Deproteinized meal (440 g) was stirred vigorously in water (4 l) for 3 h at 85°. Residual meal was removed by centrifugation and the extraction was repeated. The combined aqueous extracts were concentrated and freeze-dried to give crude polysaccharide extract (25 g) (found: total carbohydrate (as galactan by the phenol – sulfuric acid method (16)), 50; uronic acid residues, 12; protein, 25%), which gave on hydrolysis galacturonic acid, galactose, arabinose, and traces of glucose, xylose, fucose, and rhamnose. The crude polysaccharide extract in water (1300 ml) was shaken for 1 h with chloroform (325 ml) and amyl alcohol (65 ml). The chloroform layer and the emulsion which formed at the interface were separated, and the aqueous layer was poured into ethanol (1.5 volume) to give fraction 1 (11.8 g), $[\alpha]_D$ + 49.4° (*c*, 0.26) (found: uronic acid residues, 15; protein, 2%), which gave on hydrolysis galacturonic acid, galactose, arabinose, xylose, fucose, and rhamnose. The supernatant liquid was then concentrated and poured into ethanol (5 volumes) to give a precipitate which was dissolved in water and freeze-dried to give fraction 2 (arabinan, 4.9 g), $[\alpha]_D$ − 108° (*c*, 0.33), which gave on hydrolysis arabinose as the main sugar with small amounts (< 5%) of galactose and rhamnose, and traces of 2-*O*-methylxylose and 2-*O*-methylfucose. Electrophoresis showed the presence of a single component of mobility $\mu = 2.3 \times 10^{-5}$ cm^2 V^{-1} s^{-1}.

Polysaccharide fraction 1 (11 g) was chromatographed on diethylaminoethylcellulose (acetate form, 150 g) and elution with 0.04 *M* potassium acetate (10 l) and a gradient of 0.04–0.30 *M* potassium acetate (8 l) gave polysaccharide fractions 1*a* and *b*. Fraction 1*a* was brought to p*H* 5 by the addition of acetic acid, concentrated (to 600 ml) and poured into ethanol (2 volumes). The precipitate was washed with ethanol–water (4:1), dissolved in water, and freeze-dried to give arabinogalactan (4.1 g), $[\alpha]_D$ + 51° (*c*, 0.84), hydrolysis of which gave galactose, arabinose, and traces of glucose, xylose, fucose, and rhamnose. Quantitative analysis (17) of the hydrolysate showed the presence of arabinose and galactose in the proportions of 1:2.8. Electrophoresis showed the presence of a major component of mobility $\mu = 2.0 \times 10^{-5}$ cm^2 V^{-1} s^{-1} with only traces of a faster-moving component. Fraction 1*b* was treated similarly and afforded acidic polysaccharide complex (4 g), $[\alpha]_D$ + 57° (found: uronic acid residues, 24; OMe, 2%), hydrolysis of which gave galacturonic acid, galactose, arabinose, xylose, fucose, and rhamnose. Electrophoresis showed the presence of two components of mobility μ = 3.0 and 5.0 $\times 10^{-5}$ cm^2 V^{-1} s^{-1}.

Arabinan

Arabinan (290 mg) was methylated with methyl iodide and sodium hydride in dimethylsulfoxide as described by Sandford and Conrad (18), and gave methylated arabinan (240 mg), $[\alpha]_D$ − 130° (*c*, 1.69 $CHCl_3$) (found: OMe, 37.9%). A sample of the methylated polysaccharide was methanolyzed and g.l.c. on columns *a* and *b* showed components with the retention times of methyl glycosides of 2,3,5-tri- and 2,3-di-*O*-methylarabinose as major components. Although no methyl glycosides of 2-*O*-methylarabinose were detected, paper chromatography of the hydrolysate from the methylated arabinan showed the presence of 2,3,5-tri-, 2,3-di-, and 2-*O*-methylarabinose as major components, with smaller amounts of arabinose and 3-*O*-methylarabinose. Arabinan (20 mg) was oxidized in aqueous 1% sodium metaperiodate (3 ml) and aliquot portions (40 µl) were withdrawn every 2 h, diluted (× 500), and examined spectrophotometrically (19). The results indicated that oxidation was complete after 12 h with the consumption of 0.69 mol of reagent per sugar residue. Excess of periodate was destroyed by the addition of ethylene glycol, and the solution was dialyzed, and sodium borohydride was added. After 18 h, the solution was treated with Amberlite resin IR-120(H) to remove sodium ions and repeated distillations with methanol removed boric acid as methyl borate leaving a residue which gave arabinose on hydrolysis.

Arabinogalactan

Arabinogalactan (240 mg) was methylated with methyl iodide and sodium hydride in dimethylsulfoxide (18) to give methylated arabinogalactan (160 mg), $[\alpha]_D$ − 17° (*c*, 0.69 $CHCl_3$) (found: OMe, 41.1%). A sample of the methylated polysaccharide was methanolyzed and g.l.c. showed the presence of components with the retention times of methyl glycosides of 2,3,4- and 2,3,5-tri-, and 2,3-di-*O*-methylarabinose, and 2,3,4,6-tetra-, 2,3,6-tri-, and 2,6-di-*O*-methylgalactose. No accurate quantitative estimation could be made due to incomplete resolution of all peaks; however, in connection with the data recorded in Table 1, the relative peak heights indicated that methyl glycosides of 2,3,4,6-tetra-*O*-methylgalactose and

2,3-di-*O*-methylarabinose were present in the approximate proportion of 1:4. Paper chromatography of the hydrolysate from the methylated polysaccharide showed the presence of the above-mentioned but no additional sugars.

Gas-liquid Chromatography – Mass Spectrometry of Methylated Alditol Acetates from Methylated Polysaccharides

Samples of the following methylated polysaccharides were examined: methylated soybean arabinan, methylated soybean arabinogalactan, methylated lemon-peel arabinan (13), and methylated mustard seed arabinan. The latter methylated polysaccharide was prepared as described by Hirst *et al.* (6). Methylated polysaccharide (10 mg) was hydrolyzed by heating overnight on a boiling-water bath in aqueous 45% formic acid. The cooled hydrolysate was neutralized to p*H* 8 by the addition of concentrated ammonia. Sodium borohydride (75 mg) was added, the solution was kept at room temperature for 4 h, and a further quantity of sodium borohydride was added. The solution was left for 16 h, checked for completeness of reduction with the phenol sulfuric acid reagent (16), and passed through a column of Amberlite resin IR-120(H). The eluate and washings were concentrated to dryness, boric acid was removed by repeated evaporation with methanol, and the residue was acetylated with acetic anhydride (1 ml) and pyridine (1 ml) overnight. Water was added to the reaction mixture which was then concentrated to small volume and co-distilled several times with chloroform. The residue was dissolved in chloroform for g.l.c. – mass spectrometry. The proportions of methylated alditol acetates were estimated from the peak areas on the gas chromatograms and the results are summarized in Table 1.

The identities of most of the acetylated alditol acetates were established by (*i*) comparison of their retention times with those of the previously characterized products from methylated mustard seed arabinan (6, 7) or of known standards, and (*ii*) the appearance in the mass spectra of fragment ions having intensities of more than 10% of the base peak as reported by Björndal *et al.* (12). In all cases primary fragment ions, which were characteristic of the various substitution patterns, were detected. Although no standard for 3-*O*-methylarabinitol tetraacetate was available, the appearance of a primary fragment ion *m/e* 189 left little doubt as to the identity of this component. In examining the partially methylated alditol acetates from methylated soybean arabinogalactan some tailing of the g.l.c. peak of the major component, 2,3,6-tri-*O*-methylgalactitol triacetate, was observed. Since the following component, 2,6-di-*O*-methylgalactitol tetraacetate, may have been contaminated by the trimethyl ether and gives no unique additional fragment ions in the mass spectrum, the assignment of structure to this component is also based on the absence of primary fragments which could have arisen from isomeric dimethyl ethers.

We acknowledge generous financial support from the National Research Council of Canada. We thank Mr. J. M. Cashmore for assistance in the mass spectrometry and Dr. D. A. Rees for a sample of mustard seed arabinan.

Kinetics of the Reaction of Atomic Hydrogen with Vinyl Chloride

J. S. TANNER AND J. W. S. JAMIESON
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received June 29, 1970

The reaction of hydrogen atoms, produced by electric discharge, with vinyl chloride vapor has been studied at four widely different temperatures. Since the maximum yields of HCl at both 328 and 494 °C exceeded the flow rates of atomic hydrogen, the reaction was observed to have limited chain characteristics. The products were hydrogen chloride, ethylene, methane, and ethane. The specific reaction rate for HCl production was found to be about $6 \times 10^{-13} e^{-2.75 \times 10^3/RT}$ and that for production of ethylene plus ethane was found to be about $3 \times 10^{-13} e^{-2.80 \times 10^3/RT}$.

La réaction d'atomes d'hydrogène, produits par une décharge électrique, avec le chlorure de vinyle en phase a été étudiée à quatre températures différentes. A cause du fait que les rendements maxima d'HCl à 328 et 494 °C étaient plus grands que les taux de diffusion des atomes d'hydrogène, les caractéristiques d'une réaction en chaîne étaient limitées. Les produits formés sont: l'acide chlorhydrique, l'éthylène, le méthane, et l'éthane. La vitesse spécifique de réaction pour la production d'HCl est approximativement $6 \times 10^{-13} e^{-2.75 \times 10^3/RT}$ et celle pour la production d'éthylène plus éthane est d'environ $3 \times 10^{-13} e^{-2.80 \times 10^3/RT}$.

Introduction

A study of the reaction of vinyl chloride with atomic hydrogen was undertaken since it was thought that this reaction might be suitable for measurement of the hydrogen atoms available for reaction, particularly at ambient temperature. Although this possibility was eliminated after it became apparent that a chain mechanism was involved, other interesting results have been obtained.

Experimental

Materials

Hydrogen was purchased from the Linde Gases Division, Union Carbide Canada Limited and vinyl chloride was supplied by Matheson of Canada Limited.

Apparatus and Methods

The apparatus, which was a fast-flow system of the conventional Wood–Bonhöffer type, has recently been described (1). At least twice during the course of the investigation the walls of the discharge tube and the reaction vessel were coated with Na_2HPO_4 to retard the combination of hydrogen atoms. Unreacted vinyl chloride and all the condensable products except methane were collected at liquid nitrogen temperature in large traps immediately below the reaction vessel, while methane was collected according to the method of Demchuk and Gesser (2) in a further trap containing silica gel. The HCl, which was the main product of the reaction, was distilled into a removable trap containing either water or standard base so that the acid could be determined by titration with either standard base or standard acid. Methane was transferred laboriously with the use of a Töpler pump to a gas burette for measurement of the quantity of gas before verifying its purity by gas chromatography. After measurement in a gas burette all the gaseous products of the reaction (except HCl) were analyzed by gas chromatography, using helium as carrier gas, a Gow–Mac thermal conductivity cell Model 9193, TE-II, a Leeds and Northrup Speedomax Type G, Model "S" 1 s recorder, and a 9 ft Porasil B column (for ethane, ethylene, and vinyl chloride) or a 4 ft molecular sieve 5A column (for methane). In some of the early experiments a 6 ft Porapak Q column was used. Since it did not give a very good separation of ethane and ethylene it was soon replaced by the Porasil B column.

Flow rates of vinyl chloride were estimated in experiments with the hydrogen discharge off. The vinyl chloride was trapped at liquid nitrogen temperature and distilled into a known volume connected to a manometer which was used to measure the pressure of the vapor at ambient temperature. No impurities were detected in the vinyl chloride since each sample analyzed by gas chromatography gave a single peak, even at 494 °C. Thus there was no evidence of thermal decomposition under the experimental conditions used.

In all experiments the flow rate of molecular hydrogen was 92.3 μmol/s, which gave a pressure of 1.10 mm in the reaction system. The atomic hydrogen flow rates at the various reaction temperatures were estimated from the maximum extent of the reactions of ethyl chloride (3) and formamide (3) with hydrogen atoms.

Results and Discussion

The flow rates of atomic hydrogen estimated at the various reaction temperatures are given in Table 1. The only products detected were HCl, ethylene, methane, and ethane. Acetylene was specifically sought but not found. No polymer formation was observed.

Since HCl was the only chlorine-containing product found it has been assumed that the

TABLE 1. Atomic hydrogen flow rates

Temperature (°C)	H Atoms flowed μmol/s
32	1.3
141	2.1
328	1.7
494	1.4

amounts of HCl produced are equal to the amounts of vinyl chloride reacted. Alternative estimates of the amounts of vinyl chloride reacted, obtained by subtraction of the amounts of vinyl chloride recovered (estimated from gas chromatography peaks) from the amounts of vinyl chloride flowed, were more erratic.

The amounts of ethane produced were never greater than one-third of the ethylene formed. Ethane production was highest at low reactant flow rates in experiments at the lower temperatures; it decreased to negligible amounts at higher reactant flow rates, particularly at the higher temperatures. The ethane results have not been shown separately.

The results obtained from ambient temperature to 494 °C are given in Figs. 1 and 2 which show that the maximum yields of HCl at both 328 and 494° and the maximum yield of ethylene plus ethane at 494° were substantially higher than the flow rates of hydrogen atoms at these temperatures. Thus it is obvious that a chain mechanism is involved, but only to a limited extent. The results which indicate a maximum extent of reaction ("clean-up" or "plateau" values) appear to be due to the fact that the total concentration of hydrogen atoms per unit time available for reaction, although augmented by occurrence of the chain mechanism, would still be limited by the occurrence of chain termination steps.

Specific reaction rates have been calculated with an IBM 360/50 computer from the usual second-order expressions (1) for conditions of both streamline and turbulent flow. The Arrhenius plots of Figs. 3 and 4 are essentially linear (within the limits of experimental error); hence no change of mechanism is implied. Figure 3 shows that the production of HCl was very rapid ($A = 2.7 \times 10^{-13}$, $E = 2.6$ kcal, for streamline flow; $A = 8.5 \times 10^{-13}$, $E = 2.9$ kcal, for turbulent flow).

It appears unlikely, however, that the HCl could have been formed in the primary step, since the only feasible chain carrier in this reaction would be atomic chlorine. Thus the initial reaction is probably [1]. Enthalpy changes for this and subsequent reactions have been calculated from recently published standard heats of formation at 298 °K (4–6).

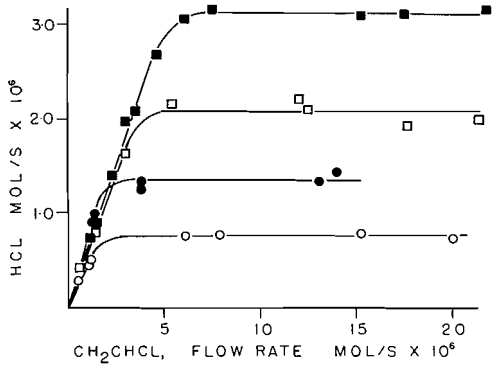

FIG. 1. HCl produced at 32 (○), 141 (●), 328 (□), and 494 °C (■).

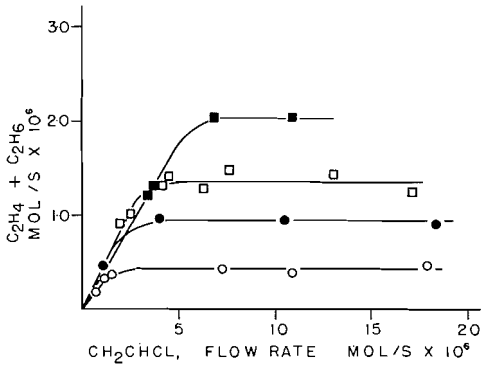

FIG. 2. Ethylene plus ethane produced at 32 (○), 141 (●), 328 (□), and 494 °C (■).

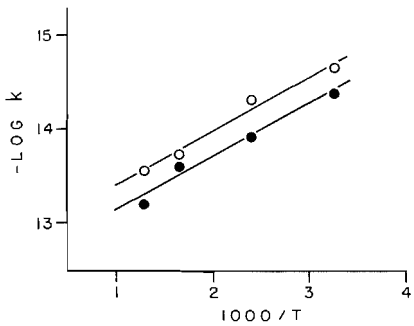

FIG. 3. Arrhenius plots for streamline flow: HCl production (●), production of ethylene plus ethane (○).

[1] $H + CH_2{=}CH{-}Cl \rightarrow CH_2{=}CH_2 + Cl$ $\quad \Delta H = -18.0$ kcal

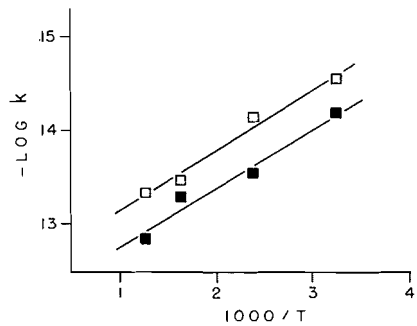

FIG. 4. Arrhenius plots for turbulent flow: HCl production (■), production of ethylene plus ethane (□).

The transition state for reaction 1 would resemble the radical C_2H_4Cl and there is some probability that this entity could exist for an appreciable time so that the reaction could take place in two steps, [2] and [3]. If so, the radical

[2] $H + CH_2{=}CH{-}Cl \rightarrow C_2H_4Cl \quad \Delta H = -40.0$ kcal

[3] $C_2H_4Cl \rightarrow CH_2{=}CH_2 + Cl \quad \Delta H = +22.0$ kcal

C_2H_4Cl might also decompose according to reaction 4, although no butadiene has been found

[4] $C_2H_4Cl \rightarrow CH_2{=}CH + HCl \quad \Delta H = +22.0$ kcal

among the products of the over-all reaction of atomic hydrogen with vinyl chloride.

Reactions 3 and 4 would probably not occur unless the radical C_2H_4Cl retained some or all of the energy released in reaction 2 so that the decomposition reactions would be exothermic, [3′] and [4′]. If the vibrationally excited radical

[3′] $C_2H_4Cl^* \rightarrow CH_2{=}CH_2 + Cl \quad \max \Delta H = -18.0$ kcal

[4′] $C_2H_4Cl^* \rightarrow CH_2{=}CH + HCl \quad \max \Delta H = -18$ kcal

$C_2H_4Cl^*$ had a sufficiently long lifetime it might also react with atomic hydrogen, [5] and [6].

[5] $H + C_2H_4Cl^* \rightarrow CH_3{-}CH_2 + Cl \quad \max \Delta H = -56.9$ kcal

[6] $H + C_2H_4Cl^* \rightarrow CH_2{=}CH + HCl \quad \max \Delta H = -121.3$ kcal

Since HCl was rapidly formed and no other chlorine-containing products, such as might have been formed by combination and other reactions of C_2H_4Cl or $C_2H_4Cl^*$, were detected, it is very likely that reaction 1 is the main primary reaction.

The chain characteristics would then be due to reaction 7, which is known (7) to be very fast. This

[7] $Cl + H_2 \rightarrow HCl + H \quad \Delta H = +0.951$ kcal

reaction not only regenerates atomic hydrogen but also can account for the rapid production of HCl.

The fact that only small quantities of ethane were found except at low flow rates of vinyl chloride might seem to imply that ethane is formed solely by the addition of excess hydrogen atoms to ethylene, [8] and [9].

[8] $H + CH_2{=}CH_2 \rightarrow CH_3{-}CH_2 \quad \Delta H = -38.9$ kcal

[9] $H + CH_3{-}CH_2 \rightarrow CH_3{-}CH_3 \quad \Delta H = -98.0$ kcal

The rate of production of ethylene plus ethane was found to be slightly slower ($A = 1.5 \times 10^{-13}$, $E = 2.6$ kcal, for streamline flow; $A = 3.6 \times 10^{-13}$, $E = 3.0$ kcal, for turbulent flow) than the rate of production of HCl, although the activation energies were virtually identical. Perhaps the most striking feature of the present investigation is that the reaction of atomic hydrogen with vinyl chloride seems to be essentially independent of flow conditions, since the measured rates of HCl production and of production of ethylene plus ethane agreed reasonably well when calculated for conditions of both streamline and turbulent flow.

Differences in these rates were probably due to the fact that some of the ethylene formed in reaction 1 reacted further to form methane. Due to the difficulty of accurately measuring the pressure of a small quantity of gas in a large volume and also the difficulty of completely transferring a small amount of a non-condensable gas with a Töpler pump into a small volume of a gas burette, quantitative results for methane were not obtained at all temperatures. At 141 °C, however, the results given in Table 2 were obtained. These data and those of Figs. 1 and 2 show that there was a reasonable carbon balance for experiments at this temperature. At the other temperatures the quantities of methane collected

TABLE 2. Methane produced at 141 °C

Vinyl chloride flowed μmol/s	Methane produced μmol/s
3.98	0.64
10.5	0.62
18.4	0.52

and measured in several experiments were of the magnitude to indicate the probability of a material balance for the overall reaction.

It appears that methane and ethane might have a common precursor, which could be either ethyl radical or methyl radical, since the formation of both methane and ethane would involve successive hydrogen atom reactions, but practically no ethane was produced at high vinyl chloride flow rates, particularly at high temperatures. Thus reaction 9 might be in competition with reactions 10 and 11. Methyl radicals formed in reaction 10

[10] $H + CH_3—CH_2 \rightarrow 2CH_3 \quad \Delta H = -11.4$ kcal

[11] $H + CH_3—CH_2 \rightarrow CH_4 + CH_2 \quad \Delta H = -2.0$ kcal

might then combine, [12], or react further with

[12] $2CH_3 \rightarrow CH_3—CH_3 \quad \Delta H = -86.6$ kcal

atomic hydrogen to form methane, [13], or react

[13] $H + CH_3 \rightarrow CH_4 \quad \Delta H = -103.2$ kcal

with HCl, [14], since it has been reported (8–10)

[14] $CH_3 + HCl \rightarrow CH_4 + Cl \quad \Delta H = +0.1$ kcal

that reaction 14 has an activation energy of less than 5 or 6 kcal.

If methylene radicals were formed in reaction 11 they could probably react readily with molecular hydrogen to form methane, reaction 15.

[15] $CH_2 + H_2 \rightarrow CH_4 \quad \Delta H = -111.6$ kcal

Termination of the chain mechanism would seem to be due to the occurrence of reactions which consume hydrogen atoms, such as reactions 8–11, 13, and 16 which would take place at the reaction vessel wall or in the first cold trap. Even at high vinyl chloride flow rates reactions 10 and 16, as well as reactions 11 and 13 which form methane, could be chain termination steps.

[16] $2H(+M) \rightarrow H_2(+M) \quad \Delta H = -104.190$ kcal

Financial assistance from the National Research Council of Canada is gratefully acknowledged. The authors are also grateful to Mr. D. W. Lemon for his assistance in the early stages of the experimental investigation.

Transannular Reactions in the Dibenzo[*a*,*d*]cycloheptene Series. V. Preparation of 10,11-Dihydro-5,10-(iminomethano)-5*H*-dibenzo[*a*,*d*]cycloheptenes

T. A. Dobson and M. A. Davis
Ayerst Research Laboratories, Montreal, Quebec

Received August 25, 1970

Treatment of the ketonitrile **2***a* with sodium borohydride gave the lactone **3***a* which underwent ammonolysis to give 10,11-dihydro-5,10-(iminomethano)-5*H*-dibenzo[*a*,*d*]cyclohepten-13-one (**5***a*). This compound was used to prepare a number of 12- and 11,12-disubstituted derivatives of the ring system.

La réduction du céto-nitrile **2***a* par le borohydrure de sodium conduit à la lactone **3***a* qui, par ammonolyse, donne la dihydro-10,11 iminométhano-5,10 5*H*-dibenzo[*a*,*d*]cycloheptène-13 one (**5***a*). Ce composé a été utilisé pour préparer un certain nombre de dérivés substitués en -12 et -11,12 de ce système cyclique.

Canadian Journal of Chemistry, **49**, 1027 (1971)

We have previously (1) described the preparation of 10,11-dihydro-10,5-(iminomethano)-5*H*-dibenzo[*a*,*d*]cycloheptene derivatives. The pharmacological properties of these compounds were of sufficient interest to prompt us to prepare derivatives of the isomeric ring system **1**. Since previous work (2–4) has shown that suitably oriented substituents at positions 5 and 10 of the dibenzo[*a*,*d*]cycloheptene nucleus readily interact to form bridged systems, the same principle was adopted in the present case.

Treatment of the ketonitrile **2***a* with sodium borohydride followed by acid treatment resulted not only in reduction of the carbonyl group but also reduction of the 10,11- double bond and formation of the lactone **3***a*. A small amount of **3***a* was also obtained when the acid treatment was omitted. Nauta and his co-workers have recently reported that borohydride treatment of **2***a* gave a tetracyclic product (5). The reduction of the 10,11- double bond accords with the similar reduction of cinnamic acid esters (6). It is not clear whether the lactone **3***a* is formed via an iminolactone generated by an intramolecular Pinner reaction (7) or by prior hydration or hydrolysis of the nitrile function.

Support for the iminolactone pathway was obtained by converting **2***a* to the formamide **2***b* by the Leuckart reaction (8) and treating this product with sodium borohydride. The major product was the amidine **4**, precluding hydration or hydrolysis of the nitrile in this instance. A small amount of the lactam **5***a* was also obtained. On the other hand, treatment of the ketal **2***c* with sodium borohydride gave moderate amounts of the amide **6***a* and the acid **6***b* as well as the nitrile **6***c*. This ready hydration and hydrolysis of the 10-nitrile function contrasts markedly with the resistance of 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene-5-nitrile to similar reaction conditions (9).

Ammonolysis of the lactone **3***a* proceeded normally, as with the structurally related 4-phenylisochromanone (10), giving a better route to the lactam **5***a*. In marked contrast, the isomeric lactone **7** decarboxylates under similar conditions (1). The substituted lactams **5***b*, *c* were prepared by using methylamine and ethylamine respectively in place of ammonium hydroxide. Reduction of **5***a–c* with lithium aluminum hydride gave the amines **1***a–c*. Similar reduction of the phenylacetyl derivative of **1***a* gave **1***d*.

Several attempts were made to prepare 11-substituted derivatives of **1**. Despite the ready addition of hydride ion to **2***a*, attempts to add secondary amines were unsuccessful. Substituted acrylonitriles are known to be less reactive than acrylonitrile in cyanoethylation reactions (11). Bromination of **3***a* with *N*-bromosuccinimide gave the bromolactone **3***b*. Unfortunately this compound did not serve as a source for other 11-substituted lactones since treating it with dimethylamine gave the amide **2***d*. Similar bromination of the lactam **5***b* gave a mixture of two epimeric bromolactams **5***d*. They[1] were formed in approximately equal amounts but only one

[1]A referee has pointed out that the difference in chemical shifts of the C-11 protons in the isomers of A and B of **5***d* (see Experimental) is most probably due to the shielding effect of the amide carbonyl group. Isomer A will therefore be the *syn*-11-bromo compound (with respect to the amide bridge) and isomer B will be the *anti*-11-bromo compound.

epimer was readily isolated in a pure state. This compound readily underwent displacement reactions when it was treated with pyrrolidine and with sodium methoxide to give **5***e*, *f* respectively. Reduction of **5***e*, *f* with lithium aluminum hydride gave the amines **1***e*, *f*.

Since **8***a*, *b* are known to exist in the carbinolamine and carbinolamide forms (4), it was of interest to determine whether or not the isomeric **9***a*, *b* exhibited the same behavior. Deketalization of **6***a* gave the ketocarboxamide **9***a* and catalytic hydrogenation of **6***c* followed by deketalization gave the amino-ketone **9***b*. Methylation of **9***b* with formic acid – formaldehyde gave **9***d*. Spectral data indicated that **9***a*, *b*, *d* existed in the open form in neutral, acidic and basic media. In contrast, **9***e* is known to exist in the hemiketal form in alkaline media (2, 3), demonstrating that the 5-keto function is able to interact with bridge substituents in certain cases.

Experimental

The n.m.r. spectra in the indicated solvents were determined using a Varian A-60A instrument; melting points were recorded on a Thomas-Hoover Uni-melt apparatus.

5-Oxo-5H-Dibenzo[a,d]cycloheptene-10-carbonitrile (2a)

This material was prepared as described by Nauta and co-workers (5) except that dimethyl formamide was used as the reaction medium. The yield was 90%.

The ethylene ketal **2***c* was prepared by heating under

reflux a mixture of **2***a* (3.0 g), ethylene glycol (4.0 ml), benzene (50 ml), and *p*-toluenesulfonic acid (250 mg) for 2 days. The product (2.9 g) had m.p. 118–120° (from ethanol).

Anal. Calcd. for $C_{18}H_{13}NO_2$: C, 78.53; H, 4.76; N, 5.09. Found: C, 78.31; H, 4.67; N, 5.28.

10,11-Dihydro-5,10-(epoxymethano)-5H-dibenzo[a,d]-cyclohepten-13-one (3a)

A mixture of **2***a* (70.0 g) and sodium borohydride (25 g) in ethanol (800 ml) was stirred and heated under reflux for 16 h. The reaction mixture was evaporated and the residue was dissolved in water. The solution was acidified and extracted with chloroform. Evaporation of the extracts and crystallization of the residue gave 56.5 g (80%) of the lactone, m.p. 148–150°; n.m.r. ($CDCl_3$), τ: 6.92 (1H at C-11, q, J = 5, 17 Hz); 6.33 (1H at C-11, q, J = 5, 17 Hz); 5.91 (1H at C-10, t, J = 5 Hz); 4.03 (1H at C-5, s); 2.69 (8-H aromatic, m).

Anal. Calcd. for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12. Found: C, 81.49; H, 4.83.

5-Formamido-5H-dibenzo[a,d]cycloheptene-10-carbonitrile (2b)

A mixture of **2***a* (3.3 g), formamide (16 ml), and acetic acid (1.6 ml) was heated under reflux for 1 h. The mixture was poured into water and the precipitate was crystallized from ethanol (charcoal) to give 2.7 g of the formamide (73%), m.p. 204–206°; γ_{max} (Nujol) 3300, 2215, and 1660 cm^{-1}.

Anal. Calcd. for $C_{17}H_{12}NO$: C, 78.44; H, 4.65; N, 10.76. Found: C, 78.29; H, 4.86; N, 10.91.

10,11-Dihydro-5,10-(iminomethano)-5H-dibenzo[a,d]-cyclohepten-13-imine (4)

A mixture of **2***b* (15.0 g), sodium borohydride (15.0 g), and ethanol (300 ml) was heated under reflux for 8 h. The mixture was concentrated and then diluted with water. The precipitate was crystallized from ethanol to give 6.5 g of the title product, m.p. 241–243°.

The mother liquors were evaporated and the residue was chromatographed on a neutral alumina column to give 1.07 g of the lactam **5***a*, m.p. 227–229°, and a further 2.5 g of the title product (total yield 67%); n.m.r. ($CDCl_3$), τ: 7.42 (1H at C-11, q, J = 4, 18 Hz); 6.91 (1H at C-11, q, J = 4, 18 Hz); 6.33 (1H at C-10, t, J = 4 Hz); 4.93 (1H at C-5, s); 4.57 (2H at HN—C—NH, unresolved multiplet); 3.18, 2.93 (8H aromatic, m).

Anal. Calcd. for $C_{16}H_{14}N_2$; C, 82.02; H, 6.02; N, 11.96. Found: C, 82.22; H, 5.99; N, 11.73.

10,11-Dihydro-5,10-(iminomethano)-5H-dibenzo[a,d]-cyclohepten-13-one (5a)

A mixture of **3***a* (35.0 g) and ammonium hydroxide (500 ml, d 0.88) was heated in an autoclave for 10 h at 175°. The solid product was collected and crystallized from ethanol to give 30.0 g (88%) of the lactam, m.p. 227–229°; n.m.r. (DMSO), τ: 7.00 (1H at C-11, q, J = 4, 16 Hz); 6.42 (1H at q, J = 4, 16 Hz); 6.18 (1H at C-10, t, J = 4 Hz); 4.98 (1H at C-5, d; singlet after D_2O exchange); 2.75 (8H aromatic, m); 1.6 (NH, m).

Anal. Calcd. for $C_{16}H_{13}NO$: C, 81.68; H, 5.57; N, 5.85. Found: C, 81.39; H, 5.40; N, 5.82.

Reaction of 2c with Sodium Borohydride

A mixture of **2***c* (5.0 g), sodium borohydride (5.0 g), and ethanol (100 ml) was heated under reflux for 2 h. The mixture was evaporated, diluted with water and extracted with chloroform. Evaporation of the extracts and crystallization of the residue from chloroform–hexane gave 3.5 g of the ketal **6***c*, m.p. 113–115°; n.m.r. ($CDCl_3$), τ: 6.24 (3H at C-10 and -11, m); 5.88 (4H, ketal, m); 2.78 (8H aromatic, m).

Anal. Calcd. for $C_{18}H_{15}NO_2$: N, 5.05. Found: N, 5.12.

Fractional crystallization of the mother liquors from **6***c* gave 0.9 g of the amide **6***a*, m.p. 172–174° (from isopropanol); λ_{max} (EtOH) 265 (ε 680), 272 mμ (ε 502).

Anal. Calcd. for $C_{18}H_{17}NO_3$: C, 73.20; H, 5.80; N, 4.74. Found: C, 73.16; H, 5.92; N, 4.83.

The original aqueous solution was acidified to give 0.2 g of the acid **6***b*, m.p. 182–184° (from isopropanol); λ_{max} (EtOH) 264 mμ (ε 640).

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44. Found: C, 73.16; H, 5.55.

Treatment of **6***c* with aqueous sodium hydroxide gave more **6***a* and *b*.

Deketalization of **6***c* (1.9 g) with a mixture of ethanol (25 ml) and 3 *N* HCl (25 ml) at room temperature gave the ketonitrile **9***c* (1.3 g), m.p. 108–110° (from isopropanol); λ_{max} (EtOH) 271 mμ (ε 16 050) (unchanged on addition of either 0.1 *N* HCl or 0.1 *N* NaOH).

Anal. Calcd. for $C_{16}H_{11}NO$: C, 82.38; H, 4.75; N, 6.01. Found: C, 82.19; H, 4.52; N, 6.10.

Similar treatment of **6***a* gave the ketoamide **9***a*, m.p. 178–180° (from isopropanol); λ_{max} (EtOH) 271 mμ (ε 15 880).

Anal. Calcd. for $C_{16}H_{13}NO_2$: C, 76.47; H, 5.22; N, 5.57. Found: C, 76.63; H, 5.08; N, 5.43.

10,11-Dihydro-12-methyl-5,10-(iminomethano)-5H-dibenzo[a,d]cyclohepten-13-one (5b)

A suspension of **3***a* (10.0 g) in 40% aqueous methylamine was heated in an autoclave for 8 h at 180°. The solids were crystallized from ethanol to give 9.0 g (87%) of the lactam, m.p. 244–246°.

Anal. Calcd. for $C_{17}H_{15}NO$: C, 81.9; H, 6.06; N, 5.62. Found: C, 81.56; H, 5.88; N, 5.33.

The same product (4.8 g) was obtained when **5***a* (5.0 g) was methylated with sodium hydride and methyl iodide in anhydrous benzene.

10,11-Dihydro-12-ethyl-5,10-(iminomethano)-5H-dibenzo[a,d]cyclohepten-13-one (5c)

A mixture of **3***a* (7.0 g), ethylamine (15.0 g), and water (50 ml) was kept at 175° for 10 h. The mixture was extracted with methylene chloride and the extracts were washed with 2 *N* HCl and evaporated. The residue was recrystallized from methanol to give 5.68 g (68%) of the lactam, m.p. 250–252°.

Anal. Calcd. for $C_{18}H_{17}NO$: C, 82.40; H, 6.46; N, 5.32. Found: C, 82.20; H, 6.51; N, 5.32.

10,11-Dihydro-5,10-(iminomethano)-5H-dibenzo[a,d]-cycloheptene Hydrochloride (1a)

Lithium aluminum hydride (5.0 g) was added portionwise to a stirred suspension of **5***a* (15.0 g) in anhydrous tetrahydrofuran (300 ml). The mixture was heated under reflux for 6 h and then cooled and cautiously

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

treated with water. The mixture was filtered and the filtrate was evaporated to dryness to leave the oily free base. The hydrochloride salt was crystallized from ethanol–ether to m.p. > 270°; n.m.r. ($CDCl_3$) (free base). τ: 7.72 (NH, s); 6.75 (CH_2—CH—CH_2, m); 5.27 (1H at C-5); 2.87 (8H aromatic, m).

Anal. Calcd. for $C_{16}H_{16}ClN$: C, 74.56; H, 6.22; Cl, 13.76; N, 5.44. Found: C, 74.54; H, 6.16; Cl, 14.29; N, 5.39.

The *N*-acetyl derivative was prepared by heating the free amine with an excess of acetic anhydride for 2 h on the steam bath. It showed m.p. 210–212° (from isopropanol).

Anal. Calcd. for $C_{18}H_{17}NO$: C, 82.14; H, 6.46; N, 5.32. Found: C, 81.87; H, 6.38; N, 5.26.

The *N*-phenylacetyl derivative was prepared from the free amine, phenylacetyl chloride, and anhydrous pyridine. It had m.p. 122–124° (from isopropanol).

Anal. Calcd. for $C_{24}H_{21}NO$: C, 84.92; H, 6.24; N, 4.13. Found: C, 84.65; H, 6.24; N, 4.01.

The *N*-methyl derivative, **1***b*, was prepared from the amine, formaldehyde, and formic acid. The hydrochloride salt had m.p. 244–247° (from isopropanol); n.m.r. ($CDCl_3$) (free base), τ: 7.61 (NCH_3, s); 6.82 (CH_2—CH—CH_2, m); 5.63 (1H at C-5, s); 2.80 (8H aromatic, m).

Anal. Calcd. for $C_{17}H_{18}ClN$: C, 75.10; H, 6.67; Cl, 13.08; N, 5.15. Found: C, 74.94; H, 6.67, Cl, 12.91, N, 5.37.

*10,11-Dihydro-12-ethyl-5,10-(iminomethano)-5H-dibenzo[a,d]cycloheptene (**1***c*)

A mixture of **5***c* (5.5 g), anhydrous tetrahydrofuran (100 ml), and lithium aluminum hydride (3.0 g) was stirred and heated over reflux for 5 h. The mixture was treated with water, filtered, and the filtrate was evaporated. The residue was converted to the hydrochloride salt (4.1 g) which had m.p. 231–234° (from isopropanol).

Anal. Calcd. for $C_{18}H_{19}ClN$: C, 75.90; H, 6.68; Cl, 12.47; N, 4.92. Found: C, 76.20; H, 6.87; Cl, 12.39; H, 4.68.

*10,11-Dihydro-12-phenethyl-5,10-(iminomethano)-5H-dibenzo[a,d]cycloheptene Hydrochloride (**1***d*)

A mixture of the *N*-phenylacetyl derivative of **1***a* (5.0 g), lithium aluminum hydride (3.0 g), and anhydrous tetrahydrofuran (50 ml) was stirred and heated under reflux for 5 h. The basic product was isolated as described above. The hydrochloride (3.0 g) had m.p. 225–228° (from methanol); n.m.r. ($CDCl_3$) (free base), τ: 7.15 (m); 6.75 (m); 5.38 (1H at C-5, s); 2.80 (13H aromatic, m).

Anal. Calcd. for $C_{24}H_{23}N.HCl.0.5H_2O$: C, 77.71; H, 6.79; Cl, 9.56; N, 3.78. Found: C, 77.71; H, 6.76; Cl, 9.29; N, 3.49.

*11-Bromo-10,11-dihydro-5,10-(epoxymethano)-5H-dibenzo[a,d]cyclohepten-13-one (**3***b*)

A suspension of **3***a* and *N*-bromosuccinimide (1.8 g) in carbon tetrachloride (30 ml) containing a trace of benzoyl peroxide was heated under reflux for 2 h. The mixture was filtered and evaporated and the residue was crystallized from ethanol to give the bromolactone (2.0 g), m.p. 167–169°; n.m.r. ($CDCl_3$), τ: 5.53 (1H at C-10, d, J = 5 Hz); 4.95 (1H at C-11, d, J = 5 Hz); 4.94 (1H at C-5, s); 2.52 (8H aromatic, m).

Anal. Calcd. for $C_{16}H_{11}BrO_2$: C, 60.96; H, 3.72; Br, 25.35. Found: C, 61.24; H, 3.71; Br, 25.08.

*5-Hydroxy-N,N-dimethyl-5H-dibenzo[a,d]cycloheptene-10-carboxamide (**2***d*)

A suspension of **3***b* (0.5 g) in ethanol (20 ml) and dimethylamine (0.5 ml) was kept at room temperature for 18 h and then evaporated. The residue was washed with water and crystallized from methanol to give 0.3 g of the amide, m.p. 230–232°; λ_{max} (EtOH) 285 mμ (ε 15 800); n.m.r. (DMSO), τ: 7.08, 6.95 (6H at $CON(CH_3)_2$, s); 4.78 (1H at C-5, s); 2.68, 2.18 (8H aromatic, m).

Anal. Calcd. for $C_{18}H_{17}NO_2$: C, 77.39; H, 6.13; N, 5.01. Found: C, 77.45; H, 6.13; N, 4.91.

*11-Bromo-10,11-dihydro-12-methyl-5,10-iminomethano-5H-dibenzo[a,d]cyclohepten-13-one (**5***d*)

A suspension of **5***b* (15.11 g), *N*-bromosuccinimide (11.4 g), and benzoyl peroxide (50 mg) in carbon tetrachloride (300 ml) was heated under reflux for 1.25 h. The mixture was filtered, the filtrate was evaporated and the residue was crystallized from ethyl acetate to give isomer A of **5***d* (8.0 g), m.p. 205–207°; γ_{max} ($CHCl_3$) 1670 cm^{-1}; n.m.r. ($CDCl_3$), τ: 2.79 (8H aromatic, m); 4.07 (1H at C-11, d); 5.19 (1H at C-5, s); 5.77 (1H at C-10, d); 7.02 (N—CH_3, s).

Anal. Calcd. for $C_{16}H_{14}BrNO$: C, 62.2; H, 4.27; Br, 24.4; N, 4.27. Found: C, 62.41; H, 4.28; Br, 24.66; N, 4.19.

Chromatography of the mother liquors on silica gel, eluting with benzene–chloroform mixture gave a further 0.5 g of isomer A and 7.0 g of almost pure isomer B of **5***d*. This material was repeatedly crystallized from benzene to give the analytical sample of isomer B, m.p. 183–186°; γ_{max} ($CHCl_3$) 1670 cm^{-1}; n.m.r. ($CDCl_3$), τ: 2.82 (8H aromatic, m); 4.52 (1H at C-11, d); 5.15 (1H at C-5, s); 5.77 (1H at C-10, d), 6.85 (N—CH_3, s.)

Anal. Found: C, 62.07; H, 4.21; Br, 24.50; N, 4.23.

*10,11-Dihydro-11-methoxy-12-methyl-5,10-(iminomethano)-5H-dibenzo[a,d]cyclohepten-13-one (**5***f*) (Isomer A)*

A suspension of **5***d* (6.7 g, isomer A) in a solution of sodium (470 mg) in anhydrous methanol was heated under reflux for 18 h. The solution was evaporated and the residue was washed with water and then crystallized from isopropanol to give 4.0 g of **5***f*, m.p. 190–193°; γ_{max} ($CHCl_3$) 1660 cm^{-1}; n.m.r. ($CDCl_3$), τ: 2.80 (8H aromatic, m); 5.17 (1H at C-5, s, 5.63 (2H at C-10 and -11, 2d, J = 4 Hz); 6.23 (O—CH_3, s); 6.92 (N—CH_3, s).

*10,11-Dihydro-11-methoxy-12-methyl-5,10-(iminomethano)-5H-dibenzo[a,d]cycloheptene (**1***f*) Hydrochloride (Isomer A)*

Lithium aluminum hydride (1.2 g) was added to a suspension of **5***f* (3.5 g) in anhydrous tetrahydrofuran (60 ml). The mixture was heated under reflux for 5 h and then treated with water. The mixture was filtered and evaporated and the residue was converted to the hydrochloride salt which was crystallized from methanol to give 2.5 g of product, m.p. 245–248°; n.m.r. ($CDCl_3$) (free base), τ: 7.60 (NCH_3, s); 6.84 (NCH_3, d, J = 3

Hz); 6.5; (1H at C-10, m); 6.35 (OCH_3, s); 5.58 (1H at C-5 and 1H at C-11, s); 2.80 (8H aromatic, m).

Anal. Calcd. for $C_{18}H_{20}ClNO$: C, 71.64; H, 6.64; N, 4.64; Cl, 11.78. Found: C, 71.84; H, 6.59; N, 4.90; Cl, 11.63.

*10,11-Dihydro-11-pyrrolidino-12-methyl-5,10-(imino-methano)-5H-dibenzo[a,d]cyclohepten-13-one (**5e**) (Isomer A)*

A mixture of **5d** (4.7 g) (isomer A) and pyrrolidine (20 ml) was heated under reflux for 3 h and then evaporated. The residue was dissolved in chloroform, washed with water, and evaporated. The residue was crystallized from ethanol to give 3.5 g of **5e**, m.p. 190–192°.

Anal. Calcd. for $C_{21}H_{22}N_2O$: C, 79.21; H, 6.96; N, 8.80. Found: C, 78.91; H, 6.96; N, 8.57.

*10,11-Dihydro-11-pyrrolidino-12-methyl-5,10-(imino-methano)-5H-dibenzo[a,d]cycloheptene (**1e**) (Isomer A)*

Lithium aluminum hydride (3.0 g) was added to a solution of **5e** (3.3 g) (isomer A) in anhydrous tetrahydrofuran (30 ml). The mixture was heated under reflux for 3 h and then worked-up in the usual manner to give the product (2.0 g), m.p. 106–107° (from ethanol).

Anal. Calcd. for $C_{21}H_{24}N_2$: N, 9.17. Found: N, 8.93.

*10-Aminomethyl-10,11-dihydro-5H-dibenzo[a,d]cyclo-hepten-5-one (**9b**) Hydrochloride*

A solution of **6c** (3.0 g) in ethanol (20 ml) and liquid ammonia (15 ml) was hydrogenated at 100 atm and 100° in the presence of Raney nickel catalyst (0.5 g) for 7 h. The crude basic product was dissolved in a mixture of ethanol (20 ml) and 3 *N* HCl (20 ml) and kept overnight. The solution was evaporated and the residue was crystallized from ethanol to give 1.3 g of the hydrochloride, m.p. 265–268°; λ_{max} (EtOH) 271 mμ (ε 16 050) (unchanged on addition of 0.1 *N* NaOH solution).

Anal. Calcd. for $C_{16}H_{16}ClNO$: C, 70.20; H, 5.88; Cl, 12.90; N, 5.12. Found: C, 69.98; H, 5.85; Cl, 12.94; N, 5.02.

Kinetics and Mechanism of the Decarboxylation of Pyrrole-2-carboxylic Acid in Aqueous Solution

G. E. DUNN AND GORDON K. J. LEE
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received August 14, 1970

The decarboxylation of pyrrole-2-carboxylic acid in aqueous buffers at 50° and ionic strength 1.0 has been found to be first order with respect to substrate at a fixed p*H*. As the p*H* is decreased, the rate constant increases slightly in the p*H* range 3–1, then rises rapidly from p*H* 1 to 10 *M* HCl. The ^{13}C-carboxyl kinetic isotope effect is 2.8% in 4 *M* $HClO_4$ and negligible at p*H* ~ 3. These observations can be accounted for by a mechanism, previously proposed for the decarboxylation of anthranilic acid, in which the species undergoing decarboxylation is the carboxylate ion protonated at the 2-position of the pyrrole ring. This intermediate can be formed both by ring-protonation of the carboxylate anion and by ionization of the ring-protonated acid. At low acidities ring-protonation is rate determining, but at higher acidities the rate of protonation exceeds that of decarboxylation.

Il a été trouvé, qu'à p*H* donné dans des solutions tampons aqueuses à 50 °C et une force ionique de 1.0, la décarboxylation de l'acide pyrrole-2 carboxylique est du premier ordre en substrat. Quand le p*H* est diminué, la constante de vitesse augmente légèrement entre p*H* 3 et 1 puis augmente rapidement du p*H* 1 à HCl 10 *M*. L'effet isotopique cinétique du carboxyle ^{13}C est de 2.8% dans $HClO_4$ 4 *M* et négligeable à p*H* ~ 3. Il est possible de rationaliser ces observations à l'aide d'un mécanisme, proposé précédemment pour la décarboxylation de l'acide anthranilique, dans lequel l'espèce qui subit la décarboxylation est l'ion carboxylate protoné à la position 2 du noyau du pyrrole. Cet intermédiaire peut être formé soit par la protonation du noyau portant l'anion carboxylate soit par ionisation de l'acide protoné sur le noyau. A basses acidités, la protonation du cycle est l'étape déterminante mais à des acidités plus élevées la vitesse de protonation est plus grande que la décarboxylation.

Canadian Journal of Chemistry, **49**, 1032 (1971)

Pyrrolecarboxylic acids have long been known to decarboxylate much more readily than most aromatic acids. In this they resemble the amino and hydroxybenzoic acids, and the resemblance may be taken as an example of the general concept which leads to the term "π-excessive" for pyrroles because of the similarity of their properties to those of benzenes with electron-releasing substituents (1). Although the mechanism of decarboxylation of pyrrolecarboxylic acids has not been investigated, Corwin and Straughn have pointed out that the decarboxylation of pyrrolecarboxylic and hydroxybenzoic acids occur under similar conditions and are subject to similar substituent effects (2). Since the mechanism of decarboxylation of hydroxybenzoic acids (3, 4) is very similar to that of the anthranilic acids previously studied in this laboratory (5–7), the present investigation of the decarboxylation of pyrrole-2-carboxylic acid uses the approach previously applied to anthranilic aicds.

Experimental

Commercial pyrrole-2-carboxylic acid was recrystallized twice from benzene and sublimed under vacuum. It had a m.p. of 204–205°.

All p*H* measurements were made with a Radiometer Model 4C p*H* meter in cells thermostatted to 50.0 ± 0.1°. The meter was calibrated against National Bureau of Standards tetroxalate and hydrogen phthalate buffers at 50°. Measurements were reproducible to 0.003 p*H* unit.

Rates were measured spectrophotometrically by following the decrease in concentration of pyrrole-2-carboxylic acid using a Beckman DU spectrophotometer. Aliquots (2 ml) of a 2×10^{-3} *M* solution of pyrrole-2-carboxylic acid in the appropriate buffer were withdrawn from the thermostat and diluted to 25 ml with 1 *M* sodium hydroxide solution. Absorbance measurements were made at 25° and at 250 nm, where pyrrole does not absorb.

Kinetic isotope effects were obtained as described previously (7).

Results and Discussion

Pyrrole-2-carboxylic acid was decarboxylated in buffered aqueous solutions of ionic strength 1.0 at 50 ± 0.01°. For each p*H* the data gave excellent first-order plots to more than 90% conversion and rate constants reproducible to within ±2%. The results at various p*H*'s are shown in Table 1. It is seen that the rate increases only slightly as p*H* decreases from 3 to 1, but then increases very rapidly with increasing acidity until it appears to begin levelling off at hydrochloric acid concentrations around 10 *M*.

Clearly the rate of decarboxylation varies with the degree of protonation of the substrate. The

[1]

HCl	(6.64 M)	31.8
HCl	(10.3 M)	35.7

*Adjusted to constant ionic strength with KCl.

acid–base equilibria of pyrrole-2-carboxylic acid are shown in the first line of eq. 1. The value of K_1 is unknown, and attempts to determine it spectrophotometrically showed no change in the u.v. spectrum from pH 3 to 10 M HCl. This is in agreement with the expectation that pK_1 should be more negative than the corresponding pK of pyrrole itself, which is −3.80 (8). The pK_2 is reported to be 4.39 (9). From these facts it is evident that the rapid increase in rate of decarboxylation as pH falls below 1 is not simply the result of a change of substrate from one protonated form to another at that pH. Clearly the decarboxylation must involve intermediates other than those related by K_1 and K_2.

The pH dependence of pyrrole-2-carboxylic acid decarboxylation recalls that of anthranilic acid (7), so the mechanism derived for anthranilic acid is applied to pyrrole-2-carboxylic acid in eq. 1. The rate equation derived by assuming a steady state for the sum of the concentrations of H_2A^* and HA^* is given by eq. 2.

$$[2] \quad k = \frac{k_A K_2 + k_{HA}[H^+]}{\frac{[H^+]}{K_1} + 1 + \frac{K_2}{[H^+]}} \times \frac{k^* K_2^* + k^+[H^+]}{(k^* + k_{-A})K_2^* + (k^+ + k_{-HA})[H^+]}$$

Since pK_1 is very negative and pK_2 is 4.39, the denominator of the first fraction in eq. 2 is very close to unity at all pH's for which rates are reported in Table 1. The general rate equation therefore reduces to eq. 3.

$$[3] \quad k = (k_A K_2 + k_{HA}[H^+]) \times \frac{k^* K_2^* + k^+[H^+]}{(k^* + k_{-A})K_2^* + (k^+ + k_{-HA})[H^+]}$$

The second factor in eq. 3 contains all the rate constants for carbon–carbon bond breaking, so this factor determines the magnitude of any kinetic isotope effect arising from isotopic substitution in the carboxyl carbon. Table 2 shows the experimental ^{13}C-carboxyl kinetic isotope effect obtained at high and low acidities. At

$HClO_4$	(4.00 M)	23.31	0.010052	2.83
$HClO_4$	(4.00 M)	22.96	0.010056	2.79
$HClO_4$	(4.00 M)	22.74	0.010053	2.81

*Adjusted to constant ionic strength with KCl.

pH 2.63 the isotope effect is negligible, but in 4 M perchloric acid it amounts to 2.8%. This shows that carbon–carbon bond breaking is rate determining at high acidities but not at low ones, so that the second factor of eq. 3 must approach unity at low acidities. That is, eq. 3 reduces to eq. 4 at low acidities.

$$[4] \qquad k = k_A K_2 + k_{HA}[H^+]$$

Figure 1 shows a plot of the rate data from pH 3.4 to 1.5 according to eq. 4, the slope and intercept of which give $k_{HA} = 2.1 \times 10^{-3}\ s^{-1}$ and $k_A K_2 = 2.9 \times 10^{-5}\ s^{-1}$. Although K_2 is not known at 50° and ionic strength 1.0, its thermodynamic value at 20° is 2.45×10^{-5} (9), so it may be concluded that k_A is of the order of 1 and, consequently, that ring protonation is about 500 times faster for the pyrrole-2-carboxylate ion than for the acid itself.

From the fact that the second factor of eq. 3 approaches unity at low acidity, k_{-A} must be small compared to k^*; but since it is not unity at high acidities, k_{-HA} must be large compared to k^+. Consequently, at high acidities eq. 3 can be approximated by eq. 5. For anthranilic acid

$$[5] \qquad k = k_{HA}[H^+]\frac{k^*K_2^* + k^+[H^+]}{k^*K_2^* + k_{-HA}[H^+]}$$

it was possible to show that $k^+[H^+]$ is negligible up to very high acidities, so that the rate expression becomes eq. 6. That $k^+[H^+]$ is also

$$[6] \qquad \frac{1}{k} = \frac{1}{k_{HA}[H^+]} + \frac{k_{-HA}}{k_{HA}k^*K_2^*}$$

negligible for pyrrole-2-carboxylic acid is shown by Fig. 2, where a plot of the data from the pH range 0.8 to 0.08 fits eq. 6, giving $k_{HA} = 2.3 \times 10^{-3}\ s^{-1}$ and $k_{-HA}/k^*K_2^* = 5.8 \times 10^{-1}$. The two values of k_{HA} obtained from eqs. 4 and 6 are

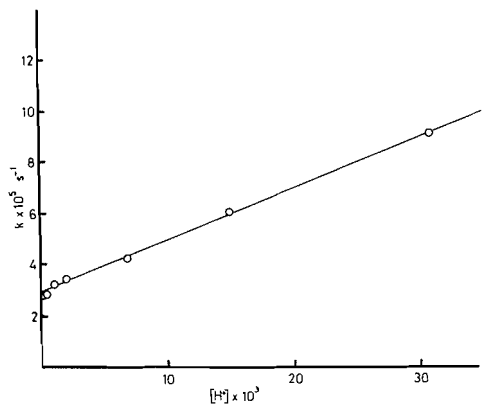

FIG. 1. A plot of rate constant *vs.* hydrogen ion concentration according to eq. 4.

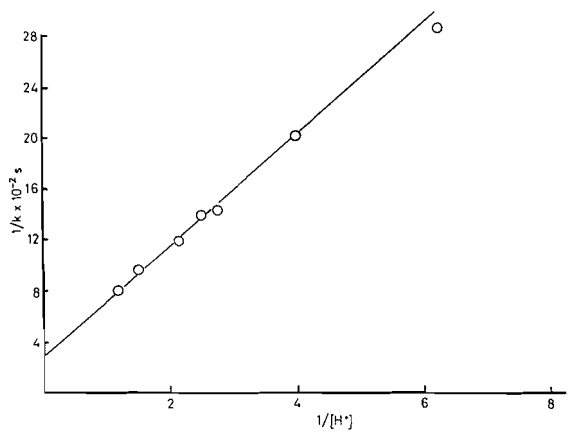

FIG. 2. A plot of rate constant *vs.* hydrogen ion concentration according to eq. 6.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

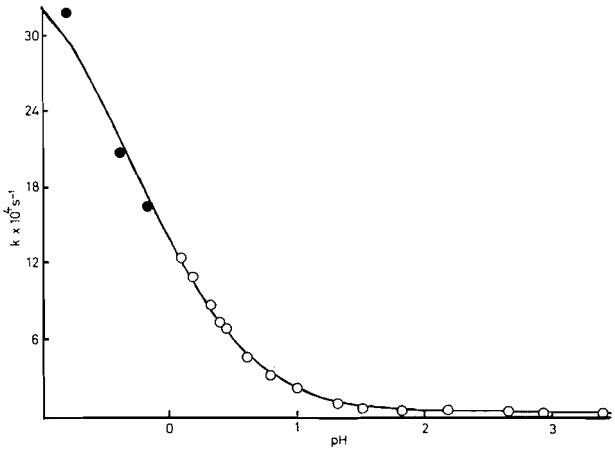

FIG. 3. A plot of rate constant *vs.* hydrogen ion concentration according to eq. 7. The line is calculated from eq. 7 and the circles are experimental points. The solid circles represent rate constants obtained at ionic strengths greater than 1.0, and are therefore not strictly comparable with the others. The p*H* values for these three points were obtained from $-\log$ [HCl].

in satisfactory agreement and have an average value of $2.2 \times 10^{-3}\ s^{-1}$. Therefore all the data obtained at ionic strength 1.0 can be accommodated by the rate expression, eq. 7. Figure 3 shows the experimental rate constants superimposed on a plot of eq. 7.

$$[7] \quad k = \frac{k_A K_2 + k_{HA}[H^+]}{1 + \frac{k_{-HA}}{k^* K_2^*}[H^+]} = \frac{(2.9 \times 10^{-5}) + (2.2 \times 10^{-3})[H^+]}{1 + 0.58[H^+]}$$

It is clear from Fig. 3 that the data obtained at constant ionic strength can be accounted for by omitting the term $k^+[H^+]$ in eq. 2; that is, by assuming that only the ionized carboxyl group decarboxylates. The data obtained at higher acidities where the ionic strength is greater than 1.0 are difficult to interpret quantitatively because for such solutions $[H^+]$ should presumably be replaced by h_0^n, and n is an additional unknown (7). However, it may be noted that if $k^+[H^+]$ is retained in eq. 5 the rate constant should increase continuously with $[H^+]$ (or h_0^n) at high acidities. On the other hand, if it is omitted, as in eq. 7, the rate constant should level off at about $3.8 \times 10^{-3}\ s^{-1}$. It will be seen from Table 1 that the rate, in fact, does not exceed this figure even in 10.3 *M* hydrochloric acid. There is, therefore, no necessity to postulate that the unionized carboxyl group decarboxylates.

It may be concluded then that pyrrole-2-carboxylic acid decarboxylates by a mechanism very similar to that of anthranilic acid. The species which decarboxylates (HA*) is an intermediate composed of the carboxylate anion protonated on the ring carbon to which the carboxylate group is attached. The intermediate can be formed both by ring-protonation of the anion (A^-) and by ionization of the ring-protonated acid (H_2A^*). At low acidities protonation is the slow step; at higher acidities the rate of protonation exceeds that of decarboxylation.

The authors are grateful to the National Research Council of Canada for financial support, to the Faculty of Graduate Studies for a fellowship, and to Mr. W. D. Buchannon for the mass-spectrometric measurements.

Crystal Structure of $Ca_3(AsO_4)_2$ [1]

R. GOPAL AND C. CALVO

Institute for Materials Research and Department of Chemistry, McMaster University, Hamilton, Ontario

Received September 17, 1970

$Ca_3(AsO_4)_2$ crystallizes in the rhombohedral space group $R3c$ with unit cell parameters $a = 14.05(1)$ Å, $\alpha = 45.05(2)°$, and $Z_R = 7$. The equivalent hexagonal axes are $a = 10.77(1)$ and $c = 37.81(3)$ Å with $Z_H = 21$. The structure was refined, using 769 symmetry independent reflections and a full matrix least squares program from a trial structure obtained from Patterson functions, to a final R value of 0.063. The structure consists of interconnected chains of CaO_n polyhedra and AsO_4 tetrahedra paralleling the c axis. The six chains surrounding the three-fold axes are each much like those in $Ba_3(PO_4)_2$ with 3Ca followed by two AsO_4 groups per half cell. The chain on the three-fold axis has only one AsO_4 per half cell with one and half cations between adjacent arsenic atoms. The mean As—O bond lengths are 1.69, 1.65, and 1.69 Å for the three independent tetrahedra. The cation sites show coordination to 6, 7, or 8 oxygen atoms in contrast to the 10 or 6 + 6 found in $Ba_3(PO_4)_2$. These structural differences arise primarily from the shorter cation – oxygen atom bond lengths in this compound. This structure is the same as that of $Ca_3(VO_4)_2$ and although closely related to that of Whitlockite differs from it because of the need to accommodate hydrogen atoms in the latter compound.

$Ca_3(AsO_4)_2$ cristallise dans le groupe spatial rhomboédrique $R3c$: $a = 14.05(1)$ Å, $\alpha = 45.05(2)°$, and $Z_R = 7$. La maille hexagonale correspondante est: $a = 10.77(1)$, $c = 37.81(3)$ Å et $Z_H = 21$. D'une structure de départ obtenue à partir d'une synthèse de Patterson et utilisant 769 réflexions indépendantes, on a obtenu, par une matrice complète de moindres carrés, une structure affinée pour laquelle le facteur $R = 0.063$. La structure est formée de chaînes de polyèdres CaO_n et de chaînes de tétraèdres AsO_4, parallèles à l'axe c et reliées entre elles. Les six chaînes disposées autour de l'axe d'ordre trois, ressemblent à celles du $Ba_3(PO_4)_2$, 3 atomes de Ca alternant avec deux groupes AsO_4 par demi-maille. La chaîne située sur l'axe d'ordre trois ne comporte qu'un seul AsO_4 par demi-maille et un cation et demi entre atomes d'arsenic voisins. Pour les trois tétraèdres indépendants, les longueurs moyennes des liaisons As—O sont 1.69, 1.65, 1.69 Å. Le cation est coordiné à 6, 7 ou 8 atomes d'oxygène, alors qu'on trouve une coordination de 10 ou 6 + 6 dans le $Ba_3(PO_4)_2$. Ces différences de structure se rattachent principalement à une distance cation–oxygène plus courte dans le présent composé. Cette structure est la même que celle du $Ca_3(VO_4)_2$, mais elle diffère de celle de la Whitlockite par la présence d'hydrogènes dans cette dernière.

Canadian Journal of Chemistry, 49, 1036 (1971)

Introduction

In nMO.X_2O_5 systems where $n = 2$ or 3, M is a divalent cation and X = P, V, or As, a transitional structure type occurs near an ionic radius for the cation corresponding to about 1 Å. For orthocompounds, $M_3(XO_4)_2$, the ideal oxygen atom packing has octahedral and tetrahedral holes consistent with M—O and X—O bond lengths near 2.0 and 1.7 Å, respectively. Thus the structures of the orthovanadates of Mg(1), Zn(2), Co(3), and Ni(4) and the orthoarsenates of Ni(5) and Co(6) are based upon close packed arrays of oxygen atoms with the divalent metal ion in an octahedrally coordinated interstice while the pentavalent ion lies in a tetrahedral one. Here the radii of the M ion is less than 0.9 Å. Those orthocompounds with large cations show structures where the cations and the oxygen atoms both pack as hard spheres to the degree consistent with the constraints imposed by the tetrahedral shape of the anion. Such a structure is shared by the phosphates, arsenates, and vanadates of Sr, Ba, and Pb (7–11) with $R\bar{3}m$ for the space group and hexagonal cell parameters near $a = 5.5$ and $c = 20$ Å. In this case one-third of the cations show the twelve-fold coordination expected for packing of hard spheres but with the two unique bond lengths separated by about 0.5 Å. The existence of polymorphs among compounds containing Ca^{2+} (12), Pb^{2+} (9), and Cd^{2+} (13, 14), is a manifestation of the intermediate size of these ions. The orthocompounds containing Ca^{2+} for these three anions have had largely unknown structures except for the structure of $Ca_7Mg_9(Ca,Mg)_2(PO_4)_{12}$ which has recently been reported (15). A close relationship between the structure of $\beta Ca_3(PO_4)_2$ and the mineral Whitlockite has long been suspected (16). Since their space group and unit cell dimensions are similar to those of $Ca_3(AsO_4)$ and $Ca_3(VO_4)_2$ (17), these structures should also be related. Further, a structural analogy has been postulated

*θ_{cal} were determined using $a = 10.767$ and $c = 37.81$ Å and the lines are indexed on the basis of a hexagonal cell. Values in italics were used in the least squares refinement to determine a and c. CuKα radiation was used.

between Whitlockite and $\beta Ca_3(PO_4)_2$ and $Ba_3(PO_4)_2$ (18, 19) since their space group is a subgroup of the latter's space group and their lattice parameters are nearly twice as long. However, the cells contain only seven formula units rather than the eight predicted by analogy. This discrepancy in the mineral has been discussed by Keppler (20).

Experimental

Single crystal of $Ca_3(AsO_4)_2$ were obtained from stoichiometric quantities of either $CaCO_3$ or $Ca(OH)_2$ with As_2O_5 reacted at high temperatures, melted in a platinum crucible and slowly cooled to room temperature. These crystals gave a diffraction pattern nearly the same as that of $Ca_3(VO_4)_2$[2] which has been shown to be rhombohedral with seven formula units per cell here and by Reden and Buerger (21). The extinctions of $Ca_3(AsO_4)_2$ are all reflections such that $-h + k + l \neq 3n$ and for $h0l$, $l \neq 2n$. Therefore the space group must be either $R3c$ or $R\bar{3}c$ with the former preferred. The latter space group with $Z_R = 7$ would require that an As ion lie at a point of $\bar{3}$ symmetry and thus probably have an octahedral environment of oxygen atoms. Although this feature is not unknown for As or V it is not likely for P.

Accurate unit cell parameters, $a = 10.77(1)$ and $c = 37.81(3)$ Å for the hexagonal cell, were obtained from a Debye–Scherrer pattern taken with CuKα radiation ($\lambda_{\alpha_1} = 1.5405$ Å) and refined by least squares. The indexed powder pattern is contained in Table 1. Z_R was taken to be seven by analogy with $Ca_3(VO_4)_2$ since the $Ca_3(AsO_4)_2$ preparations did not yield uniform samples.

Data were recorded relative to a monoclinic set of axes with the monoclinic A, B, and C equal to the hexagonal $a + 2b$, a, $\frac{1}{3}(c - a - b)$ axes, respectively. MoKα radiation was used throughout these measurements. Data of the type hkn with $n = 0$, 1, 2, or 3, $0kl$ and $1kl$ were recorded with an integrating precession camera and the intensities of these reflections measured with a Joyce–Lobel microdensitometer. In addition, the data hnl, $n = 1$, 2 were measured with a scintillation counter manually set to the proper 2θ while the crystal was

[2]The crystals were grown by C. D. Cox at the Defence Telecommunication Laboratories of Canada.

rocked through an ω angle of 2°. The intensities of the *h0l* reflections were determined by visual comparison with calibrated films. The intensities were corrected for background and Lorentz and polarization effects and transformed to the hexagonal cell. A total of 1253 reflections were examined and reduced to 769 symmetry independent reflections of which 553 were observable. Since the crystal used measured 0.08 × 0.11 × 0.15 mm^3 ignoring absorption corrections, with an average μR of 0.65 for a pseudo-sphere, leads to average errors of the order 10% in the intensity, absorption corrections were ignored.

A trial structure was obtained from slices in the three dimensional Patterson functions calculated perpendicular to the *c* axis. These were interpreted in terms of chains of Ca and As atoms distributed near x, y = (0,0)(1/6,1/3)-(1/3,1/6), and (1/2,1/2). Detailed deviations from these values were determined by a comparison of the Patterson functions of $Ca_3(AsO_4)_2$ and $Ca_3(VO_4)_2$. The nature of these chains are very much like those in $Ba_3(PO_4)_2$ (7) and $Ba_3(VO_4)_2$ (10) except for those on the three fold axis which had only half the normal number of formula units. On these axes only one As ion and its *c* glide plane related mate were placed in the trial model. This model was refined using data from both $Ca_3(AsO_4)_2$ and $Ca_3(VO_4)_2$ and subsequently calculated electron density maps used to distinguish Ca^{2+} from As^{5+}. Scattering curves for Ca^{2+} and O^- were obtained from the International Tables for X-Ray Diffraction (22) while that of As^{3+} was taken from Cromer and Waber (23). Next the oxygen atoms about the As ions on the three fold axes were found, followed by those about the remaining arsenic ions. These latter oxygen atoms were located as in $Ba_3(VO_4)_2$ with one AsO bond of the tetrahedron parallel to the *c* axis and the remaining ones nearly paralleling the glide planes of $Ca_3(AsO_4)_2$. The *R* value now stood at 0.17 with 1.5 Ca ions per rhombohedral cell remaining unaccounted for. Three Ca ions were placed on the three-fold axes between the AsO_4 groups displaced by nearly a half a rhombohedral translation from the cations already located. The central site was fully occupied and had an acceptable octahedral environment. The others were 1/4 occupied and had three of their six nearest oxygen atoms displaced by about 3 Å. When the populations of the cation sites were varied by least squares only the central one remained unchanged. At this point the chemical formulation corresponded to $Ca_{20}(AsO_4)_{14}$. The temperature factors for all atoms were varied first isotropically and then anisotropically using a full matrix least squares procedure. The program used was written by J. S. Stephens for the CDC6400. The weights, ω, were set equal to $(240 + 0.64F_o + 0.0023F_o^2)^{-1}$ with the coefficients of the observed structure factors chosen such that the difference in magnitude between the observed and calculated structure factors would be independent of $|F_o|$. The weights of unobserved reflections were set equal to zero if $|F_c| < |F_{min}|$, where F_{min} is the minimum observable value in that area of reciprocal space. Three strong reflections which seemed to be seriously affected by extinction were left out of the refinement. Multiply and symmetry related reflections were averaged and assigned randomly to one of the batches from which they arose. The refinement with this model was terminated when changes were less than one-third of the estimated standard deviations. The value of *R* and R_W ($= [\Sigma\omega|F_o| - |F_c|/\Sigma\omega F_o^2]^{1/2}$) were 0.063 and 0.085. Electron density and difference maps were prepared with particular attention given to the region near the *c* axis in quest of the remaining Ca^{2+}. No peak greater than about 1/3 of an oxygen atom could be located. On the other hand only O(1) and O(9) amongst all the oxygen atoms have near neighbor environments with only 2 calcium ions in addition to an arsenic. Further, the sum of the bond angles at O(1) deviated by 15° from the value expected if the three neighbors were coplanar suggesting that the missing cation lies in a site such as to complete a nearly tetrahedral environment about this oxygen atom. This site turned out to be one of the originally one-quarter occupied sites. A cycle of least squares refinement varying the isotropic temperature factor and the *z* coordinate of a site with the population fixed at one-half did not yield a significant improvement in *R*. In $\beta(Ca_{0.9}Mg_{0.1})_3(PO_4)_2$, however, Dickens has found this site to contain the extra Ca^{2+} (24). Thus the final cycles of refinement were preformed with this model and resulted in an *R* value of 0.063 and R_W = 0.079 when the calculated shifts ceased to be significant. The final atomic parameters are to be found in Table 2 while the magnitude of the observed and calculated structure factors are compared in Table 3.

Description of the Structure

The structure of $Ca_3(AsO_4)_2$ is most easily discussed by comparison with that of $Ba_3(VO_4)_2$ (10)[3] a recently refined isostructure of $Ba_3(PO_4)_2$. These latter structures have the rhombohedral space group $R\bar{3}m$ with the unit cell axes nearly half that of $Ca_3(AsO_4)_2$ and Z_R = 1. The structure consists of parallel chains, coincident with the three fold axis, with a sequence of $3BaO_n$, followed by two PO_4 tetrahedra, as seen in Fig. 1*a*. The central Ba ion of the triplet, Ba(I), lies at a site of $\bar{3}m$ symmetry and is strongly coordinated to six oxygen atoms which lie 2.76 Å away and weakly coordinated to a further six displaced by 3.33 Å. The first six form an octahedral environment about Ba(I) distorted by elongation along the three-fold axis while the remaining six are nearly coplanar and nearly at the same *z* level as Ba(I). The remaining Ba ions, Ba(II), are coordinated ten oxygen atoms. Three oxygen atoms are shared with Ba(I), six are coplanar and form a hexagon about Ba(II) and arise from three edges of three separate PO_4 groups lying on neighboring three fold axes. The remaining oxygen atom of this environment lies on the same three fold axis as Ba(II).

In $Ca_3(AsO_4)_2$, because of the doubled cell edges, only one quarter of the chains coincide with three fold axes. These will be called *A* chains

[3]Roman numerals will be substituted for the arabic ones in this reference.

TABLE OF OBSERVED REFLECTIONS OF Ca_3ASO_6Cl. UNOBSERVED REFLECTIONS MARKED WITH * AND INCLUDED WITH A

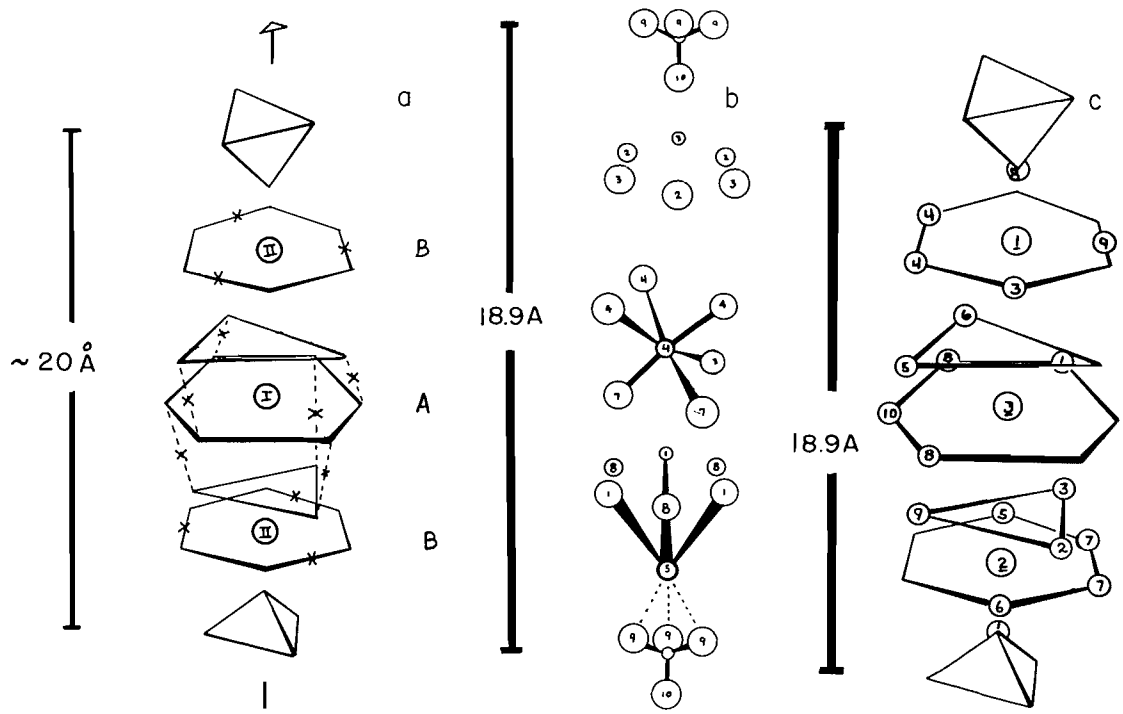

FIG. 1. (*a*) The BaO_n polyhedra and PO_4 tetrahedra in the $Ba_3(PO_4)_2$ structure are shown. The Ba ions lie at the center of the hexagonal planes (*B*,*A*,*B*) with at the corners of the outlined hexagons and triangles. The edges shared between the BaO_n polyhedra and the PO_4 groups are marked with crosses. (*b*) The *A* chain, coincident with the three fold axis, in the $Ca_3(AsO_4)_2$ structure is shown. The atoms are labelled as in Table 2 with the Ca ions at the center of the polyhedra. The strong cation–oxygen bonds are shown as filled bonds while the weak Ca(5)—O(9) bonds are shown dotted. (*c*) An idealized view of the *B* chain in the $Ca_3(AsO_4)_2$ structure is depicted. The oxygen atoms, shown as circles, around the perimeter of the hexagons and triangles are numbered as in Table 2. The cations are shown as circles with underlined numerals. The corners of the hexagons and triangles without circles correspond to broken cations oxygen bonds except for O(9) in the upper portion of the diagram which lies displaced by 30° from the comparable position in $Ba_3(VO_4)_2$. O(9) in the lower portion of the diagram is bonded only to Ca(2).

despite the fact that they contain only half as many formula units per unit length as those in $Ba_3(VO_4)_2$. The remaining chains, the *B* chains, are qualitatively much the same as those in $Ba_3(VO_4)_2$ with the polyhedral sequence $As(2)O_4$, $Ca(2)O_8$, $Ca(3)O_8$, $Ca(1)O_7$, and $As(3)O_4$. In contrast the *A* chains contain only one full cation, Ca(4), and one arsenic ion, As(1), and their glide plane related partners per cell. O(10) on the three-fold axis and O(1) bonded to As(2) and O(8) bonded to As(3) are related to O(I), the oxygen atom on the three-fold axis in $Ba_3(VO_4)_2$. Ca(4) is a cation of type *I*, when compared to this latter structure, since it lies half a rhombohedral lattice translation from the central cation, Ca(3), on the *B* chain. Ca(4) is coordinated to six oxygen atoms, as is shown in Fig. 1*b*, which lies either 2.24(4) or 2.34(4) Å from this cation. These oxygen atoms correspond to those of type *II*, those lying on the mirror planes only, in $Ba_3(VO_4)_2$. The equatorial bond angles indicate an elongation of the octahedron along the three fold axis. The bond lengths and angles for $Ca_3(AsO_4)_2$ are tabulated in Table 4. All the cation oxygen bond lengths less than 3.0 Å are given.

