanol, as evidenced by the complete identity of the two n.m.r. spectra taken before and after recrystallization, respectively, and by the absence in the latter spectrum of a singlet peak at the chemical shift expected for a methoxy group.

Dehydrohalogenation of 1,1,1,2-Tetrachloro-4-alkanones

To a 4:1 mixture (5.12 g) of 1,1,1,2-tetrachloro-6-methyl-4-heptanone (**2***f*) and 1,1,1-trichloro-6-methyl-2-hepten-4-one (**2***b*) obtained from 1,1,1-trichloro-2-hydroxy-6-methyl-4-heptanone (**2***a*) and thionyl chloride as described before was added 3 ml of chloroform and excess pyridine (1.7 ml, 0.021 mol), and the solution was refluxed at 60° for 8 h. The v.p.c. monitoring of the reaction progress revealed a gradual increase in the relative concentration of **2***b* at the expense of **2***f*. After 4 h the mixture was found to contain 50% **2***b*, 36% **2***f*, and small percentages of three unidentified by-products. The relative proportion of these by-products increased rapidly during the second half of the reaction until the product mixture contained only 10% **2***b* and 10% **2***f* after 8 h reflux time.

Similarly, stirring of a solution of a 67:26 (relative v.p.c. peak areas) mixture of **2***f* and **2***b* in glacial acetic acid in the presence of sodium acetate changed the percentage ratio to 40:50 after 12 h at room temperature, 34:63 after 200 min at 50°, and 33:42 after 22.5 h at 50° with a large percentage of by-products (25%) present in the final product mixture.

When a solution of 0.5 g of pure 1,1,1,2-tetrachloro-5,5-dimethyl-4-hexanone (**4***f*) in 3.5 g chloroform was heated at 100° for 24 h in the presence of two drops of pyridine, a reaction mixture was formed which was estimated by v.p.c. to contain starting material (**4***f*) and 1,1,1-trichloro-5,5-dimethyl-2-hexen-4-one (**4***b*) in the approximate ratio 3:7 and small quantities of unidentified by-products.

The authors wish to thank the National Research Council of Canada for the financial support of these investigations. The technical assistance of Miss Rosemary Wald is gratefully acknowledged.

Szilard–Chalmers Reactions in Dicyclopentadienyldiirontetracarbonyl

W. KANELLAKOPULOS-DROSSOPULOS AND D. R. WILES[1]
Institut fur Heisse Chemie, Kernforschungszentrum Karlsruhe, Germany

Received March 2, 1971

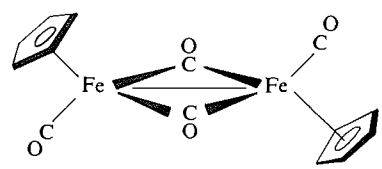
In neutron-irradiated solid $[CpFe(CO)_2]_2$ radioactive $FeCp_2$ and $Fe(CO)_5$ are formed, in addition to the radioactive parent compound. The radiochemical yields before annealing are 1.4, 3.2, and 16.0%, respectively. The predominance of $Fe(CO)_5$ over $FeCp_2$ is in keeping with previous observations. The yield of radioferrocene is not affected by subsequent thermal treatment at up to 75°, while the yields of the two carbonyl-containing compounds are increased up to 5.4 and 20.1%. The ferrocene yield is insensitive to irradiation time and temperature. From this insensitivity it is concluded that the Fe—Cp bonds are reformed by epithermal processes. Similarly the Fe—CO bonds are reformed by thermal as well as epithermal reactions.

Dans l'irradiation de $[CpFe(CO)_2]_2$ par les neutrons, il se forme du $FeCp_2$ et $Fe(CO)_5$ radioactif, en plus du composé radioactif parent. Les rendements radiochimiques avant le recuit sont respectivement de 1.4, 3.2 et 16.0%. La prédominance de $Fe(CO)_5$ sur $FeCp_2$ est en accord avec des observations précédentes. Le rendement en radioferrocène n'est pas affecté par un traitement thermique ultérieur jusqu'à 75°, alors que les rendements en composés contenant du carbonyle sont augmentés jusqu'à 5.4 et 20.1%. Le rendement en ferrocène est indépendant du temps et de la température d'irradiation. De cette non dépendance, il en a été conclu que les liaisons Fe-Cp se sont reformées par un processus épithermique. D'une façon analogue, les liaisons Fe-CO sont régénérées par des réactions aussi bien thermiques qu'épithermiques.

Canadian Journal of Chemistry, 49, 2977 (1971)

The chemical effects of neutron capture in π-bonded metalorganic compounds have been studied in a number of cases. Particularly interesting are the cyclopentadienylmetal carbonyls and the analogous benzenemetal carbonyls, where radical competition reactions can lead to the incorporation of the radioactive atoms into a small variety of distinct and different compounds without, apparently, having noticeable effect on the bulk material. Unfortunately, to date only two such systems have been studied. In neutron-irradiated benzenechromium tricarbonyl, Baumgärtner and Zahn (1) found a retention[2] of 10.0% of the radioactive atoms in their original chemical form, but also a radiochemical yield[2] of $^{51}Cr(\phi H)_2$ of 0.2% and of $Cr(CO)_6$, 13.5%. This surprisingly high yield of ^{51}Cr as the hexacarbonyl was matched in the $CpMn(CO)_3$ and $CH_3CpMn(CO)_3$ system (2) in that derivatives of the radical $—Mn(CO)_5$ were found to total some 9–10%, mostly present as $HMn(CO)_5$ and $CH_3Mn(CO)_5$. The yield of $^{56}MnCp_2$ could not be measured reliably, since a rapid exchange occurs between the carrier $MnCp_2$ and the radioactive atoms of the "inorganic" fraction.

It thus seems (2) that the newly radioactive metal atom is better able to accumulate carbonyl ligands than can be accounted for by the average composition of the target substance or by the metal–ring and metal–carbonyl bond strengths. To extend this study to another system, we have studied the binuclear $[CpFe(CO)_2]_2$ (3). Since iron has an even atomic number it does not form a monomeric Cp—Fe—CO compound, and the true structure involves two bridging carbonyls, with a *trans* configuration in the solid (4, 5).



On chemical grounds one expects thermal decomposition to give ferrocene as the major molecular product (3). Likewise, radiolysis

[1]Permanent address: Chemistry Department, Carleton University, Ottawa, Canada.

[2]The retention and yield values given here and throughout this paper refer only to the radioactive atoms. These will be present in concentrations which may be some 10^{-10} to 10^{-12} mol%, and are detectable only because of their radioactivity. Macro quantities of these compounds are added to act as "carriers" during subsequent chemical operations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

usually causes primarily rupture of the metal–carbonyl bonds. This is contrary to the predictions of the generalization mentioned above which suggests that carbonyl formation ought to be favored. Thus the present system seems to be an unusually interesting one to study.

A further reason for choosing this compound lies in its binuclear structure. One should expect (6, 7) that greater retention or yield values would be found with the simpler molecules. While this is in part true, a number of contradictory results have appeared (7, 8). These seem to be explainable on the basis of rapid formation of simple "building blocks" which then combine or exchange to form the complex product molecule. Thus the high retentions in $Ru_3(CO)_{12}$ and $Fe_3(CO)_{12}$ were explained (7) by postulating $*Ru(CO)_4$ and $*Fe(CO)_4$ fragments, respectively, and the high retention in fulvalenehexacarbonylmanganese (8) is explainable by postulating the existence of highly reactive $C_5H_4*Mn(CO)_3$ fragments. Similarly, one might imagine the involvement of $Cp*Fe(CO)_2$ fragments as building blocks in the present system.[3]

Experimental

Dicyclopentadienyldiirontetracarbonyl was obtained from Atomergic Chemicals Co. and was purified by extraction and crystallization from boiling pentane.[4] The compound is somewhat sensitive to light, especially when in solution. Therefore the compound was stored in total darkness and handled in subdued light. In particular, fluorescent light was replaced by weak incandescent light, and the chromatograph columns were wrapped in aluminum foil. The compound was nicely crystalline, showing no visible signs of impurity. Mass spectrometric and infrared analyses[5] revealed no trace of impurity.

Irradiations were done in vacuo, at −78 °C in the Rohrpost position of the FR-2 Reactor, where the thermal flux was reportedly 9×10^{13} cm^{-2} s^{-1}. Irradiated samples were stored under liquid nitrogen until they were raised to room temperature for immediate processing. The samples were not analyzed for bulk decomposition at this stage. However, the appearance of the crystals was unchanged by the irradiation. Chromatographic tests failed to show the presence of any impurity such as $FeCp_2$ or $Fe(CO)_5$.

Samples to be processed were dissolved in 1 ml of $CHCl_3$, along with $FeCp_2$ and $Fe(CO)_5$ carriers, and 0.5 ml petroleum ether was then added. After being well mixed, the solution was put on the top of a silica gel column prepared under petroleum ether. Following elution of $Fe(CO)_5$ and $FeCp_2$, the eluant was replaced by $CHCl_3$ to effect elution of the target compound. Since $Fe(CO)_5$ is somewhat volatile, this fraction was collected in a tube containing concentrated HNO_3, to convert the iron to a non-volatile form. The ferrocene was further purified by sublimation under a gentle stream of nitrogen. Attempts to influence the distribution of the activity by scavenging with iodine (to produce $CpFe(CO)_2I$) met with failure, because of the bulk reaction of I_2 with the starting compound.

Radioactivity measurements were made using a well-type NaI scintillation counter. All samples were done in duplicate, comparing the activities with that of a reference sample composed of untreated crystals of the irradiated compound. Iron analyses were performed using Titriplex III solution with thiosalicylic acid as indicator (9), following total destruction of the compounds with H_2O_2 and HNO_3. Agreement between the duplicate samples was good, better than between different irradiations, for reasons which are not yet clear.

Results

The data obtained were somewhat scattered, despite all efforts to work carefully and reproducibly. The results are shown in Figs. 1, 2, and 3, in which are shown the values obtained for the yields[6] of the parent compounds, $Fe(CO)_5$ and $FeCp_2$, as functions of irradiation time, annealing time and annealing temperatures. It is seen immediately that the yield of $FeCp_2$ is evidently insensitive to any of these variables, and remains at about 1.4% regardless of the conditions. The two carbonyl-containing compounds seem to be more sensitive to external variables, and in approximately the same way, although the $Fe(CO)_5$ relatively more so than the target compound. It is noteworthy that the yield of $*Fe(CO)_5$ is higher than that of $*FeCp_2$, even without subsequent thermal treatment.

From Fig. 1 it is seen that the radiochemical yields of the two carbonyls increase somewhat as the irradiation time is increased from 3 to 10 min. This may be a result of the accompanying γ radiation, but we have no opportunity to check this hypothesis. Rather, we used a standard 10-min irradiation for all further experiments.

[3]An asterisk will be used in this paper to indicate that the metal atom following it is radioactive, and does not imply chemical excitation.

[4]We are grateful to Mr. E. Dornberger for performing this purification.

[5]We are grateful to Drs. W. Stieglitz and B. Kanellakopulos for these analyses.

[6]We shall use the term "yield" to refer to the fraction (or percent) of the total radioactivity of a specified type in the specified chemical form, including that of the parent compound. Corrections for chemical yield are, of course, included as are decay corrections when necessary. Any attempted distinction between retention and yield seems to be awkward, and occasionally misleading.

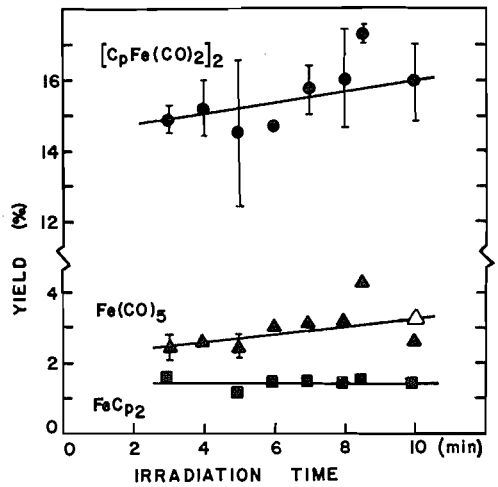

FIG. 1. Yields as a function of irradiation time at −78 °C, without annealing. The open point is taken for subsequent discussion as best representing the true value of the yield of $*Fe(CO)_5$ for a 10-min irradiation.

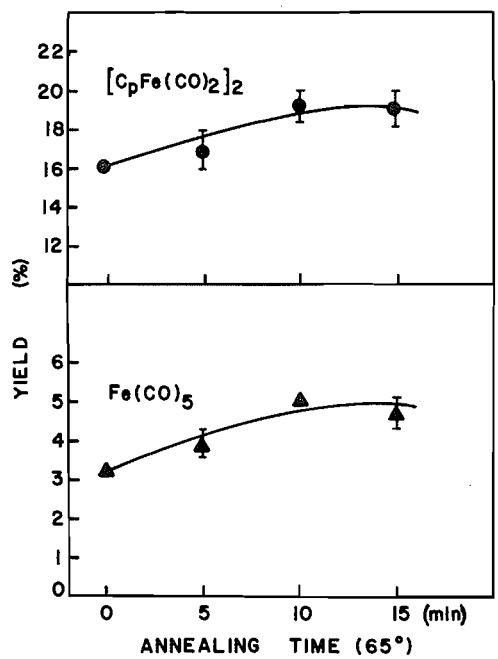

FIG. 2. Yields of $[Cp*Fe(CO)_2]_2$ and $*Fe(CO)_5$ as a function of annealing time at 65 °C, following 10 min irradiation at −78 °C.

The dependence on annealing time, Fig. 2, shows a gentle but distinct increase in the yields of the parent compound and $Fe(CO)_5$. The shapes of the curves cannot be given with certainty but the increase appears to occur mostly

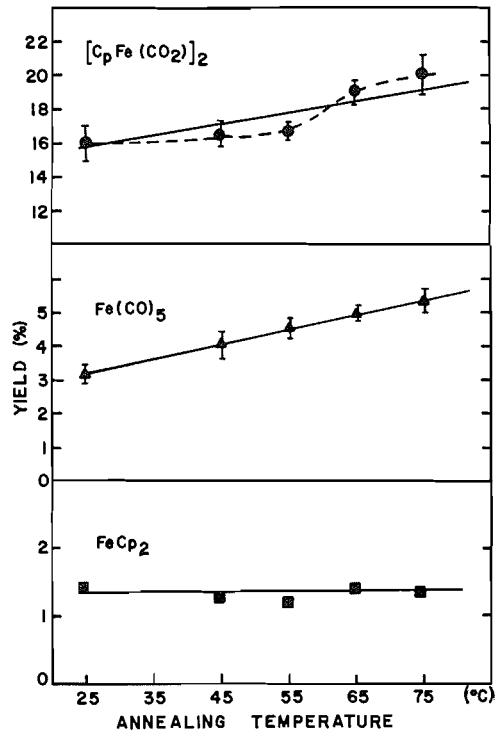

FIG. 3. Yields of $[Cp*Fe(CO)_2]_2$ and $*Fe(CO)_5$ after isochronal (15 min) annealing at various temperatures. The parameters for the straight lines drawn are given in Table 2.

in the first 10 min. Likewise the effect of increasing the annealing temperature, as given in Fig. 3, is to increase $Y_{[CpFe(CO)_2]_2}$ and $Y_{Fe(CO)_5}$, the latter relatively more. These data are given in Table 1.

The scatter in the data is too great to allow us to fix the shape of the curve of Y *vs.* temperature with great accuracy, although both can be represented to a first approximation as linear functions over the interval 25–75 °C

$$[1] \qquad Y_T^{15} = Y_{25} + \alpha\tau$$

where Y_T^{15} is the yield after 15 min of annealing at $T = 25 + \tau$ °C, and α is the slope of the line drawn in Fig. 3. It may be that the curve for $[CpFe(CO)_2]_2$ should better be taken as sigmoid in shape. Through all these changes, the yield of ferrocene-^{59}Fe remained essentially unchanged. The parameters for eq. 1 are given in Table 2.

In several irradiations carried out at reactor temperature, the ferrocene yield remained essentially unchanged at 1.4%. The other two yields were erratic but higher: up to 23 and 8%. Since

$FeCp_2$	1.4	0.000	0.0000

the reactor temperature could be neither controlled nor measured, these data are of only qualitative significance.

Discussion

Assuming that the target molecule is initially destroyed,[7] there are these general stages during which reactions might occur between the radioactive atoms and various fragments and molecules to give the observed products:

(*i*) Hot (or epithermal) reactions can occur with recoil atoms either in flight (11, 12) or just at the end of their trajectory, while the surrounding region is still thermally or electronically excited (13, 14). This latter would also include the case of little recoil but extensive ionization by the Auger effect. It is not possible at present to make a reliable estimate of the time interval between the nuclear event and the time of attainment of a quasi-stable local state. Mössbauer experiments indicate that this time is shorter than about 10^{-9} s, for several ionic cobalt compounds (15). It is generally considered that these hot and epithermal reactions are insensitive to any experimental conditions which can be applied to solids.

(*ii*) Reactions can also occur in the untreated target after initial thermal excitation has been dissipated. These reactions, if fast, may be indistinguishable from epithermal and hot reactions. If they are slow enough, however, they will be susceptible to thermal, radiation, and other influences. An extensive literature on this subject deals largely with ionic salts, but some work has been reported on thermal and radiation annealing effects in π-organometallic compounds (2, 16, 17, 23).

(*iii*) Reactions may also occur during the chemical workup of the sample. While it is often possible to minimize these effects, and even to utilize them to capture unstable species (18, 2), there is seldom any real certainty that such reactions have *not* occurred. The greatest difficulty in this respect is assessing the probable chemical behavior of the unidentified carrier-free species, which may often include some 70–80% of the radioactive atoms. While it has been common to call this the "inorganic" fraction, its initial chemical nature is entirely unknown. It is thus possible that some unknown species could exchange or react with added carriers. The clearest example of this is the reaction (19) which leads to the accumulation of some 30% of the ^{56}Mn in the form of $MnCp_2$, from neutron-irradiated $Mn_2(CO)_{10}$! This might support a contention that at least some of the unknown species are ionic in nature, since $MnCp_2$ is known to be electrostatically bonded (20). The corresponding reaction of $FeCp_2$ with ^{59}Fe atoms is found to be very much less prominent, and an upper limit of 0.02% is indicated (21) for comparable conditions.

The insensitivity of the yield of $*FeCp_2$ to external influences, either during or after irradiation, suggests that the fate of the Fe—Cp bonds is determined by epithermal (or hot) processes, or that the $*FeCp_2$ is formed on dissolution by reaction between the carrier and some radioactive species which, though reactive, was trapped in a stable position in the solid. It seems unlikely that the latter would give rise to such highly reproducible results and, considering also the upper limit for exchange referred to above, we favor the former interpretation: that the Fe—Cp bonds are reformed by epithermal reactions.

The sensitivity of both of the carbonyl-containing compounds to external influences applied shows that an important fraction of the Fe- - -CO bonds are formed by thermal processes. The relative tendencies of thermal and other (epither-

[7]The few studies in which this has been investigated suggest that true failure of bond rupture occurs in only a very small fraction of the events (10).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

mal and spurious) reactions can be derived from the values of α/Y_{25}. These values, given in Table 2, show the relative thermal tendency to be much the greater for $Fe(CO)_5$, and progressively less as the number of bonded Cp groups increases.

The fact that none of the observed product compounds decreases during annealing, but all either increase or remain constant, suggests that the three are produced independently by competitive reactions, and not by consecutive thermal reactions leading from one product to another. These latter are known in triphenylarsine (22) and suspected in $CpMn(CO)_3$ (23).

Reformation of the parent compound is most easily visualized as exchange of a $Cp^*Fe(CO)_2$ "monomer" with a molecule of the dimer. The $CpFe(CO)_2$ group is known as a constituent of a number of compounds (24). Its separate existence has been postulated by Haines and du Preez (25) as a reaction intermediate in the halogenation of $[CpFe(CO)_2]_2$. It seems possible that when trapped in a crystal lattice, the $CpFe(CO)_2$ monomer could have an independent existence, in the same way as $\cdot Mn(CO)_5$ is apparently stable in $Mn_2(CO)_{10}$ crystals, and thus be an available building block for reconstitution of the parent molecule. Although the usual form in the solid is the *trans* isomer both *cis* and *trans* are found in solution. A non-bridged structure, as is postulated (26) to account for the isomerization in solution, would be required for the most convenient exchange mechanism. Barrett and Sun (27) have estimated the energy required to break the two carbonyl bridges as 13 ± 2 kcal/mol, although the activation energy for isomerization will involve a rotational barrier as well. In an attempt to detect the presence of *cis*-$[CpFe(CO)_2]_2$ in the solid at higher temperatures, from which the presence of this nonbridged species could also be inferred, infrared (i.r.) spectra were run in KBr pellets at temperatures up to 80 °C. An increase in the intensity of a band at about 2000 cm^{-1}, assigned by Manning (26) to the *cis* compound, would indicate the formation of this species at higher temperatures. No variation in the relative band intensities was found between 20 and 80 °C.[8] It must thus be said that no evidence is at present available to support (or refute) the foregoing speculation on parent reformation.

[8]These spectra were kindly run by Dr. B. Kanellakopulos.

It is clear that a good deal of information on possible exchange reactions will be required before detailed statements can be made about the mechanisms of the radiochemical reactions described here. These data will be needed not only for CO groups, on which there are already extensive data, but also for Cp groups, which have not been studied, and for larger groups such as $CpFe(CO)_2$. Labelling of these large groups may perhaps most easily be accomplished by means of reactions such as are described in this paper (28). Preliminary studies have been made in this way on exchanges of the $—Mn(CO)_5$ group (29).

We express our sincere gratitude to Professor F. Baumgärtner for his constant interest and support, and for extending the hospitality of his Institute to D.R.W. We thank Mrs. E. Rauch for invaluable experimental assistance.

Reactions of Alkylthio Derivatives of Aluminum with Aldehydes, Ketones, and Olefins

J. M. LALANCETTE, Y. BEAUREGARD, AND M. BHÉREUR
Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke, Québec

Received March 22, 1971

The preparation of $((CH_3)_2CHS)_2AlCH_3$ and $(t\text{-}C_4H_9S)_2AlCH_3$ is reported. The reactions of $(RS)_2AlCH_3$ (R = CH_3, $(CH_3)_2CH$, $t\text{-}C_4H_9$) with ketones give aldol condensations leading to the corresponding conjugated ketones, with the acetyl group R—CO—CH_3; with other ketones, a mixture of thioacetal and enolthioether is obtained. With aldehydes, a mixture of thioacetal and enolthioether is observed. With olefins there is an addition of two RS groups on the site of the double bond, with a small percentage of allylic substitution. With conjugated ketone, the saturated ketone is obtained with the alkylthio group in β position. All those reactions proceed with good yields and appear quite general.

La préparation de $((CH_3)_2CHS)_2AlCH_3$ et de $(t\text{-}C_4H_9S)_2AlCH_3$ est rapportée. Les réactions de $(RS)_2AlCH_3$ (R = CH_3, $(CH_3)_2CH$, $t\text{-}C_4H_9$) avec les cétones donnent des condensations aldoliques conduisant à des cétones conjuguées, si le groupe acétyle R—CO—CH_3 est présent. Avec les autres cétones, un mélange de thioacétal et d'éther thioénolique est obtenu. Avec les aldéhydes un mélange du thioacétal et de l'éther thioénolique est observé. Avec les alcènes, on remarque l'addition de deux groupes RS sur le site de la liaison double ainsi qu'une certaine substitution en α du lien double. Avec les cétones conjuguées, des cétones saturées portant un groupe RS en position β sont obtenues. Ces réactions donnent de bons rendements.

Canadian Journal of Chemistry, **49**, 2983 (1971)

We have reported the preparation of thiomethyl derivatives of aluminum such as $(CH_3S)_2AlCH_3$ and $(CH_3S)_3Al$ and the reactions of those compounds with some inorganic and organic substrates (1). This paper will describe the reaction of organic derivatives of aluminum of general formula $(RS)_2AlCH_3$, where R = methyl, isopropyl, and *t*-butyl, with various aldehydes, ketones, and olefins.

The reactions of aluminum alkoxides with aldehydes and ketones are well known and widely used in organic chemistry. Depending on the experimental conditions those alkoxides can be used in oxydation or reduction reactions. The initial approach to the present work was to compare the effect of the substitution of RS groups with the RO groups on aluminum. With RS groups, the aluminum derivative was expected to give non-reversible reactions with oxygen bearing functional groups, contrary to Oppenauer oxidation, for example, when the reactions are essentially reversible. Such behavior was to be expected because of the important difference between the heat of formation of the Al—O and Al—S bonds: Al_2O_3 : $\Delta H°$: −399 kcal/mol; Al_2S_3 : $\Delta H°$: −121 kcal/mol (2). Such a large difference in heat of formation would render the system Al—S → Al—O irreversible towards Al—O.

We have noted however that the substitution of sulfur for oxygen on aluminum changes completely the reactivity of this reagent and entails very few similarities between those two families of aluminum derivatives.

Results and Discussions

Preparative Reactions

The general procedure for the preparation of alkylthio derivatives of aluminum has been reported (1). We have extended the scope of this method by using homologs of methanethiol as starting material such as isopropyl and *t*-butyl mercaptans. The pattern of the reaction was the same except that reflux temperatures were used instead of the low temperature conditions employed with methanethiol. In both cases, the product obtained was of the general formula $(RS)_2AlCH_3$, as shown by the various analyses. With R = methyl or isopropyl, the derivatives exist as a highly polymerized entity, insoluble in all non-destructive solvents. But with *t*-butyl, probably because of the steric hindrance created by the two bulky groups, and preventing its polymerization, the alkylthio aluminum derivative was then soluble in benzene and other nonpolar solvents. It has been possible, with this soluble material, to obtain i.r. and n.m.r. measurements. The elemental analyses was con-

[1] 
[2] 
[3] 
firmed with the n.m.r. of $(t\text{-}C_4H_9)_2AlCH_3$ where the two expected peaks were found at 1.48 (singlet, 3 protons) and 1.54 (singlet, 18 protons). It has been possible to obtain confirmation of the structure of $(CH_3S)_2AlCH_3$ by Raman spectroscopy.

Reactions with Ketones

Under mild experimental conditions, we have found that acetyl groups gave condensation reactions in presence of dithioalkyl derivatives of aluminum ($(RS)_2AlCH_3$ where R = methyl, isopropyl, or *t*-butyl). The condensation reaction appeared to be very specific for the acetyl groups, no such reaction being observed with other types of ketones. With ketones not having the acetyl groups, we obtained the corresponding thioketal and enol thioether with yields of the order of 60%. Such a specific reaction is of real synthetic interest. Acetone, for example, gave mesityl oxide and a similar reaction was noted with butanone, pinacolone, 4-methylpentanone-2, 3-methylbutanone. With the methylthio derivative of aluminum, the product of condensation was accompanied by a substance corresponding to the addition of one methylthio group on the double bond formed by the condensation (eq. 1). Besides those products, methyl sulfide and methyl disulfide were formed. The ratio of conjugated ketone to β-methylthio ketone was 2/1.

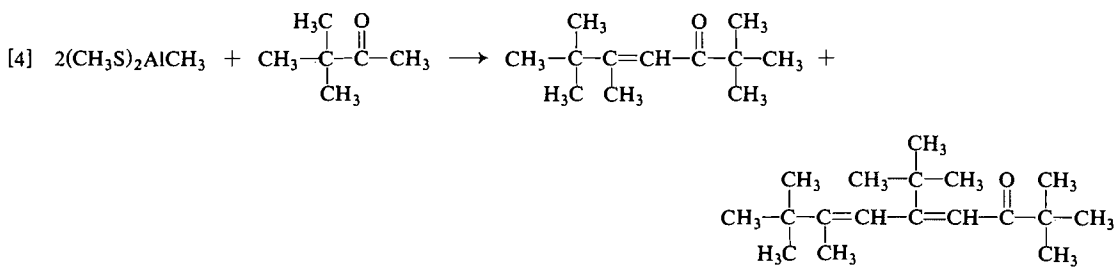
We have been able to show that the formation of the β-methylthio ketone was a secondary reaction occurring subsequent to the condensation of the starting ketone. By treating mesityloxide with $(CH_3S)_2AlCH_3$, the corresponding β-methylthio ketone was obtained with a good yield. The position of the methylthio group was clearly shown by n.m.r. In the case of mesityl oxide, for example, the β-methylthio derivative was showing three different CH_3 groups (ratio of protons: 6/3/3) and one CH_2 group (2 protons).

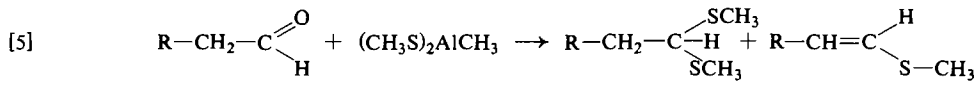
In order to ascertain the source of the protons of the CH_2 group in α to the carbonyl after addition of the CH_3S substituent, the reaction was repeated with deuterated mesityl oxide, the hydrolysis being done with D_2O and H_2O. Under both experimental conditions, the CHD group was found in the position α to the carbonyl (eq. 2). The presence of protons or deuterium in the position α to the carbonyl was clearly shown by n.m.r. From this result and from the presence of methyl sulfide and methyl disulfide among the reaction products, we believe that the reaction must be a radical process, the proton in the position being abstracted from one of the methyl groups on the aluminum derivative, after the addition of a CH_3S radical to the double bond (eq. 3). Experimental, and economical, difficulties prevented the verification of eq. 3 with $(CD_3S)_2$ $AlCD_3$ and protonated mesityl oxide.