The half-filled cation site on the three fold axis contains Ca(5) which is bonded to three O(1)s and three O(9)s. The Ca(5)—O(1) bond length is 2.61 Å and the Ca(5)—O(9) bond length is 3.04 Å. The Ca(5)—O_6 group shares a face with the AsO_4 group involving O(9)s. The short Ca(5)—As(1) separation of 3.13 Å suggests a rather strong repulsion between these positively charged ions. The remaining cations lie in general positions and deviate substantially from being colinear with the *c* axis. The reduction in Z_R from 8 to 7 should result in the loss of two oxygen atoms from the environments of each of Ca(2)

*Estimated standard deviations in parentheses. *O(nt)* represent atoms derived from those listed on Table 2 by the symmetry operations of the cell except for unit cell translations. $t = a$ or blank represent x, y, z; $b = -y, x - y, z$; $c = -x + y, -x, z$; $d = -y, -x, z + 1/2$; $e = x, x - y, z + 1/2$; $f = -x + y, y, z + 1/2$. One prime corresponds to an additional rhombohedral centering by 1/2, 2/3, 2/3 and two primes designated the added translation of 2/3, 1/3, 1/3.

and Ca(3) and one oxygen atom from Ca(1). The actual coordination numbers found are 7, 8, and 8 for Ca(1), Ca(2), and Ca(3), respectively. In addition to the cation – oxygen atom bonds lost because of the reduction in Z, Ca(1) has lost bonds to O(2) and O(9) and Ca(3) has lost bonds to O(1) and O(9)′ as is indicated in Fig. 1*c*. The range of the Ca(3)—O bond lengths extend from 2.33 to 2.69 Å, while for Ca(1) this range is from 2.26 to 2.52 Å and for Ca(2) these bond lengths range from 2.36 to 2.83 Å. The mean Ca—O bond lengths are 2.44, 2.52, 2.55, and 2.29 Å for Ca(1), Ca(2), Ca(3), and Ca(4), respectively.

The structure of $Ca_3(AsO_4)_2$ is shown in projection down the *c* axis in Fig. 2*a*, *b* and compared with the analogous projection in $Ba_3(VO_4)_2$ in Fig. 2*c*. The As(1)—O_4 tetrahedron contains a crystallographic three-fold axis with the As(1)—O(10) bond length parallel to the axis of 1.63(5) Å and the As(1)—O(9) bond length of 1.71(5) Å. This tetrahedron shows no significant angular deviation from ideality. The remaining As ions have one of their triad axes nearly parallel to the *c* axis. The As(2)—O(1) vector deviates by about 20° while the As(3)—O(8) vector shows a 13° deviation. The As(2)—O bond lengths range from 1.61 to 1.69 Å while those about As(3) range from 1.67 to 1.70 Å. Since the average estimated standard deviation on these bond lengths is 0.04 Å, these lengths do not deviate significantly from their mean values of 1.65 and 1.69 Å, respectively. The O—As—O deviates by as much as 5σ from regularity, however.

The polyhedra of oxygen atoms about the central cation of the *B* chain, Ca(3), shares an edge with each of the neighboring CaO_n polyhedra. The O(5)—O(6) edge is shared between Ca(1) and Ca(3), as seen in Fig. 3, while the O(2)—O(3) edge is common to Ca(2) and Ca(3). The bond angles subtended by these edges range from 66 to 72° and, as such, suggest some repulsion between neighboring cations. Each of these short chains is terminated by an AsO_4 group with O(8) shared between As(3) and Ca(1), and O(1) shared between As(2) and Ca(2). These *B* chains form a hexagonal array about the triad axes such that each chain participates in two hexagonal prism sharing oxygen atoms with cations in four neighboring chains. The hexagonal prisms share edges rather than faces and therefore the structure has triangular prisms devoid of cations. Adjacent chains in the hexagonal prisms are shifted by about 1/6*c*, with one As—O bond about each tetrahedron directed towards a three fold axis and two more along the edges of the hexagonal prism. Four AsO_4 groups share edges with a Ca(3)—O_8 group and one further AsO_4 group shares a single oxygen atom. In $Ba_3(VO_4)_2$ Ba(I), considered as bonded to 12 oxygen atoms, share edges with $6VO_4$ groups. The Ca(1)—O_7 group shares only one edge with an AsO_4 group while the Ca(2)—O_8 group has two such edges with two AsO_4 groups. Each such cation in $Ba_3(VO_4)_2$ shares three edges with three adjacent VO_4 tetrahedra. Thus the bonding about the hexagonal prism has become substantially more disordered compared with the $Ba_3(VO_4)_2$ structure with only seven edges shared with tetrahedra rather than twelve.

Discussion

The cations of the *B* chain are displaced from a line midway between the triad axes. The magnitude of the deviations from this line are about 1/4, 1/7, 1/2, 1/2, and 2/3 Å for As(2), As(3), Ca(1), Ca(2), and Ca(3), respectively and are related to the decrease in Z. This in turn results from the requirement for a shorter mean cation–oxygen atom bond length than in Ba or Sr orthophosphate. O(10) on the three fold axis is bonded to three Ca(3) ions which move towards this oxygen atom. As a result the bond between

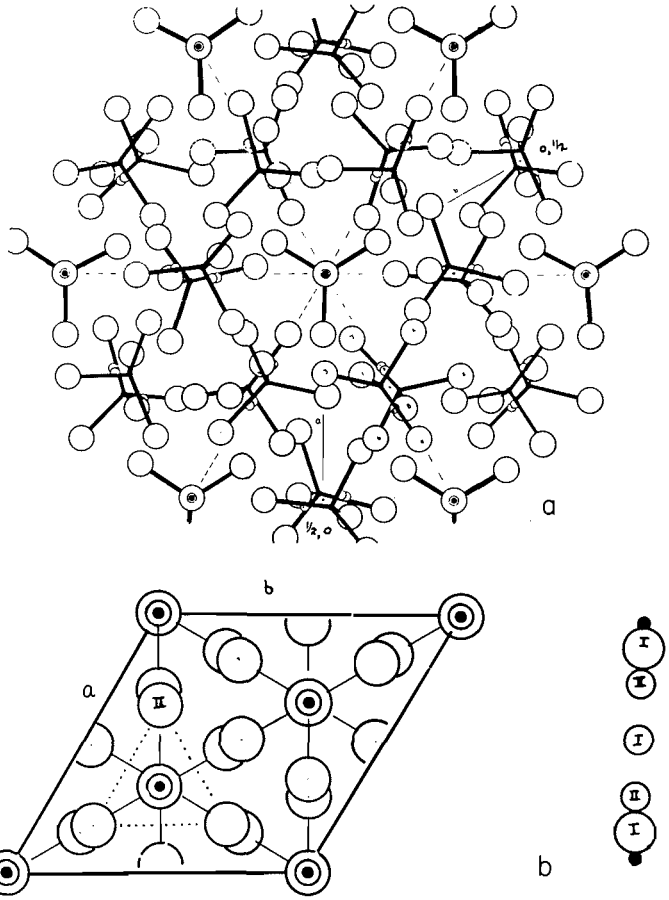

FIG. 2. (*a*) The structure of $Ca_3(AsO_4)_2$ projected another *a b* plane. A volume $\frac{1}{2}c$ thick is shown. The large open circles are oxygen atoms, the filled circles are As ions while the small open circles are cations. The three fold axis are seen as superpositions of O(10), As(1) and Q. The glide planes are represented with broken lines. (*b*) The structure of $Ba_3(VO_4)_2$ is schematic, projected down the *c* axis. The superpositions of three Ba, 2V, and 2 oxygen atoms are depicted by three concentric circles with the inner one filled and the insert shows their mutual arrangement. The type *II* oxygen atoms are shown as large circles. The mirror planes are represented by light lines in the figure. An example of the VO_4 edges shared with Ba(II) is shown dotted.

Ca(3) and the oxygen atom that would be related to O(10), if Ca(3) were at a center of symmetry, is broken and the AsO_4 group containing this oxygen atom is lost from the structure. O(8) and O(1) also move towards Ca(3) in order to achieve suitable Ca—O bond lengths. The former oxygen atom, bonded to the *B* chain at Ca(1), maintains two strong bonds to Ca(3) but O(1) is pulled by Ca(2) to such an extent that only one strong Ca(3)—O(1) bond remains in the environment of Ca(3).

As(1) lies nearly half way between any two Ca(4) ions on the same *A* chain and therefore does not lie in a position analogous with the As ions on the *B* chains. As(1) deviates slightly from being halfway between the two glide planes related Ca(4) ions on the same *A* chain. This deviation allows us to identify As(1) and O(10) with As(2) and O(1) and to assert that the former ions have been translated by about 1.3 Å from positions corresponding to half a rhombohedral lattice translation from those on the *B* chain. In addition, the As(1)—O(9) vector has been rotated so as to be displaced by 30° from the glide plane as is indicated in Fig. 1*c*.

Since the oxygen atoms of type *I* are pulled from the environment of Ca(4) the remaining oxygen atoms of that environment, three Ca(4)'s

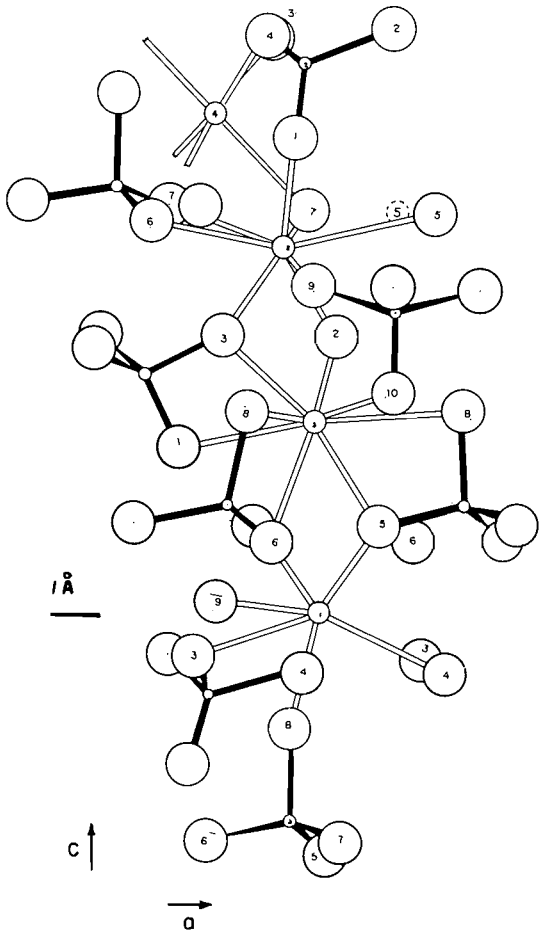

FIG. 3. One chain in the structure of $Ca_3(AsO_4)_2$ projected onto the *ac* plane. The open bonds connect Ca ions, represented by smaller open circles, and the oxygen atoms are represented by the larger open circles. The AsO_4 tetrahedra are shown with filled AsO bonds with the As represented by the smallest circles. The dotted circle represents Ca(5), the ion in the half filled site.

and three O(7)'s, reduce their *z* displacements relative to that of Ca(4) and enlarge their separations in the *ab* plane. The elongation of this octahedron along the three-fold axis, which Süsse and Buerger (10) attribute to the Ba(I)–Ba(II) repulsion, must in fact contain some contribution from other sources since Ca(5) lies about 7 Å from the Ca(4) on the same triad axis. The pertinent angle monitoring this elongation (O(II*d*)—Ba(I)—O(II*d*′)) is reduced from 114.6° in the Ba compound (10) to 105 and 101° in $Ca_3(AsO_4)_2$ and $Ca_3(VO_4)_2$. Even in Whitlockite, devoid of an extra cation, this angle is about 5° greater than the ideal value of 90° (25). The regularity of these octahedra are limited by the O(4)—O(4) and O(7)—O(7) repulsive interactions for a given separation between chains. The loss of the AsO_4 group from the structure results in a missing shared edge in the environment of Ca(2) and because an AsO_4 related by the rhombohedral centering is missing from the environment of Ca(3), these cations displace in opposite directions in the *ab* plane. The displacement of Ca(2) from the glide plane seems to be governed by O(9) which is displaced by the rotation of the As(1)—O(9) bond.

The structures of $Ca_3(AsO_4)_2$, and by analogy that of $Ca_3(VO_4)_2$, have a number of curious features. These relate to the large thermal parameter for all the atoms and particularly the exceptionally large value shown by some ions. The thermal parameters for $Ca_3(VO_4)_2$, as can be seen in Table 5, are qualitatively similar to those in $Ca_3(AsO_4)_2$ particularly so for the larger components. Thus, even considering differences between VO_4 and AsO_4 groups, it is apparent that these anomalies must be inherent in the structure. Leaving Ca(5) aside, the thermal parameters of Ca(3) are about twice as large as for the remaining calcium ions. In the arsenate the disorder of the As ions are qualitatively the same while in the vanadate it is substantially larger for V(2). O(1) shows uniformly large values for all its components, while O(2), O(6), O(9), and O(10) show at least one large component. Since the As(1)O_4 tetrahedron and Ca(5) share a face composed of three O(9) atoms, in half the cases, it is not unexpected that O(9) and probably O(10) will show anomalous effects because of positional disorder. The relatively small U_{33} component of O(10) suggests that this atom is disordered on a circle centered on the three fold axis. It is interesting to note that O(I) in $Ba_3(VO_4)_2$, which also lies on a three fold axis, could be considered to lie in an orbit with a radius of 0.18 Å (10). However, in $Ca_3(AsO_4)_2$ the magnitude of this effect should be relatively small since the Ca(5)—O(9) interaction is over 3 Å. On the other hand, the Ca(5)—O(1) bond in reasonably strong and therefore this oxygen atom would be expected to manifest a large positional disorder. The magnitude of the coefficients for O(1) are very large suggesting that the position O(1) occupies when Ca(5) is filled as compared to when it is empty differ by about 0.2 Å. Since O(1) is bonded to a Ca(3) at nearly the same

*Estimated standard deviations in parentheses.
†The U_{ij}, in Å², are computed from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where $T = \exp[-(\beta_{11}h^2 + 2\beta_{12}hk + \cdots)]$ appears × in the structure factor expression and b_j are reciprocal lattice vectors.
‡Isotropic temperature factors in Å².

z level, some of the enhanced disorder at this cation may be due to this cation displacement. The large U_{11} component for O(6) may be associated with a weak Ca(2)—O(6) bond in both $Ca_3(AsO_4)_2$ and $Ca_3(VO_4)_2$. The analogous bond in Whitlockite is 2.60 Å long (25). The structural reason for this difference between the phosphate and the other calcium compounds is not clear.

In addition the disorder implies that the apparent bond lengths deviate from their true values. Until the details of the disorder are known corrections for these effects can not be made. Since the $Ca_3(VO_4)_2$ data has been measured both from films and by diffractometer[4] models with positional disorder will be tested with these data.

Virial Scaling and Diatomic Force Constants

D. P. CHONG, P. J. GAGNON, AND J. THORHALLSSON[1]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received September 28, 1970

The application of virial scaling to calculation of diatomic force constants is studied. The ground states of H_2, LiH, BH, and Li_2 are used as test cases. We find that three-point calculations with fair-to-good wavefunctions lead to excellent k_2, fairly good k_3, but poor k_4. A wide variety of models for interpolating raw data is also investigated.

L'application de l'échelle variale au calcul des constantes de force diatomique est étudiée. Les états fondamentaux de H_2, LiH, BH et Li_2 sont utilisés comme prototypes. Il est trouvé que des calculs à trois points avec des fonctions d'ondes de passables a bonnes conduisent à des valeurs excellentes pour k_2, passablement bonnes pour k_3, mais mauvaises pour k_4. Une variété très grande de modèles pour l'interpolation des données brutes est aussi examinée.

Canadian Journal of Chemistry, 49, 1047 (1971)

Introduction

Ab initio calculations of spectroscopic constants for diatomic molecules have been a subject of considerable interest.[2] In this work, we are primarily concerned with the determination of the equilibrium internuclear separation R_e, the quadratic force constant k_2, and the cubic force constant k_3. These quantities appear in the usual Taylor's series expansion of the energy of a diatomic molecule in the Born–Oppenheimer approximation

$$[1] \quad E(R) = E(R_e) + \sum_{n=2}^{\infty} k_n(R - R_e)^n/(n!)$$

or

$$[2] \quad E(R) = E(R_e) + \tfrac{1}{2}k_2R_e^2\xi^2\left(1 + \sum_{m=1}^{\infty} a_m\xi^m\right)$$

In our notation,[3] $k_n = (d^nE/dR^n)_{R=R_e}$, $\xi = (R - R_e)/R_e$, and $(n!)a_{n-2}k_2 = 2R_e^{n-2}k_n$. Atomic units are used throughout: $e^2a_0^{-3}$ for k_2, for example.

Basically, there are three approaches. The most common practice is to determine k_n from $E(R)$ calculated at a number of values of R. Besides the errors in the computed values of $E(R)$, there are also difficulties in the numerical analysis (6, 7). To obtain force constants which reflect the behavior of the computed $E(R)$ faithfully, one must use many values of R.

At the other extreme, k_2 can be computed directly in a one-point calculation[4] at $R = R_e$. However, the results (8–11) obtained so far are not encouraging.[5] An interesting alternative was recently proposed by Parr and White (13), who considered a perturbation by the kinetic energy operator. Unfortunately, two test cases indicate that their method is extremely sensitive to how well the basis set can represent the first-order wavefunction. For example, the observed value of $\frac{1}{2}k_2R_e^2 = w_2 - w_1$, in their notation, for LiH is $-7.7647 + 8.0705 = 0.3058$; the corresponding value for the wavefunction of Browne and Matsen (14), recalculated at $R = 3.046\ a_0$ (15), is $-7.1506 + 8.0558 = 0.9052$.[6] A second test with a poorer wavefunction for BH gave much worse results.[7]

The third alternative, between these two extremes, is to calculate the force. Goodisman (16) computed the electrostatic force for H_2 and obtained a better value of k_2 than from the energy curve. However, electrostatic forces rarely give reliable values for dE/dR (9–11, 17–20). In a recent paper, Pulay (19) derived an expression for the correction to the electrostatic force in the Hartree–Fock approximation. In his actual computation (20), however, Pulay used the same basis sets for all geometrical configurations and therefore left out all the terms arising from the variation of orbital exponents. To include such terms would involve considerable additional effort, as indicated by Benston and Kirtman (9). On the other hand, the virial force can be readily calculated. In this work, we define the attractive virial force by

[1]Present address: Department of Physics, Red Deer College, Red Deer, Alberta.

[2]Numerous references can be found in refs. 1–4.

[3]The a_n coefficients (for $n \geq 1$) are those in the Dunham potential (5). However, we reserve the symbol a_0 for the Bohr.

[4]Calculations at N values of R are termed N-point calculations in this paper.

[5]An exception is the calculation of k_2 for H_2^+ by Bishop and Macias (12).

[3] $$F(R) = -(2T + V)/R$$

where T and V are the kinetic and potential energies, respectively. Fortunately, the method of scaling (21, 22) is available to make any approximate wavefunction satisfy the diatomic virial theorem (23): $F(R) = dE/dR$. Consequently, one can compute dE/dR faithfully.

With virial forces from scaled wavefunctions, one hopes to encounter less severe difficulties with the numerical analysis than in the energy approach and to be able to calculate good force constants with fewer values of R. In our preliminary investigation (24), we found that three-point calculations gave excellent results for k_2 and k_3 of LiH. The object of this paper is to report on similar calculations for the ground states of H_2, BH, and Li_2.

In the earlier study (24), the correct scaling factor η was determined by the method given by Löwdin (21). In his notation,

[4] $$\eta = -[V(1,\rho) + \rho V_\rho(1,\rho)]/[2T(1,\rho) + \rho T_\rho(1,\rho)]$$

The derivatives V_ρ and T_ρ presented some difficulties. In this work we use another method of finding η at which $(\partial E/\partial\eta)_R = 0$. The scaling on LiH has therefore been repeated.

Calculations and Results

First, we give a brief description of the unscaled wavefunctions used in this work. All of them are valence-bond (v.b.) configuration–interaction (c.i.) functions constructed with Slater-type atomic orbitals. The wavefunction for H_2 is equivalent to the symmetry–orbital c.i. Function IX of McLean, Weiss, and Yoshimine (25). The LiH function has already been published (18). The wavefunction for BH is the only new one, for which further details are given in the Appendix. Finally, the Li_2 function is that used by Kockel and Grün (26). Of the four wavefunctions, the Li_2 function is the only one for which the same set of orbital exponents is used for all three values of R. The orbital exponents for the other three wavefunctions had been partially optimized at each R: less and less completely as one goes from H_2 to LiH to BH.

The energy at the calculated R_e according to Model B (see below) of each of these unscaled wavefunctions is shown on Table 1, along with other relevant specifications. For comparison, the Hartree–Fock–Roothaan (H.F.R.) and accurate energies (27–30) are also included. Thus one sees that our H_2 wavefunction is quite good, but the Li_2 function is not even of H.F.R. quality.

The wavefunctions were then scaled so that $(\partial E/\partial\eta)_R = 0$. At each value of R, the v.b.c.i. energy was computed with all orbital exponents multiplied by a factor of 1.0 ± 0.01. Interpolation of the energy by a parabola in η then led to the optimum scale factor at each R. The calculated energies and virial forces[8] for the unscaled and scaled functions are summarized in Table 2. Although the scaling is now performed at constant R instead of constant ηR (24), the same three features appear: (*a*) The scaling factor η is close to unity. (*b*) The energy is only slightly affected. (*c*) The virial force $F(R)$ is changed considerably by the scaling. It should be noted that $F(R)$, as defined by eq. 3, from an unscaled wavefunction is not dE/dR. Examine the results for BH in Table 2, for example.

Before going into the various methods of interpolating the raw data in Table 2, we have converted the experimental spectroscopic con-

[8]All computations were performed in double precision on an IBM 360/67 computer. Extra insignificant figures were carried to reduce round-off errors.

stants (31, 32) into parameters of interest and collected them in Table 3. The percentage errors given below are based on the entries in Table 3.

Interpolation

In our earlier study (24), we used a parabolic fit on the energy (Model *A* below) and on the virial force (Model *C* below). In this work, we have examined a wide variety of simple models. The input and basic assumption in each model are specified in Table 4. Thus, Model *A* is the simple harmonic oscillator, Model *B* is the Fues oscillator (33, 34), and Models *E*, *F*, and *G* represent three different six-parameter functions. Since $F(R)$ from the unscaled wavefunctions is not dE/dR, we have tested only Models *A* and *B* on them. The results for the unscaled wavefunctions are very similar but slightly inferior to the corresponding results (Models *A* and *B*) for the scaled wavefunctions. In Tables 5 and 6, we present the results from some of the better models, and percentage errors for the scaled wavefunctions from the various models are summarized in Table 7.

When we examine the results from various models, we should bear in mind two points: the quality of the wavefunctions and the spacing $\Delta(R)$ used. As mentioned earlier, our H_2 function is quite good, but the wavefunction for Li_2 is rather poor. Consequently, we obtain very good values for R_e, k_2, and k_3 for H_2 from several models, but k_2 for Li_2 is poor regardless of which model one uses. The spacing $\Delta(R)$ is small for H_2, and for Li_2 (relative to R_e); thus the effect of using R^{-1}, instead of R, as the argument in the various polynomials is also

small, in contrast to LiH, for which $\Delta(R)$ is the largest. Another point which may be relevant is that $\Delta(R^{-1})$ for BH was chosen to be constant; the improvement in k_2 for BH in going from Model *C* to *D*, *E* to *F*, and from *H* to *I* may be related to this factor.

Turning now to the various models, we first compare Models *A* and *B*. Borkman and Parr (34) have shown some of the merits of the Fues potential (33). Our results indicate that, although Model *B* gives better force constants than *A* on the whole, k_3 from the Fues potential should be regarded with caution, since it is based on the assumption that $a_1 = -2$. Similarly, one should not place too much faith in k_4 from Model *D*, since it is based on $2a_2 = -3a_1 - 1$. In any event, Models *A* and *B* are inferior to *C* and *D*, both of which are simple to use. Model *C* appears to give the best overall results; Model *D* may be superior for k_2 when the spacing $\Delta(R^{-1})$ is constant. The disappointing performance of the two quintic polynomials in Models *E* and *F* seems surprising at first sight. However, it can be understood in terms of the presence of wiggles in the force curves for H_2 and LiH. On the other hand, the failure of Model *G* on H_2 is related to the fact that the fitted parameters are nearly linearly dependent. In short, all three six-parameter functions do not appear to have general applicability. Finally, the least-squares models give interesting results. The results from Model *H* are almost identical to those from Model *C*, as expected; those from Model *I* are similar to the ones from Model *D*. On the other hand, Model *J* does not appear to be superior. An attempt to fit $E(R)$ to a quartic in R^{-1} fails because of linear dependence.

From our results, we make the following observations: (*1*) The value of R_e is not particularly sensitive to the model, especially when

*Percentage errors are given in parentheses.

$\Delta(R)$ is not large. (*2*) Poor wavefunctions cannot lead to reliable k_2. (*3*) The best models for k_2 are *C* and *H*, or *D* and *I* for constant $\Delta(R^{-1})$. (*4*) The best models for k_3 are *C*, *H*, and *J*. (*5*) None of the models tested give accurate k_4 from three-point calculations.

Discussion

Although the results on Li_2 are mainly negative, we do learn from them that we need better wavefunctions than the one used for Li_2 in order to determine good k_2 from three-point calculations.

Since we have not discovered a method of extracting reliable k_4 from three-point calculations, we tend to believe that computations at more than three values of R are required. As Models *C* and *H* appear to perform the best on the whole, they are the ones that should be extended.

Both Models *C* and *H* are based on a cubic polynomial in R for the energy. One may wonder how well a two-point calculation performs. In Model *K*, we use the energies and forces at only R_1 and R_3. The results are presented in Table 8. The reasonable values for R_e and k_2 are deceptively encouraging. However, if we use the data at R_2 and R_3 for LiH, we get a value of 0.050 for k_2. This points out the danger of drawing definite conclusions on a few results. Hence, we must regard our conclusions as tentative and encourage other workers to test Models *C* and *H* on similar calculations.

In the present study, we obtain excellent k_2, fairly good k_3, and unreliable k_4 for H_2, LiH, and BH. The wavefunctions used for these molecules are better than R.H.F. quality. Whether or not similar results can be obtained from scaled R.H.F. wavefunctions is still an open question.

In any event, we believe that virial scaling is important and may save considerable computer time.

The authors are grateful to the National Research Council of Canada for financial support and to one of the referees for valuable comments.

Appendix

The unscaled wavefunction used for BH resembles the one used by Ohno (35).[7] As indicated in Table 1, it is a 13-term v.b.c.i. function using seven Slater-type atomic orbitals. Instead of Ohno's closed-shell configuration for the two 1s electrons, we use a split core. The orbital exponents of the 1s and 1s′ orbitals have been partly optimized at each value of R. On the other hand, the orbital exponents for the valence electrons were optimized only at R_1, since we

Chemistry of Fulvic Acid, a Soil Humic Fraction, and its Relation to Lignin[1]

G. OGNER[2] AND M. SCHNITZER
Soil Research Institute, Canada Department of Agriculture, Ottawa, Canada

Received October 21, 1970

Fulvic acid, a water-soluble soil humic fraction, was extracted from a Podzol soil and exhaustively methylated so as to make it soluble in benzene. The resulting material was separated repeatedly by column, thin layer, and preparative gas chromatography until relatively pure components were obtained. The latter were then identified by comparing their mass and micro-i.r. spectra and their gas chromatographic retention times with those of standards of known structures.

Twenty-one phenolic and benzene-carboxylic acids were identified as methyl ethers and esters. In addition, a number of polymethoxy-benzene polycarboxylic acids of as yet unknown identity were isolated.

A number of the compounds isolated have been reported to arise from the alkaline $KMnO_4$ oxidation of lignin. Since we did not oxidize the fulvic acid in the laboratory, it is likely that it originated from products resulting from the chemical and/or biological oxidation of lignin in the soil. Methylation of the fulvic acid was necessary to make the compounds extractable by organic solvents. Since methylation reduces hydrogen-bonding in the fulvic acid, it is suggested that in fulvic acid phenolic and benzenecarboxylic acids are joined by hydrogen-bonds to form a polymeric structure of yet unknown conformation. Any weakening of hydrogen-bonding will lead to a break-up of this structure.

L'acide fulvique, une fraction humique hydrosoluble d'un terroir, a été extrait d'une terre de Podzol et méthylé d'une façon exhaustive pour le rendre soluble dans le bènzène. Les produits résultants ont été séparés successivement par chromatographie sur colonne en couche mince et en phase gazeuse préparative jusqu'à ce que des composés relativement purs soient obtenus. Ces derniers ont été identifiés en comparant leurs spectres de masse et micro-i.r. ainsi que les temps de rétention en chromatographie en phase gazeuse, avec ceux de produits standards de structure connue.

Vingt et un acides carboxyliques phénoliques et benzéniques ont été identifiés comme étant des éthers méthylés et des esters. De plus, un certain nombre d'acides polycarboxyliques polyméthoxy-benzéniques, non identifiés jusqu'à présent, ont été isolés.

Un certain nombre de composés isolés ont été rapportés comme provenant de l'oxydation alcaline par $KMnO_4$ de la lignine. Puisque nous n'avons pas oxydé l'acide fulvique en laboratoire il semble que ceux-ci proviennent de produits résultant d'une oxydation chimique et/ou biologique de la lignine dans le sol. La méthylation de l'acide fulvique est nécessaire pour l'extraction des composés par les solvants organiques. Puisque la méthylation réduit les liaisons hydrogène dans l'acide fulvique, il semble que dans l'acide fulvique, les acides carboxyliques benzéniques et phénoliques soient unis par liaisons hydrogène pour former une structure polymérique de conformation encore inconnue. Toute faiblesse de la liaison hydrogène provoque une cassure de cette structure.

Canadian Journal of Chemistry, 49, 1053 (1971)

Introduction

Humic substances are among the most widely distributed natural products on the earth's surface, occurring in soils, lakes (1), rivers (2), and in the sea (3). In spite of their extensive distribution, little is known about their chemical structure, origin, synthesis, degradation, and reactions. Of special interest are fulvic acids which are water-soluble relatively low molecular weight humic materials that account for between 25 and 75% of the organic matter in soils and also for a substantial part of the organic matter in natural waters. Fulvic acids can form stable water-soluble and water-insoluble complexes with metal ions and hydrous oxides (4), interact with clay minerals (5), combine with hydrophobic organic compounds such as alkanes, fatty acids, and dialkyl phthalates and make them soluble in water (6–8). Fulvic acids can also exert considerable physiological activity in the areas of cell division and cell elongation (9). All of these properties point to a significant role of fulvic acids in reactions occurring in soils and waters, including those associated with pollution.

A fulvic acid extracted from the Bh horizon of a Podzol soil in Prince Edward Island has been under continuous investigation in this laboratory for more than a decade. Briefly, the fulvic acid is a chemically and biologically relatively stable polyelectrolyte with a number-average molecular weight of 951 (measured by vapor pressure osmometry) and contains 9.1 mequiv COOH, 3.3 mequiv phenolic OH, 3.6 mequiv alcoholic OH, and 3.1 mequiv C=O per g (4). Elemental

analysis (%) shows 50.90, C; 3.35, H; 0.75, N; 0.25, S; and 44.75, O (4). The molecular formula calculated from these data is $C_{28}H_{16}(COOH)_9(OH)_7(CO)_3$. The oxidative degradation of fulvic acid with alkaline permanganate produces 1.5% aliphatic monocarboxylic acids (ranging from acetic to caprylic acids), 3.0% oxalic acid, and 1.7% benzenecarboxylic acids (ranging from phthalic to mellitic acids) (10). Oxidation with 7.5 *N* NHO_3 yields 0.7% aliphatic dicarboxylic acids (succinic, glutaric, adipic, and pimelic acids), 5.5% nitrophenols (mainly picric acid), and 1.5% benzene-polycarboxylic acids (10). Reductive degradation such as zinc dust distillation and fusion yields polycyclic aromatic compounds the most prominent of which are naphthalene (0.1%), phenanthrene (0.1%), anthracene (0.2%), pyrene (0.1%), and perylene (0.2%) (11). X-Ray analysis indicates that the carbon skeleton of fulvic acid consists of a broken network of poorly condensed rings with appreciable numbers of disordered aliphatic chains or alicyclic structures around the edges of the aromatic layers (12).

In 1963 Barton and Schnitzer (13) proposed a new approach to unravelling the chemical structure of fulvic acid. The fulvic acid was first exhaustively methylated in order to make it soluble in benzene. The benzene-soluble methyl esters and ethers were then separated over Al_2O_3 with the aid of solvents of increasing polarity into chromatographically homogeneous fractions that differed in molecular weights, oxygen-containing functional group contents, and spectroscopic properties. The present investigation is a modification and extension of this approach. The fulvic acid was first extracted with a number of solvents of increasing polarity, then methylated and the benzene-soluble methyl esters and ethers were separated repeatedly by column, thin layer, and preparative gas chromatography until relatively pure components were obtained. The latter were then analyzed by mass spectrometry and micro-i.r. spectrophotometry. A comparison of the mass and i.r. spectra and gas chromatographic retention times of the major components isolated from the fulvic acid with those of authentic specimen led to their identification. In view of the increasing interest in humic substances in conncetion with environmental problems, we felt that the results of this investigation might be of interest to chemists.

Experimental

Fulvic Acid

Methods of extraction and purification were analogous to those reported previously (10). The purified fulvic acid accounted for approximately 75.0% of the organic matter in the original soil sample; its ash content was 1.0%.

Fractionation of the Fulvic Acid

Air-dry fulvic acid (100 g) was extracted for 24 h in a Soxhlet apparatus first with 1 l of *n*-hexane, then with 1 l of benzene, and finally with 1 l of ethyl acetate. The *n*-hexane soluble material was viscous yellowish oil (0.02 g) and contained mainly alkanes (6). The benzene and ethyl acetate extracts weighed 0.02 and 0.41 g, respectively. Both extracts were methylated with diazomethane and then separated by t.l.c. on silica gel. The benzene extract was found to consist mainly of fatty acid methyl esters (7).

The remaining 99.5 g of fulvic acid was then methylated with silver oxide-methyl iodide (13). Four successive methylations increased the methoxyl content from 0.2% for the unmethylated fulvic acid to 28.2%. The methylated fulvic acid (75.0 g) was refluxed for 24 h with 1 l of *n*-hexane. The hexane extract (0.71 g) was separated over Al_2O_3 (35.0 g) with hexane, benzene, and ethyl acetate to yield fractions weighing 0.02, 0.002, and 0.14 g, respectively. The fraction eluted with hexane contained mainly alkanes while the fraction eluted with benzene consisted chiefly of fatty acid methyl esters; the ethyl acetate extract was a complex mixture of fatty acid methyl esters and of aromatic compounds (7).

The methylated fulvic acid was then dissolved in benzene. The benzene-soluble material (41.3 g) was chromatographed over neutral Al_2O_3 (activity I, 2 kg) and eluted successively with 3 l of *n*-hexane (fraction A), benzene (fraction B), benzene – ethyl acetate (9:1)(fraction C), benzene – ethyl acetate (1:1)(fraction D), and an additional 3 l of benzene – ethyl acetate (1:1)(fraction E) to yield five fractions weighing 0.07, 0.02, 0.04, 0.51, and 0.60 g, respectively. All fractions were yellowish viscous oils. Fraction A contained only alkanes (6), whereas fractions B and C were found to contain both alkanes and fatty acid methyl esters (7). In addition, small amounts of dialkyl phthalates were isolated from fraction C (8). In total, normal plus branched-cyclic alkanes accounted for 0.16% of the ash-free weight of the fulvic acid, normal fatty acid methyl esters for 0.10%, and dialkyl phthalates for 0.03% (6–8). The alkanes and fatty acid esters ranged from C_{14} to C_{36} (6, 7). The dialkyl phthalates consisted of bis(2-ethylhexyl)-phthalate, dibutyl-phthalate, dicyclohexyl-phthalate, and benzyl-butyl-phthalate (8).

This paper deals primarily with the separation of fractions D and E, which were quantitatively the major fractions that we have isolated so far.

Analytical Techniques

Following chromatography over the Al_2O_3 column, each fraction was further separated by preparative t.l.c. on Al_2O_3 (activated at 150° for 18 h, thickness of sorbent coating: 0.5 mm). Three solvent systems were used: (*1*), toluene – ethyl acetate (3:1); (*2*), toluene – ethyl acetate (9:1), and (*3*), toluene – ethyl acetate (2:1).

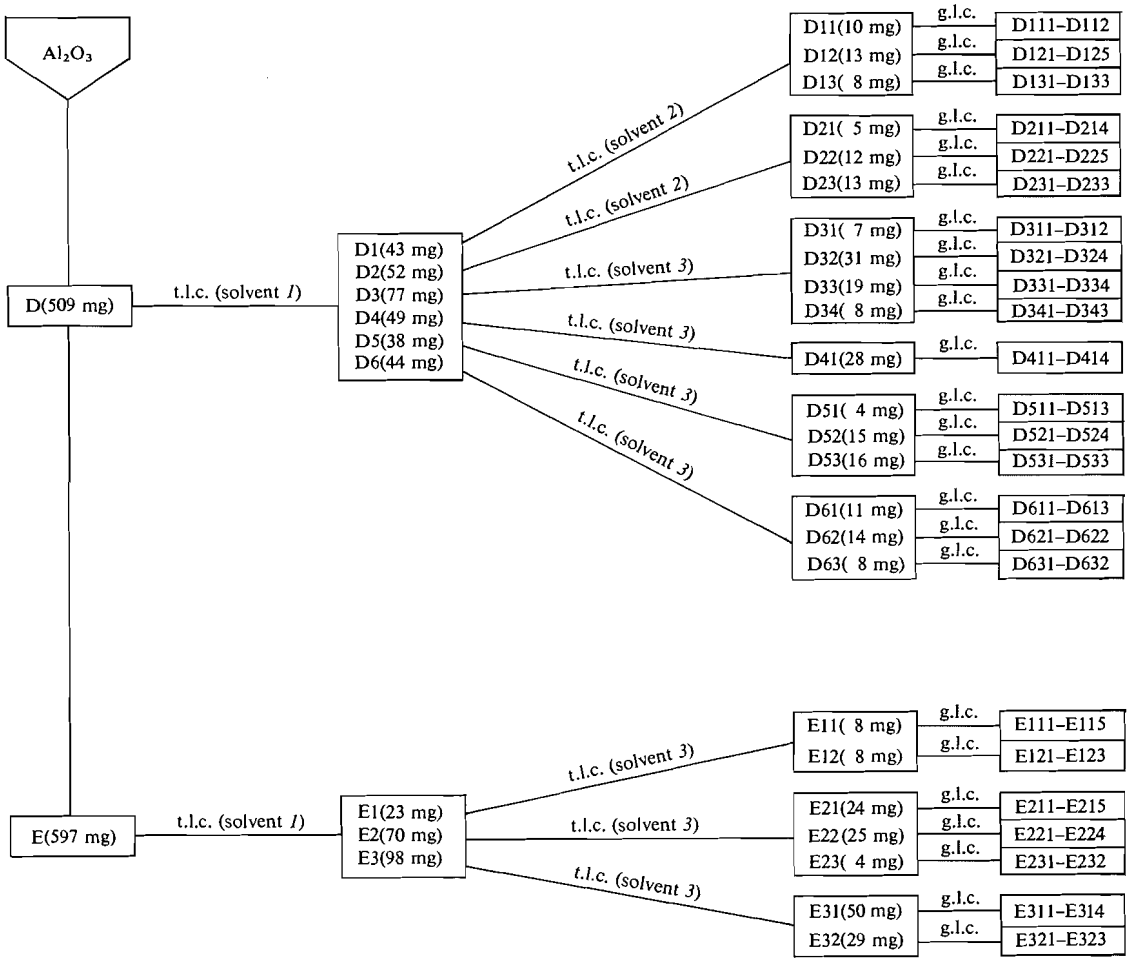

FIG. 1. Fractionation scheme.

After each t.l.c. separation, the plate was inspected under a u.v. lamp and a number of fractions were marked out, scraped off the plate, and extracted with ethyl acetate. Each fraction was subjected to at least two successive t.l.c. separations and then further separated by preparative gas chromatography (Hewlett-Packard model 402, flame ionization detector, 1800 × 4 mm glass column packed with 3% OV-17 on Chromosorb W HMDS, 60–80 mesh, programmed from 200–300° at a rate of 7.5 °C per min). Materials representing the major peaks were eluted from the gas chromatographic column, collected in capillary tubes, and analyzed by i.r. (as micro-KBr-pellets on a Beckman IR 12 spectrophotometer equipped with a beam condenser) and by mass spectrometric analysis on a CEC model 21–490 mass spectrometer using a heated direct inlet probe. The fractionation scheme is summarized in Fig. 1. The R_f values for the main fractions separated by t.l.c. are given in Table 1. The gas chromatographic separation of fraction D-51 is illustrated in Fig. 2.

Quantitative estimates of each major component were made by measuring peak areas on the gas chromatograms by triangulation. To obtain weight percentages each peak area was multiplied by its corresponding "substance-specific correction factor". The corrected area for each component was then expressed as a percentage of the sum of the corrected areas for all components (14).

All solvents used were purified by distillation through high-efficiency columns.

Origin and Preparation of Standards

When available, the known compounds used as standards were purchased as phenolic acids and benzenecarboxylic acids from commercial sources and purified by crystallization from suitable solvents. In the case of most compounds, phenolic OH groups were methylated with dimethyl sulfate (15), while COOH groups were esterified in methanol with an ether solution of diazomethane generated from diazald.

Compounds **1** and **2** (see Fig. 3 and Table 2) were pre-

Fraction	D_1	D_2	D_3	D_4	D_5	D_6	E_1	E_2	E_3
R_f value	0.53	0.43	0.32	0.24	0.17	0.11	0.53	0.46	0.33

pared by methylation and esterification of 3,4-dihydroxybenzoic acid and gallic acid, respectively. Compounds **5** and **15** were kindly supplied as acids by J. C. Pew of the Forest Products Laboratory, United States Department of Agriculture, Madison, Wisconsin and esterified with diazomethane. We thank H. Nimz of the University of Karlsruhe, Karlsruhe, West Germany, for sending us small samples of **6** and **7** as acids which we esterified. Compounds **3**, **4**, **8**, **9**, **10**, and **11** were prepared from 2,3-dimethylphenol, 2,4-dimethylphenol, 2,3,6-trimethylphenol, 2,4,6-trimethylphenol, 2,4,5-trimethylphenol, and 2,3,4-trimethylphenol, respectively, by the following procedure: 1.0 g samples were first dissolved in 5 ml of 2 *N* NaOH solution and methylated with dimethyl sulfate (15). The ethers were separated and oxidized with $KMnO_4$ (16). The resulting acids were then esterified with diazomethane. For the preparation of 12–14 it was found convenient to methylate phenolic OH groups in 2,3,4,5-tetramethylphenol, 2,3,4,6-tetramethylphenol, and pentamethylphenol with diazomethane prior to oxidation and esterification.

Compounds **16** to **21** were prepared by the esterification of the corresponding benzenecarboxylic acids which were obtained commercially.

Each compound was further purified by recrystallization and in some instances by preparative gas chromatography. The identity of each compound was verified by determining its mass and i.r. spectrum, m.p. or b.p., and by ultimate analysis. The analytical data so obtained were then compared with those published in the literature for the same compound.

Results and Discussion

Table 2 lists the yield, i.r. bands, mass spectrometric molecular ion and base peak, gas chromatographic retention time, and the identity of each compound isolated. Only for those compounds for which both mass and i.r. spectra and gas chromatographic retention times were identical with those of corresponding standards is the substitution given. Those isomers for which we were unable to obtain or prepare appropriate standards are listed without detailed substitution patterns. The base peaks for all compounds shown in Table 2 were at M-31 (OCH_3). The benzene – carboxylic acid methyl esters showed additional prominent peaks at M-59 (CO_2CH_3).

*Numerals refer to chemical structures shown in Fig. 3.

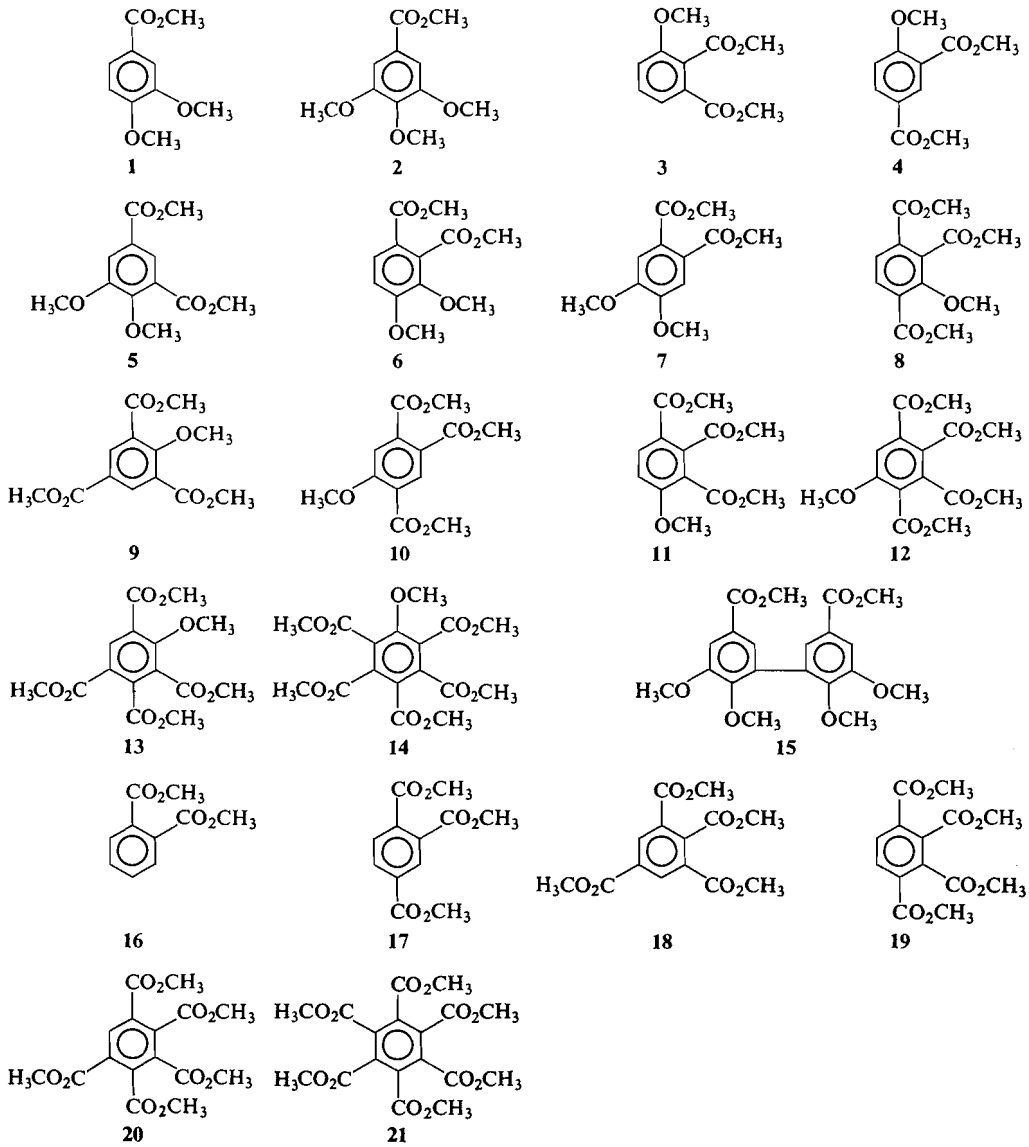

FIG. 3. Chemical structures of compounds isolated.

The results are summarized in Table 3. The most prominent methoxy-benzenecarboxylic methyl esters were fully methylated dimethoxy-benzenedicarboxylic acids, methoxy-benzenetricarboxylic acids, methoxy-benzenetetracarboxylic acids, and methoxy-benzenepentacarboxylic acid. Benzene-tetra-, -penta-, and -hexa-carboxylic acid methyl esters were the most abundant benzene-polycarboxylic acids; the latter constituted almost 25% of the total yield of products, which accounted for about 0.3% of the untreated fulvic acid. It is likely that our yield estimates are low because preliminary experiments with known benzenecarboxylic acid methyl esters showed that at least 50% of the starting material was lost during the fractionation and purification procedure. Assuming that similar losses occurred in the case of the compounds isolated from the fulvic acid, the compounds listed in Tables 2 and 3 may account for up to 0.6% of the weight of the fulvic acid.

The unmethylated fulvic acid contained only

Benzenedicarboxylic acid dimethyl esters	6.0
Benzenetricarboxylic acid trimethyl esters	2.5
Benzenetetracarboxylic acid tetramethyl esters	25.9
Benzenepentacarboxylic acid pentamethyl esters	22.7
Benzenehexacarboxylic acid hexamethyl esters	71.1
Total	310.0

0.2% or 0.07 mequiv OCH_3 per g. Since the phenolic OH and COOH content of the fulvic acid is 3.3 and 9.1 mequiv per g, respectively (4) only a maximum of about 1 in 50 phenolic OH or 1 in 130 COOH groups can occur as OCH_3 or CO_2CH_3. Thus, in the soil, practically all of the phenolic hydroxyls and carboxyls in the fulvic acid are present as OH and COOH groups.

Origin of Compounds Isolated

Compounds **1** to **11** and **15** shown in Fig. 3 have been reported to result from the oxidative degradation in the laboratory, usually with alkaline $KMnO_4$, of lignin (17). While in the present investigation the fulvic acid was not oxidized in the laboratory, it is likely that these compounds were produced by chemical and/or biological oxidation in the soil and that they originated from lignin.

The origin of benzenecarboxylic acids, however, is more difficult to assess. Two types of precursors are worthy of consideration: (*a*) polycyclic aromatic compounds, and (*b*) saturated or hydroaromatic rings that become aromatic during oxidation.

With regard to (*a*) it is noteworthy that zinc dust distillation and fusion of fulvic acid produced small amounts of aromatic polycyclics, ranging from naphthalene to perylene (11). We suggested that these products originated from the polycyclic aromatic "core" of the fulvic acid or from structures giving rise to such systems under the experimental conditions of zinc dust distillation and fusion (11). Concerning point (*b*), Reed and Purves (18), have proposed that aromatic monomeric units of lignin underwent increasing degrees of nuclear condensation as the conditions of isolation from the wood became more drastic and that the benzenecarboxylic acids produced by the alkaline $KMnO_4$ oxidation of such materials resulted from the degradation of aromatic rings attached to cycloaliphatic rings formed by the condensation. It is therefore possible that the benzenecarboxylic acids shown in Table 2 and Fig. 3 originated from the oxidative degradation in the soil of condensed lignin structures.

The data in Table 2 thus indicate a lignin origin for the fulvic acid. It is noteworthy that only traces of the components listed in Table 2 could be extracted by organic solvents from unmethylated fulvic acid. Extraction of the bulk of these compounds was possible only after methylation of the fulvic acid, a process that reduces hydrogen-bonding in the fulvic acid (6). Similarly, we found earlier (6, 7) that methylation released alkanes, fatty acids, and dialkyl phthalates from the fulvic acid and facilitated their extraction by organic solvents. While the nature of the molecular forces that hold the fulvic acid components together, and the hydrophobic organic compounds to the fulvic acid, is still a matter for conjecture, one can visualize the fulvic acid as a hydrophilic polymeric structure that can absorb hydrophobic compounds. This structure consists of lignin degradation products, that is, aromatic hydroxycarboxylic and carboxylic acids (see Table 2) which are held together by hydrogen-bonding. Any weakening of these bonds will destroy the structure.

Fractions eluted from the Al_2O_3 column with

Pyrrole Chemistry. Part XII. The Mechanism of the Reaction Between the Pyrrole Grignard Reagent and Acylating Agents[1]

C. E. LOADER AND HUGH J. ANDERSON
Department of Chemistry, Memorial University, St. John's, Newfoundland

Received October 5, 1970

Deuterium labeling experiments have shown that, in the reaction between the pyrrole Grignard reagent and methyl 1-pyrrolecarboxylate to form 1,2′-dipyrrolyl ketone, direct acylation occurs at the 2-position of the pyrrole Grignard reagent, rather than initial substitution onto the 1-position, followed by rearrangement to the 2-position. At an intermediate stage in the formation of the ketone, ring interchange takes place between the 1-substituted pyrrole rings in the intermediate and unused Grignard reagent, and as a result both pyrrole rings in the final product may originate from the Grignard reagent.

Des expériences de marquage par le deutérium ont montré que, dans la réaction entre le réactif de Grignard du pyrrole et du pyrrolecarboxylate-1 de méthyle pour former la dipyrrolyle-1,2′ cétone, l'acylation directe se fait en position 2 sur le réactif de Grignard, plutôt qu'une substitution initiale en position 1, suivie d'un réarrangement en position 2. Au cours d'une étape intermédiaire de la formation de la cétone, il se produit un échange de cycles entre le réactif de Grignard substitué en position 1 du pyrrole intermédiaire et le réactif de Grignard non utilisé; il en résulte donc que les deux cycles pyrroles du produit final peuvent provenir du réactif de Grignard.

Canadian Journal of Chemistry, 49, 1064 (1971)

In most of its reactions with acylating agents, the pyrrole Grignard reagent **1** gives products resulting from substitution at the 2-position of the pyrrole ring (1).

It was noted in the previous paper in this series (2) that the pyrrole Grignard reagent reacted with alkyl carbonates to give alkyl 1-pyrrolecarboxylates rather than the alkyl 2-pyrrolecarboxylates that might have been expected from the reaction. No reason for the selectivity of the acylation in this reaction is known. In this paper some work on the mechanism of the acylation reaction of the pyrrole Grignard reagent with esters is reported.

The intermediate in the reaction of methyl carbonate with the pyrrole Grignard reagent is probably a salt similar to **2**. The salt is hydrolyzed in the work-up of the reaction to give methyl 1-pyrrolecarboxylate (**3**), the main reaction product (Scheme 1). Although the same kind of intermediate seems likely from the reaction of ethyl acetate with pyrrole Grignard reagent the main product isolated from that reaction is not 1-acetylpyrrole but 2-acetylpyrrole (**4**) (Scheme 2) (3).

A possible reaction mechanism for the formation of 2-substituted pyrroles in the Grignard reaction is that substitution onto the 1-position of the pyrrole ring occurs first and is followed by rearrangement to give 2- or 3-substituted products. Some evidence against this mechanism in the alkylation of the pyrrole Grignard reagent has already been reported (4). If this mechanism does, however, prevail, the formation of 1-substituted products may simply be explained as being cases in which the rearrangement to the 2-position of the pyrrole ring does not occur. Alternatively, initial substitution might take place onto the 2-position with migration onto the 1-position of the pyrrole ring being possible in some cases. This latter possibility seems unlikely as a carbon–carbon bond must be broken if 1-substituted products are to be formed. Finally, direct substitution onto both the 1- and the 2-positions may occur.

A convenient method of studying the mechanism of acylation of the pyrrole Grignard reagent is offered in the case of the acylation of the reagent with methyl 1-pyrrole carboxylate. Here, if the initial attack is at the 1-position of the pyrrole ring, the intermediate **5** may be formed which then rearranges to finally give 1,2′-dipyrrolyl ketone (**6**). In the intermediate **5** the two pyrrole rings are indistinguishable, one of the rings being from the Grignard reagent and the other from the ester. Thus, if the intermediate **5** exists, both of the pyrrole rings should appear as the 2-substituted ring in the final product, 1,2′-dipyrrolyl ketone, with equal frequency. If the intermediate **5** does not exist and direct substitution onto the 2-position of the pyrrole ring in the Grignard reagent occurs, the pyrrole

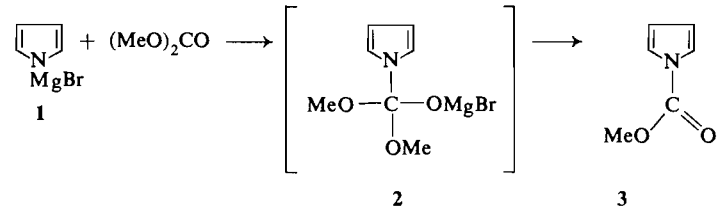
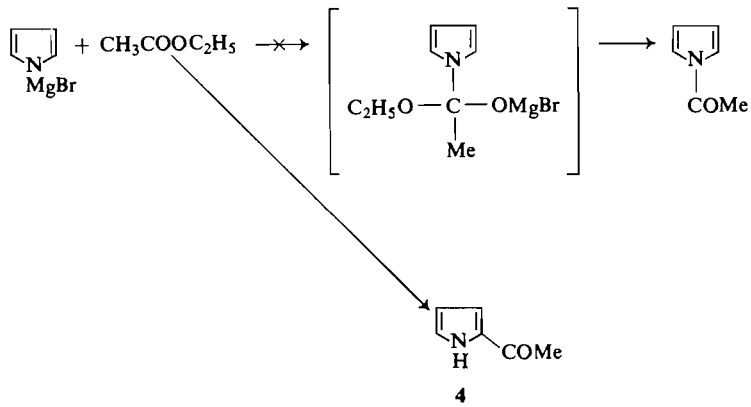
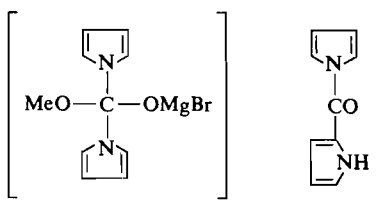


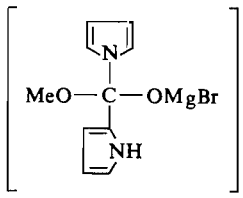
SCHEME 1



SCHEME 2

rings do not become indistinguishable. Thus, the 2-substituted pyrrole ring in the final product will originate from the Grignard reagent and the 1-substituted from the ester. In the latter case the probable intermediate involved in the reaction is the salt **7**.





In order to investigate the path of the reaction of the pyrrole Grignard reagent with methyl 1-pyrrolecarboxylate, pyrrole-d_5 was prepared (4) and converted to the pyrrole-d_4 Grignard reagent. The d_4 Grignard reagent was allowed to react with the 1-pyrrolecarboxylate in the usual way and the 1,2′-dipyrrolyl ketone was isolated by careful fractional distillation of the reaction products. Also isolated in the distillations were pyrrole, methyl 1-pyrrolecarboxylate and traces of 2,2′-dipyrrolyl ketone.

The recovered pyrrole was a mixture of deuterated pyrroles as shown by mass spectrometry, but the recovered methyl 1-pyrrolecarboxylate was almost completely free of deuteration.

The 1,2′-dipyrrolyl ketone was found to be a mixture of the d_3, d_7 and undeuterated ketones (**8**, **9**, and **6** respectively), the d_3 product predominating.

The mass spectrum (Table 1) of the mixture

*A, 1,2′-Dipyrrolyl ketone; B, from methyl 1-pyrrole-d_4-carboxylate and the pyrrole Grignard reagent; C, 1,2′-dipyrrolyl-1′-*d* ketone; D, from methyl 1-pyrrolecarboxylate and pyrrole-d_4 Grignard reagent.

of ketones showed that about 12% of the undeuterated product **6** was formed and about 19% of the d_7 compound **9** (any *N*-deuterium on the 2-substituted ring having been equilibrated to natural abundance with water in the work-up). The remaining 70% of the product was the d_3 compound **8**. Clearly some form of 'ring interchange' takes place during the reaction.

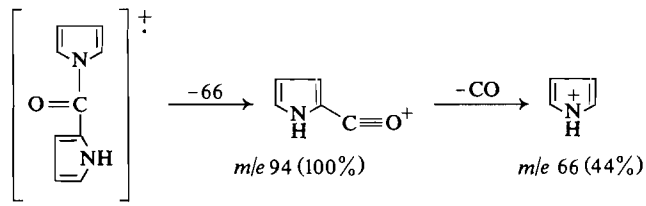
Because no tri- or tetradeuterio methyl 1-pyrrolecarboxylate is formed in the reaction, the possibility of ring interchange between the pyrrole rings of the ester and the Grignard reagent can be excluded. That the isomerization takes place in the mass spectrometer can be excluded for two reasons. The proton resonances of 1,2′-dipyrrolyl ketone could clearly be seen in the p.m.r. spectrum of the reaction product and it is difficult to devise a mechanism for the formation of the d_7 ketone **9** in the mass spectrometer by rearrangement or by pyrolysis in the inlet system. In the latter case the most likely product is a d_6 ketone, which is not found, or the undeuterated product **6**, which is present, but it is unlikely that any is formed in this way (see below). The results discussed above suggest that the exchange between the pyrrole rings takes place at some intermediate stage in the chemical reaction.

The possibility that the ring interchange may involve the 1,2′-dipyrrolyl ketone was considered. However, it was found that interchange neither took place between the ketone and the pyrrole-d_4 Grignard reagent nor was there any between the ketone and pyrrole-d_4 under the reaction conditions used.

The d_4 ketone peak (*m/e* 164) is very small compared with the d_3 ketone peak (*m/e* 163) and can be attributed almost entirely to natural abundance of isotopes in the d_3 product. The presence of the d_7 ketone **6** and the undeuterated ketone **9** can be readily explained on the basis of the intermediate **7**, their formation arising from ring interchange between the molecules of intermediate and the pyrrole Grignard reagent.

If the intermediate **7** is important, since little if any d_4 ketone is formed in the reaction, we must conclude that the deuterated ring does not interchange with the undeuterated ring although it might interchange with the Grignard reagent. A more likely possibility is that ring interchange occurs between the undeuterated ring and the Grignard reagent or with free d_5 pyrrole (present due to the incomplete formation of the Grignard reagent). In this way the formation of the d_7 ketone and undeuterated pyrrole can be explained. The ring interchange will, at the same time as giving the d_7 intermediate (and thus the d_7 ketone **9**), give undeuterated pyrrole Grignard reagent which can react with unused methyl 1-pyrrolecarboxylate to give the deuterium free ketone **6** in the product. Because 1,2′-dipyrrolyl-d_4 ketone is not formed in the reaction in an amount equal to that of the 1,2′-dipyrrolyl-d_3 ketone, for the reasons given above the most likely intermediate in the reaction is similar to **7**. Thus, direct attack at the 2-position of the pyrrole Grignard reagent by the methyl 1-pyrrolecarboxylate predominates over attack at the 1-position followed by migration to the 2-position.

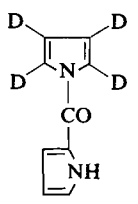
For further confirmation of this mechanism a sample of methyl 1-pyrrole-(2,3,4,5-d_4)-carboxylate was prepared and allowed to react with the pyrrole Grignard reagent to give a



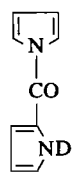
SCHEME 3

deuterated 1,2′-dipyrrolyl ketone with the deuteration having been introduced via the ester rather than via the pyrrole Grignard reagent as in the earlier case. The mass spectrum of the ketone showed deuterated parent ions at *m/e* 164, 163, and 160. The most abundant of these was the ion at *m/e* 164 (31%) and is clearly due to the d_4 ketone **10** and the product to be expected if no ring interchange takes place. However, the ion *m/e* 160 must be due to the undeuterated ketone **6** and indicates that ring interchange does occur. (The ion *m/e* 163 is almost exclusively due to the presence of about 30% trideuterated methyl 1-pyrrolecarboxylate in the 1-pyrrole-d_4-carboxylate used to prepare the ketone.) In this case the formation of d_7 ketone in the product requires not only ring interchange but reaction of the exchanged pyrrole Grignard reagent to give the d_7 product. The abundance of the ions due to the ketone formed by this mechanism showed wide variations from reaction to reaction as might be expected. In contrast, the abundance of the ions due to the ketone resulting from ring interchange only, remained almost constant.

There was no evidence to indicate that ring interchange involving the 2-substituted pyrrole ring in the intermediate took place. Once formed the carbon–carbon bond between the 2-substituted pyrrole ring and the rest of the intermediate is not broken.



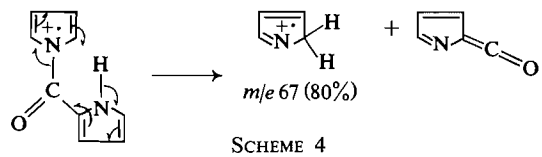
10



11

Mass Spectra (Table 1)

The mass spectrum of 1,2′-dipyrrolyl ketone **6** shows that the parent ion (*m/e* 160) fragments to give the ions *m/e* 94 and 66. The ion *m/e* 94 is the base peak and is only a little more abundant than the ion *m/e* 67. The fragmentation of the monodeuterio ketone **11** is dominated by the ions *m/e* 95, 68, and 67. Since these ions are the same as those from the undeuterated compound +1 we can assume that the fragments still contain the deuterium atom and thus that the fragmentation is dominated by the cleavage of the bond between the nitrogen of the 1-substituted pyrrole ring and the carbonyl group. The main fragmentation paths for 1,2′-dipyrrolyl ketone are shown in Schemes 3 and 4.



SCHEME 4

The deuterated 1,2′-dipyrrolyl ketone from the Grignard reaction of methyl 1-pyrrolecarboxylate with the d_4 pyrrole Grignard reagent showed parent ions at *m/e* 160, 163, 164, and 167. The most abundant ion was at *m/e* 97 and corresponds to the ion at *m/e* 94 in the nondeuterated compound. It is a deuterated ion arising from the d_3 and d_7 ketones **8** and **9**. Accurate mass measurements of the ions *m/e* 160, 163, and 167 showed them to correspond to the deuterated ketones of formulae $C_9H_8N_2O$, $C_9H_5D_3N_2O$, and $C_9HD_7N_2O$ respectively and confirms the nature of the reaction products, as shown in Table 2.

The cyclic mechanism (Scheme 4) for the

formation of the *m/e* 67 ion in the mass spectrum of 1,2′-dipyrrolyl ketone is supported by the mass spectra of the deuterated ketones. The d_1 ketone **11** shows an ion at *m/e* 68 which replaces the *m/e* 67 ion in the mass spectrum of the undeuterated ketone and indicates that the 1′-proton (deuteron) is present in these ions. Thus, the abundant *m/e* 71 ion in the mass spectrum of the mixture of ketones from methyl 1-pyrrole-d_4-carboxylate and the pyrrole Grignard reagent arises from the 1′-substituted pyrrole-d_4 ring in the ketone mixture along with the 1-proton from the 2-substituted pyrrole ring in the same molecule. By applying this mechanism to the fragmentation of the deuterated ketones it is possible to explain the presence in the mass spectra of all the ions corresponding to the *m/e* 67 ion found in the mass spectrum of 1,2′-dipyrrolyl ketone.

This work has shown that the acylation of the pyrrole Grignard reagent with methyl 1-pyrrolecarboxylate proceeds by direct attack at the 2-position of the pyrrole ring in the Grignard reagent rather than by initial attack at the 1-position followed by rearrangement to the 2-position. This is also likely to be true for the acylation of the pyrrole Grignard reagent by other esters excluding the alkyl carbonates and a few other acylating agents (5) where a different mechanism or combination of mechanisms must operate to allow for the formation of the 1-substituted pyrroles found as the main reaction products. We are continuing our study of the pyrrole Grignard reagent with particular interest in the ring interchange reaction and its mechanism.

Experimental

High resolution mass spectra were recorded on a C. E. C. 21-110B spectrometer using a direct inlet system. Gas chromatography was carried out on a Beckman GC-2A chromatograph equipped with a 13-1/2 in. column packed with Apiezon L on firebrick. The remainder of the equipment used has already been described (2).

1,2′-Dipyrrolyl Ketone

Pyrrole Grignard reagent was prepared under nitrogen from magnesium (0.6 g), bromoethane (3.0 g), and pyrrole (1.67 g) in ether (20 ml) (2). The solution was cooled to room temperature and methyl 1-pyrrolecarboxylate (3.15 g) was added in ether (10 ml) with mechanical stirring. The stirred mixture was then heated under a reflux condenser for 2 h. It was then cooled and dilute HCl (1 *M*) was added until all of the precipitated solid dissolved. The aqueous layer was separated from the organic layer and extracted several times with ether. The organic layer and the ether extracts were combined, washed with water, sodium bicarbonate solution, water, and finally dried ($MgSO_4$). The ether was removed and the residue was fractionally distilled under vacuum. The distillate consisted of pyrrole, methyl 1-pyrrolecarboxylate (1.2 g) and 1,2′-dipyrrolyl ketone (1.1 g, 27%). The dipyrrolyl ketone was recrystallized from petroleum, m.p. 61–62°, lit. (6) m.p. 58.5–60°. Full details of the physical properties of these products have already been reported (6).

Reaction of Methyl 1-Pyrrolecarboxylate with Pyrrole-d_4 Grignard Reagent

The pyrrole-d_4 Grignard reagent was prepared from pyrrole-d_5 (7) as in the preparation of pyrrole Grignard reagent above. The reagent was then used in the reaction with methyl 1-pyrrolecarboxylate as in the previous experiment. The deuterated 1,2′-dipyrrolyl ketone was repeatedly recrystallized from petroleum, m.p. 60–61°. The low boiling fractions contained pyrrole and methyl 1-pyrrolecarboxylate and were purified by gas chromatography at a column temperature of 103°. The mass spectrum of the recovered methyl 1-pyrrolecarboxylate was almost identical to that of the methyl 1-pyrrolecarboxylate used as starting material and showed no indication of deuteration. The recovered pyrrole was extensively deuterated and showed parent ions for all stages of deuteration up to pyrrole-d_5. Accurate mass measurements on the main deuterated parent ions in the mass spectrum from the deuterated 1,2′-dipyrrolyl ketone are summarized in Table 2.

Reaction of the Pyrrole-d_4 Grignard Reagent with 1,2′-Dipyrrolyl Ketone

Pyrrole-d_4 Grignard reagent was allowed to react with 1,2′-dipyrrolyl ketone under conditions similar to those used in the preparation of 1,2′-dipyrrolyl ketone above. During the addition of the ether solution of 1,2′-dipyrrolyl ketone to the Grignard reagent the ether boiled and some solid was precipitated. However, on hydrolysis and work-up, the only product isolated was 1,2′-dipyrrolyl ketone which showed no deuteration in its mass spectrum. No ring interchange could be detected when 1,2′-dipyrrolyl ketone was refluxed in ether with pyrrole-d_4 for several hours.

Methyl 1-Pyrrole-d_4-carboxylate

The ester was prepared by the method reported earlier (2) using pyrrole-d_4 Grignard reagent in the place of pyrrole Grignard reagent. The product consisted of a mixture of methyl 1-pyrrole-d_3-carboxylate (30%) and methyl 1-pyrrole-d_4-carboxylate (70%) as shown by mass spectrometry. The reasons for the formation of the large amount of the d_3 ester have not yet been investigated.

Reaction of Methyl 1-Pyrrole-d_4-carboxylate with the Pyrrole Grignard Reagent

Pyrrole Grignard reagent was allowed to react with methyl 1-pyrrole-d_4-carboxylate as for the preparation of 1,2′-dipyrrolyl ketone described above. A deuterated 1,2′-dipyrrolyl ketone was obtained from the reaction products, m.p. 60–61°. The mass spectrum of this product is recorded in Table 1.

1,2′-Dipyrrolyl-1′-d Ketone

The ketone was prepared by repeated deuterium exchange between 1,2′-dipyrrolyl ketone (500 mg) and mix-

tures of deuterium oxide (1 ml) and acetone (2 ml) (8). After four exchanges the product was about 75% deuterated as shown by the mass spectrum and was suitable for the comparison spectrum used in this work.

We are pleased to acknowledge the financial support of the National Research Council of Canada. We wish to thank Dr. W. D. Jamieson of the Atlantic Regional Laboratory, N.R.C.C. for accurate mass measurements.

A Synthesis of *d,l*-Prostaglandin E_2 Methyl Ester and Related Compounds[1]

E. S. FERDINANDI[2] AND G. JUST
Department of Chemistry, McGill University, Montreal, Quebec

Received October 21, 1970

A synthesis of *d,l*-prostaglandin E_2 (PGE_2) methyl ester is described. Two new acetylenic prostaglandins, methyl 11α,15-dihydroxy-9-oxo-prost-5-yn-13-enoate and its C_{15} epimer, were obtained as intermediates in this synthesis. A solvolytic rearrangement of a bicyclo[2.1.0]hexane to a cyclopentane vinyl system is discussed.

Une synthèse de l'ester méthylique de la *d,l*-prostaglandine E_2 (PGE_2) est décrite. Deux nouvelles prostaglandines acétylèniques, le dihydroxy-11α,15 oxo-9 prostyn-5 èn-13-oate de méthyle et son épimère en C_{15}, furent obtenus comme intermédiaires dans cette synthèse. Un réarrangement solvolytique d'un bicyclo[2.1.0] hexane en un vinylcyclopentane est discuté.

Canadian Journal of Chemistry, 49, 1070 (1971)

Introduction

There have been a number of syntheses reported of biologically potent prostaglandins (1) and their analogs (2) in the recent literature. We wish to report a synthesis *d,l*-5-dehydro PGE_2 and *d,l*-PGE_2 methyl esters which follow the general principle published (1*a*) using the modification introduced by Schneider *et al.* (1*b*, *c*). A similar synthesis was described in a recent communication by Schneider (1*g*). In this paper we wish to describe (Scheme 1): (*1*) the synthesis of the iodo ester **6***b* which constitutes the C_1—C_7 side chain of PGE_2; (*2*) the alkylation of the bicyclic ketone **7** with the iodo ester **6***b* which gave the keto ester **9**; (*3*) a study of the solvolytic transformation of the bicyclo[3.1.0]hexanone **9** to the acetylenic prostaglandin analog **11** which showed high biological activity; and (*4*) the final reduction and isomerization of **11** to *d,l*-PGE_2 methyl ester **17**.

The best synthesis of the seven carbon sidechain **6***b* was achieved by the condensation of propargyl alcohol with a C_4 unit, 4-tetrahydropyranyloxybutyl bromide (**3***b*) (Scheme 2).

The bromide **3***b* was synthesized in four steps starting with γ-butyrolactone (**1**). Treatment of the lactone with saturated aqueous hydrogen bromide at reflux for 15 h gave 4-bromobutyric acid (**2***a*) (4). This was esterified with diazomethane (5), and the resulting ester **2***b* was reduced with excess lithium aluminum hydride in diethyl ether at −50° to give 4-bromobutanol (**3***a*). Finally, treatment of the bromo alcohol **3***a* with dihydropyran and a trace of phosphorus oxychloride (6) gave **3***b*. Yields of better than 90% were realized for each step in this sequence.

Reaction of **3***b* with propargyl alcohol by the method of D'Engenieres *et al.* (3) gave 7-tetrahydropyranyloxyhept-2-yn-1-ol (**4***a*) in 50–60% yield. Only moderate yields were realized because of the formation of the two by-products **4***b* (2.5%) and **4***c* (25%) which resulted from *O*-alkylation of propargyl alcohol and **4***b*, respectively.

The iodo ester **6***b* was obtained from **4***a* by the following sequence. The hydroxy group of **4***a* was mesylated by first forming the lithium alcoholate with butyl lithium followed by slow addition of mesyl chloride in diethyl ether at 0°. The mesylate **5***a* was then treated with sodium iodide in dry acetone for 1.5 h (7) to give the corresponding iodide **5***c*. The bromide **5***b* was similarly prepared by refluxing the mesylate **5***a* with anhydrous lithium bromide in acetone for 24 h (8). Cleavage of the tetrahydropyranyl ether with dilute methanolic hydrochloric acid gave 7-iodohept-5-yn-1-ol (**5***d*) which was oxidized with excess Jones reagent (17) at 0° to the carboxylic acid **6***a* in 20% overall yield starting from **4***a*. Methylation with diazomethane gave the acetylenic iodo ester **6***b*: i.r. (film) 2240, 1740, 1163 cm^{-1}; δ 3.64 (3H, OCH_3) and 3.70 (3H, J = 2 Hz, $-CH_2I$); M^+ 266, M^+-I 139.

Alkylation of Exo-6-(1'-heptenyl)-bicyclo-[3.1.0]hexan-3-one (7)

The reaction conditions for the alkylation of bicyclic ketone **7** with the iodo ester **6** were found to be extremely critical. Best results were obtained when freshly prepared potassium *t*-butoxide dissolved in tetrahydrofuran (THF) was added slowly to a THF solution of the ketone and iodo ester at 0–5° (9, 1*c*). It was also necessary to have

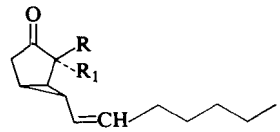
the iodo ester in a large excess relative to the ketone and rigorously dried THF in order to obtain maximum yields of the monoalkylated product. Alkylation was only achieved when iodide was the leaving group.

Alkylation of the ketone **7** with a three-fold excess of the iodo ester gave four alkylated products which were separated from the unreacted starting material by column chromatography on silica gel, and then from each other by preparative t.l.c. on silica gel (benzene–ether, 9:1). The major product was the monoalkylated compound **9**, obtained as a mixture of *cis* and *trans* (β and α) isomers in 23% yield: i.r. (film) 1740, 1165 cm^{-1}; n.m.r. ($CDCl_3$) δ 5.6–4.6 (2H, m, HC=CH), 3.62 (3H, s, OCH_3); M^+ 330. The other three products were the di- (M^+ 468), tri- (M^+ 606), and tetra- (M^+ 744) alkylated compounds obtained in 8, 11, and <5% yields respectively.