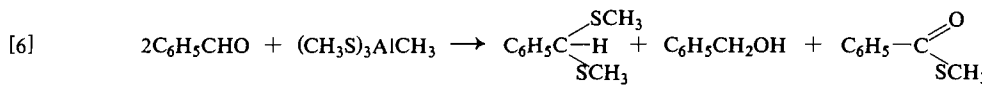
When the aluminum derivative was prepared with a bulky substituent, such as the propyl or *t*-butyl groups, the secondary reaction leading to the β-alkylthio ketone was not observed, the sole reaction being condensation. This behavior was noted with acetone, 3-methylbutanone, and pinacolone. With acetophenone, α-isopropylthio styrene was obtained and with 1,1-diphenyl acetone, there was no condensation, the starting material being recovered by hydrolysis.

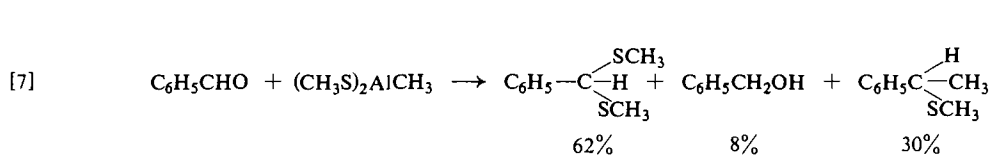
The condensation of two molecules of methyl ketone is quite general and stops after the reaction of two $COCH_3$ units. With a very hindered ketone like *t*-butyl methyl ketone, however, we found that by increasing the amount of methylthio aluminum derivative, polycondensation could be obtained. With a ratio of two carbonyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.









groups per aluminum, the normal product was obtained; but if the ratio reached one carbonyl group for two aluminum, then condensation was observed to proceed as shown in eq. 4: two or three molecules could then be involved in the condensation to give the constituents of the reaction mixture. Such a condensation of three molecules was observed solely with the above ketone; no similar reaction could be obtained with acetone, for example, even with a very large excess of the methylthio aluminum reagent.

Reactions with Aldehydes

With aliphatic aldehydes (phenylacetaldehyde, heptaldehyde, propionaldehyde, and butyraldehyde), the main reaction products were the corresponding thioacetals and thioenol ether (eq. 5). The ratio of thioacetal to methylthio olefin was of the order of 1/3.

With benzaldehyde the products of the reaction were the thioacetal, the thiolester, and smaller amounts of benzyl alcohol, when the ratio of aldehyde to reagent was of 2/1 (eq. 6). With a 1/1 molar ratio, then the thioacetal was the major product with lesser amounts of benzyl alcohol and methylthio ether (eq. 7). With cinnamaldehyde, the reaction products were the corresponding thioacetal and methylthioether, as observed with the 1/1 ratio reaction, eq. 6. The cinnamyl alcohol was not present in the reaction mixture but otherwise, the pattern of the reaction was quite similar to benzaldehyde.

The great variety of products, specially the presence of the methyl group on the carbonyl-bearing carbon cannot be explained easily. Clearly, a completely ionic mechanism cannot justify the formation of the thiol ester and the methylthioether. Consequently, as was the case with β-methylthio ketones and as it will be indicated with olefins, a free radical mechanism must be postulated to account for those products.

Reaction with Olefins and Conjugated Ketones

The reaction of $(CH_3S)_2AlCH_3$ has been examined with styrene, indene, and cyclohexene. In those experiments we have observed that there was an addition of two CH_3S groups to the double bond. With cyclohexene, beside the product of addition to the double bond, we found considerable allylic substitution (eq. 8). With conjugated ketones such as mesityl oxide, methyl vinyl ketone, cyclohexenone, isophorone, and *trans*-phenylbutanone, we observed the addition of the CH_3S group to the β position of the carbonyl to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[8] 
[9] 
give the corresponding β-methylthio ketone. With isophorone some of the thiomethyl group was also found in the γ position (eq. 9).

Those results with olefins and conjugated ketones can only be explained by a radical attack either on the double bond or the conjugated double bond. The fact that the allylic groups could be involved in the reaction is another good indication in favor of a radical mechanism.

Mechanism of Reaction of $(RS)_2AlCH_3$

From those results obtained with aldehydes, ketones, and olefins, it is not easy to establish the precise mechanism of those reactions. In many instances, it is clear that the reaction must follow a radical path. The allylic substitution with olefins, the addition of the methylthio group with conjugated olefins such as mesityl oxide and the formation of methyl disulfide are strong indications of radical reactions. It has not been possible to use scavengers in order to corroborate those indications because of the reactivity of $(RS)_2AlCH_3$ with carbonyls, active methylene, or labile protons normally found on such substances.

Some of the reaction products, thioacetals and condensation products for example, can be explained by the acid character of substances like $(RS)_2AlCH_3$. But in every reaction where an ionic mechanism could prevail, there is also a product that cannot be easily accounted for without postulating a radical: methyl disulfide in the case of condensation reactions for example.

Consequently, although ionic mechanism cannot be ruled out entirely, the pattern of action of $(RS)_2AlCH_3$ must be strongly influenced by the capacity of this family of reagents to generate radicals.

Experimental

The i.r. measurements were made on a Perkin–Elmer spectrometer, model 257, in carbon tetrachloride solutions. The n.m.r. measurements were performed with a Varian A-60 instrument, using tetramethylsilane as internal reference. Mass spectrometric determinations were made with a Hitachi Perkin–Elmer machine, model RMV-6D. Melting points are not corrected. Elemental analyses are from Schwarzkopf Microanalytical Laboratory, New York. The v.p.c. measurements were made with a Microteck G-2000-R instrument. The u.v. spectra were recorded with a Cary 14 instrument. Raman measurements were made with a double monochromator Jarrell-Ash 25-100, using an argon laser at 4880 Å, the resolution being of the order of 1 cm^{-1}.

1. Preparation of Dithioalkyl Derivatives of Aluminum

The preparation of methyl bis(methylthio)aluminum has been reported (1).

The preparation of methyl bis(isopropylthio)aluminum was done according to the same procedure, except that after the addition of the mercaptan (1100 g) to the solution trimethyl aluminum (250 g), the solution was heated under reflux for 36 h. The expected derivative precipitated slowly and was isolated in a similar way as methyl bis(methylthio)aluminum.

With methyl bis(*t*-butylthio)aluminum, the procedure was the same as with the isopropyl derivative (1100 g of *t*-butyl mercaptan reacting with 250 g of trimethyl aluminum) except that benzene instead of pentane was used as solvent. The duration of the reflux was 3 days and the solvent was evaporated, in order to obtain the reaction product which then crystallized slowly. Yield: 90% based on $(CH_3)_3Al$: n.m.r. (benzene): singlet at 1.48 (3 protons) and singlet at 1.54 (18 protons).

The analyses were performed according to the methods described earlier (1).

Anal. Calc. for $(C_3H_7S)_2AlCH_3$: Al, 14.1. Found: Al, 15.2.

Anal. Calc. for $(C_4H_9S)_2AlCH_3$: Al, 12.2. Found: Al, 11.8%.

The Raman spectrum of methyl bis(methylthio)aluminum was determined in a sealed tube, with a sample of the solid material. Bands were observed at 2935 (strong), 2900 (medium), 2897 (medium), 2891 (medium), 1433 (weak), 1200 (weak), 700 (very strong), 576 (strong), 335 (very strong), 283 (very strong) cm^{-1}. The adsorption in the region of 700 cm^{-1} can be attributed to the C—S vibration, at 576 cm^{-1} to the Al—C vibration and 335 and 283 cm^{-1} to the Al—S vibration.

2. Reactions of Methyl Bis(alkylthio)aluminum with Ketones

2.1 Reaction with Acetone

In a conical flask, at room temperature, a suspension of 15 g (0.11 mol) of $(CH_3S)_3AlCH_3$ in 150 ml of dry pentane was treated with 12 g (0.20 mol) of acetone during 2 h. The reaction mixture turned rapidly to a yellowish

For personal use only.

color. After this contact, the mixture was hydrolyzed by a slow addition of 10 ml of water and the aluminum hydroxide was filtered out. After drying over $MgSO_4$, the solvent was evaporated under vacuum leaving a yellow oil which was fractionated by distillation after analyses by v.p.c. Four components were found in this mixture. Methyl sulfide CH_3SCH_3 and methyl disulfide CH_3SSCH_3 were the first two products to appear upon v.p.c. chromatography. They were identified by comparison of their i.r. and n.m.r. spectra with those of authentic samples. The precise yield of those compounds has not been evaluated because of loss incurred by the evaporation of the solvent. They were present in more than trace amount, probably 20–30% of the total weight recovered at the end of the reaction. The third fraction, b.p. 129° was mesityl oxide, as shown by its n.m.r., i.r. and mass spectra which were identical with similar measurements made on an authentic sample. The last fraction, b.p. 78°/15 mm gave the following measurements. The n.m.r. δ: singlet (6 protons), 1.38; singlet (3 protons), 2.05; singlet (3 protons), 2.13; singlet (2 protons), 2.68. The i.r.: bands at 2980 (strong); 1710 (strong); 1180 (medium) cm^{-1}. Mass spectrum *m/e*: 41, 43, 47, 55, 83, 89, 98, 99, 146 (M^+). From those results, this last fraction must be 4-methyl-4-methylthiopentanone-2.

Anal. Calcd. for $C_7H_{14}OS$: C, 57.53; H, 9.58; S, 21.91. Found: C, 57.47; H, 9.62; S, 22.17.

The ratio of fraction 3 and 4 was 2/1 and the yield of those two fractions 65%.

The reactions with other ketones are reported in Table 1.

2.2 Reaction with Deuterated Mesityl Oxide

The reaction was performed with 5.4 g of perdeuterated mesityl oxide (Merck Sharp and Dohme), using experimental condition as in section 2.1 except that the hydrolysis was done with D_2O. The product gave an n.m.r. with a singlet (3 protons) at 2.03 and a triplet (1 proton) at 2.58 δ, $J = 2.2$ Hz, in accordance with the formulation $CD_3—CO—CHD—C(CD_3)_2SCH_3$.

The experiment was repeated under identical conditions except that the hydrolysis was done with H_2O. The same product was obtained, as indicated by similar n.m.r. and i.r spectra.

When the reaction was done with protonated mesityl oxide but the hydrolysis with D_2O, there was no incorporation of deuterium on the molecule: the ratio of the area of the peaks on n.m.r. of the reaction product were not affected and the i.r. did not indicate the presence of deuterium.

2.3 Reactions of Acetone with Methyl Bis(isopropylthio)aluminum

Using an experimental procedure as in section 2.1, acetone (11.6 g, 0.2 mol) was treated with methyl bis(isopropylthio)aluminum (19.2 g, 0.1 mol) in pentane at 0°, for 30 min. The usual procedures gave mesityl oxide (95% yield), identified by its n.m.r. and i.r. spectra.

2.4 Reactions of Acetone with Methyl Bis(t-butylthio)-aluminum

This reaction, on the same scale as in section 2.9 gave a high yield of the expected mesityl oxide. A similar behavior was noted with 3-methylbutanone and pinacolone, giving 2,5,6-trimethyl-4-heptene-3-one and 2,2,5,-6,6-pentamethyl-4-heptene-3-one with yields of 86 and 65% respectively. Those compounds were identified by comparison of their n.m.r. and i.r. spectra with authentic samples.

2.5 Reaction of Acetophenone

Using a similar experimental procedure as in section 2.1, acetophenone (12.0 g, 0.1 mol) and methyl bis(isopropylthio)aluminum (19.2 g, 0.1 mol) were reacted for 3 h at reflux temperature in pentane. The usual procedure gave 45% of α-isopropylthiostyrene. The n.m.r. δ: two doublets in the 1.15–1.40 region (6 protons); multiplet in the 2.50–3.30 region (1 proton); two doublets in the 5.1–5.5 region (2 protons); multiplet in the 7.3 region (5 protons). The i.r.: no band in the carbonyl region, band at 1665 cm^{-1} (weak). Mass spectrometry *m/e*: 120, 105, 77.

3. Reaction of Methyl Bis(alkylthio)aluminum with Aldehydes

3.1 Reaction with Benzaldehyde

In a 250 ml flask, a suspension of 6.8 g (0.05 mol) of methyl bis(thiomethyl)aluminum in 75 ml of anhydrous benzene was treated by 10.6 g (0.10 mol) of benzaldehyde. After a reflux of 1 h, the reaction mixture was cooled to 0°, hydrolyzed by water, and filtered. The organic phase, after drying over $MgSO_4$ was evaporated. The reaction mixture was formed of unreacted benzaldehyde (15%), thioacetal of benzaldehyde (15%), benzyl alcohol (29%), and methyl thiolbenzoate (41%). Those ratios were determined by v.p.c. on column 5 ft long, SE-30, 5%, at 150°. The benzaldehyde, its thioacetal, and benzyl alcohol were identified by comparison of their mass spectrum, v.p.c., and n.m.r. with those observed for samples. Methyl thiolbenzoate: the n.m.r. δ: singlet at 2.36 (3 protons); multiplet 7.35–7.83 (5 protons). The i.r. bands at 3090 (medium); 2980 (medium); 1665 (very strong); 1470 (strong) cm^{-1}. Mass spectrometry *m/e*: 152 (molecular ion), 105, 77, 51, 47.

Depending on the duration of the reaction, the temperature or the solvent (benzene or pentane) there was a slight variation of the yield of those compounds, up to 10%. However, those three products were always present.

When the reaction was repeated as above except that the molar ratio of aluminum derivative and benzaldehyde was 1/1, instead of 2/1, then the yield of thioacetal was increased, there was no longer methyl thiolbenzoate and a new compound, 1-phenyl-1-thiomethylethane appeared. In a typical experiment, no unreacted benzaldehyde was detected, there was 8% of benzyl alcohol, 62% of thioacetal, and 30% of $C_6H_5—CH(SCH_3)CH_3$, as shown by v.p.c. analysis.

1-Phenyl-1-thiomethylethane. The n.m.r. δ : doublet (3 protons) at 1.50; singlet (3 protons) at 1.78; quadruplet (1 proton) at 3.73; singlet (5 protons) at 7.15. The i.r.: bands at 3080 (medium); 3060 (medium); 3000 (strong); 2950 (strong); 1510 (strong); 1470 (very strong); 1455 (medium); 1240 (medium) cm^{-1}. Mass spectrometry *m/e*: 152 (molecular ion), 137, 121, 106, 105, 104, 103, 102, 77.

The reactions with other aldehydes are reported in Table 2.

4. Reaction of Olefins and Conjugated Ketones with Methyl Bis(methylthio)aluminum

4.1 Reaction with Cyclohexene

Using 8.0 g (0.59 mol) of methyl bis(methylthio)aluminum, the reaction with cyclohexene in excess was

Reductions with Sulfurated Borohydrides. VI. The Reduction of Nitro, Nitrile, Amide, and Nitroso Groups

J. M. LALANCETTE AND J. R. BRINDLE

Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke, Québec

Received March 22, 1971

Aromatic nitro compounds can be reduced with sulfurated sodium borohydride to the corresponding amine in high yields (≈80%) without affecting ester, nitrile, ether, halide or olefinic groups also present. With ortho-substituted nitro compounds the yields are around 60%.

Primary aliphatic nitro compounds are reduced to the corresponding nitrile in high yields. Secondary aliphatic nitro compounds are reduced to mixtures of ketones and the corresponding oxime. Tertiary aliphatic nitro compounds are not reduced.

Aromatic nitriles can be reduced to the corresponding amines with an excess of the reducing agent or converted to the corresponding thioamides with an excess of the nitrile.

Amides and nitroso can be reduced to the corresponding amines in moderate yields.

Les dérivés nitrés aromatiques peuvent être réduits en amines avec de bons rendements (≈80%) par l'hydrure de bore sulfuré, cette réduction pouvant être effectuée sans affecter les fonctions ester, nitrile, éther, halogène ou alcène présentes. Avec les dérivés ortho, les rendements sont de l'ordre de 60%.

Les dérivés nitrés aliphatiques primaires sont réduits en nitriles avec de bons rendements. Les dérivés nitrés aliphatiques secondaires sont réduits en un mélange de cétones et d'oximes correspondantes. Les dérivés nitrés aliphatiques tertiaires ne donnent pas de réaction.

Les nitriles aromatiques peuvent être réduits en amines, avec un excès de réducteur, ou en thioamides, avec un excès de nitrile.

Les amides et les nitroso peuvent être réduits en amines avec des rendements modérés.

Canadian Journal of Chemistry, 49, 2990 (1971)

We have reported the formation of sulfurated borohydrides (1, 2) according to eq. 1.

$$[1] \qquad NaBH_4 + 3S \xrightarrow[25°]{THF} NaBH_2S_3 + H_2$$

This sulfurated hydride has shown very distinctive properties in its reactions with aldehydes (3), ketones (4), and oximes (5).

We now wish to report the reduction of nitro, nitrile, amide, and nitroso groups with this new reducing agent.

Reduction of Nitro Derivatives with $NaBH_2S_3$

In order to appreciate the selectivity of $NaBH_2S_3$ a short survey of the reduction of nitro groups is indicated.

Catalytic hydrogenation, in presence of platinum or nickel (6) or chemical reduction by tin or iron, in presence of hydrochloric acid (7), can reduce simple nitro derivatives to the corresponding amines. Those procedures, however, are not very selective in presence of sensitive organic functions. With $LiAlH_4$ or mixtures of $LiAlH_4$.-$AlCl_3$, the reduction of aliphatic nitro groups generally proceeds to the level of the amino group (8). Because of the overwhelming reducing capacity of $LiAlH_4$, many other functional groups are also reduced under those conditions, such as esters, amides, nitriles, or halides. With aromatic nitro derivatives, reduction with $LiAlH_4$ leads mainly to azo derivatives and again, many other functional groups are reduced at the same time, when present (9).

With $NaBH_4$, aromatic or aliphatic nitro groups are not reduced, the only instance of reduction being observed in presence of palladium on carbon catalyst (10). With $LiBH_4$ low yields of amine (of the order of 20%) have been reported (11).

(a) Reduction of Aromatic Nitro Derivatives

We have found that sulfurated sodium borohydride can reduce aromatic nitro derivatives to the corresponding amines in very high yields. The experimental conditions of the reduction allow the transformation of the nitro group into the amino group without interference from halogen (F, Cl, Br, I), ester, nitrile, ether, or olefin groups. The results of those reductions, all performed under identical experimental conditions (24 h reflux in tetrahydrofuran (THF)) are reported in Table 1.

Our results indicate that except with sterically hindered nitro groups, yields are generally in the range of 80%. With ortho derivatives, the lower yields are related to extraction problems caused by the solubility of ortho-substituted derivatives of aromatic bases. As indicated, nitroacetophenones can be reduced to the corresponding alcohols without affecting the nitro groups.

The stoichiometry of the reaction calls for a 1/1 molar ratio of reagent and reducing agent as shown by the variation of the yield of the reduction of nitrobenzene with $NaBH_2S_3$. With a 1/1 ratio ($NaBH_2S_3/NO_2$) and a long reaction time (85 h) a yield of aniline of 92% is obtained. If the ratio is decreased to 0.5/1, then the yield, after a reflux of 24 h, is decreased to 43%; a 0.25/1 ratio lowers the yield still further to 24%. From these variations of yield in relation to the ratio of reducing agent:nitro compound, we have concluded that the 1/1 ratio is the required stoichiometry for complete reduction. It is to be noted, however, that the second hydrogen on $NaBH_2S_3$ must be somewhat more difficult to involve in the reaction, since a yield of 95% of amine was obtained with a 2/1 ratio after only 24 h, three times more rapidly than with the 1/1 ratio.

We have been able to differentiate the action of the two hydrogen atoms of the reducing agent in the following way. One mole of nitrobenzene was treated by 2 mol of sulfurated sodium borohydride. The processing of an aliquot of this reaction mixture, after 24 h, proved that reduction was complete. Then 2 mol of nitro compounds were added in the form of an equimolar mixture of *o*-nitrotoluene and *p*-nitrotoluene. The flux was then continued for another 24 h. Upon extraction, it was found that only 31% of the second portion of nitro derivatives had been reduced and that the ratio of reduction was in favor of the less hindered derivative (*o*-aminotoluene, 25%; *p*-aminotoluene, 85%). A similar behavior was noted with a mixture of *o*- and *m*-nitrotoluene and was interpreted as an indication that the first hydrogen atom of the reducing agent is more easily available than the second, and that when it has been consumed, the resulting intermediate boric ester creates steric hindrance around the second hydrogen and renders it less reactive.

(b) Reduction of Aliphatic Nitro Derivatives

In the case of aliphatic nitro compounds, the structure of the substrate has a definite role on the orientation of the reaction. With primary nitro derivatives, such as phenylnitromethane, the main reaction product, obtained in a yield of 80%, is the corresponding nitrile. Small quantities of the corresponding oxime (10%) and amine (9%) are also observed along with a trace of the hydroxylamine. A similar behavior is noted with 1-nitropropane. In the case of the secondary nitro compound such as nitrocyclohexane, 45% of cyclohexanone, 30% of cyclohexanone oxime, 19% of *N*-cyclohexylhydroxylamine and traces of cyclohexylamine are observed. Similar results were obtained with 2-nitropropane, but the yields were lower, because of solubility and volatility of reaction products. With the tertiary nitro compound, using $(CH_3)_2C(NO_2)CH_2OAC$, no reaction was observed.

(c) Discussion

The use of sulfurated sodium borohydride offers very interesting possibilities for the reduction of nitro groups mainly because of its selectivity. It has advantages over present reagents, particularly when ester, halide, nitrile, amide or olefinic groups are also present in the molecule. With aliphatic nitro derivatives, the formation of nitriles, from primary nitro compounds, of ketones and oximes from secondary nitro compounds represents new reactions of real synthetic interest.

The mechanism of this reaction must be complex and at the present time is not fully understood. With an equimolecular ratio of reducing agent to nitro compounds, a near quantitative yield of amine is observed. This result indicates that besides the two hydrogen atoms, the sulfur atoms of $NaBH_2S_3$ must play a role in the reduction. It is to be noted that besides its reducing role, $NaBH_2S_3$ behaves as a dehydrogenating agent in the reduction of primary nitro groups for example. Such a behavior had been noted previously, with ketones (4).

In order to appreciate the relative importance of electronic and steric effects in the course of the reduction, various pairs of nitro derivatives have been reduced together. These results are reported in Table 2. It can be seen from these measurements that the relative ease of reduction of the

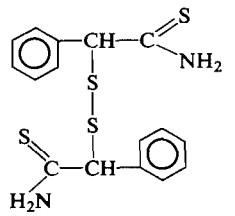
nitro group is greatly influenced by substitution in the ortho position and by the electronic effects of substituents on the aromatic structure.

Reactions of Nitriles

We have indicated above that it is possible to reduce the nitro group in presence of nitrile, without interference by the C≡N function. However, under suitable conditions it is possible to convert aromatic nitriles into either amines or thioamides. With an excess of reducing agent (2/1 ratio of $NaBH_2S_3$ to C≡N), the amine is obtained. If this ratio is inverted (1/2 ratio of $NaBH_2S_3$ to C≡N), then the major product is the corresponding thioamide.

With aliphatic nitriles, the reaction led to complex mixtures containing products of the reaction of the α methylene group. Thus β-phenylacetonitrile gave the disulfide (**1**). The various reactions of nitriles are reported in Table 3.



1

The reduction of nitriles to the corresponding amines is a well known reaction, but the formation, with good yields of aromatic thioamides from nitriles is a new method of preparation for those thioamides. The formation of thioamides from nitrile, by the action of H_2S in basic media, is known (12). With $NaBH_2S_3$, since the reaction takes place under anhydrous conditions and since $NaBH_2S_3$ alone does not give H_2S under the experimental conditions used, a mechanism calling for $NaBH_2S_3$ rather than H_2S must prevail.

Reduction of Amides and Nitroso Groups

The reduction of amides is difficult, and gives only moderate yields of the corresponding amines. Thus, benzamide gave a moderate yield of benzylamine, along with smaller amounts of dibenzylamine, thiobenzamide, and traces of benzonitrile. A similar behavior was observed with β-phenylacetamide.

Aliphatic nitroso compounds gave very complex mixtures. With nitrosobenzene, a yield of 80% of aniline was obtained with an equimolecular ratio of nitroso compound and reducing agent. When the ratio was increased to 2/1 the yield was about the same. Therefore it appears that half a mole of $NaBH_2S_3$ is required to reduce the nitroso group.

Experimental

The n.m.r. measurements were made with a Varian A-60 apparatus. The i.r. measurements were made with a Perkin–Elmer apparatus, model 257. The v.p.c. measurements were made with a Varian model 90P apparatus using a 5 ft Se30 column.

hydrofuran (THF), 0.10 mol (12.3 g) of nitrobenzene in 150 ml of THF was added dropwise. The reaction mixture was stirred and refluxed for 24 h, and was then evaporated to dryness, under reduced pressure, at room temperature. The residual solid was hydrolyzed with a 10% hydrochloric solution until p*H* 1 in presence of 250 ml of ethyl ether. The precipitated sulfur was filtered off and the filtrate washed repeatedly with ethyl ether. The aqueous fraction was neutralized to p*H* 11 with a 20% solution of NaOH, in presence of 200 ml of ethyl ether. The aqueous layer was extracted again with ether and the combined ether extracts were evaporated, giving an 84% yield of aniline. The i.r., v.p.c., and n.m.r. of the crude base confirmed its structure.

(1b) Other Reductions of Nitro Groups

The reduction of other nitro groups or mixtures of nitro derivatives has been done as described in section *1a*, the molar ratio of reagents and reducing agent, the duration and temperature of contact being indicated in Table 1. The compositions of the various mixtures has been determined by n.m.r. and v.p.c. The identification of the components of those mixtures was performed by preparative v.p.c. followed by analytical v.p.c., i.r., n.m.r., and mass spectrometry. In most cases, those measurements were compared with the results observed with authentic samples of pure bases. In Table 2, reflux for 24 h, of 0.2 mol of $NaBH_4$ and 0.1 mol of each of the nitro compounds were used in each case, the extraction procedure being the same as above.

(2) Reduction of Nitriles

The reduction of nitrile was done as described in section *1a* for nitro groups, the ratio of reagents and yields being reported in Table 3. The separation of amines from thioamide was done by extraction of the bases with 10% hydrochloric acid. The thioamides were recrystallized in CCl_4. The identification of the products thus obtained was done by comparison of n.m.r., v.p.c., and i.r. measurements obtained with authentic samples.

The structure of the disulfide **1** was established by the usual measurements. The n.m.r.: broad singlet at 2.60 (5 protons); singlet at 5.00 (1 proton); doublet at 0.5 τ (2 protons). Mass spectrometry: *m/e* 266, 232, 151, 117, 116, 91, 90, 98, 77, 64, 63, 62, 61, 60.

Anal. Calcd. for $C_{16}H_{16}N_2S_4$: C, 52.65; H, 4.38; N, 7.68; S, 53.17. Found: C, 50.84; H, 4.49; N, 7.27; S, 36.83; O, 0.0.

The differences in the calculated and found values of the elementary analysis are attributed to the difficulty of recrystallization (ethanol–water) of the disulfide. Yield: 5%.

(3) Reduction of Amides

The experimental procedure used is described in section *1a*, 0.2 mol of benzamide being treated by 0.4 mol of $NaBH_2S_3$. Using this stoichiometry with a reflux time of 120 h gave 46% of $C_6H_5CH_2NH_2$, 6% of $(C_6H_5CH_2)_2NH$ 16% of $C_6H_5CSNH_2$, and traces of C_6H_5CN and C_6H_5-CHO, while 31% of $C_6H_5CONH_2$ was recovered. For a reflux time of 24 h, the reaction gave 48% of primary amine, traces of secondary amine, 18% of thiobenzamide, and traces of benzaldehyde and benzonitrile, and about 30% of $C_6H_5CONH_2$ recovery. Approximately the same results were obtained for a contact time of 3 h. If equimolar quantities of reducing agent and amide were used for a contact time of 24 h reflux, the products were 22.4% of benzylamine, 2.5% of dibenzylamine, 25% of thiobenzamide and traces of benzonitrile and benzaldehyde with a recovery of about 50% of the starting benzamide. With a ratio of 4/1 of reducer to reagent for a 24 h reflux we obtained 45% of $C_6H_5CH_2NH_2$, 10% of $(C_6H_5CH_2)_2$-NH, 10% of $C_6H_5CSNH_2$, and traces of C_6H_5CN with about 35% of non-reacted benzamide. The dibenzylamine $(C_6H_5CH_2)_2NH$ was obtained by separation of the basic fraction on a silica gel column and identified by n.m.r., i.r., and mass spectroscopy.

Anal. Calcd. for $C_{14}H_{15}N$: C, 85.28; H, 7.62; N, 7.10. Found: C, 85.00; H, 7.50; N, 7.17.

The primary amine $C_6H_5CH_2NH_2$, the amide and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

thioamide, and the aldehyde and nitrile were identified by n.m.r. and i.r. spectroscopy for all the mentioned experiments.

A molar ratio of 2/1 of reducing agent to 2-phenylacetamide for a reflux time of 24 h gave about 41% of 2-phenylethylamine. Some corresponding thioamide is believed to be formed and a large quantity of the initial amide was recovered.

(4) Reduction of Nitroso Compounds

The experimental procedure is the same as the one used in section *1a*. For an equimolar ratio of reducing agent/nitrosobenzene, we obtained an 82% yield of aniline, which was identified by n.m.r. and i.r. analysis. With a molar ratio of 1/2, a 75% yield of aniline was obtained.

The Reaction of Thallium with Hydrocarbons

J. M. LALANCETTE AND A. LACHANCE
Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke, Québec

Received March 22, 1971

The exchange of the cyclopentadienyl anion between indium and thallium is reported along with exchange reactions between cyclopentadienylindiums, substituted with H, D, and CH_3. The pyrolysis of numerous hydrocarbons in presence of thallium to give the corresponding cyclopentadienylthallium derivative is described and related to the structure of the starting material.

L'échange de l'anion cyclopentadiényle entre l'indium et le thallium est rapporté, ainsi que des réactions d'échange entre certains cyclopentadiènеindiums substitués par H, D et CH_3. La pyrolyse d'hydrocarbures variés en présence de thallium pour donner le dérivé cyclopentadiénylthallium est décrite et reliée à la structure de l'hydrocarbure de départ.

Canadian Journal of Chemistry, **49**, 2996 (1971)

The lower elements of Group IIIA, namely indium and thallium, are known to give derivatives with cyclopentadiene involving the π electronic system of this molecule (1). Such compounds are obtained, in the case of indium (2), by the action of the cyclopentadienyl anion on a In^+ substrate. With thallium, a similar compound is formed either by the direct reaction of cyclopentadiene with the metal (3) or with a thallous salt (4), the reaction of the hydrocarbon with the metal being accompanied by an evolution of hydrogen. From the actual knowledge of the structure of those cyclopentadienyl derivatives of indium and thallium, and in analogy with ferrocene, the π system of the hydrocarbon is involved in a "half sandwich" structure as indicated in eqs. 1 and 2.

[1] $In^+ +$  $\longrightarrow$

[2] $Tl^0 +$ $\longrightarrow \frac{1}{2}H_2 +$

The chemistry of cyclopentadienylindium is not easy because of the great sensitivity of this material towards light and oxygen. It can sublime as gold leaflets in darkness, under a vacuum better than 10^{-5} mm. The derivative of thallium is more stable. It can also sublime as pale yellow crystals and its resistance towards light and oxygen is somewhat better.

(1) Exchange of the Cyclopentadienyl Anion between Indium and Thallium

Because of the great difference in the stability and reactivity of those two compounds, we have postulated that an exchange of the ligand between the two metals was possible. The postulated reaction, as illustrated by eq. 3, was found to proceed quite easily.

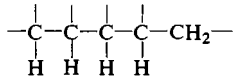
[3] 
The reaction was performed simply by mixing freshly sublimed cyclopentadienylindium with finely divided thallium. By heating the mixture under high vacuum, the cyclopentadienylthallium sublimed. The displacement of equilibrium towards cyclopentadienylthallium in eq. 3 might be explained solely by the greater stability of the thallous derivative and the very high reactivity of the indium compounds. It has been possible to show, however, that such exchange reactions were very easily done, even when the thermodynamic properties of the metal derivatives were not much modified by the reaction. Such exchanges are described by eqs. 4 and 5. In the first case, deuterated cyclopentadienyl anion was shown to exchange easily with protonated cyclopentadienylindium. A similar behavior was noted with methyl cyclopentadienyl anion and cyclopentadienylindium. In both cases, the sublimate obtained from the mixture of the reagents indicated very clearly that both forms of cyclopentadiene (with and without deuterium or with and without methyl substituent) were bonded to the metal.

(2) Reactions with other Hydrocarbons

Such an exchange was interesting in itself and we tried to repeat the reaction with other dienes

[4] 
[5] 
in order to broaden the scope of the reaction. Thallium was selected because it appeared more adequate than indium in its reactions with cyclopentadiene hydrocarbon. We found that at moderate temperature, conjugated dienes, such as cycloheptadiene would not react with thallium. At more elevated temperature, however, we were much surprised to find that several hydrocarbons gave the corresponding cyclopentadienethallium. We found that bicyclo[2,2,1]hepta-2,5-diene, 1,3-cyclohexadiene, 1,3-cycloheptadiene, 1,5-cyclooctadiene, 1,3-cyclooctadiene, 1,4-cyclohexadiene, cycloheptatriene, cycloheptene, cyclohexene, 2-pentene, 1-octene, cyclohexane, octane, and pentane, gave the corresponding cyclopentadienylthallium. However, benzene, cyclooctatraene, isoprene or isobutylene did not give the thallium derivative under similar experimental conditions. The cyclopentadienylthallium was sublimed and identified by its mass spectrum and by formation of ferrocene in ether, with $FeCl_3$ (5). The yield of the thallium derivative was of the order of 3% and about 60% of the starting hydrocarbon was recovered unreacted. Beside the thallium derivative, ethylene, acetylene, hydrogen, carbon, traces of benzene and polymeric material were also formed in the course of the reaction.

From those results, it can be concluded that the course of the thermal decomposition of an hydrocarbon of appropriate structure, a cyclopentadienyl anion or cyclopentadiene must be one of the intermediates. From the list of hydrocarbons cited above giving a positive reaction, it can be noted that with those substances, the partial structure **1** was always present, the unspecified bonds in **1** being involved in double bonds, C—C bonds or C—H bonds, depending on the cases.



1

When such an arrangement was not present, the cyclopentadienylthallium was not formed. One explanation of this observation is that the partial structure **1** can act as a precursor of either cyclopentadiene or cyclopentadienyl anion, at the high temperature of the reaction, when the starting molecule is broken down. Either the hydrocarbon or its anion can then react with thallium metal to give the cyclopentadienyl derivative that sublimes before further decomposition. It is known (6) that the pyrolysis of mixtures of hydrocarbons can produce cyclopentadiene; the present work indicates the favorable structures for the formation of this substance.

The role of the thallium in this experiment must be twofold. First, it catalyzed the decomposition of the hydrocarbon as all metals do at high temperature. Secondly, its reactivity with the cyclopentadienyl structure and the volatility of the corresponding derivative render possible the observed trapping.

Experimental

Infrared measurements were made on a Perkin–Elmer spectrometer, model 257, in Nujol. The nuclear magnetic resonance (n.m.r.) measurements were performed with a Varian A-60 instrument, using tetramethylsilane as internal reference. Melting points were made with a "Buchi" melting point apparatus and are not corrected. Mass spectrometric determinations were made with a Hitachi Perkin–Elmer apparatus model RMV-6D.

(1) Preparation of Cyclopentadienylindium

Metallic sodium (0.6 g), finely cut, was introduced under nitrogen into a solution of 2.5 ml of cyclopentadiene freshly distilled, in 100 ml of absolute dry ether. The resulting mixture was refluxed with stirring for 12–14 h to form cyclopentadienylsodium. Indium tribromide (2.8 g) was then added, and the mixture was heated for another 12–14 h in the absence of air. After removal of the solvent by distillation at atmospheric pressure, the dry residue was sublimed under high vacuum (10^{-5} mm) by gradually raising the temperature to a maximum of 150°. This procedure gave pale yellow crystals of cyclopentadienylindium.

The mass spectrum of the product was taken under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

very careful experimental conditions. All the time the product had to be kept under an inert gas such as helium and away from light, otherwise it would undergo to rapid decomposition by air or light. All manipulations were done inside a "Glove Bag" flushed with helium, the operation being performed in semi-darkness. The product was put in a small vial which was introduced into the mass spectrometer inlet. This procedure gave the expected peaks at *m/e* 180 and 178 for $C_5H_5{}^{115}In$ and $C_5H_5{}^{113}In$ with a ratio 95:5; at 115 and 113 for the two isotopes of indium; and at 65 and 66 for the cyclopentadienyl anion and cyclopentadiene. The isotopic ratio observed was correct for the natural mixture, at 180 and at 115.

(2) Preparation of Cyclopentadienylthallium

A mixture of 25 g of recrystallized Tl_2SO_4 and 10 g of KOH in 200 ml of water was treated at room temperature with 5 g of freshly distilled cyclopentadiene in a small amount of methanol. After stirring to completion of precipitation, the mixture was filtered and the precipitate was washed with ice-cold methanol and dried over KOH. The product was then purified by sublimation at 10^{-5} mm, gradually raising the temperature to 145°. This procedure gave pale white yellow crystals of cyclopentadienylthallium.

The product was submitted to a mass spectrometry determination with the same strict conditions that were used for the determination of cyclopentadienylindium. The expected peaks appeared at *m/e* 270 and 268 for $C_5H_5{}^{205}Tl$ and $C_5H_5{}^{203}Tl$, with a ratio 70:30; at 205 and 203 for thallium metal and at 66 and 65 for cyclopentadiene and cyclopentadienyl anion. The isotopic ratio was identical with the natural ratio of isotopes of Tl.

(3) Exchange between Cyclopentadienylindium and Thallium Metal

Cyclopentadienylindium (1.6 g) was prepared as above, starting from cyclopentadiene (16.4 g), sodium metal (4.8 g) and indium tribromide (21.9 g). Thin flakes of metallic thallium were prepared under nitrogen and mixed with the cyclopentadienylindium. The mixture was then heated at 50° for 30 min and sublimed at 10^{-5} mm, gradually raising the temperature to 90°. After 2 h, the product, pale white yellow crystals, was collected and submitted to mass spectrometry. The expected peaks were observed at *m/e* 270 and 268 for $C_5H_5{}^{205}Tl$ and $C_5H_5{}^{203}Tl$ with a ratio 70:30; at 205 and 203 for thallium metal; at 180 and 178 for $C_5H_5{}^{115}In$ and $C_5H_5{}^{113}In$; at 66 and 65 for cyclopentadiene and cyclopentadienyl anion.

(4) Exchange between Deuterated Cyclopentadienyl Anion and Cyclopentadienylindium

Metallic sodium (2.4 g) finely cut, was introduced under nitrogen into a solution of 8.2 g of cyclopentadiene freshly distilled in 300 ml of absolute dry ether. The resulting mixture was refluxed for 24 h to form cyclopentadienylsodium. After removal of the solvent under vacuum, 200 ml of dry *cis*-decalin were added and, keeping the system under nitrogen, the cyclopentadienylsodium was slowly hydrolyzed by adding D_2O. After hydrolysis, the NaOD was removed by decantation and the organic fraction dried over $MgSO_4$ and filtered. The deuterated cyclopentadiene was then distilled and the infrared spectra was showing a band of medium intensity at 2300 cm^{-1}.

Metallic sodium (2.7 g) was introduced under nitrogen into a solution of 9.3 g of deuterated cyclopentadiene in 200 ml of anhydrous ether. After refluxing for six days, the solvent was evaporated under vacuum and the solid residue was mixed with cyclopentadienylindium freshly sublimed.

The mixture was then heated at 50° for 10 min, then sublimed at 10^{-5} mm gradually raising the temperature to 140°. This procedure gave pale yellow crystals which were submitted to mass spectrometry analysis.

Peaks were obtained at *m/e* 183, 182, 181 for deuterated cyclopentadienylindium, at 180 and 178 for $C_5H_5{}^{115}In$ and $C_5H_5{}^{113}In$, at 115 and 113 for indium metal and at 68, 67, 66, and 65 for deuterated and non-deuterated cyclopentadiene and cyclopentadienyl anion.

(5) Exchange between Methylcyclopentadienyl Anion and Cyclopentadienylindium

Metallic sodium (5.6 g), finely cut, was introduced under helium into a solution of 17.4 g of freshly distilled methylcyclopentadiene in 200 ml of absolute dry ether. After refluxing for one week, the solvent was evaporated under vacuum and the methylcyclopentadienylsodium was then mixed with cyclopentadienylindium freshly sublimed.

After heating to 50° for 10 min, the mixture was sublimed at 10^{-5} mm gradually raising the temperature to 140°. The product (pale yellow crystals) was then submitted to a mass spectrometry analysis using the usual procedure.

The expected peaks were observed at *m/e* 194 for $CH_3C_5H_4{}^{115}In$, at 180 for $C_5H_5{}^{115}In$, at 80, 79 for methylcyclopentadiene and methylcyclopentadienyl anion and at 66, 65 for cyclopentadiene and cyclopentadienyl anion.

(6) Pyrolysis of various Hydrocarbons in presence of Thallium Metal

The reaction of cycloheptene with thallium metal to give cyclopentadienylthallium is described as a typical experiment. The experimental conditions were carefully controlled and with the apparatus used (Fig. 1), it was possible to reproduce the experiments without difficulties.

The thallium metal was washed several times with hexane to remove the high molecular weight hydrocarbon coating the pellets and after high vacuum drying introduced into a 100 ml flask. The apparatus was installed and a flow rate of approximately 19 c.c. of helium gas per minute was set on. A heating element covered by asbestos was wrapped around the thallium flask to give a temperature of 500° inside the vessel. It was important to wrap the heating elements around the whole flask. Cycloheptene was heated to its boiling point in a separate flask and a second heating element was used to keep the transfer line warm.

An acetone – Dry Ice trap was installed at the exit of the apparatus followed by a liquid air trap to condense all gases as volatile hydrocarbon vapors. Cycloheptene (5.57 g) was passed over thallium (17.9 g) at 500° for 24 h. After 1 h, pale yellow crystals began to appear at the top of the condenser. After this period, the product was

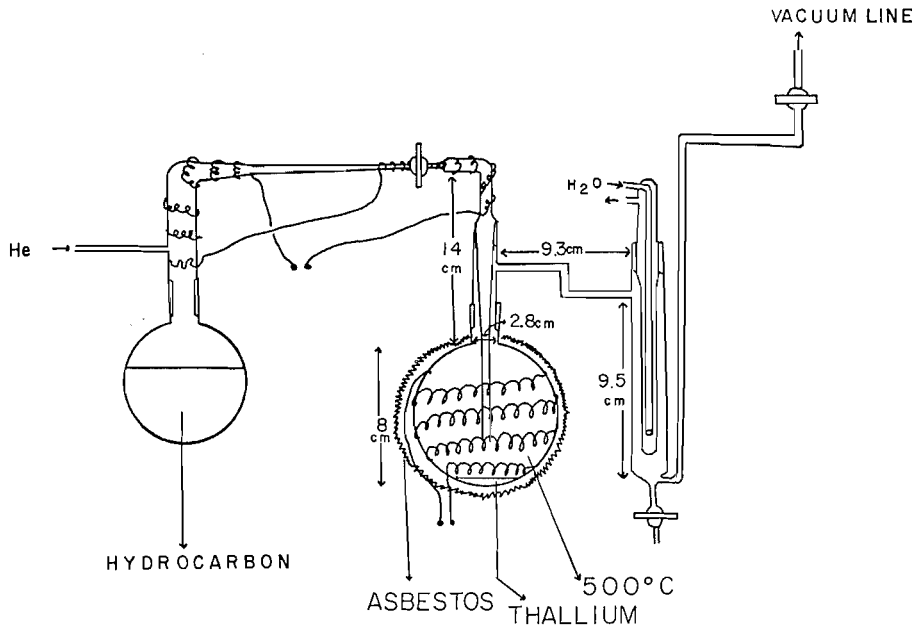


FIG. 1. Reaction apparatus.

sublimed at 10^{-5} mm, gradually raising the temperature to 145°. The unreacted liquid in the Dry Ice trap was mostly cycloheptene and traces of benzene (3.28 g). The gases trapped with liquid air were analyzed by infrared and shown to be ethylene and acetylene. The sublimation yielded white yellow crystals of cyclopentadienylthallium (0.167 g, 3% of reacted cycloheptene). A mass spectrometry analysis showed the expected peaks at *m/e* 270 and 268 for $C_5H_5{}^{205}Tl$ and $C_5H_5{}^{203}Tl$; at 205 and 203 for thallium metal with a ratio 70:30; and at 66 and 65 for cyclopentadiene and cyclopentadienyl anion.

A similar experiment was repeated with bicyclo(2,2,1)-hepta-2,5 diene, 1,3-cyclohexadiene, 1,3-cycloheptadiene, 1,5-cyclooctadiene, 1,3-cyclooctadiene, 1,4-cyclohexadiene, cycloheptatriene, cyclohexene, 2-pentene, 1-octene, cyclohexane, octane, and pentane, and cyclopentadienylthallium was obtained. With benzene, cyclooctatetraene, isoprene or isobutylene, no thallium derivative was observed.

Formation of Ferrocene

The thallium derivative obtained above was added to $FeCl_3.4H_2O$ (2 g) in a minimum quantity of ether and stirred for 1 h at 25°. After filtration over $MgSO_4$ and evaporation of the solvent, a sublimation at 25° yielded orange-yellow colored crystals of ferrocene. The product melted at 174.5 to 175.2° and an n.m.r. and infrared spectra were identical with the n.m.r. and infrared spectra of authentic ferrocene (5).

The ferrocene derivative was obtained in the course experiments with cyclohexane, 1-octene, octane, and cycloheptene.

Base-catalyzed Degradations of Carbohydrates. I. Synthesis and Alkaline Degradation of 2-*O*-β-D-Glucopyranosyl-3-*O*-methyl-D-glucose

G. O. Aspinall,[1] R. Khan, and Zofia Pawlak[2]

Department of Chemistry, Trent University, Peterborough, Ontario

Received May 19, 1971

2-*O*-β-D-Glucopyranosyl-3-*O*-methyl-D-glucose has been synthesized by two routes. Alkaline degradation of the disaccharide, followed by reduction, hydrolysis under extremely mild conditions, and further reduction, affords D-glucitol, and 3,4-dideoxy-*trans-erythro*- and -D-*threo*-hex-3-enitol.

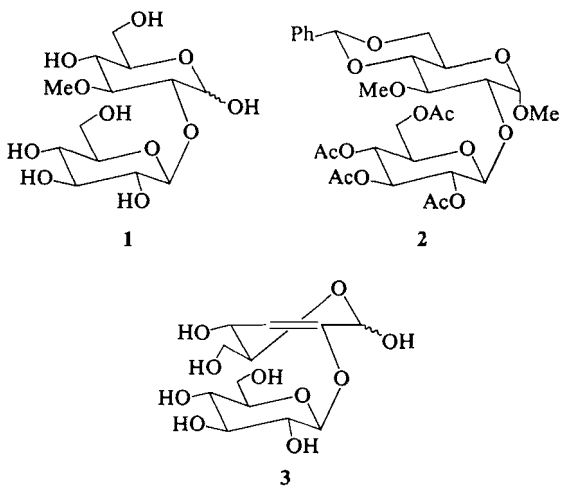
Le 2-*O*-β-D-glucopyranosyl-3-*O*-méthyl-D-glucose a été synthétisé de deux façons. La dégradation alcaline du disaccharide suivie d'une réduction et hydrolyse sous des conditions extrêmement douces conduit, après réduction ultérieure, au D-glucitol et 3,4-didéoxy-*trans-erythro*- et -D-*threo*-hex-3-enitol.

Canadian Journal of Chemistry, 49, 3000 (1971)

2-*O*-β-D-Glucopyranosyl-3-*O*-methyl-D-glucose (**1**) was required as a model compound in connection with studies on the alkaline degradation of branched oligo- and polysaccharides. Methyl 4,6-*O*-benzylidene-2-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-3-*O*-methyl-α-D-glucopyranoside (**2**) was prepared by two routes: (*i*) by condensation of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide and methyl 4,6-*O*-benzylidene-3-*O*-methyl-α-D-glucopyranoside (1), and (*ii*) by methylation of methyl 4,6-*O*-benzylidene-2-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-α-D-glucopyranoside (2, 3) with (*a*) methyl iodide and silver oxide in *N*,*N*-dimethylformamide or (*b*) diazomethane in the presence of boron trifluoride (4). Acetolysis of the glycoside (**2**) furnished a semi-crystalline disaccharide heptaacetate from which the disaccharide, 2-*O*-β-D-glucopyranosyl-3-*O*-methyl-D-glucose (**1**), was obtained on de-*O*-acetylation. The derived disaccharide alditol was characterized by the formation of a crystalline octaacetate and a crystalline octabenzoate.

Treatment of the disaccharide (**1**) with saturated lime-water gave a syrupy product whose u.v., i.r., and n.m.r. spectra indicated that elimination of methanol had occurred with the formation of 3-deoxy-2-*O*-β-D-glucopyranosyl-D-*erythro*-hex-2-enopyranose (**3**). The unsaturated disaccharide (**3**) was reduced with sodium borohydride, and mild treatment with cation-exchange resin during the work-up to destroy excess of hydride and remove sodium ions gave a syrupy mixture of products whose u.v. (λ_{max} 230 nm) and i.r. (ν_{max} 1690, 1640, and 975 cm^{-1}) spectra were consistent with the presence therein of the unsaturated ketose, 3,4-dideoxy-*trans*-D-*glycero*-hex-3-enos-2-ulose (5). The presence in the mixture of D-glucose and the unsaturated ketose was established by reduction with sodium borohydride to give D-glucitol, 3,4-dideoxy-*trans-erythro*-hex-3-enitol (**4**), and 3,4-dideoxy-*trans*-D-*threo*-hex-3-enitol (**5**), each of which was characterized by the formation of crystalline derivatives.

These results parallel those of Anet (5) on the



[1]To whom enquiries should be addressed.

5

alkaline degradation of 2,3-di-*O*-methyl-D-glucose. It is noteworthy that the enol glycoside formed on reduction of the unsaturated disaccharide (**3**), like the enol ether, 3-deoxy-2-*O*-methyl-D-*erythro*-hex-2-enitol (5), is extremely labile to acid. The observed sequence of reactions may find application in the determination of the structure of branched oligosaccharides containing a 2,3-di-*O*-substituted reducing group in that (*i*) the 3-*O*-glycosyl substituent would be eliminated on alkaline degradation, (*ii*) the 2-*O*-glycosyl substituent would be subsequently liberated on very mild acid hydrolysis, and (*iii*) the formation of the epimeric hex-3-enitols would indicate the substitution pattern of the reducing sugar residue.

Experimental

Melting points are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 polarimeter at 20 ± 2°. The i.r. and u.v. spectra were measured on Unicam SP 200 and SP 800A spectrophotometers. The n.m.r. spectra were recorded on a JEOL C-60HL spectrometer with tetramethylsilane or sodium 4,4-dimethyl-4-silapentanesulfonate as internal standards. The t.l.c. was performed with Kieselgel G (Merck) as the adsorbent, and the dried plates were sprayed with ethanolic 5% sulfuric acid and heated at about 150°. Unless otherwise stated, column chromatography was carried out on silica gel (Davison grade 950, 60–200 mesh). Paper ionophoresis was in 0.05 *M* borate buffer at p*H* 10. Unless otherwise stated light petroleum refers to the fraction of b.p. 30–60°. Solutions were concentrated below 50° under reduced pressure.

Methyl 4,6-O-Benzylidene-3-O-methyl-α-D-glucopyranoside

Methyl 4,6-*O*-benzylidene-3-*O*-methyl-2-*O*-tosyl-α-D-glucopyranoside (1) (15 g) in refluxing methanol (400 ml) and benzene (500 ml) was treated with sodium (25 g) (6) for 6 h. The t.l.c. (chloroform–acetone, 4:0.3) showed a single product. Water (200 ml) was added to the cooled reaction mixture, organic solvents were removed, and the suspension was extracted with chloroform. The dried extract was concentrated and crystallization of the residue from methanol containing a little light petroleum gave methyl 4,6-*O*-benzylidene-3-*O*-methyl-α-D-glucopyranoside (9.5 g, 96%), m.p. 137–139° (unchanged on recrystallization), (lit. (1) m.p. 150–151°); n.m.r. data ($CDCl_3$): τ 2.4–2.8 (5-proton multiplet, aromatic H's), 4.40 (1-proton singlet, benzylidene–methine), 5.20 (1-proton doublet, splitting 4 Hz), 6.36, 6.54 (3-proton singlets, C-1 OMe and C-3 OMe), 7.2–7.45 (1-proton, OH).

Methyl 4,6-O-Benzylidene-2-O-(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)-3-O-methyl-α-D-glucopyranoside (2)

(*a*) Methyl 4,6-*O*-benzylidene-3-*O*-methyl-α-D-glucopyranoside (4 g) was dissolved by stirring for 2 h in dichloromethane (38 ml) in the presence of silver carbonate (4 g) and drierite (4 g). Iodine (1 g) and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (5.5 g) were added and the mixture was stirred for 42 h at room temperature. The mixture was filtered and concentration of the filtrate afforded a crystalline residue which, on trituration with methanol, gave a chromatographically pure product (5 g, 59%), m.p. 245–246°. Recrystallization from methanol gave compound **2**, m.p. 245–246°; $[\alpha]_D$ +33.7° (*c*, 1.15 in dichloromethane); n.m.r. data: τ 2.4–2.8 (5-proton multiplet, aromatic H's), 4.42 (1-proton singlet, benzylidene–methine H), 6.47, 6.57 (3-proton singlets, C-1 OMe and C-3 OMe), 7.9–8.05 (12 protons, OAc's).

Anal. Calcd. for $C_{29}H_{38}O_{15}$: C, 55.59; H, 6.07. Found: C, 55.33; H, 6.14.

(*b*) Methyl 4,6-*O*-benzylidene-2-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-α-D-glucopyranoside (1 g) and methyl iodide (2 ml) were stirred in *N*,*N*-dimethylformamide (15 ml) with silver oxide (1 g) for 30 h. The mixture was filtered, the filtrate was concentrated, and the residue was crystallized from ethoxyethanol to give compound **2**, m.p. 245–246°, $[\alpha]_D$ +33° (*c*, 1.0 in chloroform), whose n.m.r. spectrum was identical to that of the previously prepared sample.

(*c*) Methyl 4,6-*O*-benzylidene-2-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-α-D-glucopyranoside (0.5 g) was dissolved in dichloromethane (15 ml) at 0°, boron trifluoride etherate (0.05 ml) was added, and while the temperature was maintained at 0°, a white solid (polymethylene) was removed by filtration, and the filtrate was concentrated to a syrup which was crystallized from ethoxyethanol to give compound **2**, m.p. 243–245°, $[\alpha]_D$ +31° (*c*, 1.0 in chloroform), whose n.m.r. spectrum was identical with those of previously prepared samples.

2-O-β-D-Glucopyranosyl-3-O-methyl-D-glucose (1)

The foregoing glycoside (**2**) (4 g) in acetic anhydride (10 ml) was stirred with concentrated sulfuric acid 2% in acetic anhydride (20 ml) for 4 h. The mixture was poured into ice-water containing sodium hydrogen carbonate, the product was extracted with chloroform, and the chloroform extract was washed with water, dried, and concentrated to a syrup. The t.l.c. (chloroform–acetone, 4:0.3) showed a major component with fast-moving minor components with the mobilities of the peracetates of glucose and 3-*O*-methylglucose. The mixture was chromatographed on silica gel, elution with ether – light petroleum (3:1) and ether removing benzaldehyde and monosaccharide peracetates, and elution with ether–acetone (7.5:1) giving syrupy 1,4,6-tri-*O*-acetyl-2-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-3-*O*-methyl-

α-D-glucopyranose (2.8 g, 71%), $[\alpha]_D$ +35.3° (*c*, 1.34 in dichloromethane); n.m.r. data ($CDCl_3$): τ 3.77 (1-proton doublet, $J_{1,2}$ = 3 Hz, H-1), 6.57 (3-proton singlet, C-3 OMe), 7.85–8.05 (21 protons, OAc's).

Anal. Calcd. for $C_{27}H_{38}O_{18}$: C, 49.87; H, 5.89. Found: C, 49.91; H, 5.96.

This compound was later obtained in semi-crystalline form from ether–light petroleum.

Anal. Calcd. for $C_{27}H_{38}O_{18}$: C, 49.87; H, 5.89; OMe, 4.76. Found: C, 49.97; H, 5.86; OMe, 4.51.

Methanolic barium methoxide (1.5 *N*, 3 ml) was added to the above heptaacetate (3 g) in methanol (50 ml) and the mixture was kept at room temperature for 4 h. The solution was diluted with methanol and passed through columns of Amberlite resins IR-120(H) and IR-45(OH), the resins were washed with methanol–water (1:1), and the combined eluate and washings were concentrated to a syrup. The syrup was chromatographed on a column (90 × 1.5 cm) of Dowex resin 50 WX2 (Li^+; 200–400 mesh) with water as eluant to give chromatographically and ionophoretically pure syrupy 2-*O*-β-D-glucopyranosyl-3-*O*-methyl-D-glucose (**1**), $[\alpha]_D$ +19° → +13° (*c*, 1.0 in water); n.m.r. data (D_2O): τ 4.63 (1-proton doublet, $J_{1,2}$ = 3 Hz, H-1), 6.57 (3-proton singlet, C-3 OMe).

Anal. Calcd. for $C_{13}H_{24}O_{11}$: C, 43.71; H, 6.74; OMe, 8.70. Found (after drying over P_2O_5 at 60°): C, 43.40; H, 7.02; OMe, 8.41.

In subsequent preparations chromatographically pure disaccharide (**1**) was obtained by chromatography on a cellulose column using acetone–water (7:1) as eluant.

The disaccharide (**1**) (750 mg) was treated with sodium borohydride (125 mg) in water (25 ml) for 24 h. Excess of hydride was destroyed and sodium ions were removed by treatment with cation-exchanger, and the solution was concentrated several times with methanol to remove boric acid as methyl borate to give syrupy disaccharide alditol (500 mg). The syrup (200 mg) was treated with acetic anhydride and pyridine, and the product was recrystallized from ether–light petroleum (b.p. 30–60°) to give 1,4,5,6-tetra-*O*-acetyl-2-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-3-*O*-methyl-D-glucitol (300 mg), m.p. 88–90°, $[\alpha]_D$ −13.6° (*c*, 1.04 in dichloromethane); n.m.r. data ($CDCl_3$): τ 6.46 (3-proton singlet, C-3 OMe), 7.72–7.88 (24 protons, OAc's).

Anal. Calcd. for $C_{29}H_{42}O_{19}$: C, 50.21; H, 6.10. Found: C, 50.33; H, 6.16.

A further portion (100 mg) of the syrupy disaccharide alditol was treated with benzoyl chloride and pyridine, and the product was recrystallized from ethanol to give 1,4,5,6-tetra-*O*-benzoyl-2-*O*-(2,3,4,6-tetra-*O*-benzoyl-β-D-glucopyranosyl)-3-*O*-methyl-D-glucitol (75 mg), m.p. 80–83°, $[\alpha]_D$ +25.5° (*c*, 1.35 in dichloromethane).

Anal. Calcd. for $C_{69}H_{58}O_{19}$: C, 69.58; H, 4.91. Found: C, 69.49; H, 4.67.

Alkaline Degradation of Disaccharide (1)

The disaccharide (**1**) (1 g) was kept in oxygen-free saturated lime-water (100 ml) for 40 h at 50°. The cooled solution was neutralized with carbon dioxide and concentrated, the residue was extracted with acetone, and the extract was concentrated to a syrup, $[\alpha]_D$ +3° → −4° (*c*, 1.0 in water); λ_{max} (H_2O) 198 nm (ε 5500); ν_{max} (film) 1645 cm^{-1} (C=C); n.m.r. data (D_2O): OMe protons absent.