The g.l.c. of the monoalkylated product (6′ 3% SE30 on chromosorb W, 200°) indicated that there were two compounds present (R_t = 2.90 and 4.75 min) in the ratio 3:7. In the PGE_1 series, the analogous alkylation products **i***a* and *b* obtained in the ratio 28:72 (1*c*) had retention times of 3.05 and 4.67 min on the same g.l.c. column.[3]



i

a R = H; R_1 = CO_2CH_3

b R = CO_2CH_3; R_1 = H

The minor component (R_t = 3.05 min) had been assigned the *trans* configuration, since it had been converted to $PGF_{1\alpha}$ (1*c*). Based on the close parallelism of the two sets of reactions, the minor and major components must be the *trans* (α) and *cis* (β) isomers of **9**. These isomers were carried through the final sequence of reactions without separation, since it has been found (29) that 8-iso-PGE_1 methyl ester isomerizes to the PGE_1 methyl ester in 5% methanolic sodium acetate.

The g.l.c. of the dialkylated product (6′, 3% SE30 on chromosorb W, 248°) showed two peaks (R_t = 3.50 and 5.25 min) in the ratio 1:5. Too little was known to make a structural assignment for the two dialkylated products. However, it has been shown (25) that the second condensation reaction occurs predominantly at the more substituted carbon.

The tri- and tetra-alkylated products were not eluted off the column at temperatures up to 250°.

An alternative route to the keto ester **9** involved alkylation of the bicyclic ketone **7** with an excess of the iodide **5***c* which gave the monoalkylated product **8** in 19% yield. The subsequent acid hydrolysis of the tetrahydropyranyl ether, Jones oxidation of the resulting alcohol to the carboxylic acid, and final esterification with diazomethane, gave a complicated mixture of products from which the keto ester **9** could not be isolated.

The Final Steps in the Synthesis of d,l-PGE_2 Methyl Ester

The crucial step in this prostaglandin synthesis was the solvolytic transformation of the cyclopropyl ring in **9** to the open chain diol or prostaglandin skeleton (**11** and **12**) (Scheme 3).

The acetylenic keto ester **9** was converted by the method of Swern *et al.* (26) to the diol **10***a* in 87% yield (i.r. (film) 3435 cm^{-1}; mass spectrum *m/e* 364 (M^+)). The diol **10***a* was then treated with an excess of methanesulfonyl chloride in anhydrous pyridine at −10°. The reaction was worked-up in the cold and gave the corresponding dimesylate **10***b* in 78–85% yields (i.r. (film) 1350, 1180 cm^{-1} (SO_2)).

The solvolysis of the dimesylate was carried out in acetone–water (2:1) at room temperature (22–25°) for 36 h in a nitrogen atmosphere. The reaction was followed by t.l.c. on silica gel (benzene – ethyl acetate 1:1) and was found to be more than 95% complete after this time. The solvolysis mixture consisted of five components which could be easily separated by preparative t.l.c. on silica gel using ethyl acetate as the solvent system.

The major products (R_f 0.62 and 0.48) were the isomeric hydroxy mesylates **13**, obtained in 70–80% yield (i.r. (film) 3475, 1355, 1180 cm^{-1}). A minor product (R_f 0.37) was also a hydroxymesylate but was never obtained pure for proper characterization. The other two components, R_f 0.29 and 0.19, were obtained in 11–16% yield and consisted of 5-dehydro PGE_2 methyl ester and its 8-isomer **11**, and the corresponding 15-epimers **12** (i.r. (film) 3440, 1740 cm^{-1}; n.m.r. ($CDCl_3$) δ 5.9–5.2 (*HC=CH*); *m/e* 346 (M^+-H_2O)).

Treatment of a mixture of **11** and **12** with 0.5 *M*

[3]Samples of **i***a* and *b* for g.l.c. analysis were supplied by Dr. J. E. Pike of the Upjohn Company, Kalamazoo, Michigan.

†Bioassay carried out by Dr. J. R. Weeks, The Upjohn Company, Kalamazoo, Michigan.

sodium hydroxide in methanol at 38–48° for 1.5 h gave 5-dehydro-PGB_2 methyl ester **14** (ε_{275} 28 300)(27). Prolonged heating or heating at reflux temperatures for short times caused the chromophore to disappear. Presumably **14** decomposed under these more vigorous conditions.

The configuration at C-15 of the products **11** and **12** were assigned on the basis of their bioassay for smooth muscle stimulating activity. This assignment was subsequently confirmed when **11** and **12** were independently converted to the PGE_2 and 8-iso PGE_2 methyl esters **15** and **16** respectively, which in turn showed the predicted activity for smooth muscle stimulation (28). The bioassay on rat stomach fundus for smooth muscle stimulating activity of the prostaglandin-type products obtained from the solvolysis showed that the slower moving compound (R_f 0.19) had higher activity than the faster moving one (R_f 0.29) (Table 1).

Since it is known[4] that PG's with the natural α-configuration at C-15 are more active than the ones having the unnatural β-configuration, the slower moving isomer (R_f 0.19) was assigned the

α-configuration shown in **11** while the faster moving isomer (R_f 0.29) was assigned the β-configuration **12**. The comparison of t.l.c. R_f values of the PGE_2 methyl ester, synthesized in the subsequent steps, with that of the natural PGE_2 methyl ester supported this assignment.

Treatment of **11**, a mixture of 8α and β isomers, with 5% methanolic sodium acetate for seven days at room temperature (29) gave a product with increased biological activity (Table 1). This result was consistent with the formation of more of the 8α isomer since PG's having the natural, 8α configuration are known to be more active than those having the 8β configuration.[4]

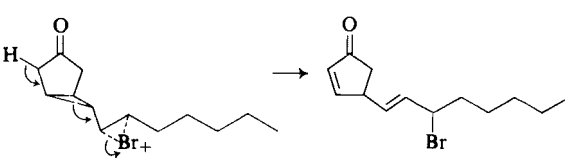
Attempts were made to improve the yields of the rearranged product by varying the leaving group, the solvolysis condition, and the type of carbonium ion generated. Because of the difficulty in synthesizing the alkylated bicyclic ketone **9** and since the side chain should not greatly affect the yields of rearranged products, the unalkylated ketone **7** was used as a model in these solvolysis studies. By analogy to the results of Wiberg and Ashe (10) where the exo isomer was found to give a cleaner reaction and more ring opened product than the endo isomer, only the exo isomer was considered in this study.

It was known that the rearrangement of the cyclopropyl carbinyl system gave, under kinetic control, the cyclopropyl carbinol as the major product (12), but that under thermodynamically controlled conditions, the homoallylic system was favored (13). In principle, thermodynamic control would be achieved by treating the glycol **20** (Scheme 4) with mineral acid. However, one competing reaction, a pinacol rearrangement (9), and, in the E-series, the known acid instability of the PG which is dehydrated to the PGA compounds (27), made this route unsuitable. The ditrichloroacetate **21** was, therefore, prepared by treating the diol **20** with excess trichloroacetylchloride in pyridine and solvolyzed in trichloroacetic acid. Under these conditions, any regenerated ditrichloroacetate would be resolvolyzed, giving effectively thermodynamic control.

The solvolysis of the ditrichloroacetate was carried out at various temperatures in trichloroacetic acid, trichloroacetic acid – dioxane 1:1, and trichloroacetic acid containing some *p*-toluenesulfonic acid. Pyrolysis of the ditrichloroacetate was also attempted. In order to determine if rearrangement had taken place, the reaction mixture was taken up in ether and washed with 5% sodium bicarbonate and water to remove all the acid solvent. Some of the resulting material was then treated with 0.5% sodium hydroxide in methanol at 50–60° for 10 min. If rearrangement took place, the resulting β-hydroxy ketone **22** would be converted to the conjugated ketone **29** in the same way the PGE_{1-3} were converted to PGB_{1-3} (27). This compound is easily identified by its u.v. spectrum (λ_{max}(MeOH) 268 mμ, ε 26 000). There was no detectable rearrangement in any of the solvolysis reactions carried out in trichloroacetic acid. The t.l.c. of the products on silica gel (benzene–ether, 7:3) showed only recovered ditrichloroacetate. Pyrolysis at 230° gave a small amount of rearrangement along with considerable charring. At 120–140°, no reaction took place.

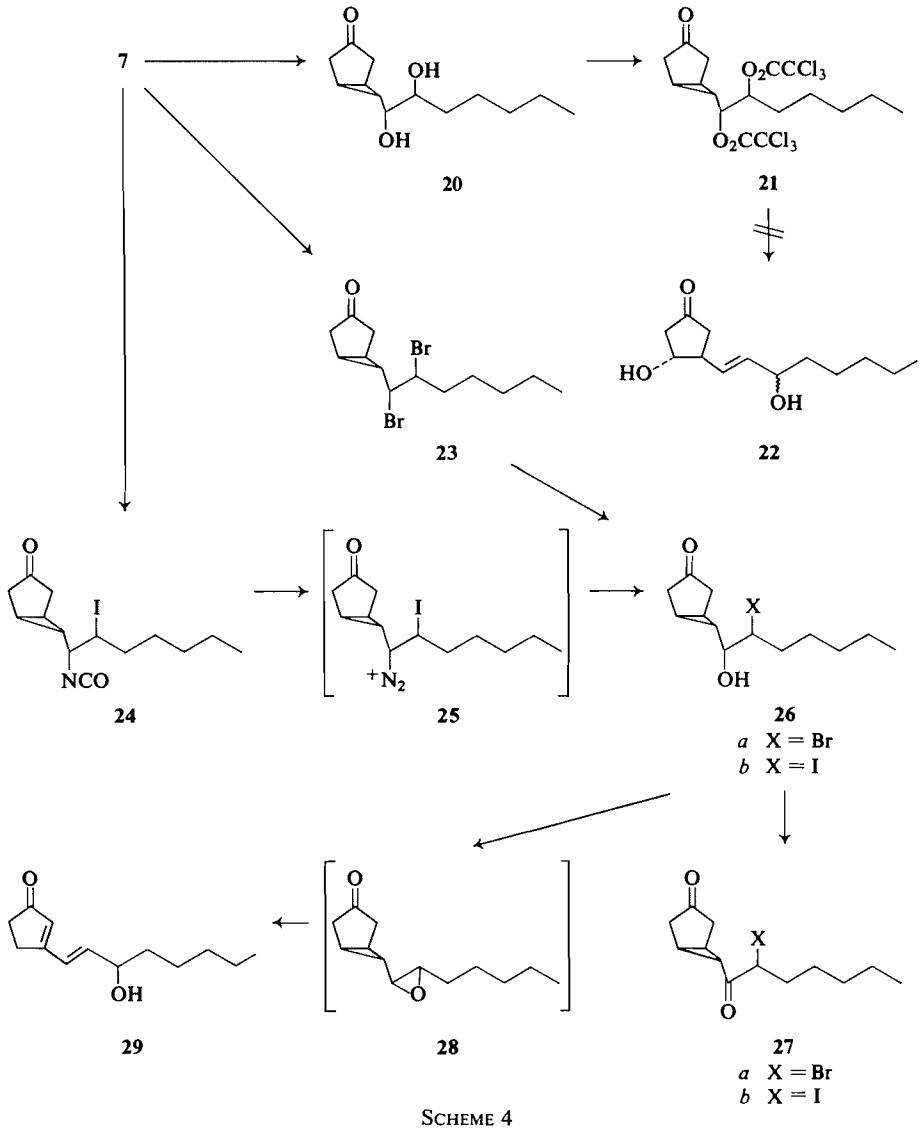
Solvolysis of the ditrichloroacetate **21** in refluxing aqueous acetone, analogous to the reaction carried out by Lumb and Whitham (14), gave, after 4 days, the starting ditrichloroacetate (65%), the glycol **20** (30%), and the rearranged diol **22** (2%). Because of the long reaction time and poor yield of the rearranged product **22**, this reaction was not further studied.

A similar solvolysis of the dibromide **23**, prepared by treating the ketone **7** with pyridinium hydrobromide perbromide (15) in anhydrous chloroform,[5] was carried out in aqueous acetone. The solvolysis was carried out at room temperature for 112 h. After separation of the components by t.l.c. (benzene–ether 7:3), the reaction mixture was found to consist of the dibromide **23** (63%), the unrearranged bromohydrin **26***a* (15%) (M^+ 289, 291; *m/e* 210, M^+-^{79}Br, ^{81}Br), and a slow moving fraction (5%) which was still a mixture of four compounds. The components of this slow moving fraction had a low R_f value which



ii iii

[5]Two products were obtained from this reaction. The desired dibromide **21** (55%) was the major product but could only be separated with much difficulty from a minor product. This minor product was not obtained pure. However bands at 1720 and 1630 cm^{-1} in the i.r. spectrum of the mixture suggested that it was an α,β-unsaturated, five-membered ring ketone such as **iii**. Such a compound would be formed if, during the bromination reaction in a slightly acidic, aprotic solvent, rearrangement of **ii** to **iii** occurred as well.



SCHEME 4

suggested that they were diols. This mixture probably contained some rearranged product, but there was not enough material available for proper characterization of its components.

The bromohydrin **26***a* was independently synthesized by treating the ketone **7** with *N*-bromosuccinimide (16). Oxidation of **26***a* with Jones reagent (17) at 0° gave the bromodiketone **27***a* in good yield (i.r. (CCl_4) 1748, 1700 cm^{-1}, n.m.r. (CCl_4) δ 4.27(t, 1H, J = 6.5 Hz, C*H*Br)).

When the bromohydrin **26***a* was treated with 0.5% methanolic sodium hydroxide at 50°, the conjugated hydroxy ketone **29** was obtained in about 30% yield (crude product ε_{268} 8500). This compound was probably formed via the epoxide **28** which is known to rearrange to the conjugated ketone under basic conditions (11).

Since the generation of a 'normal' carbonium ion gave products of rearrangement in less than 20% yield, it was decided to try to generate a 'hot' carbonium ion (19) (Scheme 4).

Addition of iodine isocyanate (20) to the olefin **7** gave the iodo isocyanate **24** in good yield: (i.r. (CCl_4) 2245 cm^{-1}). The mode of addition follows from subsequent reactions. The isocyanate was hydrolyzed to the corresponding amine in aqueous acetone. The amine was not isolated but treated, *in situ*, with formic acid and sodium ni-

trite at −4°. After 1 h at this temperature and 3.5 h at 25°, the only compound isolated was the unrearranged iodohydrin **26***b* (M^+ 336; *m/e* 209, M^+-I). If any rearrangement did occur, it was to an extent of less than 10%, and certainly no higher than in the dimesylate solvolysis. Oxidation of the iodohydrin **26***b* with Jones reagent gave the iodo diketone **27***b* (i.r. (CCl_4) 1745, 1695 cm^{-1}; n.m.r. (CCl_4), 100 Hz) δ 4.48(t, 1H, J = 4.0 Hz, C*H*I)).

Considerable work has been done to study the cyclopropylcarbinyl solvolysis and to understand the nature of the carbonium ion which was involved (21). Although rate enhancement of the solvolysis due to the participation of the cyclopropyl group adjacent to the leaving group has been widely demonstrated (10, 12*a–d*)[6] the exact nature of the carbonium ion is controversial (21, 12*e,f*, 13*a*) and the extent of rearrangement in various cyclopropylcarbinyl systems under similar solvolytic conditions is quite unpredictable (10, 14, 22).

The reason for the limited rearrangement in the bicyclo[3.1.0]hexanone system discussed above was not clear. A number of factors could influence the amount of rearrangement product. The stereochemical arrangement of the leaving groups to the migrating bond (18, 30) and the amount of ring strain in the transition state caused by bond breaking and rearranging (12*g,h*, 22, 23) have been found to greatly influence the type of products obtained in a solvolysis. Recently it was shown (24) in a modified PGE_1 synthesis that the *endo* isomer gives about twice as much rearranged product as the *exo* isomer under the same reaction conditions. In the case of the ditrichloroacetate **21**, where no reaction took place at all, the reaction might be very slow. Indeed, it was found that the dibromide solvolysis was much slower than that of the dimesylate but faster than that of the ditrichloroacetate. This order of reactivity of the leaving groups is the expected one (18). No extensive data on the reactivity of trichloroacetates, or the solvolyzing ability of trichloroacetic acid, have been reported. Another factor which may limit the amount of rearrangement is that the neighboring group participates in the formation of the cyclopropylcarbinyl carbonium ion, minimizing the effect of the cyclopropyl group, although the latter also participates in the ion formation.[6]

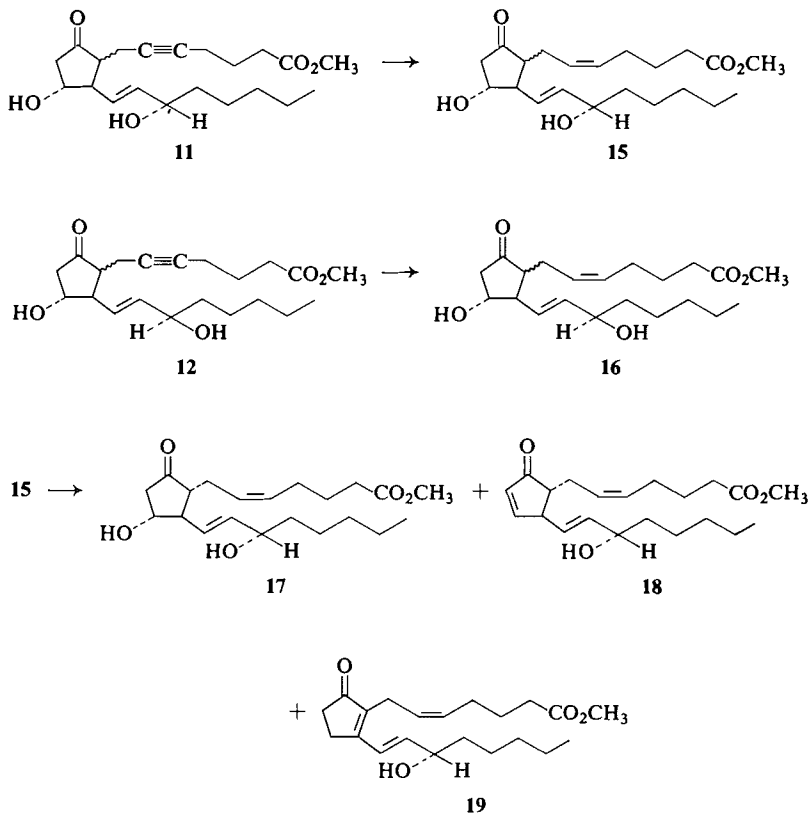
The final step in the synthesis of PGE_2 methyl ester was the reduction of the acetylenic bond to a *cis* double bond. Catalytic hydrogenation of the mixture of 5-dehydro PGE_2 methyl ester and its 8-isomer **11** using Lindlar catalyst poisoned with 1–3% quinoline (32) gave a mixture of PGE_2 and 8-iso PGE_2 methyl esters **15** in 63% yield. The corresponding mixture of 15-epi-5-dehydro PGE_2 methyl ester and its 8-isomer was hydrogenated in the same way to a mixture of 15-epi-PGE_2 methyl ester and its 8-isomer **16** (Scheme 5).

The mixture 8α- and β-PGE_2 methyl ester **15** was treated with 3% ethanolic potassium acetate solution for 94 h at 22° (28). The resulting reaction mixture consisted of one major and two minor components. The major product, isolated in 80% yield from the other two by preparative t.l.c. on silica gel (using ethyl acetate as the solvent system), was characterized as 8α-PGE_2 methyl ester **17** (i.r. (film) 3440, 1740 cm^{-1}; n.m.r. ($CDCl_3$) δ 5.6(m, 2H, *trans* *H*C=C*H*), 5.3 (m, 2H, *cis* *H*C≡C*H*); mass spectrum *m/e* 348 (M^+-H_2O)). The i.r. and mass spectra were identical with the corresponding spectra of the PGE_2 methyl ester obtained from natural PGE_2. The two minor products were identified as PGA_2 methyl ester **18** (18%) (ε_{217} 9000; mass spectrum *m/e* 348(M^+)) which was contaminated by a small amount of the second compound, PGB_2 methyl ester **19** (2%) (λ_{max} 277 mμ).

The 15-epi-PGE_2 methyl ester **16** was characterized from its mass spectrum. The fragmentation was the same as that obtained for PGE_2 methyl ester **17**. Exact mass measurement of the fragment *m/e* 348 was correct for $C_{21}H_{32}O_4$ or M^+-H_2O (calcd., 348.230045; found, 348.229694). The fragment *m/e* 190, one of the most abundant fragments in the mass spectrum of PGE_2 methyl ester (29), was correct for an empirical formula $C_{13}H_{20}O_2$ (calcd., 190.135758; found, 190.135990). Such an ion probably arises from $C_{21}H_{32}O_4$ by fragmentation of the ester side chain with hydrogen transfer to the ion fragment *m/e* 208, followed by loss of H_2O.

The R_f values of synthetic PGE_2 methyl ester obtained from natural PGE_2 were compared by t.l.c. on silica gel and 10% silver nitrate impreg-

[6]It was found that the leaving group adjacent to the cyclopropyl ring was the only one solvolyzed in all the reactions that were carried out. Indeed, in the case of the iodohydrin **26***b*, the iodide could not be solvolyzed when it was refluxed in aqueous acetone for 24 h. Therefore the cyclopropyl ring does participate in the initial solvolysis reaction.



SCHEME 5

TABLE 2. The R_f values on silica gel

Compound	10% $AgNO_3$/MIII*	Ethyl acetate
PGE_2 Methyl ester from natural PGE_2	0.31	0.27
PGE_2 Methyl ester **17**	0.31	0.27
15-epi-PGE_2 Methyl ester **16**	0.32	0.35
5-Dehydro-PGE_2 methyl ester **11**	0.39	0.27

*MIII, Ethyl acetate – methanol – water (16:2.5:10).

nated silica gel. The R_f values are listed in Table 2. The PGE_2 methyl ester **17** had the same R_f value as that of the PGE_2 methyl ester derived from natural PGE_2, confirming the stereochemical assignment at C-15 made with the 5-dehydro-PGE_2 methyl esters. The 15-epi-PGE_2 methyl ester **16** had a higher R_f value in both systems.

The bioassay (30) on the isomerized product **17**, carried out on the gerbil colon smooth muscle showed that it had very high biological activity, and in the expected order of potency[4] (Table 1). Although PGE_1 and PGE_2 activity has not been compared on gerbil colon, it was estimated[4] that PGE_2 would be several-fold more potent. On the rabbit duodenum, the activity of PGE_2 was about three-fold PGE_1 and they were equal on guinea-pig ileum (31). Further, in tests on other prostaglandins, it has not been found that esterification with methyl has any great effect on activity in isolated baths.[4] The increased activity after

epimerization indicated that isomerization had taken place, and the 8α isomer **17** (*d,l*-PGE_2 methyl ester) had been obtained.

Experimental

The instruments used in this work to characterize the compounds were: Perkin–Elmer 257 and 357 i.r. spectrometers, Varian A60 and 100 Hz n.m.r. spectrometers, MS9 high resolution mass spectrometer, Unicam u.v. spectrometer, and F&M 700 gas chromatograph. Elemental analyses were carried out by Beller, Microanalytical Laboratory, West Germany and Dr. Franz Pascher Microanalytical Laboratory, Bonn, West Germany.

Unless otherwise mentioned, the term "worked-up as usual" means extracting with a specified solvent, washing the combined extracts with water and saturated aqueous sodium chloride, drying over anhydrous sodium sulfate or magnesium sulfate, filtering, and finally evaporating the solvent *in vacuo*.

4-Bromobutyric Acid (2a)

Compound **2***a* was prepared according to the procedure of Avison *et al.* (4).

Methyl 4-Bromobutyrate (2b)

The crude 4-bromobutyric acid (**2***a*) was treated with ethereal diazomethane (5) at 0°. The ether was then removed *in vacuo* and the product was distilled at 77°/15 mm: i.r. (CCl_4) 1778, 1740 cm^{-1} (C=O); n.m.r. (CCl_4) δ 3.59 (s, 3H, OCH_3), 3.38 (t, 2H, J = 6.0 Hz, CH_2Br), 2.63–1.96(m, 4H, CH_2CH_2CO).

Anal. Calcd. on $C_5H_9O_2Br$: C, 33.15; H, 4.97; Br, 44.19. Found: C, 33.42; H, 5.06; Br, 43.98.

4-Bromobutanol (3a)

A slurry of lithium aluminum hydride (3.05 g) in anhydrous ether (250 ml) in a 1 l, three-necked flask was cooled to −60°. The bromo ester **2***b* (23.8 g), dissolved in anhydrous ether (200 ml), was added at such a rate that the temperature did not go above −50°. Following the addition, the reaction was kept below −60° for 1.5 h, then slowly allowed to warm to −10°. The reaction was then quenched with 200 ml of 2 *N* sulfuric acid at 0° and worked-up as usual with ether. The resulting alcohol **3***a* was obtained in 95% yield (b.p. 48–49°/3 mm): i.r.(CCl_4) 3630, 3300 (OH), 1060 cm^{-1} (C—O); n.m.r. (CCl_4) δ 3.68(t, 3H, J = 6.5 Hz, CH_2O), 3.46(t, 3H, J = 6.0 Hz, CH_2Br), 2.25–1.50(m, 4H, CH_2CH_2), 4.62(s, 1H, exchangeable, O*H*).

Anal. Calcd. for C_4H_9OBr: C, 31.37; H, 5.88; Br, 52.22. Found: C, 31.49; H, 5.83; Br, 51.98.

4-Tetrahydropyranyloxybutyl Bromide (3b)

One equivalent of the bromo alcohol **3***a* was treated (neat) with a slight molar excess of 3,4-dihydropyran and three drops of phosphorous oxychloride. A vigorous exothermic reaction started almost immediately after the phosphorous oxychloride had been added (in one instance, the reaction started without addition of catalyst, probably because the mixture was contaminated with some mineral acid). The reaction temperature was controlled with an ice-water bath. After the exothermic reaction had subsided, the reaction mixture was stirred at room temperature for 3 h. The mixture was then taken up in ether and washed twice with 5% aqueous potassium hydroxide, followed by usual work-up procedure. The resulting tetrahydropyranyl ether could be distilled at 82–84°/2 mm as long as the distillation apparatus was acid free, otherwise the tetrahydropyranyl ether would cleave. Purification was also achieved by column chromatography on silica gel using hexane, then hexane–benzene mixtures (2.5 to 20%) as the solvent system. The yield of **3***b* was better than 95%: i.r. (CCl_4) 1143, 1130, 1038, 1028 (C—O—C), 914, 872 cm^{-1}; n.m.r. (CCl_4) δ 4.53 (m, 1H, *H*C ketal), 4.05–3.18 (m, 6H, 2(OCH_2), CH_2Br), 2.25–1.35 (m, 10H, CH_2).

Anal. Calcd. for $C_9H_{17}O_2Br$: C, 45.59; H, 7.17; Br, 33.75. Found: C, 45.33; H, 7.38; Br, 33.93.

7-Tetrahydropyranyloxy-2-heptyn-1-ol (4a)

A 500 ml, three-necked, round-bottom flask was fitted with a Claisen adapter on the middle neck, and a stopcock adapter (nitrogen inlet), and dropping funnel on the other two necks. A mechanical stirrer was passed through the middle neck and Dry Ice condenser was placed on the other arm of the Claisen adapter. The system was flushed with nitrogen gas and flame dried. The reaction flask was charged with 0.22 mol lithium amide, the flask and condenser were then cooled to −80° (isopropyl alcohol – Dry–Ice), and 200 ml ammonia was distilled through the condenser into the flask. It was not found necessary to redistill the ammonia from sodium metal. After the distillation, the system was again flushed with nitrogen and the dropping funnel was charged with 0.10 mol propargyl alcohol in 30 ml of anhydrous ether. The alcohol was added dropwise with stirring. The coolant from the flask was then removed and the solution was stirred for 2 h. After this time, the dropping funnel was charged with 0.09 mol of the bromide **3***b* in 20 ml of anhydrous ether under a positive nitrogen pressure. The bromide was added dropwise and then the reaction mixture was stirred for 6 h at −33° (refluxing ammonia). After this time the reaction was quenched by the addition of 0.05 mol of ammonium chloride and the ammonia was allowed to evaporate overnight. The resulting solid mass was then taken up in water and ether. The ether was separated and the aqueous phase was further extracted (six times) with ether. The work-up was then continued in the usual way. The crude reaction product was chromatographed on a silica gel column (30 g silica gel to 1 g mixture). The column was eluted with hexane containing increasing amounts of ethyl acetate (2.5%–20%).

The compounds that were isolated from the reaction mixture are given below in the order that they were eluted off the column.

(1) 4-Tetrahydropyranyloxybutyl Propargyl Ether (4b)

This compound was eluted with 2.5–5% ethyl acetate in hexane and obtained in 2.5–5% yield: i.r. (CCl_4) 3310 (≡CH), 2120 (C≡C, terminal), 1124, 1105, 1079, 1038, 1023 cm^{-1} (C—O—C); n.m.r. (CCl_4) δ 4.53(m, 1H, *H*C ketal) 4.09(d, 2H, J = 2.5 Hz, $OCH_2C{\equiv}$), 3.9–3.1(m, 6H, OCH_2), 2.57(t, 1H, J = 2.5 Hz, ≡C*H*), 1.8–1.4(m, 10H, CH_2).

Anal. Calcd. for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50. Found: C, 68.10; H, 9.66.

For personal use only.

(2) 4-Tetrahydropyranyloxybutyl-7-tetrahydropyranyloxy-2-heptynyl Ether (4c)

Compound **4c** was eluted with 5–10% ethyl acetate in hexane and obtained in 20–25% yield: i.r. (CCl_4) 2230 (C≡C), 1145, 1130, 1085, 1075, 1045, 1030 cm^{-1} (C—O—C); n.m.r. (CCl_4) δ 4.59(m, 2H, *H*C ketals), 4.09 (t, 2H, J = 2.0 Hz, ≡CCH_2O), 4.0–3.2(m, 10H, CH_2O), 2.2(m, 2H, CH_2C≡), 1.9–1.3(m, 20H, CH_2).

Anal. Calcd. for $C_{21}H_{36}O_5$: C, 68.44; H, 9.85. Found: C, 68.04; H, 9.74.

(3) 7-Tetrahydropyranyloxy-2-heptyn-1-ol (4a)

This compound was eluted off the column with 20% ethyl acetate in hexane and obtained in 50–60% yield. Distillation of this compound was unsatisfactory because of tetrahydropyranyl ether cleavage: i.r. (CCl_4) 3610, 3450 (OH), 2220 (C≡C), 1140, 1123, 1039, 1025 cm^{-1} (C—O—C); n.m.r. (CCl_4) δ 4.60(m, 1H, *H*C ketal), 4.17 (t, 1H, J = 2.0 Hz, OCH_2C≡), 4.0–3.2(m, 4H, CH_2O), 2.5–2.1(m, 2H, CH_2C≡), 2.0–1.4(m, 10H, CH_2), 2.91 (s, 1H, exchangeable, O*H*).

Anal. Calcd. for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50. Found: C, 68.09; H, 9.63.

7-Tetrahydropyranyloxy-2-heptynyl Mesylate (5a)

A solution of *n*-butyl lithium (Alfa Inorganics) in hexane (66 g of 22.6% by weight) was transferred under nitrogen in a "glove bag" into a 1 l, three-necked flask. The flask was then fitted with a nitrogen inlet stopcock, mechanical stirrer, dropping funnel, and nitrogen outlet. Under a stream of nitrogen, the solution was cooled to 0° (ice-water bath) and the dropping funnel was charged with 45 g (0.212 mol) of the alcohol **4a** in 100 ml of anhydrous ether. The ethereal solution of alcohol was slowly added with stirring over a period of 1 h, then stirred at 0° for an additional hour to ensure complete salt formation. Mesyl chloride (24.3 g) in 70 ml anhydrous ether was placed into the dropping funnel and slowly added at 0°. A precipitate formed immediately. After addition (about 1 h) the solution was allowed to stand an additional 3 h. The reaction was then quenched with ice water and worked-up as usual in ether. The yields of the crude mesylate were better than 95% and were used as such for conversion to the iodide **10c**. The mesylate was purified by column chromatography on silica gel and elution with 2.5–10% ethyl acetate – hexane. This purified material was used for the alkylation: i.r. (CCl_4) 2245 (C≡C), 1390, 1188 (SO_2), 1145-1025 cm^{-1} (C—O—C).

1-Iodo-7-tetrahydropyranyloxy-2-heptyne (5c)

Sodium iodide (75 g), which had been heated in the oven at 120° for 2 h, was placed in a 2 l, three-necked flask fitted with a nitrogen gas inlet and outlet and mechanical stirrer. The sodium iodide was dissolved in 500 ml anhydrous acetone and the resulting solution was cooled to 0° under nitrogen. The crude mesylate **5a** (113 g) dissolved in 500 ml anhydrous acetone was added at once with stirring. The solution became cloudy, and finally turned into a thick, light brown slurry. This was stirred at 0–20° for 1.5 h, then diluted with ether, and worked-up the usual way. The crude iodide **5c**, obtained in 85–90% yields, was purified by column chromatography on silica gel using 2.5–10% ethyl acetate in hexane as the solvent system: i.r. (CCl_4) 2240 (C≡C), 1155–1032 cm^{-1} (C—O—C); n.m.r. (CCl_4) δ 4.60(m, 1H, *H*C ketal), 3.76(t, 2H, J = 2.0 Hz, CH_2I), 3.9–3.2(m, 4H, CH_2O), 2.30(m, 2H, CH_2C≡), 1.9–1.4(m, 10H, CH_2).

1-Bromo-7-tetrahydropyranyloxy-2-heptyne (5b)

The mesylate **5a** (1.55 g) was dissolved in anhydrous acetone under nitrogen. A slight molar excess of anhydrous lithium bromide was added and the solution was heated at 80° for 1 h. After cooling, the solution was concentrated *in vacuo*, taken up in ether, and worked-up as usual. The bromide **5b**, obtained in 85% yield, was purified by column chromatography on alumina III–IV using hexane as the solvent system; i.r. (CCl_4) 2245 (C≡C), 1142–1025 cm^{-1} (C—O—C); n.m.r. (CCl_4) δ 4.43(m, 1H, *H*C ketal), 3.79(t, 2H, J = 2.0 Hz, BrCH_2C≡), 3.7–3.1 (m, 4H, CH_2O), 2.21(m, 2H, CH_2C≡), 1.8–1.3(m, 10H, CH_2).

Anal. Calcd. for $C_{12}H_{19}O_2Br$: C, 52.36; H, 6.91; Br, 29.09. Found: C, 52.13; H, 7.10; Br, 28.89.

1-Iodo-2-heptyn-7-ol (5d)

The iodide **5c** (0.39 mol) was dissolved in 500 ml of methanol in a 1 l, three-necked flask containing a magnetic stirrer. Under a stream of nitrogen, 1 ml of concentrated hydrochloric acid was added and the solution was stirred at room temperature for 4 h. Most of the methanol was then removed *in vacuo* at room temperature, and the residue was diluted with ether, and washed with 5% sodium carbonate. The aqueous fraction was extracted with ether in the usual manner. The crude hydroxy iodide **5d** was not purified but oxidized directly with Jones reagent: i.r. (CCl_4) 3635, 3460 (OH), 2240 (C≡C), 1063 cm^{-1} (C—O); n.m.r. (CCl_4) δ 3.73(t, J = 2.0 Hz, ICH_2C≡), 3.9–3.4(m, CH_2O), 2.23(m,CH_2C≡), 1.8–1.2(m, CH_2), 3.99(s, exchangeable, O*H*).

Methyl 7-Iodo-5-heptynoate (6b)

The crude hydroxy iodide **5d**, dissolved in 1 l acetone, was placed in a 2 l three-necked flask fitted with a mechanical stirrer, dropping funnel, and thermometer.The solution was cooled to 5° and stirred while molar excess Jones reagent was added at such a rate that the temperature did not go above 10° (the addition took about 2.5 h). After the addition, isopropyl alcohol was added to destroy excess chromic acid, and the reaction mixture was diluted with water and ether. The aqueous phase separated and was extracted five times with ether. The combined ether fraction was then extracted with 5% sodium bicarbonate. This basic fraction was reacidified with 6 *N* hydrochloric acid and back extracted with ether. The ethereal solution was washed with brine, dried over sodium sulfate, filtered, and concentrated. The crude acid was then again dissolved in anhydrous ether, cooled to 0°, and treated with an ethereal solution of diazomethane. Concentration of this solution gave a brown oil which was chromatographed on a silica gel column using 10% ethyl acetate in hexane as the solvent system. The pure iodo ester **6b** was obtained as a colorless liquid in 20% overall yield from **4a**: i.r. (CCl_4) 2240 (C≡C), 1740 (C=O), 1163 cm^{-1} (C—O—C); n.m.r. (CCl_4) δ 3.70(t, J = 2.0 Hz, ICH_2-C≡), 3.64(s, OCH_3), these peaks overlap but integrate together to 5H, 2.5–2.1(m, 4H, CH_2C≡), 1.83(m, 2H, CH_2); mass spectrum: M^+ 266; *m/e* 235, M^+-OCH_3; 207, M^+-CO_2CH_3; 179, M^+-$CH_2CH_2CO_2CH_3$; 139, M^+-1; 193, M^+-$CH_2CO_2CH_3$.

6-Exo-(1'-heptenyl)-2-α and β-(6''-Carbomethoxy-2-hexynyl-bicyclo[3.1.0]hexan-3-one (9)

Iodo ester **6b** (0.0752 mol) and the bicyclic ketone **7**[7] (0.026 mol) were dissolved in 400 ml anhydrous freshly distilled tetrahydrofuran (THF).

Freshly prepared potassium *t*-butoxide (0.0395 mol) in 900 ml THF was slowly added to the stirred solution of the ketone **7** and iodide **6b** in a dry nitrogen atmosphere over a period of 6 h with the temperature being maintained between 0–5°. After about 30 min of addition, the solution became cloudy and assumed a beige color which did not change throughout the addition although the solution became thicker. This was probably due to potassium iodide precipitating out. After the base had been added, the reaction was quenched with 50 ml of 5% hydrochloric acid. The solution was then concentrated on an aspirator to about 300 ml, diluted with water, and extracted with ethyl acetate (five times, 100 ml). The combined dark organic fraction was then washed with 5% sodium thiosulfate to remove iodine, and with brine, and finally dried over sodium sulfate. The solution was then filtered and concentrated. A brown oil (19.1 g) was obtained.

Attempts to strip off unreacted ester and ketone failed at 100°/5 μ. A more efficient vacuum was required but was not available. The material was then chromatographed on a 1 kg silica gel column, eluted with hexane followed by 2.5–40% ethyl acetate in hexane. The components of the mixture were eluted in the order given below.

(1) Unreacted 7 and 6b (5% Ethyl Acetate (EtOAc))

These compounds were identified by t.l.c. comparison with the pure compounds.

(2) Monoalkylated Ketone 9 (5–10% EtOAc)

This ketone was obtained in 23% yield: i.r. (film) 1740 (C=O) ketone and ester, 1165 cm^{-1} (C—O—C); n.m.r. ($CDCl_3$) δ 5.6–4.6(m, 2H, *HC*=*CH*), 3.62(s, 3H, OCH_3). Mass spectrum: M^+ 330; *m/e* 299, M^+-OCH_3; 271, M^+-CO_2CH_3; 302, M^+-CO; 243, M^+-$(CH_2)_2CO_2CH_3$; 191, M^+-$CH_2C{\equiv}C(CH_2)_3CO_2CH_3$; 273, M^+-C_4H_9.

(3) Dialkylated Ketone (10–20% EtOAc)

This ketone was obtained in 8% yield; i.r. (film) 1740 (C=O) ketone and ester, 1168 cm^{-1} (C—O—C); n.m.r. ($CDCl_3$) δ 5.6–4.7(m, 2H, HC=CH), 3.66(s, 6H, OCH_3). Mass spectrum: M^+ 468; *m/e* 437, M^+-OCH_3; 409, M^+-CO_2CH_3; 440, M^+-CO; 329, M^+-$CH_2C{\equiv}C(CH_2)_3CO_2CH_3$; 425, M^+-C_3H_7; 411, M^+-C_4H_9.

(4) Trialkylated Ketone (20–40% EtOAc)

This ketone was isolated in 11% yield: i.r. (film) 1740 (C=O) ester and ketone, 1168 cm^{-1} (C—O—C); n.m.r. ($CDCl_3$) δ 5.6–4.6(m, 2H, *HC*=*CH*), 3.68(s, 9H, OCH_3). Mass spectrum: M^+ 606; *m/e* 575, M^+-OCH_3; 547, M^+-CO_2CH_3; 578, M^+-CO; 549, M^+-C_4H_9; 467, M^+-$CH_2C{\equiv}C(CH_2)_3CO_2CH_3$.

(5) Tetraalkylated Ketone (20–40% EtOAc)

This ketone was isolated in 5% yield: i.r. (film) 1740 (C=O) ester and ketone, 1168 cm^{-1} (C—O—C); n.m.r. ($CDCl_3$) δ 5.6–4.6(m, 2H, *HC*=*CH*), 3.79(s, 12H, OCH_3). Mass spectrum: M^+ 744; *m/e* 713, M^+-OCH_3; 685, M^+-CO_2CH_3; 716, M^+-CO; 699, M^+-C_4H_9; 605, M^+-$CH_2C{\equiv}C(CH_2)_3CO_2CH_3$. The four alkylated products were purified by preparative t.l.c. on silica gel HF 254 using benzene–ether 9:1 as the solvent system. The yields were calculated on the total amount of **12** used in the reaction.

The g.l.c. of the monoalkylated product (6', 3% SE30 on chromosorb W, 200°) showed two peaks (R_t 2.9 and 4.75 min) in the ratio 3:7. On the same column the retention times of the analogous compounds *ia* and *b*[3] were 3.05 and 4.67 min, respectively. Also on the same column (248°) the dialkylated ketone showed two peaks (R_t 3.50, 5.25) in the ratio 1:5. The tri- and tetraalkylated products did not come off the column at this temperature.

Alkylation of the Ketone 7 with 1-Iodo-7-tetrahydropyranyloxy-2-hexyne (5c)

(*a*) The procedure was used as described above except that the molar ratio of ketone to iodide was 1:1. Column chromatography of the product on silica gel (hexane and ethyl acetate solvent system) gave only one alkylated product in 30% yield. Spectral and elemental analysis showed this to be dialkylated: i.r. (CCl_4) 1750 (C=O), 1145–1025 cm^{-1} (C—O—C) tetrahydropyranyl group; n.m.r. (CCl_4) δ 5.6–4.6(m, 2H, *HC*=*CH*), 4.52 (m, 2H, *HC* ketals), 4.1–3.1(m, 8H, CH_2O).

(*b*) The procedure was the same as described above except that the molar ratio of ketone to iodide was 1:2. Column chromatography on silica gel using hexane and hexane – ethyl acetate mixtures as eluants gave the monoalkylated ketone **8** in 19% yield: i.r. (CCl_4) 1775 (C=O); 1138–1025 cm^{-1} (C—O—C) tetrahydropyranyl ether; n.m.r. (CCl_4) δ 5.5–4.6(m, 2H, *HC*=*CH*), 4.50(m, 1H, *HC* ketal), 4.0–3.0(m, 4H, CH_2O). Mass spectrum: *m/e* 302, M^+-dihydropyran (33); 84, $C_5H_8O^+$ (dihydropyran); 274, 302-CO; 245, 302-C_4H_9; 243, 302-C_3H_7O; 272, 302-CH_2O; 191, 302-side chain. No serious attempt was made to isolate polyalkylated materials.

Exo-6-(1',2'dihydroxyheptyl)-bicyclo[3.1.0]-hexan-3-one (20)

Exo-6-(1'-heptenyl)-bicyclo[3.1.0]hexan-3-one **7** (5.0 mmol) was dissolved in 25 ml ice cold 97–98% formic acid buffered with 25 mmol sodium carbonate (26) in a 100 ml three-necked flask fitted with a magnetic stirrer. The solution was cooled to 0° in an ice water bath and 5 mmol hydrogen peroxide as a 30% solution was added with stirring. The solution was brought to room temperature and stirred for 30 to 40 min under a stream of nitrogen. The formic acid was then stripped off *in vacuo* and the residue was dissolved in 80 ml of methanol. To this was added with stirring 18 g sodium carbonate dissolved in 50 ml water and the suspension was stirred at room temperature for three hours. The mixture was then acidified with 3 *N* hydrochloric acid, diluted with water, and extracted with methylene chloride in the usual manner. The yield of the diol **20** was 85%: i.r. (CCl_4) 3620, 3590 (OH), 3030 (CH, cyclopropyl), 1745 (C=O), 1060 cm^{-1} (C—O).

Exo-6-(1',2'ditrichloroacetoxyheptyl)-bicyclo[3.1.0]-hexan-3-one (21)

Anhydrous pyridine (20 ml) was placed into a 50 ml three-necked flask fitted with a magnetic stirrer, gas inlet and outlet, and a thermometer. The pyridine was cooled to 0° in an ice-water bath and trichloroacetyl chloride (20 mmol) was added. The diol **20** (4 mmol), dissolved in

For personal use only.

5 ml pyridine, was added at such a rate that the temperature did not go above 10°. The mixture was stirred at 0° for 2 h. The reaction mixture was then poured onto crushed ice and extracted with methylene chloride in the usual way. The pyridine was stripped off *in vacuo* and the ditrichloroacetate **21** was obtained in 95% yield: i.r. (CCl_4) 1768 (C=O, acetate), 1748 (C=O, ketone), 3035 (CH, cyclopropyl), 1223 cm^{-1} (C—O—C); n.m.r. (CCl_4) δ 5.31(m, 1H, C_7H—O), 4.77(m, 1H, C_6H—O).

Anal. Calcd. for $C_{17}H_{20}O_5Cl_6$: C, 39.45; H, 3.87; Cl, 41.00. Found: C, 39.83; H, 3.80; Cl, 40.09.

*Example of a Solvolysis of Ditrichloroacetate (**21**) in Trichloroacetic Acid*

A 25 ml three-necked flask was fitted with a magnetic stirrer, stopcock adapter (nitrogen inlet), and condenser. The system was flushed with nitrogen and 1.5 g anhydrous trichloroacetic acid was added. The acid was heated to 60–65° and the ditrichloroacetate (6.0 mg), dissolved in a few drops of THF, was added. After 5 min the reaction mixture was cooled, diluted with ether, and poured onto crushed ice. The ether was separated and the aqueous layer was extracted with ether. The combined ether fractions were washed with 5% sodium bicarbonate, water, and dried over magnesium sulfate. The ether was then filtered and concentrated. The product was spotted on a silica gel t.l.c. plate along with the starting material and eluted with benzene–ether 7:3. The rest of the product was diluted with methanol and a portion heated in 0.5% sodium hydroxide in methanol at 50° for 10 min and a u.v. spectrum was taken of the sample before and after the base treatment.

*Exo-6-(1'2'dibromoheptyl)-bicyclo[3.1.0]hexan-3-one (**23**)*

The bicyclic ketone **7** (3.1 mmol) was dissolved in 40 ml anhydrous chloroform in a 100 ml three-necked flask. Under a stream of nitrogen 1 equiv of pyridinium hydrobromide perbromide (15) was added to the magnetically stirred solution at room temperature over a period of 20 min. The pyridinium salt gradually disappeared leaving a yellow solution. The chloroform solution was then washed with water, dried over magnesium sulfate, filtered, and concentrated. The crude product was chromatographed on a silica gel column (30 g) eluting with hexane – ethyl acetate mixtures.

The dibromide **23** was obtained in 55% yield: i.r. (CCl_4) 3040 (CH, cyclopropyl), 1748 (C=O) 1140 cm^{-1} (C—C—C, ketone); n.m.r. (CCl_4) δ 4.18(m, 1H, C_7H), 3.72(m, 1H, C_6H).

*Solvolysis of the Dibromide **23***

The dibromide **23** (200 mg) was placed in a 50 ml flask with 30 ml of acetone–water 2:1 mixture. The solution was stirred at room temperature for 112 h. After this time the solution was diluted with water and extracted with chloroform in the usual manner. The crude products were then separated by preparative t.l.c. using benzene–ether 7:3 as solvent system. The mixture consisted of the following components:

(*1*) Starting dibromide **23** (R_f 0.86), recovered as the major component (63%), was identified by t.l.c. (benzene–ether 7:3): i.r. (CCl_4) 3040 (CH, cyclopropyl), 1748 (C=O), 1140 cm^{-1} (C—C—C, ketone).

(*2*) Bromohydrin (**26***a*) (R_f 0.39), isolated in 15% yield: i.r. (CCl_4) 3620, 3565, 3480 (OH), 3040 (CH, cyclopropyl), 1748 (C=O), 1140, 1060 cm^{-1} (C—O). Mass spectrum: M^+ 291, 289 for ^{81}Br and ^{79}Br respectively; *m/e* 271, 273, M^+-H_2O; 260, 262, M^+-HCO; 210, M^+-Br; 209, M^+-HBr; 191, 271-^{79}Br, 273-^{81}Br; 181, 260-^{79}Br, 262-^{81}Br; 81, ^{81}Br; 79, ^{79}Br.

(*3*) Mixtures of four components (R_f 0.02–0.05) obtained in 5% yield could not be characterized because of lack of material.

*Exo-6-(1'-bromo-2'-hydroxyheptyl)-bicyclo[3.1.0]-hexan-3-one (**26***a*)*

This compound was prepared according to the procedure of Guss and Rosenthal (16). The bicyclic ketone **7** (5.21 mmol) was mixed with 95% *N*-bromosuccinimide (5.25 mmol) in 25 ml water at room temperature. The reaction was stirred until all the solid *N*-bromosuccinimide had disappeared (4 h). The usual work-up in chloroform followed by column chromatography on silica gel (30 g, benzene–ether mixture elutions) gave the bromohydrin **26***a* in 60% yield.

Anal. Calcd. for $C_{13}H_{21}O_2Br$: C, 53.97; H, 7.26; Br, 27.28. Found: C, 53.90; H, 7.40; Br. 27.50.

*6-(2'-Bromo-1-oxoheptanyl)-bicyclo[3.1.0]hexan-3-one (**27***a*)*

The bromohydrin **26***a* (200 mg) was dissolved in 20 ml acetone in a 50 ml flask. The solution was cooled in an ice-water bath and stirred magnetically. A slight molar excess of Jones reagent was added dropwise and the solution was stirred for 20 min at 0°. After this time, the mixture was diluted in water and extracted with ether in the usual way. The diketo bromide **27***a* was obtained in 80% yield: i.r. (CCl_4) 3045 (CH, cyclopropyl), 1748 (C=O, ring ketone), 1700 cm^{-1} (C=O, ketone α to cyclopropyl ring); n.m.r. (CCl_4) δ 4.27(t, 1H, J = 6.5 Hz, CHBr adjacent to CH_2).

*Exo-6-(1'-iodo-2'-isocyanoheptyl)-bicyclo[3.1.0]hexan-3-one (**24**)*

This compound was prepared according to the procedure of Hassner *et al.* (20). The silver isocyanate was freshly prepared before the reaction (20, 34). The bicyclic ketone **7** (5.21 mmol) was dissolved in 25 ml anhydrous ether in a 100 ml three-necked flask fitted with a nitrogen inlet, thermometer, gas outlet, and magnetic stirrer. The flask was cooled in an ice-salt bath to −10° and silver isocyanate (15.6 mmol) was added with stirring. The reaction mixture was then cooled to −14° and iodine (5.3 mmol) was added. The solution became dark purple. It was then stirred 2 h in the cold and another 6 h at room temperature. By this time the color of the solution was canary yellow. The silver salts were then filtered through celite and the ether was removed in the cold *in vacuo*. The yield of the iodo isocyanate was 75%: i.r. (CCl_4) 3030 (CH, cyclopropyl), 2245 (NCO, v. strong), 1748 cm^{-1} (C=O).

*Hydrolysis and Nitrous Acid Deamination of Iodoisocyanate (**24**)*

The iodoisocyanate (**24**) (75 mg) was placed in a 50 ml three-necked flask fitted with a magnetic stirrer, nitrogen inlet and outlet, and thermometer. The flask was cooled to −10° in an ice-salt bath and 10 ml of aqueous acetone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(30% water) was added to hydrolyze the isocyanate. The solution was then cooled to −8° and sodium nitrite (4.7 mmol) was added in 1 ml water followed by formic acid (4.7 mmol). The solution was stirred at 0° for 1 h and then 3.5 h at room temperature. The reaction mixture was then diluted with water and extracted with ether in the usual way. Purification by preparative t.l.c. (benzene–ether 7:3) gave the iodohydrin **27***b* in approximately 60% yield: i.r. (CCl_4) 3545, 3520, 3460 (OH), 3035 (CH, cyclopropyl), 1743 (C=O), 1137 (C—C—C, ketone), 1060 cm^{-1} (C—O); n.m.r. (CCl_4) 100 MHz δ 4.19(m, 1H, C*H*—O), 3.22(m, 1H, C*H*I), 0.59(m, C*H*, cyclopropyl). Mass spectrum: M^+ 336; *m/e* 318, M^+-H_2O); 308, M^+-CO; 209, M^+-I; 191, 318-I; 181, 308-I.

Exo-6-(2′-iodo-1′-oxoheptanyl)-bicyclo[3.1.0]hexan-3-one (27b)

The iodohydrin **26***b* (60 mg), obtained from the hydrolysis and deamination of the iodoisocyanate **24**, was oxidized with Jones reagent by the same procedure as described for the oxidation of the bromohydrin (**26***a*). The resulting diketoiodide **27***b* was obtained in 80% yield: i.r. (CCl_4) 3030 (CH, cyclopropyl), 1745 (C=O, ring ketone), 1695 cm^{-1} (C=O, ketone α to cyclopropyl group); n.m.r. (CCl_4) 100 MHz δ 4.48(t, 1H, J = 4.0 Hz, C*H*I adjacent to CH_2).

Exo-6-(1′,2′-dihydroxyheptyl)-2α and β-(6″-Carbomethoxy-2″-hexynyl)-bicyclo[3.1.0]-hexan-3-one (10a)

The bicyclic keto ester **9** was treated with performic acid in buffered formic acid (26) in the same way as the unalkylated ketone **7**. The diol **10***a* was obtained in 87% yield: i.r. (film) 3440 (OH); 3035 (CH, cyclopropyl), 1740 (C=O, ketone and ester), 1165 (C—O—C, ester) 1065 cm^{-1} (C—O, alcohol); n.m.r. ($CDCl_3$) δ 3.69(s, 3H, O*CH*$_3$), 3.7–2.7(m, 4H, C*H*—O and O*H*). Mass spectrum: M^+ 364; *m/e* 333, M^+-OCH_3; 305, M^+-CO_2CH_3; 225, M^+-$CH_2C{\equiv}C(CH_2)_3CO_2CH_3$; 263, M^+-C_5H_{11}-OH; 293, M^+-C_5H_{11}; 289, M^+-C_4H_8; 346, M^+-H_2O; 315, 346-OCH_3.

Exo-6-(1′,2′-dimesyloxyheptyl)-2α and β-(6″-Carbomethoxy-2″-hexynyl)-bicyclo[3.1.0]-hexan-3-one (10b)

A 50 ml round bottom flask was fitted with a stopcock adapter, thermometer, gas outlet, and a magnetic stirrer. Anhydrous pyridine (10 ml) was added to the flask and it was cooled to −15° in an ice-salt bath. A molar excess of methanesulfonyl chloride (3.26 mmol) was added to the stirred solution under nitrogen. After the temperature was again −15°, the diol **10***a* (1.20 mmol) in 5 ml pyridine was added. The reaction was stirred in the cold for 3 h and then kept at −10° overnight. The cold reaction mixture was then poured onto crushed ice, saturated with sodium chloride, and extracted with ethyl acetate in the usual way. The ethyl acetate was evaporated *in vacuo* at room temperature and traces of pyridine were removed on a vacuum pump. The yield of the dimesylate **10***a* was 78–85%: i.r. (film) 3030 (CH, cyclopropyl), 1740 (C=O, ketone and ester), 1350, 1180 cm^{-1} (SO_2); n.m.r. ($CDCl_3$) δ 4.83(m, 1H, C_7H), 4.30(m, 1H, C_6H), 3.65 (s, 3H, O*CH*$_3$), four singlets: 189.8, 189.1, 188.0, 187.2 Hz (6H, SO_2CH_3).

Solvolysis of the Dimesylate (10b)

A solution of the dimesylate **10***b* (380 mg) in 20 ml acetone–water (2:1) was stirred in a nitrogen atmosphere at room temperature for 36 h.[8] The mixture was then diluted with water and extracted with methylene chloride. The methylene chloride extract was dried over anhydrous sodium sulfate, filtered, and concentrated. The reaction products were separated by preparative t.l.c. on silica gel using ethyl acetate as the solvent system. The components of the mixture were detected on the t.l.c. plates in the following manner: silica gel HF 254 (E. Merck) was used which enabled the detection of the hydroxy mesylate bands on the plates by means of short wavelength u.v. light. The prostaglandin bands could be detected only by spraying with 10% phosphomolybdic acid in ethanol, a destructive process. In order to recover the prostaglandins, a small part of the mixture was sacrificed for detection purposes and applied on a 4 × 10 cm plate. The remainder was spread on 20 × 20 cm plates and separated by measuring the R_f obtained from the small plate. This made the separation difficult since the bands did not travel uniformly.

The silica gel was extracted a few times with methanol. The methanol was then evaporated and the residue was taken up in methylene chloride, dried over sodium sulfate, and filtered through celite. The recovery by this procedure was better than 95%.

The components of the reaction mixture separated on the t.l.c. plates are listed below.

(1) Exo-6-(1′-hydroxy-2′-mesyloxyheptyl)-2-(6′-carbomethoxy-2″-hexynyl)-bicyclo[3.1.0]-hexan-3-one (13)

This compound was obtained in 70–80% yield from the starting dimesylate **10***b*. Three hydroxymesylates were obtained (R_f 0.62, 0.48, 0.37). The latter (R_f 0.37) was obtained only in small amounts and could not be obtained pure for proper characterization. The first two (R_f 0.62, 0.48) had identical i.r. and n.m.r. spectra. Both gave the same prostaglandin mixture on recyclizing, therefore no stereochemical assignment could be made: i.r (film) 3475 (OH), 3030 (CH, cyclopropyl), 1740 (C=O, ketone and ester), 1355, 1180 (SO_2), 1070 cm^{-1} (C—O); n.m.r. ($CDCl_3$) 100 MHz δ 4.72(m, 1H, C*H*, mesylate), 3.68(s, 3H, O*CH*$_2$), 3.34(m, 1H, C*H*, alcohol), 3.09, 3.07(s, 3H, SO_2CH_3), 0.64(m, C*H*, cyclopropyl).

(2) 8α and 8β-5-Dehydro-15-epi-PGE$_2$ Methyl Ester 12 (R_f 0.29)

This was obtained in 5–8% yield from the starting dimesylate **10***b*: i.r. (film) 3440 (OH). 1740 (C=O, ester and ketone), 1170 (C—O—C, ester), 1070 cm^{-1} (C—O); n.m.r. ($CDCl_3$) 100 MHz δ 5.9–5.2(m, 2H, *HC*=C*H*), 4.1(m, 2H, C*H*—O), 3.66(s, 3H, O*CH*$_3$). Mass spectrum: *m/e* 346, M^+-H_2O; 328, M^+-$2H_2O$; 315, M^+-H_2O, OCH_3; 297, M^+-$2H_2O$, OCH_3; 317, M^+-H_2O, HCO; 293, M^+-C_5H_{11}; 285, M^+-$2H_2O$, C_3H_7; 275, M^+-H_2O, C_5H_{11}; 207, M^+-H_2O, $C_8H_{11}O_2$ (ester side chain).

(3) 8α and 8β-5-Dehydro-PGE$_2$ Methyl Ester 11 (R_f 0.19)

This was obtained in 5–8% yield from the starting dimesylate **10***b*: i.r. (film) 3400 (OH), 1740 (C=O ketone,

[8]In another run lasting 24 h, similar results were obtained.

For personal use only.

ester), 1163 (C—O—C, ester), 1080 cm^{-1} (C—O); n.m.r. ($CDCl_3$) 100 MHz δ 5.9–5.2(m, 2H, *HC*=C*H*), 4.1 (m, 2H, C*H*—O), 3.68(s, 3H, OCH_3). Mass spectrum: *m/e* 346, M^+-H_2O. The fragmentation was identical with that of the 15-epi-5-dehydro PGE_2 methyl ester **12**.

Anal. Calcd. for $C_{21}H_{32}O_5$: C, 69.12; H, 8.79. Found: 69.02; H, 8.83.

*PGE_2 and 8-iso PGE_2 Methyl Ester **15***

5-Dehydro PGE_2 and 8-iso PGE_2 methyl ester **11** (10.3 mg) was placed in a sample cup with a small amount of ethyl acetate. Lindlar catalyst (32) (75 mg) was placed in a micro-hydrogenation flask and connected to a low pressure hydrogenation apparatus (35). Ethyl acetate (3 ml), containing 1 mg quinoline,[9] was added to the flask, and the mixture was hydrogenated for 4 h. The solution was filtered through celite and the solvent was evaporated *in vacuo*. The crude products were chromatographed on silica gel (t.l.c.) using ethyl acetate solvent system. The PG band was detected and extracted as was previously described. The isomeric mixture of **15** was obtained in 63% yield: n.m.r. ($CDCl_3$) 100 MHz δ 5.62 (m, 2H, *trans HC*=C*H*), 5.38(m, 2H, *cis HC*=C*H*), 4.1 (m, 2H, C*H*—O), 3.70(s, 3H, OCH_3).

Mass spectrum: *m/e* 348, M^+-H_2O; 330, M^+-$2H_2O$; 317, M^+-H_2O, OCH_3; 316, M^+-$3H_2O$, CH_3OH; 299, M^+-$2H_2O$, OCH_3; 298, M^+-$2H_2O$, CH_3OH; 299, M^+-C_5H_{11}; 277, M^+-H_2O, C_5H_{11}; 208, M^+-H_2O, $C_8H_{12}O_2$ (ester side chain with hydrogen transfer); 190, M^+-$2H_2O$, $C_8H_{12}O_2$.

*15-Epi-PGE_2 and 15-Epi-8-iso PGE_2 Methyl Ester **16***

The hydrogenation on 15-epi-5-dehydro PGE_2 and 15-epi-8-iso-5-dehydro PGE_2 methyl ester **12** was carried out in the same way as described for **11**. Because of lack of material, an n.m.r. spectrum could not be taken. Mass spectrum: *m/e* 348, M^+-H_2O. Mass measurement found: 348.229694; calcd. for $C_{21}H_{32}O_4$: 348.230045; other possible empirical formulae for this mass are: $C_{16}H_{32}N_2O_6$, $C_{19}H_{30}N_3O_3$, and $C_{24}H_{30}NO$. These are ruled out because **16** could not contain any nitrogen. Mass measurement of *m/e* 190: 190.135990; calcd. for $C_{13}H_{18}O$, 190.135758; another possible empirical formula for this mass is $C_{11}H_{16}N_3$ which is again ruled out because **16** contains no nitrogen.

Anal. Calcd. for $C_{21}H_{34}O_5$: C, 68.85; H, 9.23. Found: C, 70.12; H, 9.94.

*Epimerization of the Isomeric Mixture of **15***

The PGE_2 and 8-iso PGE_2 methyl ester mixture **15** (6.3 g) was dissolved in 3 ml of a 3% ethanolic potassium acetate solution and stirred at room temperature for 94 h. The reaction mixture was then diluted with water and extracted with pure methylene chloride. The organic layer was dried over anhydrous magnesium sulfate, filtered, and concentrated *in vacuo*. Preparative t.l.c. separation of the crude mixture on silica gel, using ethyl acetate as the solvent system, gave two compounds:

(*1*) PGA_2 methyl ester **18** made up 18% (0.7 mg) of the reaction mixture: u.v. (MeOH) 217 mμ, ε 9000; mass spectrum: M^+ 348, *m/e* 330, M^+-H_2O; 317, M^+-OCH_3; 299, 330-OCH_3; 298, 330-CH_3OH; 287, 330-C_3H_7; 190, 330-$C_7H_{10}CO_2CH_3$ + H-transfer); 207, M^+-$C_7H_{10}CO_2$-CH_3; 141, $[C_7H_{10}CO_2CH_3]^+$. The PGA_2 methyl ester was contaminated with about 2% PGB_2 methyl ester **19**: u.v. (MeOH) 277 mμ, ε 2200.

(*2*) PGE_2 methyl ester **17** made up 80% (2.9 mg) of the reaction mixture: 100 MHz n.m.r. ($CDCl_3$) using 109 scans which were analyzed with a computer of average transients (c.a.t.): δ 5.6(m, 2H, *trans HC*=C*H*), 5.3(m, 2H, *cis HC*=C*H*), 4.1(m, 2H, C*H*—O) 3.6(s, 3H, OCH_3). Accurate chemical shifts were not obtained because of drifting in the spectrometer. Mass spectrum: *m/e* 348, M^+-H_2O; the spectrum was identical to the PGE_2 methyl ester spectrum taken before epimerization. Because of the small amount of material, a good elemental analysis could not be obtained. However, from the spectral data and bioassay results, there was no doubt that this compound was *d,l*-PGE_2 methyl ester.

[9]More than 3% quinoline, by weight, to the amount of catalyst makes the reaction very slow. Best results were obtained using 1–2% quinoline.

We wish to thank the Upjohn Company, Kalamazoo, Michigan for generous samples of 6-exo-(1′-heptenyl)-bicyclo[3.1.0]hexan-3-one (7) and comparison samples of α- and β-isomers of 6-exo-(1′-heptenyl)-2-(6″-carbomethoxyhexyl)-bicyclo[3.1.0]hexan-3-one (**iii***a* and *b*) and natural PGE_2.

We wish to thank Dr. L. Wolfe of the Montreal Neurological Institute and Dr. J. R. Weeks of the Upjohn Company for carrying out the bioassays.

Financial assistance by the National Research Council of Canada and the Upjohn Co. is gratefully acknowledged.

Proton Magnetic Resonance Studies of Rotational Isomerism in Halotoluene Derivatives. VI. Rotational Barrier and Conformational Energy Differences in α,α,2,3,6-Pentachlorotoluene

M. A. H. STEWART, T. SCHAEFER, H. M. HUTTON, AND C. M. WONG
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received November 12, 1970

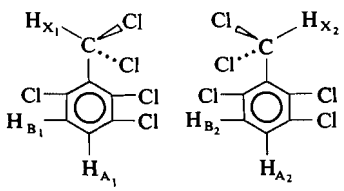
Rotation by π radians about the sp^2–sp^3 carbon–carbon bond of the dichloromethyl group in α,α,2,3,6-pentachlorotoluene interconverts the two conformations which are characterized by coplanarity of the aromatic ring with the C—H bond of the sidechain. The ring protons undergo effective nonmutual exchange during this rotation. The rate of rotation as a function of temperature is extracted by line-shape fitting of the ring p.m.r. spectra. The rotation is characterized by a negative entropy of activation. The free energy difference between the two conformations is 50 ± 20 cal/mol at 240 °K.

Une rotation de π radians autour de la liaison carbone–carbone sp^2–sp^3 du groupe dichlorométhyle du pentachloro-α,α,2,3,6 toluène interconvertit les deux conformations qui sont caractérisés par une disposition coplanaire du noyau aromatique et de la liaison C—H du substituant. Les protons du noyau changent leur environnement magnétique durant cette rotation et on peut obtenir la vitesse de rotation en fonction de la température par une simulation de la forme de raie du spectre de résonance magnétique. Cette rotation est caractérisée par une entropie d'activation négative. La différence d'énergie libre entre les deux conformations est 50 ± 20 cal/mol à 240 °K.

Canadian Journal of Chemistry, 49, 1085 (1971)

Introduction

Barriers to rotation about the sp^2–sp^3 carbon–carbon bond in α,α,2,4,6-pentachlorotoluene (PCT), α,α-dichloro-2,4,6-tribromotoluene (DCTBT), and α,α,α′,α′,2,3,5,6-octachloro-*p*-xylene (POCX) are known from line-shape analyses of rate dependent p.m.r. spectra (1–4). In all these molecules, rotation of the dichloromethyl group(s) causes effective mutual exchange of either the ring or methine protons. Semiempirical barrier calculations are also documented for model compounds of this series (4, 5). When the dichloromethyl group rotates through 180° in α,α,2,3,6-pentachlorotoluene (3PCT), conformation **1** is converted to **2** but, in contrast to PCT for example, nonmutual exchange of ring proton shifts



1 **2**

occurs. Thus B_1 exchanges with B_2, A_1 with A_2 so that at fast rates the ring proton spectrum becomes the AB part of an ABX spectrum. The shifts of the methine proton in **1** and **2** are not equal, in contrast to the corresponding conformations of PCT (1), nor are the populations of **1** and **2** the same.

By means of the computer program DNMR2 (6, 7) the rate-dependent p.m.r. spectra of 3PCT can be fitted to the rate constants for the hindered rotation of the dichloromethyl group. The spectral behavior is different than for the compounds above, providing a relatively independent check on the barriers obtained for the latter. In addition any buttressing effect of the chlorine atom at position 3 should become apparent. The solvent toluene-d_8 is used in this study because it causes sufficiently large solvent shifts of the ring proton resonances allowing an unambiguous assignment of resonance peaks to the four effectively different ring protons.

Experimental

The 3PCT was prepared by free radical chlorination of 2,3,6-trichlorotoluene in a manner similar to that described for PCT (1). It was dissolved as a 20 mol % solution in toluene-d_8, containing internal tetramethylsilane (TMS) as reference and lock signal. After careful degassing, p.m.r. spectra were taken at different temperatures on a DA60I spectrometer by the procedure described for PCT (1). More dilute solutions presented intolerable signal to noise problems while more concentrated solutions precipitated 3PCT at unacceptably high temperatures. Proton assignments could not be made in those other solvents which presented no solubility problems at temperatures necessary to the experiment. The temperatures were accurate to at least 1 °K and relative temperatures to better than 0.5 °K (3).

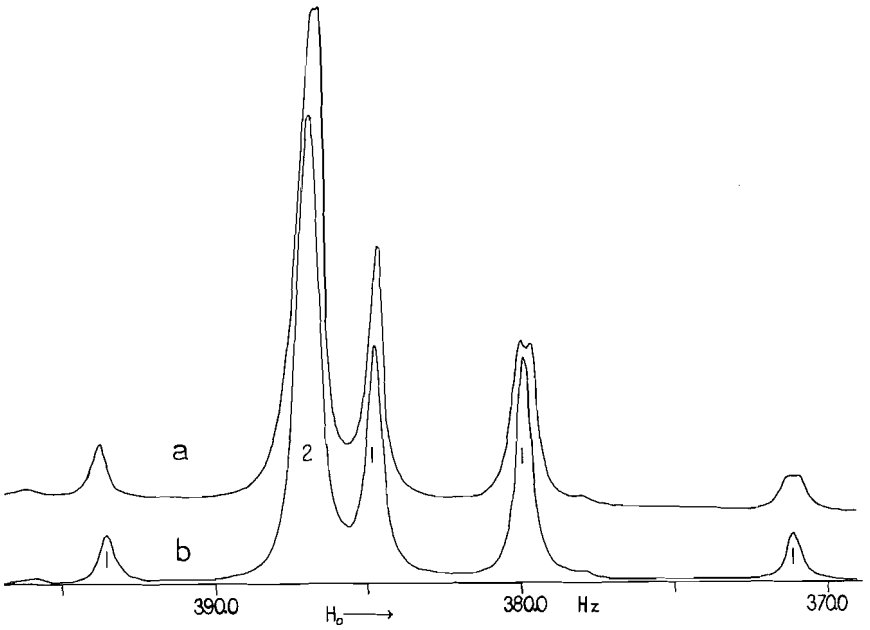


FIG. 1. In the upper part, *a*, the ring proton resonance spectrum of α,α,2,3,6-pentachlorotoluene at 255 °K is calculated on the assumption that conformation **2** of the text corresponds to the well defined quartet centered at high field and marked 1. In the lower part, *b*, it is assumed that this quartet corresponds to conformation **1** of the text. The latter agrees with the experimental spectrum in Fig. 3A.

Results and Discussion

(1) Assignment of the AB Quartets at Low Temperatures

At 255 °K, rotation of the dichloromethyl group is slow and the ring proton spectrum consists of two AB quartets, weakly coupled to the methine proton (see Fig. 3A). The quartet with an internal shift of 10.4 Hz (J = 8.7 Hz) is assigned to the ring protons of **1**, the quartet with an internal shift of 2.5 Hz (J = 8.9 Hz) to the ring protons of **2**. The assignment rests on the known stereospecificity of the long-range coupling constants between the methine and ring protons in such compounds (1, 8). Thus, in **1** and **2** the coupling over six bonds to H_A is less than −0.1 Hz in magnitude. The coupling over five bonds to H_B in **1** is less than 0.1 Hz but is 0.5 Hz in **2**. Now the proton system in **2** is tightly coupled so that the phenomenon of deceptive simplicity (9) or virtual coupling (10) leads to an effective coupling of roughly [0.5 + (−0.1)]/2 Hz between the ring protons and the methine proton. On the other hand, the ring protons in **1** are not tightly coupled and their resonance should display existing long-range couplings as large as 0.5 Hz. In Figs. 1*a* and *b* the theoretical spectra for the incorrect and correct assignments are displayed (compare with experimental spectrum in Fig. 3A).

(2) Assignment of Peaks at High Temperature

Of course, at this stage the assignment of the individual protons in **2** is still in question. Thus, does the resonance of B_2 lie to high or to low field of A_2? The clue to this question lies in the shape of the collapsed AB spectrum at temperatures where the rotation of dichloromethyl group is rapid. In Fig. 3F the two peaks at high field are broader than the other two at low field. Since the six-bond coupling between the methine proton and proton 4 is unobservable in both conformations (8), while the coupling between the methine proton and proton 5 is 0.5 Hz in **2** and less than 0.1 Hz in **1**, the resonance of the B protons should be 0.2 to 0.3 Hz broader than the resonance of the A protons. The pair of peaks at high field in Fig. 3F is therefore assigned to H_B in the averaged spectrum of **1** and **2**.

(3) Intrinsic Temperature Dependence of the Chemical Shifts

The chemical shifts of the coalesced and of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

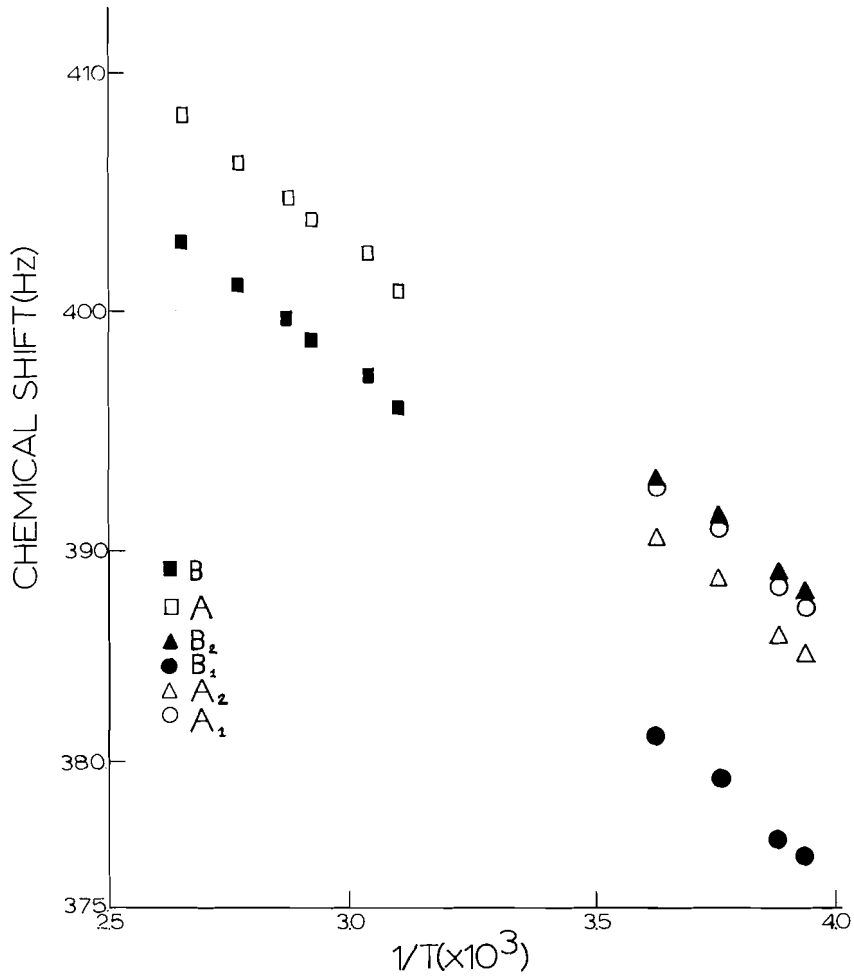

FIG. 2. The observed ring proton chemical shifts of α,α,2,3,6-pentachlorotoluene are plotted *vs.* $1/T$. At low temperatures there are four observable shifts corresponding to protons A_1, A_2, B_1, B_2 of the conformation **1** and **2** of the text. At high temperatures the shifts of A_1 and A_2 and of B_1 and B_2 are averaged by the exchange process to give the shifts marked A and B, respectively. The latter shifts are defined by eqs. 1 and 2 of the text.

uncoalesced spectra of 3PCT in toluene-d_8 are a linear function of $1/T$. In Fig. 2 the two ring proton shifts above coalescence temperatures are plotted *vs.* $1/T$ over a temperature range of 55 °C. The averaged shifts of H_A and H_B relative to internal TMS are given by eqs. 1 and 2 (r = correlation coefficient, T in °K). From eqs. 1 and 2

[1] Shift of H_A in Hz = 453.26 − 16 950 $(1/T)$

$(r = 0.9997)$

[2] Shift of H_B in Hz = 444.75 − 15 760 $(1/T)$

$(r = 0.9997)$.

the internal shift between H_B and H_A can be calculated at a given temperature.

Now at 255 °K, where the four chemical shifts are observed[1] to be 385.7, 387.5, 388.2, and 377.1 Hz, one has four possible assignments of the shifts to the four individual protons, given

[1]The internal shift of the proton resonance in the tightly coupled quartet is not easily obtainable from the spectrum at 60 MHz. However, after the spectral work was complete a 100 MHz instrument became available. At this frequency the internal shift of the quartet was easily measured. This value could then be used together with the position of the intense central peak of the quartet to calculate the chemical shift of the A_2 and B_2 protons.