Anal. Calcd. for $C_{12}H_{20}O_{10}\cdot H_2O$: C, 42.10; H, 6.43. Found (after drying for 1 day at 40°): C, 41.99; H, 6.57.

Anal. Calcd. for $C_{12}H_{20}O_{10}$: C, 44.44; H, 6.17. Found (after extended drying at 40°): C, 43.40; H, 7.02.

Sodium borohydride (0.3 g) was added to the syrupy alkaline degradation product (0.2 g) in water (10 ml), and the solution was warmed to 40° and then kept at room temperature overnight. Excess of hydride was destroyed by the addition of acetone, sodium ions were removed by treatment with cation-exchange resin, and the solution was repeatedly concentrated with methanol to remove boric acid as methyl borate to give a syrup (0.2 g); λ_{max} (H_2O) 230 nm; ν_{max} (film) 1690 (C=O), 1640 (C=C), 975 cm^{-1} (*trans* H—C=C—H).

The syrup (0.2 g) containing the unsaturated ketose was treated with sodium borohydride (0.3 g) in water (10 ml) overnight and the reaction product was worked-up as described above. The t.l.c. of the resulting syrup (ethanol–chloroform, 3:1) showed components with the mobilities of glucitol and 3,4-dideoxy-*trans*-D-*threo*-hex-3-enitol. A further quantity (4 g) of syrup, similarly prepared, was separated by chromatography on a column of silica gel to give two fractions. The slower-moving component (1.6 g) was characterized as D-glucitol by conversion into the hexaacetate, m.p. and mixed m.p. 99°, $[\alpha]_D$ +9° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_{18}H_{26}O_{12}$: C, 49.76; H, 5.99. Found: C, 49.74; H, 5.88.

The faster-moving fraction (2 g) was triturated with warm acetone (4 ml) and separated into acetone-soluble and acetone-insoluble fractions. The acetone-soluble fraction (0.5 g) was stirred for 24 h with anhydrous cupric sulfate (2 g) in acetone (50 ml) containing concentrated sulfuric acid (0.15 ml). The filtered solution was neutralized with sodium carbonate, filtered, and concentrated to a syrup which was extracted with warm pentane. Removal of solvent from the extract and crystallization from methanol furnished 3,4-dideoxy-1,2:5,6-di-*O*-isopropylidene-*trans*-D-*threo*-hex-3-enitol (0.25 g), m.p. and mixed m.p. (with sample prepared by the method of Tipson and Cohen (7)) 80–81°, $[\alpha]_D$ +57.1° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_{12}H_{20}O_6$: C, 63.15; H, 8.78. Found: C, 62.98; H, 8.81.

The di-*O*-isopropylidene derivative (0.2 g) was heated at 50° for 1 h in 0.05 *N* hydrochloric acid in 50% aqueous methanol (3 ml). The cooled solution was diluted with water, neutralized with anion-exchanger, and concentrated. The residue was crystallized from ethanol to give 3,4-dideoxy-*trans*-D-*threo*-hex-3-enitol (**5**) (70 mg), m.p. and mixed m.p. 63–64°, $[\alpha]_D$ −14° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_6H_{12}O_4$: C, 48.64; H, 8.10. Found: C, 48.52; H, 8.38.

In a similar manner the acetone-insoluble fraction (0.5 g) was converted into 3,4-dideoxy-1,2:5,6-di-*O*-isopropylidene-*trans-erythro*-hex-3-enitol (0.3 g), m.p. and mixed m.p. (with sample prepared from 1,2:5,6-di-*O*-isopropylidene-D-glucitol 3,4-thionocarbonate (8)) 69–70°, $[\alpha]_D$ +0.5° (*c*, 1.0 in chloroform).

Anal. Calcd. for $C_{12}H_{20}O_4$: C, 63.15; H, 8.78. Found: C, 63.11; H, 9.09.

Hydrolysis of the di-*O*-isopropylidene derivative

furnished 3,4-dideoxy-*trans-erythro*-hex-3-enitol (**4**) (80 mg), m.p. and mixed m.p. 63–64°, $[\alpha]_D$ 0° (*c*, 5.0 in chloroform).

Anal. Calcd. for $C_6H_{12}O_4$: C, 48.64; H, 8.10. Found: C, 48.62; H, 8.40.

Oligoribonucleotide Synthesis III.[1,2] Synthesis of Trinucleotides Using a Stepwise Phosphotriester Method

THOMAS NEILSON AND EVA S. WERSTIUK
Department of Biochemistry, McMaster University, Hamilton, Ontario

Received November 18, 1970[3]

A convenient general synthesis for protected di- and triribonucleotides of predetermined sequence is described. Starting with a 5′-*p*-methoxytrityl-2′-*O*-tetrahydropyranyl-ribonucleoside, the nucleoside unit destined to become the 5′-terminal of the oligomer, 2′-*O*-tetrahydropyranyl-nucleosides are coupled together by β,β,β-trichloroethyl 3′–5′-phosphotriester linkages. A two-step process is used for each coupling, (*a*) the terminal 3′-hydroxyl group is phosphorylated using β,β,β-trichloroethylphosphate activated by triisopropylbenzenesulfonyl chloride (TPS) and (*b*) re-activation of the newly inserted diphosphate grouping by TPS is followed by condensation with the 5′-hydroxyl of the incoming nucleoside derivative. These phosphotriester derivatives can be isolated and purified in good yield by silica gel column chromatography in methanol – methylene chloride. The fidelity of 3′–5′ linkage is checked. The p.m.r. spectra can indicate the nature and ratio of the bases in these protected oligomers. Deblocking conditions to give free trinucleoside diphosphates are described.

Une synthèse générale et pratique des di- et triribonucléotides protégés et de séquence prédéterminée est décrite. En partant du 5′-*p*-méthoxytrityl-2′-*O*-tétrahydropyranyl-ribonucléoside qui est le nucléoside unité destiné à devenir le groupe terminal en 5′ de l'oligomère, les 2′-*O*-tétrahydropyranyl-nucléosides sont couplés ensemble par des liens dus au β,β,β-trichloroéthyl 3′–5′-phosphotriester. Un processus en deux étapes est utilisé pour chaque couplage: (*a*) le groupe hydroxyl en 3′ terminal est phosphorylé en utilisant le β,β,β-trichloroéthylphosphate activé par le chlorure de triisopropylbenzènesulfonyl (TPS) et (*b*) la réactivation du groupement diphosphate, nouvellement inséré grâce au TPS est suivie d'une condensation avec le groupement hydroxylé en 5′ du dérivé nucléoside d'attaque. Ces dérivés phosphotriester peuvent être isolés et purifiés, avec un bon rendement, par chromatographie sur colonne de silica gel avec un mélange méthanol – chlorure de méthylène. La fidélité du couplage 3′–5′ a été vérifiée. Des spectres r.m.p. peuvent indiquer la nature et le pourcentage des composants dans ces oligomères protégés. Des conditions de débloçage pour obtenir des diphosphates trinucléoside libres sont décrites.

Canadian Journal of Chemistry, 49, 3004 (1971)

Oligoribonucleotide fragments corresponding to the anti-codon loop and neck region of transfer RNA_F^{Met} (*E. coli*) (3) and to the double stranded stem region (two complementary oligoribonucleotides) of transfer RNA_2^{Ala} (yeast) (4) have been isolated from partial Ribonuclease T1 digestions on the native molecules. Similar but reduced activities relative to their parents have been found in codon triplet and in aminoacyl-tRNA synthetase recognition respectively, indicating the elements for binding must be wholly or partially contained within the base sequence of those fragments. Specific points for transfer RNA interaction should become apparent on measuring the activities of a series of oligoribonucleotides with single base changes.

Only a limited number of oligonucleotides of known length and sequence are currently available, as fragments from enzymic digests are controlled by specific cleavage points in a polyribonucleotide. Chemical synthesis on the other hand is theoretically capable of providing all possible oligoribonucleotides. Should a particular sequence within a transfer RNA molecule be considered a possible function site, a 'tailor-made' oligoribonucleotide could be prepared and checked for activity. Thus sequences corresponding to (*a*) the anticodon loop and neck region of a transfer RNA_F^{Met} molecule may provide further information on the nature of anticodon–codon binding as well as clarify the function of the adjacent minor base and (*b*) the doubly stranded stem region (two complementary oligoribonucleotides) may establish the elements of aminoacyl-$tRNA_2^{Ala}$ synthetase recognition sites.

The current status of oligoribonucleotide synthesis leaves much to be desired. The general methods available (5, 6) provide no material longer than a trinucleotide. Because low capacity DEAE–cellulose chromatography in aqueous salt solutions was used as the purification pro-

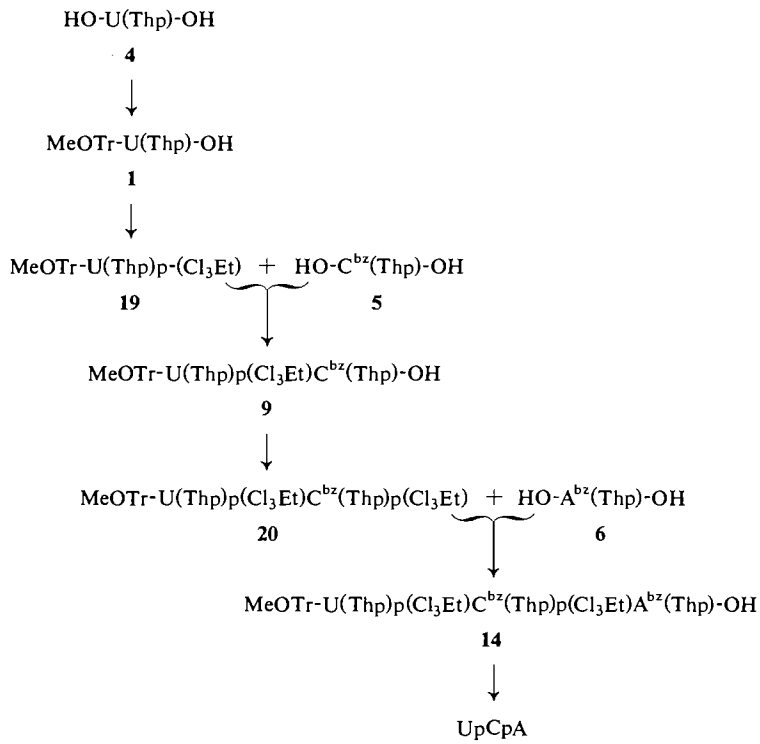
[3]Revision received June 15, 1971.



SCHEME 1

cedure, only small amounts of material were isolated. Interest in this area has been rekindled following two recent developments. (*a*) Ready solubility of tertiary phosphates of oligodeoxyribonucleotides in non-polar solvents allowed relatively large quantities of intermediates to be handled by silica gel chromatography (7–10). Consequently, the slower aqueous chromatographic procedures can be by-passed, at least until after the various protecting groups have been removed late in overall synthesis. (*b*) Mild mineral acid (p*H* 2) (11) accomplished smooth removal of the *O*-tetrahydropyranyl grouping with negligible isomerization of the 3′–5′-diphosphate internucleotidic linkage. Certain acid-labile protecting groups could now be used to block hydroxyl groups of ribofuranoside rings.

In this communication we report a new convenient stepwise synthesis for oligoribonucleotides, one which promises to be generally applicable to the preparation of mixed oligonucleotides. 2′-*O*-Tetrahydropyranyl-*N*-acylnucleosides (1, 11) are joined together in a stepwise manner using 3′–5′-phosphotriester linkages to give protected di- and triribonucleotides. The initial nucleoside in the phosphate coupling is a corresponding 5′-*O*-*p*-methoxytrityl derivative and is destined to become the 5′-terminal nucleoside in the proposed di- and triribonucleotide. Hence the synthesis starts from the 5′-terminal while most syntheses proceeded in the opposite direction. It is anticipated that coupling of these trinucleotides and subsequent deblocking of the product, will provide a block synthesis for much longer oligoribonucleotides of predetermined length and sequence.

Choice of the 'third group' of the phosphotriester internucleotidic linkage was the β,β,β-trichloroethyl grouping (Cl_3Et) which has been successfully employed in deoxyoligonucleotide synthesis by Eckstein (6, 12). Insertion followed a two stage procedure: (*a*) phosphorylation of 3′-hydroxyl group of a nucleoside with β,β,β-trichloroethylphosphoryl dichloride and (*b*) coupling of the new phosphate center with the 5′-hydroxyl group of the next nucleoside using triisopropylbenzenesulfonyl chloride (TPS). Conversion of the phosphotriester linkage to the native 3′–5′-diphosphate was effected by treatment with a Cu–Zn couple in *N*,*N*-dimethylformamide at 60°. A simplification of step *a* was employed in the present instance. β,β,β-Tri-

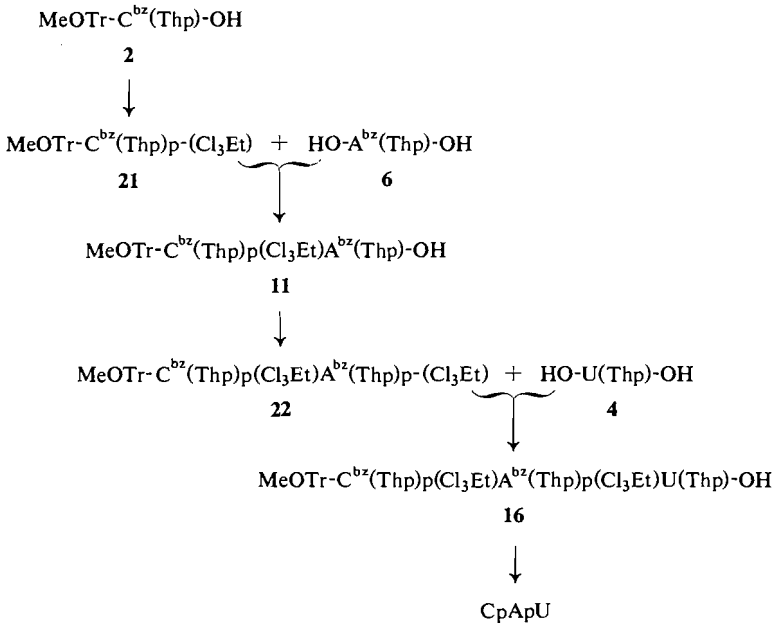

SCHEME 2

chloroethyl phosphate was activated in pyridine using TPS and this complex smoothly phosphorylated the 3′-secondary hydroxyl group of the nucleoside, thus by-passing the need of its more reactive and acidic phosphoryl dichloride derivative. Protected dinucleoside phosphates were prepared either using method A or B illustrated by the synthesis of blocked UpC (Scheme 1) and blocked CpA (Scheme 2) respectively. All protected trinucleoside diphosphates were prepared by the same method illustrated by the synthesis of blocked UpCpA (Scheme 1) and blocked CpApU (Scheme 2). Figure 1[4] shows the amounts of reactants and yields of products for the other protected di- and triribonucleotides prepared, as well as the method employed.

5′-*O*-*p*-Monomethoxytrityl-2′-*O*-tetrahydropyranyluridine (**1**) was prepared in 86% yield from the lower R_F diastereoisomer of 2′-*O*-tetrahydropyranyluridine (**4**) (11) by a high dilution procedure using 1.1 equiv of *p*-anisylchlorodiphenyl methane in pyridine – methylene chloride.

Preparation of Protected Dinucleoside Phosphates

Method A

The bis-cyclohexylamine salt of β,β,β-trichloroethylphosphate (12) was converted to its corresponding pyridinium salt and activated in pyridine using 2 equiv of TPS. Phosphorylation of **1** was carried out in pyridine, progress being monitored by t.l.c., to give 5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranyluridine-3′-β,β,β-trichloroethylphosphate (**19**) as its pyridinium salt. Immediate activation of (**19**) with 1 equiv of TPS and coupling with the 5′-hydroxyl of N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**5**) (1) (the higher R_F diastereoisomer was used as the low R_F diastereoisomer is only slightly soluble in pyridine) gave the blocked UpC, 5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranyluridylyl(3′-β,β,β-trichloroethyl-5′)N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**9**) in 63% yield over the two coupling steps. All phosphorylations were carried out in the dark under anhydrous conditions and preferably sealed under nitrogen. All blocked dinucleotides were eluted from silica gel columns by 2% methanol – methylene chloride. Although

[4]To condense the huge structural formulae necessary to describe a protected oligoribonucleotide, a shorthand method suggested by the IUPAC–IUB commission on Biochemical Nomenclature is adopted (Biochem. **9**, 4022 (1970)).

For example, 5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranyluridylyl(3′-β,β,β-trichloroethyl-5′)N^4-benzoyl-2′-*O*-tetrahydropyranylcytidylyl(3′-β,β,β-trichloroethyl-5′)-N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine can be written as MeOTr-U(Thp)p(Cl_3Et)C^{bz}(Thp)p(Cl_3Et)A^{bz}-(Thp)–OH.

FIG. 1. Summary of preparation of protected oligoribonucleotides.

19 is a salt, its large lipophilic trityl group allowed facile solution in methylene chloride, thus a simple extraction procedure could be used for its isolation.

Method B

The first stage of the formation of diphosphate linkage of blocked CpA, N^4-benzoyl-5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranylcytidylyl-(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**11**), was described in method A. However, after the second coupling step, column chromatography was unable to separate cleanly **11** from excess N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**6**) (1). Separation was accomplished by careful tritylation of the mixture in high dilution which ensured only 5′-*O*-tritylation. Excess **6** was converted to its corresponding 5′-trityl derivative **3** and silica gel column chromatographic separation of **3** and **11** was routine.

This 'back-tritylation' suggested a convenient method for checking the fidelity of the 3′–5′ linkages. Blocked dinucleotide material containing 3′–3′ linkages, arising from possible condensation with the 3′-hydroxyl of the incoming nucleoside, would obtain a second 5′-trityl group under mild tritylation conditions. Any such ditrityl material would be easily detected by t.l.c. Routine mild tritylation on all blocked dinucleotides showed no further reaction indicating the non-existence of 3′–3′-triphosphate formation. Steric interference between the neighboring 2′-*O*-tetrahydropyranyl group of the incoming nucleoside and the bulky arylsulfonic – phosphoric anhydride, together with the secondary nature of the 3′-hydroxyl group, apparently forbids reaction. Consequently no specific 3′-hydroxyl protection was necessary for the incoming nucleosides.

Preparation of Protected Triribonucleoside Diphosphates

Compound **9** was treated with the activated complex of bis-pyridinium β,β,β-trichloroethylphosphate and TPS to give blocked UpCp **20**, an intermediate in the formation of the phosphotriester bond. Immediate activation of **20** with TPS and condensation with N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**6**) (1) gave the blocked triribonucleotide, UpCpA **14** in 61% yield over two steps. Elution of the protected trinucleotides occurred with 2.5–3.0% methanol – methylene chloride, those containing N^2-benzoylguanosine residues being more sluggish.

The p.m.r. data in Table 1 show the resonance bonds for the aromatic protons of the heterocyclic bases and for the anomeric protons of the protected di- and trinucleotides. Signals attributed to H-2 and -8 singlets of adenine, H-8 singlets of guanine, H-5 doublets of uracil, and 1′-anomeric doublets of the ribofuranoside moieties were

easily identified. The H-6 doublets of uracil and H-6 doublets of cytosine always lay under the ortho-protons of any *N*-benzoyl protecting groups, however, these multiplets always integrated for the correct number of protons. The H-5 doublets of cytidine were always obscured by the large phenyl resonance of the trityl group. Despite the existence of these overlapping resonances, the nature and ratio of the bases within a protected oligomer could be determined.

Deblocking of Trinucleoside Diphosphates

A three-step deblocking procedure was carried out in the following order. (*a*) β,β,β-Trichloroethyl groups were removed from the phosphate residue using a Cu–Zn couple (6, 12) in *N*,*N*-dimethylformamide for 1 day at 50 °C. (*b*) Ammonolysis of the amide groups on the heterocyclic bases was accomplished in half-saturated methanolic ammonia (1) for 2 days at room temperature. (*c*) Hydrolytic removal of the trityl and tetrahydropyranyl groups was achieved by maintaining the solution p*H* at 2 (11) for 1 day at ambient temperatures.

It is essential that the 2′-hydroxyl remains blocked during the alkaline conditions of ammo-

For personal use only.

nolysis because of possible isomerization of the 3′–5′ phosphodiester bonds to a mixture of 2′–5′ and 3′–5′ phosphodiester linkages, thus destroying the whole purpose of specific 2′-blocking.

Characterization of the trinucleoside diphosphates, all one spot materials on p.c. and t.l.c. systems, was carried out by comparison with known R_F literature values (5). Base composition and the fidelity of the 3′–5′-phosphodiester linkages were checked using pancreatic ribonuclease (PR) or snake venom diesterase (SVD) digestions. Yields for the trinucleotides were calculated from spectrophotometric data assuming a 90% hypochromicity factor, all were *ca.* 80% (Table 2).

Experimental

The p.m.r. spectra were recorded on a Varian T60 or Varian HA-100 spectrometer in 10–15% (w/v) DMSO-d_6 – D_2O solutions, and line positions are reported in p.p.m. from the reference (TMS).

Silica gel (Baker Analyzed Reagent) was used for column chromatography; and Analtech prescored silica gel plates were employed for t.l.c. The plates were developed in 5 or 10% methanol in methylene chloride mixtures.

The t.l.c. detection was carried out using a ceric sulfate spray (1 g $H_4Ce(SO_4)_4$ in 10% aqueous sulfuric acid solution) and followed by heating the plates at 300–400 °C. Compounds containing a trityl group develop as yellow spots, while others appear as brown spots.

It was essential that moisture be excluded from all coupling reactions. After evaporation *in vacuo* of the pyridine solution, normal pressure was restored with dry nitrogen and *not* atmospheric air. All such evaporations were carried out in the temperature range 30–40 °C.

Emulsion, frequently obtained during methylene chloride extractions of aqueous pyridine solutions, was broken by the addition of a few milliliters of saturated sodium chloride solution.

*5′-O-Methoxytrityl-2′-O-tetrahydropyranyluridine (**1**)*

The lower R_F diastereoisomer of 2′-*O*-tetrahydropyranyluridine (**4**) (11) (1.6 g; m.p. 185–187°) was dissolved in anhydrous pyridine (8 ml) and methylene chloride (40 ml). *p*-Anisylchlorodiphenylmethane (1.65 g, 1.1 equiv) was added portionwise to the solution and the reaction mixture was sealed and left at room temperature overnight in the dark. The t.l.c. indicated the disappearance of starting material (R_F 0.1 → 0.6–0.9 in 5% CH_3OH–CH_2Cl_2). After quenching with ethanol (20 ml), the mixture was added to ice-water (100 ml) and extracted with methylene chloride (3 × 50 ml). The combined organic extracts were washed with distilled water (3 × 50 ml) and evaporated *in vacuo* to an oil, the last traces of pyridine being removed by co-distillation with toluene (2 × 25 ml). Column chromatography on silica gel was applied. Elution with 1% CH_3OH–CH_2Cl_2 gave the desired 5′-*O*-monotrityl material as an off-white solid foam (2.52 g, 86%) which was sufficiently pure for further conversions. The p.m.r. spectrum showed signals (δ TMS) at 7.85 (1H doublet, $J \sim 8$ Hz; 6-proton of uracil); 7.5 (14H multiplet; trityl aromatic protons); 6.10 (1H doublet; 1′-anomeric proton); 5.45 (1H doublet; $J \sim 8$ Hz; 5-proton of uracil); 4.95 (1H singlet; Thp acetal proton); 4.41 and 4.15 (3H multiplets, sugar protons); 3.85 (3H singlet; MeO of *p*-methoxytrityl); 1.65 (6H broad multiplet; *C*-methylenes of Thp).

Method A

*5′-O-p-Methoxytrityl-2′-O-tetrahydropyranyluridine-3′-β,β,β-trichloroethylphosphate (**19**)*

The bis-cyclohexylamine salt (720 mg, 2 equiv) of mono-β,β,β-trichloroethylphosphate (12) was dissolved in anhydrous pyridine (50 ml) (warming was necessary) and converted to the corresponding pyridinium salt by repetitive evaporation *in vacuo* and solution in pyridine (4 × 40 ml).

Triisopropylbenzenesulfonyl chloride (1 g, 4 equiv) was added to the pyridinium salt in pyridine (40 ml) whereupon a yellow coloration developed. Thirty minutes later, 5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranyluridine (**1**) (500 mg, 1 equiv; R_F 0.6 in 5% CH_3OH–CH_2Cl_2) was added as a pyridine solution (5 ml). The reaction mixture was sealed under nitrogen and left at room temperature for 1–2 days in the dark. The t.l.c. indicated the phosphate coupling was complete (R_F 0.6 → 0.1 in 5% CH_3OH–CH_2Cl_2). Ice (5 g) was added and the quenched reaction left for 30 min, poured into ice-water (100 ml) and then extracted with methylene chloride (4 × 50 ml). The combined organic extracts were washed with distilled water (4 × 50 ml). Methylene chloride was removed by evaporation *in vacuo* and replaced by anhydrous pyridine (50 ml). This pyridine solution containing the pyridinium salt **19** of desired nucleotide derivative was used immediately to form blocked dinucleoside phosphate derivatives.

*5′-O-p-Methoxytrityl-2′-O-tetrahydropyranyluridylyl-(3′-β,β,β-trichloroethyl-5′)N⁴-benzoyl-2′-O-tetrahydropyranylcytidine (**9**)*

Triisopropylbenzenesulfonyl chloride (TPS) (500 mg, 2 equiv) was added to the pyridine solution of blocked uridylate derivative **19** prepared in the previous experiment and the activation was allowed to proceed for 30 min at room temperature in the dark. The high R_F diastereoisomer of N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**5**) (1) (720 mg, 2 equiv; m.p. 162–164°; R_F 0.61 in 10% in CH_3OH–CH_2Cl_2) dissolved in anhydrous pyridine (10 ml) was added and the reaction mixture was left at room temperature for 1–2 days in the dark. After 1 day, a further portion of TPS (100 mg) was added to ensure complete reaction by the second day as indicated by t.l.c. (R_F 0.1 → 0.55 in 5% CH_3OH–CH_2Cl_2). Ice (5 g) was added and after 30 min the aqueous pyridine solution was poured into ice-water (50 ml) and extracted by methylene chloride (4 × 50 ml). The combined organic extracts were washed with water (4 × 50 ml) and evaporated *in vacuo* to an oily residue, the last traces of pyridine being removed by co-distillation with toluene (2 × 25 ml). The residue was dissolved in methylene chloride (50 ml) whereupon some triisopropylbenzenesulfonic acid separated and was removed. Column chromatography on silica gel was applied to the filtrate. Elution with 1.5% CH_3OH–CH_2Cl_2 gave a trace of 5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranyluridine (**1**) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the excess N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**5**) (306 mg). The t.l.c. indicated that the expected order of elution should have been **1**, **19**, and **5**. Elution with 2% CH_3OH–CH_2Cl_2 gave the blocked dinucleotide (UpC) (640 mg, 63%) as a pale yellow solid foam.

*5′-O-p-Methoxytrityl-2′-O-tetrahydropyranyluridylyl-(3′-β,β,β-trichloroethyl-5′)N⁴-benzoyl-2′-O-tetrahydropyranylcytidine-3′-β,β,β-trichloroethyl-phosphate (**20**)*

The bis-cyclohexylamine salt (180 mg, 2 equiv) (12) of β,β,β-trichloroethylphosphate was converted to its corresponding pyridinium salt as described previously. Triisopropylbenzenesulfonyl chloride (250 mg, 4 equiv) was added to the pyridinium salt in anhydrous pyridine (5 ml). After 30 min, blocked UpC **9** (250 mg, 1 equiv) dissolved in pyridine (5 ml) was added to the yellow solution which was sealed under nitrogen and allowed to stand at room temperature for 1–2 days in the dark. The t.l.c. indicated almost complete reaction (R_F 0.55 → 0.1 in 5% CH_3OH–CH_2Cl_2). Ice (2 g) was added, followed 30 min later by a similar methylene chloride extraction process as used for **19**. Blocked UpCp **20** was obtained as its pyridinium salt in pyridine and was used immediately in the next step.

*5′-O-p-Methoxytrityl-2′-O-tetrahydropyranyluridylyl-(3′-β,β,β-trichloroethyl-5′)N⁴-benzoyl-2′-O-tetrahydropyranylcytidylyl(3′-β,β,β-trichloroethyl-5′)N⁶-benzoyl-2′-O-tetrahydropyranyladenosine (**14**)*

Triisopropylbenzenesulfonyl chloride (TPS) (125 mg, 2 equiv) was added to the pyridine solution of blocked UpCp **20** pyridinium salt (described above). After 30 min, N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**6**) (1) (190 mg, 2 equiv; R_F: 0.30 in 5% CH_3OH–CH_2Cl_2) was added and the reaction mixture sealed under nitrogen and allowed to stand at room temperature for 1–2 days in the dark. A further portion of TPS (50 mg) was added after 1 day to ensure complete coupling by the second day, as indicated by t.l.c. in 5% CH_3OH–CH_2Cl_2 (R_F 0.1 → 0.50). A similar work-up to that used for **9** was employed and column chromatography on silica gel utilized for purification. Elution with 2% CH_3OH—CH_2Cl_2 (500 ml) gave some unreacted blocked UpC **9** (40 mg). Elution with 2.5% CH_3OH–CH_2Cl_2 (500 ml) gave excess blocked nucleoside **6** (80 mg). Elution with 3% CH_3OH–CH_2Cl_2 (750 ml) gave the blocked UpCpA **14** (195 mg, 61%) as a pale yellow solid foam. Again the column elution differed from that indicated by t.l.c. (**9**, **14**, and **6**).

Method B

*N⁴-Benzoyl-5′-O-p-methoxytrityl-2′-O-tetrahydropyranylcytidine-3′-β,β,β-trichloroethylphosphate (**21**)*

The bis-cyclohexylamine salt (0.608 g, 13.6 mmol; 2 equivs) of mono-β,β,β-trichloroethylphosphate was converted into its pyridinium salt as described previously. Triisopropylbenzenesulfonyl chloride (TPS) (0.840 g, 27.2 mmol; 4 equiv) was then added to the pyridinium salt. After 1 h, a pyridine solution of N^4-benzoyl-5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranylcytidine (**2**) (1) (0.480 g, 6.8 mmol; 1 equiv; R_F: 0.63 in 5% CH_3OH–CH_2Cl_2) was added to the yellow solution and the reaction mixture sealed under nitrogen and set aside at room temperature in the dark. After 1–2 days t.l.c. indicated complete conversion into a product of R_F: 0.0–0.18 in 5% CH_3OH–CH_2Cl_2. Ice (5 g) was then added followed 30 min later by a similar methylene chloride extraction as described for **9**. Blocked Cp **21** was obtained as its pyridinium salt in pyridine and was used immediately to form blocked dinucleotide phosphate derivatives.

*N⁴-Benzoyl-5′-O-p-methoxytrityl-2′-O-tetrahydropyranylcytidylyl(3′-β,β,β-trichloroethyl-5′)N⁶-benzoyl-2′-O-tetrahydropyranyladenosine (**11**)*

Triisopropylbenzenesulfonyl chloride (TPS) (0.230 g, 7.5 mmol; 1.1 equiv) was added to the blocked cytidylate derivative **21** and the activation allowed to proceed for 30 min at room temperature in the dark. The low R_F diastereoisomer of N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**6**) (1) (0.620 g, 13.6 mmol; 2 equivs; R_F: 0.19 in 5% CH_3OH–CH_2Cl_2) was then added, and the reaction mixture set aside at room temperature in the dark for 1–3 days. On the second day a further portion of TPS (0.115 g, 0.55 equiv) was added to speed coupling. The t.l.c. indicated *ca.* 90% conversion into a product of R_F: 0.49 in 5% CH_3OH–CH_2Cl_2. Ice (5 g) was then added to the mixture, and stirring continued for further 30 min. The reaction mixture was then poured into ice-water (60 ml) and repeatedly extracted with methylene chloride (5 × 30 ml). The combined organic extracts were washed with water (5 × 30 ml) and evaporated *in vacuo* to give an oily residue. The last traces of pyridine were removed by co-distillation with toluene (2 × 25 ml). Methylene chloride (30 ml) was then added to the residue, and the precipitated triisopropylbenzenesulfonic acid was filtered off. The filtrate was purified by chromatography on silica gel (40 g) in methylene chloride. Elution with 2.0% methanol – methylene chloride mixture (600 ml) yielded a *ca.* 1:1 mixture of **6** and **11** (0.813 g, R_F: 0.31 and 0.22 in 5% CH_3OH–CH_2Cl_2). Continued elution with 2.5% methanol – methylene chloride mixture (600 ml) gave an enriched sample **11** (0.436 g, R_F: 0.23 in 5% CH_3OH–CH_2Cl_2), which was purified further by chromatography on silica gel (40 g) as before. Pure CpA **11** was isolated (0.300 g, R_F: 0.22 in 5% CH_3OH–CH_2Cl_2) on elution with 2.5% methanol – methylene chloride mixture (400 ml). The mixture of **6** and **11** (obtained above) (0.813 g, R_F: 0.31 and 0.22 in 5% CH_3OH–CH_2Cl_2) was treated with an excess of *p*-anisylchlorodiphenylmethane (0.43 g, 1.4 mmol; *ca.* 1.5 equiv, based on a 1:1 mixture of **6** and **11**) in anhydrous pyridine (10 ml). The reaction mixture was set aside at room temperature in the dark. After 2 days t.l.c. indicated *complete* conversion of **6** into N^6-benzoyl-5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranyladenosine (**3**) (1) (R_F: 0.78 in 5% CH_3OH–CH_2Cl_2). Ice (5 g) was then added, and stirring continued for further 30 min. The reaction mixture was then poured into ice-water (100 ml), and repeatedly extracted (5 × 30 ml) with methylene chloride. The combined organic extracts were washed with water (5 × 30 ml), and evaporated *in vacuo* to give a pale yellow glass. This material was purified by chromatography on silica gel (20 g) in methylene chloride. Elution with 1–2% methanol – methylene chloride mixtures (400 ml and 400 ml) yielded pure **3** (0.687 g, R_F: 0.80 in 5% CH_3OH–CH_2Cl_2). Continued elution with 2.5% methanol – methylene chloride mixtures yielded pure **11** (0.277 g; R_F: 0.33 in 5% CH_3OH–CH_2Cl_2) (total yield of **11** 0.577 g, 62%).

N^4-Benzoyl-5′-O-p-methoxytrityl-2′-O-tetrahydropyranylcytidylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-O-tetrahydropyranyladenosine-3′-β,β,β-trichloroethylphosphate (22)

The bis-cyclohexylamine salt (0.270 g, 6.0 mmol; 2 equivs) of mono-β,β,β-trichloroethylphosphate was converted into its pyridinium salt as described previously. Triisopropylbenzenesulfonyl chloride (TPS) (0.365 g, 12 mmol; 4 equivs) was then added to the pyridinium salt. After 1 h, a pyridine solution (5 ml) of blocked CpA **11** (0.399 g, 3 mmol; 1 equiv; R_F: 0.33 in 5% CH_3OH–CH_2Cl_2) was added to the yellow solution, and the reaction mixture sealed under nitrogen and set aside at room temperature in the dark. After 1–2 days t.l.c. indicated complete conversion into a product of R_F: 0.0–0.14 in 5% CH_3OH–CH_2Cl_2. Ice (5 g) was then added followed 30 min later by a similar methylene chloride extraction as described for **11**. Blocked CpAp **22** was obtained as its pyridinium salt in pyridine and was used immediately in the next step.

N^4-Benzoyl-5′-O-p-methoxytrityl-2′-O-tetrahydropyranylcytidylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-O-tetrahydropyranyladenylyl(3′-β,β,β-trichloroethyl-5′)2′-O-tetrahydropyranyluridine (16)

Triisopropylbenzenesulfonyl chloride (TPS) (0.97 mg, 3.3 mmol; 1.1 equiv) was added to the pyridine solution of blocked CpAp **22** pyridinium salt (described above). After 30 min the low R_F diastereoisomer of 2′-O-tetrahydropyranyluridine (**4**) (11) (0.147 g, 4.5 mmol; 1.5 equiv; R_F: 0.14 in 5% CH_3OH–CH_2Cl_2) was added, and the reaction mixture sealed under nitrogen, and set aside at room temperature for 1–3 days in the dark. A further portion of TPS (0.97 mg, 1.1 equiv) was added after 2 days to speed coupling. The t.l.c. indicated *ca.* 90% conversion into a product of R_F: 0.30 in 5% CH_3OH–CH_2Cl_2. After a similar work-up described for **9**, the product was purified by chromatography on silica gel (15 g) in methylene chloride. Elution with 2% methanol – methylene chloride mixture (400 ml) yielded an impure sample of **16** (0.205 g, R_F: 0.30 and 0.46 and 0.58 in 5% CH_3OH–CH_2Cl_2). Continued elution with 2.5–3.0% methanol – methylene chloride mixtures (600 ml + 600 ml) yielded a pure sample of CpApU **16**, (0.278 g, 48%; R_F: 0.30 in 5% CH_3OH–CH_2Cl_2) as a pale yellow solid foam.

Uridylyl(3′–5′)cytidylyl(3′–5′)adenosine (UpCpA)

5′-O-p-Methoxytrityl-2′-O-tetrahydropyranyluridylyl-(3′-β,β,β-trichloroethyl-5′)N^4-benzoyl-2′-O-tetrahydropyranylcytidylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-O-tetrahydropyranyladenosine (**14**) (10 mg) was dissolved in *N*,*N*-dimethylformamide (0.5 ml) and magnetically stirred with Cu–Zn couple (*ca.* 10 mg) for 1 day at 50 °C. The deblocking was followed by t.l.c. in 10% CH_3OH–CH_2Cl_2 (R_F: 0.8 → 0.0). An intermediate (R_F: 0.5) resulting from removal of only one of the β,β,β-trichloroethyl groups could be observed. Incomplete reaction could be corrected by an additional amount of Cu–Zn couple.

Half-saturated (at 0°) methanolic ammonia (1 ml) was added and the ammonolysis stirred for 2 days at room temperature. *N*-Ammonia solution (1 ml) was added and the Cu–Zn couple filtered off and washed with further dilute ammonia. Careful evaporation of the filtrate and washings *in vacuo* removed ammonia and methanol and brought the solution p*H* to 8–10. Dowex 50W (NH_4^+ form) (*ca.* 200 mg) was added and the mixture magnetically stirred for 15 min. The resin was filtered off and washed thoroughly in form of a short column with water. The filtrate and washings were pooled and the solution volume adjusted to *ca.* 10 ml by evaporation *in vacuo*. The o.d. loss for this treatment was 5%.

Hydrochloric acid solution (0.1 *N*) was added until solution p*H* was 2. Hydrolysis proceeded at room temperature for 1–2 days and was monitored by t.l.c.[5] on cellulose plates (R_F: 0.9 → 0.2). UpCpA (110 $O.D._{260}$, 90%) was isolated and purified using preparative paper chromatography.[5] Enzymic analysis using pancreatic ribonuclease (PR) showed complete digestion into equal amounts of Up,Cp, and A.

Cytidylyl(3′–5′)adenylyl(3′–5′)uridine (CpApU)

N^4-Benzoyl-5′-O-p-methoxytrityl-2′-O-tetrahydropyranyl cytidylyl(3′-β,β,β-trichloroethyl-5′)N^6-benzoyl-2′-O-tetrahydropyranyl adenylyl(3′-β,β,β-trichloroethyl-5′)-2′-O-tetrahydropyranyl uridine (**16**) (10 mg) was deblocked using the same procedure as for protected UpCpA **14**. CpApU (116 $O.D._{260}$, 87%) was isolated and purified using preparative paper chromatography.[5] Enzymic analysis using snake venom diesterase (SVD) showed complete digestion into equal amounts of C, pA, and pU.

Alkylations of the Side-chain Nucleophiles of Cysteine, Methionine, Histidine, and Lysine Derivatives with Allyl Bromide, 1-Bromo-2-butyne, and 2-Bromoacetophenone

J. Bryan Jones and David W. Hysert

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received April 26, 1971

Comparative studies on the reactions of cysteine, methionine, histidine, and lysine derivatives with allyl bromide, 1-bromo-2-butyne, and 2-bromoacetophenone have been carried out in connection with an evaluation of the potential of reagents incorporating ethylenic and acetylenic functions for protein modification.

Des études comparatives sur les réactions de dérivés de la cystéine, histidine, et lysine avec le bromure d'allyle, le bromo-1 butyne-2 et la bromo-2 acétophénone, ont été menées à bien. Ces études sont reliées à une évaluation du potentiel des réactifs à l'incorporation de fonctions éthyléniques et acétyléniques pour une modification de protéines.

Canadian Journal of Chemistry, **49**, 3012 (1971)

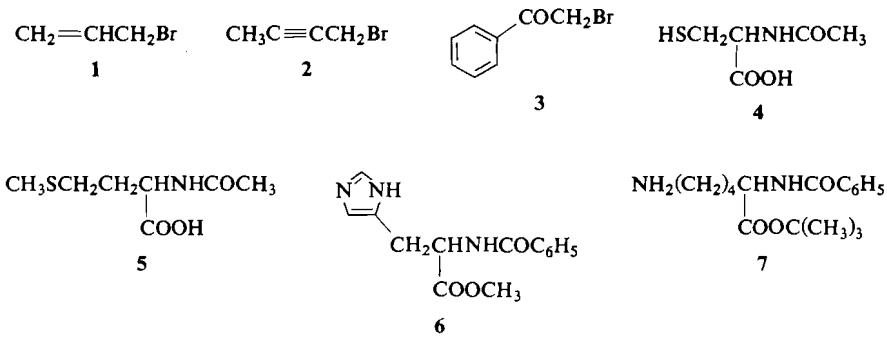
Introduction

Our studies on alkylating agents containing ethylenic and/or acetylenic bonds were prompted by our interest in the design of bifunctional reagents of rigorously defined stereochemistry as structural probes (1) for proteins and nucleic acids and of *endo* or *exo* active site directed irreversible inhibitors (2) for which precise orientation of the alkylating function towards the selected target nucleophile could be achieved. Appropriate combinations of ethylenic and acetylenic bonds, with their unique *cis*/*trans* and linear geometries, appeared to provide an attractive possibility for achieving the degree of stereochemical control desired. However, in view of the potential instability of molecules containing poly-en/yne chains it was decided to carry out the exploratory surveys on relatively simple olefinic and acetylenic derivatives in order to determine the practicability of the concept. Since synthetic difficulties were anticipated with respect to the incorporation of many of the protein and nucleic acid alkylating functions of proven value (2–8) into polyunsaturated carrier molecules the more easily introducible allylic and propargylic halide functions were selected for the initial evaluations.[1]

Preliminary studies (16) had indicated allylic and propargylic bromides to be of potential value for modifying nucleophiles representative of those present in cysteine, methionine, histidine, and lysine residues and side-chain alkylations of selected derivatives of the latter amino acids themselves with allyl bromide (**1**) and 1-bromo-2-butyne (**2**) have now been carried out. For comparative purposes, all of the amino-acid derivatives studied were again reacted with 2-bromoacetophenone (**3**), which was taken as representative of the widely used α-halomethylcarbonyl series of protein alkylating agents (2–8).

The reactions of a spectrum of cysteine, methionine, histidine, and lysine derivatives with the alkylating agents **1**–**3** were surveyed initially and for each amino acid, compounds in which the α-amino groups were protected by acylation were used routinely. In contrast carboxyl groups were converted to appropriate esters only when alkylation of this function was found to constitute a significant competitive reaction. The most satisfactory experimental results were obtained with the derivatives **4**–**7** and the reactions observed for these compounds are summarized in Scheme 1. Each of the latter experiments was carried out in 30–50% aqueous ethanol solutions with the apparent p*H* being maintained within the range encountered *in vivo* either with a p*H*-stat or by the addition of the requisite amount of suitable bases, such as sodium hydroxide, sodium bicarbonate, sodium carbon-

[1]Somewhat surprisingly, in spite of their well documented susceptibility to nucleophilic attack (9) such functions have had very limited applications as biological or amino acid alkylating agents (10–15).



ate, and triethylamine. Although it was found convenient to repeat some reactions in non-aqueous solvents, such as methanol, ether or dimethylacetamide, in order to facilitate isolation and separation of the products, in no case was the product distribution found to be significantly different within the limited range of conditions surveyed.

Alkylation of *N*-acetyl-L-cysteine (**4**), with each of **1–3** in 30% aqueous ethanol at 25° at p*H* 8 proved to be facile and the expected products **8***a–c* were obtained in 85–95% yields. No further reactions to the corresponding sulfonium bromides nor alkylations of the carboxyl group were observed under the mild reaction conditions surveyed.

Reactions of **1–3** with *N*-acetyl-DL-methionine (**5**) in 30% aqueous ethanol at 25° also proceeded smoothly within the p*H* range 3–8 to give the expected sulfonium bromides **9***a–c* in excellent (95–100%) yields. Since **9***a–c* were obtained as non-crystallizable gums, elemental analyses were performed on the reineckate salt derivatives. Again no alkylations of the carboxyl group occurred nor did the often unstable (16, 17) sulfonium salts exhibit any tendencies to undergo decomposition.

Histidine studies were first attempted on the commercially available α-*N*-acetyl derivative **16**. When **16** was treated in refluxing 50% aqueous ethanol with stoichiometric amounts of **1–3**, mixtures were formed which contained carboxyl modified products in addition to the expected imidazole ring alkylation possibilities. Use of a large excess of the alkylating agents in dimethylacetamide as solvent converted compound **16** exclusively into the deliquescent, non-crystalline tris-alkylated salts **17** (Scheme 2). The complications arising from competitive alkylation of the carboxyl group and the product isolation difficulties encountered with α-*N*-acetyl histidine derivatives were finally overcome by using α-*N*-benzoyl-L-histidine methyl ester (**6**) as the substrate. Treatment of **6** either in 50% aqueous ethanol or in methanol at 25° with a moderate excess of allyl bromide (**1**) or 1-bromo-2-butyne (**2**), or with 1 equiv of 2-bromoacetophenone (**3**), afforded mixtures containing up to 90% of alkylated products in which the N-3 mono alkylated and N-1, N-3 bis-alkylated compounds, **10***a–c*, and **12***a–c* respectively, predominated. In addition, lesser (5–10%) amounts of the products of N-1 alkylation, **11***a–c*, were present. When a two-fold excess of 2-bromoacetophenone was used, the N-1, N-3 diphenacyl bromide **12***c* was formed exclusively in 98% yield. In the normal aqueous ethanol reaction solutions, and at elevated temperatures in methanol, hydrolyses of **12***a*, *b* to the corresponding zwitterions **13***a*, *b* proved to be serious competitive processes.

The structural assignments of the mono-alkylated histidine compounds were made on the basis of analyses of the spectral data and from steric considerations. Each of the mono-alkylated isomeric pairs **10** and **11** showed characteristic differences in their p.m.r. spectra. For the allyl and but-2-ynyl products, the positions of the C-4 proton peaks of the compounds assigned the N-3 structures exhibit upfield shifts of ≃0.5 p.p.m. relative to the same hydrogen resonances in the corresponding N-1 isomers. These differences can be accounted for by the anisotropic shielding of the C-4 proton to be expected for compounds such as **10***a*, *b* possessing an unsaturated substituent at N-3.[2] In addition,

[2]For the phenacyl derivatives **10***c* and **11***c*, the corresponding p.m.r. data were equivocal.

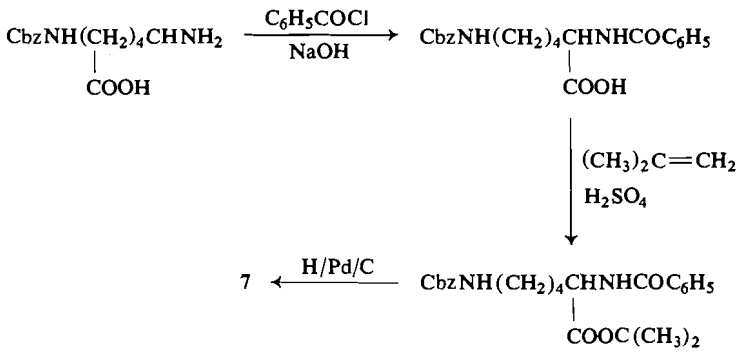

SCHEME 3

the α-amino hydrogen resonances of the N-3 compounds **10** exhibit downfield shifts of ≃0.5 p.p.m. relative to those of the same peaks in compounds **11**. Such chemical shift divergences can be rationalized in terms of intramolecular hydrogen bonding of the α-amino proton with N-1 for structures **10**;[3] the geometries of the isomeric N-1 substituted derivatives **11** do not allow such possibilities.

Examinations of molecular models of **6**, **10**, and **11** and considerations of the steric factors involved (*cf.* ref. 19) indicate that for both the mono- and bis-alkylation processes reactions at the N-3 positions should proceed much more readily than at the more hindered N-1 sites.[4]

In contrast to the amino acid residues discussed above, modifications of lysine ε-amino groups in proteins have been effected largely by reagents other than alkylating agents (5–8). However, a number of examples of their modification by halomethyl carbonyl reagents have been reported (5–8, 21).

Several lysine derivatives were evaluated in the search for a suitably protected compound. α-*N*-Acetyl-L-lysine (22) was rejected since its treatment with **1–3** gave complex mixtures of alkylation products which included significant proportions of carboxyl-modified compounds. Owing to the susceptibility to hydrolysis at p*H* 9 of the lysine methyl esters surveyed, protection of the carboxyl group as the less easily hydrolyzed *t*-butyl ester became necessary and the lysine derivative finally adopted was the α-*N*-benzoylated *t*-butyl ester **7**. This was prepared in 72% overall yield from ε-*N*-carbobenzyloxy-L-lysine as outlined in Scheme 3. Its alkylation by allyl bromide (**1**) and 1-bromo-2-butyne (**2**) proceeded smoothly in 50% aqueous ethanol at 25° within the p*H* range 9–11 to give the corresponding mono- and bis-alkylated derivatives **14***a*, *b* and **15***a*, *b* in solvent and p*H* dependent yields within the range 10 to 40%. In contrast the reaction of **7** with 2-bromoacetophenone (**3**) turned out to be exceedingly complex in both aqueous and non-aqueous solvents under a variety of reaction and work-up conditions. Disappointingly, none of **14***c* or **15***c*, nor any other identifiable products, could be isolated from the multiple component reaction mixture.[5] However, in view of the success already achieved with halomethylcarbonyl modification of other lysine ε-amino groups (5–8, 21) the inconclusive results of this last model reaction cannot be regarded as being representative of the types of reactions to be expected with suitable proteins.

The alkylation patterns observed above (Scheme 1) with allyl bromide (**1**), 1-bromo-2-butyne (**2**), and with the reference halomethylcarbonyl reagent **3**, largely parallel those of biological alkylating agents of proven value (2-8) and the results obtained confirm that the potential of appropriate compounds incorporat-

[3]The i.r. studies (18) have demonstrated the existence of such hydrogen bonding in various histidine derivatives. Although studies in the 900–750 cm^{-1} i.r. region were helpful in a similar structural assignment problem for *N*-carboxymethyl-L-histidines (19) the corresponding portions of the spectra of the isomeric pairs **10** and **11** were not sufficiently distinctive to be of value in this regard.

[4]Consideration of these factors was important with respect to the kinetic studies carried out subsequently (20).

[5]The complexity of the reaction mixture probably reflects the instability of the expected products **14***a* and **15***a*, and of 2-bromoacetophenone itself, to the moderately basic conditions surveyed (16, 23).

ing allylic and propargylic bromide functions for protein modification warrants further consideration. However, before their applicability with respect to the types of selective and/or sequential alkylations outlined in the Introduction can be realistically evaluated, further information on the relative rates and p*H* profiles to be expected for the various alkylation reactions is desirable. Kinetic studies which will provide some of these data are now in progress.

Experimental

All starting materials and products were purified until no impurities could be detected by g.l.c., t.l.c., and spectroscopic analyses. The p.l.c. separations were effected on silica gel G containing G.E. phosphor 118-2-7 using chloroform – methanol – ammonium hydroxide (90:15:1; v/v/v) as the developing solvent and the compounds were visualized with a Blak-Ray u.v. lamp (Ultra-Violet Products Inc.). All other general details of the methods, equipment, etc. used were as described previously (16). Since within each series of amino acid derivatives the alkylation procedures were generally identical, only the allyl bromide conditions have been fully described. The experimental procedures reported are those giving optimum yields of the desired products. Although in some cases this required the reaction to be carried out in non-aqueous solvents in order to facilitate the work-up procedure the analogous reactions in aqueous ethanol within the range of physiological p*H* always gave very similar product distributions.[4]

Materials

Allyl bromide (**1**), 1-bromo-2-butyne (**2**), and 2-bromoacetophenone (**3**) were obtained and purified as before (16). *N*-Acetyl-L-cysteine (**4**) and *N*-acetyl-DL-methionine (B.D.H.), L-histidine (Eastman), α-*N*-acetyl-L-histidine and α-*N*-acetyl-L-lysine (Calbiochem.), and ε-*N*-carbobenzoxy-L-lysine (Mann) were used as purchased. α-*N*-Benzoyl-L-histidine methyl ester (**6**), prisms from water, m.p. 158–159° (lit. (24) m.p. 160°) $[\alpha]_D^{22}$ −26.4° (*c*, 2.3 in CH_3OH) was prepared in 80% yield from L-histidine according to the procedure of Gerngross (24).

α-N-Benzoyl-L-lysine t-Butyl Ester (7)

ε-*N*-Carbobenzoxy-L-lysine was converted in 98% yield into its α-*N*-benzoyl derivative, microcrystals from benzene – petroleum ether b.p. 40–60° (1:1), m.p. 131–133° (lit. (25) m.p. 132–133°) as described by Irving and Gutman (25). The α-*N*-benzoyl-ε-*N*-carbobenzoxy-L-lysine obtained (20.1 g, 52 mmol) was dissolved at 0° in methylene chloride (200 ml) containing concentrated sulfuric acid (1 ml). Liquid isobutylene (35 g, 624 mmol) was then added and the mixture was shaken in a stoppered flask for 2 days. Following rotary evaporation of the reaction mixture, the residual solid was extracted with ether (3 × 150 ml) and the combined ether solution was washed successively with 5% aqueous hydrochloric acid (200 ml), 5% aqueous sodium hydroxide (200 ml), and saturated aqueous sodium chloride (200 ml). Evaporation of the dried ($MgSO_4$) ether solution gave a colorless solid (20.25 g) which after two recrystallizations from isopropyl ether yielded α-*N*-benzoyl-ε-*N*-carbobenzoxy-L-lysine *t*-butyl ester as fine needles (17.3 g), m.p. 86.5–87.5°, $[\alpha]_D^{25}$ −14.5° (*c*, 3.5 in CH_3OH); i.r. ($CHCl_3$) 3425, 3344, 1718, 1712, and 1653 cm^{-1}; p.m.r. ($CDCl_3$) δ 1.1–2.0 (6H, m, $NHCH_2(CH_2)_3$), 1.48 (9H, s, $OC(CH_3)_3$), 3.17 (2H, q, J = 5 Hz, $NHCH_2CH_2$), 4.69 (1H, q, J = 6 Hz, $CH_2CH(NH)CO$), 5.03 (2H, s, $C_6H_5CH_2O$), 5.20 (1H, m, J = 5 Hz, $CONHCH_2$), 6.93 (1H, d, J = 6 Hz, $CHNHCO$), 7.2–7.5 (8H, m, *m*- and *p*-aromatic, C_6H_5CO and $C_6H_5CH_2O$) and 7.7–8.0 p.p.m. (2H, m, *o*-aromatic, C_6H_5CO).

Anal. Calcd. for $C_{25}H_{32}N_2O_5$: C, 68.16; H, 7.32; N, 6.36. Found: C, 68.15; H, 7.52; N, 6.24.

A solution of α-*N*-benzoyl-ε-*N*-carbobenzoxy-L-lysine *t*-butyl ester (17.06 g, 38.7 mmol) in absolute ethanol (350 ml) containing concentrated hydrochloric acid (4 ml) and 10% palladium-on-charcoal (600 mg) was shaken in an atmosphere of hydrogen at 25° for 1 h. The filtered reaction solution was evaporated and the residual solid dissolved in 10% aqueous hydrochloric acid (200 ml). The acid extract was washed with ether (2 × 100 ml) and then brought to p*H* 12 with sodium hydroxide. Extraction of the basified mixture with ether (4 × 100 ml) followed by evaporation of the dried ($MgSO_4$) ether solution yielded an oil (9.95 g). Fractional distillation gave α-*N*-benzoyl-L-lysine *t*-butyl ester (7) b.p. 185–186°/0.1 Torr; $[\alpha]_D^{25}$ −19.3° (*c*, 2.3 in CH_3OH); i.r. ($CHCl_3$) 3448, 1721, and 1661 cm^{-1}; p.m.r. ($CDCl_3$) δ 1.0–2.6 (10H, m, $NH_2(CH_2)_4$), 1.50 (9H, s, $C(CH_3)_3$), 4.51 (1H, q, J = 5 Hz, $CH_2CH(NH)CO$), 7.5–7.6 (4H, m, *m*- and *p*-aromatic and $NHCO$), and 7.7–7.9 p.p.m. (2H, m, *o*-aromatic).

Anal. Calcd. for $C_{17}H_{26}N_2O_3$: C, 66.64; H, 8.55; N, 9.14. Found: C, 66.48; H, 8.73; N, 9.01.

Alkylation of N-Acetyl-L-cysteine (4)

(a) With Allyl Bromide (1)

Allyl bromide (2.42 g, 20 mmol) in methanol (20 ml) (or less conveniently, aqueous ethanol) was added with stirring at 25° to a solution of *N*-acetyl-L-cysteine (1.63 g, 10 mmol) in methanol (20 ml) containing 10 *N* aqueous sodium hydroxide (2.0 ml, 20 mmol). After stirring for a further 15 min, the reaction mixture was poured into water (400 ml) and the resulting solution was washed with ether (4 × 40 ml) and then acidified to p*H* 1 with concentrated hydrochloric acid. Sodium chloride (to saturation) was added and the mixture then extracted with chloroform (6 × 100 ml). Evaporation of the dried ($MgSO_4$) chloroform extracts afforded a solid residue (1.71 g) which was recrystallized from ethyl acetate to give *N*-acetyl-*S*-allyl-L-cysteine (**8***a*) as rhombs, m.p. 123–124° (lit. (14) m.p. 120–122°); $[\alpha]_D^{25}$ −31.0° (*c*, 2.2 in CH_3OH) (lit. (14) $[\alpha]_D^{21}$ −34°); i.r. (KBr) 3378, 1745, and 1727 cm^{-1}; p.m.r. (CF_3COOH) δ 2.28 (3H, s, $NHCOCH_3$), 3.20 (2H, d, J = 6 Hz, SCH_2CH), 3.24 (2H, d, J = 6 Hz, $CH_2{=}CHCH_2S$), 5.05 (1H, q, J = 6 Hz, $CH_2CH(NH)CO$), 5.26 (2H, d, J = 2 Hz, $CH_2{=}CHCH_2$), 5.6–6.0 (1H, m, $CH_2{=}CHCH_2$),[6] and 7.70 p.p.m. (1H, broad d, J = 6 Hz, $CHNHCO$).