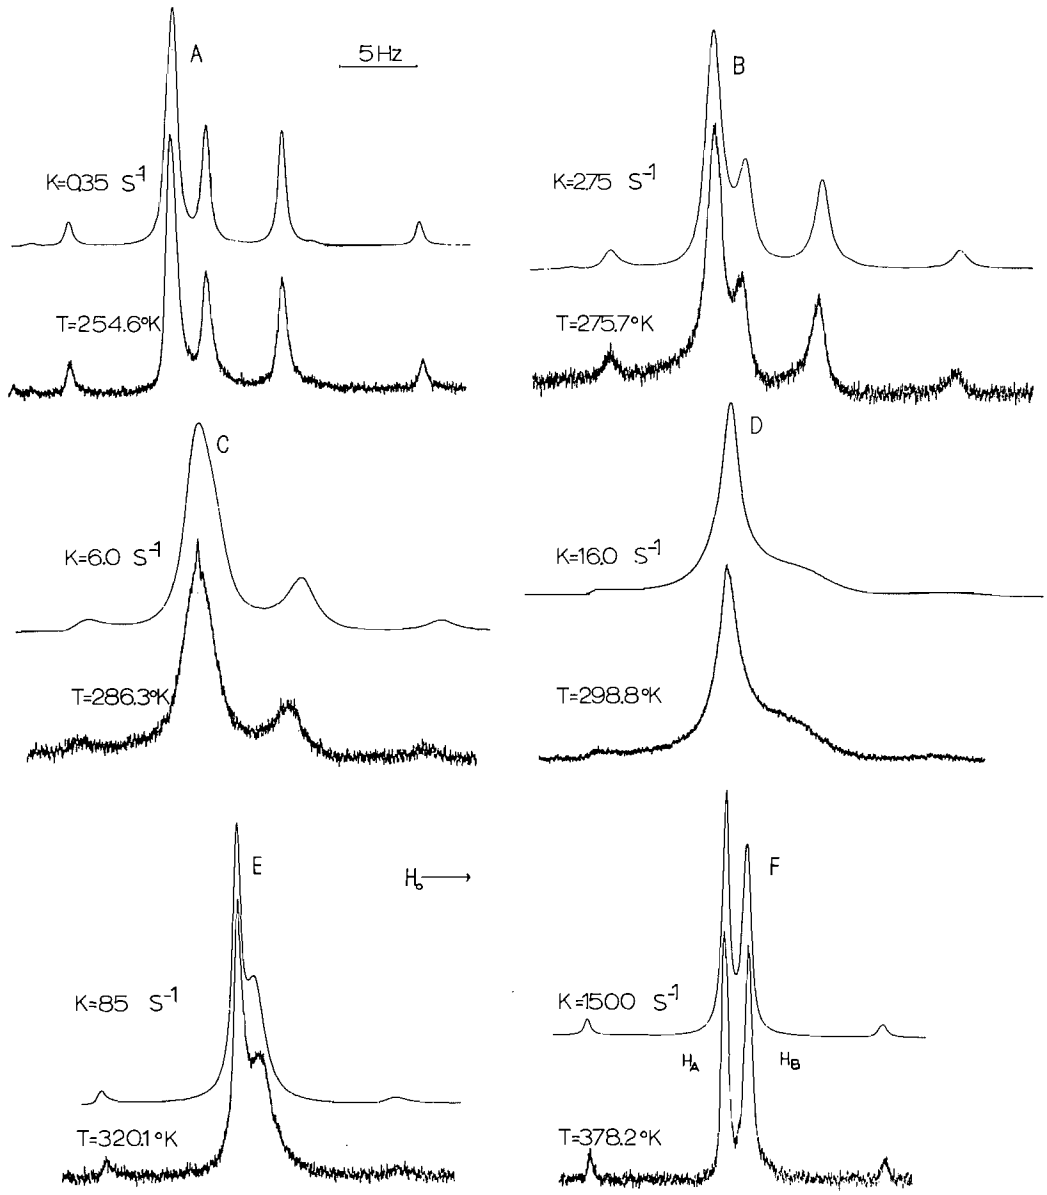

FIG. 3. The observed and calculated ring proton resonance spectra of α,α,2,3,6-pentachlorotoluene are shown at six representative temperatures and rate constants, k, for rotation of the dichloromethyl group.

that the original assignment of the quartets to **1** and **2** is correct. The four observed shifts predict different, averaged internal shifts between H_B and H_A. When population differences are taken into account (see below) the four assignments correspond to averaged internal shifts of $\pm 6.3 \pm 0.3$ and of $\pm 3.7 \pm 0.3$ Hz. Equations 1 and 2 predict this shift to be $+4.1$ Hz and therefore the correct assignment[2] is A_1(387.5 Hz), B_1(377.1 Hz), A_2(385.7 Hz), and B_2(388.2 Hz) at 255 °K.

In Fig. 2 the chemical shifts at temperatures where the exchange rate is slow are also plotted

[2]A detailed rationalization of this assignment in terms of substituent and solvent effects is given in ref. 11.

TABLE 1. Observed and calculated chemical shifts* of the ring protons of α,α,2,3,6-pentachlorotoluene in toluene-d_8 as a function of temperature in the absence of exchange. Rate constants for the conversion of **1** and **2**

*In Hz at 60 MHz to low field of internal TMS. The absolute shifts are accurate to about 0.1 Hz but the internal shifts are more accurate.
†Observed from experimental spectra.
‡At this and higher temperatures the shifts are calculated from eqs. 1–3, as explained in the text.
§At this and higher temperatures the means of the two sets of shifts reproduce the observed shift of the A and B protons in the coalesced spectrum to within experimental error.
‖These rate constants were extracted from spectra in which the effective T_2 values contribute substantially to the observed line-shapes and were therefore disregarded when computing activation parameters.

as a function of $1/T$. Between 255 and 276 °K the internal shift between B_1 and B_2 is given by eq. 3. Thus the solvent effect on the shift between these two protons changes by only 0.15 Hz over this temperature range and only by a further 0.3 Hz between 282 and 323 °K. Because the shift between A_1 and A_2 is only about 2 Hz, less than 20% of the shift between B_1 and B_2, the corresponding peaks are relatively insensitive to changes in the exchange rate and hence it is unimportant to correct for its temperature variation. The fitting procedure below concentrated on the line-shape changes observed in the B portion of the spectra.

[3] Internal shift in Hz = $8.43 + 667\,(1/T)\,(r = 0.993)$.

In Table 1 the calculated values of the chemical shifts of the four distinct protons are given. These are the shifts which would be observed as a function of temperature in the absence of exchange and include the temperature-dependent solvent effects. Note that experimental values are given between 255 and 276 °K. Between 323.5° and 361 °K the appropriate means of the shifts in Table 1 reproduce the measured shifts of the quartet observed at high temperatures.

(4) Relative Populations of the Two Conformations

At temperatures below 243 °K the two methine peaks of **1** and **2** are separated sufficiently to allow the determination by weighing of the areas of the two peaks. At 233 °K the substrate crystallizes from solution. At four temperatures in this 10° interval the ratio of the areas was 0.91 ± 06. A similar estimation of the relative intensities of the two AB quartets gave 0.91 ± 0.06 with **2** more abundant than **1** (a determination made when a 100 MHz spectrometer became available gave 0.90 ± 0.06). Extensive overlap of peaks made a more accurate estimation at these and other temperatures impossible.

It seems reasonable that steric interactions among chlorine atoms in **1** will destabilize **1** relative to **2**. The original assignment above is further supported by the fact that the resonance of the methine proton in **2** lies to low field of its resonance in **1**. Steric crowding involving the chlorine substituents at positions 2 and 3 is expected to

ΔH^*(kcal/mol)	13.3±0.3	13.1±0.4	14.6±0.3
ΔS^*(cal/mol deg)	−7.0±0.7	−7.3±1.3	−1.1±0.7
ΔG^*(kcal/mol)	15.4±0.1(298 °K)	15.4±0.1(286 °K)	14.9±0.1(304 °K)

[a]Quoted errors are standard deviations from least square plots.
[b]α,α,2,3,6-Pentachlorotoluene.
[c]α,α,α′,α′,2,3,5,6-Octachloro-*p*-xylene.
[d]α,α,2,4,6-Pentachlorotoluene.

deshield the methine proton more in **2** than in **1** (12).

The free energy difference between **1** and **2** is 50 ± 20 cal/mol at 240 °K. The normalized populations are $P_1 = 0.48$ and $P_2 = 0.52$. For line-shape fitting purposes the normalized populations must be known as a function of temperature. Direct trials showed assumption $P_1 = P_2 = 0.50$ to be indistinguishable from $P_1 = 0.48$ when computing line-shapes in the region of interest between 276 and 323 °C. Therefore $P_1 = 0.48$ was assumed throughout.

A rough calculation (13) of the entropy difference between **1** and **2** was performed as follows. The translational contribution to this difference is zero. The low-frequency vibrations of **1** and **2** are probably very nearly equal and therefore the vibrational contribution is taken as zero. The rotational contribution can be calculated from the products of the principal moments of inertia of **1** and **2**. These turn out to be 4.010×10^{17} amu^{3}Å^6 for **1** and 4.015×10^{17} amu^{3}Å^6 for **2**. The rotational contribution is therefore effectively zero. Hence the free energy difference between **1** and **2** is indicated to be independent of temperature. On this basis, $P_1/P_2 = 0.93$ at 375 °K, well within experimental error of the ratio at 243 °K.

(5) Extraction of Rate Constants and Activation Parameters

Line-shapes were generated by the computer program DNMR2 (7) adapted to an IBM 360/65 computer and were compared visually with the experimental spectra. Input data were $P_1 = 0.48$, $J_{AB} = 8.8$ Hz for both **1** and **2**, $J_{AX} = -0.1$ Hz for both **1** and **2**, $J_{BX} = 0.5$ Hz for **2** and $J_{BX} = 0.1$ Hz for **1**. The four chemical shifts for each rate constant k, were taken from Table 1. Best fits at high and low temperature extremes (narrow peaks) were obtained for an effective T_2 of 0.80 s, this value also being used at intermediate temperatures. Because a wrong T_2 can cause relatively large errors in the extracted rate constants, only those rate constants obtained for rather large line widths were employed in the extraction of activation parameters. Thus in Table 1 only the rate constants between 275.7 and 323.5 °K were so employed.

In Fig. 3 some representative observed and calculated spectra are displayed as an indication of the agreement obtainable between observation and theory. The spectral quality is only fair, a consequence of the relatively low solubility and the high molecular weight of the substrate. Some

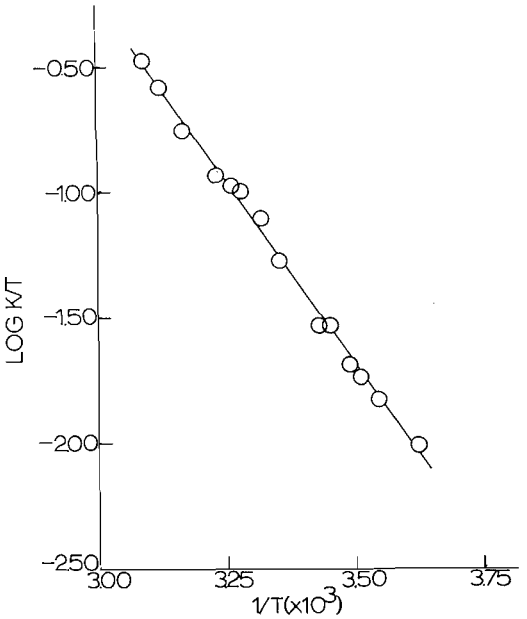

FIG. 4. A plot of log (k/T) *vs.* $1/T$ for the activated rotation of the dichloromethyl group in α,α,2,3,6-pentachlorotoluene. The least squares line for the temperature range from 276 to 324 °K as shown has a correlation coefficient of 0.998.

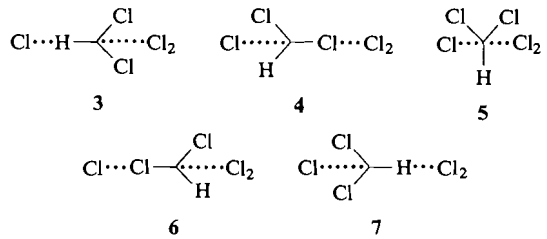
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the methine resonances were also fitted but were relatively insensitive to k. In Table 1 the error indicated for k refers to the value which, when added or subtracted to the quoted value of k, yields a computed spectrum clearly incompatible with the observed spectrum.

Activation parameters were derived from least squares plots of $\log k$ and $\log k/T$ *vs.* $1/T$. Figure 4 shows a plot of $\log k/T$ *vs.* $1/T$, $r = 0.997$. Table 2 gives the parameters for 3PCT and also for POCX and PCT. The quoted errors are standard errors. A transmission coefficient of 1/2 was assumed (1, 14).

(6) Discussion of Activation Parameters

The conformations of the dichloromethyl group in 3PCT can be represented as in **3** to **7** (**1** and **2** above correspond to **3** and **7**, respectively). The subscript 2 in these diagrams refers to the two chlorine substituents at ring positions 2 and 3.



As discussed previously (1, 4) for PCT, **4** and **6** are the high energy (transition state) conformations and **5** lies at least 7 or 8 kcal/mol above the ground state conformations **3** and **7**. Therefore the measured barrier for 3PCT corresponds to the higher [3] of **4** and **6**. Now **3** is a little less stable than **7** because of the enhanced steric interaction or buttressing effect of the chlorine substituents at position 2 and 3 of the ring. It would therefore be sensible to assume that the transition state **4** is of higher free energy than **6**. The measured ΔG^* is 15.4 kcal/mol for both POCX and 3PCT, in agreement with this assumption. $\Delta G^* = 14.9$ kcal/mol for PCT, suggesting $\Delta G_4^* - \Delta G_6^* = 0.5 \pm 0.2$ kcal/mol for 3PCT. This difference evidently arises from increased steric hindrance in **4** causing a more negative ΔS^* than in **6**. If the data in Table 2 can be believed, ΔH^* is somewhat smaller in 3PCT than in PCT. The implication that increased steric hindrance in the transition state can markedly lower the entropy relative to the ground state while somewhat decreasing the internal energy ($\Delta E = \Delta H + P\Delta V$, ΔV very small), is intriguing but speculative. Replacement of the chlorine substituent at position 3 by much bulkier groups is indicated as a test.

[3] A molecule sufficiently activated to pass the lower of **4** or **6** will not be able to pass the higher of **4** or **6** and hence will not cause an effective exchange of the ring protons.

We are grateful to the National Research Council of Canada for financial assistance.

The Total Synthesis of a Thebaine Analogue and of the Corresponding "Bentley Adduct"

K. WIESNER, J. G. MCCLUSKEY, J. K. CHANG, AND V. ŠMŮLA
Natural Products Research Center, University of New Brunswick, Fredericton, New Brunswick

Received October 22, 1970

We are reporting the synthesis of the thebaine analogue **6** in which the nitrogen atom has been translocated within the ethanamino bridge from position 17 to 16. This compound has been further transformed by successive Diels–Alder and Grignard reactions into the derivative **3**.

Nous rapportons la synthèse d'un analogue de thébaine **6** dans laquelle l'atome d'azote a été transposé, à l'intérieur du pont éthanamino, de la fonction 17 à 16. En effectuant successivement des réactions de Diels–Alder et de Grignard, ce composé a été transformé en **3**.

Canadian Journal of Chemistry, 49, 1092 (1971)

Introduction

Some time ago we synthesized (1, 2) various 1,5-methanobenzazocines as typified for example by **1** (see Formula Scheme 1). These compounds were found[1] to have some analgesic properties to a certain extent free of the deleterious pharmacodynamic side effects hitherto associated with the use of morphine and its congeners. This possibly novel type of activity may be attributed to the location of the nitrogen atom since the benzomorphans, as typified by **2**, are known (3) to have morphine-like analgesic activity. Unfortunately, the compounds with the translocated nitrogen atom generally lacked potency. Despite this lack of potency it was hoped that compound **3** might be very much more active since, while lacking only the ether bridge and still featuring the translocated nitrogen atom, it otherwise resembles compound **4** reported by Bentley and co-workers (4) as an analgesic 500 times more potent than morphine itself.

The preparation of Bentley's compound **4**, which involved successive Diels–Alder and Grignard reactions upon thebaine **5**, is clearly adaptable to our preparation of **3** provided that a thebaine analogue **6**, having the translocated nitrogen atom, is available. However, this, or a similar compound, does not occur naturally and it cannot be prepared by simply relocating the nitrogen atom within the ethanamino bridge of thebaine. Consequently, we have devised a very efficient total synthesis of the thebaine analogue **6** which we have converted by Bentley's method into the desired product **3**. Since we believe that the synthesis of **3** has some novel and interesting features, we are reporting the synthesis in detail in the present paper.

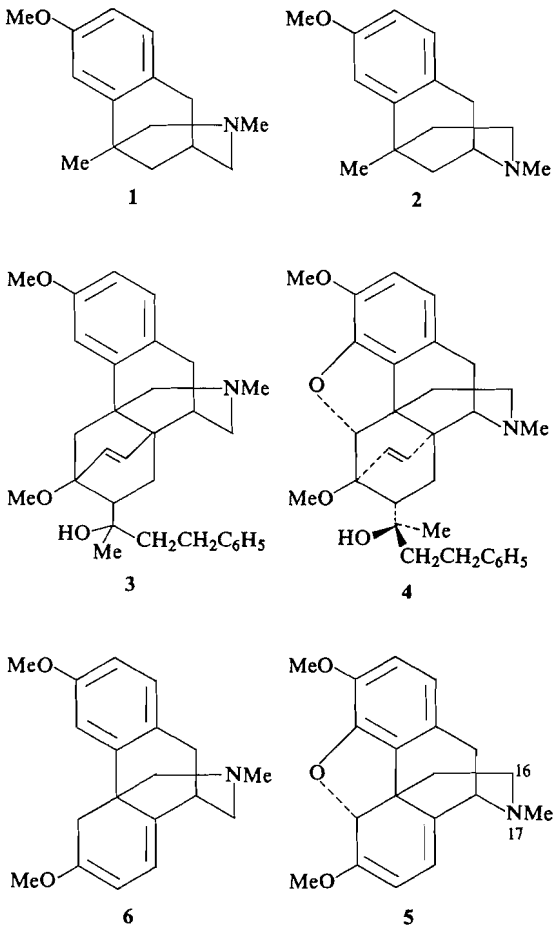
Discussion

The pyrrolidine enamine (5) of 7-methoxy-2-tetralone **7** (see Formula Scheme 2) (6) was alkylated with ethyl bromoacetate to obtain the 1-monosubstituted 7-methoxy-2-tetralone **8** in high yield.[2] The subsequent alkylation of the sodium enolate of **8** with the ketal tosylate **9** (7) afforded the 1,1-disubstituted 7-methoxy-2-tetralone **10***a* in a very high yield also. This alkylation is a novel procedure which, in the present case, affords far superior yields of the diketo lactam **12** than can be obtained by the use of the methyl vinyl ketone equivalents recently listed (8).

The ester group of the 1,1-disubstituted tetralone **10***a* was saponified thus permitting a convenient removal of neutral impurities and the concomitant isolation of the acid **10***b*. This was sufficiently pure to permit its direct conversion into the acid azide **10***c* which was heated in dry toluene for 1 h at 80° to afford the isocyanate **10***d*. Refluxing this solution with an excess of sodium hydride for 6 h gave the sodium salt of the secondary lactam **11***a* which could be converted into the *N*-methyl lactam **11***b* *in situ* by adding methyl iodide. In practice, the secondary lactam **11***a* was first crystallized from ethanol and then *N*-methylated with sodium hydride and methyl iodide. The deketalization of the *N*-methyl

[1]The pharmacological properties of these and other compounds were determined by Ayerst Laboratories, Montreal, Quebec.

[2]The i.r., n.m.r., and mass spectra were recorded and were in agreement with the structures assigned to this and the other compounds reported here. Such data are recorded in the Experimental.



FORMULA SCHEME 1

lactam **11***b* to the diketo lactam **12** in acetone containing *p*-toluenesulfonic acid was followed by an acid-catalyzed aldol cyclization in benzene. The resulting α,β-unsaturated lactam **13** was obtained, after crystallization from ethanol, in *an overall yield of 21% from 7.*

The next phase of the synthesis involved the conversion of this α,β-unsaturated keto lactam into the thebaine analogue **6**. This operation requires the shift of the oxygen functional group from C-7 to -6 and it was accomplished via the endoperoxide as outlined in Formula Scheme 3.

The C-7 carbonyl group of the α,β-unsaturated keto lactam **13** was reduced with sodium borohydride and the resulting hydroxyl group of the product **14***a* was eliminated by pyrolysis of the corresponding benzoate **14***b*. This afforded the diene lactam **15** which, in ethanol containing eosin as photosensitizer, readily added oxygen on exposure to direct sunshine, presumably to form the endoperoxide **16** (9). This adduct, being unstable, was not isolated and the reaction mixture was hydrogenated over Adam's catalyst to give the diol **17**. The C-6 hydroxyl group of this compound was oxidized with Jones' reagent and the C-14 hydroxyl group of the resulting γ-hydroxy keto lactam **18** was eliminated using thionyl chloride in benzene containing pyridine. The product, the β,γ-unsaturated keto lactam **19**, on treatment with methyl orthoformate in methanol containing *p*-toluenesulfonic acid, gave the ketal lactam **20** which readily eliminated one molecule of methanol on pyrolysis in refluxing xylene to afford the methoxydiene lactam **21**. The lactam carbonyl group of this compound was reduced with lithium aluminum hydride to give the non-crystalline dienol ether amine **6**, the desired thebaine analogue, in 16% yield from **13**.

The Diels–Alder adduct **22** was prepared by refluxing the dienol ether **6** with methyl vinyl ketone. A subsequent Grignard reaction with phenethyl magnesium bromide afforded the non-crystalline tertiary alcohol **3** in 30% yield from **6**. This, the final compound of the series, was characterized as its sharply melting crystalline picrate. It is assumed to have the stereochemistry depicted in **3**, Formula Scheme 4, which is the same as the corresponding Bentley adduct (3), since the steric outcome of the Diels–Alder and Grignard reactions is unlikely to differ despite the missing ether bridge and the translocated nitrogen atom.

The overall yield of the Bentley adduct **3** from the tetralone **7** is 1%. This is mitigated by the mass increase by which 2.7 g of **3** are obtained from every 100 g of the starting material **7** and by the convenience of the route which is best evaluated by the fact that we have prepared several batches of several grams of **3** for pharmacological tests.

Experimental

All melting points were determined with a Gallenkamp melting point apparatus. The i.r. spectra were recorded on a Perkin–Elmer 237B spectrophotometer as chloroform solutions in sodium chloride (0.5 mm) cells. Pertinent maxima are cited in reciprocal cm. The u.v. spectra were taken on a Beckman DK-2, in absolute ethanol. Absorption maxima are given in nm with extinction coefficients in parentheses. The n.m.r. spectra were recorded on

Varian Associates' 56.4 mHz or T-60 spectrometers using 10–15% solutions in $CDCl_3$ with tetramethylsilane as internal reference. The chemical shifts are expressed in τ values and coupling constants, *J*, in Hz. The low resolution mass spectra were taken on a Hitachi Perkin–Elmer RMU-6D while high resolution mass spectra were taken at the Mass Spectroscopy Laboratory, Chemistry Department, University of Alberta, Edmonton, Alberta. All elemental analyses were performed by Dr. F. Pascher, Mikroanalytisches Laboratorium, Bonn, Federal Republic of Germany.

1-Monosubstituted-7-methoxy-2-tetralone (8)

7-Methoxy-2-tetralone (7) (500 g) in benzene (1.3 l) containing pyrrolidine (300 ml) was refluxed under nitrogen for 4 h with continuous removal of a water azeotrope using a Dean–Stark trap. The mixture was cooled in an ice bath, ethyl bromoacetate (780 ml) was added in small portions and then heating to reflux was resumed. After 24 h, water (1.7 l) was added and the heating was maintained a further 5 h. The organic phase was then separated, rinsed with cold water (1.0 l), dried ($MgSO_4$), and distilled to afford the 1-monosubstituted-7-methoxy-2-tetralone **8** (500 g), b.p. 160–170° (90 μ); i.r., 1720 cm^{-1} (unresolved ketone and ester C=O); n.m.r., τ 2.7–3.3 (3H, m, Ar *H*), 5.84 (2H, q, *J* = 7.5 Hz, $CO_2CH_2CH_3$), 6.21 (3H, s, OCH_3), 8.76 (3H, t, *J* = 7.5 Hz, $CO_2CH_2CH_3$); mass spectrum, M^+ calculated 262, observed 262.

1,1-Disubstituted-7-methoxy-2-tetralone (10a)

The 1-monosubstituted tetralone **8** (200 g) was refluxed in dry benzene (1.5 l) containing sodium hydride (38.5 g of 55% dispersion in oil) under dry nitrogen. After 1 h, a

Ar OCH_3), 8.8 (3H, s, CCH_3), 8.95 (3H, t, J = 7 Hz, $CO_2CH_2CH_3$); mass spectrum, M^+ calculated 376, observed 376.

Ketal Acid (10b)

The crude disubstituted tetralone **10***a* (313 g) was vigorously stirred with aqueous sodium hydroxide (5.5 l of 5% w/v) at 100° for 90 min. After being cooled, the aqueous phase was decanted, extracted with chloroform (3 × 300 ml), and then carefully neutralized with acetic acid. The resulting precipitate was extracted into chloroform (3 × 300 ml) which was rinsed with brine, dried ($MgSO_4$), and evaporated to the crude ketal acid **10***b* (170 g), i.r., 3600–3000 (—COOH), 1770 and 1710 (carboxyl and ketone C=O), 1060, 1045, 950 cm^{-1} (ketal); n.m.r., τ 2.3 (1H, diffuse s, CO_2H), 6.2 (7H, s, OCH_2CH_2O and Ar OCH_3), 8.8 (3H, s, CCH_3).

Secondary Lactam 11a

To the ketal acid **10***b* (70 g), in dry tetrahydrofuran (800 ml) at −5°, were added successively triethylamine (31.9 ml), ethyl chloroformate (21 ml), and, after 2 h, sodium azide (36 g) in distilled water (85 ml). After a further 1 h, the reaction mixture was decanted, evaporated to a reduced volume (*ca.* 150 ml), and partitioned between dichloromethane (350 ml) and aqueous sodium bicarbonate (100 ml of 10% w/v). The organic phase was further rinsed with ice water (2 × 100 ml), then dried ($MgSO_4$) and evaporated *in vacuo* to the oily acid azide **10***c* (70.6 g); i.r., 2145 (CON_3), 1710 cm^{-1} (ketone C=O). This, in dry toluene (1.2 l), was heated at an oil bath temperature of 80° for 1 h. The resulting solution of the isocyanate **10***d* (i.r., 2255 —NCO, 1710 cm^{-1} ketone C=O) was cooled, was treated with *fresh* sodium hydride (20.0 g of 55% dispersion in oil), and was then heated to reflux. After 6 h, the mixture was cooled, rinsed with water (1.2 l), then dried ($MgSO_4$), and evaporated. The solid residue was rinsed with ether and crystallized from ethanol to afford the pure secondary lactam **11***a* (35 g), m.p. 211–213°; i.r., 3400 (N—H), 1735 (keto C=O), 1670 (sec-lactam C=O), 1605, 1570, 1500 (aromatic), 1055, 1040, 945 cm^{-1} (ketal); n.m.r., τ 6.1 (3H, s, $ArOCH_3$), 6.25 (4H, s, OCH_2CH_2O), 8.7 (3H, s, CCH_3); mass spectrum, M^+ calculated 345, observed 345.

Anal. Calcd. for $C_{19}H_{23}NO_5$: C, 66.10; H, 6.67; N, 4.06. Found: C, 65.93; H, 6.64; N, 4.07.

N-Methyl Lactam (11b)

The secondary lactam **11***a* (76.5 g), in dry benzene (2.2 l) containing fresh sodium hydride (15 g of 55% dispersion in oil), was heated to reflux for 1 h. Methyl iodide (42 ml) was added and a gentle reflux was maintained. After 20 h, the mixture was cooled, extracted with water (1.7 l), dried ($MgSO_4$), and evaporated to the crude *N*-methyl lactam (**11***b*) (90 g) a portion of which was crystallized from ethanol for analysis, m.p. 90–110° (EtOH solvate); i.r., 1735 (ketone C=O), 1645 (*tert*-lactam C=O), 1605, 1570, 1500 (aromatic), 1055, 1040, 945 cm^{-1} (ketal); n.m.r., τ 6.05 (3H, s, Ar OCH_3), 6.19 (4H, s, OCH_2CH_2O), 7.2 (3H, s, NCH_3), 8.65 (3H, s, CCH_3); mass spectrum, M^+ calculated 359.1733, observed 359.1732.

Anal. Calcd. for $C_{20}H_{25}NO_5 \cdot 1/2C_2H_5OH$: C, 66.00; H, 7.33; N, 3.67. Found: C, 65.69; H, 7.21; N, 3.69.

Diketo Lactam (12)

The crude *N*-methyl lactam (**11***b*) (80.3 g), in acetone (600 ml) containing *p*-toluenesulfonic acid (3g), was heated to reflux for 2.5 h. The solvent (300 ml) was distilled, aqueous sodium bicarbonate (500 ml of 2% w/v) was added, and the mixture was then extracted with dichloromethane (3 × 100 ml) which was dried ($MgSO_4$) and evaporated to the diketo lactam **12** (68 g). A portion of this was purified by preparative layer chromatography (silica gel) and then crystallized from ethanol, m.p. 149–151°; i.r., 1740, 1720 (ketone C=O), 1650 (*tert*-lactam C=O), 1605, 1570, 1500 cm^{-1} (aromatic); n.m.r., τ 6.2 (3H, s, Ar OCH_3), 7.16 (3H, s, NCH_3), 7.87 (3H, s, CH_3CO); mass spectrum, M^+ calculated 315.1471, observed 315.1472.

Anal. Calcd. for $C_{18}H_{21}NO_4$: C, 68.57; H, 6.67. Found: C, 68.25; H, 6.67.

α,β-Unsaturated Keto Lactam (13)

The crude diketo lactam **12** (68 g), in dry benzene (4.0 l) containing *p*-toluenesulfonic acid (22 g), was refluxed with continuous removal of a benzene water azeotrope with a Dean–Stark trap. After 22 h, the mixture was rinsed with water (2.0 l) and saturated aqueous sodium bicarbonate (500 ml), then dried ($MgSO_4$), and evaporated. The residue was rinsed with hexane then crystallized from ethanol to afford the α,β-unsaturated keto lactam **13** (55 g), m.p. 156–158°; i.r., 1680, 1635 (α,β-unsaturated ketone), 1650 (*tert*-lactam C=O), 1605, 1570, 1500 cm^{-1} (aromatic); u.v., 230 mμ (ε 12 100); n.m.r., τ 4.0 (1H, s, conjugated C=C*H*), 6.2 (3H, s,

Ar OCH_3), 7.22 (3H, s, NCH_3); mass spectrum, M^+ calculated 297, observed 297.

Anal. Calcd. for $C_{18}H_{19}NO_3$: C, 72.60; H, 6.40; N, 4.72. Found: C, 72.30; H, 6.38; N, 4.63.

α,β-Unsaturated Hydroxy Lactam (14a)

The α,β-unsaturated keto lactam **13** (60 g) was stirred in methanol (600 ml) containing water (5 ml) and sodium borohydride (21 g) for 30 min at 0°. The solvent was then partly distilled (300 ml) *in vacuo* and the residue was partitioned between water (600 ml) and chloroform (3 × 200 ml) which was subsequently rinsed with brine, dried ($MgSO_4$), and evaporated to the crude α,β-unsaturated hydroxy lactam **14***a* (70 g); i.r., 3590, 3400 (hydroxyl), 1635 cm^{-1} (*tert*-lactam C=O); n.m.r., τ 4.38 (1H, s, C=C*H*), 6.25 (3H, s, Ar OCH_3), 7.30 (3H, s, NCH_3); mass spectrum, M^+ calculated 299, observed 299.

Diene Lactam (15)

The crude hydroxy lactam **14***a* (70 g), in dry tetrahydrofuran (500 ml) containing dry pyridine (27 ml), was treated dropwise with benzoyl chloride (36 ml) at 0°. After 20 h, the mixture was filtered then evaporated *in vacuo* to 200 ml. This was partitioned between water (500 ml) and chloroform (3 × 100 ml) which was subsequently rinsed with saturated aqueous sodium bicarbonate, then dried ($MgSO_4$), and evaporated to the crude non-crystalline benzoate **14***b* (90 g); i.r., 1710 (benzoate C=O), 1635 (*tert*-lactam C=O), 1605, 1600, 1580, 1570, 1500 (aromatic), 1270, 1120 cm^{-1} (benzoate C—O). This was then pyrolyzed (3 × 30 g portions) in an evacuated tube heated at one end to 200°. After 20 h a sublimate was dissolved in chloroform (50 ml) which was rinsed with saturated aqueous sodium bicarbonate (100 ml) and water (50 ml), and was then dried ($MgSO_4$), and evaporated. The residue crystallized from ether to afford the pure diene lactam **15** (3 × 10 g), m.p. 142–145° (dec.); i.r., 1635 (*tert*-lactam C=O), 1605, 1570, 1500 cm^{-1}; u.v., 279 nm (ε 5500); n.m.r., τ 4.26 (3H, s, C=C*H*—C*H*=C*H*—), 6.25 (3H, s, Ar OCH_3), 7.30 (3H, s, NCH_3); mass spectrum, M^+ calculated 281, observed 281.

Anal. Calcd. for $C_{18}H_{19}NO_2$: C, 76.87; H, 6.76; N, 4.98. Found: C, 76.90; H, 6.91; N, 4.80.

Diol Lactam (17)

The diene lactam **15** (11.7 g), in ethanol (675 ml of 95%) containing eosin (30 mg), was exposed to sunlight while oxygen was bubbled through the solution. After 7 h, platinum oxide (2 g) was added and the mixture was shaken under hydrogen for 20 h, at room temperature and pressure. The mixture was then filtered and evaporated to the crude diol lactam **17** (13.4 g) a portion of which was purified by crystallization from methanol, m.p. 286–288°; i.r., 3375, 3255 (2 × hydroxyl O—H), 1620 (*tert*-lactam C=O), 1600, 1570, 1500 cm^{-1} (aromatic); mass spectrum, M^+ calculated 317.1624, observed 317.1627.

γ-Hydroxy Keto Lactam (18)

The crude diol lactam **17** (13.4 g) was stirred for 2 h at room temperature in glacial acetic acid (150 ml) containing sodium dichromate·dihydrate (7 g). The solvent was then evaporated *in vacuo* and the residue was partitioned between aqueous sodium bicarbonate (500 ml of 5% w/v) and chloroform (3 × 200 ml); the chloroform layer was dried ($MgSO_4$) and evaporated. The residue was crystallized from ethanol to afford the γ-hydroxy keto lactam **18** (6.67 g), m.p. 274–276° (dec.); i.r., 3580, 3200 (hydroxyl O—H), 1705 (ketone C=O), 1635 (*tert*-lactam C=O), 1605, 1570, 1500 cm^{-1} (aromatic); u.v., 220 nm (ε 1250); n.m.r., τ 6.24 (3H, s, Ar OCH_3), 7.26 (3H, s, NCH_3); mass spectrum, M^+ calculated 315, observed 315.

Anal. Calcd. for $C_{18}H_{21}NO_4$: C, 68.57; H, 6.67; N, 4.44. Found: C, 68.17; H, 6.58; N, 4.44.

β,γ-Unsaturated Keto Lactam (19)

The γ-hydroxy keto lactam **18** (2.42 g), in dry benzene (40 ml) containing dry pyridine (2.8 ml), was treated with thionyl chloride (1.09 ml) then stirred in an ice bath. After 1 h, the mixture was extracted with saturated aqueous sodium bicarbonate (40 ml), then dried ($MgSO_4$), and evaporated to the crude β,γ-unsaturated keto lactam **19** (2.35 g) which was crystallized from ethanol, m.p. 166–168°; i.r., 1720 (unconjugated ketone C=O), 1640 (*tert*-lactam C=O), 1605, 1570, 1500 cm^{-1} (aromatic); u.v., 220 nm (ε 3000); n.m.r., τ 4.44 (1H, broad singlet, C=C*H*), 6.25 (3H, s, Ar OCH_3). 7.25 (3H, s, NCH_3); mass spectrum, M^+ calculated 297.3570, observed 297.3571.

Methoxydiene Lactam (21)

The β,γ-unsaturated keto lactam **19** (298 mg), in absolute methanol (9 ml) containing *p*-toluenesulfonic acid (60 mg) and methyl orthoformate (3.6 ml), was heated to reflux for 45 min. The mixture was then partitioned between dilute aqueous sodium bicarbonate (50 ml) and chloroform (3 × 15 ml). This was rinsed with brine (15 ml), then dried ($MgSO_4$), and evaporated to afford the oily β,γ-unsaturated ketal lactam **20** (400 mg); i.r., 1630 cm^{-1} (*tert*-lactam C=O); n.m.r., τ 4.55 (1H, broad singlet, C=C*H*), 6.2 (3H, s, Ar OCH_3), 6.77 (3H, s, OCH_3), 6.78 (3H, s, OCH_3), 7.25 (3H, s, NCH_3). This, in dry xylene (20 ml), was heated to reflux for 1 h. The solvent was evaporated and the residue was purified by preparative layer chromatography (alumina) to obtain the methoxydiene lactam **21** (180 mg) as crystals from benzene, m.p. 172–174°; i.r., 1630 cm^{-1} (*tert*-lactam C=O); u.v., 281 nm (ε 9700); n.m.r., τ 4.32 (1H, d, J = 6 Hz, =C*H*—C*H*=), 5.11 (1H, d, J = 6 Hz, =C*H*—C*H*=), 6.21 (3H, s, Ar OCH_3), 6.39 (3H, s, OCH_3), 7.27 (3H, s, NCH_3); mass spectrum, M^+ calculated 311, observed 311.

Anal. Calcd. for $C_{19}H_{21}NO_3$: C, 73.30; H, 6.75; N, 4.50. Found: C, 73.19; H, 6.70; N, 4.40.

Methoxydiene Amine (6)

The methoxydiene lactam **21** (956 mg), in dry tetrahydrofuran (17 ml) containing lithium aluminum hydride (310 mg), was heated to reflux for 1.5 h. Saturated aqueous sodium potassium tartrate (100 ml) was then added and the mixture was extracted with chloroform (3 × 30 ml) which was dried ($MgSO_4$) and evaporated to the oily methoxydiene amine **6** (916 mg); i.r., 2780 (Baumann), 1660 (C=C), 1605, 1575, 1500 (aromatic); n.m.r., τ 4.35 (1H, d, J = 6 Hz, =C*H*—C*H*=), 5.18 (1H, d, J = 6 Hz, =C*H*—C*H*=), 6.20 (3H, s, Ar OCH_3), 6.43 (3H, s, OCH_3), 7.90 (3H, s, NCH_3); mass spectrum, M^+ calculated 297, observed 297.

Diels–Alder Adduct (22)

The methoxydiene amine **6** (916 mg) was heated in methyl vinyl ketone (6 ml) to reflux for 20 h. The solvent was evaporated and the residue, in dichloromethane (15 ml), was extracted into sulfuric acid (30 ml of 3%). This was rinsed with chloroform (2 × 15 ml) and was then basified with ammonium hydroxide. The mixture was then extracted with chloroform (3 × 25 ml) which was dried ($MgSO_4$) and evaporated to the oily Diels–Alder adduct **22** (950 mg) which afforded a crystalline hydrochloride from ethanol–ether, m.p. 232–234°.

Anal. Calcd. for $C_{23}H_{29}NO_3 \cdot HCl \cdot 2H_2O$: C, 62.80; H, 7.75; Cl, 8.10; N, 3.19. Found: C, 62.03; H, 7.31; Cl, 8.27; N, 3.18.

A portion of the hydrochloride was converted into the free base, i.r., 1710 cm^{-1} (ketone C=O); n.m.r., τ 3.76 (2H, s, —C*H*=C*H*—), 6.18 (3H, s, Ar OCH_3), 6.6 (3H, s, OCH_3), 7.9 (3H, s, NCH_3), 7.98 (3H, s, CCH_3); mass spectrum, M^+ calculated 367, observed 367.

Tertiary Carbinol (3)

The Diels–Alder adduct **22** (950 mg), in dry ether (400 ml), was treated with the Grignard reagent from magnesium (600 mg) and phenethyl bromide (3 ml) in ether (20 ml). After 3 h at reflux, the mixture was treated with saturated aqueous ammonium chloride (100 ml). The ether phase was separated, dried ($MgSO_4$), and evaporated. The resulting residue was purified by chromatography (alumina: activity III–IV: eluent petroleum ether and benzene) to afford the oily tertiary alcohol **3** (420 mg) which gave a picrate as crystals from ethanol, m.p. 222°.

Anal. Calcd. for $C_{21}H_{39}NO_3 \cdot C_6H_3N_3O_7$: C, 63.30; H, 5.98; N, 7.98. Found: C, 63.24; H, 6.14; N, 8.05.

A portion of the picrate was converted into the free base, i.r., 3460 (hydroxyl O—H), 1675 (C=C), 1605, 1570, 1500 cm^{-1} (aromatic); n.m.r., τ 2.75–3.25 (8H, m, Ar *H*), 3.78 (2H, J_{A-B} = 9 Hz, $\Delta\nu_{A-B}$ = 42 Hz, —C*H*=C*H*—), 5.27 (1H, s, O*H*), 6.2 (3H, s, Ar OCH_3), 6.5 (3H, s, OCH_3), 7.98 (3H, s, NCH_3), 8.98 (3H, s, CCH_3); mass spectrum, M^+ calculated 473, observed 455 ($M^+ - H_2O$).

We wish to thank the Ayerst Laboratories, Montreal, for a grant which enabled us to carry out this entire investigation.

N-Bromosuccinimide-Induced Dimethyl Sulfoxide Oxidation of Acetylenes[1]

SAUL WOLFE, W. R. PILGRIM, T. F. GARRARD, AND P. CHAMBERLAIN
Department of Chemistry, Queen's University, Kingston, Ontario

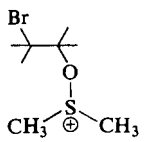
Received October 22, 1970

The addition of less than 2 mol equiv. of *N*-bromosuccinimide (NBS) to a solution of diphenylacetylene in anhydrous dimethylsulfoxide (DMSO) leads to the formation of benzil in near-quantitative yield at room temperature. Under the same conditions stilbene gives the dibromo adduct. The conditions for this novel oxidation *of an acetylene* have been examined in some detail and it has been established that *anhydrous DMSO* must be employed as the *solvent* and that NBS is uniquely able to induce the oxidation. Preliminary studies indicate that alkyl aryl, dialkyl, and terminal acetylenes are converted to the corresponding α-dicarbonyl compounds, and that diphenylbutadiyne is oxidized to diphenyltetraketone. Optimum conditions for these latter oxidations have not yet been established.

L'addition à la température ordinaire de *N*-bromosuccinimide (NBS), moins de 2 équivalents, à une solution de diphénylacétylène dans du diméthylsulfoxyde (DMSO) conduit à la formation de benzil avec un rendement presque quantitatif. Dans les mêmes conditions, le stilbène conduit au dérivé dibromé. Les conditions conduisant à cette nouvelle oxydation *d'un acétylène* ont été examinées en détail et il a été établi que du *DMSO anhydre* doit être utilisé comme *solvant* et que seul le NBS peut induire l'oxydation. Des études préliminaires indiquent que les arylalkylacétylènes, dialkylacétylènes, et acétylènes vrais sont transformés en composés carbonylés-α correspondants et que le diphénylbutadiyne est oxydé en diphényltetracétone. Les conditions optimales pour ces dernières oxydations n'ont pas encore été établies.

Canadian Journal of Chemistry, 49, 1099 (1971)

The combination of an *N*-haloamide or imide and an aqueous medium is often employed to convert an alcohol into a ketone or an olefin into a halohydrin (1). Hypohalous acid, formed *in situ* by hydrolysis of the halogen source, is thought to be the oxidizing agent in most of these reactions (2). However, recent work by van Tamelen and Sharpless (3) and by Dalton and co-workers (4) indicates that the intervention of HOX is not obligatory. In aqueous glyme, *N*-bromosuccinimide (NBS) appears to effect direct transfer of positive bromine to a double bond (3); and, in the reaction of NBS with an olefin in moist dimethyl sulfoxide (DMSO), attack on the brominated cation or bromocarbonium ion is at least 95% by the DMSO (4). The bromohydrin is then produced by hydrolysis of the oxysulfonium intermediate **1**.



1

Acetylenes resemble olefins in a number of respects in their behavior towards these halogenating agents. With hypobromous acid, dibromoketones are produced (5) and, with *N*-chlorosuccinimide or NBS in alcoholic solvents, the products are dichloro (6) or dibromoketals (7). In aqueous glyme, NBS effects direct transfer of bromine to a triple bond (7). This similar behavior of olefins and of acetylenes suggested that, in DMSO, a brominated *vinyl* cation might, like its dihydro analog, be trapped by the solvent to give **2**, an unsaturated oxysulfonium cation. In the case of **2**, however, competition may now occur between hydrolysis and either unimolecular (**2** → **3**; eq. 1) or bimolecular (**2** + DMSO → **4**; eq. 2) elimination of dimethyl sulfide. Loss of $Br^{\oplus}$ and dimethyl sulfide from **4**, formed by the reactions of **2** or **3** with DMSO, would then lead, as indicated in eq. 3, to **5**, an α-diketone, in what might be described as NBS-induced DMSO oxidation.

5

Although the scheme just depicted is intended to represent a working hypothesis rather than a mechanistic proposal, it will be noted that there are formal precedents for it in the well-known Kornblum (8) and Pfitzner–Moffatt (9) oxidations, and in the conversion of benzylamines to benzaldehydes upon diazotization in anhydrous DMSO (10). It may also be noted that oxidation of acetylenes to α-diketones has been observed previously: stearolic acid is converted to 9,10-diketostearic acid by neutral aqueous permanganate (11); and the highly strained acetylenes 3,3,6,6-tetramethyl-1-thiacycloheptyne and cyclooctyne undergo air oxidation to α-diketones (12).

Addition of NBS (0.5 g, 2.8 mmol) at room temperature to a solution of diphenylacetylene (**6**) (0.25 g, 1.4 mmol) in anhydrous DMSO (10 ml) afforded a bright yellow solution which was allowed to stand for 24 h at room temperature and then diluted with water. Chloroform extraction of the strongly acidic aqueous solution and work-up of this extract afforded benzil (**7**) *in 98% yield* (eq. 4). Repetition of the experiment for 30 min at 80° led to the formation of benzil *in 92% yield*. In contrast to these results, stilbene (**8**) reacted at room temperature with NBS in anhydrous DMSO to give the adduct meso-stilbene dibromide (**9**) (eq. 5).

Table 1 summarizes a number of experiments performed to define the conditions for the oxidation of diphenylacetylene, and the following main conclusions may be drawn: (*a*) DMSO must be utilized as the solvent since its presence in stoichiometric quantities in refluxing methylene chloride, benzene, carbon tetrachloride, or dioxane leads to only traces of benzil (*cf.* ref. 13); (*b*) NBS may function as a catalyst for the oxi-

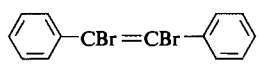
*Determined by n.m.r.
†NBS, dried but not recrystallized.
‡Calcium carbonate, 4.53 mmol, were added to the reaction mixture.
§Cyclohexene, 9.49 mmol, was added to the reaction mixture.
‖NBS, recrystallized and dried.
¶Acetic anhydride, 8.70 mmol, was substituted for the NBS. The product consisted of unreacted **11** and CH_3SCH_2OAc, the product of a Pummerer reaction of the anhydride with the solvent.

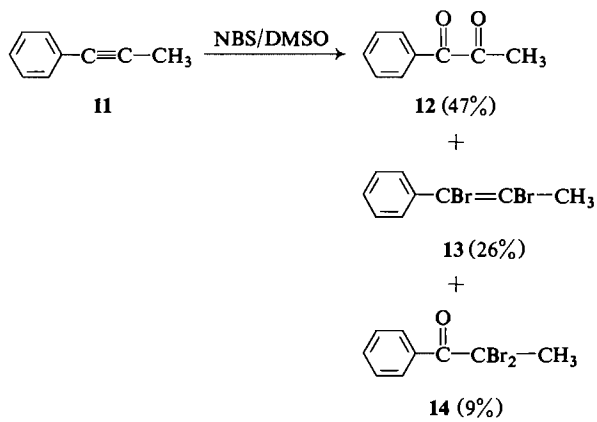
dation as implied by the above scheme; based on acetylene consumed, the ratio (mmol of diketone)/(mmol of NBS) is always greater than unity. However, because NBS is itself slowly consumed by DMSO (4), high conversions to benzil require 1–2 mol equiv of NBS per mol of acetylene; (*c*) NBS is unique in its ability to catalyze the reaction; with molecular bromine and pyrrolidone hydrotribromide (14), no diketone is produced, and with *N*-bromoacetamide the yield of benzil is only 19% after 100 h at room temperature. These findings are compatible with an initiation step for the reaction which involves direct transfer of bromine from NBS to the triple bond; (*d*) the reaction is inhibited by water; the only product formed (in a very slow reaction) in moist DMSO is diphenylacetylene dibromide (**10**).



10

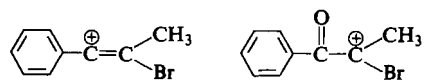
A preliminary study of the scope of the oxidation indicates that the conversion of acetylenes to α-diketones with NBS in DMSO may be a general reaction, but the optimum conditions for different types of substrates will differ from those established for **6**. The experiments summarized in Table 2 refer to the oxidation of 1-phenylpropyne (**11**) to 1-phenylpropanedione (**12**). For the conditions examined, the optimum conversion (47%) was realized with 0.4 *M* solutions containing 1 mol equiv of NBS per mol of substrate at 90°. In contrast to the oxidation of **6**, a diarylacetylene, the oxidation of **11**, an alkyl arylacetylene, produced significant quantities of bromine-containing side-products (eq. 6). These products, the dibromide **13** and the

[6]



11 → **12** (47%) + **13** (26%) + **14** (9%)

dibromoketone **14**, may be considered to result from a competition for the intermediates **15** and **16**[2] between a bromine source in the medium (Br_2, HBr, NBS) (4) and the DMSO solvent. It is not at present clear why the bromine sources compete successfully for these cations when one of the substituents is an alkyl group and not when two aryl substituents are present. Oxidation of **9** in the presence of calcium carbonate (to remove HBr) did not reduce the yields of the side-products; and addition of cyclohexene to an oxidation mixture (to remove Br_2) caused the oxidation to be quenched. Replacement of the NBS by acetic anhydride led only to a Pummerer reaction of the anhydride with the solvent (15), the acetylene being recovered unchanged. We are presently examining alternatives to DMSO for the oxygen transfer step.



15 **16**

Oxidations of 2-butyne (**17**) and phenylacetylene (**18**) with NBS in anhydrous DMSO were performed at room temperature. In each case the total product was then treated with a derivatizing agent to yield biacetyl (**19**) (as the dihydrazone, see eq. 7) and phenylglyoxal (**20**) (as the di-*p*-nitrophenylhydrazone; see eq. 8), respectively. The derivatives were recovered in 20–25% yields. For these two oxidations, detailed examination of the reaction mixtures, and variation of the experimental conditions, were not performed.

It was of interest to examine the oxidation of a compound containing more than one triple bond. Polyacetylenes are readily available synthetic (16) and naturally occurring (17) compounds, and the polyketones potentially available from these substrates would be useful in several ways: base-catalyzed cyclization of the polyketone derived from a non-conjugated polyacetylene could be compared with the analogous treatment of a poly-β-ketone (18); and examination of molecular models suggests that a conjugated polyketone derived from a conjugated polyacetylene might adopt a chiral and, in favorable cases, a helical conformation (19).

[2]It has been established (5, 7) that electrophilic addition of halogen to **9** affords the vinyl cation $PhC^{\oplus}{=}CXCH_3$ preferentially.

Diphenylbutadiyne (**21**) was selected as the substrate for the preliminary study since the potential oxidation product, diphenyltetraketone (**22**) is a known compound (19, 20). Oxidation of **21**, at room temperature for 48 h or at 100° for 2 h, in DMSO containing 2 mol equiv of NBS appeared to proceed smoothly to give **22** (eq. 9). The compound was identified by its reversible color reaction with water (20, 21): red(anhydrous) ⇄ yellow(hydrate), by acid-catalyzed decarbonylation to benzil (22), and by formation of the known dioxime (20). However, although the reaction evidently proceeded smoothly, and no other product could be detected after extended reaction periods, we have been unable to crystallize the compound in either of its two forms. Both forms have been crystallized (19, 20). Consequently, although the reaction shows promise as a route to polyketones, more work is needed and is in progress.

Experimental

Melting points were determined on Fisher–Johns or Kofler hot stage m.p. apparati, and are uncorrected. The i.r. spectra were recorded on a Beckman IR 5A instrument, and calibrated against the 6.238 μ peak of polystyrene. The n.m.r. spectra were obtained on Varian A60 or T60 spectrometers as 10% solutions in chloroform-*d* or carbon tetrachloride. Tetramethylsilane was employed as an internal standard.

All solvents were dried before use by standard procedures. Dimethyl sulfoxide was refluxed over calcium hydride and then distilled under reduced pressure. It was stored in sealed bottles over 4A molecular sieves. *If the calcium hydride treatment was omitted, no oxidation took place.*

N-Bromosuccinimide was Fisher reagent grade material and was dried under reduced pressure over phosphorus pentoxide before use. Some samples, as indicated in Tables 1 and 2, were recrystallized prior to the drying procedure (23).

Diphenylacetylene was prepared from benzil by the method of ref. 24; it was purified by distillation under reduced pressure, followed by crystallization from 95% ethanol.

1-Phenylpropyne was prepared by methylation of lithium phenylacetylide in liquid ammonia (25). In the n.m.r. spectrum the methyl group of this compound appears at τ 8.02.

Diphenylbutadiyne was prepared by oxidative coupling of lithium phenylacetylide with potassium permanganate (26).

1,2-Dibromo-1,2-diphenylethylene (**10**) was prepared by bromination of diphenylacetylene. Diphenylacetylene (0.5 g, 2.8 mmol) was dissolved in chloroform (10 ml). A solution of bromine (2.8 mmol) in carbon tetrachloride was then added all at once. The color of the red solution slowly faded during a 4 h period at room temperature. Removal of the solvent then afforded a

[7] 
17 19

[8] 
18 20

[9] 
21 22

7 Dioxime

white solid, m.p. 65–173°. This was recrystallized from absolute ethanol to give 0.6 g of **10**, m.p. 211–212° (lit. (27) m.p. 211°).

1,2-Dibromo-1-phenylpropene (**13**) was prepared by bromination of 1-phenylpropyne. The acetylene (1.1 g, 9.5 mmol) in chloroform (10 ml) was cooled in an ice-bath and a solution of bromine (1.52 g, 9.5 mmol) in chloroform (20 ml) was added dropwise with stirring. When the addition was complete the solvent was removed from the colorless solution and the residual oil distilled.

Anal. Calcd. for $C_9H_8Br_2$: C, 39.17; H, 2.90. Found: C, 39.51; H, 2.97.

In the n.m.r. spectrum, the methyl peak of this compound appears at τ 7.42.

1-Phenyl-2,2-dibromopropane-1-one (**14**) was prepared from propiophenone. The ketone (1.0 g, 7.45 mmol) and NBS (2.6 g, 14.9 mmol) were refluxed in carbon tetrachloride (20 ml) containing 2 mg of benzoyl peroxide over a 100 W Photoflood No. 2 bulb. After 10 min an orange coloration appeared in the mixture and, after an additional 8 min, the color disappeared and the reaction was complete. Filtration followed by evaporation of the solvent yielded **14** as a pale yellow oil. This oil was found to be homogeneous by t.l.c. and by n.m.r. In the n.m.r. spectrum the methyl group appears at τ 7.30. Distillation of a portion of the oil gave crystalline material, m.p. 30–31° (lit. (28) 31°). This material gave a yellow 2,4-dinitrophenylhydrazone, m.p. 266–267°.

1-Phenylpropanedione (**12**) was prepared from propiophenone by oxidation with selenium dioxide (29). In the n.m.r. spectrum the methyl group of this compound appears at τ 7.72.

Oxidation of Diphenylacetylene

Diphenylacetylene (0.25 g, 1.4 mmol) was dissolved in anhydrous DMSO. The solution was stirred and NBS (0.5 g, 2.8 mmol) was added in one portion. The solid dissolved immediately to give a bright yellow solution. There was no temperature change. After 24 h at room temperature the solution was diluted with water (60 ml), and a pale yellow solid precipitated. The solid was isolated by extraction into chloroform (the aqueous phase was found to have p*H* 2). The chloroform extract was washed successively with water and saturated sodium chloride, and was then dried ($MgSO_4$) and evaporated. The pale yellow oil (280 mg) crystallized on standing. Its i.r. spectrum was identical with that of benzil. Recrystallization from methylene chloride – petroleum ether (30–60°) afforded light yellow needles, m.p. 94.5–95.5°, undepressed on admixture with benzil.

Anal. Calcd. for $C_{14}H_{10}O_2$: C, 79.98; H, 4.79. Found: C, 79.38; H, 4.75.

The compound gave a pale orange 2,4-dinitrophenylhydrazone (2,4-DNP) derivative, m.p. 190–191°, undepressed on admixture with the 2,4-DNP derivative of benzil.

Attempted Oxidation of trans-Stilbene

trans-Stilbene (0.253 g, 1.4 mmol) and NBS (0.25 g, 1.4 mmol) were dissolved in anhydrous DMSO (5 ml). There was no temperature change, but the solution gradually developed a pale yellow color. After 24 h at room temperature the solution was diluted with water (30 ml) and extracted with three 10 ml portions of chloroform. The combined chloroform extracts were washed

with water, dried, and evaporated to give 210 mg of a white solid, m.p. 124–214°. Recrystallization from xylene afforded 180 mg of fine white crystals, m.p. 241–242°. A mixture m.p. with meso-stilbene dibromide (30) was not depressed and the i.r. spectra of the two compounds were identical.

Oxidation of 1-Phenylpropyne

1-Phenylpropyne (512 mg, 4.41 mmol, freshly distilled) was dissolved in anhydrous DMSO (10 ml), the solution was stirred, and NBS (798 mg, 4.46 mmol) was added in one portion. A yellowish-orange color formed immediately and the reaction mixture became warm. The flask was fitted to a reflux condenser equipped with a calcium chloride drying tube and the contents were stirred at 90° for 45 h. By this time the solution was deep yellow. The solution was cooled, poured into 30 ml of a 1:1 mixture of petroleum ether (30–60°) and benzene, and water (10 ml) was added. When this mixture was shaken the yellow color diminished in intensity but the organic layer remained pale yellow. It was washed with nine 10 ml portions of water. The combined aqueous extracts were then back extracted with 20 ml of petroleum ether (30–60°) and the combined organic extracts, after drying over magnesium sulfate, were evaporated to give 993 mg of an orange oil. Integration of the methyl region of the n.m.r. spectrum of this oil and comparison with the spectra of standard mixtures revealed the oil to contain **12** (40%), **13** (22%), **14** (8%), and unreacted 1-phenylpropyne (14%). Based on acetylene consumed, the conversion to **12** is 47%.

The oil obtained from an oxidation conducted at room temperature with 2 mol equiv of NBS per mol of 1-phenylpropyne was heated under reflux for 0.5 h with *p*-nitrophenylhydrazine (0.5 g), ethanol (15 ml), and acetic acid (2 drops). The precipitated solid was collected by filtration and, after recrystallization from ethanol, melted at 254–255°. The reported m.p. of 1-phenylpropanedione di-*p*-nitrophenylhydrazone is 256–257° (31).

Oxidation of 2-Butyne

A solution of 2-butyne (0.2 ml) and NBS (712 mg, 4 mmol) in anhydrous DMSO (10 ml) was stirred at room temperature for 26 h. The yellow reaction mixture was then diluted with water (50 ml) and extracted with four 25 ml portions of ether. The yellow color remained in the organic layer. This layer was dried over magnesium sulfate and concentrated under reduced pressure at 20°. The residue was treated with water (10 ml) and 85% hydrazine hydrate (1 ml) and the resulting mixture stirred at room temperature for 2 h. The oil which separated during this period was extracted into chloroform. The chloroform extract was dried over anhydrous magnesium sulfate and evaporated. The semi-solid product was recrystallized from ethanol to give biacetyldihydrazone, m.p. 155–157° (lit. (32) 158°).

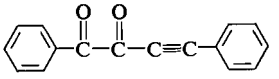
Oxidation of Phenylacetylene

A solution of phenylacetylene (306 mg, 3 mmol) and NBS (534 mg, 3 mmol) in anhydrous DMSO (10 ml) was stirred at room temperature for 20 h. The yellow mixture was then diluted with water (50 ml) and extracted with three 40 ml portions of ether. The ether extract was dried and evaporated. The i.r. spectrum of the resulting yellow oil showed a single strong carbonyl peak at 5.85 μ. The oil was treated with a solution of *p*-nitrophenylhydrazine (0.6 g) and glacial acetic acid (2 drops) in ethanol (15 ml). The resulting solution was refluxed for 0.5 h; during this period a deep red solid precipitated. This was collected and recrystallized from ethanol. It melted at 309–311° (phenylglyoxal di-*p*-nitrophenylhydrazone melts at 310–311.5° (33)).

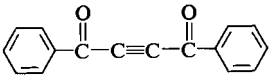
In a second experiment, conducted with the same quantities of materials, the total reaction mixture was treated after 20 h with *p*-nitrophenylhydrazine (2.0 g), and stirring was continued for an additional 2.5 h. Addition of water precipitated a dark solid which was collected, washed with ethanol, and dried *in vacuo*. The di-*p*-nitrophenylhydrazone weighed 317 mg (corresponding to a 25% recovery, based on starting acetylene) and melted at 308–310°.

Oxidation of Diphenylbutadiyne

(*a*) Diphenylbutadiyne (116.3 mg, 0.58 mmol) was stirred in anhydrous DMSO (3 ml) at room temperature, and NBS (414 mg, 2.32 mmol, 4 mol equiv) was added in portions during a 10 min period. After 2 h the solution, now orange and strongly acidic, was diluted with water (10 ml) and extracted with methylene chloride. This extract was washed with water until the washings were neutral, and then dried over anhydrous magnesium sulfate and evaporated to dryness. The resulting yellow oil showed i.r. absorption at 3.0, 3.3, 4.56 (w), 5.8–6.05 (s), 6.3, 6.7, 6.9, 7.65, and 8.9 μ. The presence of both carbonyl and acetylenic stretching bands suggests that the initial stage of the reaction affords **23** rather than **24**. The t.l.c. analysis of the oil showed it to consist mainly of unreacted diphenylbutadiyne. Therefore, the yellow



23



24

oil was redissolved in DMSO (3 ml) and the solution treated with NBS (0.4 g, 2.3 mmol). After 48 h the now bright red solution was diluted with water and extracted with methylene chloride to give, after drying and evaporation of the solvent, a red oil. The t.l.c. analysis showed this oil to contain only a trace of diphenylbutadiyne; its i.r. spectrum showed broad carbonyl absorption at 5.8–6.0 μ. Attempts to crystallize the oil from a variety of solvents were unsuccessful. The oil turned yellow when placed on a column of alumina (Woelm, grade IV), but no material could be eluted.

(*b*) Diphenylbutadiyne (202 mg, 1.0 mmol) and NBS (356 mg, 2 mmol) were dissolved in anhydrous DMSO (10 ml) and the solution was stirred at room temperature for 3 days. The deep red solution was then evaporated to dryness under high vacuum. When the red residue was treated with water (0.4 ml) it immediately turned yellow. Sulfuric acid (0.6 ml) and nitric acid (0.3 ml) were then added and the mixture was refluxed for 1 h. Then glacial acetic acid (1 ml) was added and the mixture was re-

fluxed for a further 2 h (22). Addition of water (10 ml) followed by extraction with petroleum ether, drying of the organic extract and evaporation, afforded a yellow solid. After two recrystallizations from petroleum ether (30–60°) this yellow solid melted at 93–94°. A mixture m.p. with benzil was not depressed.

(*c*) The above experiment was repeated and, after evaporation of the DMSO and addition of water (red → yellow), the mixture was extracted with carbon tetrachloride. The yellow carbon tetrachloride extract was dried and concentrated; after the residue had been maintained at 0.1 mm for 0.5 h it turned red. When this residue was exposed to air the yellow color reappeared instantly. The residue was dissolved in benzene and the yellow solution subjected to slow distillation. After a part of the benzene (and the trace of water) had been removed, the red color reappeared,

(*d*) Diphenylbutadiyne (1.0 g, 5 mmol) was dissolved in anhydrous DMSO (10 ml), and NBS (1.80 g, 10 mmol) was added in four portions at 3 h intervals. When the addition was complete the solution was stirred for 30 h and then extracted with three 100 ml portions of petroleum ether (30–60°) to remove the traces of unreacted diphenylbutadiyne. The red DMSO phase was then diluted with water (50 ml) (red → yellow) and extracted with three 50 ml portions of ether. The ether extract was washed thoroughly with water, dried, and evaporated to a residue which weighed 1.5 g. This residue was dissolved in ethanol (20 ml), hydroxylamine hydrochloride (690 mg, 10 mmol) was added, and this solution was refluxed briefly and then allowed to stand overnight. Water was added, the mixture extracted with chloroform, and the dried chloroform extract evaporated. The resulting product was purified by column chromatography on silica gel (25 g) with graded mixtures of petroleum ether (30–60°) and ether. Recrystallization from benzene–petroleum ether gave the dioxime of diphenyltetraketone, m.p. 173–175° dec. (lit. (20) 176°).

We thank the National Research Council of Canada for support of this work.

Dielectric Studies. Part XXXI. Analysis of the Dielectric Data of Phenol and its Polymerized Forms

M. D. MAGEE
Department of Chemistry, University of Bradford, Yorkshire, England
AND
S. WALKER
Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received November 4, 1970

The dielectric absorption and dispersions of several solutions of phenol in *p*-xylene have been measured at four microwave frequencies and at 2 MHz at a temperature of 25 °C. The data have been analyzed in terms of a mean relaxation time, a distribution parameter, and an apparent dipole moment which are useful empirical parameters for assessing the state of aggregation of the phenol molecules. The relaxation time at the lowest practicable concentration (0.02 mole fraction) is long for a molecule expected to relax predominantly by an intramolecular process. This and the behavior of the relaxation time and apparent dipole moment with increasing concentration are considered in terms of a model based on progressive association into an extended series of multimers, the trimer having a zero (or low) dipole moment and higher multimers becoming increasingly flexible.

On a mesuré l'absorption et la dispersion diélectrique de solutions de phénol dans le *para*-xylène à quatre fréquences microonde ainsi qu'à 2 MHz, à 25 °C. Les résultats ont été analysés en termes d'un temps de relaxation moyen, d'un paramètre de distribution ainsi que d'un moment dipolaire apparent qui sont des paramètres empiriques utiles pour caractériser l'état d'aggrégation des molécules de phénol. Le temps de relaxation à la concentration la plus faible à laquelle il a été possible de le mesurer (0.02 en fraction molaire), est grand pour une molécule dont le processus de relaxation serait à prédominance intramoléculaire. Ce fait ainsi que la variation du temps de relaxation et du moment dipolaire apparent avec la concentration ont été interprétés en termes d'un modèle basé sur une association progressive en un nombre de plus en plus grand de multimères, le trimère possédant un moment dipolaire nul (ou faible) et les multimères d'ordre supérieur étant progressivement de plus en plus flexibles.

Canadian Journal of Chemistry, 49, 1106 (1971)

Introduction

Association of phenol in solutions has been studied by several physical methods (1) notable among which are infrared, nuclear magnetic resonance (n.m.r.), and polarization measurements. Fischer (2) has employed radiofrequency measurements to study the relationship between dielectric relaxation and self-association of phenols in carbon tetrachloride, while Aihara and Mansel Davies (3) considered some aspects of association in a more general study. More recently Garg and Smyth (4) have studied alcohols at microwave and lower frequencies. Malecki and Doperala (5) have also shown how dielectric polarization yields much information on the association of alcohols. However, detailed microwave investigations of the dielectric relaxation of phenol in solution with a view to obtaining more data on self-association seem to be lacking although this technique yields relaxation times, distribution coefficients, and dipole moments, each of which might be sensitive to the interactions. Our publications (6, 7) on dilute solutions of phenols have not been primarily concerned with association.

The initial intent in the present study was to examine phenol, a molecule well known to associate in dilute solution at different concentrations, in an attempt to determine how sensitive the relaxation parameters are to changes in the nature of the associated species, and how they correlate with dipole moment alteration.

Experimental

Apparatus

The apparatus and procedure for determining the dielectric constant (ε') and loss factor (ε'') have been described previously (8) and sources of error have been assessed (9). Measurements were made at four microwave frequencies ($\omega/2\pi$); 9.313, 16.20, 23.98, and 34.86 GHz. In addition the dielectric constant (ε_0) was determined at a frequency (2 MHz), very low compared with the microwave measurements, using a "Dipolmeter" DM 01. The viscosity (η) of each solution was measured using an Ubbelohde viscometer with the pure solvent as a standard. The solutions were made up in *p*-xylene and all measurements were made at 25 ± 0.01 °C.

Evaluation of Data

The Cole–Cole (10) equation

$$[1] \qquad \varepsilon' - i\varepsilon'' = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + (i\omega\tau_0)^{(1-\alpha)}}$$

was fitted to the data by an iterative method using an Elliott 803 computer. The disposable parameters of eq. 1 are a mean relaxation time (τ_0), a distribution coefficient (α), and the high frequency dielectric constant (ε_∞). From the dispersion of the dielectric constant ($\varepsilon_0 - \varepsilon_\infty$) the apparent dipole moment of phenol can be found from Debye's equation (11)

$$[2] \quad \mu = \left[\frac{9k}{4\pi N} \cdot \frac{(\varepsilon_0 - \varepsilon_\infty)}{f_2} \cdot \frac{M_1 T}{(\varepsilon_1 + 2)^2 d_1}\right]^{\frac{1}{2}}$$

where k is Boltzmann's constant, N is Avogadro's number, f_2 is the mole fraction of the solute, M_1 is the molecular weight of the solvent, d_1 is the density of the solvent of dielectric constant ε_1, and T is the absolute temperature.

The procedure used previously (6, 7, 9) of analyzing the data into two discrete relaxation times is assumed to be vitiated for the phenol solution owing to the multiplicity of dipolar hydrogen bonded species likely to be present.

Purification of Materials

The phenol was distilled from a spinning band column of 30 theoretical plates and a small central fraction selected. It was stored in a dark stoppered bottle in a darkened dry cupboard until needed. The *p*-xylene was dried and distilled over sodium and stored in amber winchesters over sodium wire.

Results

The accuracy of the loss factor and dielectric constant results for each waveband have been discussed previously (9) and the experimental results are given in Table 1 together with values of the dielectric constant and loss factor calculated by the Cole–Cole equation from the parameters giving the best fit. In Table 2 the mean relaxation time, distribution coefficient, static and high frequency dielectric constants, and apparent dipole moments of each solution are listed. Since the viscosities of the more concentrated solutions are appreciably greater than those of the dilute solutions, the reduced relaxation times (τ') are listed also, where

$$[3] \quad \tau' = \tau_0 \eta_1 / \eta$$

and η_1 is the viscosity of the solvent and η that of the solution. The relevant parameters τ_0, τ', and μ_{app} are plotted against concentration expressed as mole fraction in Figs. 1 and 2.

Discussion

From the plot of the mean and reduced relaxation times against concentration in Fig. 1, the limiting value at infinite dilution obtained by extrapolation is about 10×10^{-12} s. Of the values in Fig. 1 this would be the nearest to the relaxation time of an isolated phenol molecule in *p*-xylene. The value is surprisingly similar to the relaxation times obtained for rigid molecules of similar size and shape in similar environments *e.g.* bromobenzene in cyclohexane (8) at 20 °C ($\tau_0 = 12 \times 10^{-12}$ s) and nitrobenzene in *p*-xylene (12) at 25 °C ($\tau_0 = 13.1 \times 10^{-12}$ s). However, an important factor expected to shorten the mean relaxation time of an isolated phenol molecule is a contribution from OH group relaxation with a con-

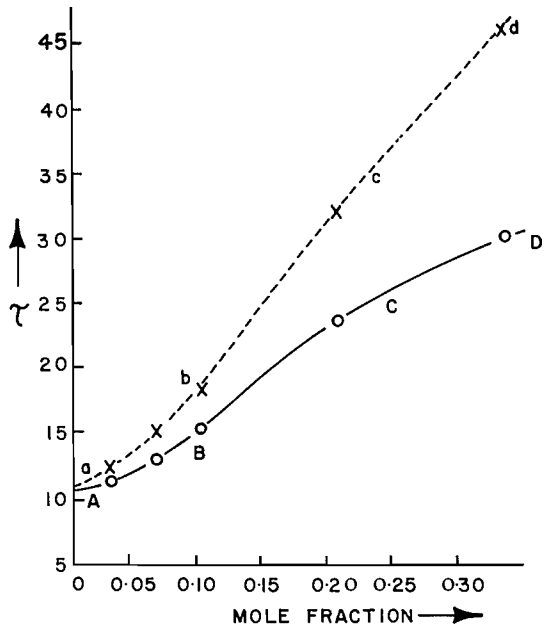

FIG. 1. Variation of mean (curve *abcd*) and reduced (curve *ABCD*) relaxation times of phenol with concentration at 25 °C. Relaxation times are in ps. The continuous curve is a calculated one and is to be compared with the data in Table 2.

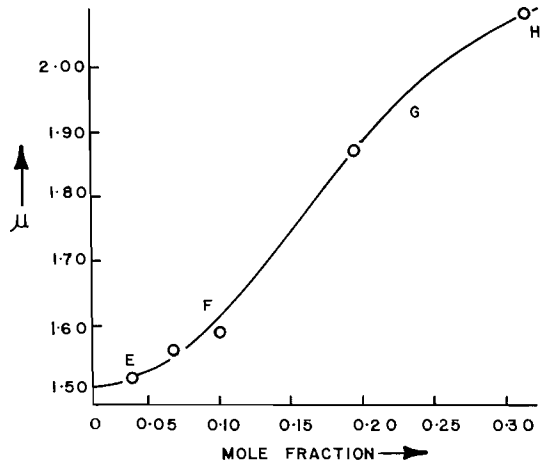

FIG. 2. Variation of apparent dipole moment (in D) of phenol with concentration in *p*-xylene at 25 °C. The continuous curve is a calculated one and is to be compared with the data in Table 2.

siderably shorter relaxation time. Hydroxyl group relaxation has been noted in previous communications (6, 7) on a variety of phenols in some of which the double bond character and therefore the rotational energy barrier of the C—O bond is greater than that of the phenol itself. Hydroxyl group relaxation has also been demonstrated by other workers (3, 13) in a number of phenols, and from this work it seems reasonable to expect OH group rotation in phenol to have a relaxation time of about 3.5×10^{-12} s (13).

There is a number of ways of estimating the mean relaxation time from the contributing group and molecular relaxation times (14) and it is enlightening to carry this out for phenol. The linear relationship

$$[4] \qquad \tau_0' = C_1\tau_1' + C_2\tau_2'$$

where τ_1' is the overall molecular relaxation time and τ_2' the group relaxation time will yield rather too long an estimate for τ_0', providing that the weight factor C_1 is less than about 0.6 and τ_1' and τ_2' are not too dissimilar (14). The weight factors C_1 and C_2 can be obtained by bond or group dipole moment considerations:

(*a*) Group moments: the hydroxyl group moment of 1.54 D (15) acts at 76° (16) from the direction of the O—C bond, so that the component (μ_1') along the bond responsible for molecular relaxation is (1.54 (15) cos 76°) D, while the component (μ_2') perpendicular to the bond responsible for group relaxation is (1.54 sin 76°) D. The weight factors for the molecular process (C_1) and the group process (C_2) are, respectively,

$\mu_1'^2/(\mu_1'^2 + \mu_2'^2) = 0.06$ and $\mu_2'^2/(\mu_1'^2 + \mu_2'^2) = 0.94$.

(*b*) Bond moments: the moment along the H—O bond is taken to be 1.5 D and that along the C—O bond is 1.0 D (16), the angle between the bonds (17) being 115°. There is also a component along the C—O axis due to the *p*-CH bond. This is taken to be 0.4 D acting into the benzene ring (16). Resolving as in (*a*), the component (μ_1') along O—C is (1.4–1.5 cos 65°) D and (μ_2') perpendicular to the O—C bond (1.5 sin 65°) D. The weight factors are obtained as before as $C_1 = 0.20$ and $C_2 = 0.80$.

The difference in C values for the two methods may perhaps be attributed to the neglect of mesomeric moments in (*b*) whereas this is allowed for in the group moments in (*a*). The calculations do show, however, that the contribution from group relaxation should be dominant. Inserting these values in eq. 4 and taking τ_2' to be 3.4×10^{-12} s, and τ_1' to be that already quoted for bromobenzene (12×10^{-12} s), owing to its similar size and shape to phenol, we obtain the estimated values for τ_0' of 3.9×10^{-12} s (group moments) and 5.1×10^{-12} s (bond moments). These values are less than a half of the observed value in Table 2, and it will be recalled that the estimate will tend to be too long (14).

More direct comparison can be made with the mean relaxation time of anisole, a molecule which primarily differs from phenol only in having a larger rotating group, OCH_3 instead of OH. Since both the group and molecular relaxation times (18) of this molecule should be longer than those of phenol, the mean relaxation time should also be longer. In fact, the value obtained is only 8.2×10^{-12} s at 25 °C in cyclohexane. 2,6-Di-*tert*-butylphenol is also a useful molecule for assessing the expected influence of the OH group. Although this is a much bigger molecule than phenol, its mean relaxation time is only 8.6×10^{-12} s in *p*-xylene at 25 °C, and this, of course, can be due only to a predominant contribution of OH relaxation with a short relaxation time, since the molecular relaxation time must be longer than that of benzotrichloride which in *p*-xylene at 25 °C has a value of 20×10^{-12} s (19). Clearly therefore, 10×10^{-12} s is anomalously long for the dilute solution relaxation time of phenol, and it seems that even at our lowest concentrations the mean relaxation time of phenol might be substantially lengthened by intermolecular association, due either to solute–solute interactions or to hydrogen bonding of the phenol to the π-electron cloud of the solvent.

Association by hydrogen bonding would lengthen the mean relaxation time (*i*) by introducing bigger species into solution, (*ii*) by lengthening the group relaxation time, and (*iii*) possibly by creating a longer relaxation time associated with the formation and disruption of the complexes. Dimers and higher multimers are, in fact, present in phenol solution at low concentrations as is shown by infrared data (20). Thus, in carbon tetrachloride, about 40% of the phenol is polymerized even at a concentration of 0.02 mole fraction, and although this fraction would be expected to be lower in a more interactive solvent such as *p*-xylene, it must still be considerable. It seems likely, therefore, that self-association is an important influence upon the mean relaxation time at our lowest concentration, but it is possible that solvent–solute interactions may also lengthen τ_0.