(b) With 1-Bromo-2-butyne (2)

Reaction of *N*-acetyl-L-cysteine (1.63 g, 10 mmol) with 1-bromo-2-butyne (2.66 g, 20 mmol) for 25 min under the

[6]The shape of this proton resonance peak is characteristic of the allyl group.

For personal use only.

above conditions yielded *N*-acetyl-*S*-(1-but-2-ynyl)-L-cysteine (**8***b*) as cubes (1.8 g) from 2-propanol-petroleum ether b.p. 40–60°, m.p. 101.5–102.5°; $[\alpha]_D^{25}$ −73.1° (*c*, 2.3 in CH_3OH); i.r (KBr) 3344, 1718, 1600, and 1548 cm^{-1}; p.m.r. (CF_3COOH) δ 1.77 (3H, t, J = 2 Hz, $CH_3C{\equiv}$), 2.28 (3H, s, $COCH_3$), 3.2–3.4 (4H, m, $\equiv CCH_2S$ and SCH_2CH), 5.05 (1H, q, J = 6 Hz, $SCH_2CH(NH)CO$), and 7.74 p.p.m. (1H, broad d, J = 6 Hz, $CHNHCO$).

Anal. Calcd. for $C_9H_{13}NO_3S$: C, 50.21; H, 6.09; N, 6.51; S, 14.89. Found: C, 50.24; H, 6.22; N, 6.39; S, 14.88.

(c) With 2-Bromoacetophenone (3)

Treatment of *N*-acetyl-L-cysteine (1.63 g, 10 mmol) with 2-bromoacetophenone (3.98 g, 20 mmol) and triethylamine (2.02 g, 20 mmol) under the conditions described for the allyl bromide reaction gave *N*-acetyl-*S*-phenacyl-L-cysteine (**8***c*), needles (2.4 g) from acetonitrile, m.p. 148–149°; $[\alpha]_D^{25}$ −43.0° (*c*, 1.1 in CH_3OH); i.r. (KBr) 3279, 1698, 1681, 1595, and 1550 cm^{-1}; p.m.r. (CF_3COOH) δ 2.32 (3H, s, $COCH_3$), 3.25 (2H, d, J = 5 Hz, SCH_2CH), 4.14 (2H, s, $COCH_2S$), 5.05 (1H, q, J = 5 Hz, $CH_2CH(NH)CO$), 7.46–7.90 (3H, m, *m*- and *p*-aromatic), 8.08 (2H, d of d, J = 1.6 Hz, *o*-aromatic), and 8.25 p.p.m. (1H, broad d, J = 7 Hz, $CHNHCO$).

Anal. Calcd. for $C_{13}H_{15}NO_4S$: C, 55.50; H, 5.38, N, 4.98; S, 11.40. Found: C, 55.41; H, 5.49; N, 5.16; S, 11.25.

Alkylation of N-Acetyl-DL-methionine (5)

(a) With Allyl Bromide (1)

Allyl bromide (1.21 g, 10 mmol) and *N*-acetyl-DL-methionine (0.96 g, 5 mmol) in 50% aqueous ethanol (50 ml) was stirred at 25° for 24 h. Water (40 ml) was added and the aqueous mixture was washed with chloroform (4 × 50 ml). The aqueous solution was then evaporated at 40°. The residual gum was dried *in vacuo* over P_2O_5 to give *N*-acetyl-*S*-allyl-DL-methionine sulfonium bromide (**9***a*) as a non-crystallizable, deliquescent glass (1.62 g), i.r. (KBr) 3226, 1730, 1661, and 1541 cm^{-1}; p.m.r, (CF_3COOH) δ 2.44 (3H, s, $COCH_3$), 2.69 (2H, broad m, CH_2CH_2CH), 2.98 (3H, s, $CH_3\overset{+}{S}$), 3.67 (2H, broad t, J = 7 Hz, $CH_2CH_2\overset{+}{S}$), 4.18 (2H, m, $CH_2{=}CHCH_2\overset{+}{S}$), 5.05 (1H, broad q, J = 7 Hz, $CH_2CH(NH)CO$), 5.63–6.16 (3H, m, $CH_2{=}CHCH_2$),[6] and 8.66 p.p.m. (1H, broad d, J = 7 Hz, $CHNHCO$). Elemental analysis was carried out on the reineckate (26) salt, m.p. 120°.

Anal. Calcd. for $C_{14}H_{24}N_7O_3S_5Cr$: C, 30.53; H, 4.39; N, 17.81; S, 29.11. Found: C, 30.34; H, 4.79; N, 17.99; S, 30.30.

(b) With 1-Bromo-2-butyne (2)

From *N*-acetyl-DL-methionine (0.96 g, 5 mmol) and 1-bromo-2-butyne (1.33 g, 10 mmol) under the above conditions was obtained *N*-acetyl-*S*-(1-but-2-ynyl)-DL-methionine sulfonium bromide (**9***b*) as a deliquescent, non-crystallizable glass (1.64 g), i.r. (KBr) 3257, 2247, 1730, 1661, and 1538 cm^{-1}; p.m.r. (CF_3COOH) δ 1.95 (3H, t, J = 2.5 Hz, $CH_3C{\equiv}$), 2.37 (3H, s, $COCH_3$), 2.60 (2H, broad m, CH_2CH_2CH), 3.0 (3H, s, $CH_3\overset{+}{S}$), 3.66 (2H broad t, J = 7 Hz, $\overset{+}{S}CH_2CH_2$), 4.32 (2H, broad m, $\equiv CCH_2\overset{+}{S}$), 5.0 (1H, broad q, J = 7 Hz, $CH_2CH(NH)CO$), and 8.40 p.p.m. (1H, broad d, J = 7 Hz, $CHNHCO$). Elemental analysis was performed on the reineckate (26) salt, m.p. 107–110° (dec.).

Anal. Calcd. for $C_{15}H_{24}N_7O_3S_5Cr$: C, 32.01; H, 4.30; N, 17.44; S, 28.50. Found: C, 31.70; H, 4.19; N, 16.69; S, 27.90.

(c) With 2-Bromoacetophenone (3)

Application of the above allyl bromide conditions to *N*-acetyl-DL-methionine (0.96 g, 5 mmol) and 2-bromoacetophenone (1.99 g, 10 mmol) afforded *N*-acetyl-*S*-phenacyl-DL-methionine sulfonium bromide (**9***c*) again as a deliquescent glass (1.86 g), i.r. (KBr) 3236, 1727, 1672, and 1538 cm^{-1}; p.m.r. (CF_3COOH) δ 2.38 (3H, s, $COCH_3$), 2.74 (2H, broad m, CH_2CH_2CH), 3.20 (3H, s, $CH_3\overset{+}{S}$), 3.88 (2H, broad m, $\overset{+}{S}CH_2CH_2$), 5.06 (1H, broad q, J = 7 Hz, $CH_2CH(NH)CO$), 5.45 and 5.59 (2H, ABq, J = 17 Hz, $COCH_2\overset{+}{S}$), 7.50–8.06 (5H, m, aromatic), and 8.40 p.p.m. (1H, broad d, J = 7 Hz, $CHNHCO$). The reineckate (26) salt derivative m.p. 116–117° (dec.) was used for elemental analytical characterization.

Anal. Calcd. for $C_{19}H_{26}N_7O_4S_5Cr$: C, 36.29; H, 4.17; N, 15.62; S, 25.50. Found: C, 36.34; H, 3.99; N, 14.96; S, 24.58.

Alkylation of α-N-Benzoyl-L-histidine Methyl Ester (6)

(a) With Allyl Bromide (1)

Allyl bromide (605 mg, 5 mmol), α-*N*-benzoyl-L-histidine methyl ester (273 mg, 1 mmol) and sodium bicarbonate (84 mg, 1 mmol) in methanol (10 ml) (or less conveniently, 50% aqueous ethanol) was stirred at 25° for 18 days. The reaction mixture was then evaporated and the residue extracted with boiling chloroform (or acetonitrile). Evaporation of the chloroform solution yielded a mixture from which the following compounds were isolated by p.l.c.

(i) α-*N*-Benzoyl-*N*-3-allyl-L-histidine methyl ester (**10***a*, R_f 0.92), as a glass (66 mg), i.r. ($CHCl_3$) 3425, 3322, 1739, and 1650 cm^{-1}; p.m.r. ($CDCl_3$) δ 3.16 (2H, d, J = 4 Hz, $=CCH_2CH$), 3.66 (3H, s, OCH_3), 4.46 (2H, d of t, J = 0.5 and 5Hz, $NCH_2CH{=}CH_2$), 4.9–5.4 (3H, m, CH_2-$CH{=}CH_2$ and $CH_2CH(NH)CO$), 5.7–6.2 (1H, m, $CH_2CH{=}CH_2$),[6] 6.76 (1H, broad s, $NCH{=}C$), 7.3–7.6 (4H, m, *m*- and *p*-aromatic and $NCHN$), 7.9–8.1 (2H, m, *o*-aromatic), and 8.50 p.p.m. (1H, broad d, J = 8 Hz, $CHNHCO$).

Mol. Wt. Calcd. for $C_{17}H_{19}N_3O_3$: 313.1426. Found (mass spectrum): 313.1425.

(ii) α-*N*-Benzoyl-*N*-1-allyl-L-histidine methyl ester (**11***a*, R_f 0.84), also as a glass (11 mg), i.r. ($CHCl_3$) 3448, 1742, and 1661 cm^{-1}; p.m.r. ($CDCl_3$) δ 3.28 (2H, broad d, J = 4 Hz, $=CCH_2CH$), 3.84 (3H, s, OCH_3), 4.4-4.7 (2H, m, $NCH_2CH{=}CH_2$), 4.8–5.4 (3H, m, $CH_2CH{=}CH_2$ and CH_2CHCO), 5.5–6.2 (1H, m, $CH_2CH{=}CH_2$),[6] and 7.2–8.0 p.p.m. (8H, m, aromatic, $NCH{=}C$, $NCHN$ and $CHNHCO$).

Mol. Wt. Calcd. for $C_{17}H_{19}N_3O_3$: 313.1426. Found (mass spectrum): 313.1428.

(iii) α-*N*-Benzoyl-*N*-1,*N*-3-diallyl-L-histidine methyl ester imidazolium bromide (**12***a*, R_f 0.37), a hygroscopic glass (88 mg) with i.r. ($CHCl_3$) 1742 and 1650 cm^{-1}; p.m.r. (CD_3CN) δ 3.42 (2H, m, $=CCH_2CH$), 3.74 (3H, s, OCH_3), 4.4–6.3 (11H, m, $\overset{+}{N}CH_2CH{=}CH_2$ and $CH(NH)CO$), 7.4–7.6 (4H, m, *m*- and *p*-aromatic and $\overset{+}{N}CH{=}C$), 7.9–8.1 (2H, m, *o*-aromatic), 8.68 (1H, d, J = 8 Hz, $CHNHCO$), and 8.85 p.p.m. (1H, s, $\overset{+}{N}CH\overset{+}{N}$).

Approximately 25% of the starting material **6**, R_f 0.65, was recovered from every reaction and in the aqueous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

solvent reactions partial hydrolysis of **12***a* always occurred to give α-*N*-benzoyl-*N*-1,*N*-3-diallyl-L-histidine imidazolium carboxylate zwitterion (**13***a*, R_f 0.11) as a solid, m.p. 218–219.5°; i.r. (KBr) 1653, 1631, and 1418 cm^{-1}; p.m.r. (DMSO-d_6) δ 3.0–3.4 (2H, broad d, J = 6 Hz, $=CCH_2$-CH), 4.4–6.4 (11H, m, $\overset{+}{N}CH_2CH{=}CH_2$ and CH_2CH-(NH)CO), 7.3–8.0 (6H, m, aromatic and $\overset{+}{N}CH{=}$), 8.1–8.4 (1H, broad d, J = 7 Hz, CHN*H*CO), and 9.17 p.p.m. (1H, s, $\overset{+}{N}CH\overset{+}{N}$).

(b) With 1-Bromo-2-butyne (2)

From 1-bromo-2-butyne (665 mg, 5 mmol) and α-*N*-benzoyl-L-histidine methyl ester (273 mg, 1 mmol) under the above conditions were obtained:

(*i*) α-*N*-Benzoyl-*N*-3-(1-but-2-ynyl)-L-histidine methyl ester (**10***b*, R_f 0.90), as a gum (79 mg); i.r. ($CHCl_3$) 3436, 3333, 2247, 1736, 1653, and 1484 cm^{-1}; p.m.r. ($CDCl_3$) δ 1.81 (3H, t, J = 2 Hz, $CH_3C{\equiv}CCH_2$), 3.17 (2H, d, J = 5 Hz, $=CCH_2CH$), 3.69 (3H, s, OCH_3), 4.62 (2H, q, J = 2 Hz, $CH_3C{\equiv}CCH_2N$), 4.98 (1H, d of t, J = 5 and 7 Hz, CH_2CH(NH)CO), 6.88 (1H, s, $NCH{=}C$), 7.3-7.6 (3H, m, *m*- and *p*-aromatic), 7.62 (1H, s, NC*H*N), 7.85–8.05 (2H, m, *o*-aromatic), and 8.35 p.p.m. (1H, d, J = 7 Hz, CHN*H*CO).

Mol. Wt. Calcd. for $C_{18}H_{19}N_3O_3$: 325.1426. Found (mass spectrum): 325.1426.

(*ii*) α-*N*-Benzoyl-*N*-1-(1-but-2-ynyl)-L-histidine methyl ester (**11***b*, R_f 0.80) as a gum (65 mg); i.r. ($CHCl_3$) 3448, 3279, 2242, 1739, 1661, and 1481 cm^{-1}; p.m.r. ($CDCl_3$) δ 1.77 (3H, t, J = 1 Hz, $CH_3C{\equiv}CCH_2$), 3.33 (2H, d, J = 6 Hz, $=CCH_2CH$), 3.77 (3H, s, OCH_3), 4.62 (2H, q, J = 1 Hz, $CH_3C{\equiv}CCH_2N$), 5.03 (1H, q, J = 6 Hz, CH_2CH(NH)CO), 7.24 (1H, broad s, $NCH{=}C$), 7.3–7.6 (4H, m, *m*- and *p*-aromatic and NC*H*N) and 7.7–7.9 p.p.m. (3H, m, *o*-aromatic and CHN*H*CO).

Mol. Wt. Calcd. for $C_{18}H_{19}N_3O_3$: 325.1426. Found (mass spectrum): 325.1425.

(*iii*) α-*N*-Benzoyl-*N*-1,*N*-3-di(1-but-2-ynyl)-L-histidine methyl ester imidazolium bromide (**12***b*, R_f 0.53) as a hygroscopic glass (125 mg); i.r. ($CHCl_3$) 3268, 2252, 1736, 1650, and 1522 cm^{-1}; p.m.r. ($CDCl_3$) δ 1.73 and 1.83 (6H, two t, J = 1 Hz, $CH_3C{\equiv}CCH_2\overset{+}{N}$), 3.5–3.8 (2H, broad m, $=CCH_2CH$), 3.71 (3H, s, OCH_3), 5.02 and 5.21 (5H, two broad q and m, J = 1 Hz, $CH_3C{\equiv}CCH_2\overset{+}{N}$ and CH_2CH(NH)CO), 7.2–7.5 (3H, m, *m*- and *p*-aromatic), 7.74 (1H, s, $\overset{+}{N}CH{=}C$), 8.0–8.2 (2H, m, *o*-aromatic), 9.02 (1H, d, J = 8 Hz, CHN*H*CO), and 9.91 p.p.m. (1H, s, $\overset{+}{N}CH\overset{+}{N}$).

Anal. Calcd. for $C_{22}H_{24}BrN_3O_3$: C, 57.65; H, 5.28; N, 9.17; Br, 17.44. Found: C, 57.17; H, 5.24; N, 9.27; Br, 17.71.

Unchanged starting material **6**, R_f 0.61 (≃20%) was always recovered together with varying amounts of the product of hydrolysis of **12***b*, α-*N*-benzoyl-*N*-1,*N*-3-di(1-but-2-ynyl)-L-histidine imidazolium carboxylate zwitterion (**13***b*, R_f 0.18) which was isolated as a glassy solid i.r. (KBr) 2252, 1639, 1610, and 1385 cm^{-1}; p.m.r. (DMSO-d_6) δ 1.6–2.1 (6H, m, $CH_3C{\equiv}CCH_2$), 3.2–3.4 (2H, broad m, $=CCH_2CH$), 4.1–4.5 (1H, m, CH_2CH-(NH)CO), 5.0-5.3 (4H, m, $CH_3C{\equiv}CCH_2\overset{+}{N}$), 7.3–7.9 (6H, m, aromatic and $\overset{+}{N}CH{=}C$), 8.10 (1H, d, J = 6 Hz, CHN*H*CO), and 9.32 (1H, s, $\overset{+}{N}CH\overset{+}{N}$).

(c) With 2-Bromoacetophenone (3)

Under the conditions outlined above for allyl bromide, 2-bromoacetophenone (200 mg, 1 mmol), α-*N*-benzoyl-L-histidine methyl ester (273 mg, 1 mmol) and sodium bicarbonate (84 mg, 1 mmol) gave after a 2 day reaction period:

(*i*) α-*N*-Benzoyl-*N*-3-phenacyl-L-histidine methyl ester (**10***c*, R_f 0.84) as a glass (159 mg); i.r. ($CHCl_3$) 3436, 3333, 1736, 1698, and 1650 cm^{-1}; p.m.r. ($CDCl_3$) δ 3.12 (2H, d, J = 5 Hz, $=CCH_2CH$), 3.62 (3H, s, OCH_3), 4.96 (1H, m, CH_2CH(NH)CO), 5.35 (2H, s, $COCH_2N$), 6.78 (1H, s, $NCH{=}C$), 7.3–8.1 (11H, m, aromatic and NC*H*N), and 8.48 p.p.m. (1H, d, J = 8 Hz, CHN*H*CO).

Anal. Calcd. for $C_{22}H_{21}N_3O_4$: C, 67.50; H, 5.41; N, 10.74. Found: C, 67.00; H, 5.59; N, 10.04.

(*ii*) α-*N*-Benzoyl-*N*-1-phenacyl-L-histidine methyl ester (**11***c*, R_f 0.72) as a glass (11 mg); i.r. ($CHCl_3$) 3448, 1742, 1706, 1658, and 1486 cm^{-1}; p.m.r. ($CDCl_3$) δ 3.0–3.3 (2H, broad m, $=CCH_2CH$), 3.70 (3H, s, OCH_3), 4.7–5.1 (1H, broad m, CH_2CH(NH)CO), 5.46 (2H, broad s, $COCH_2N$), 6.54 (1H, broad s, $NCH{=}C$), 6.80 (1H, broad s, NC*H*N), 7.0–8.1 (10H, broad m, aromatic), and 8.70 p.p.m. (1H, broad d, J = 8 Hz, CHN*H*CO).

Anal. Calcd. for $C_{22}H_{21}N_3O_4$: C, 67.50; H, 5.41; N, 10.74. Found: C, 67.87; H, 5.81; N, 10.59.

(*iii*) α-*N*-Benzoyl-*N*-1,*N*-3-diphenacyl-L-histidine methyl ester imidazolium bromide (**12***c*, R_f 0.56) as a pale yellow solid (190 mg) m.p. 130–131.5°; i.r. (KBr) 3247, 1736, 1698, and 1650 cm^{-1}; p.m.r. ($CDCl_3$) δ 3.1–3.5 (2H, broad m, $=CCH_2CH$), 3.52 (3H, s, OCH_3), 4.7-5.1 (1H, broad m, CH_2CH(NH)CO), 5.95 and 6.18 (4H, two s, $COCH_2\overset{+}{N}$), 7.0–8.1 (16H, m, aromatic and $\overset{+}{N}CH{=}C$), 8.70 (1H, broad d, J = 7 Hz, CHN*H*CO), and 9.57 p.p.m. (1H, s, $\overset{+}{N}CH\overset{+}{N}$).

Anal. Calcd. for $C_{30}H_{28}BrN_3O_5$: C, 61.02; H, 4.78; N, 7.12. Found: C, 60.58; H, 5.07; N, 6.95.

Some (≃10%) starting material **6** (R_f 0.61) was always recovered but none of the zwitterion **13***c* was detected presumably owing to the decreased reaction period required for the 2-bromoacetophenone reactions.

When 2-bromoacetophenone was used in 5 *M* excess, a 98% yield of **12***c* was isolated.

Alkylation of α-N-Benzoyl-L-lysine t-Butyl Ester (7)

(a) With Allyl Bromide (1)

Allyl bromide (121 mg, 1 mmol), α-*N*-benzoyl-L-lysine *t*-butyl ester (306 mg, 1 mmol) and sodium carbonate (106 mg, 1 mmol) in ether (10 ml) (use of methanol or 50% aqueous ethanol also gives similar results) was stirred at 25° for 5 days. The mixture was then filtered and the filtrate evaporated. The p.l.c. of the residue gave:

(*i*) α-*N*-Benzoyl-ε-*N*-allyl-L-lysine *t*-butyl ester (**14***a*, R_f 0.73) as a gum (40 mg); i.r. ($CHCl_3$) 3436, 1733, and 1664 cm^{-1}; p.m.r. ($CDCl_3$) δ 1.49 (9H, s, $C(CH_3)_3$), 1.2–2.2 (6H, broad m, $NHCH_2(CH_2)_3CH$), 2.72 (2H, broad m, $NHCH_2CH_2$), 3.45 (2H, broad m, $CH_2{=}CHCH_2N$), 4.64 (1H, broad q, J = 6 Hz, CH_2CH(NH)CO), 5.1–5.4 (2H, m, $CH_2{=}CHCH_2$), 5.8–6.2 (1H, broad m, $CH_2{=}CHCH_2$),[6] 6.5–6.9 (1H, broad m, CHN*H*CO), 7.3–7.6 (3H, m, *m*- and *p*-aromatic) and 7.8–8.1 p.p.m. (2H, m, *o*-aromatic).

Mol. Wt. Calcd. for $C_{20}H_{30}N_2O_3$: 346.2256. Found (mass spectrum): 346.2253.

(*ii*) α-*N*-Benzoyl-ε-*N*,*N*-diallyl-L-lysine *t*-butyl ester (**15***a*, R_f 0.96) as a gum (205 mg); i.r. ($CHCl_3$) 3425, 1727, and 1664 cm^{-1}; p.m.r. ($CDCl_3$) δ 1.49 (9H, s, $C(CH_3)_3$), 1.2–2.1 (6H, m, $NCH_2(CH_2)_3$), 2.44 (2H, t, J = 6 Hz, NCH_2CH_2), 3.08 (4H, d, J = 6 Hz, $CH_2{=}CHCH_2N$), 4.72 (1H, q, J = 7 Hz, $CH_2CH(NH)CO$), 5.0–5.3 (4H, m, $CH_2{=}CHCH_2$), 5.6–6.1 (2H, m, $CH_2{=}CHCH_2$),[6] 7.10 (1H, d, J = 7 Hz, $CONHCH$), 7.3–7.5 (3H, m, *m*- and *p*-aromatic) and 7.75–7.95 p.p.m. (2H, m, *o*-aromatic).

The Structure of Fumarofine

C. K. Yu, J. K. Saunders, and D. B. MacLean
Department of Chemistry, McMaster University, Hamilton, Ontario

AND

R. H. F. Manske
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received April 14, 1971

A structure is proposed for fumarofine (F-38), an alkaloid of *Fumaria officinalis*. It is shown by spectroscopic methods to be another representative of the spirobenzylisoquinoline group of alkaloids.

Une structure est proposée pour la fumarofine (F-38), un alcaloïde du *Fumaria officinalis*. Par des méthodes spectroscopiques il est montré que celle-ci est apparentée au groupe spirobenzylisoquinoléine des alcaloïdes.

Canadian Journal of Chemistry, 49, 3020 (1971)

In 1938 Manske (1) isolated and identified several isoquinoline alkaloids from the plant *Fumaria officinalis* L. Among these were protopine, cryptopine, (±)-stylopine, (+)- and (±)-scoulerine, and sinactine. Besides these alkaloids of established structure, he reported the presence of two new alkaloids, F-37 ($C_{21}H_{23}NO_5$) and F-38 ($C_{20}H_{19}NO_6$). Two minor alkaloids were found later (2) in the same plant corresponding in composition to $C_{20}H_{21}NO_5$ and to $C_{20}H_{17}NO_5$, which were named fumaritine and fumariline, respectively. These alkaloids and F-37, fumaricine, have been shown to have a spirobenzylisoquinoline system (3). Here the structure of F-38, to which we assign the name fumarofine, will be reported.

Fumarofine (**1**) has absorption ascribed to a hydroxyl (3450 cm^{-1}) and a carbonyl (1700 cm^{-1}) group in its i.r. spectrum. An examination of its 100 MHz p.m.r. spectrum in DMSO-d_6 shows one singlet of area 1 at 8.65 δ which is assigned to a phenolic hydroxyl proton. A total area of seven protons is observed in the region 6.0–7.5 δ. One AB quartet centered at 7.18 and 7.36 δ (J_{AB} = 8 Hz) is assigned to ortho aromatic protons and a signal at 6.26 δ with an area of 2 to methylenedioxy protons. The three remaining singlets, two of which are probably due to para aromatic protons and one to an alcoholic OH, are at 7.24, 6.68, and 6.29 δ. A methoxyl signal at 3.80 δ is apparent in the spectrum. A signal at 4.33 δ (area 1) is probably due to a benzylic hydrogen geminal to a hydroxyl group. A disadvantage of the p.m.r. spectrum in DMSO-d_6 is the intense signal arising from undeuterated DMSO which obscures the signals in the high field region. Unfortunately, a spectrum in $CDCl_3$ could not be obtained because of insolubility. The data are recorded in Table 1.

When fumarofine was treated with diazomethane, its methyl ether, **2**, was obtained. The p.m.r. spectral data of **2** in DMSO-d_6 and in $CDCl_3$ are given in Table 1. In DMSO-d_6 the appearance of one additional methoxyl signal at 3.87 δ and the disappearance of the signal at 8.65 δ confirms that one phenolic hydroxyl group is present in fumarofine. In the region 6.0–7.5 δ, one AB quartet, one methylenedioxy signal, and three singlets are still observable. The signal corresponding to the benzylic hydrogen geminal to a hydroxyl group stays at 4.33 δ. When deuterium oxide was added to the solution of *O*-methylfumarofine in DMSO-d_6, the signal at 6.44 δ disappeared. This observation provides convincing evidence for the presence of an active hydrogen in the molecule, presumably a hydroxyl hydrogen.

When the p.m.r. spectrum of the methyl ether was run in $CDCl_3$, a signal appeared at 2.53 (area 3), which was obscured in the spectrum in DMSO-d_6, and is assigned to an *N*-methyl group.

In order to confirm the presence of one hydroxyl group in the molecule, the ether **2** was acetylated with acetic anhydride and pyridine to give **3**. The p.m.r. spectrum of **3** in $CDCl_3$ shows a signal assigned to an acetyl group at 2.22. The signal of the hydrogen geminal to the hydroxyl group in fumarofine methyl ether shifts

TABLE 1. The p.m.r. signals of **1**, **2**, and **3** in p.p.m. (δ)

1 $R_1 = R_2 = H$

2 $R_1 = CH_3; R_2 = H$

3 $R_1 = CH_3; R_2 = CH_3—CO$

from 4.45 to 4.98 δ in the acetylated compound. In the region 6.0–7.5 δ, a signal at 7.09 δ (area 2) is assigned to two ortho protons, a signal at 6.12 δ (area 2) to the methylenedioxy group, and signals at 7.30 (area 1) and 6.53 δ (area 1) to two para aromatic protons. The data are given in Table 1.

Although i.r. and p.m.r. data reveal much about the functional groups and the structural units, the skeleton is still unknown. Since fumarofine occurs in the same plant as fumaricine, fumariline, and fumaritine, it may be structurally related to these alkaloids. Its properties preclude it belonging to the protoberberine, phthalide isoquinoline, or the protopine groups. When the mass spectrum of fumarofine is compared with those of the spirobenzylisoquinoline group found in the same plant (4) definite conclusions cannot be drawn about its structure. When, however, the spectra of sibiricine (4) and fumarofine are compared, there appears a remarkable similarity. Both compounds have the molecular ion peak as their base peak and most of the intense ions occur in the high mass end and in the region between *m/e* 140–200. Moreover, many peaks characteristic of a spirobenzylisoquinoline with a ketone and a hydroxyl group in the five-membered ring are present in fumarofine. It is, therefore, reasonable to assume that both compounds have the same carbon skeleton. The substitution pattern in fumarofine can be deduced from the presence of the dihydroisoquinolinium ion at *m/e* 192, which shows that the phenolic hydroxyl and methoxyl group must be present in ring A; therefore, the methylenedioxy group must be in ring D.

The spectral data suggest structure **1** but further p.m.r. data are required for a definitive assignment of the stereochemistry and the substitution pattern. In fumarofine the chemical shift difference of the aromatic AB quartet (δ_{HA} = 7.18, δ_{HB} = 7.36) indicates that the carbonyl is ortho to the methylenedioxy group. In those spirobenzylisoquinoline alkaloids of known structure in which the carbonyl group is ortho to the aromatic protons the chemical shift difference between two adjacent protons is much larger. For example, a difference of 0.4 p.p.m. is observed in sibiricine (5) because of the strong deshielding effect of the carbonyl function on the ortho proton. The substitution in ring D has been confirmed by a nuclear Overhauser effect (n.O.e.) experiment (6) in which an n.O.e. of 9% is observed at H-10 when H-9 in fumarofine is saturated.

Confirmation of the substitution pattern in ring A rests on the following n.O.e. experiment. Saturation of H-9 causes a 4% increase in area of the absorption at 7.24 δ which must be assigned to H-1, while saturation of the *O*-CH_3 results in an increase in area of 25% at 6.68 δ, presumably H-4. These data suggest that the

hydroxyl and methoxyl groups in ring A are at C-2 and -3, respectively. The structure of fumarofine is shown in structure **1**. Further evidence for the configuration at C-9 in structure **1** comes from the fact that H-9 is unaffected when the N—CH_3 is irradiated. If H-9 and N—CH_3 were on the same side of the plane of the five-membered ring a large n.O.e. would be expected. The n.O.e. data are recorded in Table 2.