If the enhanced relaxation time of phenol at this concentration is primarily due to self-association, then at lower concentrations than those accessible by this technique, the mean relaxation time should fall rapidly. Radio-frequency measurements (21) have revealed behavior of this sort for solutions of eugenol in carbon tetrachloride. At eugenol concentrations below 0.01 mole fraction the mean relaxation time shortens so rapidly that it is impossible to extrapolate reliably to the infinite dilution value.

The plots of mean and reduced relaxation time against concentration in Fig. 1 may be compared with the behavior of apparent dipole moment against concentration in Fig. 2. There is closer correspondence in shape and variation in gradient between the dipole moment plot (*EFGH*) and the reduced relaxation time plot (*ABCD*) than with the mean relaxation time plot (*abcd*). In fact the regions *AB* and *EF* in the respective plots covering mole fractions between 0.02 and 0.08 indicate much less variation in these parameters than between *BC* and *FG* covering the range 0.08–0.20. Between 0.20 and 0.25 the reduced relaxation time and the apparent dipole moment plots begin to level off, and this is to be contrasted with the mean relaxation time plot which is virtually linear between mole fractions 0.08 and 0.25. It is inter-

esting to note that the reduced relaxation time which is mainly reflecting the increasing sizes of the complexes with rising concentration parallels the behavior of the increasing dipole moment which reflects alignment of the dipoles due to association. This suggests that it might be possible to construct a model system based on such data from which some insight into the phenol behavior can be obtained.

Theoretical Treatment

Let us consider that the phenol associates into a whole series of multimers. We shall denote the monomer, dimer etc. by A_1, A_2 etc. and corresponding concentrations by a_1, a_2 etc. Activities will be taken as equivalent to concentrations

$$[5]\quad \begin{aligned} 2A_1 &\rightleftarrows A_2 & K_2 &= a_2/a_1^2 \\ A_1 + A_2 &\rightleftarrows A_3 & K_3 &= a_3/a_1a_2 \\ &\vdots & &\vdots \\ A_1 + A_{n-1} &\rightleftarrows A_n & K_n &= a_n/a_1a_{n-1} \end{aligned}$$

Provided that solutions are not too strong the total concentration of phenol is

$$[6]\quad a = a_1 + 2a_2 + 3a_3 + \cdots + na_n$$

From eq. 5 this becomes

$$[7]\quad a = a_1 + 2K_2a_1^2 + 3K_3K_2a_1^3 + \cdots + nK_nK_{n-1}\cdots K_2a_1^n$$

Each step in the formation of the multimers is the creation of a hydrogen bond between hydroxyl groups. The successive reactions are therefore chemically very similar, the size of the reacting species being the major difference; therefore let us consider the case where

$$K_2 = K_3 = K_4 = \cdots = K_n = K$$

This assumption should hold more closely for higher multimers than for the dimer and trimer (and there is some evidence (22), which we shall discuss later, that K_3 is somewhat greater than K_2); thus this assumption becomes more justifiable with increasing concentration. Thus we have from [7]

$$[8]\quad a = a_1 + 2Ka_1^2 + 3K^2a_1^3 + \cdots + nK^{n-1}a_1^n$$

The degree of association of the phenol is conveniently expressed in terms of a parameter α_1, the proportion of phenol remaining in the monomeric form

$$[9]\quad \alpha_1 = a_1/a$$

$$[10]\quad (1/\alpha_1) = 1 + 2Ka_1 + 3K^2a_1^2 + \cdots + nK^{n-1}a_1^{n-1}$$

Provided that Ka_1 $(= Ka\alpha_1) < 1$ (which is the case for the solutions examined here) this sums to

$$[11]\quad \frac{1}{\alpha_1} = \frac{1}{(1 - Ka_1)^2} = \frac{1}{(1 - Ka\alpha_1)^2}$$

Equation 11 enables α_1 to be determined as a function of "a" (the initial phenol concentration) for any chosen value of K. Let us now apply a similar type of treatment to the dipole moments.

We may write

$$[12]\quad a\mu^2 = a_1\mu_1^2 + a_2\mu_2^2 + a_3\mu_3^2 + \cdots + a_n\mu_n^2$$

$$[13]\quad = a_1\mu_1^2 + Ka_1^2\mu_2^2 + K^2a_1^3\mu_3^2 + \cdots + K^{n-1}a_1n_{\mu_n}^2$$

$$[14]\quad (\mu^2/\alpha_1) = \mu_1^2 + Ka_1\mu_2^2 + K^2a_1^2\mu_3^2 + \cdots + K^{n-1}a_1^{n-1}\mu_n^2$$

For a cyclic trimer, μ_3 is close to zero so let $\mu_3 = 0$. The dipole moment of the higher multimers might be expected to tend to a limiting value since eventually curling and folding will occur (16). Hence the model consists of the formation of a series of multimers, initially approximately linear, with the exception of A_3, for which the non-polar cyclic structure is assumed to be preferred, but the higher multimers becoming increasingly folded so that their dipole moments do not increase linearly but reach a limiting value of μ_m.

Utilizing these ideas in eq. 14, extracting μ_m^2 from the series and performing the summation yields

$$[15]\quad \left[\frac{\mu^2}{\alpha_1} - \mu_1^2\right]\frac{1}{Ka_1} = \mu_2^2 + \frac{(Ka_1)^2}{1 - Ka_1}\mu_m^2$$

Whereas the additivity of μ^2 is well known, there is no precise additivity for relaxation times. In a previous paper we considered various relationships between the observed mean relaxation time (τ_0') and component relaxation times (τ_1', τ_2') and their weight factors (C_1, C_2) for systems having two contributory relaxation times. The simplest relationships are (*i*) a linear approximation eq. 4, which is true for the mean relaxation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

time obtained from low frequency measurements but generally a poor approximation for the mean relaxation time obtained from microwave measurements, and (*ii*) a logarithmic approximation

$$[16] \quad \log \tau_0' = C_1 \log \tau_1' + C_2 \log \tau_2'$$

which in general is likely to give better agreement with the results of microwave measurements than is eq. 4.

In the more general case of several contributory relaxation times, these equations can be extended to

$$[17] \quad \tau_0 = \sum_{i=1}^{n} C_i \tau_i$$

$$[18] \quad \log \tau_0 = \sum_{i=1}^{n} C_i \log \tau_i$$

Now C_i is related to the concentration (a_i) and dipole moment (μ_i) of the ith relaxing species by the following equation

$$[19] \quad C_i = \frac{a_i \mu_i^2}{\sum_{i=1}^{n} a_i \mu_i^2}$$

a special case of which we have already used in the calculation of the weight factors expected for group and overall relaxation in phenol monomer. Using eq. 19 in eqs. 17 and 18 and simplifying via eq. 12 yields

$$[20] \quad a\mu^2 \tau_0 = \sum_{i=1}^{n} a_i \mu_i^2 \tau_i$$

in the linear approximation, and

$$[21] \quad a\mu^2 \log \tau_0 = \sum_{i=1}^{n} a_i \mu_i^2 \log \tau_i$$

in the logarithmic approximation. For phenol association the subscripts i refer to the ith multimer. We are assuming that $\mu_3 = 0$ and therefore the term in $a_3\mu_3^2 \log \tau_3$ or $a_3\mu_3^2\tau_3$ is eliminated. The overall relaxation time of complexes should increase as the number of included monomer units increases, but this would be counteracted by the increasing flexibility of the chains leading to a rising number of intramolecular relaxation modes of shorter relaxation time. Thus it would not seem unreasonable to suppose that the relaxation time of the higher multimers approached a constant value τ_m. This supposition permits a treatment of eqs. 20 and 21 analogous to the treatment of dipole moments and giving, in the linear approximation

$$[22] \quad \left[\frac{\mu^2\tau_0}{\alpha_1} - \mu_1^2\tau_1\right]\frac{1}{Ka_1} = \mu_2^2\tau_2 + \frac{(Ka_1)^2}{1 - Ka_1}\mu_m^2\tau_m$$

and in the logarithmic approximation

$$[23] \quad \left[\left(\frac{\mu^2 \log \tau_0}{\alpha_1} - \mu_1^2 \log \tau_1\right)\right]\frac{1}{Ka_1} = \mu_2^2 \log \tau_2 + \frac{(Ka_1)^2}{1 - Ka_1}\mu_m^2 \log \tau_m$$

It may be considered that the supposition of τ_i approaching the constant value τ_m overemphasizes the influence of flexibility. An alternative approximation would be that the relaxation times of the multimers increase directly in proportion to their size *i.e.* that $\tau_n = n\tau_{unit}$ where τ_{unit} might be expected approximately to equal τ_1, the overall relaxation time of a monomeric phenol molecule. Internal modes of relaxation, however, would have the effect of shortening τ_{unit}. Utilizing this approximation in the linear approximation gives

$$[24] \quad \left(\frac{\mu^2\tau_0}{\alpha_1} - \mu_1^2\tau_1\right) = Ka_1\mu_2^2\tau_2 + [4(Ka_1)^3 + 5(Ka_1)^4 + \ldots (n+1)(Ka_1)^n + \ldots]\mu_m^2\tau_{unit}$$

The portion of eq. 24 in brackets is part of a series of the form

$$1 + ax + (a + b)x^2 + (a + 2b)x^3 + \cdots$$

where $a = 2$ and $b = 1$ in our case. This series has a finite sum and subtraction of the missing terms $(1 + 2x + 3x^2)$ gives $x^3(4 - 3x)/(1 - x)^2$ where x is Ka_1. Hence we obtain

$$[25] \quad \left(\frac{\mu^2\tau_0}{\alpha_1} - \mu_1^2\tau_1\right)\frac{1}{Ka_1} = \mu_2^2\tau_2 + \frac{(Ka_1)^2}{(1 - Ka_1)^2}(4 - 3Ka_1)\cdot\mu_m^2\tau_{unit}$$

The treatment has yielded a series of equations by which the data can be plotted in the form of a straight line from a knowledge of μ, μ_1, τ_0, τ_1, and K. Figures 3, 4, 5, and 6 show the results plotted according to eqs. 15, 22, 23, and 25, respectively, where concentrations are expressed in mole fractions using 5 mf^{-1} (see later) for the

TABLE 3. Dipole moment and relaxation time data for phenol–*p*-xylene solutions expressed in terms of the functions yielded by eqs. 15, 22, 23, and 25. The equilibrium constant for multimer formation is taken to be 5 mf^{-1} and infinite dilution values of the phenol dipole moment and relaxation time are 1.50 D (*i.e.* μ_1) and 10 ps (*i.e.* τ_1), respectively

value of the association constant. The relevant variables are tabulated in Table 3.

Further Discussion of Results

The dipole moment data plotted in Fig. 3 according to eq. 15 give a good linear plot. From the slope μ_m is obtained as 7.41 D, and the intercept gives μ_2 as 2.24 D. Similarly the reduced relaxation time data plotted according to eq. 23 (see Fig. 5) in the logarithmic approximation, yields an excellent straight line, but the two equations based on the linear approximation yield gentle curves (see Fig. 4). Thus logarithmic additivity of relaxation times would again seem the better approximation for microwave data.

From the straight line in Fig. 5 and the values of μ_2 and μ_m derived from Fig. 3, τ_2 is found to be 12×10^{-12} s and $\tau_m = 42 \times 10^{-12}$ s corresponding to a mean relaxation time for the higher multimers of 65×10^{-12} s in the 0.275 *mf* solution.

In Fig. 6 the plot differs only slightly from linearity and permits τ_{unit} to be estimated as about 8×10^{-12} s in reasonable agreement with the extrapolated relaxation time for phenol monomer of 10×10^{-12} s (and in good agreement with the mean relaxation time of anisole of 8.2×10^{-12} s). The τ_2 estimate is again 12×10^{-12} s.

Since the treatment of the data requires a prior knowledge of *K*, some discussion of the choice of 5 mf^{-1} is required. Pimentel and McClellan (1) quote several values for phenol in systems similar

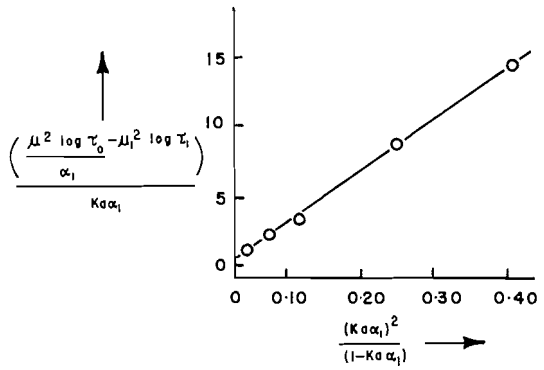

FIG. 5. Plot of dipole moment and relaxation time data according to eq. 23. In this case, for simplicity, τ_1 is expressed in units of 10^{-11} s.

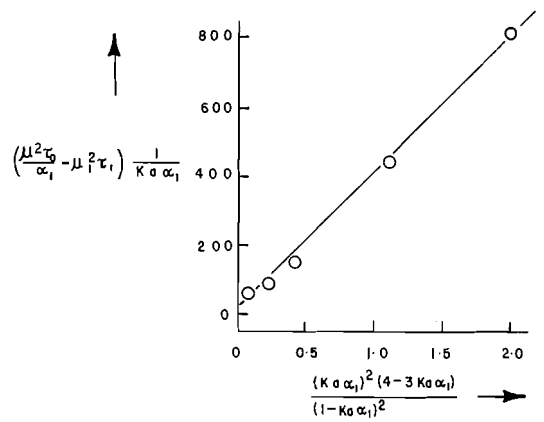

FIG. 6. Plot of dipole moment and relaxation time data according to eq. 25. Like Fig. 4 this graph is not exactly linear because of the faulty assumption for relaxation time addition.

to ours: 0.57 l mole^{-1} for phenol in benzene by vapor pressure and infrared measurements and 0.843 l mole^{-1} for phenol in toluene by a distribution method, while Mecke (20) gives data obtained from infrared measurements on the basis of a model identical to ours from which association constants of 0.24 and 3 l mol^{-1} can be calculated for phenol in benzene and carbon tetrachloride, respectively. The conversion of 1 mol^{-1} to mf^{-1} involves a factor of $1000d/M$ (where d is density of the solution and M is the molecular weight of the solute) which for $d \sim 1$ and $M \sim 100$ is close to 10. Hence the values quoted above are close to $5\,mf^{-1}$ in aromatic solvents.

It is relevant to ask how credible is the model assumed. Workers on n.m.r. interpreted their data (22) on the basis of a far simpler model consisting of a single equilibrium between monomer and multimer, all other multimers being neglected. The change in chemical shift was calculated for a monomer–dimer equilibrium, then monomer–trimer, and finally monomer–tetramer. For phenol in carbon tetrachloride the monomer–trimer equilibrium gave the closest data fit, and therefore the trimer was assumed to be the dominant species over the concentration range employed. However, for methanol a monomer–tetramer model gave the best fit.

While there is further evidence (5) that the trimer has the greatest formation constant for hydroxyl compounds in fairly inert solvents, such as carbon tetrachloride and cyclohexane, it seems that a model which excludes all except one multimer is unlikely to be valid in more interacting solvents such as benzene and *p*-xylene. In our case exclusion of all multimers except the cyclic trimer would lead to a marked fall in apparent dipole moment because three polar species are removed in the formation of each trimer of low dipolarity. Hence other polymers exist or the trimer could not be cyclic; a series of multimers seems most probable. The most likely explanation for the higher formation constant of the trimer is that it possesses some special structural stabilization such as cyclization, and if this is disregarded we must again fall back upon the model of an extended series of multimers. Of course, we are mindful of the possibility and even probability that K_3 is somewhat greater than the other equilibrium constants, but the equating of K_3 with the remaining constants may be a better approximation for this system than the neglect of all equilibrium constants except K_3.

The data appertaining to the curves are tabulated in Table 3 and the values of μ and τ for the various solutions calculated from these parameters are included for comparison. The continuous lines in Figs. 1 and 2 are also calculated. It is interesting that τ_m is about five times greater than τ_{unit} and μ_m is also about five times greater than μ_1. This suggests that folding and curling of the multimer chains dominate over straight chain formation when the multimer length is somewhat more than five monomer units. Beyond this complexity, internal relaxation mechanisms may become dominant and the model with τ_m approach-

For personal use only.

ing a limiting value may have some validity. This agrees with n.m.r. work which indicates formation of molecular "clusters" which lose their rigidity above about 0.2 mole fraction (23). Both dipole moment and the relaxation time of the dimer seem low, possibly illustrating flexibility in the dimer.

In conclusion, it seems likely that none of the methods applied to the phenol systems has provided an unambiguous insight as to the various polymers present in the phenol solutions; the success of the model is judged by the ability of the species invoked to fit the experimental data but it still remains a possibility that another model, probably more complex, would give an equally good fit to the data. The procedure we have adopted leads to reasonable values for the various parameters, although it does not then necessarily follow that our model is the correct one. Treatments such as that given here, while limited by the complexity of the system and the nature of simplifying approximations, can nevertheless be illuminating. It would seem at present, however, that no one physical technique yields a complete picture of the behavior of phenols in solution, and by bringing together several techniques more confidence can be gained as to whether the species postulated from the results of one technique are tenable in the light of others or whether more than one model will fit the experimental data. In this treatment an independent accurate determination of K would be invaluable since at the moment we are fitting three parameters K, μ_2, and μ_m to the dipole moment data and two more to the relaxation time data, τ_2 and τ_m. Here we have obtained the order of magnitude of K from the compilation of Pimentel and McClellan (1) and varied it slightly to obtain the best plots and an internally self-consistent set of parameters.

We may conclude that the dielectric absorption approach is of value in that information may be gained on the changing size of the complexed species in solution with increasing concentration, while the dipole moment values may reflect the geometry of the polymerized species.

We wish to thank Mr. B. K. Morgan for his technical assistance. One of us (M.D.M.) thanks Professor D. A. Long for providing the opportunity to complete parts of this work.

Ellipsometric Determination of the Spectra of Adsorbed Molecules

M. J. DIGNAM,[1] B. RAO, M. MOSKOVITS,[2] AND R. W. STOBIE
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received October 29, 1970

This paper presents a detailed analysis of the application of ellipsometry to obtaining the optical spectra (principally infrared (i.r.)) of molecules adsorbed on reflecting surfaces. Both external and total internal reflections are considered and the conditions for optimum sensitivity examined. A new empirical quantity, the relative complex optical density, is defined which exhibits thin film properties well, particularly in the case of multiple reflection measurements. An explicit expression is derived for this density function (relating it to the optical constants of the media and other system parameters), which is both reasonably simple and correct to second order terms in the film thickness. It is shown that for thin films, no higher order terms need be included, but that in general the second order term must be retained. Various limiting cases are examined to gain insight into the optical behavior of thin films, and to the same end, model calculations performed for CCl_4 physically adsorbed on Ag, Ni, Sb, and Ge. In relation to conventional reflection spectroscopy, ellipsometric spectroscopy is shown to have three major advantages: (*1*) in general, higher sensitivity to adsorbate properties; (*2*) very much lower sensitivity to absorption of radiation by the adjacent gas phase; (*3*) more information, permitting the optical constants and film thickness to be determined. Finally, the practicability of the technique is demonstrated by presenting preliminary results for CH_3OH reversibly adsorbed on Ag, showing clearly the C—H stretching bands.

Cette publication présente une analyse détaillée de l'application de l'ellipsométrie pour obtenir le spectre optique (principalement i.r.) de molécules absorbées sur des surfaces réfléchissantes. Les réflexions externes ainsi que les réflexions totales internes sont considérées et les conditions de sensibilité optimum sont examinées. Une nouvelle quantité empirique, la densité optique complexe relative, est définie, elle montre bien les propriétés des films minces, particulièrement dans le cas des mesures de réflexions multiples. Une expression explicite est dérivée pour cette fonction de densité (la reliant à des constantes optiques du milieu et d'autres paramètres du système), qui est raisonnablement simple et correcte jusqu'aux termes du second ordre pour l'épaisseur du film. Il est démontré que pour les films minces, des termes d'ordres supérieurs ne sont pas nécessaires, mais qu'en général, le terme du second ordre doit être retenu. Plusieurs cas limites sont examinés afin de mieux comprendre le comportement optique des films minces et dans le même but, des calculs modèles ont été effectués pour CCl_4 physiquement absorbé sur Ag, Ni, Sb et Ge. Par rapport à la spectroscopie de réflexion conventionnelle, la spectroscopie ellipsométrique possède trois avantages majeurs: (*1*) en général, une sensibilité supérieure aux propriétés d'un adsorbate; (*2*) beaucoup moins de sensibilité à l'absorption de radiation par la phase de gaz adjacent; (*3*) plus d'information, permettant de déterminer les constantes optiques et l'épaisseur du film. Finalement, la practicabilité de la technique est démontrée en présentant les résultats préliminaires pour CH_3OH absorbé réversiblement sur Ag, montrant clairement les bandes C—H de valence.

Canadian Journal of Chemistry, 49, 1115 (1971)

Introduction

Infrared spectroscopy has been applied extensively for the study of adsorption processes on solid surfaces, both to obtain information on adsorbate states as well as on catalytic surface properties (1). Adsorption phenomena frequently are limited to films of monolayer thickness, that is, of thickness about 10 Å or less. The usual method for obtaining the i.r. spectrum of adsorbed species is to employ a standard transmission spectrometer and an absorption cell filled with a porous or powdered material. A more recent technique (2) uses a stack of evaporated metal films, again in conjunction with a standard spectrometer. This technique is restricted to very thin metal films, since metals absorb strongly in the infrared. Thus, for both these techniques, it is extremely doubtful, that the substrate properties correspond to those for the material in bulk. For this reason alone, there is a distinct advantage in studying adsorption processes on bulk metallic surfaces using specular reflectance spectrometry. Lack of sensitivity employing a single reflection has prompted the use of multiple reflections between parallel surfaces (3). Such studies have been carried out on evaporated nickel (4), aluminum (5), silver (6, 7), copper (8), and on germanium by attenuated total internal reflection (9). Even for these studies, quantitative interpretation of the reflected intensity data is difficult, as the intensity is influenced by the refractive index of the film and the substrate optical constants in addition to the film absorption coefficient. Apart from the above problems, conventional i.r.

reflection and transmission techniques suffer from the fact that corrections have to be applied to take into account absorption of radiation by the gas phase whenever reversible adsorption is studied. For reflection studies in particular, such a correction could be so large as to obscure the absorption due to the surface species.

The use of polarized radiation (ellipsometry) for obtaining the spectrum of thin films has to date only been attempted by Bartell and Churchill (10), who used the technique successfully in the u.v.–visible for various films, including organic dyes dispersed in collodion, chelates, and Lewis bases on chromium and nickel; and by Bashara and Peterson (11) who calculated the optical properties of thin layers of polybutadiene evaporated onto Cr and Au films. Such a technique has certain major advantages for obtaining the spectrum of the optical constants of adsorbed molecules in general, and in the i.r. region in particular. A polarization state is uniquely characterized by the amplitude and phase relation between its parallel and perpendicular components. In the gas phase, the two components of the polarized radiation are attenuated to the same extent; thus, the gas phase exerts little influence on the results. In a sense one has an "ideal reference signal" in the use of polarized radiation. Furthermore, the analysis of reflected polarized radiation, both with respect to its phase and amplitude factors, provides information from which the thickness, the refractive index, as well as the chemical extinction coefficient of adsorbed films can be determined.

This paper consists of a detailed study of the application of ellipsometry to obtain the spectra of the optical constants of thin films, followed by model calculations relating to the i.r. spectra of monolayer films. The potential of this technique for monolayer films is then discussed and compared with that for conventional specular reflectance spectrometry.

When plane polarized light is incident on a reflecting surface, amplitude and phase changes are established between the components of the electric vector which lie parallel (p-component) and perpendicular (s-component) to the plane of incidence; the reflected light, is, therefore, in general elliptically polarized. The theory, both for semi-infinite reflecting substrates, and substrates covered by one or more uniform films, is well known (12). We begin by presenting the relevant equations in terms of which we define a quantity called the relative complex optical density D. For thin films and for either single or multiple reflections, D is shown to be proportional to the film thickness and to be nearly independent of substrate optical constants for substrates of good reflectivity. It is, therefore, a very convenient function for exhibiting the properties of thin films. The case of attenuated total internal reflection is also considered.

Reflection Equations

General Relations

Vasicek (13) gives the following expressions for the complex reflection coefficient, r_{jk}, for polarized light incident on medium k from the incident medium j.

$$r_{jk}^{p} = \frac{\hat{n}_k \cos \phi_j - \hat{n}_j \cos \phi_k}{\hat{n}_k \cos \phi_j + \hat{n}_j \cos \phi_k} \quad [1]$$

$$r_{jk}^{s} = \frac{\hat{n}_j \cos \phi_j - \hat{n}_k \cos \phi_k}{\hat{n}_j \cos \phi_j + \hat{n}_k \cos \phi_k} \quad [2]$$

where the superscripts p and s identify the polarization state of the incident light, n_j, is the complex refractive index of medium j, and ϕ_j is the complex angle of propagation in medium j measured from the normal to the interface. The angles ϕ_j and ϕ_k are related through Snell's law

$$\hat{n}_j \sin \phi_j = \hat{n}_k \sin \phi_k \quad [3]$$

The complex reflection coefficients for a film (medium 2) of uniform thickness d, separating the incident phase (medium 1) from a semi-infinite third phase (medium 3) can be expressed as follows

$$R_v = \frac{r_{12}^{v} + r_{23}^{v} \exp(-ix)}{1 + r_{12}^{v} r_{23}^{v} \exp(-ix)} \quad [4]$$

where

$$x = 4\pi(d/\lambda_0)\hat{n}_2 \cos \phi_2 \quad [5]$$

v = s or p, and λ_0 is the wavelength of the light in vacuo.

By analogy with transmission spectroscopy, we define the optical density function for a single reflection, D_v, as follows

$$D_v = \log_e (\bar{R}_v/R_v) \quad [6]$$

where $\bar{R}_v$ is the value of the complex reflection coefficient for the bare substrate. Thus in the case of external reflection from a metal surface, say, $\bar{R}_v$ is the value of R_v for $d = 0$ and $\hat{n}_1 = \bar{\hat{n}}_1$. The distinction between the value of $\hat{n}_1$ for the bare substrate case and for the film covered substrate case must be made since film formation results from adsorption of molecular species from phase 1; the composition of phase 1 therefore differs in general in the two cases. In the case of attenuated total internal reflection, the phase of variable composition is phase 3 so that $\bar{R}_v = R_v\,(d = 0, \hat{n}_3 = \bar{\hat{n}}_3)$.

To distinguish D_v from the conventional optical density function (which is defined in terms of intensities, not amplitudes), it will be referred to as the complex optical density for v polarized light. It is in general a function of the optical constants of all three phases. Finally, we define the relative complex optical density for a single reflection

$$D = D_p - D_s \quad [7]$$

The relationship between D and the conventional empirical ellipsometric quantities is obtained immediately on making the substitution $R_v = \rho_v \exp(i\delta_v)$ to obtain

$$D = \log_e (\tan \bar{\Psi}/\tan \Psi) + i(\bar{\Delta} - \Delta) \quad [8]$$

Thus the real part of D, $\mathscr{R}(D)$, is simply related to the relative amplitude attenuation, $\rho_p/\rho_s = \tan \psi$, while the imaginary part of D, $\mathscr{I}(D)$, is simply related to the relative phase retardation, $\Delta = \delta_p - \delta_s$, with $\bar{\Psi}$ and $\bar{\Delta}$ referring to the bare substrate condition. Accordingly, D can be readily calculated from conventional ellipsometric data.

In a precisely analogous manner, we define the relative complex optical density function for N identical reflections, D_N, in terms of the complex reflection coefficients for such multiple reflections, $R_{vN} = R_v^N$, to obtain

$$D_N = ND = \log_e (\tan \bar{\Psi}_N/\tan \Psi_N) + i(\bar{\Delta}_N - \Delta_N) \quad [9]$$

where the meaning of Ψ_N, Δ_N etc. is clear from the context. The relative complex optical density is seen to be related to the empirical ellipsometric parameters, Ψ and Δ, in exactly the same way for multiple reflection as it is for a single reflection.

Contribution to D from the Change in $\hat{n}_1$ (or $\hat{n}_3$)

For purposes of analysis, it is convenient to divide D into two parts, $D = D^{(g)} + D^{(f)}$, where $D^{(g)}$ is the contribution to D resulting from changing $\bar{\hat{n}}_1$ to $\hat{n}_1$ (or $\bar{\hat{n}}_3$ to $\hat{n}_3$) while maintaining $d = 0$ (*i.e.* no film formation), whereas $D^{(f)}$ is the contribution to D resulting from the formation of the film. Substituting the values of R_v and $\bar{R}_v$ given by [4] into [6], noting that $r_{13}^v = (r_{12}^v + r_{23}^v)/(1 + r_{12}^v r_{23}^v)$, we obtain

$$D_v = D_v^{(g)} + D_v^{(f)} \quad [10]$$

$$D_v^{(g)} = \log_e (\bar{r}_{13}^v/r_{13}^v) \quad [11]$$

$$D_v^{(f)} = \log_e \left[\left(\frac{1 + r_{12}^v r_{23}^v \exp(-ix)}{r_{12}^v + r_{23}^v \exp(-ix)} \right) \left(\frac{r_{12}^v + r_{23}^v}{1 + r_{12}^v r_{23}^v} \right) \right] \quad [12]$$

where $\bar{r}_{13}^v$ is the value of r_{13}^v for $\hat{n}_1 = \bar{\hat{n}}_1$ (or $\hat{n}_3 = \bar{\hat{n}}_3$). On substituting for r_{jk}^v from [1] and [2], and for ϕ_j from [3], the following expression for $D^{(g)}$ is obtained in terms of the optical constants and angle of incidence

$$D^{(g)} = \log_e [(1 + a/2)/(1 - a/2)] \quad [13]$$

where

$$a = \frac{i2(\bar{y} - y) \sin \phi_1 \tan \phi_1}{y\bar{y} + \sin^2 \phi_1 \tan^2 \phi_1} \quad [14]$$

$$y = (\sin^2 \phi_1 - \varepsilon_3/\varepsilon_1)^{1/2} \quad [15]$$

$\varepsilon_j = \hat{n}_j^2$ is the complex dielectric constant of medium j, and $\bar{y}$ is the value of y for $\varepsilon_1 = \bar{\varepsilon}_1 = \bar{\hat{n}}_1^2$ (or $\varepsilon_3 = \bar{\varepsilon}_3 = \bar{\hat{n}}_3^2$).

For the case of external reflection and $|\bar{\varepsilon}_1 - \varepsilon_1| \ll 1$, $D^{(g)} = a[1 + a^2/12 + \cdots] \simeq a$; also $y\bar{y} + \sin^2 \phi_1 \tan^2 \phi_1 \simeq y^2 + \sin^2 \phi_1 \tan^2 \phi_1 = \tan^2 \phi_1 - \varepsilon_3/\varepsilon_1$, and $\bar{y} = y\,[1 + \varepsilon_3(\bar{\varepsilon}_1 - \varepsilon_1)/\bar{\varepsilon}_1\varepsilon_1 y^2]^{1/2} \simeq y + \frac{1}{2}\varepsilon_3(\bar{\varepsilon}_1 - \varepsilon_1)/\bar{\varepsilon}_1\varepsilon_1 y$, which lead to the result

$$D^{(g)} \doteqdot i\left[\frac{\sigma - 1}{(\varepsilon_1 \sin^2 \phi_1 - \varepsilon_3)^{\frac{1}{2}}}\right]\left[\frac{\sin \phi_1 \tan \phi_1 \varepsilon_1^{\frac{1}{2}}(-\varepsilon_3)}{\varepsilon_1 \tan^2 \phi_1 - \varepsilon_3}\right] \quad [16]$$

where $\sigma = \varepsilon_1/\bar{\varepsilon}_1$. For studies in the infrared in which phase 1 is either a vacuum or a gas, typically $|\bar{\varepsilon}_1 - \varepsilon_1| \leqslant 10^{-3}$; the approximations employed in obtaining [16] will therefore introduce a negligible error. In the case of total internal reflection and an angle of incidence not too close to the critical angle (*i.e.* for $|\bar{\varepsilon}_3 - \varepsilon_3| \ll |\varepsilon_1 \sin^2 \phi_1 - \varepsilon_3|$) we may proceed as before, except that we now have $\bar{y} = y[1 + (\varepsilon_3 - \bar{\varepsilon}_3)/\varepsilon_1 y^2]^{1/2} \simeq y + \frac{1}{2}(\varepsilon_3 - \bar{\varepsilon}_3)/\varepsilon_1 y$. Once again this leads to [16], however, in this case $\sigma = \bar{\varepsilon}_3/\varepsilon_3$. Precisely at the critical angle, defined by $\varepsilon_1 \sin^2 \phi_1 = \bar{\varepsilon}_3$, $D^{(g)} \doteqdot -2i(1 - \varepsilon_3/\bar{\varepsilon}_3)^{1/2}(\varepsilon_1/\bar{\varepsilon}_3 - 1)^{1/2}$. This approximation is only valid for $|\varepsilon_1 \sin^2 \phi_1 - \bar{\varepsilon}_3| \ll |\bar{\varepsilon}_3 - \varepsilon_3|$, a condition virtually impossible to achieve. It is clear, however, that $|D^{(g)}|$ will increase very rapidly as the critical angle is approached.

Thin Films

Equation 12 may be written in the form

$$D_v^{(f)} = \log_e \left[\frac{1 - ixf(x)r_{12}{}^v r_{23}{}^v/(1 + r_{12}{}^v r_{23}{}^v)}{1 - ixf(x)r_{23}{}^v/(r_{12}{}^v + r_{23}{}^v)}\right] \quad [17]$$

where

$$f(x) = \frac{1 - \exp(-ix)}{ix} = 1 - \frac{ix}{2!} - \frac{x^2}{3!} + \cdots$$

For thin films (and certainly for monolayer films observed in the infrared), $|x| \ll 1$ so that $D_v^{(f)}$ may be expanded first in powers of $xf(x)$ and then on substituting for $f(x)$, in powers of x, to give on simplifying

$$D_v^{(f)} = ix\left[\frac{1/r_{13}{}^v - r_{13}{}^v}{1/r_{23}{}^v - r_{23}{}^v}\right]\left[1 - \frac{ix}{2}\left(\frac{1/r_{13}{}^v - r_{13}{}^v}{1/r_{12}{}^v - r_{12}{}^v}\right) + \cdots\right] \quad [18]$$

On substituting for $r_{jk}{}^v$ from [1] and [2], for x from [5], and for ϕ_j from [3], we obtain, after considerable algebra, the following expression for $D^{(f)} = D_p^{(f)} - D_s^{(f)}$

$$D^{(f)} = i\frac{4\pi d}{\lambda_0} \sin \phi_1 \tan \phi_1 \varepsilon_1^{\frac{1}{2}}\left(\frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2}\right)\left[\frac{\varepsilon_2 - \varepsilon_3}{\beta}\right][1 - T_2 + \cdots] \quad [19]$$

where

$$T_2 = \frac{2\pi d}{\lambda_0}\frac{(\varepsilon' \tan^2 \phi_1 - \varepsilon'')(\varepsilon_1 \sin^2 \phi_1 - \varepsilon_3)^{\frac{1}{2}}}{\beta}$$

$$\beta = -(\varepsilon_1 - \varepsilon_3)(\varepsilon_1 \tan^2 \phi_1 - \varepsilon_3)/\varepsilon_3$$

$$\varepsilon' = \varepsilon_1(1 - \varepsilon_1/\varepsilon_2 - \varepsilon_1/\varepsilon_3 + \varepsilon_2\varepsilon_1/\varepsilon_3^2)$$

$$\varepsilon'' = \varepsilon_2 - 2\varepsilon_1 + \varepsilon_2\varepsilon_1/\varepsilon_3$$

At first glance it would appear that for sufficiently thin films, both the real and imaginary parts of $D^{(f)}$, $\mathscr{R}(D^{(f)})$, and $\mathscr{I}(D^{(f)})$ respectively, are proportional to the film thickness. Although this is generally true, in the particular case of external reflection involving a dielectric film and dielectric substrate, it is not. For such a case, $\varepsilon_1, \varepsilon_2$, and ε_3 are all real valued and positive; furthermore, for external reflection $\varepsilon_1 \sin^2 \phi_1 - \varepsilon_3$ is negative, making T_2 totally imaginary. The first non-vanishing contribution to $\mathscr{R}(D^{(f)})$ arises, therefore, from the second order term, T_2, so that in the thin film limit, $\mathscr{R}(D^{(f)})$ is proportional to d^2, not d. (This situation has been noted previously by Saxena (14) although the present approach to the problem differs somewhat from his.) To cover all possible thin film cases, it is therefore necessary to include the second order term; in the majority of cases, however, and in particular those involving total internal reflection, or external reflection from a metallic substrate, the term T_2 and higher order terms can generally be neglected for sufficiently thin films. Thus for total internal reflection, and a non-absorbing film and substrate, $\varepsilon_1, \varepsilon_2$, and ε_3 will again be real valued with, however, in this case, $\varepsilon_1 \sin^2 \phi_1 - \varepsilon_3$ either zero or positive. The second order term, T_2, will accordingly be real valued (zero at the critical angle defined by $\sin^2 \phi_1 = \varepsilon_3/\varepsilon_1$) and hence negligible compared with 1 for small d. Again for external reflection from a metallic substrate and a nonabsorbing film, ε_1 and ε_2 will be real valued with $|\varepsilon_3| \gg \varepsilon_1$ and ε_2, $\mathscr{R}(\varepsilon_3)$ large and negative (~ -100) and $|\mathscr{R}(\varepsilon_3)| > |\mathscr{I}(\varepsilon_3)|$. It follows, therefore, that $|\mathscr{R}(T_2)| > |\mathscr{I}(T_2)|$ and hence that T_2 may usually be neglected for thin films since the dominant contribution to $\mathscr{R}(D^{(f)})$ will come from the leading term. In the limit of a perfectly reflecting metal, $\varepsilon_3 \to -\infty$ so that $T_2 \to 0$ and $(\varepsilon_2 - \varepsilon_3)/\beta \to 1$.

Before discussing further the consequences of [16] and [19], we note here that since

$$\frac{\tan \psi}{\tan \bar{\psi}} = \frac{1 - \tan(\bar{\psi} - \psi)/\tan \bar{\psi}}{1 + \tan(\bar{\psi} - \psi)/\tan \bar{\psi}} \simeq 1 - \left[\frac{1}{\tan \bar{\psi}} + \tan \bar{\psi}\right](\bar{\psi} - \psi)$$

$$\text{for } |\bar{\psi} - \psi| \ll \pi/4$$

$$\mathscr{R}(D^{(f)}) \simeq [\cot \bar{\psi} + \tan \bar{\psi}](\bar{\psi} - \psi)$$

For thin films, therefore, $\mathscr{R}(D^{(f)})$ is seen to be to a good approximation proportional to the change in ψ brought about by adsorption, so that usually $\bar{\psi} - \psi$, as well as $\bar{\Delta} - \Delta$, will be proportional to film thickness. For N identical reflections $D_N{}^{(f)} = ND^{(f)}$ remains proportional to film thickness for all N. As no such proportionality relationship exists between $(\bar{\psi}_N - \psi_N)$ and $(\bar{\psi} - \psi)$, in general $(\bar{\psi}_N - \psi_N)$ will not be linear in thickness, although $(\bar{\Delta}_N - \Delta_N) = \mathscr{I}(D_N) = N\mathscr{I}(D) = N(\bar{\Delta} - \Delta)$ will.

We turn now to an evaluation of the influence of the change in composition of phase 1 (phase 3 for total internal reflection), resulting from the addition to phase 1 (phase 3) of the adsorbate, on the determination of the film optical constants. A convenient measure of this will be given by the ratio $D^{(g)}/D^{(f)}$ which, from [16] and [19], takes the form

$$[20] \qquad \frac{D^{(g)}}{D^{(f)}} = \left[\frac{(\sigma - 1)/4\pi(d/\lambda)}{(\varepsilon_1 \sin^2 \phi_1 - \varepsilon_3)^{\frac{1}{2}}}\right]\left(\frac{\varepsilon_2}{\varepsilon_2 - \varepsilon_1}\right)\left[\frac{\varepsilon_1 - \varepsilon_3}{\varepsilon_2 - \varepsilon_3}\right][1 - T_2 + \cdots]^{-1}$$

For the case of a thin dielectric film on a metallic substrate of good reflectivity, making the substitutions $\varepsilon_j = \hat{n}_j{}^2 = (n_j - ik_j)^2$, and $\bar{\varepsilon}_1 = 1$ leads to the following approximations

$$(\varepsilon_1 - \varepsilon_3)/(\varepsilon_2 - \varepsilon_3) \simeq 1$$

$$(\varepsilon_1 \sin^2 \phi_1 - \varepsilon_3)^{1/2} \simeq k_3$$

$$(\sigma - 1) = \varepsilon_1 - 1 \simeq 2(n_1 - 1) - 2ik_1$$

$$\varepsilon_2/(\varepsilon_2 - \varepsilon_1) \simeq \varepsilon_2/(\varepsilon_2 - 1)$$

$$[1 - T_2 + \cdots]^{-1} \simeq 1$$

so that

$$[21] \qquad \frac{D^{(g)}}{D^{(f)}} \simeq \frac{(n_1 - 1) - ik_1}{2\pi k_3(d/\lambda_0)}\left(\frac{\varepsilon_2}{\varepsilon_2 - 1}\right)$$

In arriving at [21], the inequalities $K_3 \gg n_3, |\hat{n}_1|, |\hat{n}_2|$, and $1 \gg (n_1 - 1), K_1$, have been used. Since $|\varepsilon_2|$ will typically be of the order of 2 or larger, the condition that $D^{(f)}$ be the dominant term in D may be stated as follows

$$d/\lambda_0 \gtrsim (n_1 - 1)/K_3, \quad K_1/K_3 \qquad [22]$$

For a monolayer film and observation in the infrared, $d/\lambda_0 \sim 10^{-4}$ whereas typically K_3 will be greater than 10 (at 10μ, $K_3 = 69$ for Ag, 5.6 for Sb) so that [22] requires that $(n_1 - 1)$ and K_1 be less than 10^{-3}, a condition which will virtually always be satisfied for phase 1, a gas phase at reasonable pressures. Under certain conditions, however, even though $D^{(f)}$ will dominate, $D^{(g)}$ will make a significant contribution to D which should be taken into account in the calculations.

The effect on D arising from the change of composition of phase 1, is not completely accounted for by $D^{(g)}$, since $D^{(f)}$ is also a function of ε_1. For $|\bar{\varepsilon}_1 - \varepsilon_1| \ll 1$, however, the contribution arising in this way will always be very small.

For the case of a thin dielectric film and total internal reflection, upon setting $\bar{\varepsilon}_3 = 1$, $(\varepsilon_1 - \varepsilon_3)/(\varepsilon_2 - \varepsilon_1) \simeq -1$, $\varepsilon_2/(\varepsilon_2 - \varepsilon_3) \simeq \varepsilon_2/(\varepsilon_2 - 1)$, $(\sigma - 1) = 1/\varepsilon_3 - 1 \simeq -2(n_3 - 1) + 2ik_3$ and $\varepsilon_1 = {n_1}^2$, we obtain

$$\frac{D^{(g)}}{D^{(f)}} \simeq \frac{(n_3 - 1) - ik_3}{2\pi({n_1}^2 \sin^2 \phi_1 - 1)^{\frac{1}{2}}(d/\lambda_0)} \left(\frac{\varepsilon_2}{\varepsilon_2 - 1}\right) \qquad [23]$$

where the inequalities ${n_1}^2 \gg |\varepsilon_2|, |\varepsilon_3|$ have been employed. The condition that $D^{(f)}$ be the dominant term in D in this case becomes

$$\frac{d}{\lambda_0} \gtrsim \frac{(n_3 - 1)}{({n_1}^2 \sin^2 \phi_1 - 1)^{\frac{1}{2}}}, \frac{K_3}{({n_1}^2 \sin^2 \phi_1 - 1)^{\frac{1}{2}}} \qquad [24]$$

Unlike the case of a metallic reflector, the above condition is sensitive to the angle of incidence, particularly so close to the critical angle. Taking as an example germanium ($n_1 = 4$) and $\phi_1 = \pi/4$, $({n_1}^2 \cdot \sin^2\phi_1 - 1)^{1/2} = \sqrt{7} \simeq 2.6$. On comparing the case of total internal reflection with that of reflection from a metallic substrate involving the same film material and adsorbing gas, we have $[D^{(g)}/D^{(f)}$ for total internal reflection$]/[D^{(g)}/D^{(f)}$ for reflection from a metal$] \simeq K_{metal}/({n^2}_{dielectric} \sin^2 \phi_1 - 1)^{1/2} \gtrsim 10$. Thus contributions to D from the gas phase will in general be much more important in the case of total internal reflection. To minimize such contributions, the angle of incidence should be chosen well removed from the critical angle.

Highly Reflecting Metallic Substrate

As noted earlier, in the limit of a perfectly reflecting metallic substrate, $T_2 = 0$ and $(\varepsilon_2 - \varepsilon_3)/\beta = 1$ so that [19] reduces to the following, high reflectivity, thin film, approximation

$$D^{(f)} = i(4\pi d/\lambda_0) \sin \phi_1 \tan \phi_1 {\varepsilon_1}^{1/2}(1 - \varepsilon_1/\varepsilon_2) \qquad [25]$$

Expanding $(\varepsilon_2 - \varepsilon_3)/\beta$ in powers of $1/\varepsilon_3$ gives $1 + (\varepsilon_1/\cos^2 \phi_1 - \varepsilon_2)/\varepsilon_3 +$ higher order terms, so that for real systems and an angle of incidence not too large, the error incurred in using [25] will be of the order of $|\varepsilon_2|/|\varepsilon_3|$ compared with unity, or since $\varepsilon_3 \simeq -{K_3}^2$ for a metal, whereas for a dielectric film, $\varepsilon_2 \simeq {n_2}^2$, the error will be of the order of $(n_2/K_3)^2$ compared with unity. Even for a very good metallic reflector, however, the approximation will break down for a sufficiently large angle of incidence. It is interesting to note that for an angle of incidence defined by $\cos \phi_1 = n_2/n_1$, the error introduced in using [20] is greatly reduced, being now only of the order of $(n_2/K_3)^4$ which will nearly always be negligible compared with unity. Thus for angles of incidence which are not too large, and particularly for $\cos \phi_1 \simeq n_2/n_1$, $D^{(f)}$ is seen to be very nearly independent of substrate optical constants where the substrate is a good metallic reflector. No equivalent approximation exists in the case of total internal reflection.

Since $\tan \bar{\psi}$ is 1 to first order for a good metallic reflector ($\tan \bar{\psi} = 1 - \gamma$ say), then $\cot \bar{\psi} + \tan \bar{\psi}$ will be 2 to second order (*i.e.* $\cot \bar{\psi} + \tan \bar{\psi} = 2 + \gamma^2 + \gamma^3 + \cdots$) so that $\mathscr{R}(D^{(f)}) \doteqdot 2(\bar{\psi} - \psi)$ under these conditions. Thus $2(\bar{\psi} - \psi)$ will show essentially the same dependence on substrate optical con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

stants, or lack of it, as does $\mathscr{R}(D^{(f)})$. Once again, however, for multiple reflection $2(\bar{\psi}_N - \psi_N)$ may show a pronounced dependence on substrate optical constants even though $(\bar{\psi} - \psi)$ does not, since $\tan \bar{\psi}_N$ will not be close to unity, even for a highly reflecting substrate, for N sufficiently large. This point will be illustrated by numerical calculations in Section 3.

Finally, on setting $\varepsilon_1 = 1$ and $\varepsilon_2 = (n_2 - ik_2)^2$, we obtain from [25]

$$\mathscr{R}(D^{(f)}) = \alpha \sin \phi_1 \tan \phi_1 [n_2/(n_2^2 + k_2^2)^2] \quad [26]$$

$$\mathscr{I}(D^{(f)}) = (4\pi d/\lambda_0) \sin \phi_1 \tan \phi_1 \left[1 - \frac{n_2^2 - k_2^2}{(n_2^2 + k_2^2)^2}\right] \quad [27]$$

where $\alpha = 4\pi k_2(2d)/\lambda_0$ and is the conventional base e optical density of a film of thickness $2d$ and absorption coefficient $\chi = 4\pi k_2/\lambda_0$. A plot of $\mathscr{R}(D^{(f)})$ *vs.* λ_0 will therefore be a good representation of the absorption spectrum of the film (α *vs.* λ_0) provided that $n_2/(n_2^2 + k_2^2)^2$ does not change too rapidly across any given absorption band. This condition will frequently not be met, so that in general a complete analysis of data for D *vs.* λ_0 must be carried out to yield, amongst other things, α *vs.* λ_0. In this connection it is worth pointing out that conventional specular reflectance spectrometry, performed on thin films for the case $\varepsilon_1 = \bar{\varepsilon}_1 = 1$ and using the bare substrate as the reference system, will yield an optical density for p-polarized light very nearly equal to $2\mathscr{R}(D)$ (since $|R_s| \simeq |\bar{R}_s|$ for thin films (6)). Such spectra cannot be regarded, therefore, as true absorption spectra, and may in fact frequently be misleading if so interpreted.

Multiple Reflections and Optimum Conditions

We consider next the consequence, with regard to signal sensitivity, of employing parallel plate multiple reflection cells, or multiple reflection prisms in the case of total internal reflection. We begin by applying the constraint that the cell or prism geometry must be such as to pass the entire incident light beam, apart from absorption losses. In the case of the total internal reflection prism, we apply the further constraint that the entrance and exit faces of the prism be normal to the incident and exiting beam, respectively. This is to avoid problems that would otherwise arise due to changes in the angle of refraction with wave length.

A light beam, incident on the entrance aperture of a parallel plate reflection cell, and of width w in the plane of incidence, can be made to enter the cell in its entirety only if the separation between the plates is equal to or greater than t where t is given by

$$t = w/2 \sin \phi_1 \quad [28]$$

The situation corresponding to [28] is illustrated in Fig. 1 *A* for $\phi_1 > \pi/4$. The corresponding optimum geometry for a total internal reflection cell and $\phi_1 > \pi/4$ is shown by the broken line in Fig. 1*A*. If the shape of the internal reflection cell is limited to a rectangular parallelepiped, the optimum geometry for $\phi_1 > \pi/4$ is illustrated in Fig. 1*B*, and represented by the equation

$$t = w \sin \phi_1 \quad [29]$$

For $\phi_1 < \pi/4$, the geometry which minimizes the separation between the reflecting surfaces is the same for reflection cell and reflection prism, as illustrated in Fig. 1*C*, and is represented by [28]. For reflecting surfaces of length L and separation, t, the number of reflections, N, suffered by the light beam is given by

$$N = L/t \tan \phi_1 \quad [30]$$

so that the maximum number of reflections which can be achieved with a parallel plate reflection cell at all angles of incidence, and for a simple prism at $\phi_1 \leqslant \pi/4$ is given by

$$N = 2(L/w) \cos \phi_1 \quad [31]$$

whereas for a simple prism and $\phi_1 \geqslant \pi/4$

$$N = (L/w)/\sin \phi_1 \tan \phi_1 \quad [32]$$

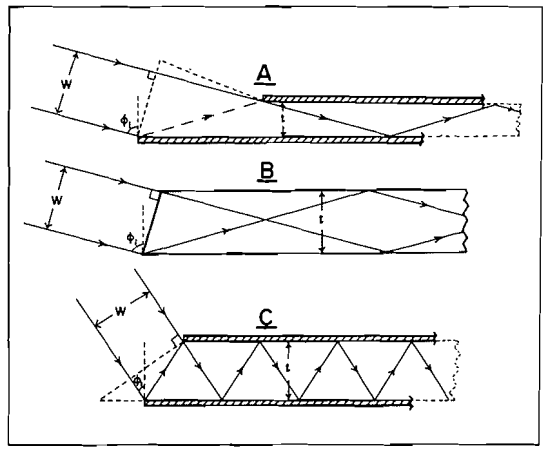

FIG. 1. Optimum geometry for: *A*, parallel plate reflection cell, $\phi_1 > \pi/4$; *B*, total internal reflection prism, $\phi_1 > \pi/4$; *C*, both reflection cell and reflection prism, $\phi_1 < \pi/4$.

As the relative complex optical density for N identical reflections, D_N, is simply ND, combining [19] with [31] and [32] in turn leads to the result

$$[33] \qquad D_N^{(f)} = i\left(\frac{4\pi d}{\lambda_0}\right)\left(\frac{L}{w}\right)F_N(\phi_1)\left(\frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_2}\right)\left(\frac{\varepsilon_2 - \varepsilon_3}{\varepsilon_1 - \varepsilon_3}\right)\left(\frac{-\varepsilon_3}{\varepsilon_1^{\frac{1}{2}}}\right)[1 - T_2 + \cdots]$$

where $F_N(\phi_1) = 1/(\tan^2\phi_1 - \varepsilon_3/\varepsilon_1)$ for a simple prism and $\phi_1 \geqslant \pi/4$, otherwise $F_N(\phi_1) = 2\sin^2\phi_1/(\tan^2\phi_1 - \varepsilon_3/\varepsilon_1)$. Similarly from [16], [31], and [32]

$$[34] \qquad D_N^{(g)} = i\left(\frac{L}{w}\right)F_N(\phi_1)\left[\frac{\sigma - 1}{(\varepsilon_1\sin^2\phi_1 - \varepsilon_3)^{\frac{1}{2}}}\right]\left(\frac{-\varepsilon_3}{\varepsilon_1^{\frac{1}{2}}}\right)$$

We seek now the angle of incidence which maximizes $|D_N^{(f)}|$. If measurement precision is not intensity limited, this same condition will provide optimum sensitivity. If it is intensity limited, then for optimum sensitivity, to a good approximation $|r_{13}^{p}|^{2N}|D_N^{f}|$ must be a maximum, where $|r_{13}^{p}|^{2N}$ is proportional to the intensity of the p-component following N reflections, this intensity always being less than or equal to that of the s-component. For a good metallic reflector in the infrared, we may set $\varepsilon_1 \simeq 1$ and $|\tan^2\phi_1 - \varepsilon_3/\varepsilon_1| \simeq (\tan^2\phi_1 + K_3^2 + n_3^2) \simeq (\tan^2\phi_1 + K_3^2)$. Then, on setting $\partial|D_N^{f}|/\partial\phi_1 = 0 = \partial|F_N(\phi_1)|/\partial\phi_1$, we obtain $\tan^2\phi_1 = K_3$, with the corresponding value of $D_N^{(f)}$ given by setting $F_N(\phi_1) \simeq 2/(1 + K_3)^2$. Making this substitution into [33] and neglecting terms of order $1/K_3$ with respect to unity, the following expressions for $D_N^{(f)}$ at the angle which maximizes $(D_N^{(f)})$ is obtained

$$[35] \qquad (D_N^{(f)})_{max} \simeq i(4\pi d/\lambda_0)(L/w)2[1 - 1/\varepsilon_2]$$

The exact choice of angle is not critical, however, since $|F_N(\phi_1)|$ (and hence $D_N^{(f)}$) varies by less than a factor of 2 over the range of angles defined by $\tan\phi_1 = 1$ to K_3. (For $\tan\phi_1 = 1$ or K_3, $F_N(\phi_1) \simeq 1/(1 + K_3^2) > 1/(1 + K_3)^2 \simeq \frac{1}{2}(F_N(\phi_1))_{max}$.) Equation 35 represents conditions for optimum sensitivity at fixed (L/w) only if measurement precision is not intensity limited, as mentioned previously. Under such conditions, however, the restriction placed on the reflection cell geometry becomes unnecessary, a more convenient geometry being one of fixed separation for all incident angles. For such a cell, $D_N^{(f)}$ will be given by [33] with w replaced by t and $F_N(\phi_1)$ by $\sin\phi_1/(\tan^2\phi_1 - \varepsilon_3/\varepsilon_1)$. Employing the same approximation as before (*i.e.* setting $-\varepsilon_3/\varepsilon_1 \simeq K_3^2$) a maximum for this function is found at a slightly smaller angle given by $\tan^2\phi_1 = (K_3/\sqrt{2})[(1 + 1/8K_3^2)^{1/2} - 1/2\sqrt{K_3}] \simeq K_3/\sqrt{2}$, and the function is found to vary by about a factor of $\sqrt{2}$ in the angular range defined by $\tan\phi_1 = 1$ to K_3. The situation is therefore not greatly altered on going to this geometry.

For total internal reflection, $|r_{13}^{p}|^{2N} = 1$ independent of ϕ_1 and N, so that the angle which maximizes $|D_N^{(f)}|$ for fixed (L/w), also maximizes $|r_{13}^{p}|^{2N}|D_N^{f}|$ for the same conditions. As $|F_N(\phi_1)|$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

increases monotonically as ϕ_1 decreases from $\pi/2$ towards the critical angle ($\sin \phi_1 = n_3/n_1$), its maximum permissible value occurs at the critical angle, and is given by $(F_N(\phi_1))_{crit} = 2(n_1^2/n_3^2 - 1)$. Making this substitution into [33] and setting $\varepsilon_3 \simeq 1, \varepsilon_1 = n_1^2$ we obtain

$$[36] \qquad (D_N^{(f)})_{max} = i(4\pi d/\lambda_0)(L/w)2n_1(1 - \varepsilon_2/n_1^2)[1 - 1/\varepsilon_2]$$

Unlike the case of multiple reflection from a metal, for multiple internal reflection, $(D_N^{(f)})_{max}$ decreases rapidly as the angle of incidence is increased. Taking germanium as an example, $F(\phi_1) = 30$ at the critical angle, 14.7°, whereas at 20°, $F_N(\phi_1) = 3.34$ and at 45°, 1.07. For the study of monolayers, it would therefore seem desirable to operate close to the critical angle. A serious practical difficulty arises in attempting to do so, however, in that the angular distribution of light in a collimated beam generally covers several degrees, except in the case of a laser source.

To treat the case of multiple reflection from a metal substrate under conditions in which measurement precision is light intensity limited, we look for conditions which maximize $|r_{13}^p|^{2N}|D_N^{(f)}|$ simultaneously with respect to L/w and ϕ_1. For a given value of ϕ_1, the optimum value of L/w, $(L/w)_{opt}$, is that which maximizes $|r_{13}^p|^{2N}(L/w)$ where N is given by [31]. Substituting for N and equating the derivative with respect to L/w to zero leads to the result that when $(L/w) = (L/w)_{opt}$, $\log_e |r_{13}^p|^{2N} = -1$. Thus for any given angle of incidence, the optimum number of reflections is that which leads to a reduction in the intensity of the p-component of a factor of $1/e$. For a metal in the infrared, $\cos \phi_3 \simeq 1$ to a good approximation. Making this substitution into [1] and setting $\hat{n}_1 = 1$ gives $|r_{13}^p|^2 \simeq (1 - b)/(1 + b)$ where $b = 2n_3 \cos \phi_1/[1 + (K_3^2 + n_3^2)\cos^2 \phi_1] \simeq 2n_3 \cos \phi_1/(1 + K_3^2 \cos^2 \phi_1)$. We then have for the case of optimum number of reflections, $-1 = \log_e |r_{13}^p|^{2N} \simeq -N.2b$ since $b \ll 1$, which on substituting for b from above and for N from [31] gives

$$[37] \qquad (L/w)_{opt} \simeq (1 + K_3^2 \cos^2 \phi_1)/8n_3 \cos^2 \phi_1$$

The optimum angle of incidence is now obtained by maximizing $(L/w)_{opt} \cdot |F_N(\phi_1)| \simeq \tan^2 \phi_1(1 + K_3^2 \cos^2 \phi_1)/4n_3(\tan^2 \phi_1 + K_3^2)$. This function possesses no maximum in the interval $[0,\pi/2]$, but rather increases monotonically with ϕ_1 from 0 at $\phi_1 = 0$ to $1/4n_3$ at $\phi_1 = \pi/2$. This curious result is the consequence of two competing effects, the decrease of $D^{(f)}$ for a single reflection towards zero as ϕ_1 approaches $\pi/2$, and the increase of $|r_{13}^p|^2$ towards unity as ϕ_1 approaches $\pi/2$, the latter effect allowing more reflections, approaching in fact an infinite number as ϕ_1 approaches $\pi/2$. The two effects battle to a standoff, and finite sensitivity is maintained to the limit. The result is, of course, strictly a mathematical curiosity since to achieve this result at $\phi_1 = \pi/2$, an infinitely long reflection cell would be required (see [31]). Furthermore, close to $\phi_1 = \pi/2$, the relationship for $(L/w)_{opt} \cdot F_N(\phi_1)$ would no longer be a good approximation due to imperfections (scattering centers) in the reflecting surfaces. Fortunately, once again the choice of angle of incidence is not very critical since $(L/w)_{opt} \cdot |F_N(\phi_1)|$ varies by less than a factor of 2 over the interval $[\pi/4,\pi/2]$. (At $\phi_1 = \pi/4$, $(L/w)_{opt} \cdot F_N(\phi_1) \simeq \frac{1}{2}[(1 + 2/K_3^2)/(1 + 1/K_3^2)]/4n_3 > \frac{1}{2}(1/4n_3)$). Values for $(L/w)_{opt} \cdot F_N(\phi_1)$ approaching $1/4n_3$ are therefore readily achievable. Substituting this value into [33], and making the usual approximations leads to the following expression for the optimum value of $D_N^{(f)}$

$$[38] \qquad (D_N^{(f)})_{opt} \simeq i(4\pi d/\lambda_0)(K_3^2/4n_3)[1 - 1/\varepsilon_2]$$

It is apparent that for intensity limited conditions, the feasibility of achieving useful results for monolayer films would depend critically on the optical constants of the metal, *i.e.* on the ratio K_3^2/n_3. If a laser source were used, however, this limitation would be removed.

Since $D_N^{(f)}$ varies only slowly with ϕ_1 where $(L/w) = (L/w)_{opt}$, a more practical solution to the optimization problem and one which leads to nearly as good a result as [38], is to fix (L/w) from practical considerations and then determine the value of ϕ_1 which maximizes $|r_{13}^p|^{2N}|F_N(\phi_1)|$. This problem involves the solution of a quartic equation. For $(L/w) \gtrsim K_3(K_3 + 3)/8n_3$, however, the optimum conditions are to a good approximation still given by [37], which on solving for $\tan^2 \phi_1$ becomes

$$[39] \qquad (\tan^2 \phi_1)_{opt} \simeq 8n_3(L/w) - K_3^2 - 1$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Even for (L/w) smaller than $K_3(K_3 + 3)/8n_3$, however, [39] will give a value for $|r_{13}{}^p|^{2N}|F_N(\phi_1)|$ which is greater than half the optimum value, provided only that the calculated angle, ϕ_1, is $\pi/4$ or greater (*i.e.* provided that $(L/w) \gtrsim (K_3{}^2 + 2)/8n_3$).

We compare now the relative sensitivities to thin film detection of total internal reflection measurements and reflection measurements from a metallic substrate, first for multiple reflection with L/w the same for the two cases, then for single reflections, the angle of incidence in each case being chosen to maximize $D_N{}^{(f)}$. The ratio for the multiple reflection case is obtained directly from equations [35] and [36], the sensitivity for internal reflection being the greater by a factor of $n(1 - \varepsilon_2/n^2)$ where n is the refractive index of the internal reflectance prism. Thus operating precisely at the critical angle, multiple total internal reflection has a significant sensitivity advantage over multiple reflection from metal surfaces (a factor of nearly 4 for Ge). The situation is reversed, however, if one must operate at an angle of incidence only a few degrees greater than the critical angle, which will generally be the case, or if one is dealing with a case in which $|n^2 - \varepsilon_2| < n$. This analysis takes no account of loss of sensitivity due to intensity loss. Whenever sensitivity is intensity limited, multiple total internal reflection will clearly be potentially much more sensitive.

Repeating the above analysis, but this time for single reflection measurements, the following approximate relations are obtained. For the case of the metal substrate, setting $T_2 = 0$, $-\varepsilon_3 \simeq K_3{}^2 \gg 1$, and $\varepsilon_1 = 1$ as before, we find that the optimum angle of incidence is given by $\tan^2 \phi_1 = \frac{1}{2}K_3{}^2[1 + (1 + 8/K_3{}^2)^{1/2}] \simeq K_3{}^2$ and that at this angle

$$[40] \qquad (D^{(f)})_{max} \simeq i\left(\frac{4\pi d}{\lambda_0}\right)\left(\frac{K_3}{2}\right)[1 - 1/\varepsilon_2]$$

For total internal reflection, the optimum angle of incidence is still the critical angle, leading to a value for $D^{(f)}$ at this angle given by

$$[41] \qquad (D^{(f)})_{max} \simeq i\left(\frac{4\pi d}{\lambda_0}\right) n_1 \left[\frac{(1 - \varepsilon_2/n_1{}^2)}{(1 - 1/n_1{}^2)^{\frac{1}{2}}}\right][1 - 1/\varepsilon_2]$$

In the infrared, and for most metals, the condition $(K_{metal}/2) > n_{dielectric}$ will apply so that even operating at the critical angle in the total internal reflection case, the sensitivity is about the same or greater for reflection from a metal substrate. This advantage will be retained even when measurement sensitivity is intensity limited, since the intensity loss on single reflection will be small.

The analysis in this section has been based on the implicit assumption that the incident beam of light is perfectly parallel. Except where lasers are used, angular spreads of several degrees must normally be tolerated in the interest of maintaining reasonable intensity levels. This in turn will mean that different portions of the incident beam will undergo different numbers of reflections (cell design can guarantee that the various components of the beam differ in their number of reflections by an even integer, so that the light emerges from the cell as a single beam). We have shown that for a metal reflection cell of fixed length and spacing, $D_N{}^{(f)}$ varies only slowly with the angle of incidence in the interval $\tan \phi_1 = 1$ to K_3 so that the error involved in not taking explicit account of the angular spread will be very small for mean angles of incidence within this range. The situation for total internal reflection near the critical angle is, however, an entirely different one as $D_N{}^{(f)}$ varies rapidly with angle of incidence for such conditions.

Numerical Calculations

A computer program was written to calculate D, given the optical constants for the incident medium, the film, and the substrate, as well as values for the system parameters, λ_0, d, and ϕ_1. The calculations were based on the exact equations [1] to [12] and involved no mathematical approximations. To facilitate comparison of the calculated results for different angles of incidence, both with each other and with those based on the thin film, high reflectivity approximation [25], we have in the case of metal substrates plotted the results in the form $100\ D/\sin \phi_1 \tan \phi_1$, which we subsequently refer to as D_N. For angles of incidence, $\phi_1 \geqslant \pi/4$, these results correspond, therefore, to values of D_N which would be achieved using a simple prismatic multiple reflection cell (Fig. 1*B*) of shape factor $L/w = 100$. In the case of total internal reflection, the results are plotted in the form $200\ D \cos \phi_1$ and again

are referred to as D_N. These results correspond to values of D_N which would be obtained using a cell of optimum geometry (Fig. 1, *A* and *C*) and a shape factor $L/w = 100$.

The above calculations have been carried out for external reflection from adsorbed films of CCl_4, CH_3OH, H_2O, and cyclohexane on Ag, Ni, and Sb, Ag representing a very good, Ni a good, and Sb a poor reflecting substrate, and for internal reflection for the Ge/CCl_4 system. In all cases, the film optical constants have been taken to be those for the bulk liquid state, with the thickness, corresponding to one monolayer, calculated from the bulk liquid density. The calculations do not reflect, therefore, the specific nature of the interactions between the adsorbate and adsorbent and are intended only to test the equations developed herein and to gain insight into the optical behavior of such systems. The optical constants for the metals were obtained by interpolation from the tables of ref. 15. Their normal incidence reflectivities have been plotted in Fig. 2 for purposes of comparison.

To check the accuracy of eqs. 16 and 19 for $D^{(g)}$ and $D^{(f)}$ these quantities were calculated from [16] and [19] as well as from the exact equations [1] to [12]. In no case did the results for $|D_N{}^{(f)}|$, $(L/w) = 100$, differ by more than about 10^{-5} absolute. For $D_N{}^{(g)}$, the difference was also less than 10^{-5}. Omitting the second order term, T_2, led in some cases to a 10^3 fold increase in the discrepancy. Thus at $\lambda = 14.79\ \mu$, $\phi_1 = 85°$, on neglecting the term T_2, the error in $\mathcal{R}(D_N{}^{(f)})$ is 1.4×10^{-7} and is reduced to 8.0×10^{-10} on including T_2.

The results for CCl_4 adsorbed on Ag, assuming

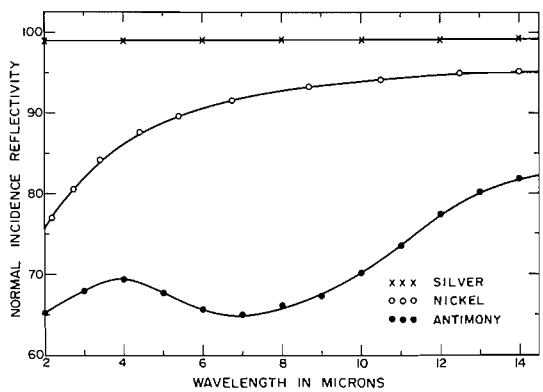

FIG. 2. Wavelength dependence of the normal incidence reflectivity for Ag, Ni, and Sb.

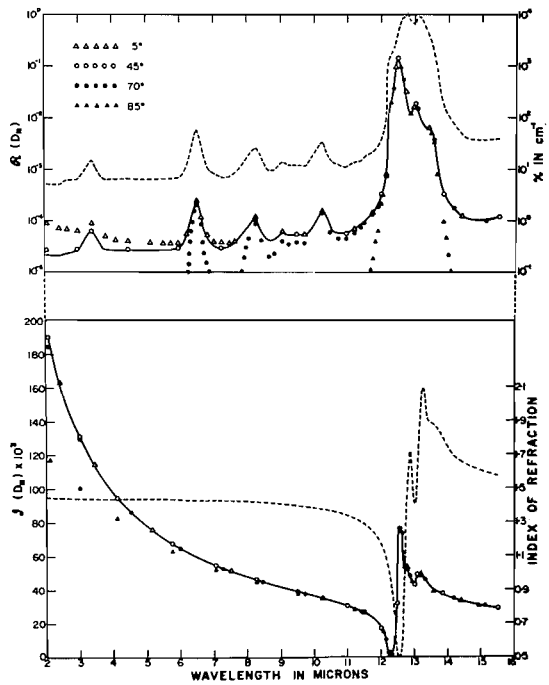

FIG. 3. Influence of angle of incidence on D_N for a monolayer film of CCl_4 (liquid state) on Ag. The solid lines were calculated using the approximate equation, [25]. The absorption coefficient χ and refractive index for liquid CCl_4 are shown as broken lines for comparison.

$\varepsilon_1 = \bar{\varepsilon}_1 = 1$, are presented graphically in Fig. 3, along with the values for the film optical constants (16) and curves calculated using the high reflectivity approximation, [25]. For values of $\mathcal{R}(D_N)$ which are large enough to measure (*i.e.*, $\mathcal{R}(D_N) > 10^{-3}$), it is effectively independent of angle of incidence from 5 to 85°, as predicted (*cf.* eq. 25 and related discussion). The accurately calculated values for $\mathcal{R}(D_N)$ at 45° angle of incidence are virtually indistinguishable from those calculated using the high reflectivity approximation over the entire wavelength range investigated, again an anticipated result, since at this angle the condition $\cos\phi_1 = n_2/n_1$ is very nearly met. Proceeding to larger angles of incidence, the discrepancy becomes progressively worse. The similarity of $\mathcal{R}(D_N)$ *vs.* wavelength to the adsorption spectrum, while close, is as expected by no means exact, a fact most clearly illustrated over the absorption band at 13 μ.

Again from Fig. 3 we see that the $\mathcal{I}(D_N)$ curves are virtually indistinguishable from each other and from that calculated using the high reflectivity

approximation for angles of incidence of 5 to 70° with a small discrepancy appearing at 85°.

In Fig. 4, the results for CCl_4 adsorbed on Ag, Ni, and Sb are compared for an angle of incidence of 45°, whereas in Fig. 5 the same comparison is made for an angle of incidence of 85°. The agreement between the exact calculations and the high reflectivity approximation is seen to decrease with decreasing substrate reflectivity and increasing angle of incidence. Although not reported here, similar results were obtained for CH_3OH, H_2O, and cyclohexane films.

The results calculated for total internal reflection employing a Ge prism are graphed in Fig. 6. The rapid fall-off in sensitivity as the angle of incidence is increased from the critical angle is clearly apparent.

To examine quantitatively the effects arising from absorption of light by the gas phase, D_N for CCl_4 adsorbed on Ag was calculated first for $\varepsilon_1 = \bar{\varepsilon}_1 = 1$, then for ε_1 given by that for CCl_4 gas at 100 Torr. In Table 1 these results are compared for an angle of incidence of 45°. The difference between the two results is always small in the case of $\mathscr{I}(D_N)$ and is small in the case of $\mathscr{R}(D_N)$ except near the absorption peak for the gas phase, when $K_1 \sim 10^{-3}$. Even here, the film contribution to D_N dominates, a result which can be deduced from [21]. This is in contrast with conventional absorption spectroscopy where absorption due to the gas phase can completely swamp the absorption due to the surface film. To show this, the conventional base e optical density for N identical reflections and for p-polarized light, $\mathscr{D}_N$, was calculated both for the vacuum case and for the case in which CCl_4 gas is present at 100 Torr. It is easily shown that

$$[42] \quad \mathscr{D}_N = 2N \log_e [|\bar{R}_p|/|R_p|] + 4\pi k_1 S/\lambda_0$$

where S is the path length of the light in the gas phase. The results using [42] and setting $S = 10^{-2}$ cm are presented in Table 2 and illustrate clearly the much greater dependence on gas phase absorption of $\mathscr{D}_N$ than of $\mathscr{R}(D_N)$. They also illustrate that for the vacuum case, and for K_2 not too small, $\frac{1}{2}\mathscr{D}_N \simeq \mathscr{R}(D_N)$, a point noted earlier. The

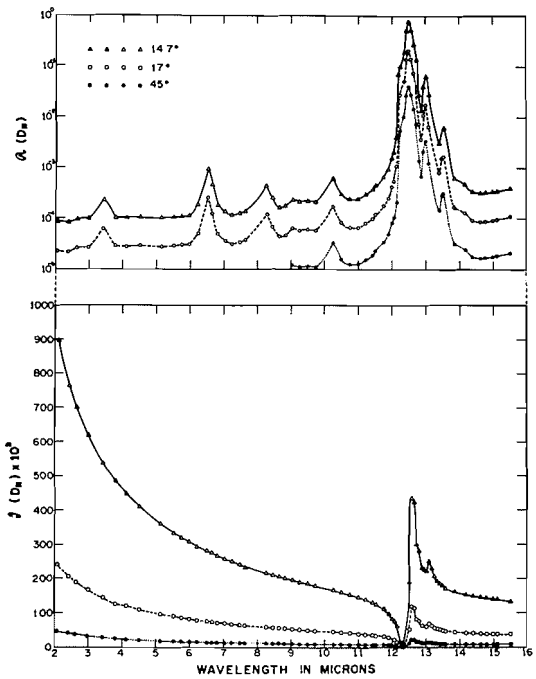

FIG. 6. Influence of angle of incidence on D_N (total internal reflection) for a monolayer film of CCl_4 (liquid state) on Ge, calculated at the critical angle, 14.7° and two larger angles.

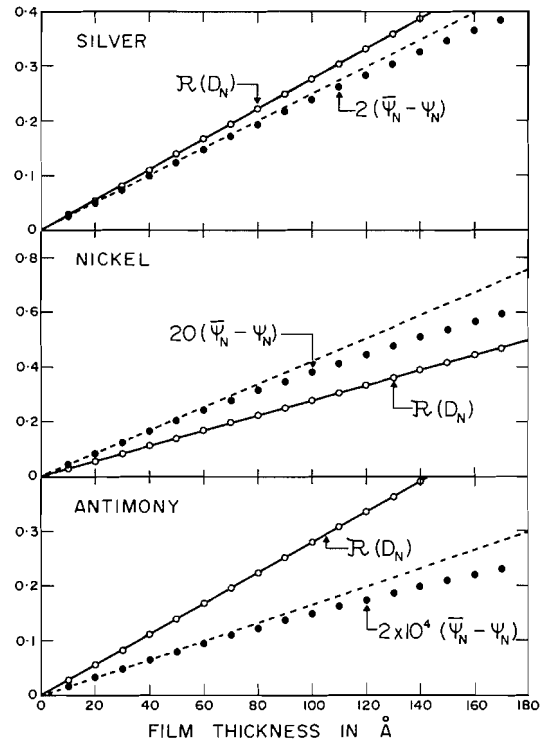

FIG. 7. Comparison of the extent to which $\mathscr{R}(D_N)$ and $(\bar{\psi}_N - \psi_N)$ are proportionally related to the film thickness for CCl_4 adsorption on Ag, Ni, and Sb, respectively. (Wavelength 12.8 μ, 45° angle of incidence.)

value $S = 10^{-2}$ cm is of course unrealistically small, but compensation to about this degree could possibly be achieved using a dual beam spectrophotometer to measure $\mathscr{D}_N$ and placing a compensating gas absorption cell in the reference beam. Because of difficulties arising due to multiple reflections between cell windows, etc., it is very unlikely that compensation to within 10^{-2} cm could in fact be achieved. The case chosen is, of course, extreme in that pressures as high as 100 Torr could usually be avoided. For substantially lower pressures, D_N will be virtually independent of the gas concentration, with significant effects still remaining in the case of $\mathscr{D}_N$.

Ellipsometric measurements cannot be made, usefully, close to or at normal incidence, but neither can conventional absorption measurements since the sensitivity is extremely poor under these conditions (6).

We show next the advantage of the function $\mathscr{R}(D_N)$ over $\bar{\psi}_N - \psi_N$ in relation to thin films and multiple reflection experiments. In Fig. 7, $\mathscr{R}(D_N)$ and $(\bar{\psi}_N - \psi_N)$ are plotted against film thickness for CCl_4 adsorbed on Ag, Ni, and Sb for an angle of incidence of 45° and at 12.8 μ. The lack of linearity of the graphs of $(\bar{\psi}_N - \psi_N)$ is apparent. Again in Table 2, $\mathscr{R}(D_N)$ and $2(\bar{\psi}_N - \psi_N)$ are tabulated for a monolayer of CCl_4 adsorbed on Ag, Ni, and Sb and at a number of wavelengths (*i.e.* a number of values for K_2). The pronounced dependence of $2(\bar{\psi}_N - \psi_N)$ on substrate properties compared with $\mathscr{R}(D_N)$ is dramatically illustrated. For single reflection measurements (*i.e.* $N = 1$), $\mathscr{R}(D)$ and $2(\bar{\psi} - \psi)$ are virtually indistinguishable. Of course, $\mathscr{R}(D_N)$ contains neither more nor less information than $(\bar{\psi}_N - \psi_N)$, given that the substrate optical constants are known, since one can be calculated from the other.

Finally, the need for retaining second order terms in film thickness for the case of external reflection from a weakly absorbing substrate is demonstrated in Fig. 8, where $\mathscr{R}(D_N)$ and $\mathscr{I}(D_N)$ ($L/w = 100$, $\phi_1 = 70°$, $\lambda_0 = 5461$ Å) for a non-absorbing film of refractive index 1.5 on silicon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

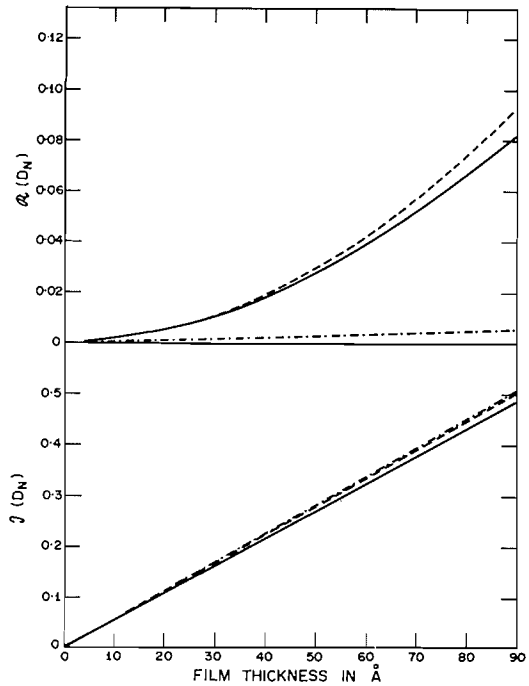

FIG. 8. D_N *vs.* film thickness for a non-absorbing film of refractive index 1.5 on Si, the calculations being performed using the exact equations (—) and using eq. 19 both including the terms T_2 (- - -) and excluding it (-·-·-) ($\phi_1 = 70°$, $\lambda_0 = 0.5461\ \mu$, $L/W = 100$).

are plotted against film thickness. D_N was calculated using the "exact" equations, and using [19] both with $T_2 = 0$ (*i.e.* ignoring second order terms in thickness) and including T_2.

Discussion

It has been shown in the previous sections, both from theory and from sample calculations, that $2\mathscr{R}(D_N)$ is very nearly the same as the conventional base e optical density $\mathscr{D}_N$ which would be obtained using standard specular reflectance spectrometry and p-polarized light. The connection between these can be easily seen, since $2\mathscr{R}(D_N) = N \log_e (\bar{I}_p/\bar{I}_s)/(I_p/I_s)$ whereas $\mathscr{D}_N = N \log_e (\bar{I}_p/\bar{I}_r)/(I_p/I_r)$, where I stands for intensity and the subscripts p, s, r, refer to p-component, s-component, and reference beam, respectively. Thus in ellipsometric spectrometry the s-component takes the place of the reference beam of conventional spectrometry and since I_s is in general much less dependent on the presence of a film than is I_p (*i.e.* $\bar{I}_s \simeq I_s$), the two density functions measure virtually the same thing. Furthermore, if measurement precision is intensity limited, there will be little to choose between them in this regard. If on the other hand precision is not intensity limited, then $\mathscr{R}(D_N)$ should be measurable with considerably greater precision than is possible for $\frac{1}{2}\mathscr{D}_N$, since the ellipsometric quantities required to calculate $\mathscr{R}(D_N)$ do not depend on intensity measurements for their evaluation, whereas $\mathscr{D}_N$ does. Drift in light intensity and photodetector–amplifier gain will therefore effect the measurement of $\mathscr{D}_N$, but not that of $\mathscr{R}(D_N)$.

In addition to the question of precision, however, there is another major advantage to be gained in measuring $\mathscr{R}(D_N)$ by ellipsometry rather than $\frac{1}{2}\mathscr{D}_N$ by conventional spectrometry, and that concerns the relative effectiveness of the "reference" beam in the two cases. Since the s- and p-components of the light beam used in ellipsometry travel exactly the same path, have exactly the same spatial intensity distributions, and are effected identically on transmission through both isotropic media and phase boundaries normal to the propagation direction, the s-component represents in a sense an ideal "reference" beam which cannot be matched by conventional reflection spectrometry. Thus the settling of dust or fogging of windows will effect directly the measured value of $\frac{1}{2}\mathscr{D}_N$, but will have no effect on the measured value of $\mathscr{R}(D_N)$. Again, compensation for light absorption in the gas phase is extremely difficult to achieve with accuracy in the case of conventional reflection spectrometry, whereas it is automatically achieved in ellipsometry as illustrated in the previous sections.

Although the above advantages of ellipsometry over conventional spectrometry are substantial, perhaps the most important advantage derives from the fact that in addition to providing the spectrum of $\mathscr{R}(D_N) \simeq \frac{1}{2}\mathscr{D}_N$, ellipsometry simultaneously provides the spectrum of the phase shift, $\mathscr{S}(D_N) = \bar{\Delta}_N - \Delta_N$. Thus, if the film thickness is measured by an independent technique, the complex refractive index spectrum of the film can be calculated from the measured spectrum of D_N and the optical constants of the substrate using [1] to [12] or [33] and [34] and one of the many equation solving procedures. It is clear that for a metallic substrate, the substrate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

optical constants need not be known very accurately since D_N is only weakly dependent on these. In fact, to the extent that [25] is a satisfactory approximation, they need not be known at all. It is, however, quite unnecessary to make this approximation, the main value served by it being the insight it provides into the optical behavior of such systems. If a gas phase is present in contact with the reflecting surface, its optical constants will likewise not be required very accurately.

The question now arises as to whether or not the film thickness as well as the spectrum of $\hat{n}_2$ can be determined from an ellipsometric spectrum alone. At first glance the answer would appear to be no since at any given wavelength there are two data (ψ_N, Δ_N, or D_N etc.) and three unknowns, $\hat{n}_2$ and d. Bartell and Churchill (10), working in the u.v.–visible region of the spectrum, overcame this problem in the following way. If $K_2 = 0$, then the experimental values of $\mathscr{R}(D_N)$ and $\mathscr{I}(D_N)$ (or $\bar{\Delta}_N - \Delta_N$, $\bar{\psi}_N - \psi_N$) provide 2 independent data from which the two unknowns, n_2 and d, can be evaluated. The only problem remaining, therefore, is that of locating one or more spectral regions where $K_2 \simeq 0$, a problem which Bartell and Churchill solved without difficulty. That the above technique for calculating d will not always work can be seen from the following analysis. It has been shown that over a fairly wide range of conditions, the high reflectivity approximation, [25] or [26] and [27], represents the optical behavior of such systems very well. However, from these equations we see that for $K_2 = 0$, $\mathscr{R}(D) = 0$ so that the two data are reduced to one and n_2 and d may not be independently evaluated. The same situation arises without approximation in the case of total internal reflection. That Bartell and Churchill did not encounter this difficulty is due to the fact that [25] is a poor approximation in the u.v., since $|\varepsilon_3|$ is not very much larger than $|\varepsilon_1|$ and $|\varepsilon_2|$ in this spectral region. This problem cannot be resolved for the case of reflection from a metal in which $|\varepsilon_3| \gg |\varepsilon_1|$ and ε_2 simply by operating at large angles of incidence where [25] is no longer valid, since the angular dependent factor in $D_N^{(f)}$ is independent of ε_2 for $T_2 \simeq 0$.

A solution to this problem lies in an entirely different direction. It involves using simultaneously all of the ellipsometric data covering a spectral region which spans one or more absorption bands for the film. Since d is presumed to be independent of wavelength, such a set of data will be, numerically, only one less than that required to calculate all the unknowns. An additional relationship is available, however, in that the wavelength dependence of the real and imaginary part of ε_2 are related. One equation based on this relationship is the Kramers–Kronig integral equation (17) used to resolve normal incidence reflectance data for a semi-infinite reflector into the spectrum of n and K for the reflecting medium. Two approaches to this problem based on this principle, but differing substantially from each other in detail, are being investigated now and will be reported upon shortly. At present one of the methods has been successful in reducing synthetic ellipsometric spectra generated via [25] (and hence satisfying precisely the condition $\mathscr{R}(D_N) = 0$ when $K_2 = 0$).

One question that remains concerns the feasibility of making ellipsometric measurements in the infrared region of the spectrum and with sufficient precision to evaluate the spectrum of n_2 and K_2. Bartell and Churchill demonstrated the feasibility of the technique for the ultraviolet spectrum, but abandoned it apparently because of the extremely tedious nature of the data collecting process. Automated ellipsometers now exist, however, with a capability of 1 measurement per second at 0.01° angular precision (18). We are in the process of perfecting an automatic, wavelength scanning, ellipsometer for operation in the wavelength interval 0.5 to 5μ. Its present capabilities are one measurement per second at better than 0.05° angular precision and a wavelength resolution of 0.002μ, the data being directly stored on paper tape in digital form. The collecting of data is therefore no longer a serious problem, nor is data processing. The question of sensitivity is now examined.

An angular precision of 0.05° corresponds to a precision of about 10^{-3} in $\mathscr{R}(D_N)$ and $\mathscr{I}(D_N)$. This is a hundred times the precision required to just detect the absorption and dispersion effects in Figs. 2 to 5 caused by the principle absorption peaks at about 13 μ. A more general statement about precision may be obtained, however, on combining [26] with [32] to give: $\mathscr{R}(D_N) \simeq \alpha(L/w)[n_2/(n_2^2 + K_2^2)^2]$ or since in general for dielectric films, $n_2^2 \gg K_2^2$ and $n_2 \sim 1$, we have $\mathscr{R}(D_N) \sim \alpha(L/w)$, so that to be detectable, the absorption coefficient, χ, must satisfy the inequality

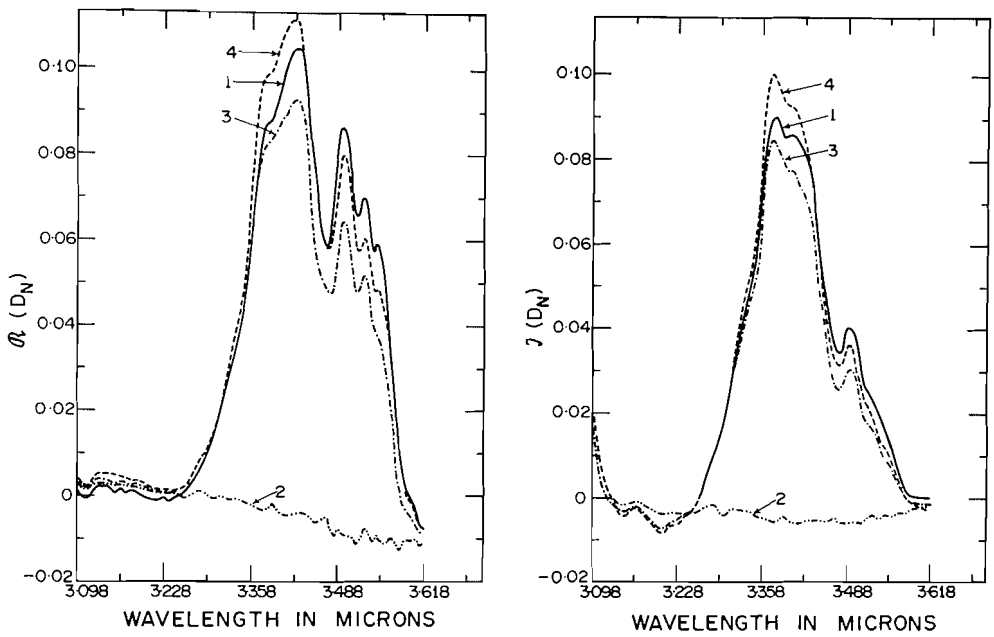

FIG. 9. Experimentally determined spectrum of D_N for CH_3OH adsorbed on Ag, 80° angle of incidence, 16 reflections, 5 Torr CH_3OH at 25 °C. Curves *1*, first adsorption scan; curves *2*, following desorption; curves *3* and *4*, second and third adsorption scans.

$$[43] \qquad \chi \gtrsim \delta[\mathscr{R}(D_N)]/(L/w)d$$

where $\delta[\mathscr{R}(D_N)]$ is the precision of the measurement of $\mathscr{R}(D_N)$. Setting the precision to 10^{-3}, L/w to 100, and d to 10 Å $= 10^{-7}$ cm, the condition becomes $\chi \gtrsim 10^2$ cm^{-1}. For liquid CCl_4 in the vicinity of the 13 μ absorption peaks, $\chi \sim 10^4$ cm^{-1}, which is 100 times above the threshold for detection, the same result obtained by direct inspection of Figs. 2 to 5.

In Table 3, values for χ for a number of common stretching and bending modes are listed along with references. They are typically of the order of 10^3 cm^{-1} or larger and hence readily detectable under the above conditions.

As final evidence of the practicability of the technique, we present in Fig. 9 our first, and preliminary, data obtained for CH_3OH adsorbed on vacuum deposited silver mirrors, 5 in. in length and spaced 1/16 in. apart. Measurements were made at 80° angle of incidence, which with the above geometry gives 16 reflections and $L/w = 46$. A flow system was employed with hydrogen as the carrier gas. The plates were first subjected to a flow of pure hydrogen gas for 3 h at 250 °C. Upon cooling to 25°, the bare substrate

TABLE 4. Comparison of frequencies for the peaks of $\mathscr{R}(D_N)$ for CH_3OH reversibly adsorbed on Ag with those for the absorption peaks for CH_3OH irreversibly adsorbed on Fe (24)

Present bands for CH_3OH on Ag		Bands for CH_3OH on Fe	
In μ	In cm^{-1}	cm^{-1}	Assignment
3.38	2960	2960	Asymmetric C—H stretch for CH_3
3.42	2924	2934	Asymmetric C—H stretch for CH_3
3.50	2860	2860	Symmetric C—H stretch for CH_3
3.52	2840	—	
3.55	2818	2820	Symmetric C—H stretch for CH_3O

measurements were made at a scan rate of 2 μ/h, then CH_3OH introduced into the flow stream at a partial pressure of 5 Torr (relative pressure of 0.05) and a second scan made. Pure hydrogen was once again passed through the cell until no detectable rate of change of optical properties was observed (this took about 10 min) and a third scan made. The procedures leading to scans 2 and 3 were repeated twice more, leading to a total of three "adsorption scans". The complex optical density function was calculated using runs 1 and 2, 1 and 3, 1 and 5, and 1 and 7, the results appearing in Fig. 9.

As the spectrum virtually disappears upon flushing the cell with pure hydrogen, CH_3OH is apparently reversibly adsorbed. All three adsorption scans show five peaks in the spectrum of $\mathscr{R}(D_N)$ in the vicinity of C—H stretching frequencies. The frequencies of the peaks are given in Table 4 and compared with those determined by Byholder and Wyatt (24) for CH_3OH adsorbed on silica supported iron, using transmission spectroscopy.

It is clear from Fig. 9 that a much weaker absorption band could be detected with our present instrument. Bearing in mind that this instrument is the first working model, and uses a conventional globar light source, further instrument improvement coupled with the probable development of tuneable lasers should provide virtually unlimited sensitivity. The present instrument, which will be described in detail in a subsequent publication, provides ample sensitivity for most purposes. Extension of the technique to the far infrared, while challenging, presents no serious obstacles.

The authors are grateful to the National Research Council of Canada for supporting this research and for a scholarship (M.M.), and to the Province of Ontario for a Fellowship award (R.W.S.). They would also like to express their appreciation to Mr. J. Roth for his invaluable assistance in the programming involved in reducing the raw ellipsometric data to spectra of $\mathscr{R}(D_N)$ and $\mathscr{I}(D_N)$.

NOTES

Circular Dichroism of the Copper(II) *N,N'*-Bis(alanyl)stilbenediamine Complexes

M. PARRIS AND A. E. HODGES
Chemistry Department, Carleton University, Ottawa, Canada

Received September 29, 1970

The preparations of the three diamides, RR(or RS or SS)-*N,N'*-bis(*S*-alanyl)stilbenediamine are described. The circular dichroism spectra of the 1:1 copper(II) complexes are compared to those of similar compounds previously described.

La préparation des trois diamides, RR (ou RS ou SS)-*N,N'*-bis(*S*-alanyl)stilbènediamine est décrite. Le spectre de dichroïsme circulaire de leurs complexes 1:1 avec le cuivre (II) est comparé avec ceux de composés similaires décrits prédécemment.

Canadian Journal of Chemistry, **49**, 1133 (1971)

The interaction between metal ions and peptide-like compounds has been reviewed (1). Peptides readily coordinate to copper(II) ion with the loss of the amide protons, two per molecule in the case of *N,N'* diamides (2), to form complexes only slightly distorted from planarity. Dissymmetric complexes of this type will exhibit Cotton effects in the visible region which are expected to be characteristic of the particular coordination environment (3). Accordingly, we present here the circular dichroism (c.d.) spectra for copper(II) complexes of some dissymmetric diamides of known absolute configurations, comparable to those previously described (8, 12).

Experimental

Materials

Established procedures were used for the preparation of *meso*-stilbenediamine (4), m.p. 120–121°, and for the preparation and resolution of *rac*-stilbenediamine (5), m.p. 80–82°, $(-)_D$ stien d tartrate, $|\alpha|_D$ −11.2° (0.10 g, 5 ml H_2O), $(-)_D$ stien, m.p. 82–83°, $|\alpha|_D$ −88° (0.048 g, 5 ml ether), $(+)_D$ stien d tartrate $|\alpha|_D$ +42° (0.041 g, 5 ml H_2O), $(+)_D$ stien, m.p. 81–83°, $|\alpha|_D$ +87° (0.049 g, 5 ml ether). L-alanine was obtained from Nutritional Biochemicals Corp., $|\alpha|_D$ +14.25° (2 *M*, 2 *N* HCl), and converted to phthaloyl L alanine by standard methods (6).

Preparation of Ligands

The procedure was adapted from that of Sheehan and Hess (7) and has been previously described (8).

RS-N,N'-bis(S-alanyl)stilbenediamine (1)

Using *meso*-stilbenediamine the intermediate RS-*N,N'*-bis(phthaloyl-*S*-alanyl)stilbenediamine was prepared, m.p. > 300°, $|\alpha|_D$ +58° (0.3%, DMF). Treatment with aqueous base converted the dihydrochloride from the hydrazinolysis into free amide, which was crystallized from aqueous methanol m.p. 258–259°, $|\alpha|_D$ +11° (0.7%, methanol).

Anal. Calcd. for $C_{20}H_{26}N_4O_2$, $2\frac{1}{2}$ H_2O: C, 60.2; H, 7.77; N, 14.0. Found: C, 60.5; H, 7.61; N, 13.9.

SS-N,N'-bis(S-alanyl)stilbenediamine (2)

$(-)_D$ Stilbenediamine was converted to SS-*N,N'*-bis-(phthaloyl-*S*-alanyl)stilbenediamine, m.p. > 300°, $|\alpha|_D$ +104° (0.35%, DMF), which was hydrazinolyzed. The amide dihydrochloride was recrystallized from aqueous HCl, m.p. 277–278° (decomp.), $|\alpha|_D$ +31.6° (1%, H_2O).

Anal. Calcd. for $C_{20}H_{26}N_4O_2.2$ HCl: C, 56.2; H, 6.60; N, 13.1. Found: C, 56.7; H, 6.04; N, 13.3.

RR-N,N'-bis(S-alanyl)stilbenediamine (3)

$(+)_D$ Stilbenediamine was converted to RR-*N,N'*-bis-(phthaloyl-*S*-alanyl)stilbenediamine, m.p. 155–156°, $|\alpha|_D$ −27.3° (1%, DMF) which was hydrazinolyzed. The amide dihydrochloride was recrystallized from aqueous HCl, m.p. 286–287° (decomp.), $|\alpha|_D$ +0.78° (1.3%, H_2O).

Anal. Found: C, 55.9; H, 6.87; N, 13.1.

Cupric Complexes

Aqueous solutions were prepared as previously described (8).

Discussion

Although the absolute configuration of stilbenediamine has not been determined crystallographically or chemically, a configurational relation has been established (9) between $(+)_D$ propanediamine, $(+)_D$ cyclohexanediamine, $(+)_D$ cyclopentanediamine, and $(-)_D$ stilbenediamine using the long wavelength absorption band of the *trans*-dichlorobis(diamine)cobalt(III) ions (10). The absolute configurations of the first three diamines are known from crystallographic studies (11) so that $(-)_D$ stilbenediamine is assigned the absolute configuration SS.

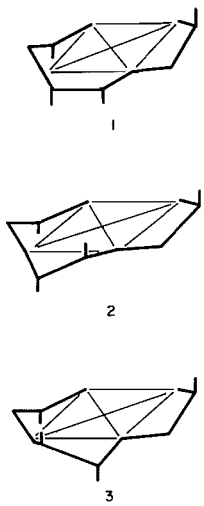

FIG. 1. Absolute configurations of compounds **1**, **2**, and **3** (see text).

The three 1:1 cupric complexes will have the structures indicated schematically in Fig. 1. Their visible absorption and c.d. spectra are shown in Fig. 2. If these spectra are compared to those previously described (8, 12), it seems evident that there are the expected three contributory bands beneath the total absorption envelope. The central band at about 500 nm has a negative c.d. related to λ chirality of the terminal rings (carbons 1 and 2) which is related to the ligand's absolute configuration in two ways. Firstly, SS-cyclohexanediamine always imposes δ chirality on the bridging ring (carbons 3 and 4) independently of the rest of the structure. This is, not unexpectedly, the strongest effect and overrides all other conformational preferences. A δ chirality is then transmitted to the terminal rings via the planar C—N—CO system (1). This effect is observed in RR-*N*,*N*′-bisglycylcyclohexanediamine, in RR-*N*,*N*′-bis(*S*-alanyl)cyclohexanediamine and in SS-*N*,*N*′-bis(*S*-alanyl)cyclohexanediamine (8, 12). Secondly, the terminal rings will tend to be non-planar in order to minimize any carbonyl–methyl interaction (13). A λ chirality here relates to S substitution, that is, the substituent becomes axial. This effect is seen in *N*,*N*′-bis(*S*-alanyl)ethanediamine, in **1**, in RS-*N*,*N*′-bis(*S*-alanyl)cyclohexanediamine, and in *N*,*N*′-bis(*S*-alanyl)butanediamine (8, 12).

Optical activity in two bands lying at about 450 and 550 nm appears to arise only upon dissymmetric substitution at the bridging ring.

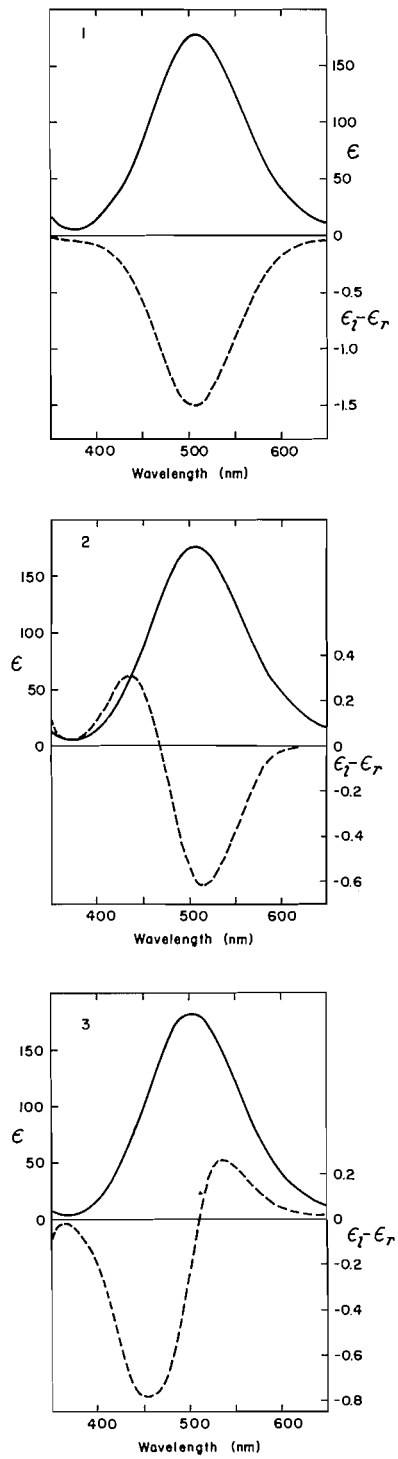

FIG. 2. Absorption spectra (—) and associated circular dichroism (---) for compounds **1**, **2**, and **3** (see text).

For personal use only.

In this case positive c.d. at 450 nm and negative at 550 nm is associated with S substitution and the magnitude of the effect varies according to the bulk of the substituent. This is seen in **2** and **3**, in S-*N*,*N*′-bisglycylpropanediamine, in SS-*N*,*N*′-bisglycylbutanediamine (8, 12) and in SS-*N*,*N*′-bis(*S*-alanyl)butanediamine and RR-*N*,*N*′-bis-(*S*-alanyl)butanediamine (14). In these cases, *i.e.*, in other than fused ring systems, there appears to be no significant preference transmitted to the terminal rings (*e.g.*, terminal λ for R bridge substitution), as judged by the absence of any marked optical activity in the 500 nm region.

We would like to thank both Dr. C. Benezra of The University of Ottawa and Dr. D. H. Busch of The Ohio State University for affording c.d. facilities.

Electronic Levels of Methyl Amines by Photoelectron Spectroscopy and an i.n.d.o. Calculation

A. B. Cornford, D. C. Frost, F. G. Herring, and C. A. McDowell
The Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received October 5, 1970

The ionization potentials of the methyl amines down to 20 eV binding energy, have been determined by photoelectron spectroscopy, and are compared with those predicted by i.n.d.o.-l.c.a.o.-s.c.f. theory. The first ionization potential for each compound refers to the removal of an electron from the lone pair, and is shown to be the one most affected by the inclusion of one center repulsion integrals in the i.n.d.o. calculations.

Les potentiels d'ionisation des méthylamines, en descendant jusqu'au niveau de 20 eV d'énergie de liaison, ont été déterminés par spectroscopie photoélectronique et comparés avec les valeurs prédites par la théorie i.n.d.o.-l.c.a.o.-s.c.f. Le premier potentiel d'ionisation de chaque composé se rapporte à l'enlèvement d'un électron du doublet libre et il est démontré que c'est celui qui est le plus affecté par l'inclusion, dans les calculs i.n.d.o., d'intégrales correspondant à une répulsion d'un centre.

Canadian Journal of Chemistry, **49**, 1135 (1971)

The first ionization potentials (i.p.'s) of the methyl amines have been measured by photoionization (1) and by photoelectron spectroscopy (2). We have obtained the 584 Å high resolution spectra of these compounds using a spectrometer with a hemispherical analyzer (3), and our adiabatic values for the first i.p.'s agree with those of ref. 1, which are all rather lower than those reported by Al-Joboury and Turner (2). Our actual values are 8.99 eV for the mono- , 8.25 eV for the di- , and 7.80 eV for the tri-substituted compounds. Our samples were C.P. grade, obtained from Matheson of Canada, and were found to contain no significant amount of impurities.

As far as inner i.p.'s are concerned, those re-

			20.6	20.2		23.9	23.8	
			25.4	25.4				

*This molecule having C_{3v} symmetry the orbitals may be classified accordingly A_1, E, A_2, E, E, A_1, A_1 in order of increasing energy.

ported by Al-Joboury and Turner are probably somewhere between adiabatic and vertical values, and so strictly speaking cannot be compared with results which are the vertical i.p.'s corresponding to the maxima in the vibrational bands. These are the values required for comparison with the i.n.d.o. calculations.

As in previous studies (4–7) we have carried out both c.n.d.o./2 and i.n.d.o.-l.c.a.o.-s.c.f. calculations (8). This type of calculation has proved useful in the identification of the molecular orbital from which the photoelectron is removed. The results are given in Table 1. A consideration of the data in this Table shows that the inclusion of one center exchange integrals, on going from the c.n.d.o./2 to the i.n.d.o. scheme, most markedly affects the calculated values for first i.p.'s of the molecules. The values of the first i.p.'s from the i.n.d.o./2 method are uniformly lower whereas the remaining ones are essentially the same, in all cases for both types of calculation. The first i.p.'s for all three molecules are associated with the removal of an electron from an orbital with electron density localized on the nitrogen atom, which closely approximates a lone pair orbital. It is, therefore, not unreasonable that this energy level will be the most affected by the inclusion of the one center repulsion integrals in the i.n.d.o. calculations. It should also be pointed out that both computational schemes lead to the same ordering of the molecular energy levels.

The calculations satisfactorily reproduce the trend in the first i.p.'s found on going from ammonia (5) through to trimethylamine, with the i.n.d.o. method being superior since it more correctly predicts the first i.p. of ammonia. The observed and calculated trends are of a decrease in the ionization potentials on going from ammonia to trimethylamine, which parallels the decrease in the dipole moment for the same series. It is tempting to suggest that this is because of changes in the overall hybridization of the nitrogen atom as more methyl groups are attached to it, *i.e.* a change of the lone pair orbital groups from an sp^3 hybrid towards a pure p orbital. The magnitude of the change in bond angle, however, on going from ammonia (107.1°) to trimethylamine (108.7°) does not seem to be sufficient to account for the trend in the first i.p.'s or the dipole moments (8). It is possible, however, that the trend in first i.p. reflects a progressive stabilization of the positive ion by hyperconjugation due to the increasing number of methyl groups.

The i.p.'s of the methyl-substituted amines, other than the first i.p., all arise from the removal of electrons in orbitals associated with the nitrogen–carbon bonding framework, and exhibit a similar decrease on successive methylation.

This work was supported by generous financial grants from the National Research Council of Canada. We wish to thank Mr. J. P. Louwerens for assistance with the computations.

Infrared Spectrum and Hydrogen Bonding in Solid and Liquid Trimethylamine Hydrate $(CH_3)_3N.10\frac{1}{4}H_2O$[1]

MICHAEL FALK
Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received November 6, 1970

The OD band profiles of dilute HDO in liquid TMA.$10\frac{1}{4}H_2O$ differ only slightly from those in liquid water, showing that the distribution of hydrogen-bond strengths has the same general form in the two media. Absence of shoulders at frequencies corresponding to the OD stretching frequencies of HDO in ice and in crystalline TMA hydrate points to the absence of structurally well-defined ice-like or clathrate-like regions above the melting point of the crystalline TMA hydrate.

Les profiles des bandes OD et HDO dilué de la TMA.$10\frac{1}{4}H_2O$ liquide diffèrent seulement un peu de ceux dans l'eau liquide, montrant que la distribution des forces des liaisons hydrogènes a la même forme générale dans les deux milieux. L'absence des épaulements aux fréquences correspondant aux fréquences de valence du OD de HDO, dans la glace et dans l'hydrate TMA cristallin indique l'absence de régions de structure bien définies comme dans la glace ou un clathrate, ceci au-dessus du point de fusion de l'hydrate TMA cristallin.

Canadian Journal of Chemistry, 49, 1137 (1971)

Interactions between water and non-polar parts of solute molecules have often been described in terms of ordered regions which possess the structure of one of the ices or clathrate hydrates (1). The purpose of the present study has been to determine whether the hydrogen bonding scheme characteristic of a crystalline clathrate persists above the melting point.

The shape of the distribution of hydrogen bonds may be deduced from the infrared band profiles of the OD stretching fundamental of isotopically dilute HDO (2–6). Such band profiles were obtained above and below the melting point of the crystalline hydrate of trimethylamine (abbreviated TMA), of ideal composition $4TMA.41H_2O$. The crystal structure of this hydrate is known from the work of Panke (7), and important structural evidence on the aqueous solution has been provided by the recent X-ray diffraction study of Folzer, Hendricks, and Narten (8).

Experimental

Infrared spectra in the region of 2500 cm^{-1} were recorded on a Perkin–Elmer spectrophotometer model 521. A low-temperature infrared cell of the Wagner–Hornig type was used. TMA was obtained as 25 weight% aqueous solution from Anachemia Chemicals Co., Montreal, and was used without further purification. D_2O of 99.85% isotopic purity was from Merck, Sharp, and Dohme Co., Montreal. Stock solutions of TMA in H_2O, and in H_2O to which 2 to 4 mol% of D_2O was added, were prepared by weight to give the TMA–water ratio of 1:10.25, which corresponds to the stoichiometry of the hydrate. The liquid samples were studied as films of 28 μm thickness in sealed CaF_2 cells; spectra of pure H_2O and of H_2O containing a few percent D_2O were recorded for comparison under identical conditions.

Upon cooling in sealed CaF_2 cells, the films of TMA solution froze to a polycrystalline solid, which had a melting point of 5.2 ± 0.2°, recorded spectroscopically as in ref. 9. The melting point confirms that the solid was essentially pure TMA.$10\frac{1}{4}H_2O$, which has the reported melting point of 5.0° (7). Unfortunately, the films obtained with sealed cells were too thick for a spectral study, the transmittance of crystalline samples in the 2500 cm^{-1} region being much lower than that of the liquid samples. To obtain sufficiently thin films we had to resort to rapid cooling of capillary films of TMA solution held between AgCl or CaF_2 plates. The thickness of these films was not accurately known. Another disadvantage was the possibility of some volatilization of TMA during the preparation of the films. This would raise the water content in excess of the desired stoichiometry, TMA.$10\frac{1}{4}$-H_2O, which upon cooling would lead to an admixture of ice. However, the constancy of the relative intensities of the bands due to H_2O and TMA in the spectra of the capillary films gave us confidence that we were dealing with nearly stoichiometric hydrate.

Results and Discussion

Figure 1 shows the OD stretching profiles of isotopically dilute HDO in the four media: water, TMA solution, ice, and TMA hydrate. These profiles were obtained by subtracting the absorbances of the undeuterated films from those of the partly deuterated films, and normalizing to unit height.[2]

The half-width of the OD stretching band of

[1]NRCC No. 11 777.

[2]The peak absorptivity of the OD band in TMA solution was a few percent higher than that in water; that of the OD band in ice and the crystalline hydrate could not be determined because of uncertain film thickness.

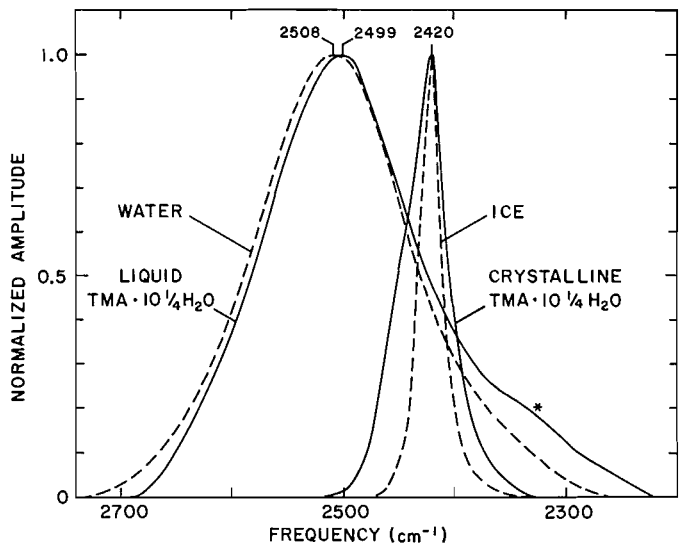

FIG. 1. Normalized OD stretching profiles of HDO in water (27°), TMA solution (27°), ice (−147°), and TMA hydrate (−149°). The shoulder marked with an asterisk is an artifact caused by the absorption of atmospheric CO_2.

isotopically dilute HDO in solid TMA.$10\frac{1}{4}H_2O$ is 50 to 60 cm^{-1}, compared to the values of 25 to 35 cm^{-1} for HDO in ice in the same temperature interval of −160 to −65°. Hydrates which contain fully ordered water molecules have OD half-widths of a few cm^{-1} (3, 5, 10, 11). The reason for the breadth of the band in ice I is its configurational disorder, which leads to a distribution of surroundings of individual OH groups (12). The two crystallographically distinct OH groups in ice ("axial" OH, pointing along the *c*-axis, and "equatorial" OH, forming an angle of about 109° with the *c*-axis) form hydrogen bonds of almost identical length (13), hence the corresponding two OH bands are too closely overlapped to be resolved. The much larger breadth of the band in TMA hydrate is due to the presence of twelve crystallographically distinct OH groups which form OH · · · O bonds with lengths from 2.740 to 2.850 Å and OH · · · N bonds with lengths of 2.668 and 2.705 Å (7). The bands due to the OD stretching frequencies of the individual hydroxyl groups must be broadened by hydrogen disorder as in ice, hence we cannot expect to resolve the resulting broad envelope. The envelope is highly asymmetric, in contrast to that of ice, which is symmetric and approximately Lorentzian (14). The half-width of this envelope is only slightly temperature-dependent, as the wide variety of hydrogen-bond lengths which correspond to the twelve distinct OH groups persists at all temperatures. As the widths of the individual subbands diminish at low temperatures, the band envelope begins to show some structure. Although the peak frequency is practically the same for the TMA hydrate and ice, the center of gravity of the band is about 10 cm^{-1} higher for TMA hydrate. This indicates that the *average* strength of hydrogen bonding in the hydrate is slightly lower than that of ice, in qualitative agreement with the average hydrogen-bond distance being about 2.80 Å in the hydrate (7) compared to about 2.76 Å in ice (13).

The OD band profile of isotopically dilute HDO in TMA.$10\frac{1}{4}H_2O$ above the melting point differs relatively little from that of HDO in water, showing that the distributions of hydrogen-bond strengths in the two media have the same general form. A closer inspection shows that the TMA solution has an increased absorbance on the low-frequency side of the band, a decreased absorbance on the high frequency side, and a downward shift of the peak frequency of about 9 cm^{-1} with respect to pure water. This indicates a small overall shift toward stronger hydrogen bonding when TMA is dissolved in water. However, at least a part of that shift must be due to the water–trimethylamine OH · · · N bonds, which are stronger than the water–water OH · · · O bonds. In crystalline TMA.$10\frac{1}{4}H_2O$ the OH · · · N bond distances

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

are 2.668 and 2.705 Å, much shorter than the OH · · · O bonds, which vary in length from 2.74 to 2.85 Å (7). Thus the distribution of water–water hydrogen-bond strengths in TMA solution must be nearly the same as that in pure water. The same conclusion has been reached earlier for aqueous solutions of dimethyl sulfoxide (15).

The OD band profile of HDO in water has appreciable intensity near 2440 cm^{-1}, corresponding to the peak frequency of HDO in ice and in crystalline TMA.$10\frac{1}{4}H_2O$ near the melting point. In the corresponding band profile in liquid TMA.$10\frac{1}{4}H_2O$ the relative intensity at 2440 cm^{-1} is slightly increased. However, there is no detectable shoulder near this frequency. This shows that while hydrogen bonding similar in strength to that occurring in crystalline ice or TMA hydrate does occur in water and, increasingly so, in aqueous solution of TMA, structurally well-defined regions do not persist above the melting point. Any "iceberg" regions are ill-defined and their OD stretching spectrum merges with that of the remainder of water.

The present observations and their interpretation are in full agreement with the findings of Folzer, Hendricks, and Narten (8) that the radial distribution function of the TMA solution is very similar to that of pure water and with their conclusion that long-range order (beyond 8 Å) is absent in the solution as well as in water.

I wish to thank Mr. P. F. Seto for technical assistance, Prof. G. A. Jeffrey for suggesting this investigation, and Drs. A. H. Narten and Cynthia Folzer for sending me a preprint of ref. 8 prior to its publication and for several discussions.

sigmoid curve. This may seem to be the case at initial dithionite concentration below 5×10^{-2} *M*. However, by increasing initial $S_2O_4^{-2}$ concentration or by adding HSO_3^- above 10^{-2} *M*, the rapid decomposition suddenly stops, sometimes leaving a relatively high dithionite concentration, as shown in Fig. 5 of ref. 4. In other words, what should be the curvature of the low portion of the S shaped curve is actually a sharp step, due to the sudden breakdown of the fast reaction. This is also evident in Figs. 4 and 5 of ref. 1, in which the agreement between theory and experiment appears rather poor. Thus, the rapid reaction cannot be simply autocatalytic and attempts to fit the overall decomposition curve to only a rate equation with two terms (the induction period and the autocatalytic term) may lead to erroneous results.

The results by Spencer, by Wayman and Lem, and by us, obtained under differing conditions, underline a rather unsatisfactory understanding of the decomposition mechanism. The p*H* variation recorded by Wayman and Lem (2) seems to confirm that initial and final stages of the reaction (p*H* decreasing) are distinct from the rapid reaction (p*H* increasing) in agreement with ref. 4. A thorough interpretation would require a complete knowledge of all the side reaction products formed in the various stages of the reaction. However, the curves show a rapid decrease of $[H^+]$ at the onset of the rapid reaction, probably related with the catalyst formation.

The rate-determining step of the overall slow reaction, as proposed by Spencer and by us (4, 5), is

$$\cdot HSO_2 + \cdot SO_2^- + HSO_3^- \rightarrow \text{Intermediate products}$$

Among the intermediate products, the sulfoxylate ion may be responsible for the formation of sulfur and/or sulfide ion (4) according, for instance, to reactions 6, 7, and 8 of ref. 2. The increased reaction rate (it is unclear whether the induction period or the fast reaction) by addition of Na_2S suggests that sulfide ion may be the catalyst. The presence of polythionates among the end products (5), the non-stoichiometric amount of bisulfite with respect to thiosulfate ion (2), and the disappearance of the catalyst by addition of bisulfite ion (4) are all in agreement with this suggestion. Moreover the absence of any fast reaction in the decomposition of ZnS_2O_4 (Fig. 1 of ref. 3), which gives only the S shaped slow reaction, is probably related to the low solubility of ZnS, as pointed out by Lem and Wayman.

For personal use only.

e.p.r.), both laboratories showing an initial slow reaction (the "induction" period) followed by a fast decomposition reaction; but Burlamacchi and co-workers have shown (2) that under some conditions the rapid reaction may be interrupted, and the concentration of dithionite may level off at some value well above zero. This was not observed by us (3, 4): Figs. 3–5 of ref. 3 show a sharp discontinuity at the conclusion of the rapid reaction, at which time more than 90% of the dithionite was decomposed and the remaining concentration was less than 0.5 m*M* in all cases. Nor was it observed by Burlamacchi and co-workers when they worked at our low initial concentrations, but only at much higher concentrations. They attribute the slowing up of the fast reaction to the removal of the catalyst by chemical reaction. We would not disagree with this interpretation, and we stated that the fast reaction is slow in the absence of a catalyst (4). In a later publication (5) we described experiments in which certain ions Zn^{2+}, Cd^{2+}, and In^{3+} slowed up the decomposition reaction, and we attributed this to anti-catalytic activity.

There are two questions raised by Burlamacchi and co-workers related to the mechanism of the reaction which require comment. They have to do with the rate limiting reaction for the slow initial reaction and the nature and mode of action of the catalyst. We have proposed that the rate limiting reaction for the slow initial reaction is

[1] $HS_2O_4^- + H_2O \rightarrow HSO_2^- + HSO_3^- + H^+$

while Burlamacchi and co-workers (1, 2) and Spencer (6) have proposed as the rate-determining step for the decomposition reaction

[2] $\cdot HSO_2 + \cdot SO_2^- + HSO_3^- \rightarrow$ Intermediate products

Reaction 2 depends upon the presence initially of a reaction product HSO_3^-; it does not account for the fall in p*H* which we observed during the initial slow reaction; and it cannot lead to an overall kinetic equation which fits the measured rates of reaction. We find it much easier to accept a two-body reaction of an ion and a neutral body, reaction 1, than a three-body reaction involving two negative ions and a neutral body, reaction 2.

Burlamacchi and co-workers complain of the poor fit of the calculated and observed decomposition curves in two Figs. of ref. 3, but since ours is the first proposal of an overall kinetic equation that predicts accurately the length of the induction period (Figs. 3–5 and 11 of ref. 3) and reasonably well the shape of the rest of the decomposition curve, we consider the fit remarkably good. We specifically stated that a two-term equation could not fully reflect all the influences on the rate of decomposition, and that "a better equation would have at least two more terms", the purposes of which were described (3).

We have proposed (4) that the fast reaction may be written as

[3] $HSO_2 + HS_2O_4^- \rightarrow S_2O_3^{2-} + HSO_3 + H^+$

a reaction very similar to that proposed by Rinker and co-workers (7). The reaction, according to our view, takes place rapidly in a solution of HSO_2^- and $HS_2O_4^-$ in the presence of an electron sink which can accept an electron from one of the reactants, allowing a fast reaction to occur between the resulting radical and the remaining ion. We have suggested that colloidal sulfur, sometimes observed to be present, sulfides and polysulfides may behave as such catalysts, and we have shown that sulfide does in fact act as a catalyst for the fast reaction (4). We regard it as probable that any sufficiently powerful electron acceptor will perform this role, and equally probable that any reaction which removes such electron acceptors from solution will retard the rate of the fast reaction. This explains, to a first approximation, the nature of the catalyst.

Electrophilic Additions to Ethylidenenorbornene and Vinylnorbornene

T. C. SHIELDS

Union Carbide Corporation, Chemicals and Plastics, Research and Development Department, South Charleston, West Virginia 25303

Received October 5, 1970

Electrophilic and free radical additions to 5-ethylidenebicyclo[2.2.1]hept-2-ene and 5-vinylbicyclo-[2.2.1]hept-2-ene have been carried out with peracetic acid, hydrogen chloride, and methanol. In contrast to chlorosulfonyl isocyanate, peracetic acid primarily attacks the exocyclic double bond in 5-ethylidene-bicyclo[2.2.1]hept-2-ene. Several other electrophilic additions are discussed which demonstrate the unpredictable reactivity of the norbornyl system.

Des additions électrophiles et radicaliques de l'acide peracétique, de l'acide chlorhydrique, et du méthanol ont été faites sur l'éthylidène-5 bicyclo[2.2.1]heptène-2 et sur le vinyl-5 bicyclo[2.2.1]heptène-2. La réaction de l'acide peracétique qui attaque principalement la double liaison exocyclique de l'éthylidène-5 bicyclo[2.2.1]heptène-2 contraste avec celle de l'isocyanate de chlorosulfonyle. Plusieurs autres additions électrophiles qui démontrent la réactivité imprévisible du système norbonyle sont discutées.

Canadian Journal of Chemistry, 49, 1142 (1971)

Additions to norbornenyl olefins have resulted in some unusual rearrangements; the homoconjugated molecule 5-ethylidenebicyclo[2.2.1]hept-2-ene (1) (also called ethylidenenorbornene or EN) however has received relatively little attention. Recent work by Moriconi reports the puzzling fact that chlorosulfonyl isocyanate (CSI) adds exclusively to the norbornenyl ring double bond in dicyclopentadiene (2) and exclusively to the exocyclic double bond in EN (3). This impels us to report our findings with electrophilic additions to norbornenes.

In contrast to the behavior with CSI, peracetic acid treatment of EN results in products of epoxidation (83% yield) of both the ring double bond, **1**, and the exocyclic double bond, **2**, in a 1:6 ratio, respectively (Scheme 1). The *bis* epoxide **3** could be prepared with persistent peracid exposure.

Hydrochlorination of VN requires stannic chloride catalysis. Sodium–ammonia reduction of the products obtained afforded only the anticipated vinylnorbornane. An n.m.r. examination of the mixed hydrochlorides conforms with that of a mixture of *exo*-2-chloro-5 (and -6) vinylbicyclo[2.2.1]heptane (**4**). Three products arise from the reduction of EN hydrochlorides, 1-ethyltricyclo[2.2.1.$0^{2,6}$]heptane (**5**), *endo*-5-ethylbicyclo[2.2.1]hept-2-ene (**6**), and 2-ethylidenebicyclo[2.2.1]heptane (**7**) in a ratio of 3:4:13, respectively.

Three main products arise from hydrochlorination of EN (Scheme 2). Only one, the major product, which was retained longest by g.l.c., was isolated and characterized. Its n.m.r. spectrum agrees with the structure of *exo*-2-chloro-6-ethylidenebicyclo[2.2.1]heptane (**8**). On the basis of their hydrocarbon derivatives the other products are presumed to be *exo*-5-chloro-2-ethyltricyclo[2.2.1.$0^{2,6}$]heptane (**9**) and *exo*-2-chloro-2-ethylbicyclo[2.2.1]hept-5-ene (10); no dichlorides were found. In another experiment using chloroform as solvent the amount of **8** increased to over 80% of the mixture. The predominance of **8** is surprising in light of the earlier findings of Schleyer and O'Connor (4) with hydrochlorination of 5-methylenebicyclo[2.2.1]hept-2-ene in ether in which the tertiary chloride predominated.

Sulfuric acid catalyzed methanolations were then carried out on EN and VN as well as dicyclopentadiene (5). The products generated were identified easily by n.m.r. and are shown in Scheme 3.

The nortricyclene (**12**) is observed as the main methanolation product from EN. No tertiary ether was isolated; this may be caused by the fact that a second methanolation is possible on the remaining norbornenyl ring double bond of the methoxy analog of **10**. A very small amount of high boiling material (~5%), possible dimethoxy products, were observed by g.l.c.

In order to examine the free radical chlorination of EN and VN, treatment with *t*-butylhypochlorite was employed along with irradiation in a paraffin solvent (Scheme 4). The g.l.c. examination of the mixture from VN indicated a complex mixture of at least seven components.

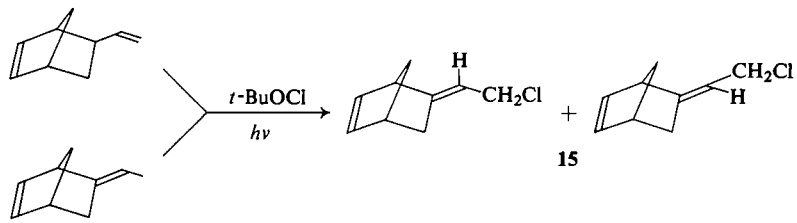
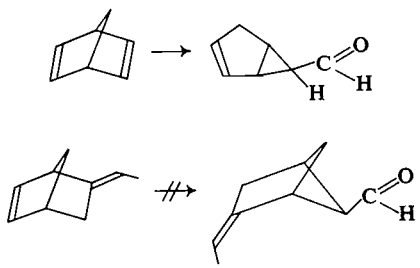


SCHEME 4

One component of shorter retention time was isolated by preparative g.l.c. It possesses an n.m.r. spectrum with a narrow multiplet at δ 6.10 (2H, norbornyl olefinic), a multiplet at 5.45 (1H, ethylidene olefinic), a pair of doublets (J = 7.8 Hz) at 4.10 and 3.92 (2H, chlorine geminal), and a complex pattern between 3.60 and 1.10 (6H, alkyl). The ratio of the doublets was variable with different experiments and varied with examination of different distillation crops. These data suggest a mixture of *cis*- and *trans*-2(2′-chloro)ethylidenetricyclo[2.2.1]hept-5-ene (**15**).

The unpredictability of electrophilic additions to norbornyl systems is readily apprehended here. One might expect epoxidation of EN to result in 2-ethylidene-5-formylbicyclo[2.1.1]hexane from a rearrangement analogous to that observed by Meinwald *et al.* (6) with norbornadiene. Instead expoxidation takes place in the normal manner but not exclusively on one double bond.



As previously noted CSI adds exclusively to the exocyclic double bond in EN (2) and the norbornenyl ring double bond in dicyclopentadiene (1). In the case of CSI, mechanistic changes can range from the concerted ($\pi^2s + \pi^2a$) to stepwise electrophilic. In addition dichlorocarbene (a generally accepted electrophilic reagent) adds to the five-membered ring double bond in dicyclopentadiene (7).

The secondary chloride **8** is the main product from EN hydrochlorination; on the other hand treatment of 5-methylene-2-norbornene by hydrochloric acid in ether prepares the tertiary chloride as the main product (4). In contrast to this, methanolation of EN in strong acid results mainly in the nortricyclyl ether **12**. It should also be mentioned that hydrochlorination of EN is quite rapid and spontaneous, presumably because of homoconjugation; however norbornadiene, also homoconjugated, undergoes hydrochlorination far more slowly.[1]

On the basis of these observations one can only say that these electrophilic additions are quite sensitive to reaction environment and subtle changes in substrate; until such time as a consistent, systematic clarification of these phenomena appears, hasty mechanistic supposition in this area should probably be avoided.

Experimental

Materials

Peracetic acid (25% in ethyl acetate), EN (UCC Plant Grade), VN (UCC Plant Grade), hydrogen chloride (Matheson Company CP. 99%), stannic chloride (analyzed reagent), sodium metal, redistilled ammonia, and freshly prepared *t*-butyl hypochlorite were used in the following experiments.

Procedure

General

Boiling points are uncorrected and distillations were performed on a short path column under non-equilibrium conditions. The n.m.r. spectra were taken in CCl_4 unless otherwise noted. Products were quenched with ice water, extracted with pentane, and dried over anhydrous sodium sulfate. Vacuum fractional distillation was employed and the products were isolated on an 8′ silicone gum rubber 10% SE 30 60-80S column between 110–150°. Unless otherwise noted all reactions were carried out in a mechanically stirred, three-neck, round-bottom pyrex flask equipped with nitrogen purge and reflux condenser.

Epoxidations

The EN (50.0 g, 0.417 mol) was dissolved in 100 ml pentane. Peracetic acid (80.2 g, 0.334 mol) was added dropwise at 0° for 3.5 h. The mixture was stirred 1 h longer, quenched, made alkaline with aqueous KOH, and extracted with pentane. Vacuum fractional distillation afforded two cuts; cut A (30–31°/0.8 mm) 34.4 g

[1]Unpublished results.

and cut B (33°/0.8 mm) 3.5 g, total yield 37.9 g, 0.278 mol, 83% based on peracid. Isolation of the main constituent, 2,2-methyloxirane-bicyclo[2.2.1]hept-5-ene (**2**) of cut A was accomplished by preparative g.l.c.: n.m.r. δ 6.18 (m, 2H, olefinic), 2.90 (q superimposed on a m, $J = 4.3$ Hz, 2H), a complex pattern 2.50–1.30 [containing prominences 2.20 (1H), 1.80 (2H), 1.43 (2H)], and 1.15 (d, $J = 4.30$, 3H, methyl). The i.r. bands appear at 3060, 1265, and 910 cm^{-1}.

Anal. Calcd. for $C_9H_{12}O$: C, 79.36; H, 8.88. Found: C, 79.42; H, 8.57.

The n.m.r. spectrum of cut B shows it contains a 50:50 mixture of epoxides **1** and **2**. This is revealed by the appearance of characteristic olefin patterns at 6.2 (norbornenyl) and 5.3 (ethylidene) in a 2:1 ratio. By the relationships of integrated areas of the two types of olefinic protons in **1** and **2** appearing in cuts A and B a product ratio of 14% **1** and 86% **2** was calculated.

The EN (75.0 g, 0.625 mol) was dissolved in 100 ml pentane at 25° and 75 g peracetic acid added over a period of 1.5 h. The pentane mixture was washed with ice water and made alkaline with a second wash of aqueous base before reintroduction into the reaction flask. Peracetic acid (125 g) was added over a period of 3 h at 45°. After quenching and washing with aqueous base, vacuum fractional distillation afforded cut A (45–56°/0.5–0.3 mm) 12.1 g containing 31% epoxides and 37% *bis*-epoxide and cut B (68°/0.3 mm) 39.7 g *bis*-epoxide. Yields based on EN, 46.4%, *bis*-epoxide, 4.4% epoxides.

Anal. Calcd. for $C_9H_{12}O_2$: C, 71.03; H, 7.95. Found: C, 71.34; H, 8.18.

Hydrochlorinations

The EN (48.0 g, 0.40 mol) was exposed to a stream of hydrogen chloride gas at 25° for 1 h. The product was washed with aqueous base and extracted with pentane. Vacuum fractional distillation afforded a mixture (42°/1.5 mm) consisting of 14% (7.6 g) *exo*-5-chloro-2-ethyltricyclo[2.2.1.$0^{2,6}$]heptane (**9**), 22% (14.1 g) *exo*-2-chloro-2-ethylbicyclo[2.2.1]hept-5-ene (**10**) and 64% (34.9 g) *exo*-2-chloro-6-ethylidenebicyclo[2.2.1]heptane (**8**). Isolation of **8** was accomplished by preparative g.l.c.: n.m.r. δ 5.40 (m, 1H, olefinic), 3.80 (m, 1H, chlorine geminal), 3.20–1.10 (complex pattern 11H, alkyl).

Anal. Calcd. for $C_{10}H_{13}Cl$: C, 69.02; H, 8.31; Cl, 22.67. Found: C, 69.20; H, 8.49; Cl, 22.41.

In a separate reaction employing the same procedure except that 8.0 g EN in 70 ml chloroform was exposed to HCl gas for 2 h, the product ratio changed to 8.5% **9**, 10% **10**, and 81.5% **8**.

Stannic chloride (0.25 ml) was dissolved in VN (38.4 g, 0.32 mol) and hydrogen chloride gas bubbled into the mixture for 10 min. The product was washed with aqueous base and extracted with pentane. Vacuum distillation (37°/1.0 mm) afforded 16.1 g (0.10 mol) of *exo*-2-chloro-5 (and -6) -vinylbicyclo[2.2.1]heptane (**4**): n.m.r. δ 6.20–4.70 (m, 3H, characteristic vinyl pattern), 3.80 (m, 1H, chlorine geminal), 2.60–0.70 (m, 9H, alkyl).

Anal. Calcd. for $C_9H_{13}Cl$: C, 69.02; H, 8.31; Cl, 22.67. Found: C, 69.31; H, 8.13; Cl, 22.53.

Metal–Ammonia Reductions

A mixture of 25.4 g (0.163 mol) EN hydrochlorides was mixed with 20 ml pentane and added dropwise to a solution of 9.0 g sodium in liquid ammonia (177 g). After quenching the mixture excess sodium with NH_4Cl, adding water and extracting with pentane, vacuum fractional distillation (34°/2 mm) of the extract resulted in 18.5 g (0.152 mol, 93% yield) of a mixture of 3 hydrocarbons **4**, **5**, and **6**, in a ratio of 3:4:13 which were all isolated by preparative g.l.c. They were identified as 1-ethyltricyclo[2.2.1.$0^{2,6}$]heptane (**5**): n.m.r. δ 2.10–0.70 complex pattern with prominences at 1.93, 1.26, 1.10, and 0.85, *endo*-5-ethylbicyclo[2.2.1]hept-2-ene (**6**): n.m.r. δ 6.00 (m, 2H, olefinic), 2.75 (m, 2H, norbornyl bridgehead), 2.10–0.40 (m, 10H, alkyl), and 2-ethylidenebicyclo[2.2.1]heptane (**7**): n.m.r. δ 5.20 (m, 1H, olefinic), 2.60 and 2.45 (m, 2H, norbornyl bridgehead), 2.15–1.0 (m, 11H, alkyl). Elemental analysis was performed on the mixed hydrocarbons.

Anal. Calcd. for C_9H_{14}: C, 88.46; H, 11 56. Found: C, 88.38; H, 11.34.

Similar treatment of VN hydrochlorides (18.0 g, 0.115 mol) rendered 12.1 g (0.10 mol, 89% yield) of one hydrocarbon product which possesses an n.m.r. superimposable on that of 2-vinylbicyclo[2.2.1]heptane.

Methanolations

Hydrocarbon (9.0 g) was dissolved in 50 ml methanol and stirred at 5° while 50 ml 96% sulfuric acid was added from a buret over a period of 20 min. The material was stirred 20 min longer, quenched, and neutralized with aqueous KOH. Pentane extraction and distillation resulted in the following.

(*a*) From EN two major products (**11** and **12**) (31°/3 mm) arise which were isolated by preparative g.l.c., 5-ethylidene-2-methoxybicyclo[2.2.1]heptane (**11**) (2.26 g, 0.015 mol, 20% yield): n.m.r. δ 5.30 (m, 1H, olefinic), 3.20 (s on m, 4H, oxygen geminal, 2.80–0.80 (m, 11H, alkyl) and 2-ethyl-5-methoxytricyclo[2.2.1.$0^{2,6}$]heptane (**12**) (3.24 g, 0.021 mol, 29% yield): n.m.r. δ 3.37 (m, 1H, oxygen geminal), 3.20 (s, 3H, methoxy), 2.00–0.70 (m, 13H, alkyl with prominences at 1.90, 1.65, 1.20, 0.98, and 0.88). Elemental analysis was performed on the mixture.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.14; H, 10.59. Found: C, 78.30; H, 10.48.

Two products of longer g.l.c. retention time comprising ~5% of the total product were not identified.

(*b*) Treatment of VN rendered upon distillation (29–30°/3.0 mm) 5.5 g, 0.036 mol, 49% yield, of 2-methoxy-5 (and -6) -vinylbicyclo[2.2.1]heptane (**13**); n.m.r. δ 5.90–4.70 (m, 3H, characteristic vinyl pattern), 3.21 (s on m, 4H, oxygen geminal), 2.40–0.80 (m, 9H, alkyl).

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.14; H, 10.59. Found: C, 78.07; H, 10.43.

(*c*) Treatment of dicyclopentadiene afforded (48°/1.3 mm) 5.15 (0.031 mol, 46% yield) of *exo*-9-methoxy-*exo*-tricyclo[5.2.1.$0^{2,6}$]dec-3 (and -4) ene (**14**): n.m.r. δ 5.54 (m, 2H, olefin), 3.19 (s on m, 4H, oxygen geminal), 2.60–1.10 (m, 10H, alkyl). Material has the odor of anise (5).

Anal. Calcd. for $C_{11}H_{16}O$: C, 80.46; H, 9.83. Found: C, 80.26; H, 9.61.

Reaction with t-Butylhypochlorite

The VN (50.0 g, 0.417 mol) in 100 ml pentane was magnetically stirred and the dropwise addition of 21.5 g (0.2 mol) of *t*-butylhypochlorite was carried out over a period of 2 h with a 100 W tungsten lamp irradiating the mixture. Distillation afforded 9.2 g of mixed products. EN (50.0 g, 0.417 mol) treated in a like manner for

2.33 h resulted in 34.9 g of mixed products. Both reaction mixtures contained one product, **15**, in less than 15% yield. Isolation of **15** by preparative g.l.c. was performed. Its n.m.r. spectrum (see Discussion) suggested it to be a mixture of *cis*- and *trans*- 2(2′-chloro)ethylidenebicyclo-[2.2.1]hept-5-ene (**15**).

The ^{19}F and ^{1}H Nuclear Magnetic Resonance Spectra of 2-Thienylcarbonyl Fluoride and 2-Thiazolylcarbonyl Fluoride

KJELD SCHAUMBURG
Chemical Laboratory V, H. C. Ørsted Institute, DK-2100 Copenhagen Ø, Denmark

Received April 21, 1970[1]

The preparation of 2-thienylcarbonyl and 2-thiazolylcarbonyl fluorides from the corresponding carboxylic acids is described. The n.m.r. spectroscopic parameters are determined and compared with experimental data for similar systems. Theoretical values for the coupling constants have been obtained in the CNDO/2 approximation and they are compared with the experimental data.

Les fluorures des acides thiophènecarboxylique-2 et thiazolecarboxylique-2 ont été préparés à partir des acides correspondants. Les paramètres spectroscopiques (r.m.n.) sont déterminés et comparés avec des valeurs expérimentales trouvées pour des systèmes similaires. Les valeurs théoriques des constantes de couplage obtenues en utilisant l'approximation CNDO/2 sont comparées avec les données expérimentales.

Canadian Journal of Chemistry **49**, 1146 (1971)

Introduction

In a growing number of publications, long-range coupling constants in substituted aromatic aldehydes have been cited (1). The carbonyl fluorides constitute a series of molecules with structures closely related to the aldehydes. Recently a correlation between long-range H–H and H–F coupling constants in benzaldehyde and benzoyl fluoride was reported (2). It is our primary aim to investigate if this can be extended to other aromatic systems.

In most cases long-range coupling constants in the aromatic aldehydes have been interpreted in terms of σ–π polarization assuming the σ-contribution to be negligible.

In our calculation of coupling constants we have used the CNDO/2 approximation (3, 4) which only permits calculation of the σ-contribution to the coupling constants. This was done in order to perform calculations of sulfur containing heterocycles on the same level of approximation as for the oxygen and nitrogen containing rings. The present version of the CNDO/2 approximation includes coulomb integrals between occupied and vacant orbitals. Hereby the major part of the correction to the coupling constants obtained by configuration interaction is included. For small molecules of known geometry the coupling constants obtained in this type of CNDO/2 calculation are in better agreement with experimental data than results from simple CNDO/2 calculation. On this basis we have found it of interest to apply the method to the calculation of coupling constants in aromatic carbonyl fluorides.

Experimental Methods and Results

2-Thienylcarbonyl fluoride was prepared according to the method of Yarowenko and Raksha (5) from the corresponding acid. Diethylenglycoldiethylether was used as solvent in the preparation. The yield was approximately 70%. The carbonyl fluoride was distilled into an n.m.r. tube containing diethylenglycoldiethylether as solvent

(10% v/v). The TMS and $CFCl_3$ were added as internal standard and the tube sealed in vacuum.

2-Thiazolylcarbonyl fluoride was prepared according to the same procedure from 2-thiazolecarboxylic acid.

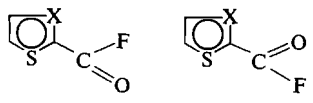
Spectra were recorded on a Varian HA-100 spectrometer at 32° using expanded sweep (6). Chemical shift and coupling constants were obtained using the LAOCOON iterative procedure on all lines observed. The experimental data are listed in Table 1.

The relative signs of the coupling constants were obtained from tickling experiments for 2-thienylcarbonyl fluoride. The three H–H coupling constants were found to have the same sign (positive) (7).

The long-range H–F coupling constants $J_{F,H(4)}$ and $J_{F,H(5)}$ were shown to have the same sign, which, in accordance with calculation, is taken to be positive. The coupling constant $J_{F,H(3)}$ is less than 0.2 Hz. The structure of the observed ^{19}F spectrum was in agreement with the data obtained from the ^1H spectrum.

For thiazolylcarbonyl fluoride, homonuclear INDOR (8) experiments showed the two long-range H–F coupling constants to be of the same sign. In accordance with the calculations they are taken to be positive. The ^{19}F spectrum was in agreement with the parameters obtained from the ^1H spectrum.

To carry out the CNDO/2 calculations the geometries of the molecules are required. In the carbonyl fluorides, as in the corresponding aldehydes, two planar conformations **1** and **2** exist.



1 **2**

X = CH, N

The geometry of 2-thienylcarbonyl fluoride is unknown. However, it was assumed that it can be composed of the unperturbed thiophene ring (9) and the CCOF fragment of acetylfluoride (10). Similarly, the geometry of 2-thiazolylcarbonyl fluoride was assumed to be composed of CCOF fragment (10) and the unperturbed thiazole ring (11). In the calculation an sp basis set was used. The resulting coupling constants are listed in Table 2. The calculations yielded the total molecular energy for each conformation. For 2-thienylcarbonyl fluoride **2** is stable by 565 cal/mol relative to **1** whilst for 2-thiazolylcarbonyl fluoride, **1** was found to be stable by 188 cal/mol relative to **2**. To obtain the weighted mean coupling constant (see Table 2) which can be compared to the experimental data these energy differences were used.

Discussion

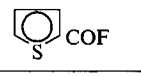
The H–H coupling constants observed in the two carbonyl fluorides are close to the data observed for the corresponding aldehydes given in Table 1. The long-range H–F coupling constants decrease in the order $J_{F,H(5)} > J_{F,H(4)} > J_{F,H(3)}$ in both compounds. The $J_{F,H(5)}$ coupling constant representing the coupling via sulfur is almost unchanged going from thiophene to thiazole. The $J_{F,H(4)}$ constant is reduced to about one-third going from thiophene to thiazole reflecting a coupling path involving the nitrogen atom.

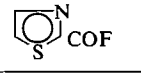
In accordance with the results obtained for benzaldehyde and benzoylfluoride (2) we should expect the same sign for long-range coupling constants in aldehydes and carbonyl fluorides, the magnitude of the H–F coupling constants being two to six times the value of the H–H coupling constants. For 2-thiophenealdehyde only $J_{CHO,H(5)}$ has been reported (12) and the sign is not known. From data obtained for 3 bromo-2-thiophenealdehyde (13) $J_{CHO,H(5)}$ can be assumed to be positive. The ratio between $J_{H,F}$ and $J_{H,H}$ is within the range mentioned above. For thiazole again $J_{CHO,H(5)}$ has been observed (14) while $J_{CHO,H(4)}$ is very small. The results parallel the data observed for the carbonyl fluoride, and the ratio $J_{H,F}/J_{H,H}$ is again within the range given above.

The theoretical calculation of coupling constants yields results which are significantly different for the two configurations **1** and **2** and the weighted mean values are in considerably better agreement with experiment than any single conformation.

The $^3J_{H,H}$ coupling constants are relatively insensitive to conformational changes between **1** and **2** and the values are of the right order of magnitude. The $^4J_{H,H}$ constant is calculated much larger than the experimental value. This is a

TABLE 2. The CNDO/2 calculation of coupling constants in thiophene- and thiazole-2-carbonyl fluorides. The mean value is obtained assuming a Boltzmann distribution between two planar conformations for which energies are calculated in the CNDO/2 approximation



Constant (p.p.m.)	**1**	**2**	Mean value	**1**	**2**	Mean value
$J_{3,4}$	1.983	3.500	+3.090	—	—	—
$J_{3,5}$	1.397	3.173	+2.693	—	—	—
$J_{4,5}$	3.078	2.847	+2.909	1.932	2.274	+2.076
$J_{3,F}$	0.158	−3.602	−2.586	—	—	—
$J_{4,F}$	3.050	−0.245	+0.645	2.570	0.799	+1.827
$J_{5,F}$	0.006	2.034	+1.485	0.618	4.427	+2.217

general feature observed in all the heterocycles studied (15).

The $J_{F,H(5)}$ and $J_{F,H(4)}$ coupling constants are calculated to be positive in both thienyl- and thiazolylcarbonyl fluorides and the relation $J_{F,H(5)} > J_{F,H(4)}$ is found for both systems in accordance with experiment. The $J_{F,H(3)}$ constant is calculated to be negative in thiophene. The very small value observed for this coupling constant does not permit a definite sign determination.

When the CNDO/2 data presented are judged it should be emphasized that for planar aromatic systems we have essentially calculated the σ-contribution to the long-range coupling constants. The procedure used does not allow for a σ–π polarization as used in the rationalization of the coupling constant for aromatic aldehydes (1). Since both mechanisms undoubtedly are of importance our data present only one of the two contributions. The present data demonstrate that a semiquantitative agreement can be obtained from the σ-contribution only.

In the present study considerable interest was focused on the possibility of freezing out the conformations **1** and/or **2** for the carbonyl fluorides thus establishing a more direct correlation between experimental and calculated data. However, the reactivity of carbonyl fluorides restricts the possible choice of solvents considerably. The 2-thienylcarbonyl fluoride sample investigated here shows a considerable broadening of the ^{19}F signal already at 0° C and at −40° the signal was about 100 Hz broad. At lower temperature no suitable solvent has been found.

The author expresses his gratitude to Northern Europe University Computing Centre for computational facilities, and to Dr. H. J. Jakobsen for helpful discussions.

Received October 23, 1970

Reactions between niobium(V), tantalum(V), and protactinium(V) chlorides and bromides and sodium *N,N*-diethyldithiocarbamate (Nadtc) have been examined in non-aqueous, non-oxygenated organic solvents. Complexes obtained are of the types $Mdtc_4X$, $Mdtc_3X_2$, $Mdtc_3S$, $Mdtc_2X_3$, and $Mdtc_2X_3.nC_6H_6$ (n = 0.7–1.0); not all complexes have been isolated for each metal. Within each group the niobium(V) and tantalum(V) complexes are isostructural; possible structures are discussed in the light of results from infrared (i.r.) and nuclear magnetic resonance (n.m.r.) spectra, molecular weight, and electrical conductivity measurements.

Des réactions entre, d'une part des chlorides (et bromures) de niobium(V), de tantale(V) et de protactinium(V) et d'autre part de *N,N*-diethydithiocarbamate de sodium (Nadtc) ont été examinées dans des solvants non-aqueux et ne contenant pas d'oxygène. Des complexes des types $Mdtc_4X$, $Mdtc_3X_2$, $Mdtc_3S$, $Mdtc_2X_3$ et $Mdtc_2X_3.nC_6H_6$ (n = 0.7 à 1.0) ont été obtenus; tous les complexes n'ont pas été isolés pour chaque métal. A l'intérieur de chaque groupe, les complexes du niobium(V) et du tantale(V) sont isostructuraux; les structures possibles sont discutées à la lumière des spectres i.r. et r.m.n., des masses moléculaires et des conductivités électriques mesurés.

Canadian Journal of Chemistry, 49, 1151 (1971)

Introduction

As part of our studies (1) on reactions between sodium *N,N*-diethyldithiocarbamate (Nadtc) and anhydrous metal halides in non-aqueous solvents, we have studied reactions (which have been the subject of a preliminary communication (2)), involving the niobium(V), tantalum(V), and protactinium(V) halides. Almost all of the work on dithiocarbamate complexes of these elements has been reported only recently (3). For example, it has been shown (4) that carbon disulfide can be inserted into the niobium(V) and tantalum(V) pentamides forming, in the latter case $Tadtc_5$ (dimethyl derivative) while the niobium(V) pentamide is reduced, $Nbdtc_4$ being the final product. The reduction is thought to occur because of the steric strain imposed on an intermediate complex, $Nbdtc_5$, which liberates a dithiocarbamate radical; the latter subsequently forms tetramethyl thiuram disulfide. This is one of the relatively rare examples of a major difference in the chemistry of niobium and tantalum. The complex $Tadtc_5$ has also been reported (5) to form in the reaction between stoichiometric quantities of tantalum(V) chloride and Nadtc in acetonitrile solution. The compound $Nbdtc_4$ is also formed (5, 6) from reactions of Nadtc with niobium(IV) chloride, while with niobium(V) bromide the product (6) is the more complex species $Nb_2Br_3dtc_5$. Salts of disubstituted dithiocarbamates also react (7) with niobium(V) and tantalum(V) halides in alcohol solutions producing monomeric compounds of the type $Mdtc_2(OR)_2X$ (X = Cl, Br).

It was noted (8), in work concerning the actinide(IV)–dithiocarbamate complexes, that protactinium(V) chloride reacts with Nadtc in both ethanol and methylene chloride solutions, but the metal(V) complexes were not identified.

Reaction conditions, particularly regarding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

the choice of organic solvent, are extremely important in determining the nature of the products from reactions between Nadtc and high valent metal halides. The latter readily react with alcohols, and we have recently shown (9) that Nadtc reacts with several non-oxygenated solvents including methylene chloride, acetonitrile, and chloroform. This paper reports in detail the results of studies between the above mentioned halides and Nadtc in both methylene chloride and benzene.

Results and Discussion

Reactions between niobium(V) and tantalum(V) chlorides and bromides and Nadtc, have been examined in both methylene chloride and benzene solutions under dry, oxygen-free conditions. The protactinium(V) chlorides and bromides have been investigated only in methylene chloride solution using 1:5 stoichiometries.

In this latter solvent all the reactions are vigorously exothermic and produce the organic product dtc_2CH_2 (9) in addition to the desired metal complexes. This organic species is formed in negligible yields from the reaction between Nadtc and methylene chloride at room temperature even after prolonged standing but yields increase to over 90% when the mixture is refluxed. The strongly exothermic nature of the MX_5–Nadtc reactions in methylene chloride (sufficient to boil the solutions in some cases) means that yields of the organic product of up to 40% can occur, thus contaminating the metal complexes. When making up a reaction mixture of a given stoichiometry, the amount of Nadtc is therefore correspondingly increased to compensate for the formation of the organic material. Production of this species can be eliminated by carrying out reactions between the metal halides and Nadtc in benzene although the mixtures must be heated under reflux to obtain an appreciable reaction rate. However, these reactions result in the formation of additional species not observed in the reactions carried out in methylene chloride. Thus the nature and number of products is dependent on the stoichiometry of the reacting species, the solvent, and the temperature. The complexes which have been isolated are listed below: $Mdtc_4X$, M = Nb, Ta, Pa; X = Cl, Br; $Mdtc_3X_2$, M = Nb, X = Cl (X = Br in trace amounts); $Mdtc_3S$, M = Nb, Ta; $Mdtc_2X_3$ and $Mdtc_2X_3.nC_6H_6$, M = Nb, Ta; X = Cl, Br; n = 0.7–1.0.

It is significant to note that the complexes $Mdtc_5$ have not been observed in this work, although $Tadtc_5$ is reported to be produced (5) when the reaction between $TaCl_5$ and Nadtc in 1 to 5 stoichiometry is carried out in acetonitrile. Also, in all reactions between NbX_5 and Nadtc in benzene, the deep violet complex $Nbdtc_4$ is produced in yields up to 50%, consistent with the previous observation (4) that Nb(V) is reduced in the presence of dithiocarbamate.

Figures 1 and 2 summarize the results of the MX_5–Nadtc reactions (M = Nb, Ta, X = Cl, Br) with the differences in the behavior of $TaCl_5$ noted in Fig. 2. These figures illustrate how the various complexes, $Mdtc_4X$, $Mdtc_2X_3$, and $Mdtc_2X_3.(0.7–1.0\ C_6H_6)$ are formed and interconverted. $Nbdtc_3Cl_2$ is the only example of a compound of this particular stoichiometry isolated in a pure state, and is formed only in the reaction between $NbCl_5$ and Nadtc (1:3 ratio) in benzene. In the corresponding reaction involving $NbBr_5$, trace amounts of $Nbdtc_3Br_2$ have been observed (X-ray powder patterns), but this complex has not been isolated in a pure state. It is likely that excessive production of $Nbdtc_4$ ($\sim$ 60%) from the $NbBr_5$ reaction (compared to $\sim$ 20% from the $NbCl_5$ reaction) is seriously upsetting the Nb(V) to Nadtc stoichiometry and inhibiting the formation of the tris(dithiocarbamato) complex.