The p.m.r. results on fumarofine differ from other members of this series in that there is an unusually large n.O.e. between H-9 and -5 and the chemical shift of H-1 is further downfield than in the related alkaloids, sibiricine (5) and fumariline (3). These facts can be explained by the conformation shown in **4** in which ring B is in a twist form and the OH is hydrogen bonded to the nitrogen causing the five-membered ring to be twisted so that the carbonyl group is closer to ring A with H-1 in the deshielding zone. H-9 is also forced to be closer to H-5. No such effect, however, is observed in sibiricine where the stereochemistry at C-9 is different. Thus, structure **4** is fully compatible with the mass spectral, i.r. and p.m.r. data.

One other piece of evidence supporting the proposed structure of fumarofine comes from its u.v. spectrum. The reported u.v. spectrum of **5** (7), λ_{max} (EtOH) 237 (4.52),[1] 292 (4.13), and 310 (4.01), is similar to that of sibiricine **8**, λ_{max} (EtOH) 205 (4.80), 240 (3.94), 291 (3.91) and 313 (3.99) but differs greatly from that of *O*-methylfumarofine, λ_{max} (EtOH) 208 (4.45), 235 (4.35), 259 (3.96), 286 (3.37), and 350 (3.40). On the other hand, the u.v. spectrum of **6**, λ_{max} (EtOH) 234 (4.47), 260 (4.08), 283 (3.60), and 354 (3.52), is similar to that of the methyl ether of fumarofine. The spectra of **5** and **6** are a composite of two chromophoric systems, the tetrahydroisoquinoline system and the 1-indanone system. The absorptions corresponding to the latter chromophore are different for different substitution patterns. The resemblance of the u.v. spectrum of **2** to that of **6** indicates that they have the same chromophoric system.

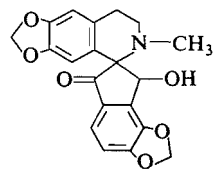
7



8

The characteristic ions in the mass spectra of the synthetic compound, **7** and sibiricine, **8** (4), are also found in the spectrum of fumarofine as expected. The spectrum (Fig. 1) is dominated by the molecular ion and the M-CH_3 ion. The molecular ion can undergo cleavage alpha to the >CHOH or alpha to the >C=O group in the five-membered ring to give ions **9** and **10**, respectively (Scheme 1). The former fragments by a mechanism already discussed (4) to the dihydroisoquinolinium ion **11** and the isoquinolinium ion at *m/e* 192 and 190, respectively, while the latter by processes already described (4) can lead to ion **12** at *m/e* 324 and to ion **13** at *m/e* 206.

When the spectrum is examined more closely, however, it seems to be more complicated than that of **8**. Many additional peaks appear in the high mass range, such as M-CO and its subsequent decomposition product ions. Multiplicity in the middle of the spectrum (*m/e* 150–220) appears, as shown in Fig. 1. One possible

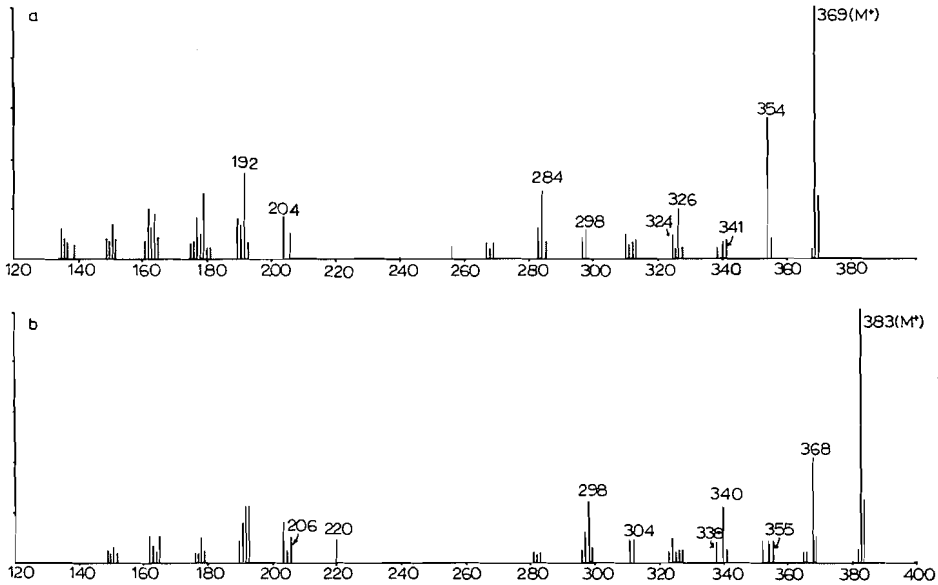


FIG. 1. The mass spectra of (*a*) fumarofine and (*b*) *O*-methylfumarofine.

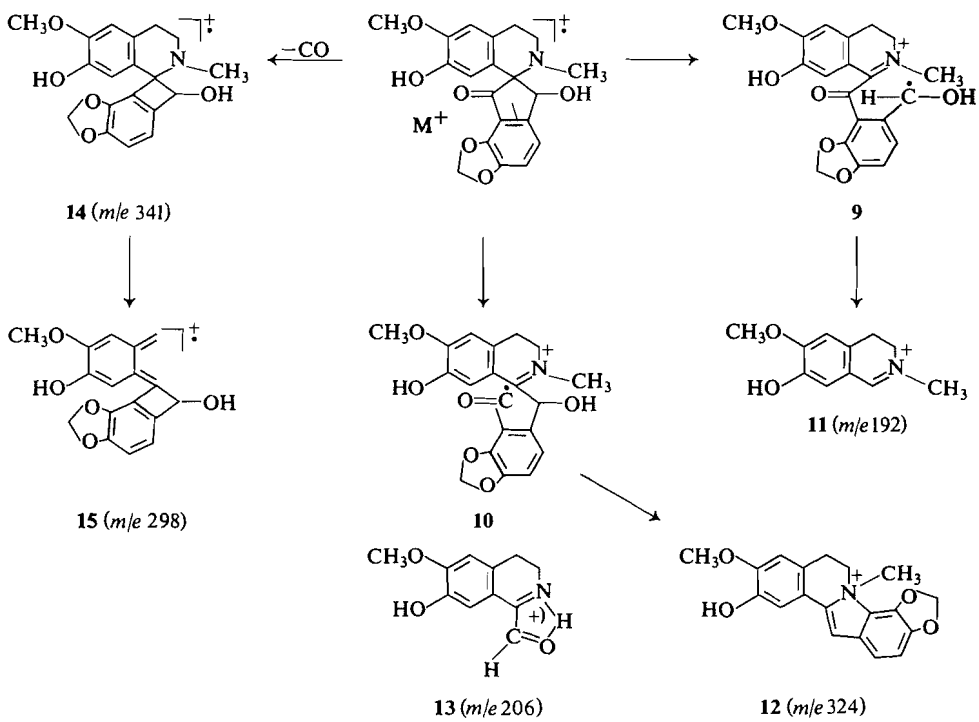

SCHEME 1

explanation for these differences is that the substitution of methoxyl and hydroxyl in ring A increases the possibility of the decomposition of the molecular ion as well as the fragment ions. Expulsion of CO from the molecular ion forms ion **14**, which by a retro-Diels–Alder decomposition can produce ion **15** at *m/e* 298. If the fragment C_3H_7N is lost from **14**, ion *m/e* 284 will be formed.

In the high mass range, there is a peak of composition $C_{18}H_{16}NO_5$, corresponding to the loss of CH_3CO which may arise by fragmentation of the aromatic ring. It is well documented that aromatic methyl ethers (8) can lose CH_3 and CO successively to give an ion, M-CH_3CO. Other possibilities are by loss of CH_3 from **14** or loss of CO from M-CH_3.

In the region *m/e* 150–200, most peaks are doublets and most of them contain a nitrogen atom. The source of these ions must be the isoquinoline moiety. The only useful and characteristic ion in this region, however, is the dihydroisoquinolinium ion, *m/e* 192, which is the most intense peak in this area.

The spectrum of *O*-methylfumarofine is also recorded in Fig. 1. In the high mass range (above *m/e* 250), all the peaks are 14 mass units higher than the corresponding peaks in fumarofine, and the peak intensities vary little. In the range between *m/e* 150 and 200 multiplicity of the peaks is much reduced in comparison to that of fumarofine. The peaks at *m/e* 192 and 206 in fumarofine are shifted to *m/e* 206 and 220 in **2**. These ions correspond to the isoquinolinium ion and the ion containing one nitrogen and three oxygens.

Experimental

Apparatus, Methods, and Materials

Mass spectra were determined on a C.E.C. 21-110B double-focusing mass spectrometer. Samples were introduced through a direct inlet system. Spectra are plotted in terms of relative abundance, with the most intense peak (base peak) taken as 100%. Only those peaks with an intensity equal to or greater than 3% of the most intense peak have been recorded.

The high resolution mass spectra were recorded on Ilford Q-2 photographic plates, which were developed in the usual manner. The spectra were then recorded on magnetic tape, using a Gaertner comparator-densitometer linked to a Datex system. They were processed on a CDC-6400 computer using a modified version of the HIRES program of Tunnicliff and Wadsworth (9).

The 100 MHz p.m.r. spectra were recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ or DMSO-d_6 using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V4315 frequency counter incorporated in the instrument. Double irradiation was achieved by employing a Hewlett-Packard 201C audiogenerator at the desired frequency.

A Perkin–Elmer 337 grating i.r. spectrometer was used to record i.r. spectra and a Cary 14 spectrometer was used for the u.v. spectrum.

Melting points were determined on a Kofler hot stage and are uncorrected.

Methylation of Fumarofine

Fumarofine (25 mg) was dissolved in methanol (5 ml) and excess diazomethane in ether added to the solution which was then allowed to stand for 3 h. The solvents were allowed to evaporate and the residue recrystallized from methanol–ether, m.p. 245–246 °C.

The u.v. spectrum: λ_{max} (EtOH) 208, 235, 259, 286, and 250 mμ; log ε 4.45, 3.96, 3.37, and 3.40.

The i.r. spectrum: ν_{OH} (KBr) 3450 cm^{-1}; $\nu_{C=O}$ (KBr) 1700 cm^{-1}.

Accurate mass measurement of the molecular ion gave the following result: calcd. for $C_{21}H_{21}NO_6$, 383.137; found, 383.138.

Acetylation of O-Methylfumarofine

O-Methylfumarofine (17 mg) was dissolved in acetic anhydride (4 ml) and pyridine (2 ml). The mixture was stirred at room temperature under a nitrogen atmosphere for 60 h. The excess acetic anhydride and pyridine were evaporated under reduced pressure, the residue triturated in aqueous sodium carbonate, and the suspension extracted several times with chloroform. The chloroform extract was dried over sodium sulfate, and evaporated to a residue which could not be induced to crystallize but on an analytical thin layer plate it showed only a single spot. The mass spectrum showed a molecular ion at *m/e* 425. Insufficient material was available for a combustion analysis.

Mass Spectra of Spirobenzylisoquinoline Alkaloids

C. K. Yu and D. B. MacLean
Department of Chemistry, McMaster University, Hamilton, Ontario

Received April 14, 1971

The mass spectra of a number of spirobenzylisoquinoline alkaloids, several of their derivatives, and some model compounds are recorded and discussed. Fragmentation mechanisms are proposed for the formation of the major ions in the spectra of compounds containing one and two oxygen functions in the five-membered ring. The spectra of compounds containing a carbonyl group differ markedly from those having a hydroxyl group in the five-membered ring. Several model compounds were synthesized and characterized and their spectra compared with those of the alkaloids.

Les spectres de masse d'un certain nombre d'alcoloïdes du type spirobenzylisoquinoléine, de quelques uns de leurs dérivés, ainsi que de quelques composés types, sont rapportés et discutés. Des mécanismes de fragmentation sont proposés pour la formation des ions principaux dans les spectres des composé qui renferment une et deux fonctions oxygène dans le cycle à cinq atomes. Les spectres des composés qui renferment un groupement carbonyle différent considerablement de ceux ayant un groupe hydroxyle dans le noyau à cinq atomes. Plusieurs composés types ont été synthétisés et caractérisés dans le but de comparer leurs spectres avec ceux des alcaloïdes.

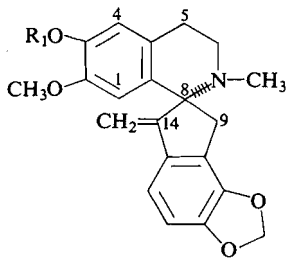
Canadian Journal of Chemistry, **49**, 3025 (1971)

The mass spectra of many classes of isoquinoline alkaloids have been investigated (1, 2) but a systematic study of the mass spectra of spirobenzylisoquinoline alkaloids has not been reported. Most of the known spirobenzylisoquinoline alkaloids were isolated several decades ago but it is only recently that their structures have been elucidated. The structures of known alkaloids are shown below along with two derivatives **4** and **8**. The mass spectra of ochotensine and ochotensimine have been reported (3) but their fragmentation does not show a characteristic pattern that can be used for diagnostic purposes. On the other hand the spirobenzylisoquinoline compounds with oxygenated substituents in the five-membered ring show distinct fragmentation patterns. The spectra of several alkaloids of this type have been reported (4–7) but none has been analyzed in detail. The present work will deal with the fragmentation pattern of known alkaloids of the spiro series oxygenated in the five-membered ring and with several model compounds.

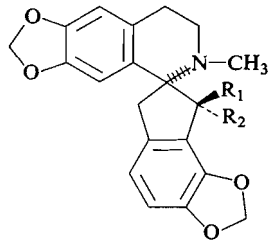
The model compounds were synthesized by methods already described (8, 9). Since the compounds are new and the orientation of substituents found in one product differed from that reported (8) a description of the syntheses will precede a discussion of the mass spectra.

In 1968 the condensation of 3-hydroxy-4-methoxyphenylethyl amine with ninhydrin to a compound named 3-hydroxy-2-methoxyochotensinan-8,13-dione was reported (8). When we used the amine hydrochloride in the condensation with ninhydrin a different product was obtained to which we assign structure **11**. The phenol **11** was characterized as its *O*-methyl ether, **12**, as the former proved difficult to purify. The i.r. spectrum of **12** did not show hydroxyl absorption but had two absorptions in the carbonyl region at 1700 and 1745 cm^{-1}. The 60 MHz p.m.r. spectrum (Fig. 1) shows two methoxyl signals at 3.28 and 3.73 δ, one singlet of area 2 at 6.86 δ corresponding to two aromatic protons in ring A, a multiplet of area 4 in the region 7.7–8.1 δ arising from the protons in ring D, and signals from the remaining protons in the range 2.5–3.5 δ. When the spectrum was run on the 220 MHz instrument, the aromatic signal at 6.86 δ was split into a well-defined AB quartet with a coupling constant of 8 Hz (see inset Fig. 1). Thus, in the condensation of ninhydrin and 3-hydroxy-4-methoxyphenylethylamine under our conditions cyclization took place at the carbon ortho rather than para to the hydroxyl group to form **11** (Scheme 1).

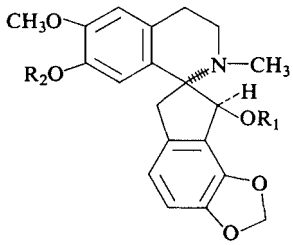
Manske and Ahmed (9) have reported the synthesis of an analogue of ochrobirine in high yield. They treated 3,4-methylenedioxyphenylethylamine with ninhydrin in absolute ethanol at low temperature and were able to isolate pure para cyclized product **13**, which was later transferred into **14**, the analogue of ochrobirine,



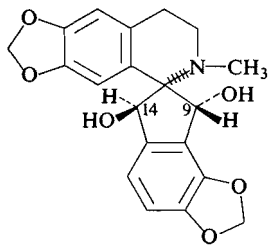
1 Ochotensimine $R_1 = CH_3$
2 Ochotensine $R_1 = H$



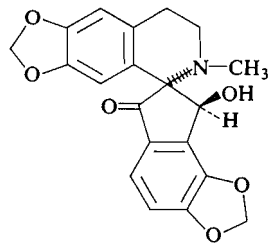
3 Fumariline $R_1 + R_2 = O$
4 Dihydrofumariline $R_1 = OH$; $R_2 = H$



5 Fumaricine $R_1 = H$; $R_2 = CH_3$
6 Fumaritine $R_1 = H$; $R_2 = H$
7 Fumarophycine $R_1 = COCH_3$; $R_2 = H$
8 Diacetylfumaritine $R_1 = R_2 = COCH_3$



9 Ochrobirine



10 Sibiricine

by successive methylation and sodium borohydride reduction. We used their procedure with 3,4-dimethoxyphenylethylamine and ninhydrin at ice-water temperature. The product **15**, bright yellow crystals, melted at a temperature different from **12**. The p.m.r. spectrum of **15** had two singlets at 5.91 and 6.65 δ in the aromatic region replacing the AB quartet of **12**. Apparently, cyclization occurs at the para position in this instance as shown in Scheme 1. The signal at 6.65 δ is broader than the other singlet presumably because of benzylic coupling to H-5. The same situation has also been observed in the spectrum of sibiricine (5) in which two singlets, one at 6.54, the broader signal, and one at 6.04 δ, were assigned to H-4 and -1, respectively.

When compound **12** was methylated with formic acid and formaldehyde and reduced with sodium borohydride two major products were detected on t.l.c. They were separated by thick layer chromatography and subjected to spectroscopic investigation. Both products, **17** and **18**, were dihydro compounds as shown by their mass spectra and both show hydroxyl and carbonyl absorption in their i.r. spectra. When one carbonyl group is reduced, the interaction between R_1 and OCH_3 at C-1 (see

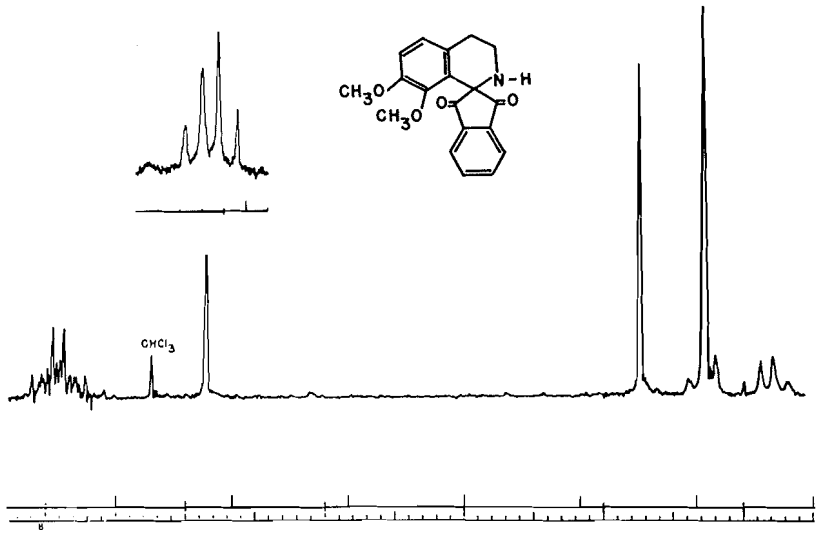

FIG. 1. The 60 MHz p.m.r. spectrum of **12**.

17 or **18**) is such that this OCH_3 group is forced to sit behind the remaining carbonyl group. The interaction between R_2 and N-CH_3 forces the *N*-methyl group to stay in front of the carbonyl group. As a result, the second carbonyl group is not readily accessible to hydride attack under mild reaction conditions and only dihydro compounds are obtained.

The assignment of stereochemistry to **17** and **18** is based on two facts. Firstly, on t.l.c. plates compound **17** has a higher R_f value than that of **18**, indicating that the latter is adsorbed more firmly on the surface of the silica gel. Since internal hydrogen bonding in **17** may reduce the interaction between adsorbent and compound (10) it moves faster on t.l.c. Secondly, when the 100 MHz p.m.r. spectra of the compounds are compared a sharp singlet is observed at 5.08 δ in **17** and a very broad signal centered at 5.26 δ in **18**. These signals are assigned to the C-9 protons in each case. Analogous signals have been observed in ochrobirine (6) in which the broad signal at 5.42 δ was assigned to the proton at H-14 on the same side of the plane as the N—CH_3 group while the sharp singlet at 4.88 δ was assigned to H-9 which is on the opposite side of the plane. Thus, the stereochemistry of **17** and **18** is established.

When **15** was reduced with sodium borohydride one major compound **16** was detected on t.l.c. The molecular ion peak in the mass spectrum appears four mass units higher than in **15**, indicating that both carbonyl groups are reduced in this instance. Since there is less steric hindrance present in this molecule, both carbonyl groups are accessible to hydride attack.

Before considering the mass spectra of the model compounds and the alkaloids with two oxygens in the five-membered ring it is appropriate to begin with compounds with one oxygen in the five-membered ring. Several compounds with one hydroxyl group are available, one with a single carbonyl group, and two with acetyl groups. The composition of all ions referred to in the subsequent discussion has been determined by high resolution mass spectrometry. Labelling studies on the natural compounds were precluded because of their paucity or because of lack of suitable chemical methods for introduction of label.

The mass spectra of dihydrofumariline (**4**), fumaricine (**5**), and fumaritine (**6**) have been published before (4) but are repeated here for convenience in Fig. 2. In Scheme 2 ions labelled *a*, *b*, and *c* are derived from fumaricine, fumaritine, and dihydrofumariline, respectively. The base peak, ion **20**, in the spectra of these compounds is assumed to arise as shown in Scheme 2. This mechanism has been supported by a deuterium labelling experiment, in which the hydroxyl hydrogen was replaced by deuterium causing a shift of one mass unit in the base peak.

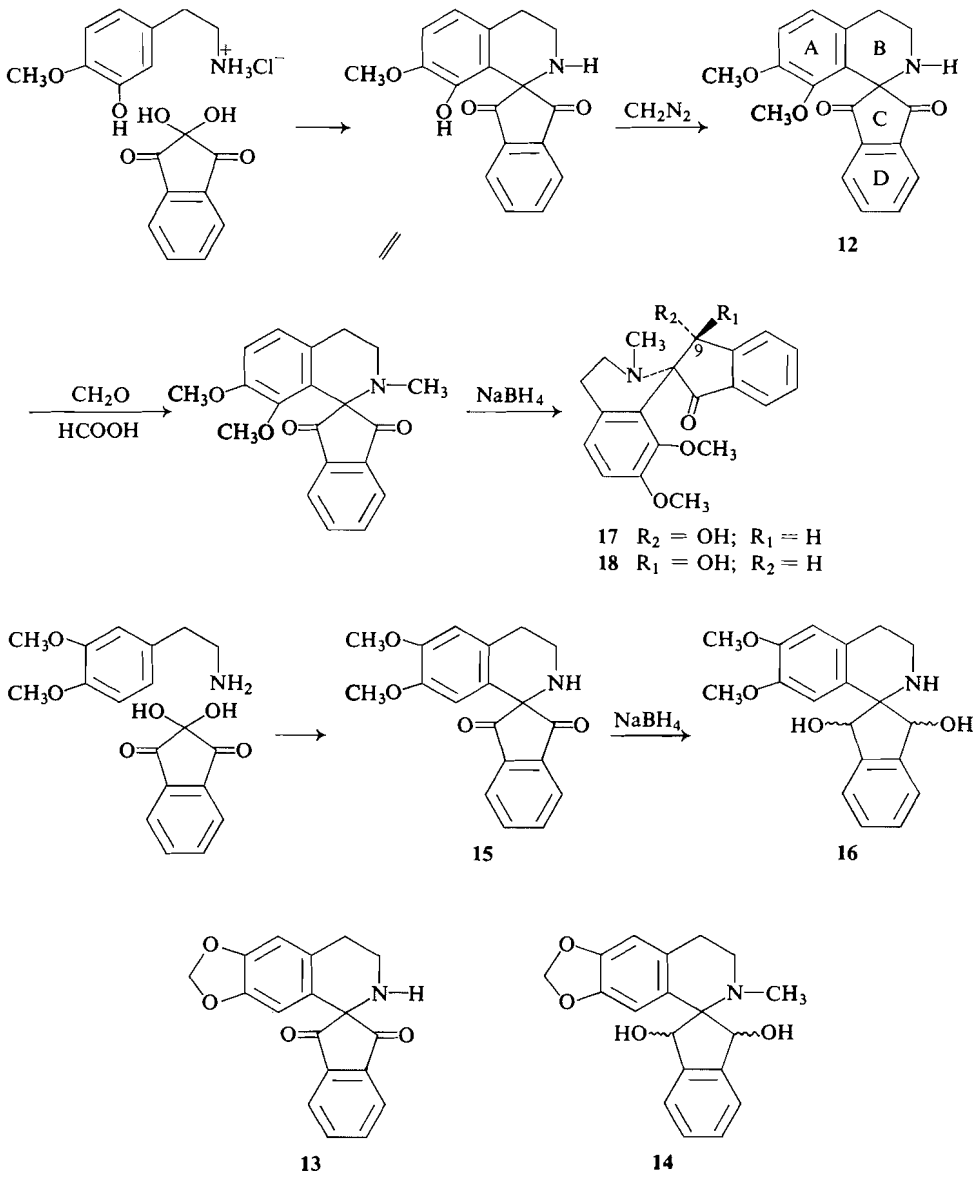

SCHEME 1

A small peak two mass units lower than the base peak is assigned to the isoquinolinium ion **21**, formed from **19** by C—C bond cleavage followed by the loss of one hydrogen from the isoquinoline moiety and rearrangement of another, or by loss of two hydrogens from **20**. Both ions, **20** and **21**, are characteristic of many isoquinoline alkaloids (1, 2). The same bond rupture with charge retention by the other portion of the molecule leads to ion **22**, *m/e* 163, which upon losing CO yields ion **23** at *m/e* 135 but both are of low intensity.

In the high mass end of the spectrum the M-CH_3 ion shows a constant intensity relative to the molecular ion ((intensity of M-CH_3)/(intensity of M^+) is about 1.4–1.7), which indicates that the source of the methyl radical must be a common structural unit, presumably the N—CH_3 group. In dihydrofumariline (**4**), the only source of the M-CH_3 ion is the methyl

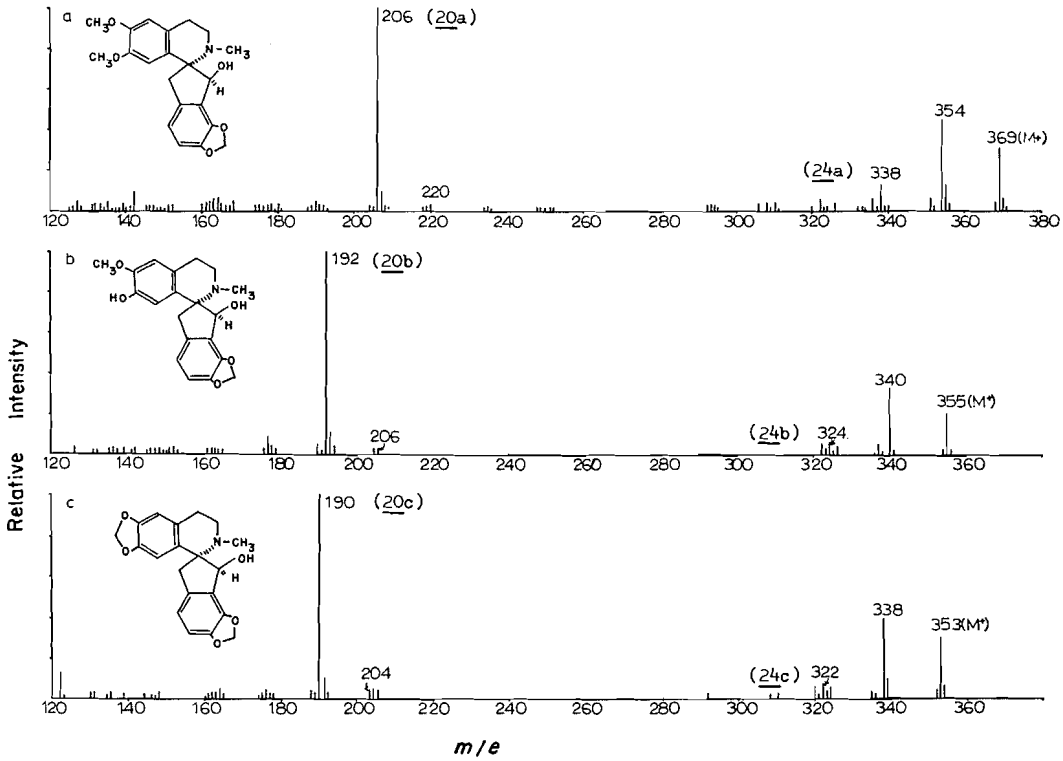

FIG. 2. The mass spectra of (*a*) fumaricine (**5**), (*b*) fumaritine (**6**), and (*c*) dihydrofumariline (**4**).

group attached to the nitrogen atom, and it is assumed that in these systems it is lost upon electron impact.

An M-31 peak is observed in all three cases corresponding in composition to M-OCH_3. In **5** and **6** this ion may be attributed to the loss of OCH_3 from the substituent in ring A. In **4**, however, the ion at M-31 can come only from another source. We propose that ion **19** expels a neutral fragment CH_2O and a radical H· to form an ion of type **24** which occurs in all of the spirobenzylisoquinoline compounds with oxygenated substituents in the five-membered ring. It is likely therefore that ions **24***a* and *b* contribute significantly to the M-31 peak in **5** and **6**, respectively.

An ion of low intensity 14 mass units higher than the base peak has been found to contain one nitrogen and three oxygen atoms; its structure will be discussed later.