All these complexes, including the $Padtc_4X$ species are air sensitive, but are stable in anhydrous oxygen-free media. They are soluble in ethanol, but further reactions occur, possibly resulting in the formation of alkoxide species. For example, pale yellow solids isolated from solutions of $Padtc_4Cl$ in ethanol show bands characteristic of ethoxy groups in the 1000–1100 cm^{-1} region of their infrared spectra. The products, which appear to contain no halide, have not been fully characterized.

The green benzene soluble $Mdtc_3S$ complexes are the only air stable complexes isolated during this work. They form only in benzene solutions when there is a ratio of MX_5 to Nadtc of at least 1:4 and are readily separated from the benzene insoluble $Mdtc_4X$ complexes which are also formed in such reactions.

Properties and Possible Structures of the Complexes

Extensive use has been made of X-ray powder diffraction photographs in the identification of

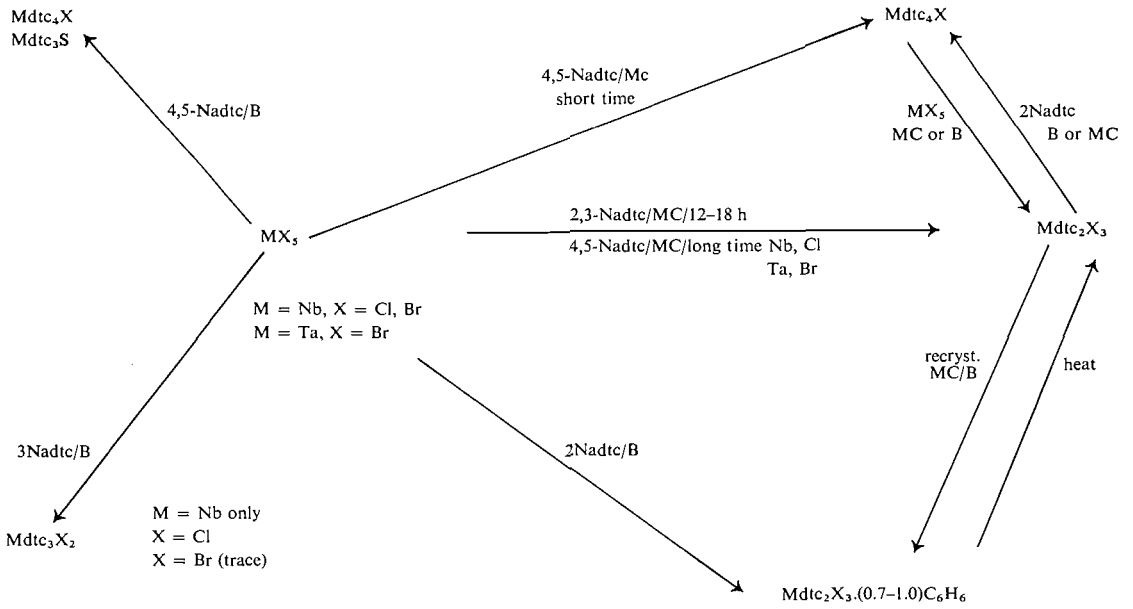

FIG. 1. Summary of reactions between $NbCl_5$, $NbBr_5$, and $TaBr_5$ and Nadtc. B = Benzene, MC = methylene chloride; all NbX_5/Nadtc/B reactions also produce $Nbdtc_4$ (not shown above), all MX_5/Nadtc/MC reactions also produce dtc_2CH_2 (not shown above).

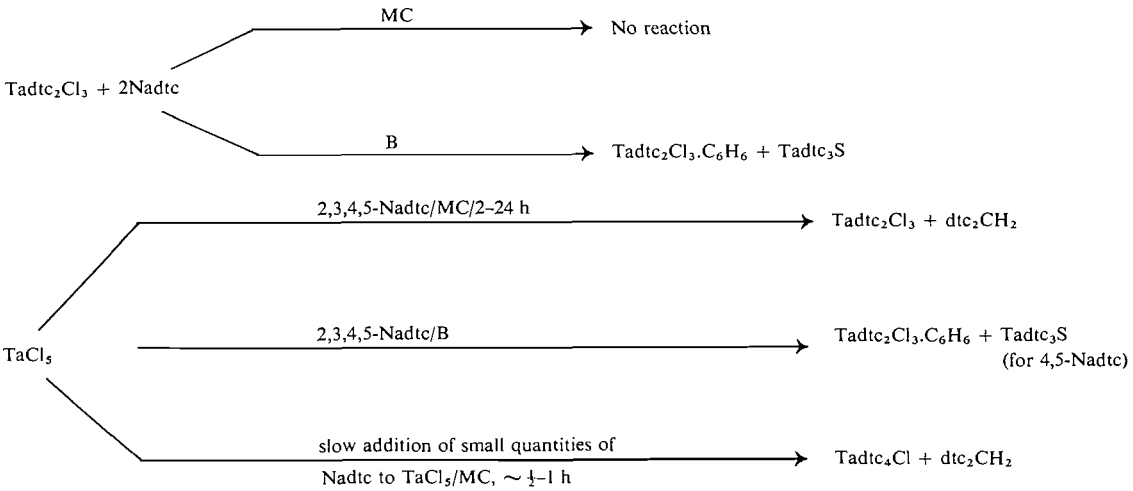

FIG. 2. Summary of major differences in behavior of $TaCl_5$.

the various products from the reactions. For niobium and tantalum the members of each group of complexes have identical powder patterns and it is therefore probable that they have a very similar orientation of ligands about the metal ion. Values of $\sin^2\theta$ for one member of each isostructural series are listed in Table 1. The protactinium compounds gave relatively poor X-ray powder diffraction patterns.

The n.m.r. spectra of concentrated methylene chloride solutions of the niobium and tantalum complexes all show a well resolved triplet in the region 8.6–8.7 τ (J = 7 Hz) and a quartet around 6.2–6.3 τ (J = 7 Hz) due to the ethyl protons, integrating in the ratio 3:2. The benzene adducts also show a singlet at 2.7 τ, with the integration indicating between 0.7 and 1.0 molecule of benzene per metal atom. The chemical shifts are

almost invariant with the compound under study.

Signals arising from inequivalent ethyl groups have not been observed in spectra recorded at 42 °C, although certain other dithiocarbamate complexes (7, 10, 11) do show such effects. In one complex, $Tadtc_3S$, the n.m.r. spectrum has been recorded down to −60 °C and although there is some slight loss of resolution and general broadening of the peaks, there is no evidence of inequivalences. We interpret these data to mean that, in solution, the complexes contain equivalently bonded dithiocarbamate groups. This does not necessarily imply that the alkyl groups are in totally equivalent positions with respect to the metal ion in the solid, indeed on the basis of recent structural data on dithiocarbamate complexes (1, 12, 13) they almost certainly are not. Different signals arising from alkyl protons having small site inequivalences may not be detected, either because of a rapid exchange mechanism (4), or because of small conformational changes within the molecules in solution.

The infrared absorption spectra of all the complexes correspond rather closely to the complex spectrum of Nadtc. Each niobium and tantalum compound in the various groups has an identical infrared spectrum except for small differences in the region of the metal–halogen stretching frequencies. The absence of a strong absorption in the 850–950 cm^{-1} region ruled out the existence of M=O species and the absence of water was immediately apparent.

While no attempt has been made to make peak assignments for all the absorptions in the highly complex spectra, some of the major bands have been assigned in Table 2. Almost all the complexes have the C···N stretching frequency (14) between 1500 and 1525 cm^{-1}, implying considerable double bond character. This must confer a substantial degree of rigidity to the dithiocarbamate structure, suggesting that free rotation about this bond is absent (15), or at least hindered. There is little change in the band positions when the spectra are recorded in solution (except for the $Mdtc_3S$ species) and this, together with the above n.m.r. data suggests that the dithiocarbamate groups are chelated to the metal by the two sulfur atoms. The C···N frequencies for the niobium and tantalum complexes are considerably higher than those of the protactinium complexes (Table 2) and than those recorded (1) for the 8-coordinated actinide(IV) and lanthanide(III) dithiocarbamate complexes $Mdtc_4$ and $Mdtc_4^-$, respectively. If the niobium and tantalum complexes $Mdtc_4X$ and $Mdtc_2X_3$ are formulated as $[Mdtc_4]^+X^-$ and $[Mdtc_4]^+[MX_6]^-$ (see later) then the positive charge on the cation would facilitate the electron movement from the NR_2 group towards the metal thus increasing the strength of the C···N bond. These formulations are further discussed below.

The $Mdtc_3S$ complexes show two C···N frequencies in the solid state, like the somewhat analogous compound $Rudtc_3NO$ (16). In solution the former complexes have only one C···N stretching frequency and equivalent dithiocar-

†Recorded in methylene chloride solution.

bamates in the n.m.r. spectrum, unlike the ruthenium compound which has both monodentate and bidentate dithiocarbamate groups. It appears, therefore, that the $Mdtc_3S$ complexes undergo a structural change when dissolved. It is possible that in the solid state the complexes $Mdtc_3S$ involve 6 coordinate metal species with two bidentate and one monodentate dithiocarbamate, and a crystal structure determination is now being carried out on $Nbdtc_3S$ in an attempt to confirm this. It is not clear what occurs when these species are dissolved, although in methylene chloride the tantalum compound is monomeric and could be seven coordinated.

The spectra of the complexes in the region of the C···S frequency are quite similar and all, apart from those of protactinium, show two bands in the 995–1015 cm^{-1} region. It is somewhat surprising that the $Mdtc_3S$ complexes do not show additional features in this region which has been mentioned as being particularly useful in providing structural information on dithiocarbamate complexes (4, 17).

The metal–sulfur vibration is assigned (Table 2) to the strong peak in the 360–370 cm^{-1} region (4). In addition, the $Mdtc_3S$ complexes have very strong bands at 483 (Ta) and 502 cm^{-1} (Nb), assigned to the M═S stretching frequencies.

In the infrared spectra of the $[Mdtc_4]^+X^-$ (M = Nb, Ta) complexes, there are no observed peaks that can be assigned to the metal–halogen stretching frequency, and this is entirely consistent with the formulation of the complexes as above. Furthermore for $[Tadtc_4]^+Cl^-$ the observed molecular weight of 424 is in good agreement with the expected value of 404 for the ionic species, compared to an expected value of 808 for a monomeric, non ionic unit $[Tadtc_4Cl]$. The complexes appear to be 1:1 electrolytes in 10^{-3} *M* solutions of both acetonitrile and methylene chloride. For example, $[Nbdtc_4]^+Br^-$ has a conductance of 120 $ohm^{-1}\,cm^2\,mol^{-1}$ in the former solvent, and $[Tadtc_4]^+Br$ has a value of 60 $ohm^{-1}\,cm^2\,mol^{-1}$ in the methylene chloride, in good agreement with other conductance data (18) in the latter solvent. In the cation the metal is probably eight coordinated by sulfur atoms from four bidentate dithiocarbamate groups (1, 12, 13).

The complexes $Padtc_4X$, X = Cl, Br, are significantly different from the above niobium and tantalum compounds. A medium intensity band at 317 cm^{-1} in the infrared spectrum of $Padtc_4Cl$ may be associated with a metal–chlorine stretching vibration. This observation contrasts with the apparent ionic nature of the protactinium(V) tropolone halides, PaT_4Cl and PaT_4Br (19). In addition these latter complexes are remarkably stable towards aqueous solution, behavior which contrasts markedly with the rapid hydrolysis of the dithiocarbamate complexes on exposure to moist air.

The infrared spectra of the $Mdtc_2X_3$ complexes are identical in the 200–650 cm^{-1} region except for the strong metal–halogen absorptions listed in Table 2. These bands are very close to those observed (20) in the complexes $[R_4N]^+[MX_6]^-$ (R = alkyl, M = Ta, Nb; X = Cl, Br).

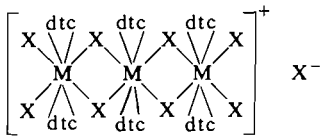
Also, the complexes $Mdtc_2X_3$ can be synthesized by reactions of the following type

$$[Tadtc_4]^+Br^- + [R_4N]^+[TaBr_6]^- \xrightarrow[18\text{ h at room temperature}]{\text{methylene chloride}} Tadtc_2Br_3 + [R_4N]^+Br^-$$

It therefore appears highly likely that the complexes are indeed of the type $[Mdtc_4]^+[MX_6]^-$. They appear to be 1:1 electrolytes in both 10^{-3} *M* solutions of acetonitrile and methylene chloride as illustrated by $Tadtc_2Cl_3$ for which the conductance is 150 $ohm^{-1}\,cm^2\,mol^{-1}$ in acetonitrile and 50 $ohm^{-1}\,cm^2\,mol^{-1}$ in methylene chloride. The molecular weights of $Mdtc_2Cl_3$ (M = Nb and Ta) in methylene chloride are 757 and 870, respectively, suggesting a formulation $[Mdtc_2Cl_3]_n$ where $n = 1.5$ or a multiple thereof. These high values may be due to the existence of ion-pairs in solution and if this is so, then as the concentration of the complexes in solution is reduced, the molecular weights should approach the values of 495 (Nb) and 583 (Ta) for the $[Mdtc_4]^+[MCl_6]^-$ species. Over the range of concentrations studied (~ 1–4×10^{-2} *M*), the values obtained are almost constant, and below about 10^{-2} *M* the sensitivity of the instrument decreases rapidly making accurate measurements impossible.

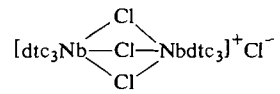
On the other hand, a possible trimeric structure, such as



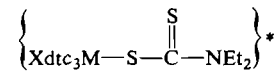
would satisfy the observed molecular weight data, but it is difficult to see how such complexes would arise from the above mentioned reactions between $[Mdtc_4]^+X^-$ and $[R_4N]^+[MX_6]^-$.

It seems unlikely that in the series $Mdtc_2X_3 \cdot nC_6H_6$ the benzene is chemically bonded to the transition metal since the infrared bands associated with benzene (Table 2) are virtually identical with those of liquid benzene. It is therefore assumed that the benzene is simply trapped in cavities in the lattice although these cavities do not appear to be large enough to accommodate molecules such as toluene or *p*-xylene.

The infrared spectrum of $Nbdtc_3Cl_2$ appears to have no peak above 200 cm^{-1} which can be assigned to an Nb—Cl stretching mode, although this does not rule out the possibility of bridging halides, the vibrations of which may be below 200 cm^{-1} (21). The complex is an electrolyte with an equivalent conductance in 10^{-3} *M* acetonitrile solution of 135 $ohm^{-1}\,cm^2\,mol^{-1}$ and the molecular weight (677) approximates to the value required for a monomer (607) or multiple thereof. A possible structure therefore would be



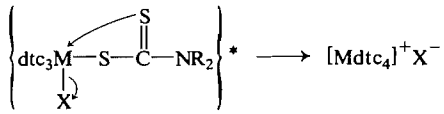
It is interesting to speculate on the mechanism of formulation of the $Mdtc_3S$ complexes, since the formation of these clearly involve decomposition of the dithiocarbamate ligand. Since the $[Mdtc_4]^+X^-$ complexes are the initially isolated species in the present study, it appears that the reactions involving the successive replacement of four halides by dithiocarbamate groups are fast. These replacements probably account for the observed rapid color changes in several of the reactions in methylene chloride. The existence of an activated complex



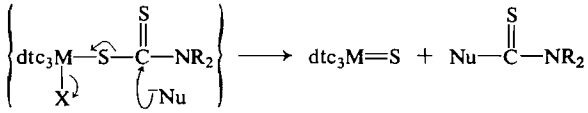
(dtc implies bidentate ligands) is postulated in an attempt to explain the formation of the $Mdtc_3S$ complexes. The presence of a monodentate ligand could arise from steric considerations (note that it has already been suggested (4) that $Nbdtc_5$ is unstable for steric reasons), although these should not be too severe in the light of the ability of the relatively small Ti^{4+} ion to accommodate eight sulfur atoms (12). However, this activated complex would be susceptible to several modes of decomposition as indicated below, although it is recognized that the reactions may be considerably more complicated.

The oils isolated in small yields from all reactions where the $Mdtc_3S$ complexes are formed could correspond to the organic fragments (or products from their further reactions) in (*b*) and (*c*). At room temperature in methylene chloride, reaction (*a*) occurs exclusively while at higher temperatures (boiling benzene) reactions (*b*) or (*c*) have significant rates and the net result is a mixture of $[Mdtc_4]^+X^-$, $Mdtc_3S$, and oils. However, it should be noted that while the isolation of $[Mdtc_4]^+X^-$ is consistent with the existence of the activated complex, the latter is not a prerequisite to the production of the former. In the

(*a*) intramolecular displacement

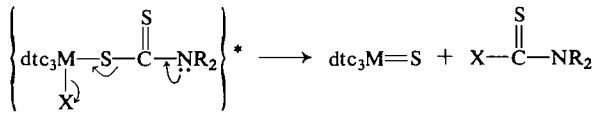


(*b*) nucleophilic attack



(Nu^- could be dtc^- or X^-)

(*c*) electron migration



room temperature reactions in methylene chloride, the initially formed $[Mdtc_4]^+X^-$ species react further with equilibrium amounts of unreacted MX_5 with the result that reactions carried out over a long period of time produce the $[Mdtc_4]^+[MX_6]^-$ complexes. In no case has the $Mdtc_3S$ species been observed in reactions (between MX_5 and Nadtc in the 1:2 or 1:3 ratios in benzene) which produce $[Mdtc_4]^+[MX_6]^-$ and the reason for this is not clear. However, it should be noted that the reaction

$$[Mdtc_4]^+[MX_6]^- + [R_4N]^+X^- \rightarrow [Mdtc_4]^+X^- + [R_4N]^+[MX_6]$$

does not occur, at least under the conditions employed for the reverse reaction. It is therefore possible that, in reactions producing $[Mdtc_4]^+$-$[MX_6]^-$, the activated complex reacts only to give $[Mdtc_4]^+$ because of some stabilizing influence of the $[MX_6]^-$ ion, and not by routes (*b*) or (*c*)

The position of the compound $Tadtc_5$ in this proposed scheme is not clear, nor indeed is it obvious why we have not observed its formation in this work. A formulation such as $[Tadtc_4]^+$-dtc^- would appear to be ruled out from i.r. and n.m.r. spectral data (4) and clearly further work is needed on this extremely interesting molecule.

Experimental

All compounds were prepared in dry nitrogen filled glove boxes with the usual precautions being taken against the radioactive hazards associated with protactinium 231.

Materials

Niobium and tantalum pentachlorides were purchased from Alfa Inorganics and the bromides were prepared by direct reaction between the appropriate elements. Protactinium pentachloride (22) and pentabromide (23) were prepared as described previously. All halides were purified by vacuum sublimation prior to use. Commercial $Nadtc.3H_2O$ was dehydrated under high vacuum (10^{-6} Torr) at 80 °C and used without further purification. All solvents were deoxygenated by flushing with nitrogen and stored over fresh molecular sieves (4A) under nitrogen. Alumina was deactivated with ethyl acetate and dried under vacuum (10^{-6} Torr); silica gel was also dried under high vacuum.

Physical Measurements

All samples were suitably protected from the atmosphere during physical measurements. Infrared studies were carried out on a Beckman I.R. 12 Infrared spectrometer with samples mounted as Nujol mulls between KBr plates, in the region 400–4000 cm^{-1}, and between polythene plates in the region 200–650 cm^{-1}. The instrument was periodically calibrated using polystyrene.

X-Ray diffraction and proton n.m.r. studies were carried out as previously described (9). Concentrated methylene chloride solutions of the compounds at 40–42 °C were used for the latter work and the methylene protons of the solvent were used as the reference peak (4.73 τ) and checked periodically using TMS.

Molar conductivities were measured on a YSI model 31 conductivity bridge at 1 kHz, at room temperature (24 °C).

Molecular weights were determined ebullioscopically using a Gallenkamp semi-micro ebulliometer. The instrument was calibrated using the organic compound dtc_2CH_2, and all samples were run in methylene chloride (10 ml).

Analyses

For the niobium and tantalum compounds, microanalyses for carbon, hydrogen, nitrogen, sulfur, and constant weight ash (M_2O_5) were carried out by F.

Pascher, Bonn, West Germany; carbon assays on the protactinium compounds were done in the Analytical Services Division, A.E.R.E. Harwell. Metals were determined gravimetrically as M_2O_5 after overnight hydrolysis of methylene chloride solutions of the complexes with concentrated ammonia, filtration and ignition. Halides were determined gravimetrically as silver salts. Results of the analyses are listed in Table 3.

Syntheses of the Complexes

(1) $Mdtc_4X$ ($M = Nb, X = Cl, Br; M = Ta, X = Br$)

(*a*) To a suspension of the metal(V) halide (~ 1.0 g) in methylene chloride (10 ml) an excess, or a 4 or 5 molar ratio of Nadtc was added slowly with constant mixing. After the reaction subsided and cooled the mixture was stoppered and allowed to stand overnight. The brightly colored methylene chloride solution was separated by centrifugation, the solvent removed under vacuum (10^{-3} Torr), and the residue washed (5–10 ml aliquots) with benzene (~ 50 ml) to remove the organic material dtc_2CH_2. The remaining solid was dissolved in the minimum amount of methylene chloride and crystals of pure $Mdtc_4X$ obtained by the slow addition of benzene or diethylether.

(*b*) The metal pentahalides (~ 1 g) and Nadtc (1:4 stoichiometry) were refluxed in benzene (30 ml) for 4 h. The benzene solution was removed by centrifugation, and the solid residue, after washing (5–10 ml aliquots) with benzene (~ 50 ml), was dissolved in methylene chloride. This solution was centrifuged, concentrated, and yielded crystals of the $Mdtc_4X$ complexes on addition of benzene or diethyl ether.

(2) $Tadtc_4Cl$

$TaCl_5$ (1 g) and methylene chloride (20 ml) were placed in a 50 ml flask equipped with a magnetic stirrer. Nadtc in small portions (30 mg) was added with rapid mixing, and the solution was allowed to cool between each addition. When no further reaction occurred, a small excess of Nadtc (150 mg) was added, the stirring stopped and the solution stoppered for 1 h. The $Tadtc_4Cl$ was isolated as in *1(a)*. This reaction is extremely sensitive to the conditions employed and $Tadtc_2Cl_3$, instead of the above complex, has been isolated in very high yields on several occasions.

(3) $Padtc_4$ X($X = Cl, Br$)

These complexes were prepared as under *1(a)* except that the products were recrystallized from benzene–ether or methylene chloride – isopentane mixtures. Each preparation involved 0.08–0.10 g of the appropriate pentahalide in 1 ml of methylene chloride.

(4) $Mdtc_2X_3$ and $Mdtc_2X_3.C_6H_6$ ($M = Nb, Ta; X = Cl, Br$)

(*a*) The procedure in *1(a)* was followed except that the stoichiometry of MX_5:Nadtc was between 1:2 and 1:3.5. The complexes $Mdtc_2X_3$ were isolated by crystallization from concentrated methylene chloride solutions using diethylether, pentane, or *p*-xylene as the precipitating solvent. Using benzene as the precipitating agent, crystals of the $Mdtc_2X_3.(0.7–1.0)C_6H_6$ complexes were obtained. The benzene can be removed by prolonged pumping (10^{-3}–10^{-6} Torr) at 50–60 °C.

The number of benzene molecules on the latter type of complex was estimated by integrations of n.m.r. signals: *i.e.* the ratio of methyl to methylene to benzene protons gave *n*, the number of moles of benzene.

Complex	Ratio of methyl to methylene to benzene	*n*
$Nbdtc_2Cl_3.nC_6H_6$	12.0:8.0:5.0	0.83
$Nbdtc_2Br_3.nC_6H_6$	12.0:8.0:4.2	0.70
$Tadtc_2Cl_3.nC_6H_6$	12.0:8.0:5.8	0.97
$Tadtc_2Br_3.nC_6H_6$	12.0:8.0:5.0	0.83

(*b*) The benzene adducts were also isolated, using the procedure outlined in *1(b)*, from reactions between MX_5 and Nadtc in 1:2 or 1:3 ratios in benzene under reflux for 4 h (except for $NbCl_5$ and Nadtc in the 1:3 ratio).

(5) $Nbdtc_3Cl_2$

The reaction between $NbCl_5$ (~ 1 g) and Nadtc (1:3 stoichiometry) in benzene under reflux for 4 h gave a deep violet solution ($Nbdtc_4$) and a dark brown insoluble residue which was separated by centrifugation and washed (5–10 ml aliquots) with benzene (50 ml). The remaining brown solid was dissolved in methylene chloride, the solution centrifuged, concentrated, and a red-brown solid precipitated by slow addition of diethylether. Final purification of the complex was achieved by chromatography on a deactivated alumina column using a 75–25 *v/v* methylene chloride – benzene mixture as the eluting solvent. The rapidly moving brown fraction was evaporated to dryness and recrystallized from methylene chloride, pure $Nbdtc_3Cl_2$ being obtained on addition of diethylether.

(6) $Mdtc_3S$ ($M = Nb, Ta$)

The crude products were obtained by concentration of, and addition of diethylether to, the benzene solutions, obtained after the reactions described in *1(b)*. The complexes were purified by chromatography on a deactivated alumina column using benzene (or a 50–50 benzene – methylene chloride mixture) as the eluting solvent. The rapidly moving green phase was collected, concentrated, and produced the $Mdtc_3S$ complexes on addition of diethylether or pentane.

(7) $Nbdtc_4$

The resulting benzene solutions from reactions *4(b)* and *5* and between NbX_5 and Nadtc with stoichiometries of less than 1:4 gave the known compound (4) $Nbdtc_4$ (satisfactory chemical analysis has been obtained). The benzene solutions from reactions *1(b)* between NbX_5 and Nadtc with ratios greater than 1:4 also contained $Nbdtc_3S$. In these cases, the solutions were chromatographed on a silica gel column using methylene chloride or a methylene chloride benzene (50–50 *v/v*) mixture as eluting solvent. The $Nbdtc_4$ was left as an immobile phase on the column while $Nbdtc_3S$ was rapidly eluted.

(8) Other Products

In all reactions involving the formation of the $Mdtc_3S$ complexes, there also occurred, in small yields, various colored oils. These were generally immiscible with benzene and were either removed from the benzene by decantation or were left on the column during subsequent purification of the sulfide complexes. They were not investigated further.

(9) Interconversion Reactions $Mdtc_4X \rightleftharpoons Mdtc_2X_3$ (M = Nb, Ta)

The complexes $Mdtc_4X$ were heated under reflux in benzene or methylene chloride for 2 h with 1:1 molar ratios of MX_5. The reactions yielded $Mdtc_2X_3.nC_6H_6$ and $Mdtc_2X_3$, respectively

$$Mdtc_4X + MX_5 \rightarrow 2Mdtc_2X_3$$

The complexes $Mdtc_2X_3$ (or the benzene adducts) reacted with Nadtc (1:2 molar ratios) in benzene under reflux or methylene chloride after 2 h to produce $Mdtc_4X$ (except M = Ta, X = Cl) together with dtc_2CH_2 from methylene chloride and $Mdtc_3S$ from benzene. These were isolated as previously described.

The methylene chloride solutions immediately after the reactions *1(a)* between MX_5 and Nadtc (1:4) contain $Mdtc_4X$ which can be isolated as described. However, when these solutions were left at room temperature for various periods of time, the $Mdtc_2X_3$ complexes were isolated. The times involved were, M = Ta, X = Cl, 1 h; M = Nb, X = Cl, 7 days; M = Ta, X = Br, 14 days; M = Nb, X = Br, no conversion observed up to 28 days.

The $Mdtc_4X$ complexes (M = Nb, Ta) reacted with $[(C_2H_5)_4N][MX_6]$, prepared as previously described (20), in 1:1 ratios at room temperature in methylene chloride solution to produce the $Mdtc_2X_3$ complexes. Reactions were usually complete within 18–24 h.

We thank the Senate Research Committee of Lakehead University, the National Research Council of Canada, and the Ontario Department of University Affairs for generous financial support of this work. We also acknowledge stimulating discussions with Dr. A. N. Hughes and Professor K. W. Bagnall.

Metastable Peak Analysis; a Method for Elucidating Fragmentation Mechanisms and Ion Structures in Mass Spectrometry. Part II.[1] Water Loss from the Molecular Ion of 1,2-Cyclohexanediol

F. BENOIT AND J. L. HOLMES
Chemistry Department, University of Ottawa, Ottawa, Canada

Received October 22, 1970

Defocussed metastable peaks have been used to elucidate the hitherto apparently complex fragmentation of the molecular ion of 1,2-cyclohexanediol. It was shown that the predominant mode of water loss from the molecular ion involved "scrambling" of six hydrogen atoms, those in the 4- and 5-methylene groups and the hydroxyl pair. A minor water elimination involves simple hydroxyl–hydroxyl interaction.

Les pics dus aux ions métastables obtenus par la technique de défocalisation ont été utilisés pour élucider la fragmentation jusqu'alors considérée complexe de l'ion moléculaire du cyclohexanediol-1,2. On a pu montrer que le mode principal d'élimination d'eau de l'ion moléculaire implique un processus selon lequel six atomes d'hydrogène (ceux des groupes méthylènes 4 et 5 ainsi que ceux des deux groupes OH) sont indiscernables. Un processus moins important d'élimination d'eau implique une interaction hydroxyle–hydroxyle.

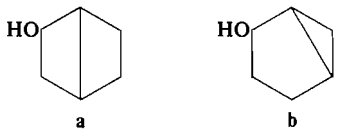
Canadian Journal of Chemistry, 49, 1161 (1971)

Introduction

The use of deuterium labeling is an established procedure to aid the determination of ion fragmentation mechanisms in mass spectrometry. It is a successful technique particularly where there is no loss of positional identity of hydrogen/deuterium atoms in the molecular or fragment ions; in such cases (for example the elucidation of the fragmentation mechanism of ethyl butyrate (1)) the results usually allow unequivocal determination of the fragmentation mechanism and also permit reasonable speculation as to ion structures. However, where hydrogen "scrambling" is involved, results are often obtained which are ambiguous or uninterpretable, solely on the basis of peak shifts or relative peak heights. An early example was the loss of both OH and OD from the molecular ion of the carboxyl deuterated derivative (2, 3) of benzoic acid. The problem was elegantly solved (2) by the use of relative heights of the *metastable peaks* for the above processes. It was concluded that the molecular ion existed in two forms, one unrearranged which only lost OD and one in which the carboxyl and the two ortho ring hydrogen atoms had become indistinguishable. Various molecular ion structures have been proposed to account for these and similar observations (2–4). Such use of the relative heights of metastable peaks in conjunction with isotopic labeling is developing as a useful tool in the investigation of hydrogen "scrambling" and ion structures (5–7). It is assumed in such experiments that the relative intensities of a group of metastable peaks arising from a particular fragmentation are directly proportional to the relative abundances of their isomeric labeled precursor ions.

In this paper we report on the use of separately defocussed metastables to yield new information about a particularly difficult problem, namely the mode of water loss in the dissociation of the molecular ion of 1,2-cyclohexanediol. The mass spectrum of this molecule and deuterium labeled analogs have been recently thoroughly investigated by Buchs (8) and by Strong and Djerassi (9). Buchs was unable to formulate a fragmentation mechanism consistent with all his results; he stated that "even though we possessed a very complete series (thirteen) of deuterated derivatives of *cis* and *trans* 1,2-cyclohexanediols we think that it would be hazardous to attempt to establish a detailed fragmentation scheme by assigning a definite structure to each ion". He did, however, conclude that water loss occurred via three mechanisms: (*i*) by interaction between the two hydroxyl groups; (*ii*) by interaction between a hydroxyl group and a hydrogen atom in the 4 or 5 position; (*iii*) without participation of the hydroxyl hydrogen atoms. Strong and Djerassi (9) likewise suggested that at least four processes (distinguishing (*ii*) above as two) were involved in

[1]Part I: J. L. Holmes, D. McGillivray, and N. S. Isaacs. Can. J. Chem. **48**, 2791 (1970).



a b

the loss of water from the molecular ion. They proposed the specific ion structures (**a**, **b**) shown below as resulting from (*ii*); and that (*i*) produced the molecular ion of cyclohexene oxide. It was suggested that (*iii*) possibly involved the intermediate formation of an aldehydic ion.

To obtain the results described below we have used a modification of Jennings' (10) method of metastable defocussing. We have scanned magnetically at a series of constant electrostatic sector voltages varied by 0.1 V intervals, such that each metastable was examined in narrow sections thus enabling virtually complete resolution of metastables which otherwise would have overlapped each other. Provided that the energy profile of the ion beam exiting the ion source is both narrow and uniform, graphical summation of the sections produces the total metastable and the results of such summations are presented in the figures described below.

Results and Discussion

Our results for loss of H_2O, HDO, and D_2O obtained by comparing fragment peak heights in the mass spectrum of *cis*-1,2-cyclohexanediol-O-d_2 (**1**) agree closely with those of Strong and Djerassi (9). We also observe that the *cis* and *trans* isomers yield identical spectra. The separated, defocussed metastable peaks for water loss from **1** and *cis*-1,2-cyclohexanediol-3,3,5,5-d_4 (**2**) were of identical shape and those for **2** are shown in Fig. 1. Their heights are in the approximate ratio 6:8:1 for loss of H_2O, HDO, and D_2O, respectively. Figure 2 shows the metastable peaks for water loss (HDO and H_2O) from *trans*-1,2-cyclohexanediol-4-d_1 (**3**); these are in the ratio 2:1 for H_2O and HDO, respectively. In our experience, such sets of metastable peaks for the loss of labeled neutral fragments have the same width at half height and thus their heights may be taken as a proper measure of their relative abundances (given an energetically homogeneous ion beam).

Although it is formally possible that the observed metastables are unrelated and/or overlapping sets, it is probable that a single process gives rise to the above-mentioned metastables and that the mechanism involves "equilibration" or loss of distinguishability of four hydrogen and

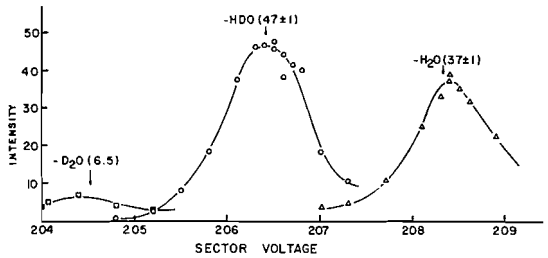


FIG. 1. Defocussed metastables for water loss from the molecular ion of *cis*-1,2-cyclohexanediol-3,3,5,5-d_4.

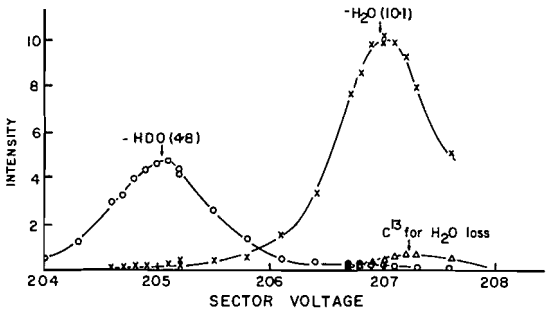

FIG. 2. Defocussed metastables for water loss from the molecular ion of *trans*-1,2-cyclohexanediol-4d_1.

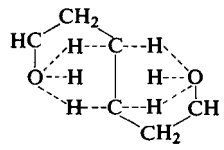
two deuterium atoms in **1** and **2** and 5 hydrogen and 1 deuterium atoms in **3**. From the previous work (8, 9), hydrogen atoms at the 4 and 5 ring positions have been shown to be involved in water loss while those in the 3 position are not. We suggest that this equilibration may take place via a symmetrical species **c** such as that shown below in which the 1–2 carbon bond is broken



c

thus allowing independent interaction of the hydroxyl groups with the 4 and 5 ring methylenes. The dotted lines are used to indicate possible and not partial bonding. In a structure such as **c**, any of the six hydrogen atoms may be bonded to either a C-4 or C-5 carbon or oxygen atom and thus have become indistinguishable. The location of the oxygen atoms is indeterminate but positioning them directly above and below the 4–5 carbon bond would allow their interaction with any of the six hydrogen atoms. Such a structural representation is compatible with the experimental observations. Since structural repre-

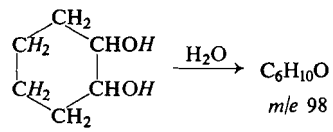
†Corrected for 12% water loss by mechanisms other than equilibrating one.

sentation of such ions must be highly speculative, we propose that in fragmentation schemes, atoms which have become indistinguishable and are randomly lost in a neutral or charged fragment be appropriately identified. As an example the present system is illustrated below. Further analysis of the metastables for dissociations of the $(M - H_2O)^+$ ion is in progress and will be reported in a future publication. This may yield more information concerning the structure of **c**.



The above results indicate that some of the water lost from the molecular ion contains randomly selected hydrogen atoms; if this were the *only* mode of water loss then the fragment ion peaks will be in the same ratio as the metastables, provided that those ions which fragment in the source with loss of water, are, *before dissociation*, as "scrambled" as those which dissociate in the first field-free region. This is not observed; for example, the relative peak heights corrected for ^{13}C natural abundance and $[M - H_2O - H]$ for water loss from **1** are in the ratio 35:49:16 for loss of H_2O, HDO, and D_2O, respectively, in good agreement with the previous work (9). If it is assumed that H_2O loss (35 units) from **1** can only occur via a "scrambling" mechanism then, on the basis of the relative heights of the metastables, 88% of the total water loss occurs via this mechanism. The residual water loss is D_2O (10 units) and it could arise from the simple hydroxyl–hydroxyl interaction noted previously (8, 9). This discrepancy is not due to partial "scrambling" in those ions giving rise to the normal spectrum because such an effect would be expected to yield an excess of (M − HDO) fragment ions. Thus 98% of the water loss can be accounted for by the above two mechanisms. Using this result and a similar calculation it should be possible also to correlate the relative peak and metastable heights for **2** and **3**. The results of the calculations are presented in Table 1. They show that when correction is made for the simple mechanism (10%), the relative peak heights are in good accord with the relative metastable heights. It should be stressed that these calculations do not allow evaluation of the relative abundances of the molecular ions which are dissociating by the two mechanistically distinguishable pathways.

Whereas previous workers needed to invoke three (8) or four (9) mechanisms adequately to

For personal use only.

account for the water loss from 1,2-cyclohexanediol, our investigation reveals that this fragmentation can better be explained by *two* mechanisms, one involving a direct interaction between hydroxyl groups, the other a complex interaction resulting in the loss of distinguishability of six hydrogen atoms (the four C-4 and C-5 methylene hydrogens and the two hydroxyl hydrogens) which are then randomly lost in the eliminated water molecule.

It is probable that other fragmentation mechanisms, hitherto presented as involving many complex parallel routes, will similarly be simplified (11, 12) and shown to involve one or several "scrambling" processes. At present the events which lead to random losses of hydrogen atoms in ion fragmentations are poorly understood but the frequent appearance of the appropriate metastable peaks indicates that the necessary rearrangements require an appreciable time to take place. It is still uncertain as to whether "scrambling" is a time and/or energy dependent effect or whether it is always complete *before* the ion dissociates. Some recent evidence (13, 14) indicates that the former is the case, particularly at low electron energies, but other results are equivocal (15).

Apart from energy considerations, it may well be found that structural features, present in the ground-state geometry of a molecule, may be important in atom scrambling. Further studies are in preparation for publication.

Experimental

Trans-1,2-cyclohexanediol was obtained commercially from Aldrich; the *cis* isomer was prepared from cyclohexene (16). The O-d_2 diol was prepared by recrystallizing the compound from successive quantities of D_2O. Compounds **2** and **3** were gifts from Dr. G. Singy. The mass spectra were obtained using a Hitachi–Perkin–Elmer RMU6D and metastable defocussing was achieved using a modified Hitachi–Perkin–Elmer RMU7.

The authors wish to thank T. Blackburn and A. Philpot for invaluable experimental assistance. One of us (F.B.) is grateful to the Province of Ontario for financial support. This work was supported by a National Research Council of Canada grant. The authors wish to thank Dr. G Singy for compounds **2** and **3** and Dr. R. Rye for use of the Hitachi RMU7 Mass Spectrometer.

Reaction of Cyclopropenones with Heteroaromatic Nitrogen Compounds

J. W. LOWN AND K. MATSUMOTO[1]
Department of Chemistry, University of Alberta, Edmonton, Alberta

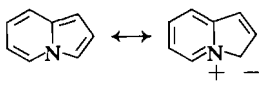
Received November 19, 1970

Diphenylcyclopropenone reacts with a variety of heteroaromatic nitrogen compounds to give in good yield either (*a*) 1,2-diphenyl-3-indolizinyl *cis*-1,2-diphenyl acrylates and aza analogs, (*b*) 5,6-diphenyl-7-hydroxypyrrolo[1,2-*b*]pyridazines and similar structures, or (*c*) adducts in which cycloaddition takes place to an N=N bond. Proof of structure of the new heterocycles is based on deuterium labelling experiments, hydrogenolysis to known compounds, and the preparation of chloro and iminoether derivatives. Cycloheptenocyclopropenones in the examples studied form heterocycles of type *b*.

La diphénylcyclopropénone réagit avec une variété de composés hétéroaromatiques contenant de l'azote et conduit avec de bons rendements soit (*a*) aux *cis*-diphényl-1,2 acrylates (et leurs analogues azotés) de diphényl-1,2 indolizinyle-3, (*b*) aux diphényl-5,6 hydroxy-7 pyrrolo[1,2-*b*]pyridazines et structures similaires, ou (*c*) des composés d'addition dans lesquels la cycloaddition se fait sur le lien —N=N—. Les preuves de structure de ces composés sont basées sur des expériences impliquant des marquages par le deutérium, des hydrogénolyses conduisant à des composés connus et la préparation de dérivés chlorés et iminoéthers. Dans les cas examinés, les cyclohepténocyclopropénones conduisent à des hétérocycles du type *b*.

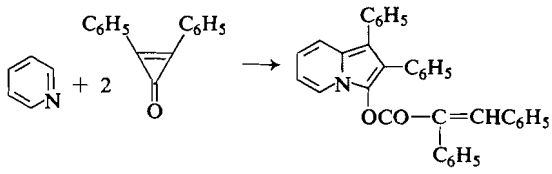
Canadian Journal of Chemistry, **49**, 1165 (1971)

Indolizine (**1**) is one of the fundamental nitrogen heterocyclic systems which has been neglected in comparison to its isomer indole (*1*). Recently interest has been generated in this system since Boekelheide and co-workers have shown indolizine adds to activated acetylenes

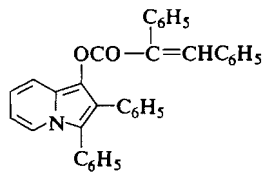


1

under dehydrogenating conditions to form the theoretically important class of cyclazines (2) in a reaction in which the indolizine reacts as an azomethine ylide, 1,3-dipole (3). Convenient synthetic routes to indolizines are few in number. There are also no synthetic routes which are readily adaptable to the preparation of aza-analogs of indolizine. An interest in the chemistry of cyclopropenones (4) led us to reinvestigate the suggested reaction of pyridine with diphenylcyclopropenone to form diphenylindolizinol derivatives (5) and to extend this reaction to include cycloheptenocyclopropenone and a variety of heteroaromatic nitrogen compounds. Breslow reports pyridine reacts with diphenylcyclopropenone in refluxing methanol to give a compound $C_{35}H_{25}NO_2$ tentatively assigned the indolizinol ester structure **2** or **3**. The product shows a prominent ester carbonyl absorption at 1730 cm^{-1} in the i.r. spectrum (5) like other similar adducts described below. We confirmed the implied cyclization step to the pyridine 2 position by examining the corresponding product obtained from pyridine-d_5. Accurate mass spectral peak measurement confirmed the incorporation of only four deuterons in the product.



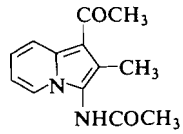
2



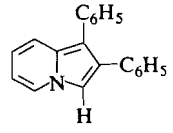
3

The adduct yields 1 mol of *cis*-1,2-diphenylacrylic acid on mild alkaline hydrolysis. More vigorous basic hydrolysis leads to extensive decomposition which is not unexpected in view of the reported similar behavior of indolizine **4** (6). Hydrogenolysis of the pyridine adduct with an equimolar mixture of lithium aluminum hydride and aluminum chloride afforded the known 1,2-diphenylindolizine (**5**) isolated at the picrate

[1]NRCC Postdoctorate Fellow, 1969 to present.



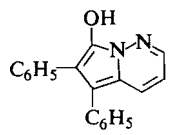
4



5

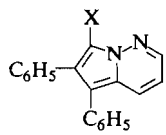
derivative thus proving the structure of the adduct as **2** unambiguously. Compound **5** was not isolated directly since the instability of indolizines unsubstituted in the 1 position has been noted previously (13).

Pyridazine reacts readily with diphenylcyclopropenone to give a different type of product $C_{19}H_{14}N_2O$ as a green crystalline solid *i.e.* corresponding to the incorporation of only 1 equiv of the cyclopropenone and is assigned the 5,6-diphenyl-7-hydroxypyrrolo[1,2-*b*]pyridazine structure **6** which, like similar compounds



6

formed in this work, gave a positive color reaction for phenolic hydroxyl with ferric chloride and showed strong i.r. absorption at 3570 cm^{-1} typical of phenolic type hydroxyl shifted approximately 100 cm^{-1} by interaction with the chloroform solvent (7). Indolizinols and similar structures are reported to give a color reaction with ferric chloride (8). Structure **6**, which is an analog of a plausible intermediate in the formation of **2** and similar structures, receives support by its smooth conversion to the chloro compound **7***a*, $C_{19}H_{13}ClN_2$, by treatment with phosphorus oxychloride. Such reactions are



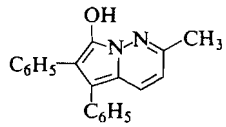
7

a X = Cl

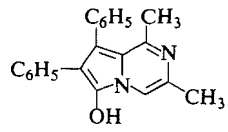
b X = OCH_2CH_3

typical of amidic groups in heterocyclic systems, *e.g.* the conversion of α-pyridone to 2-chloropyridine (9). Compound **6** was also converted smoothly to the iminoether **7***b* in 87% yield with triethoxonium fluoroborate (*vide infra*). Nitrogen-1 in compound **6** would not be expected to react with a further equivalent of diphenylcyclopropenone since pyrrolopyridazines have been shown to be inert to quaternization (10).

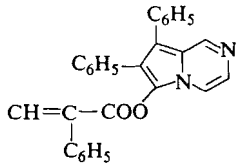
Reaction of diphenylcyclopropenone in methanol with a first group of heteroaromatic nitrogen compounds resulted in the clean formation of either of the two types of adducts exemplified by **2** and **6**. In no case was a mixture of products obtained (see Tables 1 and 2). 3-Methylpyridazine reacted to give the pyrrolo[1,2-*b*]pyridazine (**8**), $C_{20}H_{16}N_2O$, in good yield which like **6** showed a strong phenolic hydroxyl absorption



8



9



10

in the i.r. The position of quaternization of pyridazines is dictated by the position of ring substituents (11). The expected initial attack by N-1 of 3-methylpyridazine on diphenylcyclopropenone is in accordance with the formation of **8**. Investigation of a series of alpha methyl substituted pyridines and isoquinolines revealed that no reaction took place with cyclopropenones presumably for similar reasons of steric hindrance.

2,6-Dimethylpyrazine gave 1,3-dimethyl-7,8-diphenyl-6-hydroxypyrrolo[1,2-*a*]pyrazine (**9**), $C_{21}H_{18}N_2O$, in contrast to the behavior of pyrazine itself which gave 7,8-diphenyl-6-pyrrolo[1,2-*a*]pyrazinyl *cis*-1,2-diphenylacrylate (**10**), $C_{34}H_{24}N_2O_2$, which like **2** shows a prominent ester absorption at 1730 cm^{-1} in the i.r. spectrum. Compounds **2** and **10** and similar structures all show a sharp singlet at 7.78 δ characteristic of the vinyl proton in the 1,2-diphenylacrylic acid moiety (4*b*, *c*). The difference in reactivity of 2,6-dimethylpyrazine and pyrazine cannot be accounted for at this time since repeated attempts to acylate **9** by reaction with *cis*-1,2-diphenylacryloyl chloride or excess diphenylcyclopropenone regenerated **9** unchanged. Paquette similarly reports that normal

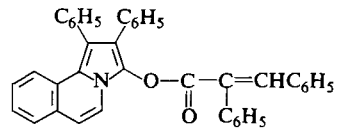
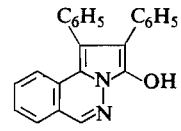
15

A difference in the reactivity of aza groups in nitrogen heterocycles towards cyclopropenones is exemplified by the ready reaction of isoquinoline to form 1,2-diphenyl-3-pyrrolo[1,2-*a*]-isoquinolinyl *cis*-1,2-diphenylacrylate (**16**), $C_{39}H_{27}NO_2$, in contrast to the complete lack of reactivity of quinoline under similar conditions. In compound **16** cyclization of the first diphenylcyclopropenone moiety to the quinoline 1-position is confirmed by the observation of a 7.5 Hz AB quartet due to protons-5 and -6 centered at 7.75 and 6.61 δ. The chemical shift of proton-5 relative to that in the corresponding adduct **24** obtained from cinnoline favors the orientation shown.

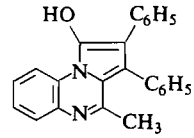
Phthalazine and 2-methylquinoxaline in contrast reacted readily with diphenylcyclopropenone but with the formation of the 1:1 adducts **17**, 1,2-diphenyl-3-hydroxypyrrolo-[1,2-*a*]-phthalazine, $C_{23}H_{16}N_2O$, and **18**, 4-methyl-2,3-diphenyl-1-hydroxypyrrolo[1,2-*a*]quinoxaline, $C_{24}H_{18}N_2O$, both of which showed prominent



16



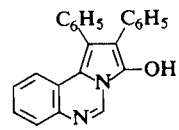
17



18

hydroxyl absorption in the i.r. spectrum. The latter evidence together with the correct integration of the aromatic region of the n.m.r. spectrum precludes addition across the N=N bond of phthalazine as occurred in the case of benzocinnoline and cinnoline (*vide infra*). In these additions as in the case of pyridazine there was no tendency for reaction of diphenylcyclopropenone with the second nitrogen.

The corresponding third product, isomeric with **17**, obtained from quinazoline is assigned the 1,2-diphenyl-3-hydroxypyrrolo[1,2-*c*]quinazoline structure **19** because of the susceptibility



19

of N-3 of quinazoline to quaternize readily and the general reactivity of the 3,4-bond towards addition (14). Also there have been no cases reported of alkylation of the N-1 position in quinazoline (15). Structures **17**–**19** receive support by their conversion into the corresponding iminoethers **20**–**22** with triethoxonium fluoroborate.

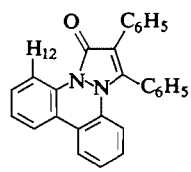
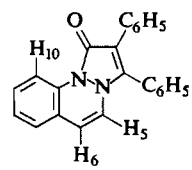
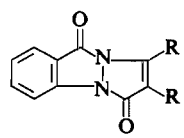
In all cases examined so far reaction has involved initial attack by an aza nitrogen on the carbonyl group of the cyclopropenone (which is supported by the observed lack of reactivity of all alpha substituted nitrogen heterocycles) followed by cyclization to an adjacent carbon (confirmed in the case of pyridine by the deuterium labelling experiment). Reaction of diphenylcyclopropenone with 3,4-benzocinnoline which lacks a free carbon alpha to the aza nitrogen resulted in the formation of a third type of adduct **23** formulated as the 2,3-diphenyl-1-ketopyrazolo[1,2-*a*]cinnoline, $C_{27}H_{18}N_2O$, in which addition occurs across the N=N double bond. The n.m.r. spectrum of **23** shows all the aromatic protons are intact and the i.r. spectrum shows a strong tertiary amidic carbonyl absorption at 1660 cm^{-1} but no hydroxyl group. The absence of any enolizable hydrogen is confirmed by the recovery of **23** unchanged after treatment with phosphorus oxychloride (contrast **5** and **7**). Similarly **23** is unaffected by treatment with trifluoroacetic acid unlike adducts of types **6**, **8**, **9**, **17**, and **18**, all of which undergo keto-enol displacements as the p*H* is altered. Observation of an 8 Hz doublet at 8.94 δ in the n.m.r. spectrum



23



24



25

of **23** assigned to H-12 (the paramagnetic shift of which *ca.* −1.4 p.p.m. is in accordance with the *peri* effect exemplified by model compounds **26** and **27** (16)) allows an unambiguous assignment of structure **24** to the analogous cinnoline adduct. The n.m.r. spectrum of **24** shows H-10

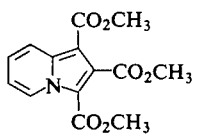
*See footnote to Table 1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

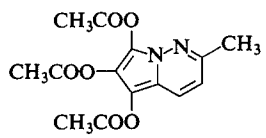
as an 8 Hz doublet at 9.4 δ (corresponding to a paramagnetic *peri* shift of *ca.* −1.6 p.p.m.) and a clear 8 Hz AB quartet due to H-5 and -6 centered at 5.93 and 6.86 δ thus defining the orientation of addition of the diphenylcyclopropenone moiety (contrast structure **16**). This is in accordance with expectation since cinnolines without exception quaternize at N-1 (17) and also indicates that in the reaction of nitrogen heterocycles with cyclopropenones attack by the nitrogen occurs at the carbonyl carbon, a result which is consistent with the formation of **2** from pyridine. Compound **24** shows a strong amide carbonyl at 1640 cm^{-1} in the i.r. spectrum and shows no hydroxyl or evidence of an enolizable proton.

Structures containing a fused pyrazolone ring are well documented, *e.g.* **25** (18).

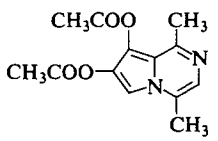
It has been remarked elsewhere that diphenylcyclopropenone in certain of its reactions behaves like a more reactive form of diphenylacetylene (4*a*). The analogy is useful here since pyridine, pyridazine, and a pyrazinium ylide react with activated acetylenes to afford indolizine structures and aza analogs of the indolizine skeleton *e.g.* **28–30** respectively (19, 10, 20).



28

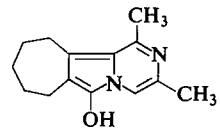


29

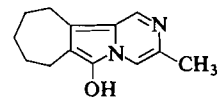


30

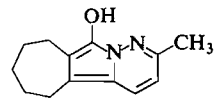
Cycloheptenocyclopropenone (5) reacts readily with 2,6-dimethylpyrazine to give a 1:1 adduct which shows a strong hydroxyl band at 3570 cm^{-1} and is similar in properties to those of adducts **6**, **8**, **9**, and **17–19** and is assigned structure **31**. Similarly adducts **32** and **33** are obtained from 2-methylpyrazine and 3-methylpyridazine respectively (see Table 5).



31



32



33

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 421 spectrophotometer, and only the principal, sharply defined peaks are reported. The n.m.r. spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$, with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Absorption spectra were recorded in 'spectro'-grade solvents on a Beckman DB recording spectrophotometer. Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. The ionization energy, in general, was 70 eV. Peak measurements were made by comparison with perfluorotributylamine at a resolving power of 15000. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for t.l.c. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalysis Ltd., Montreal, Quebec and by Mrs. D. Mahlow of this department.

Reaction of Diphenylcyclopropenone with Heteroaromatic Nitrogen Compounds

The reaction conditions and purification procedures are illustrated by the following examples. The analytical and spectroscopic properties of other compounds similarly prepared are summarized in Tables 1 and 2.

(a) Reaction of Diphenylcyclopropenone with Pyridine

A solution of 4.12 g (0.02 mol) of diphenylcyclopropenone (5) and 1.6 g (0.02 mol) of pyridine in 50 ml of methanol was heated under reflux for 2 h during which time the solution became dark yellow and a green precipitate formed. After cooling, 2.01 g of a 1,2-diphenyl-3-indolizinyl *cis*-1,2-diphenylacrylate were collected (40% yield) and purified by recrystallization from chloroform–ethanol.

Anal. Calcd. for $C_{35}H_{25}NO_2$ (mol. wt. 491.1885): C, 85.52; H, 5.13; N, 2.85. Found (491.1880 (mass spectrum)): C, 85.47; H, 5.23; N, 2.77.

The i.r. spectrum $\nu_{max}(CHCl_3)$: 1728 cm^{-1} (ester C=O). The n.m.r. $\delta_{TMS}(CDCl_3)$: 7.0–7.5 (21H, multiplet, aromatic and indolizine ring protons) 7.93 (1H, singlet, vinyl proton). The absorption spectrum $\lambda_{max}(CH_3CN)$: 249 (log ε 5.50); 268 (sh) (log ε 5.41); 330 mμ (sh) (log ε 4.76).

(b) Control Reaction of Diphenylcyclopropenone with Pyridine-d_5

A solution of 3.0 g (0.015 mol) of diphenylcyclopropenone and 1.2 g (0.015 mol) of pyridine-d_5 (99%, Merck, Sharpe and Dohme of Canada Ltd.) in 50 ml of methanol was heated under reflux for 1.5 h. After cooling the green solid was collected and purified by recrys-

For personal use only.

tallization from chloroform–ethanol, 1.55 g (43% yield) m.p. 188°.

Mol. Wt. Calcd. for $C_{35}H_{21}D_4NO_4$: 495.2198. Found: 495.2192.

(c) Reaction of Diphenylcyclopropenone with Pyridazine

A solution of 2.06 g (0.01 mol) of diphenylcyclopropenone and 0.8 g (0.01 mol) of pyridazine in 40 ml of methanol was heated under reflux for 2 h. Upon cooling and setting aside for 24 h, a mass of green crystals precipitated and was collected and purified by recrystallization from methanol affording 5,6-diphenyl-7-hydroxypyrrolo[1,2-*b*]pyridazine, 2.37 g (83% yield), m.p. 158° (dec.).

Anal. Calcd. for $C_{19}H_{14}N_2O$ (mol. wt. 286.1106): C, 79.70; H, 4.93; N, 9.78. Found (286.1100 (mass spectrum)): C, 79.82; H, 4.86; N, 9.69.

The i.r. spectrum ν_{max}(Nujol): 3200 cm^{-1} (br) (OH). The n.m.r. spectrum $\delta_{TMS}(CF_3COOH)$: 6.66 (1H, singlet enolizable proton); 7.2–7.7 (10H, multiplet, aromatic protons); 8.0–9.0 (3H, multiplet, indolizine ring protons). The absorption spectrum $\lambda_{max}(CH_3CN)$: 253 (log ε 5.18); 276 (sh) (log ε 5.07); 430 mμ (log ε 4.54).

(d) Reaction of Diphenylcyclopropenone with 2,6-Dimethylpyrazine

A solution of 2.06 g (0.01 mol) of diphenylcyclopropenone and 1.08 g (0.01 mol) of 2,6-dimethylpyrazine in 40 ml of methanol was allowed to stand at room temperature for 3 days. The initially orange solution gradually turned dark red and a yellow solid which had precipitated was collected and purified by recrystallization from methanol giving 1,3-dimethyl-7,8-diphenyl-6-hydroxypyrrolo-[1,2-*a*]-pyrazine, 2.52 g (80% yield), m.p. 216° (dec.). This material shows only one spot on silica t.l.c. in 1:4 methanol–benzene which moved to a different position in acidic eluants. When exposed to air the yellow solid turned orange and finally red, but when the latter red material was recrystallized from methanol, the yellow form, m.p. 216°, was recovered unchanged. The sensitivity of this product to p*H* like others of similar structure described in this paper is attributed to facile keto–enol tautomerizations.

Anal. Calcd. for $C_{21}H_{18}N_2O$ (mol. wt. 314.1419): C, 80.23; H, 5.77; N, 8.91. Found (314.1418 (mass spectrum)): C, 80.04; H, 5.63; N, 8.86.

The i.r. spectrum ν_{max}(Nujol), 3500 br (OH), 1623 cm^{-1} (C=O). The n.m.r. spectrum $\delta_{TMS}(CF_3COOH)$ 2.35 (3H, broad singlet, CH_3), 3.05 (3H, broad singlet, CH_3); 6.7–8.0 (10H, aromatic protons), 10.15 (1H, broad singlet, 4-indolizine ring proton). The absorption spectrum $\lambda_{max}(CH_3CN)$ 280 (sh) (log ε 5.00); 325 (log ε 5.04); 388 mμ (log ε 4.84).

(e) Reaction of Cycloheptenocyclopropenone with 2-Methylpyrazine

A solution of 2.44 g (0.02 mol) of cycloheptenocyclopropenone (5) and 1.88 g (0.02 mol) of 2-methylpyrazine in 50 ml of methanol was heated under reflux for 2 h and set aside at room temperature overnight. A green crystalline solid precipitated and was collected and purified by recrystallization from methanol–dimethoxyethane giving 7,8-cyclohepteno-3-methyl-6-hydroxypyrrolo[1,2-*a*]pyrazine, 2.15 g (49% yield), m.p. 170° (dec.).

Anal. Calcd. for $C_{13}H_{16}N_2O$ (mol. wt. 216.1263): C, 72.19; H, 7.46; N, 12.95. Found (216.1267 (mass spectrum)): C, 72.23; H, 7.39; N, 12.37.

The i.r. spectrum ν_{max}(Nujol): 3500 (br) OH, 1619 cm^{-1} (C=O). The n.m.r. spectrum $\delta_{TMS}((CD_3)_2SO)$ 0.8–2.0 (10H, multiplet, cycloheptено protons), 3.07 (3H, singlet, CH_3), 6.5–8.5 (3H, multiplet, aromatic protons). The absorption spectrum $\lambda_{max}(CH_3CN)$: 303 (log ε 4.93); 365 mμ (log ε 4.65).

Hydrogenolysis of 1,2-Diphenyl-3-indolizinyl cis-1,2-Diphenylacrylate with Lithium Aluminum Hydride and Aluminum Chloride (21)

To a suspension of 1.23 g (2.5 mmol) of 1,2-diphenyl-3-indolizinyl *cis*-1,2-diphenylacrylate and 1.17 g (12 mmol) of aluminum chloride in 200 ml of dry ether was added with stirring a solution of 0.17 g (4.4 mmol) of lithium aluminum hydride in 50 ml of dry ether. The mixture was heated under reflux for 24 h with continued stirring. The excess lithium aluminum hydride was decomposed cautiously with methanol and a slight excess of 20% aqueous sodium carbonate was added with cooling. The ether layer was washed with water and dried ($MgSO_4$). The filtered ether solution was concentrated to *ca.* 50 ml, a saturated solution of picric acid in ethanol was added, and the mixture set aside for 2 days during which time a green solid precipitated. The collected 1,2-diphenylindolizine picrate, 0.15 g (12% yield), had m.p. 149–150° (ethanol) (lit. m.p. 146–148° (22)). The mass spectrum showed a base peak at *m/e* 269 corresponding to $C_{20}H_{15}N$ for diphenylindolizine.

Preparation of Iminoethers from Indolizinol Analogs with Triethoxonium Fluoroborate

Reaction conditions and purification procedures are exemplified for the preparation of the iminoether from the phthalazine adduct (see also Tables 3 and 4).

To a dried solution of 0.168 g (0.5 mmol) of 1,2-diphenyl-3-hydroxypyrrolo[1,2-*a*]phthalazine in 10 ml of chloroform was added with stirring at room temperature a freshly prepared solution of 2 mmol triethoxonium fluoroborate (23) in 10 ml of methylene chloride. After the addition was completed, stirring was continued for 2 h and the solution was set aside overnight. The mixture was treated with 50% aqueous potassium carbonate solution and filtered. The filtrate was washed with water and dried ($MgSO_4$). Evaporation of the solvent and trituration of the residual oil with 60% aqueous methanol afforded 1,2-diphenyl-3-methoxypyrrolo[1,2-*a*]phthalazine, 0.15 g (83% yield), m.p. 129–130° (aqueous methanol).

Anal. Calcd. for $C_{25}H_{20}N_2O$ (mol. wt. 364.1575): N, 7.69; Found: (364.1574 (mass spectrum)): N, 7.78%.

The n.m.r. spectrum $\delta_{TMS}(CDCl_3)$: 1.27 (3H, triplet CH_3); 3.81 (2H, quartet, J = 7 Hz CH_2CH_3); 7.0–7.8 (12H, multiplet, aromatic protons), 8.10 (1H, singlet, 6 proton); 8.32 (1H, doublet, J = 8 Hz, 10 proton). Absorption spectrum $\lambda_{max}(CH_3CN)$: 261 (log ε 5.40); 292 (sh) (log ε 5.61); 320 (sh) (log ε 5.18); 387 mμ (log ε 4.02).

Preparation of 7-Chloro-5,6-diphenylpyrrolo[1,2-b]-pyridazine

A mixture of 1.43 g (5 mmol) of 5,6-diphenyl-7-hydroxypyrrolo[1,2-*b*]pyridazine and 20 ml of phosphorus oxychloride was heated under reflux for 2 h and the

excess phosphorus oxychloride was removed *in vacuo*. Trituration of the residual oil with ethyl acetate gave a brown solid which was recrystallized from chloroform and ethanol giving 7-chloro-5,6-diphenylpyrrolo[1,2-*b*]-pyridazine, 1.03 g (68% yield), m.p. 164°.

Mol. Wt. Calcd. for $C_{19}H_{13}N_2Cl$: 304.0767. Found (mass spectrum): 304.0760.

Synthesis of D-Idurone

WALTER SOWA
Department of Organic Chemistry, Ontario Research Foundation, Sheridan Park, Ontario
Received November 27, 1970

D-Idurone was prepared by periodate oxidation of D-*glycero*-D-*ido*-heptonolactone.

On rapporte la préparation de la D-idurone par oxydation périodique de la D-*glycero*-D-*ido*-heptonolactone.
Canadian Journal of Chemistry, 49, 1176 (1971)

L-Iduronic acid is a major constituent of the anticoagulant heparin according to recent evidence obtained from chemical degradation studies (1) and by 220 MHz p.m.r. spectroscopy (2). Contrary to earlier work (3–6), D-glucuronic acid appears to be a minor rather than a major component of the mucopolysaccharide. The p.m.r. data at 220 MHz confirm that L-idosyluronic acid residues occur also in dermatan (chondroitin sulfate B) and possibly heparitin (2).

Synthetic L-iduronic acid is not readily available. It has been prepared by application of the cyanohydrin synthesis to 1,2-*O*-isopropylidene-α-D-*xylo*-pentodialdo-1,4-furanose, the product of periodate oxidation of 1,2-*O*-isopropylidene-α-D-glucofuranose (7). In this procedure 1,2-*O*-isopropylidene-β-L-idofuranurono-6,3-lactone is separated from the co-product, 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone, by column chromatography on clay. Reported recently is an alternative synthesis also based on chain extension of 1,2-*O*-isopropylidene-α-D-*xylo*-pentodialdo-1,4-furanose (8). The *xylo* derivative, or its 3-benzyl ether, is ethynylated to yield a mixture of 5-epimeric, 7-carbon acetylenic sugars. The epimeric heptynes are separated by fractional distillation or by silica gel chromatography and converted by ozonolysis into derivatives of D-glucuronic and L-iduronic acids.

For many purposes in investigations of natural polymers containing L-iduronic acid, the enantiomer would serve as a reference compound. The first synthesis of a D-iduronic acid derivative appears to be that of Perlin and associates who recently reported the preparation of the α- and β-anomers of methyl D-iduronopyranoside by catalytic oxidation of the corresponding D-idopyranosides (footnote 5 in ref. 2). The present note describes a simple synthesis of D-iduronic acid, in the form of its lactone, by oxidation of D-*glycero*-D-*ido*-heptonolactone with periodic acid. Also reported is a modified procedure for the isolation of L-idurone synthesized by the cyanohydrin route.

The synthetic method employed for D-idurone is analogous to that for L-glucurone derived from D-*glycero*-D-*gulo*-heptonolactone (9). Oxidative (periodate) removal of the primary alcohol of a heptonolactone results in inversion of the molecule with the penultimate carbon atom of the heptonolactone becoming C-1 of the hexuronic acid lactone. On treatment of D-*glycero*-D-*ido*-heptonolactone with a molar equivalent of periodic acid, there was obtained a mixture of starting material, D-idurone and D-arabinose. The pentose arises from glycol cleavage of the heptonolactone at C_2—C_3, as in the preparation of L-glucurone (9). D-Idurone was isolated by preparative paper chromatography. On a millimolar scale, the yield was around 50%. A useful crystalline derivative is the dibenzyl dithioacetal. To minimize degradation of the uronic acid, it was advantageous to use trifluoroacetic acid instead of hydrochloric acid as a catalyst for thioacetalation.

The preparation of D-idurone was further simplified by oxidizing a mixture of D-*glycero*-D-*ido*-heptonolactone and D-*glycero*-D-*gulo*-heptonolactone, thus avoiding isolation of pure *ido* starting material. The mixture of heptonolactones was easily obtainable either from D-glucose by the cyanohydrin synthesis (10) or by epimerization of commercially-available D-*glycero*-D-*gulo*-heptonolactone with pyridine. After periodate oxidation of the mixed lactones, both D-idurone and L-glucurone were isolated by paper chromatography in butanol–ethanol–water (5:2:1 v/v), a solvent system in which they are widely-separated.

The straightforward resolution of D-idurone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and L-glucurone suggested a modified isolation procedure for obtaining L-idurone from the reaction of 1,2-*O*-isopropylidene-α-D-*xylo*-pentodialdo-1,4-furanose and cyanide. Instead of separating the 5-epimeric 1,2-*O*-isopropylidene hexuronolactones on clay (7), the mixture was first hydrolyzed to remove the acetal groups and then chromatographed on paper. L-Idurone and D-glucurone were readily isolated.

Experimental

Melting points were determined on a Fisher–Johns m.p. apparatus and are uncorrected. Optical rotations were done on a Carl Zeiss photoelectric polarimeter 0.005° using a sodium spectral light source. Preparative paper chromatography was on Whatman 3MM sheets with (*a*) *n*-butanol–pyridine–water (6:4:3 v/v) and (*b*) *n*-butanol–ethanol–water (5:2:1 v/v) as developing solvents. Qualitative paper chromatography was on Whatman No. 4 paper. Spray reagents for visualization of compounds were alkaline silver nitrate (11) and *p*-anisidine hydrochloride (12). Solutions were concentrated under reduced pressure using a rotary evaporator and a water bath at a temperature of 50° or less.

D-Idurone from D-Glycero-D-ido-heptonolactone

D-*Glycero*-D-*ido*-heptonolactone, m.p. 151–152°, was obtained by paper chromatographic separation of the mixture of epimeric heptonolactones resulting from treatment of D-glucose with sodium cyanide (10). As an alternative to the cyanohydrin procedure, the same mixture of heptonolactones was obtained by refluxing commercial D-*glycero*-D-*gulo*-heptonolactone (10 g) in pyridine (100 ml) for 24 h. The pyridine was removed *in vacuo* and the resulting syrup was redissolved in 80% ethanol in order to crystallize some of the unepimerized D-*glycero*-D-*gulo*-heptonolactone. The mother liquor was treated with activated carbon and evaporated to a syrup which contained an approximately 1:1 ratio of D-*glycero*-D-*gulo*- and D-*glycero*-D-*ido*-heptonolactones. The two lactones were resolved well by solvent (*a*). On a small scale it was more convenient to isolate D-*glycero*-D-*ido*-heptonolactone chromatographically rather than through the cadmium salt cadmium bromide double salt (13).

A solution of periodic acid (H_5IO_6, 228 mg) in water (5 ml) was added to a solution of D-*glycero*-D-*ido*-heptonolactone (208 mg) in water (5 ml). The reaction mixture was left for 15 min at room temperature and barium carbonate (150 mg) was added. The mixture was filtered and the filtrate evaporated to a syrup. This was evaporated with acetic acid to fully lactonize the sugar acids. Paper chromatography indicated that the syrup consisted of D-*glycero*-D-*ido*-heptonolactone, D-idurone, and a small amount of D-arabinose. Preparative paper chromatography of the mixture (200 mg) in solvent (*b*) provided D-idurone (95 mg) having $[\alpha]_D^{21}$ −30° (*c*, 1.5 in water). Yields were generally around 50%. The specific rotation reported for L-idurone is $[\alpha]_D^{25}$ +30° (*c*, 1 in water) (14).

A mixture of syrupy D-idurone (50 mg), trifluoroacetic acid (0.5 ml), and toluenethiol (0.07 ml) was left for 2 h at 5° and then evaporated to dryness. The product was recrystallized twice from ethyl acetate and dried at 40° over phosphorus pentoxide *in vacuo* to obtain D-idurone dibenzyl dithioacetal (47 mg) having m.p. 165–166° and $[\alpha]_D^{21}$ −9.7° (*c*, 1.1 in pyridine).

Anal. Calcd. for $C_{20}H_{22}O_5S_2$: C, 59.09; H, 5.46; S, 15.77. Found: C, 59.42; H, 5.72; S, 15.99.

The preparation was also carried out by oxidation of the 1:1 mixture of heptonolactones obtained above from pyridine epimerization of D-*glycero*-D-*gulo*-heptonolactone. In a typical run, the mixture (208 mg) was oxidized, worked-up as described previously, and chromatographed in solvent (*b*) to yield D-idurone (56 mg) and L-glucurone (45 mg), $[\alpha]_D^{23}$ −16.4° (*c*, 2.2 in water). On Whatman No. 4 paper, the rates of movement of D-idurone and L-glucurone (and their enantiomers) relative to rhamnose (R_{Rh}) were 1.25 and 0.90 respectively. The solvent system is based on that of Masamune and Satake (15) who reported R_{Rh} 1.24 and 0.92 for L-idurone and D-glucurone in *n*-butanol–methanol–water (5:2:1 v/v).

Paper Chromatographic Isolation of Synthetic L-Idurone

To 1,2-*O*-isopropylidene-α-D-*xylo*-pentodialdo-1,4-furanose and sodium bicarbonate (1.2 g) in water (40 ml) containing several lumps of Dry Ice and cooled in an ice bath was added a cold solution of sodium cyanide (0.8 g) in water (30 ml) (7). The reaction mixture was kept at 5° for 36 h, at room temperature for the same period and then heated at 60° for 5 h with aeration by a stream of air. The solution was evaporated to dryness and the residue redissolved in water (20 ml). The more concentrated solution, with its p*H* maintained at 2 with 10% hydrochloric acid, was extracted with ethyl acetate (10 × 50 ml). The extract was dried (Na_2SO_4), filtered, and evaporated to dryness. The syrupy mixture at this point was not lactonized by heating in toluene followed by dilution with petroleum ether to precipitate the lactones (7). Instead, the residue was hydrolyzed in 90% trifluoroacetic acid (30 ml) for 15 min at room temperature (16). The solution was evaporated to dryness and the residue lactonized by evaporation with acetic acid. The resulting mixture (2.3 g) of L-idurone and D-glucurone was separated by chromatography in solvent (*b*). From 1.00 g of syrup on two sheets (46 × 57 cm) of 3 MM paper, the yields of L-idurone, $[\alpha]_D^{21}$ +30° (*c*, 1.9 in water) and D-glucurone, m.p. 175–177°, were 0.43 and 0.37 g, respectively. The L-idurone was converted to the dibenzyl dithioacetal, m.p. 166–167°, $[\alpha]_D^{22}$ +9.6° (*c*, 1.2 in pyridine).

Anal. Calcd. for $C_{20}H_{22}O_5S_2$: C, 59.09; H, 5.46; S, 15.77. Found: C, 59.60; H, 5.47; S, 15.28.

Total Synthesis of α,β-DL-Allose and α,β-DL-Galactose. Stereoselective *cis*-Hydroxylation by Osmium Tetroxide

U. P. SINGH[1] AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received October 30, 1970

The reaction of osmic acid with 1,6-anhydro-3,4-dideoxy-β-DL-*erythro*-hex-3-enopyranose and its 2-*O*-methyl and 2-*O*-acetyl derivatives in either pyridine or dioxane solution has produced 1,6-anhydro-β-DL-allopyranose and 1,6-anhydro-β-DL-galactopyranose and the corresponding 2-*O*-methyl and 2-*O*-acetyl derivatives. These or their fully acetylated derivatives could be hydrolyzed to α,β-DL-allose and α,β-DL-galactose and the 2-*O*-methyl derivatives. The proportion of *allo* to *galacto* product obtained varies widely with the solvent used in hydroxylation, showing that attack by osmic acid is subject to steric control.

La réaction de l'acide osmique avec le DL-anhydro-1,6 didéoxy-3,4 β-hexèno-3 pyranose et ses dérivés *O*-méthyl-2 ou *O*-acétyl-2 soit en solution dans la pyridine ou le dioxanne conduit aux DL-anhydro-1,6 β-allopyranose et DL-anhydro-1,6 β-galactopyranose et les dérivés correspondants *O*-méthyl-2 ou *O*-acétyl-2. Ces produits ou leurs dérivés complètement acétylés peuvent être hydrolysés en α,β-DL-allose et α,β-DL-galactose et les dérivés *O*-méthyl-2. Les proportions des produits *allo* et *galacto* obtenus varient grandement avec le solvant utilisé pour l'hydroxylation montrant ainsi que l'attaque par l'acide osmique est sujette au contrôle stérique.

Canadian Journal of Chemistry, 49, 1179 (1971)

Introduction

A recent communication (1) from this laboratory has reported the preparation of α,β-DL-glucose from 1,6-anhydro-3,4-dideoxy-β-DL-*erythro*-hex-3-enopyranose, (**1**, R = H), obtained by the reaction of *n*-butyllithium with 1,6:2,3-dianhydro-4-deoxy-β-DL-*ribo*-hexopyranose, a compound in turn obtained from acrolein dimer (2). The present paper describes the stereoselective reaction of osmic acid with **1** (R = H, CH_3— or CH_3CO—) to produce α,β-DL-allose and α,β-DL-galactose and their 2-*O*-methyl derivatives (Scheme 1).