The spectra of fumarophycine (**7**) and its *O*-acetate (**8**) are recorded in Fig. 3 (7, 11). They bear little resemblance to the unacetylated precursor **6** but are dominated by peaks arising from the acetyl groups. Both compounds lose CH_3CO and CH_3CO_2H forming ions at *m/e* 354 and 337, respectively, in **7** and at *m/e* 396 and 379, respectively, in **8**. Examination of the spectra under high resolution, however, shows the presence of ions common to **6**, **7**, and **8**, at *m/e* 355, 324, 206, 192, and 190. These ions are all relatively weak and the relationship among the compounds is apparent only when it is possible to determine the compositions by high resolution studies.

The spectrum of fumariline (**3**) (Fig. 4) is distinctly different from that of **4**, **5**, and **6**. It does not show an intense peak corresponding to **20***c*, since there is not a readily available hydrogen to facilitate the process for its formation. The isoquinolinium ion at *m/e* 188 (**21***c*), however, is still discernible in the spectrum since a process in which hydrogen is lost and undergoes rearrangement in the isoquinoline moiety is still feasible. The base peak at *m/e* 322 is a singlet and corresponds in composition to $C_{19}H_{16}NO_4$. It is apparently formed by ring opening to **25** with loss of CO followed or preceded by loss of H.

25 **24**

SCHEME 3

In the absence of a labelling experiment, the hydrogen is assumed to come from H-9 (Scheme 3). Upon loss of a molecule of formaldehyde from the methylenedioxy group ion **24***c* yields an ion at *m/e* 292 which decomposes further to give an ion at *m/e* 264, both of low intensity. A peak corresponding to M-CH_3 at *m/e* 336 is small but observable in the spectrum. The source of this methyl radical is probably the methyl group attached to the nitrogen atom.

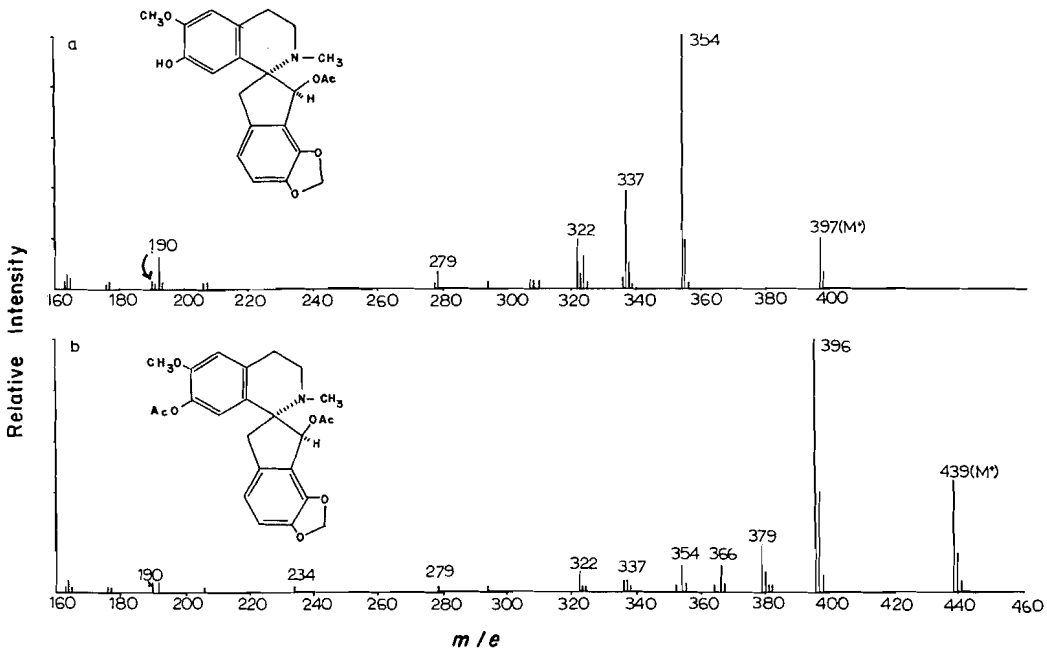

FIG. 3. The mass spectra of (*a*) fumarophycine (**7**) and (*b*) *o*-acetylfumarophycine (**8**).

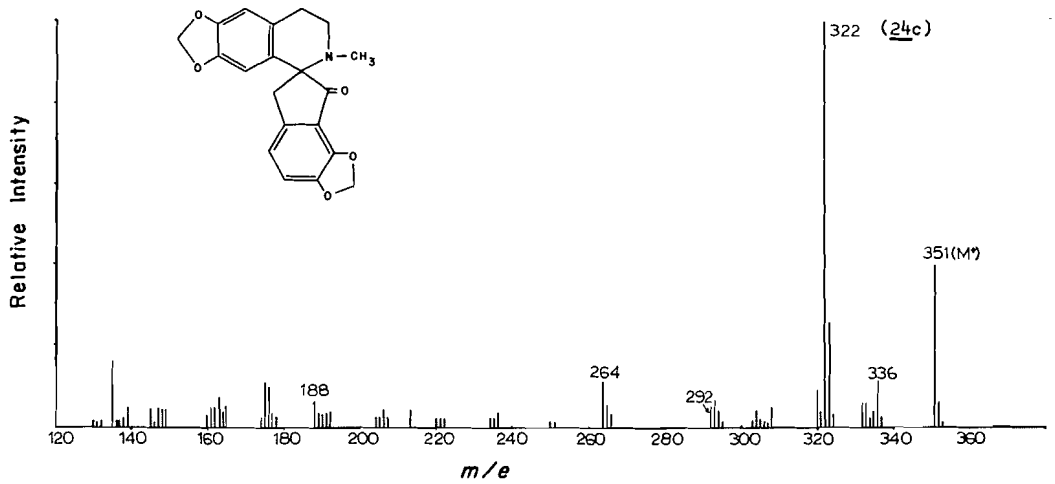

FIG. 4. The mass spectrum of fumariline (**3**).

The model compound **17** and sibiricine (**10**), both of which have a carbonyl and a hydroxyl group in the five-membered ring, are now examined. (The spectra of **17** and **18** are nearly identical and only one is discussed.) The spectrum of **17** is recorded in Fig. 5 and a scheme for its fragmentation in Scheme 4. The molecular ion is the most intense ion in the spectrum and fragmentation seems to be initiated by cleavage of the bonds β to nitrogen and adjacent to oxygen. Thus ion **26** is formed by cleavage adjacent to the OH group; its decomposition is analogous to that of **19** in the fumaricine series yielding **27** and **28** at *m/e* 206 and 204, respectively. Their intensity is nearly alike in contrast with fumaricine in which the ion of higher mass is

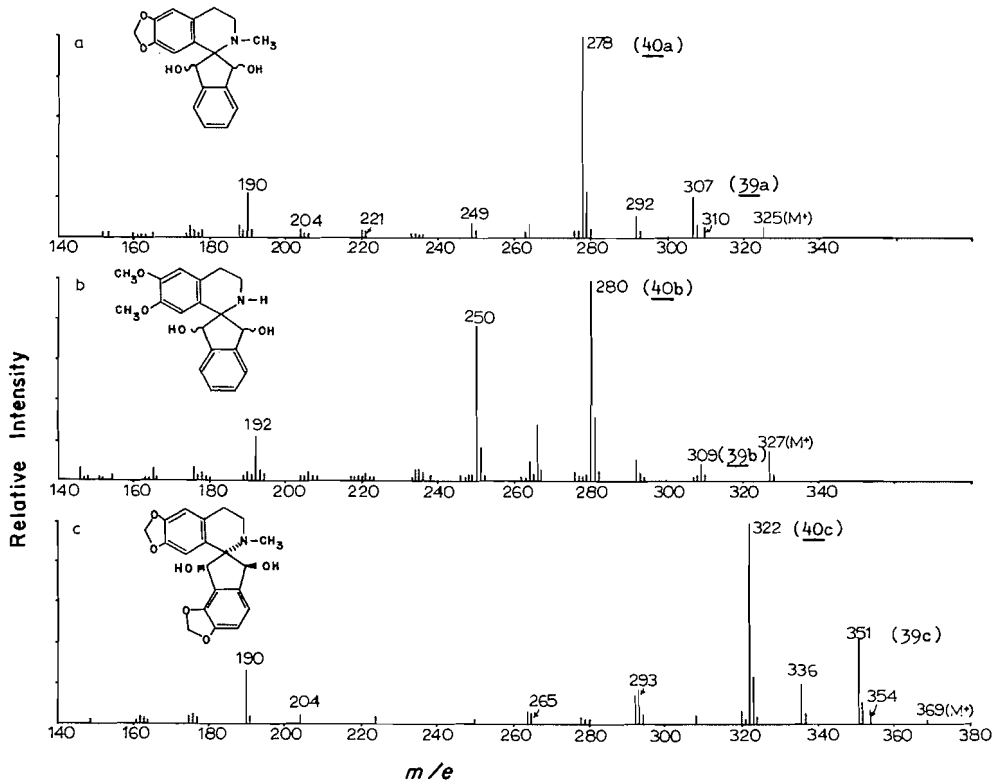

FIG. 7. The mass spectra of (*a*) compound **14**, (*b*) compound **16**, (*c*) ochrobirine (**9**).

much more intense. Fission of the bond adjacent to the carbonyl group leads to **29** which loses CO and OH to form **30**. (Compare Scheme 3 in which fumariline loses CO + H).

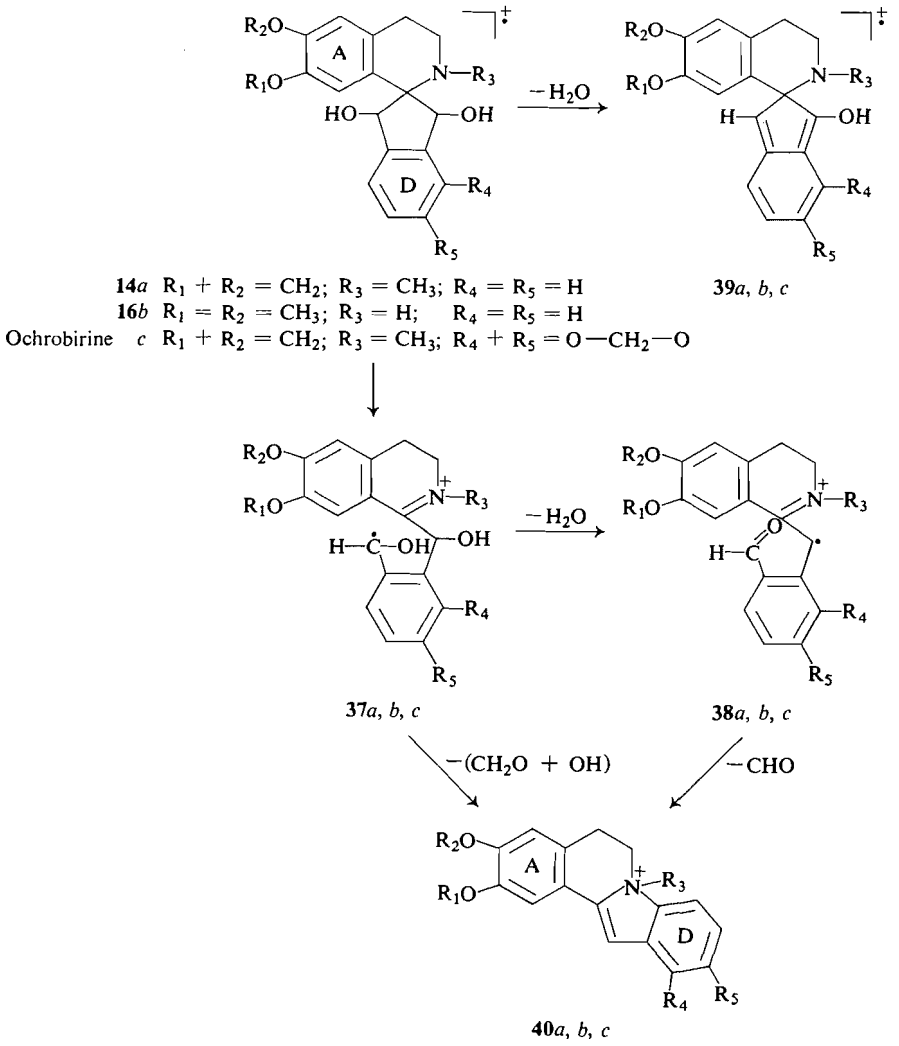
A moderately intense peak at *m/e* 220 has the composition $C_{12}H_{14}NO_3$ and must come from the isoquinoline moiety. It is postulated (Scheme 5) that the molecular ion expels a methyl radical from the nitrogen atom to form an intermediate ion **31** which decomposes to the daughter ion **32**. The process involves the loss of a methyl radical from the nitrogen atom, a fragmentation observed earlier in the spectrum of dihydrofumariline. Ions of type **32** occur in the spectra of all the spirobenzylisoquinoline compounds with hydroxyl groups in the five-membered ring but their intensity is very low in the spectra of fumaritine, fumaricine and dihydrofumariline.

The spectrum of sibiricine (**10**) (Fig. 6) and its fragmentation (Scheme 6) are very similar to that of **17**. The benzylic cleavage of the molecular ion may give either **33** or **34**, both of which may decompose further to give a series of peaks similar to those from **17**. Ion **34** can decompose by loss of CO and OH to give ion **35**, while ion **33** can give rise to the dihydroisoquinolinium ion, *m/e* 190, and the smaller isoquinolinium ion, *m/e* 188. The peak at *m/e* 204 (**36**) has one nitrogen and three oxygen atoms and must form in the manner shown in Scheme 5.

The loss of CH_3 is again a prominent peak (*m/e* 352) and must result through loss of the *N*-methyl group. The peak at *m/e* 338 corresponds to loss of CO and H and may form in the same way as ion **35** or by loss of CHO in one step from a methylenedioxy group. The spectra of **10** and **17** are alike and combine features found in the spectra of compounds with a carbonyl group in the five-membered ring, *e.g.* fumariline, and those with a hydroxyl group in the five-membered ring, *e.g.* dihydrofumariline.

The mass spectra of **14**, **16**, and ochrobirine (**9**) all of which have two hydroxyl groups in the spiro ring are recorded in Fig. 7. The spectra show a pattern distinct from that of sibiricine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



SCHEME 7

and of **17**. The parent peak is only 10% of the base peak or less, while in sibiricine (**10**) and **17** it is the base peak, and the dihydroisoquinolinium ion is reduced in intensity.

The M-H_2O and the base peak (M-CH_3O_2) may be formed by the processes shown in Scheme 7. The loss of H_2O from **37** leads to the more stable radical **38** in which the radical center is benzylic and also conjugated to the immonium ion. The M-H_2O peak may also come from the molecular ion directly to form ion **39**. The base peak, ion **40**, can be derived either from **38** by losing a CHO radical or from **37** by concerted elimination of the neutral fragments, CH_2O and OH. The latter process is analogous to the elimination of (CO + OH) from sibiricine, in which an M-OH ion peak cannot be detected. The course of further decomposition of **40***a*, *b*, and *c* is different, each depending on the substituents either in ring A or in ring D. Ion **40***a* loses a CHO radical followed by expulsion of CO to give small peaks at *m/e* 249 and 221, while ion **40***c* can lose either CHO or CH_2O, presumably from different rings, to yield ions at *m/e* 293 and 292, each of which is capable of losing a molecule of CO to produce the respective ions at *m/e* 265 and 264. The situation is quite different in **40***b* where two methoxyl groups are in ring A. The ejection of the stable neutral fragment, CH_2O, to give an even electron ion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

seems to be a favorable process since the daughter ion peak at *m/e* 250 is quite intense. In the high mass range, when $R_3 = CH_3$, there is a small peak corresponding to M-CH_3. There is also a peak corresponding to M-($CH_3 + H_2O$), which can be derived either from ion M-CH_3 by losing H_2O or from M-H_2O by losing a CH_3 radical.

In the spectra of **14** and **9**, there is a small peak 14 mass units higher than the dihydroisoquinolinium ion and its composition has been determined to be $C_{11}H_{10}NO_3$. This ion will form in a manner similar to the corresponding ion in sibiricine and, therefore, can be assigned the structure **36** (Scheme 6).

Experimental

Apparatus, Methods, and Materials

Mass spectra were determined on a C.E.C. 21-110B double-focusing mass spectrometer. Samples were introduced through a direct inlet system. Spectra are plotted in terms of relative abundance, with the most intense peak (base peak) taken as 100%. Only those peaks with an intensity equal to or greater than 3% of the most intense peak have been recorded.

The high resolution mass spectra were recorded on Ilford Q-2 photographic plates, which were developed in the usual manner. The spectra were then recorded on magnetic tape, using a Gaertner comparator-densitometer linked to a Datex system. They were processed on a CDC-6400 computer using a modified version of the HIRES program of Tunnicliff and Wadsworth (12).

The p.m.r. spectra were routinely run on a Varian A-60 or Varian T-60 instrument in $CDCl_3$ using tetramethylsilane as internal standard. The 100 MHz spectra were recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V4315 frequency counter incorporated in the instrument. Double irradiation was achieved by employing a Hewlett–Packard 201C audiogenerator at the desired frequency.

A Perkin–Elmer 337 grating i.r. spectrometer was used to record i.r. spectra.

Melting points were determined on a Kofler hot stage and are uncorrected.

The alkaloids, fumariline, fumaricine, fumaritine, sibiricine, ochrobirine, and compounds **13** and **14**, were obtained from Dr. R. H. F. Manske of the University of Waterloo, Waterloo, Ontario. Fumarophycine was obtained from Dr. N. M. Mollov of the Bulgarian Academy of Science, Sofia, Bulgaria.

*7-Methoxy-8-hydroxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2′-(1′,3′-indandione) (**11**)*

3-Hydroxy-4-methoxyphenylethylamine hydrochloride (940 mg), prepared according to the method of Ramirez and Burger (13), was added to a solution of ninhydrin (950 mg) in absolute alcohol (20 ml). The mixture was left at room temperature for 5 days. The solvent was evaporated, the residue dissolved in hot water, basified with saturated sodium bicarbonate solution, and extracted with chloroform. The chloroform extract was dried over sodium sulfate and evaporated to dryness. The red semi-crystalline solid obtained from chloroform–hexane melted at 92–95 °C. The mass spectrum showed a molecular ion at *m/e* 309.

*7,8-Dimethoxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2′-(1′,3′-indandione) (**12**)*

Compound **11** (70 mg) was dissolved in methanol (10 ml) and excess diazomethane in ether was added to the solution which was then allowed to stand for 3 h. The solvents were allowed to evaporate and the residue recrystallized from methanol. The yellow crystalline prisms melted at 158 °C. The i.r. spectrum: $\nu_{C=O}$ ($CHCl_3$) 1700, 1745 cm^{-1}.

Anal. Calcd. for $C_{19}H_{17}NO_4$: C, 70.6; H, 5.3. Found: C, 70.6; H, 5.4.

7,8-Dimethoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline-1-spiro-2′-(1′,3′-indandione)

Compound **12** (50 mg) was mixed with formic acid (2 ml) and formaldehyde (2 ml), and heated on a steam bath for 12 h. Water was added to the mixture which was basified with saturated sodium bicarbonate solution and extracted with chloroform. The chloroform extract was washed with water, dried over sodium sulfate, and evaporated to dryness. The yellow residue was crystallized from methanol–ether, m.p. 158–159 °C. The i.r. spectrum: $\nu_{C=O}$ ($CHCl_3$) 1700, 1745 cm^{-1}.

Anal. Calcd. for $C_{20}H_{19}NO_4$: C, 71.2; H, 5.6; N, 4.2. Found: C, 71.2; H, 5.8; N, 4.3.

*6,7-Dimethoxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2′-(1′,3′-indandione) (**15**)*

The procedure for preparing **15** was similar to that for the preparation of **13** (9), but 3,4-dimethoxyphenylethylamine was used instead of 3,4-methylenedioxyphenylethylamine. The product **15** was recrystallized from chloroform–hexane, m.p. 175–179 °C. The i.r. spectrum: $\nu_{C=O}$ ($CHCl_3$) 1710, 1750 cm^{-1}.

Anal. Calcd. for $C_{19}H_{17}NO_4$: C, 70.6; H, 5.3; N, 4.6. Found: C, 70.5; H, 5.3; N, 4.6.

*6,7-Dimethoxy-1,2,3,4-tetrahydroisoquinoline-1-spiro-2′-(1′,3′-indandiol) (**16**)*

Compound **15** (100 mg) was dissolved in ethanol and sodium borohydride (100 mg) was added. The mixture was allowed to stand at room temperature for 2 h. The solvent was evaporated, water was added, and the mixture was extracted with ether. The ether extract was dried over potassium carbonate and evaporated to dryness. Compound **15** was purified on basic silica gel by thick layer chromatography and, after elution, recrystallized from ethanol, m.p. 176–180 °C. The i.r. spectrum: ν_{OH} ($CHCl_3$) 3560 cm^{-1}.

Anal. Calcd. for $C_{19}H_{21}NO_4$: C, 69.7; H, 6.4; N, 4.2. Found: C, 69.5; H, 6.3; N, 4.3.

*Preparation of **17** and **18***

Sodium borohydride (200 mg) was added slowly to a solution of 7,8-dimethoxy-2-methyl-1,2,3,4-tetrahydro-

isoquinoline-1-spiro-2′(1′,3′-indandione) (200 mg) in methanol (10 ml) and the mixture stirred at room temperature for 10 h. The solvent was evaporated, water (5 ml) was added, and the aqueous suspension was extracted with ether. The ether extract was dried over potassium carbonate and evaporated to dryness. The mixture was separated by thick layer chromatography on basic silica gel (developed in methanol–chloroform 1:20). The faster moving fraction after elution was crystallized from ethanol to give **17** (65 mg), m.p. 171–173 °C. The i.r. spectrum: $\nu_{C=O}$ ($CHCl_3$) 1705 cm^{-1}.

Anal. Calcd. for $C_{20}H_{21}NO_4$: C, 70.8; H, 6.2; N, 4.1. Found: C, 70.8; H, 6.2; N, 4.3.

The slower moving fraction after elution was crystallized from ethanol to give **18** (67 mg), m.p. 183–186 °C. The i.r. spectrum: $\nu_{C=O}$ ($CHCl_3$) 1710 cm^{-1}.

Anal. Calcd. for $C_{20}H_{21}NO_4$: C, 70.8; H, 6.2; N, 4.1. Found: C, 70.7; H, 6.2; N, 4.2.

We thank the National Research Council of Canada for financial support and Dr. R. H. F. Manske and Dr. N. M. Mollov for samples of the alkaloids used in this study.

NOTES

An Apparent Stereochemical Effect in MnO_2 Oxidation of Some Allylic Alcohols

BERT FRASER-REID, BERNARD J. CARTHY, N. L. HOLDER, AND MARK YUNKER[1]
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received May 19, 1970[2]

3,4-Di-*O*-acetyl-D-xylal undergoes acid-catalyzed reaction with ethanol to give the anomeric mixture of ethyl 2,3-dideoxy-4-*O*-acetyl-D-*glycero*-pent-2-enopyranosides which can be separated after deacetylation. The α-D anomer **1** is readily oxidized by manganese dioxide to the α,β-unsaturated ketone but the β-D anomer **2** is inert. Thorough investigation of the 100 and 220 MHz n.m.r. spectra of **1** and **2**, their acetates, and dinitrobenzoates indicates that each exists conformationally pure in the half-chair form having the benefit of the anomeric effect. Hence in the oxidizable anomer **1** the C-4 allylic hydroxyl group is pseudo-equatorial; in the unoxidizable one it is pseudoaxial. Hydrogen bonding does not appear to be the reason for failure of **2** to oxidize.

The ethoxy groups of **1** and **2** are found to be ABX_3 system with unusually large separation for the AB protons.

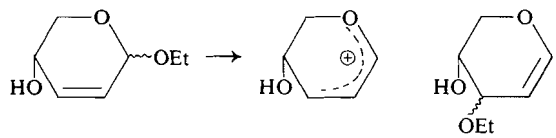
Le di-*O*-acétyl-3,4-D-xylal soumis à une réaction acido-catalysée dans l'éthanol, donne un mélange anomérique de didéoxy-2,3-*O*-acétyl-4-D *glycéro*-pentene-2-pyranosides d'éthyle. L'isomère-α-D- **1** est rapidement oxydé par le bioxyde de manganèse en cétone α,β insaturée, par contre l'isomère β **2** est inerte. L'examen des composés **1** et **2** ainsi que de leurs dérivés acétates et dinitrobenzoates, en r.m.n. 100 et 220 MHz a montré que chacun des isomères est exclusivement sous forme d'une demie chaise grâce à "l'effet anomérique". Ainsi, l'isomère oxydé **1** possède une hydroxyle allylique en C-4 pseudo équatorial. Tandis que dans **2**, le même groupe est pseudo axial.

Les groupes éthoxy dans **1** et **2** forment des systèmes ABX_3 avec une séparation inhabituellement grande des protons AB.

Canadian Journal of Chemistry, **49**, 3038 (1971)

In a recent publication from this laboratory (1) it was reported that when ethanol reacted with 3,4-di-*O*-acetyl-D-xylal under boron trifluoride catalysis (2) a mixture was produced which, after deacetylation, could be separated chromatographically into what appeared to be α- and β-anomers of ethyl 2,3-dideoxy-D-*glycero*-pent-2-enopyranoside. The faster running component **1***a* behaved normally on manganese dioxide oxidation, being converted to an α,β-unsaturated ketone within 8 h. The slower running substance **2***a*, however, gave no evidence for ketone formation after 14 days of exposure to manganese dioxide.

It seemed strange that **1***a* and **2***a* would display such a difference in oxidizability if the only difference between both compounds was the orientation of the ethoxy group at the remote anomeric center. Both compounds characterized as their dinitrobenzoate esters **1***b* and **2***b* respectively gave satisfactory microanalyses (3). As expected for an anomeric pair, both **1***a* and **2***a* lost the aglycon readily (4) to give the same strong ion, **3**, corresponding to M^+-OCH_2CH_3 at



1*a* or **2***a* **3** **4**

m/e 99. Structure **4** which could also lead to ion **3** is excluded since **1** and **2** from their n.m.r. and i.r. spectra are not vinyl ethers.

The specific rotations for **1***a* and **2***a* were +22.2 and +44.3° respectively, but it was considered unwise to use these values for assigning configuration according to the original

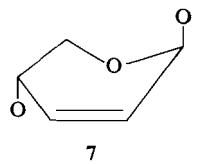
6

basis (5), since it is now clear that specific rotation and conformation are inextricably related (6).[3] Furthermore, no direct correlation could be established between the ketone and its alcohol progenitor since the ketones (**5** and **6**) obtainable from the anomers, form a DL pair and are therefore indistinguishable by n.m.r. spectroscopy.

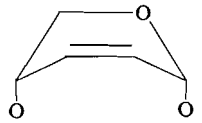
The two substances were therefore subjected to detailed n.m.r. examination in the hope of finding an explanation for the difference in their oxidizability. The spectrum of the slower-running substance **2***a* will be discussed first since it is simpler.

Compound 2

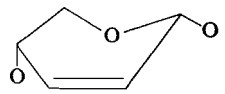
The signal for H-1 in the 100 MHz spectrum of **2***a* (Fig. 1*b*) was a doublet (J_{12} = 3.0 Hz) completely devoid of any long-range coupling; *i.e.* J_{13} = 0. Recent studies on vinyl–allylic couplings indicate that a combination of three- and four-bond parameters such as this requires pseudoequatorial orientation for the allylic proton H-1 (7–9). These same criteria can also be applied at the other "end" of the molecule to H-4. Although the signal for H-4 itself is obscured, the three-bond coupling, J_{34}, can readily be deduced from the signal for H-3. Thus J_{34} = 4.0 Hz, and since the quartet for H-2 possesses no additional fine structure (Fig. 1*b*), $J_{24} \simeq$ 0 Hz. Hence the implication is that H-4 (like H-1) is pseudoequatorial, and compound **2** must either have the β-D-arrangement **7** or the α-D-arrangement **8**. Proof that these alternatives were correct, was supplied by the quartet at τ 5.88 whose geminal coupling of 13.0 Hz assigned it to one of the C-5 protons (shown below to be the axial, H′-5) the coupling of 3.0 Hz indicated gauche relationship to H-4.



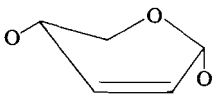
7



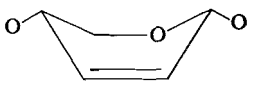
8



9



10



11

In order to confirm this reasoning, the dinitrobenzoate **2***b* was examined since H-4 had been made observable by the esterification (Fig. 2).

[3]Indeed, as will be seen, the more dextrorotatory substance is the β-D anomer, **2***a*, in contravention of the isorotation rules (5).

It was necessary to ensure that esterification had affected only the chemical shift and not the orientation of H-4 or any other proton. One very dramatic effect of esterification was in the decreased chemical shift for the olefinic protons which now gave overlapping signals even at 220 MHz (Fig. 2*d*). Because of this, H-3, -2, and -1 which comprised an ABX system in **2***a* are transformed into an AA′X system in **2***b*. The spacings displayed by H-1 in the ester, J', are therefore expected to be the average of J_{12} and J_{13} (11). Using J_{12} and J_{13} (3.0 and 0 Hz respectively) obtained from the parent alcohol **2***a*, the calculated value for J' was found to be 1.5 Hz in agreement with the observed value, (recorded in Table 1 as J_{12}). However the doublet (for H-1) remained "pure" suggesting that esterification had not altered the orientation around C-1; *i.e.* H-1 was still pseudoequatorial in **2***b*. Nor had the arrangement around H-4 been altered since the low field quartet for the equatorial H′-5 showed no dramatic changes in either its chemical shift or its spacings as compared with the alcohol, **2***a* (see Table 1). The other C-5 proton (H-5) not readily discernable in **2***a* (Fig. 1*b*) but now obvious at τ 6.03 in the 220 MHz spectrum of **2***b* (Fig. 2*d*) had a vicinal coupling of 1.7 Hz. The two vicinal couplings indicate gauche relationships between *both* C-5 protons and H-4.