Results and Discussion

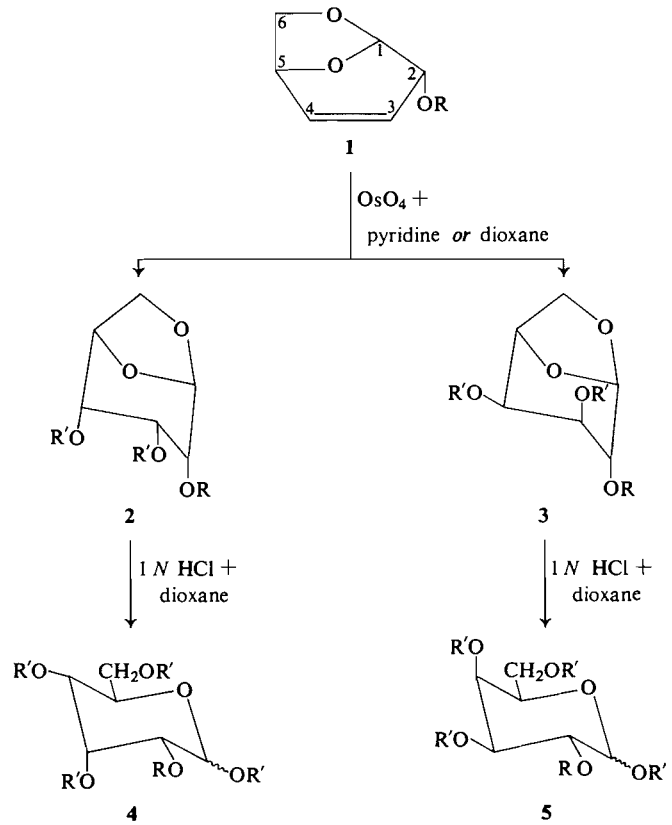
The 100 MHz p.m.r. spectra were obtained for all of the compounds isolated and are in full agreement with the structures and conformations proposed and shown in Scheme 1. Signals for most of the protons could be determined by spin decoupling and these provided observed proton couplings which clearly supported these structures and conformations. Details are described in the Experimental.

Two methods were employed for the *cis* hydroxylation of olefin **1** with osmic acid. The first involved reaction in pyridine (3) while the second employed dioxane as the solvent (4). Reaction of **1** (R = H) with osmic acid in pyridine gave a mixture from which the products **2** (R = R′ = H) and **3** (R = R′ = H) together or separately could not be isolated. When the crude reaction mixture was treated with pyridine and acetic anhydride, the acetylated derivatives **2** (R = R′ = CH_3CO) and **3** (R = R′ = CH_3CO) could be isolated and separated by repeated chromatography in yields of 36 and 30% respectively. Osmic acid in dioxane gave a much cleaner reaction with **1** (R = H) and provided an 85% yield of an isolable solid whose elemental analysis and p.m.r. spectrum showed it to be a 2:1 mixture of **2** and **3** (R = R′ = H). Repeated attempts to separate these two isomers were unsuccessful. Accordingly the mixture was first converted to the triacetate and then separated by chromatography as above to provide excellent yields of the pure triacetates **2** and **3** (R = R′ = CH_3CO).

The reaction of **1** with osmic acid in either pyridine or dioxane was quite satisfactory when R was methyl or acetyl, and gave a mixture of the corresponding dihydroxy compounds **2** and **3** (R′ = H, R = CH_3, or CH_3CO) in crude yields that were practically quantitative.

Hydrolysis of **2** (R = R′ = CH_3CO) with a mixture of 1 *N* hydrochloric acid with dioxane (2:1 by volume) gave solid α,β-DL-allose in 91% yield based on the triacetate precursor. The 100 MHz p.m.r. spectrum in D_2O showed that this

[1]Postdoctoral Fellow 1969–1971.



SCHEME 1

α,β-DL-allose existed as an equilibrium mixture of α- and β-furanose and α- and β-pyranose structures, with the β-pyranose isomer in great predominance. Similar isomeric distributions have been reported for aqueous solutions of several D-monosaccharides (5). This spectrum was identical with the p.m.r. spectrum (in D_2O) of authentic α,β-D-allose,[2] thus providing final proof of the structure of **4** (R = R′ = H). Treatment with acetic anhydride and pyridine converted the α,β-DL-allose to the solid pentaacetate **4** (R = R′ = CH_3CO) which, from the integrated areas of the C-1 proton signals in its p.m.r. spectrum, was shown to be a mixture of the α and β anomers in the approximate ratio of 1.0:3.6.

Hydrolysis of **3** (R = R′ = CH_3CO) under the same conditions as employed for the hydrolysis of **2** (R = R′ = CH_3CO), gave α,β-DL-galactose **5** (R = R′ = H) as a crystalline solid in 92% yield. The 100 MHz spectrum in D_2O showed two anomeric proton signals in the approximate area ratio of 1:1 corresponding to the α- and β-pyranose structures. No evidence was noted indicating the presence of the α- and/or β-furanose isomer. The p.m.r. spectrum of the viscous, syrupy DL-galactose pentaacetate **5** (R = R′ = CH_3CO) showed that this substance was a 1.0:2.7 mixture of the α and β anomers. An identical p.m.r. spectrum was obtained from the pentaacetate of authentic D-galactose.

cis-Hydroxylation of the oily 2-*O*-acetyl-1,6-anhydro-3,4-dideoxy-β-DL-*erythro*-hex-3-enopyranose (**1**, R = CH_3CO) in pyridine gave a product which showed only two spots on a thin layer chromatogram. A combination of column chromatography and fractional crystallization provided in good yield a 65:35 mixture of what was at first considered to be the two isomers 2-*O*-acetyl-1,6-anhydro-β-DL-allopyranose (**2**, R′ = H, R = CH_3CO), an oil, and 2-*O*-acetyl-

[2]The p.m.r. spectrum of α,β-D-allose in D_2O was kindly provided by Professor S. J. Angyal, University of New South Wales, Kensington, N.S.W., Australia.

TABLE 1. Ratio of *allo* to *galacto* isomer obtained by reaction of OsO_4 with **1***

Compound **1** R	In pyridine	In dioxane
H	36:30 (As triacetate) (66)	51:27 (As triacetate) (78) 2:1 (Unacetylated) (85)
CH_3CO	65:35 (96)	9:1 88:7.5 (As triacetate) (96)
CH_3	1:3 (~100)	4:3 (98)

*The overall yields (%) are in parentheses.

1,6-anhydro-β-DL-galactopyranose (**3**, R′ = H, R = CH_3CO), a solid. Separation was facilitated by the fact that the *allo* but not the *galacto* isomer is soluble in methylene chloride. Both substances showed only one spot on a thin layer chromatogram. The 100 MHz p.m.r. spectrum of the *galacto* isomer agreed completely with the assigned structure. However, that of the "*allo*" isomer, the major product, showed the presence of *three* singlets in the region where the acetyl methyl proton signals normally occur. The integrated area of these three signals was equivalent to three of the 12 protons. It is thus quite apparent that the advantageous orientation of the hydroxyl groups has permitted acetyl migration during the procedure of isolation of the *allo* monoacetate. We were unable to avoid this migration and also could not separate the three isomeric *allo* monoacetates. *cis*-Hydroxylation in dioxane solution resulted in similar unavoidable acetyl migration. Complete acylation of the *allo* or the *galacto* monoacetates gave the triacetates identical to those described above. Acid-catalyzed hydrolysis of the *allo* and *galacto* monoacetates gave respectively α,β-DL-allose and α,β-DL-galactose in excellent yield.

cis-Hydroxylation of **1** (R = CH_3) with osmic acid in pyridine gave a syrup which showed two spots on a thin layer chromatogram. The p.m.r. spectrum indicated two anomeric proton signals in the relative area ratio of 1:3. The two substances were separated by column chromatography and their 100 MHz p.m.r. spectra clearly identified the minor product, a solid, as 2-*O*-methyl-1,6-anhydro-β-DL-allopyranose, (**2**, R′ = H, R = CH_3) and the major product, also a solid, as the *galacto* isomer **3** (R′ = H, R = CH_3). Osmic acid in dioxane also produced both **2** and **3** (R′ = H, R = CH_3) but in the ratio of 4:3 respectively. Acylation of the mixture of isomers **2** and **3** (R′ = H, R = CH_3) provided the corresponding diacetates **2** and **3** (R′ = CH_3CO, R = CH_3) which could be separated as solids by column chromatography. Acid-catalyzed hydrolysis of the *allo* diacetate **2** (R′ = CH_3CO, R = CH_3) gave crystalline 2-*O*-methyl-α,β-DL-allose (**4**, R′ = H, R = CH_3). Its p.m.r. spectrum in D_2O showed the presence of α- and β-furanose along with the α- and β-pyranose structures, again with the β-pyranose isomer in large predominance. Acetylation of 2-*O*-methyl-α,β-DL-allose gave the corresponding tetraacetate **4** (R′ = CH_3CO, R = CH_3). The 100 MHz p.m.r. spectrum of this compound indicated that it was a single compound possessing the β-anomeric structure.

Acid-catalyzed hydrolysis of 1,6-anhydro-2-*O*-methyl-β-DL-galactopyranose (**3**, R′ = H, R = CH_3) provided 2-*O*-methyl-α,β-DL-galactopyranose (**5**, R′ = H, R = CH_3) whose 100 MHz p.m.r. spectrum in D_2O showed the presence of only the α- and β-pyranose structures and was identical to the p.m.r. spectrum of authentic 2-*O*-methyl-α,β-D-galactose.[3]

Table 1 shows the ratio of the *allo* to *galacto* isomers obtained by the osmic acid oxidation of **1** when R = H, CH_3CO, or CH_3.

Except for the reaction of osmic acid with **1** (R = H) in pyridine where product isolation was difficult, it is clear that *cis* hydroxylation with osmic acid is susceptible to steric approach control. For the compounds where R = H or CH_3CO in **1**, for both pyridine and dioxane, the oxymethylene group of the 1,6-anhydro ring offers greater resistance to approach of the osmic acid to the double bond than does either the hydroxy or the acetoxy group. Such steric hindrance to the reaction of osmic acid with a

[3]A sample of 2-*O*-methyl-α,β-D-galactose was kindly supplied by Professor R. U. Lemieux and Dr. T. L. Nagabhushan of the Department of Chemistry at the University of Alberta, Edmonton, Alberta.

double bond has already been noted (3, 6), and is reminiscent of the steric control exerted by alkyl, alkoxy, or acetoxy substituents, situated α or β to the double bond in the cyclohexene ring system, to reaction of peroxy acids with the double bond (7). Contrary to the observation that an α hydroxy group, probably by hydrogen bonding, directs the peroxy acid to the double bond on the side of the ring on which the hydroxyl group is located (7), no clear evidence of such an effect has been observed for the osmic acid reaction in this work. A methoxy group appears to provide a definitely greater steric resistance to approach to the double bond by osmic acid than does the oxymethylene group when hydroxylation is carried out in pyridine, whereas in dioxane, the methoxy group has *slightly less* hindrance than does the oxymethylene group. It is not clear why such a marked difference occurs in the behavior of osmic acid in the two solvents employed. It is known that an isolable complex is formed between one molecule of osmic acid and two molecules of pyridine (8), thus suggesting that the species attacking the double bond during *cis* hydroxylation in pyridine is the 1:2 complex.

Experimental

Melting points and boiling points are uncorrected.

Elemental analyses were made by Mrs. Darlene Mahlow and Mrs. A. Dunn of our microanalytical laboratory. The i.r. absorption spectra were obtained by Mr. R. Swindlehurst with a Perkin–Elmer Model 421 spectrophotometer. The 60 MHz p.m.r. spectra were made by Mr. Swindlehurst using a Varian A-60 instrument. The 100 MHz spectra and spin decoupling experiments were carried out by Mr. G. Bigham and his associates. Tetramethylsilane was the internal reference. Signal assignments were made with the aid of double irradiation spin decoupling. Coupling constants reported were estimated from the signal spacings where this was possible and are therefore approximate values.

Column and thin layer chromatography were carried out using silica gel G (E. Merck and Co.) as adsorbant. Solvents were usually removed by rotary evaporator under vacuum unless otherwise stated.

*Reaction of 1,6-Anhydro-3,4-dideoxy-*β*-*DL*-erythro-hex-3-enopyranose (**1**, R = H) with Osmic Acid*

(a) In Pyridine

Compound **1** (R = H) in pyridine was treated with osmic acid according to published directions (3) but at room temperature for 20 h. The orange solution obtained after the addition of sodium bisulfite was evaporated at 40° under vacuum to dryness rather than extracted with chloroform, and the product freeze-dried under vacuum. The crude product was treated with excess acetic anhydride in pyridine at 60° for 0.5 h, then stirred overnight at room temperature. The mixture was poured into ice water and extracted with chloroform (5 × 20 ml). The extract was dried (magnesium sulfate) and then freed from solvent. The crude viscous semi-solid showed two spots on a thin layer chromatogram (solvent, ethyl acetate – chloroform, 1:1). Repeated column chromatography using a 1:1 mixture of ethyl acetate – chloroform as eluent gave in the *first fraction*, solid 1,6-anhydro-2,3,4-tri-*O*-acetyl-β-DL-galactopyranose (**3**, R = R′ = CH_3CO) which crystallized from dichloromethane as colorless needles melting at 114–115°; yield, 30%. The i.r. spectrum in chloroform showed strong absorption at 1745 cm^{-1} (C=O).

Anal. Calcd. for $C_{12}H_{16}O_8$: C, 50.00; H, 5.59. Found: C, 50.27; H, 5.45.

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.58 for H-1 (doublet, $J_{1,2} \sim 1.5$ Hz); 5.26 for H-2 (narrow quartet, $J_{2,3} \sim 1.0$, $J_{1,2} \sim 1.5$ Hz); 4.75 for H-3 and -4 (multiplet, $J_{3,4} \sim 2.5$, $J_{4,5} \approx 2.5$ Hz); 5.56 for H-5 (multiplet, $J_{5,6exo} \sim 5.0$, $J_{4,5} \sim 2.5$, $J_{3,5} \sim$ 2.5 Hz, long range); 5.68 for H-6*endo* (quartet, $J_{5,6endo} \sim$ 0.5, $J_{6endo,6exo} \sim 7.5$ Hz); 6.30 for H-6*exo* (quartet, $J_{4,6exo} \sim 1.5$ Hz); 7.90 for two CH_3 (singlet); 8.00 for one CH_3 (singlet).

The *second fraction* gave *1,6-anhydro-2,3,4-tri-O-acetyl-*β*-DL-allopyranose* (**2**, R = R′ = CH_3CO), which produced colorless prisms from dichloromethane–pentane, melting at 128–129°; yield, 36%. The i.r. spectrum in chloroform showed strong absorption at 1745 cm^{-1} (C=O).

Anal. Calcd. for $C_{12}H_{16}O_8$: C, 50.00; H, 5.59. Found: C, 50.23; H, 5.34.

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.49 for H-1 (doublet, $J_{1,2} \sim 2.5$ Hz); 4.80–4.95 for H-2 and -4 (multiplet); 4.75 for H-3 (triplet, $J_{2,3} \approx J_{3,4} \sim 5.0$ Hz); 5.33 for H-5 (complicated doublet, $J_{4,5} \sim 2.5$, $J_{5,6endo} \sim 1.5$, $J_{5,6exo} \sim 5.0$ Hz); 6.07 for H-6*endo* (quartet, $J_{5,6endo} \sim 1.5$, $J_{6exo,6endo} \sim 8.5$ Hz); 6.22 for H-6*exo* (quartet, $J_{5,6exo} \sim 5.0$ Hz); 7.85 for CH_3 (singlet); 7.87 for CH_3 (singlet); and 8.03 for CH_3 (singlet).

(b) In Dioxane

A mixture of compound **1** (R = H) (0.43 g) and 1.0 g of osmic acid in 10 ml of dry dioxane was stirred at room temperature for 24 h, following published directions (6). The thick syrup obtained after treatment with hydrogen sulfide and removal of solvent (6) solidified on standing. The crude material (0.46 g, 85%) was shown by its p.m.r. spectrum in deuteriomethanol to be a 2:1 mixture of **2** (R = R′ = H) and **3** (R = R′ = H). The mixture was treated with acetic anhydride in pyridine and the triacetates separated by column chromatography as in section *a* above, to give *1,6-anhydro-2,3,4-tri-O-acetyl-*β*-DL-allopyranose* as colorless prisms melting at 128–129°. Mixed m.p. with sample from section *a*, 127–129°; yield, 0.49 g (51% based on **1**, R = R′ = H), and *1,6-anhydro-2,3,4-tri-O-acetyl-*β*-DL-galactopyranose* as fine needles melting at 114–115°. Mixed m.p. with sample from section *a*, 114–115°; yield, 0.265 g (27% based on **1**, R = R′ = H).

α,β-DL-*Allose* (**4**, *R = R′ = H*)

A solution of 288 mg of **2** (R = R′ = CH_3CO) in 10 ml of 1 *N* aqueous hydrochloric acid containing 5 ml of dioxane was heated for 5 h in an oil bath at ~100°. The mixture was cooled and then neutralized with Amberlite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

IRA 400 (OH^-) and filtered. The solvent was removed and the residue freeze-dried. The colorless powder was crystallized from water–methanol, producing fine needles melting at 181–183°; yield, 165 mg (91%). Reported m.p. of an equimolar mixture of D- and L-allose, 180° (9).

Anal. Calcd. for $C_6H_{12}O_6$: C, 40.00; H, 6.71. Found: C, 39.81; H, 6.64.

The 100 MHz p.m.r. spectrum obtained in deuterium oxide after a 72 h period required for completion of mutarotation agreed fully with that of authentic α,β-D-allose, and showed signals for the anomeric proton at τ 4.23 (doublet, $J_{1,2} \sim 4.0$ Hz for the α-furanose isomer); 4.36 (doublet, $J_{1,2} \sim 2.4$ Hz for β-furanose isomer); 4.45 (doublet, $J_{1,2} \sim 4.0$ Hz for α-pyranose isomer); and 4.72 (doublet, $J_{1,2} \sim 8.0$ Hz for β-pyranose isomer, the major species). The 100 MHz p.m.r. spectrum of **4** (R = R′ = H) taken from a freshly prepared solution in deuterium oxide showed only the anomeric proton signals for the α- and β-pyranose isomers in the approximate ratio of 1.0:2.5.

α,β-DL-Allose Pentaacetate (4, R = R′ = CH_3CO)

Treatment of 90 mg of **4** (R = R′ = H) with 5 ml of acetic anhydride and 5 ml of pyridine at room temperature for 24 h, gave solid α,β-DL-*allose pentaacetate* (**4**, R = R′ = CH_3CO) which provided colorless needles from ether–pentane; m.p. 132–133°; yield, 190 mg (98%).

Anal. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.24; H, 5.64. Found: C, 49.19; H, 5.45.

The i.r. spectrum in Nujol showed carbonyl absorption at 1760 cm^{-1}.

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 3.82 (doublet, $J_{1,2} \sim 4.0$ Hz for H-1 of the α-isomer) and at 4.06 (doublet, $J_{1,2} \sim 8.5$ Hz for H-1 of the β-isomer) with signal area ratio α:β = 1.0:3.6. Other signals were found at τ 4.90–5.20 for H-2 and -4 (multiplet); 4.34 for H-3 (triplet, $J_{2,3} \approx J_{3,4} \sim 3.0$ Hz); 5.8–6.0 for H-5, -6*exo*, and -6*endo* (multiplet); 7.40, 7.90, and 8.02 (three singlets for each of three methyl groups).

α,β-DL-Galactose (5, R = R′ = H)

Hydrolysis of 288 mg of **3** (R = R′ = CH_3CO) by the same method used to hydrolyze **2** (R = R′ = CH_3CO) gave crude α,β-DL-*galactose* as a glassy solid which crystallized from methanol–ether as colorless needles melting at 144–147°; yield, 178 mg (93%). Reported m.p. of an equimolar mixture of D- and L-galactose, 143–144° (10), 163° (11).

Anal. Calcd. for $C_6H_{12}O_6$: C, 40.00; H, 6.71. Found: C, 40.10; H, 6.68.

The 100 MHz p.m.r. spectrum in deuterium oxide, taken after the compound had been in solution 1 h, was completely superimposable on a 100 MHz p.m.r. spectrum of authentic α,β-D-galactose in deuterium oxide. No change was observed in the spectrum taken after either substance had been kept in solution for a period of 5 days.

α,β-DL-Galactose Pentaacetate (5, R = R′ = CH_3CO)

Acetylation of 90 mg of **5** (R = R′ = H) with acetic anhydride and pyridine (5 ml of each) for 24 h at room temperature gave crude pentaacetate as a viscous liquid which was purified by distillation to give a colorless syrup boiling at 155–160° at 0.1 mm; yield, 192 mg (98%).

Anal. Calcd. for $C_{16}H_{22}O_{11}$; C, 49.24; H, 5.64. Found: C, 48.94; H, 5.55.

The 100 MHz p.m.r. spectrum in deuteriochloroform was identical to that of authentic α,β-D-galactose pentaacetate in deuteriochloroform and showed by the integrated area of the two signals for the anomeric proton, that the α and β anomers were present in the approximate ratio of 1.0:2.7.

2-O-Acetyl-1,6-anhydro-3,4-dideoxy-β-DL-erythro-hex-3-enopyranose (1, R = CH_3CO)

A solution of **1** (R = H) (1.28 g, 0.001 mol) in a mixture of 5 ml of acetic anhydride and 5 ml of dry pyridine, first heated for 0.5 h at 60° then stirred overnight at room temperature, was poured into an ice–water mixture. The chloroform extract (5 × 20 ml) was dried (magnesium sulfate) and freed from solvent. The residual yellow liquid was twice distilled under vacuum to give **1** (R = CH_3CO) as a colorless liquid boiling at 93–95° at 0.5 mm; yield, 1.68 g (99%).

Anal. Calcd. for $C_8H_{10}O_4$: C, 56.47; H, 5.92. Found: C, 56.70; H, 6.05.

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.50 for H-1 (triplet, $J_{1,2} \sim 2.0$, $J_{1,3} \sim 1.5$ Hz); 5.28 for H-2 (quartet, $J_{1,2} \sim 2.0$, $J_{2,3} \sim 4.0$ Hz); 4.25 H-3 (doublet of quartets, $J_{3,4} \sim 10$, $J_{2,3} \sim 4$, $J_{1,3} \sim 1.5$ Hz); 3.70 for H-4 (doublet of quartets, $J_{3,4} \sim 10$, $J_{4,5} \sim 5$, $J_{2,4} \sim 1.5$ Hz); 5.25–5.35 for H-5 (multiplet); 6.25–6.40 for H-6*exo* and -6*endo* (multiplet); and 6.34 for CH_3 (singlet).

The i.r. spectrum (neat) showed strong absorption at 1735 cm^{-1} (C=O).

Reaction of 2-O-Acetyl-1,6-anhydro-3,4-dideoxy-β-DL-erythro-hex-3-enopyranose (1, R = CH_3CO) with Osmic Acid

(a) In Pyridine

Compound **1** (R = CH_3CO) was treated with osmic acid by the procedure employed for the similar oxidation of **1** (R = H) except that the solution obtained after addition of sodium bisulfite was continuously extracted with chloroform for 48 h. The extract was dried (magnesium sulfate) and freed from solvent at 45° under vacuum. The syrupy residue (crude yield, 96%) showed two closely situated spots on a thin layer chromatogram (solvent, 3% methanol in dichloromethane). The 60 MHz p.m.r. spectrum in deuteriochloroform showed two anomeric proton signals in the area ratio 65:35.

This syrup was separated into its two components by column chromatography using 3% methanol in dichloromethane as eluent. The first fraction (15 ml) was discarded (a gum). The second fraction (50 ml) gave a solid later identified as **3** (R = CH_3CO, R′ = H). The last fraction (200 ml) gave a mixture of **2** and **3** (R = CH_3CO, R′ = H) as a syrup (640 mg). A solution of this syrup in 15 ml of dichloromethane, seeded with the solid obtained from the second fraction, deposited all of the *2-O-acetyl-1,6-anhydro-β-DL-galactopyranose* (**3**, R = CH_3CO, R′ = H). Total yield, 31.5%; m.p. after sublimation at 130–135° at 0.1 mm, 144–145°.

Anal. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.92. Found: C, 46.93; H, 5.55.

The i.r. spectrum (KBr pellet) showed bands at 3470 and 3390 (OH) and at 1715 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in trifluoroacetic acid (a solvent required to effect solution and which had no deleterious effect on the solute) showed signals at τ 4.25

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

for H-1 (singlet, $w/2 \sim 3.5$ Hz); 4.85 for H-2 (singlet, $w/2 \sim 4$ Hz); 5.50–5.80 for H-3 and -4 (multiplet); 5.10–5.30 for H-5 (multiplet, $J_{5,6exo} \sim 4$ Hz); 5.39 for H-6*endo* (doublet, $J_{6exo,6endo} \sim 8.0$ Hz); 6.08 for H-6*exo* (quartet showing long range coupling with H-1 and -4*exo*); and 7.76 for CH_3 (singlet).

Acetylation of **3** (R = CH_3CO, R′ = H) gave the triacetate **3** (R = R′ = CH_3CO) as a crystalline solid (needles from dichloromethane–pentane) melting at 114–115° and completely identical with the triacetate obtained above. Hydrolysis of this triacetate gave α,β-DL-galactose, also identical with the α,β-DL-galactose obtained above.

The dichloromethane mother liquor obtained after removal of the 2-*O*-acetyl-1,6-anhydro-β-DL-galactopyranose, was freed from solvent to provide a syrup (crude yield 60%) which gave only one spot on a thin layer chromatogram (solvent, 3% methanol in dichloromethane). Attempts to crystallize this failed, hence it was purified by distillation; b.p. 134–135° at 0.5 mm. Analysis agreed with the substance being a mixture of *2-*, *3-*, and *4-O-acetyl-1,6-anhydro*-β-DL-*allopyranose* (**2**).

Anal. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.92. Found: C, 47.09; H, 6.07.

The i.r. spectrum in carbon tetrachloride showed absorption at 3565 and 3605 (shoulder) (OH) and at 1752 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in deuteriochloroform possessed signals at τ 4.54 for H-1 (poorly resolved narrow multiplet, $w/2 \sim 6$ Hz); 5.10–5.40 for H-2, -3, and -4 (complex multiplets); 5.40–5.60 for H-5 (multiplet); 6.15–6.50 for H-6*exo* and -6*endo* (multiplets); 7.98–8.02 (three singlets for CH_3).

Acetylation of a portion of this syrupy mixture gave crystalline (from dichloromethane–pentane) *1,6-anhydro-2,3,4-tri-O-acetyl*-β-DL-*allopyranose* (**2**, R = R′ = CH_3CO) melting at 128–129° and identical with the 1,6-anhydro-DL-*allo* triacetate obtained above.

Hydrolysis of the remainder of the syrupy mixture of monoacetates gave α,β-DL-*allose* (**4**, R = R′ = H) identical with that obtained above.

(b) In Dioxane

Compound **1** (R = CH_3CO) (0.67 g) was treated for 48 h with osmic acid according to the procedure used for the oxidation of **1** (R = H) above. The 60 MHz p.m.r. spectrum in deuteriochloroform of the syrup obtained (crude yield, 0.8 g, 99%) showed it to be a mixture of **2** (R = CH_3CO, R′ = H) and **3** (R = CH_3CO, R′ = H) in the ratio 9:1. This crude mixture was acetylated as usual and the two triacetates separated by column chromatography as described for the mixture of triacetates obtained following the osmic acid reaction with **1** (R = H) in pyridine. The products **2** (R = R′ = CH_3CO) and **3** (R = R′ = CH_3CO), obtained in yields of 88 and 7.5% respectively, were identical to those obtained above from the acetylation of the products obtained from the osmic acid reaction with **1** (R = H) in pyridine.

1,6-Anhydro-2-O-methyl-3,4-dideoxy-β-DL-*erythro-hex-3-enopyranose* (**1**, *R = CH_3*)

The general procedure for methylation (12) was modified as follows. A solution of **1** (R = H) (2.65 g, 0.02 mol) in 50 ml of dry 1,2-dimethoxyethane (DME) was added dropwise over a 1 h period to a well-stirred mixture of 0.8 g (0.04 mol) of sodium hydride and 5.68 g (0.04 mol) of methyl iodide in 50 ml of dry DME. The reaction flask was kept in a water bath at 20° to avoid temperature rise. The mixture was stirred for 3 h at 20°, then stirred and heated under reflux for an additional hour. The bulk of the solvent (75 ml) was removed by fractional distillation and the cooled residue was diluted with ether to precipitate the sodium iodide. Filtration and subsequent removal of solvent from the filtrate by fractional distillation gave a residue which was purified by distillation and afforded 2.20 (77.5%) of colorless liquid **1** (R = CH_3) boiling at 53–55° at 0.1 mm.

Anal. Calcd. for $C_7H_{10}O_3$: C, 59.14; H, 7.09. Found: C, 59.08; H, 7.02.

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.47 for H-1 (narrow triplet, $w/2 \sim 4.5$, $J_{1,2} \sim 1.0$ Hz); 6.74 for H-2 (doublet of triplets, $J_{2,3} \sim 3.5$; $J_{2,4} \sim 1.0$ Hz); 4.25 for H-3 (doublet of quartets, $J_{3,4} \sim 10$, $J_{1,3} \sim 1.0$ Hz); 3.81 for H-4 (quartet of doublets, $J_{4,5} \sim 4.7$ Hz); 5.30–5.42 for H-5 (multiplet); 6.35–6.45 for H-6*exo* and -6*endo* (narrow multiplet, $w/2 \sim 4$ Hz); 6.61 for OCH_3 (singlet).

Reaction of 1,6-Anhydro-2-O-methyl-3,4-dideoxy-β-DL-*erythro-hex-3-enopyranose (**1**, R = CH_3) with Osmic Acid*

(a) In Pyridine

Compound **1** (R = CH_3) (3.0 g, 0.0118 mol) was oxidized with osmic acid in pyridine as described for the oxidation of **1** (R = CH_3CO). The syrup obtained (crude yield 2.08 g, ~100%) showed two closely situated spots on a thin layer chromatogram (solvent, 10% methanol in dichloromethane). The 60 MHz p.m.r. spectrum of this crude syrup showed two anomeric proton signals in the area ratio of 3:1.

The two components were separated by column chromatography using 10% methanol in dichloromethane as eluent. From the *first fraction* was obtained a solid which, after sublimation at 135–140° at 0.1 mm, formed needles which melted at 124–125°; yield of *1,6-anhydro-2-O-methyl*-β-DL-*galactopyranose* (**3**, R = CH_3, R′ = H) was 1.20 g, 58%.

Anal. Calcd. for $C_7H_{12}O_5$: C, 47.74; H, 6.87. Found: C, 47.98; H, 6.80.

The 100 MHz p.m.r. spectrum in trifluoroacetic acid showed signals at τ 4.21 for H-1 (broad singlet, $w/2 \sim 4$, $J_{1,2} \sim 1.5$ Hz); 6.16 for H-2 (narrow multiplet, $w/2 \sim 3.5$ Hz); 5.52–5.65 for H-3 and -4 (multiplet); 5.20–5.35 for H-5 (multiplet); 5.45 for H-6*endo* (doublet, $J_{6exo,6endo} \sim 8.5$ Hz); 6.14 for H-6*exo* (quartet, $J_{5,6exo} \sim 5.0$ Hz); 6.37 for CH_3 (singlet).

The i.r. spectrum in Nujol had a broad band at 3350 cm^{-1} (OH).

Acetylation of **3** (R = CH_3, R′ = H) as usual gave *1,6-anhydro-2-O-methyl-3,4-di-O-acetyl*-β-DL-*galactopyranose* (**3**, R = CH_3, R′ = CH_3CO) which from ether–pentane formed colorless needles melting at 102–103°; yield, 98%.

Anal. Calcd. for $C_{11}H_{16}O_7$: C, 50.77; H, 6.20. Found: C, 50.78; H, 6.00.

The 100 MHz p.m.r. spectrum in deuteriochloroform showed signals at τ 4.57 for H-1 (triplet, $J_{1,2} \sim 1.5$, $J_{1,3} \sim 1.2$ Hz); 6.77 for H-2 (triplet, $J_{2,3} \sim 1.5$ Hz); 4.73–4.90 for H-3 (multiplet); 4.60–4.73 for H-4 (multiplet, $J_{4,5} \sim 4.5$, $J_{4,6exo} \sim 1.5$ Hz); 5.50–5.65 for H-5

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(multiplet, $J_{5,6exo} \sim 5.0$ Hz); 5.70 for H-6*endo* (doublet, $J_{6endo,6exo} \sim 7.0$ Hz); 6.31 for H-6*exo* (complicated quartet); 6.60 for OCH_3 (singlet); 8.00 and 8.06 each a singlet for CH_3).

The i.r. spectrum in chloroform showed bands at 1765 (shoulder) and 1745 cm^{-1} for C=O.

The *second fraction* from the chromatographic separation above provided 400 mg of syrup which was a mixture of **2** and **3** (R = CH_3, R′ = H) as shown by the p.m.r. spectrum and by t.l.c. This was acetylated as usual and gave a solid which showed two spots on a thin layer chromatogram (solvent, ethyl acetate). Column chromatography, with ethyl acetate as eluent, provided from the first fraction the compound *1,6-anhydro-2-O-methyl-3,4-di-O-acetyl*-β-DL-*galactopyranose* (**3**, R = CH_3, R′ = CH_3CO) whose colorless needles from ether–pentane melted at 102–103°; yield, 74%. This was identical with the product obtained from the acetylation of pure **3** (R = CH_3, R′ = H) above. The second fraction from the chromatography of this acetylated mixture was *1,6-anhydro-2-O-methyl-3,4-di-O-acetyl*-β-DL-*allopyranose* (**2**, R = CH_3, R′ = CH_3CO) whose fine needles from ether–pentane melted at 133–134°, yield, 23%.

Anal. Calcd. for $C_{11}H_{16}O_7$: C, 50.77; H, 6.20. Found: C, 50.78; H, 6.00.

The i.r. spectrum in chloroform showed a band at 1750 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in deuteriochloroform had signals at τ 4.45 for H-1 (doublet, $J_{1,2} \sim 2.5$ Hz); 6.45–6.57 for H-2 masked by the signal for OCH_3 (narrow multiplet); 4.82–4.92 for H-3 and -4 (multiplet, $J_{2,3} \sim 3$, $J_{4,5} \sim 1.0$ Hz); 5.33–5.45 for H-5 (multiplet); 6.05–5.35 for H-6*exo* and -6*endo* (multiplet, $J_{6exo,\ 6endo} \sim$ 8.5 Hz); 6.48 for OCH_3 (singlet); 7.94 and 8.06, each a singlet for CH_3.

The *third fraction* from the chromatographic separation of the products of osmic acid oxidation of **1** (R = CH_3) in pyridine gave a viscous oil (crude yield, 16.3%) which was distilled in a sublimation apparatus to provide *1,6-anhydro-2-O-methyl*-β-DL-*allopyranose* (**2**, R = CH_3, R′ = H) as a colorless solid, m.p. 99–100°.

Anal. Calcd. for $C_7H_{12}O_5$: C, 47.73; H, 6.87. Found: C, 47.97; H, 6.79.

The i.r. spectrum (film) showed a broad band at 3400 cm^{-1} (OH).

The 100 MHz p.m.r. spectrum in trifluoroacetic acid had signals at τ 4.09 for H-1 (doublet, $J_{1,2} \sim 2.5$ Hz); 6.20–6.33 for H-2 (multiplet, $J_{2,3} \sim 4.0$ Hz); 5.72–5.80 for H-3 and -4 (multiplet, $J_{4,5} \sim 1.2$ Hz); 5.02–5.15 for H-5 (multiplet); 5.95–6.05 for H-6*exo* and -6*endo* (multiplet, $J_{6exo,6endo} \sim 3.0$ Hz); 6.40 for OCH_3 (singlet).

(b) In Dioxane

Compound **1** (R = CH_3) (1.68 g) was treated with osmic acid for 24 h according to the procedure described for the oxidation of **1** (R = H) above. The crude product was a colorless syrup (2.04 g, 98%). The p.m.r. spectrum in deuteriochloroform showed it to be a mixture of **2** (R = CH_3, R′ = H) and **3** (R = CH_3, R′ = H) in the approximate ratio of 4:3. Separation of these compounds was accomplished by column chromatography as for the case of the products of the osmic acid reaction with **1** (R = CH_3) in pyridine above. Overall yield of **2** (R = CH_3, R′ = H), 1.01 g, 49%, and of **3** (R = CH_3, R′ = H) 0.95 g, 46%.

2-O-Methyl-α,β-DL-*allose* (**4**, R = CH_3, R′ = H)

Hydrolysis of 0.8 g of **2** (R = CH_3, R′ = H) by the method used to hydrolyze **2** (R = R′ = CH_3CO) above gave a syrup (crude yield, 0.85 g, 96%) which was purified by column chromatography using chloroform methanol (1:1) as eluent. The resulting viscous oil gave *2-O-methyl*-α,β-DL-*allose* (**4**, R = CH_3, R′ = H) as colorless needles from methanol–ether melting at 111–113°.

Anal. Calcd. for $C_7H_{14}O_6$: C, 43.30; H, 7.27. Found: C, 43.18; H, 7.24.

The 100 MHz p.m.r. spectrum in deuterium oxide, obtained after **4** (R = CH_3, R′ = H) had been in solution for 48 h, showed four anomeric proton signals which indicated the presence in solution of α-furanose and -pyranose as well as the β-furanose and -pyranose structures in the approximate area ratio, at equilibrium, of 1.0:2.6:1.0:11.0 respectively. The spectrum showed signals at τ 4.11 for H-1 (α-furanose isomer, doublet, $J_{1,2} \sim 2.5$ Hz); 4.30 for H-1 (β-furanose isomer, doublet, $J_{1,2} \sim 4.0$ Hz); 4.56 for H-1 (α-pyranose isomer, doublet, $J_{1,2} \sim 4.0$ Hz); 4.87 for H-1 (β-pyranose isomer, doublet, $J_{1,2} \sim 8.0$ Hz); 6.74 for H-2 (β-pyranose, doublet of doublets, $J_{2,3} \sim 3.0$, $J_{1,2} \sim 8.0$ Hz); 5.38 for H-3 (β-pyranose, triplet, $J_{3,4} \sim 3.0$ Hz); 5.16 for OH (broad singlet); 6.42 for OCH_3 (singlet); 5.90–6.20 (complex multiplet for remaining protons).

2-O-Methyl-α,β-DL-*allose Tetraacetate* (**4**, R = CH_3, R′ = CH_3CO)

Acetylation of **4** (R = CH_3, R′ = H) (0.36 g) with acetic anhydride and pyridine as usual gave 0.63 g (98% crude yield) of solid *2-O-methyl*-α,β-DL-*allose tetraacetate* (**4**, R = CH_3, R′ = CH_3CO) which formed colorless needles from dichloromethane–pentane, melting at 125–126°.

Anal. Calcd. for $C_{15}H_{22}O_{10}$: C, 49.72; H, 6.12. Found: C, 49.62; H, 6.08.

The i.r. spectrum in chloroform showed strong absorption at 1755 cm^{-1} (C=O).

The 100 MHz p.m.r. spectrum in deuteriochloroform indicated that the tetraacetate was a single compound, the β-pyranose isomer. The t.l.c. also indicated only one compound. The p.m.r. signals occurred at τ 4.12 for H-1 (doublet, $J_{1,2} \sim 8.0$ Hz); 6.65 for H-2 (quartet, $J_{1,2} \sim 8.0$, $J_{2,3} \sim 3.0$ Hz); 4.18 for H-3 (triplet, $J_{3,4} \sim 3.0$ Hz); 5.00–5.20 for H-4 (multiplet, $J_{4,5} \sim 10$ Hz); 5.60–6.00 for —CH_2— and H-5 (multiplet); 6.61 for OCH_3 (singlet); 8.15 and 8.20 each a singlet for CH_3; 8.07 a singlet for two CH_3.

2-O-Methyl-α,β-DL-*galactose* (**5**, R = CH_3, R′ = H)

Hydrolysis of 0.8 g of **3** (R = CH_3, R′ = H) with 15 ml of 1 *N* hydrochloric acid containing 5 ml of dioxane according to the procedure for the hydrolysis of **2** (R = R′ = CH_3CO) gave *2-O-methyl*-α,β-DL-*galactopyranose* (**5**, R = CH_3, R′ = H) as a syrup. Purification by column chromatography, using methanol–chloroform (1:2) as eluent, produced a solid which crystallized from ethanol–ether as colorless prisms melting at 140–141°; yield, 695 mg, 80%.

Anal. Calcd. for $C_7H_{14}O_6$: C, 43.30; H, 7.27. Found: C, 43.27; H, 7.04.

The 100 MHz p.m.r. spectrum in deuterium oxide was identical to that of an authentic sample of 2-*O*-methyl-α,β-D-galactopyranose in the same solvent.

We are grateful to the National Research Council of Canada for financial support which assisted us in the pursuit of this work. We thank Professor S. J. Angyal of the University of New South Wales, Kensington, N.S.W., Australia for the p.m.r. spectrum of α,β-D-allose and Professor R. U. Lemieux and Dr. T. L. Nagabhushan of this Department for a sample of 2-*O*-methyl-α,β-D-galactose.

Radiation Effects with a Model Lipid Membrane[1]

A. PETKAU

Medical Biophysics Section, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba

Received November 16, 1970

A cell is described that permits a model phospholipid membrane and the two adjacent aqueous compartments to be irradiated with a collimated beam of X-rays. During a 2 h irradiation a marked increase in $[H^+]$ in the aqueous phases is observed. A protonmotive force, given by the H^+ Nernst potential, is generated when one compartment only is irradiated or when both compartments separated by a membrane made structurally asymmetric by the adsorption of alamethicin, are irradiated equally.

The results of irradiations in N_2O, N_2, and O_2 indicate that the membrane scavenges the superoxide O_2^-. The effect is discussed in terms of a clearing field that is derived from the potential at the membrane interfaces.

La cellule décrite permet d'irradier une membrane phospholipidique modèle et ses deux compartiments aqueux par un faisceau de rayons-x munie d'un collimateur. Durant les deux heures d'irradiation, une augmentation marquée en $[H^+]$ a été observée dans les phases aqueuses. Une force protomotrice, obtenue par le H^+ du potentiel de Nernst, est générée quand un compartiment seulement est irradié ou lorsque les deux compartiments, séparés par une membrane structurellement a symétrique constituée d'alaméthicine, sont également irradiés.

Les résultats des irradiations dans le N_2O, N_2, et O_2 indiquent que la membrane élimine le superoxyde O_2^-. L'effet est discuté en terme de l'éclaircissement du champ obtenu par la différence de potentiel aux interfaces de la membrane.

Canadian Journal of Chemistry, 49, 1187 (1971)

Introduction

The response of irradiated membrane systems has been of interest over a considerable number of years (1–4) but the properties examined are few. Among the functional properties studied, radiation-induced permeability changes to ions have received much attention (3–8). They have been mimicked with agents known to react with sulfhydryl groups (9, 10) or largely prevented by the radioprotective action of cystamine, a compound known to react with the hydrogen atom (H•), hydroxyl radical (•OH), and possibly with the superoxide radical (O_2^-) at near neutral p*H* (11). Significantly, the radioprotective effect of cystamine was observed even if it were largely unbound to the irradiated membranes. This suggests that the compound reacts with the radicals, formed in the radiolysis of the extracellular water, before they reach the membrane surface to react with it.

The ability to scavenge radicals from a distance raises the interesting possibility that the membrane may influence which radicals reach it preferentially. The derivative force associated with the potential of membrane interfaces may exert an effect in this regard as far as any charged radicals are concerned. Of the radicals generated during the radiolysis of aerated water that are known to react with sulfhydryl groups, namely H•, •OH, the hydrated electron (e_{aq}^-), and O_2^- (12), only the latter two might conceivably be influenced in this manner. Since the potential of the interface nearest the bulk aqueous phase is positive (13) these radical anions may be accelerated toward the membrane, thus overcoming a limitation of diffusion-controlled reactions. By virtue of its property of acting over a distance, the membrane-associated electric field may be expected to produce an amplified effect not seen otherwise. In this communication irradiation experiments at near neutral p*H* on a model phospholipid membrane – water system are described and the observed p*H* changes are explained in terms of electric field effects on the charged free radicals produced during the radiolysis of water.

[1]A.E.C.L. Contribution No. 233/70.

Experimental Procedure

Irradiation Cell

The cell in which the membrane was irradiated is shown in Fig. 1. It consisted of two square compartments, each 1 cm deep and containing approximately 10 ml of double distilled water, separated by a 0.16 cm thick Teflon septum. At a level of 0.6 cm from the surface of the water a 0.2 cm diameter aperture for membrane location was milled in a portion of the septum thinned to a thickness of 0.013 cm. Each compartment was fitted with a combination p*H* electrode in a position that was well removed from the collimated direct X-ray beam. LiF

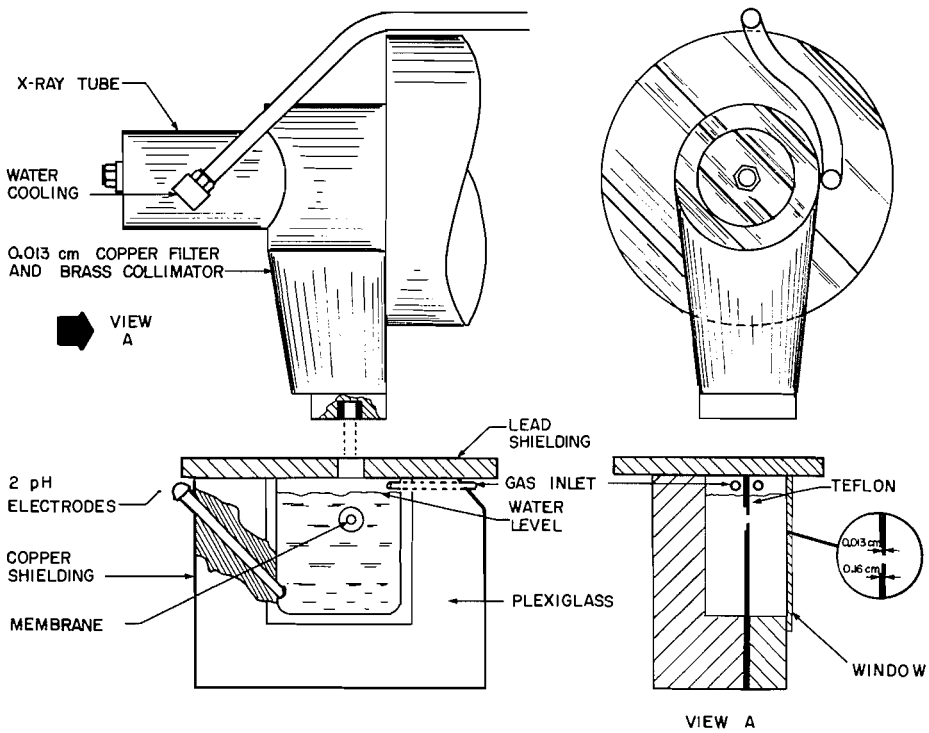

FIG. 1. Apparatus for irradiating a model phospholipid membrane.

dosimetry at the position of the p*H* bulbs indicated that a dose rate of 0.7 rad/min occurred at the electrodes from scattered radiation. Calibration measurements made with standard p*H* solutions before and after a 2 h irradiation showed that the performance of the electrodes was not measurably affected. The cell and the electrodes were fitted into a copper case that was grounded electrically. The copper case had two small rectangular openings, one over the window, so that the membrane could be observed through a low power microscope (not shown), and the other over that part of the top where the X-ray beam entered the cell through a suitable hole in a 0.63 cm thick lead shield. The cell was aligned with the X-ray tube in a position that ensured that the membrane aperture lay in the path of the collimated beam. The temperature of the water in the cell was kept at 37 °C by means of the heating stage (not shown) that supported it. A large, light-tight lead box was built around the X-ray tube and irradiation cell.

Membrane Formation

The composition of the phospholipid extract has been described previously (14). The reactivity of chloroform and methanol with the primary radicals produced in the radiolysis of water can be substantial (15) and for this reason the use of a chloroform–methanol solvent system was avoided. Instead, 15–19 mg of the phospholipid extract was dissolved in the apolar hydrocarbon, tetradecane, to form the membrane solution. The solution was applied under water to the aperture with a fine sable-hair brush as previously described (16). The black, bimolecular phospholipid membrane then developed in due course by a thinning process (16).

Membrane Irradiation

As shown in Fig. 1 radiation was obtained from a water-cooled X-ray tube (100 KVP, 9.5 mA, 0.013 Cu filter, half-value layer 0.38 cm water, and brass collimator) positioned directly above the membrane. The dose rate at the surface of the water for a source-target distance of 8.4 cm was 500 rad/min and corresponded to a dose rate of about 130 rad/min in the water at a level opposite the center of the membrane. The thin membrane (~100 Å) was partially protected from the direct beam by an intervening portion of the much thicker Teflon septum for which an attenuation factor of 19.5 was calculated. Therefore, the estimated dose rate at the geometric center of the membrane from the direct beam was reduced to about 26 rad/min. The actual dose rate would be somewhat higher because of scattered radiation distributed in and about the membrane. Nevertheless, the difference by a factor of 5 in the dose rates to the water at the level of the geometric center of the membrane and the membrane itself would be maintained to a first approximation since it is due to the attenuation of the direct beam in the Teflon septum. The difference was desirable because it permitted the production of primary radicals from the radiolysis of water in numbers adequate for an effect to be observed and spared the membrane to a certain degree from the direct effects of radiation.

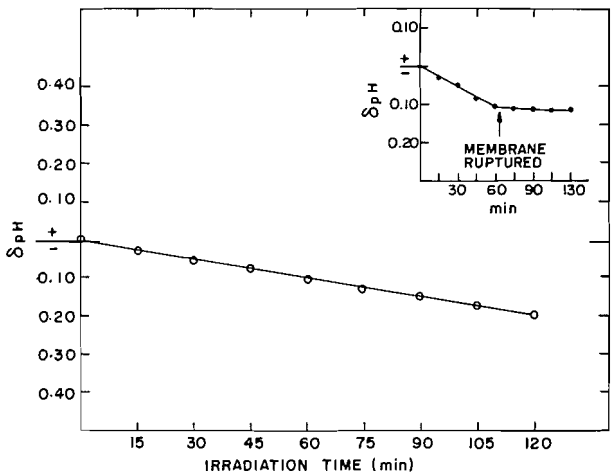

FIG. 2. Decrease in p*H* of aerated water in either compartment during a 2 h irradiation in the presence of a phospholipid membrane. Both compartments irradiated equally. *Inset*: Decrease in p*H* of aerated water in either compartment during a 2 h irradiation. The membrane ruptured at the 63 min mark.

In addition, collimation of the beam directed much of the radiation energy into a column of water nearest the membrane. Distribution of the H^+ by diffusion throughout the aqueous phase was permitted and may have produced a dilution effect. The absence of stirring was intentional in order to avoid interference with diffusion patterns set up naturally in the presence and absence of the membrane.

pH Measurement

During an irradiation the p*H* measurements were made every 15 min to a precision of 0.001 p*H*. The high resistance of the membrane ($\sim 10^{10}$ ohms) largely isolated the two aqueous compartments electrically and permitted the use of the two reference electrodes for the detection of any transmembrane potentials. A multi-pole switching arrangement was used to connect the two reference electrodes as desired to an electrometer amplifier (input resistance 10^{14} ohms) for the voltage measurements.

Results

Most of the irradiations were carried out on membranes formed by the first application of the lipid solution. In some duplicate runs the membrane formed after the second or third application was used but the change in p*H* was the same. As Fig. 2 shows, irradiation of the phospholipid membrane – water system produced in either aqueous compartment a linear decrease in p*H* with dose. Since the p*H* of both compartments was constant prior to irradiation the change is significant and indicates a first order reaction. It is equivalent to a net production of approximately 10^{15} H^+ and is about an order of magnitude greater than the total number of phospholipid and cholesterol molecules in the membrane. It seemed unlikely, therefore, that the change in p*H* was caused by radiation effects within the membrane.

An alternative explanation that the excess lipid material, left on the Teflon septum or in the aqueous phases, produced the change in p*H* was discounted for the following reasons. When a membrane was formed in the usual way and then ruptured prior to irradiation a different result was obtained. In this situation, as well as others, where two, three, or more dozens of membranes were formed and ruptured, the p*H* decreased at first and then increased, Fig. 3, in a manner that closely paralleled the p*H* response of aerated water, irradiated at the same dose rate.

Additional support was obtained by shielding about half the thickness of the septum and all of one aqueous compartment from the direct beam. In this situation the membrane and the shielded compartment received scattered radiation only and as Fig. 4 shows, the p*H* change in the two compartments was quite different. In the compartment exposed to the direct beam the p*H* change was similar to the result shown in Fig. 2 and was much more marked than in the other compartment which received scattered radiation only. The H^+ concentration gradient ΔpH generated across the membrane by the unequal radiation field gave rise to a trans-

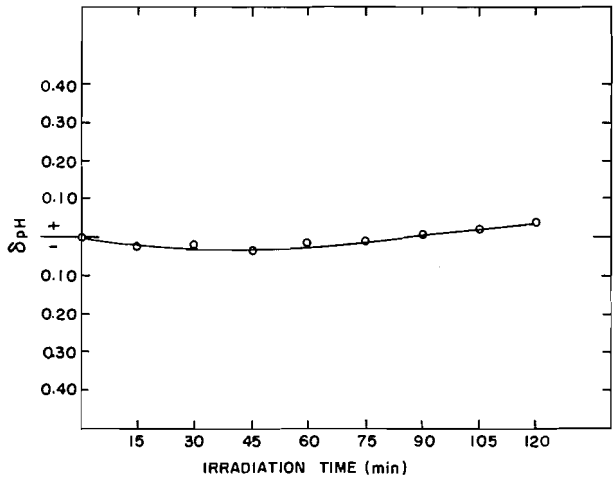

FIG. 3. Change in pH of aerated water in either compartment during a 2 h irradiation in the presence of phospholipid material left from rupturing one or more membranes prior to irradiation.

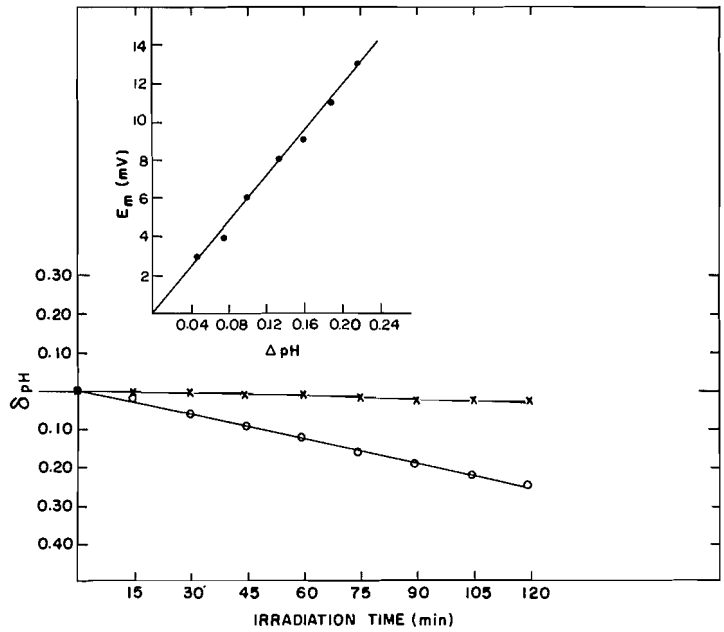

FIG. 4. Change in pH of aerated water in the irradiated (o--o) and shielded (x--x) compartments in the presence of a phospholipid membrane. *Inset*: Nernst potential (E_m) *vs.* the H^+ concentration gradient (ΔpH) that developed across the membrane during the unequal irradiation of the two aqueous compartments. E_m/pH unit = 60 mV.

membrane potential, E_m, as shown in the inset of Fig. 4. From the slope of the line, E_m/pH unit = 60 mV, a value for the H^+ Nernst potential that is satisfactorily close to the expected at 37 °C.

Finally, some membranes ruptured in the course of a 2 h irradiation. It was found that the decrease in pH changed abruptly once the membrane collapsed (Fig. 2, inset). The result confirms that the decrease in pH is due to the presence of the membrane and that it does not depend on any lipid material, sorbed to the Teflon septum or dispersed in the aqueous phases.

The composition of the phospholipid membrane may readily be altered by the adsorption

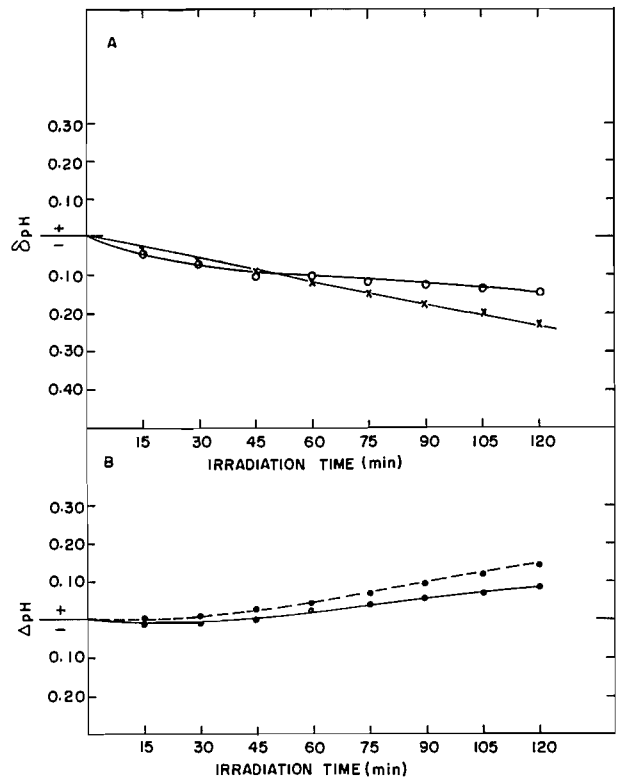

FIG. 5. (A) Change in pH of aerated water on the modified (o--o) and unmodified (x--x) side of a phospholipid membrane. The membrane was modified on one side with alamethicin (2×10^{-8} g/ml) and both sides were irradiated equally.

(B) The ΔpH (solid line) across the membrane obtained by plotting the difference between the two graphs of Fig. 5A. Positive values of ΔpH indicate δpH (modified side) < δpH (unmodified side). The ΔpH (broken line) corrected for effect on δpH of unbound alamethicin.

of a water-soluble cyclopeptide. If it is added to one aqueous compartment only, a structurally asymmetric membrane may be formed. Equal irradiation of both aqueous phases may then show up a differential effect on pH. Figure 5A shows the result of such an experiment. It is seen that the change in pH of the water on the side modified with alamethicin[2] is quite different from that on the unmodified side. The resultant pH gradient across the membrane is shown in Fig. 5B, solid line, where (+) values of ΔpH indicate the decrease in pH on the modified side was smaller than that on the other. It may be adjusted for the effect on pH of unavoidably irradiating the residual unbound alamethicin in solution. The corrected ΔpH, shown in Fig. 5B, broken line, is substantial and further emphasizes a role for the membrane interfaces in mediating the radiation-induced reactions.

Taken together the results of Figs. 2–5 suggest that the radiation-induced reactions in the aqueous phase were influenced in some way by the organization of the phospholipid material into a membrane. Following the initial ionization by radiation, the major radiochemical reactions in aerated water involve $\cdot OH$, H_3O^+, and e_{aq}^- (18). H_2O_2 and O_2^- are subsequently produced by reactions 1 and 2, respectively (15, 19). In addition, the hydrated electron may react with itself or with $\cdot OH$, $H\cdot$, H_2O_2, and H_2O to produce OH^- (15, 19). Except for the case of H_2O, the rate constants of these reactions are

[1] $$\cdot OH + \cdot OH \rightarrow H_2O_2$$

[2] $$e_{aq}^- + O_2 \rightarrow O_2^-$$

[2]Alamethicin, a cyclopeptide antibiotic derived from Trichoderma viride, was kindly made available by the UpJohn Company of Canada. Its amino acid composition has been given (17) as $(GluN)_2(Glu)_1(Pro)_2(Gly)_1$-$(Ala)_2(Dimethyl\ ala)_8(Val)_2(Leu)_1$. The amount added was 2×10^{-8} g/ml.

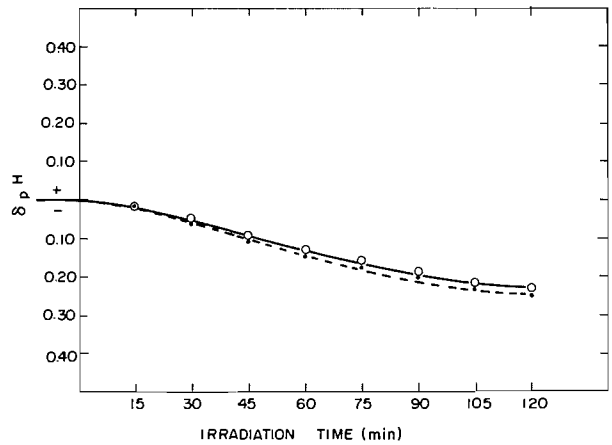

FIG. 6. The radiation-induced pH change in N_2-saturated water in the presence (solid line) and absence (broken line) of a phospholipid membrane.

within the diffusion-controlled range (15, 20). To account for the observed net production of H^+ in the presence of the membrane one might consider that a large number of OH^- was sorbed to the membrane or that the H_2O_2, generated by reaction 1, was responsible. The first possibility requires the membrane to sorb an inordinate number of OH^- (to a concentration of about 50 M) and may therefore be discounted. The second alternative can also be excluded because the addition of H_2O_2 to the aqueous phase in an amount 10^3 times that generated over the course of a 2 h irradiation decreased the pH by only 0.03 of a unit. Therefore, another explanation appears to be required, namely that the membrane affects the production of OH^- in the aqueous phase.

The results shown in Figs. 2–5 were obtained in aerated water and may be complicated by reactions involving O_2 and CO_2. These difficulties are obviated by saturating the water at 1 atm with nitrogen or nitrous oxide. The irradiation data are shown in graphical form in Figs. 6 and 7, respectively. They represent well-known results from the radiation chemistry of water (19, 21) and demonstrate the absence of a membrane effect if no oxygen is present.

In oxygen saturated water the e_{aq}^- reacts rapidly with O_2 by reaction 2 to form the superoxide radical anion O_2^-. Figure 8 shows the result obtained in this situation both with and without the membrane. The decrease in pH is significantly less in the absence of the membrane than in its presence. For instance, the probability that the difference between the two points, corresponding to an irradiation time of 75 min, might have occurred by chance is less than 0.001. The greater decrease in pH in the presence of the membrane may be accounted for if it is considered that the O_2^- is scavenged by the membrane. On this basis reaction 3 (22) would

$$[3] \qquad O_2^- + \cdot OH \rightarrow OH^- + O_2$$

be competitively inhibited, resulting in a decrease in the relative number of OH^- produced. Reaction 3 is fairly fast ($8.0 \times 10^9\ M^{-1}\ s^{-1}$) suggesting that the O_2^- scavenging activity of the membrane must also be quite fast to be competitive.

Discussion

Diffusion of the O_2^- radical to the phospholipid membrane must be one of the first factors to be considered as a basis for the effect of the membrane on the pH during irradiation. The distance over which the radical will diffuse by random walk is determined by its half-life and its diffusion constant. For the case of O_2^- in oxygenated water at near neutral pH (6.65) its half-life may be estimated to be 28 ms (23). The

TABLE 1. Root mean square diffusion distance (χ) within one half-life by random walk

Radical	Half-life (ms)	Diffusion constant (cm^2/s)	χ (μm)
O_2^-	28*	1.59×10^{-5}†	4.5

*In oxygenated water at pH 6.65 (ref. 23).

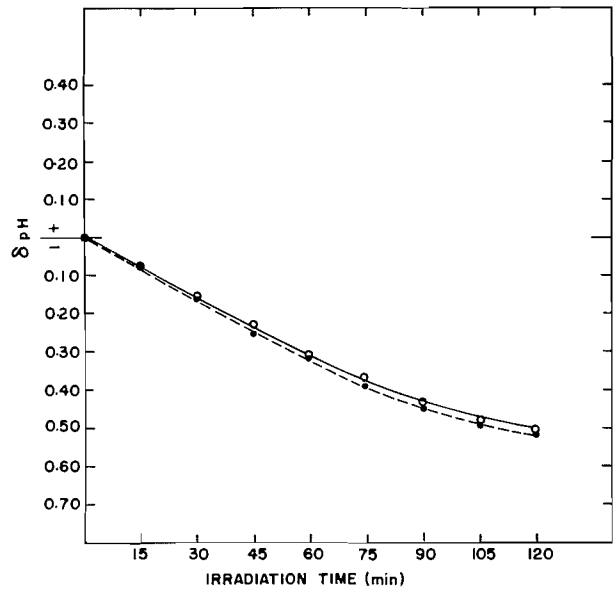

FIG. 7. The radiation-induced pH change in N_2O-saturated water in the presence (solid line) and absence (broken line) of a phospholipid membrane.

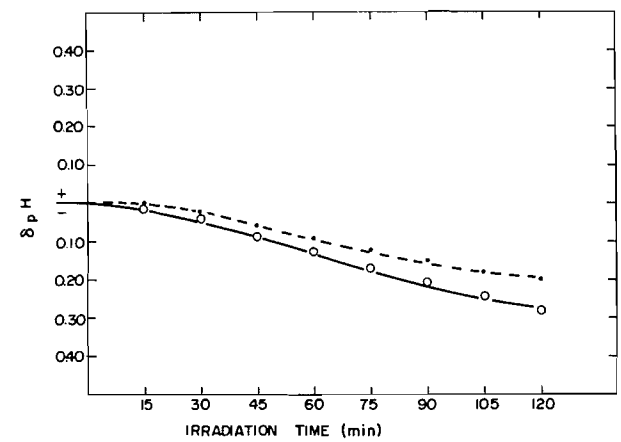

FIG. 8. The radiation-induced pH change in O_2-saturated water in the presence (solid line) and absence (broken line) of a phospholipid membrane.

diffusion constant of O_2^- may be calculated from its known mobility (22) and is equal to 1.59×10^{-5} cm^2/s at 21 °C. The root mean square diffusion distance of O_2^- by random walk for $P(t) \geqslant 0.99$, where $P(t)$ is the probability that the particular O_2^- still exists after one half-life, is then 4.5 μm, Table 1. If the diffusion distance is measured in a direction perpendicular to the plane of the membrane then it signifies the depth of the layer of water, adjacent to the membrane, from which the radicals may reach it within one half-life by diffusion. Although the calculated diffusion distance is substantial, it appears to be insufficient to account for the net production of H^+, indicated by the decrease in pH in Figs. 2 and 8. This is true if all the O_2^- generated within this distance of the membrane, diffused to it and reacted with it in a manner that produced neither H^+ or OH^-. From geometric and statistical considerations, however, it is clear that not all the radicals within the layer will reach the mem-

brane since at least an equal number must be expected to diffuse in the opposite direction under the experimental conditions. The thickness of the water layer can, of course, be readily increased at the expense of decreasing the value of $P(t)$.

The number of charged radicals, such as O_2^-, that reach the membrane from a given distance may be increased by introducing a clearing field. The derivative force of the potential associated with phospholipid membrane interfaces may serve in this capacity. The interface potential for an idealized phospholipid membrane has been described (13) and it was shown to be strongly positive in a plane near the aqueous phase and in fact extended into it for a considerable distance, especially in distilled water when ionic screening is minimal. From the equation $v = E\mu$, where v = velocity of the charged species in an electric field (cm/s), E = electric field (V/cm), and μ = mobility of the charged species ($cm^2/V\ s$), the range of the charged species within one half-life may be calculated if the potential, from which the electric field is derived, is known as a function of distance into the aqueous phase. In Table 2 the results of these calculations are tabulated for O_2^-, assuming that the potential to a first approximation falls off exponentially at rates given by the halving distances in the first column. A half-life of 28 ms for O_2^- was taken as being appropriate for the experimental conditions (23) and its mobility at 21 °C has been given as $65^{\pm 8}$ cm^2 $ohms^{-1}$ (22), which converts to a value of 0.67×10^{-3} $cm^2/V\ s$.

Although the maximum range as given in Table 2 is larger than the diffusion distance over the same period of time (Table 1) the most important difference is that the range defines the thickness of the water layer nearest the membrane within which most of the O_2^- generated are collected at the membrane. The collection efficiency is therefore much improved over the diffusion case, considered earlier, where at least half of the number generated will diffuse away from the membrane. The range may be extended by increasing the number of half-lives considered in the calculation.

TABLE 2. Effect of membrane interface potential on the range of the superoxide radical (O_2^-) within one half-life

Halving distance for interface potential (cm)	Electric field $E = d\psi/dx$* (V/cm)	Range (μm) O_2^-
10^{-6}	2.1×10^4	0.20
10^{-5}	2.1×10^3	1.24
10^{-4}	2.1×10^2	5.78
10^{-3}	21	6.25
10^{-2}	2.1	0.77

*The interface potential $\psi = \psi_0 e^{-x/a}$, where $\psi_0 = 60$ mV, the potential at the membrane interface ($x = 0$), x = perpendicular distance from the membrane and a = attenuation constant.

As shown in Table 2 the electric field within a short range of the membrane is large enough to act effectively as a clearing field (24) for O_2^-. It suggests an explanation for the membrane effect on pH when the irradiation occurs in oxygen-saturated water.

In O_2, reactions 2, 3, and 4 are important.

$$[4] \quad O_2^- + O_2^- \xrightarrow{2H_2O} H_2O_2 + O_2 + 2OH^-$$

Reaction 2 is fast (19) ensuring that virtually all the e_{aq}^- are converted to O_2^-. Inhibition of reaction 3 ($k_3 = 8.0 \times 10^9\ M^{-1}\ s^{-1}$ (22)) in the aqueous phase by virtue of the clearing field concentrating O_2^- near the membrane might favor reaction 4. However, reaction 4 is fairly slow ($k_4 = 1.7 \times 10^7\ M^{-1}\ s^{-1}$ (22, 25)) and might conceivably be inhibited by a suitably fast reaction of O_2^- with the membrane, *e.g.* electron transfer. The overall production of OH^- would then be reduced and, in principle, account for the membrane effect on pH observed in Fig. 8. The mechanism suggested is relevant to the pH change observed in aerated water (Figs. 2 and 3) although the presence of carbon dioxide adds to the number of reactions to be considered.

The ion clearing effect of the membrane electric field is suggested by data obtained during the irradiation of a black phospholipid membrane in a dilute aqueous solution of silver nitrate (work in progress). Following a short period of irradiation the membrane developed a speckled appearance due to the deposition of particles that possessed the lustre and reflectance of silver. The heaviest deposit was obtained in N_2-saturated water while in aerated or O_2-saturated water the deposit was about equal. The result is of interest for several reasons. In N_2-saturated water Ag^+ was reduced by the hydrated electron (26) which, as it can be shown, was not generated in sufficient numbers within the membrane to lead to a visible deposit of silver. Therefore, either the Ag^+ was reduced in the aqueous phase and then sorbed to the mem-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

brane by a non-electrostatic process or the Ag^+, sorbed to the membrane as an ion (13), was reduced *in situ*. The second alternative seems favored but implies that the e_{aq}^- was collected at the membrane. In O_2-saturated water the situation is similar except that the reduction of Ag^+ would involve the redox couple,

$$\begin{aligned} Ag &\rightarrow Ag^+ + e & E_{Ag,Ag^+} &= -0.799\ V \\ O_2^- &\rightarrow O_2 + e & E_{O_2^-,O_2} &= +0.56\ V \\ Ag^+ + O_2^- &\rightarrow Ag + O_2 & E_{cell} &= 0.239\ V \end{aligned}$$

which has a favorable total cell emf of 0.239 V (27, 28).

The clearing effect of the membrane electric field is operative only under conditions where there exists a non-equilibrium distribution of ions or a varying electric field derived from a changing interface potential or from a variable degree of ionic screening. The p*H* measurements indicate that a non-equilibrium distribution of ions was established during the irradiation and because of the collection and possible sorption to the membrane of some of them the electric field may have varied as well (13). In this respect, reactions of the collected ions, such as O_2^- and the e_{aq}^-, with components of the membrane is of much interest but no experimental information on this point is available for model phospholipid membranes. Potential energy field calculations have shown that ethanolamine interacts more strongly with anions than does choline (29) suggesting that the phospholipid, phosphatidylethanolamine, may be one of the more reactive components.

The miniscule size of the membrane ($\sim 10^{-8}$ g), relative to the volume of water affected ($\sim$10 ml on either side), implies an amplification factor in the mediation effect that one might associate with a physical force, such as an electric field, acting over a distance. Inasmuch as the electric field arises from the structural organization within the membrane it is not a property of the constituent molecules *per se* and emphasizes the need to heed structure in evaluating the radiation effects observed. An interesting illustration, relevant to the phospholipid membrane considered here, is the large increase in the rate of radiolysis of sodium linoleate at critical micelle concentrations (30).

In a biological cell, ionic screening and other factors would reduce the interface potential halving distances considered in Table 2 and limit the effective electric field to perhaps a few hundred ångströms from the membrane (13). The range for O_2^-, as calculated in Table 2, would be correspondingly reduced. However, the collection of the radical anions at membranes may, nevertheless, be significant in a cell of normal size because of their general distribution within the cytoplasmic space. Important reactions with membrane constituents may then ensue. Notable in this regard is the change in the erythrocyte membrane, affecting monovalent cation permeability, following the alteration of sulfhydryl groups (31). A short chain reaction has been described to account for the high rate of disappearance of sulfhydryl groups in oxygenated aqueous solutions at neutral p*H* (12). The fact that both O_2^- and O_2 are used up in the proposed reaction scheme is of additional interest because it suggests a basis for the oxygen depletion effect on survival of irradiated bacteria (32). Furthermore, the estimated lifetime of 10 ms for the oxygen-sensitive species suspected to be induced within the irradiated cell (32) is not inconsistent with O_2^- being that oxygen-sensitive species. The obvious implications for radiation effects on the DNA replication system, associated with the bacterial cell membrane (33, 34), appear not to have been investigated. Indeed, the general lack of information on reactions involving O_2^- and biological components is surprising, particularly in view of the widespread radiosensitizing effect of oxygen.

The technical assistance of W. S. Chelack is acknowledged. Appreciation is also expressed to Dr. Alberta B. Ross, Radiation Chemistry Data Center, University of Notre Dame, Notre Dame, Indiana, for information on reactions with O_2^-; to Dr. Klaus Schmidt, Argonne National Laboratory, Argonne, Illinois, for information on O_2^- mobility; and to Mrs. H. G. Hamel, Information Services, A.E.C.L., for locating reference material. The helpful discussions with Drs. R. S. Dixon, J. A. Raleigh, and A. Sawatzky are gratefully acknowledged.

New Synthesis of Columbianetin and Related Coumarins[1]

WARREN STECK
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received September 17, 1970

2,4-Dihydroxy-3-(3-methyl-2-butenyl)benzaldehyde was obtained from 2,4-dihydroxybenzaldehyde with either 3-hydroxy-3-methyl-1-butene or 1-bromo-3-methyl-2-butene. Oxidation of the product in neutral medium with *m*-chloroperoxybenzoic acid gave (±)-2,3-dihydro-2-(1-hydroxy-1-methylethyl)-4-hydroxybenzofuran-5-aldehyde, whose condensation product with malonic acid was (±)-3-carboxycolumbianetin. Oxidation in acidic medium gave (±)-2,2-dimethyl-3,5-dihydroxybenzopyran-6-aldehyde, whose condensation product with malonic acid was (±)-3-carboxylomatin. (±)-Columbianetin and (±)-lomatin were obtained by decarboxylation.

Le dihydroxy-2,4 (méthyl-3 butènyl-2)-3 benzaldéhyde est obtenu par réaction du dihydroxy-2,4 benzaldéhyde avec soit l'hydroxy-3 méthyl-3 butène-1 ou le bromo-1 méthyl-3 butène-2. L'oxydation de ce produit par l'acide *m*-chloroperbenzoique en milieu neutre conduit au (±)-dihydro-2,3 (hydroxy-1 méthyl-1 éthyl)-2 hydroxy-4 benzofuraldéhyde-5 qui par condensation avec l'acide malonique fournit la (±)-carboxy-3 columbianétine. L'oxydation en milieu acide donne le (±)-diméthyl-2,2 dihydroxy-3,5 benzopyrannealdéhyde-6 qui par condensation avec l'acide malonique conduit à la (±)-carboxy-3 lomatine. La (±)-columbianétine et la (±)-lomatine sont obtenues par décarboxylation.

Introduction

Columbianetin (**4***b*) is a natural plant coumarin (1) which has been shown (2) to be a biogenetic precursor of angular furanocoumarins. It is apparently identical with the lactone zosimol (3) and is isomeric with the angular pyranocoumarin lomatin (4). The synthesis of racemic columbianetin has been reported recently by Shipchandler, *et al.* (5) who employed a ten-step route starting from 2,6-dihydroxybenzoic acid; the overall yield of product was about 2%. An alternative four-step synthesis starting from β-resorcylaldehyde (**1***a*) is described below. Lomatin (**3***a*) and dihydroseselin (**3***c*) were also synthesized similarly.

Results and Discussion

2,4-Dihydroxybenzaldehyde (**1***a*) was treated with 3-hydroxy-3-methyl-1-butene in the presence of boron trifluoride etherate (6) to obtain the 3-methyl-2-butenyl derivatives **1***b*, *c*, and *d*, which were separated by column chromatography on silicic acid. The conversion of starting material was always low, about 20–30%, so that yields in this step were poor. However, residual starting material could be recovered easily and recycled several times. Austin and Seshadri (6) reported **1***b* and *d* as the products of this reaction but their m.p. and n.m.r. data for the former compound were different from those obtained in this study. For example, my compound **1***b* melted abruptly at 140.5–141.0°, not at the reported 113–116°, and showed no broad peak (δ 9.0–9.8) in its n.m.r. spectrum. The t.l.c. and g.l.c. indicated it was pure. To ensure its identity it was cyclized in dilute acid to 2,2-dimethyl-7-hydroxychroman-6-aldehyde (**6***a*), a known compound (7); the cyclization product agreed with the literature report in m.p., had appropriate u.v. and n.m.r. spectra, and gave dihydroxanthyletin (**7***a*) on construction of a coumarin pyrone ring by usual methods (7).

Compound **1***c* has not been described previously as a product of the reaction, but was isolated in reasonable quantities in this study. Its structure follows not only from its u.v. and n.m.r. spectra in conjunction with elemental analysis, but also from its alternate preparation from the disodium salt of **1***a* and 1-bromo-3-methyl-2-butene, in which it was the major product. The structure **1***c* was confirmed by treating the product with phenyldiazomethane (8) to form **1***f*, which was the same compound as that obtained by boiling the sodium salt of **1***e* with 1-chloro-3-methyl-2-butene in toluene.

Oxidation of **1***c* in chloroform with 1 equiv of *m*-chloroperoxybenzoic acid gave a product which n.m.r. and u.v. spectra indicated was **5**. It could not be crystallized. The n.m.r. signals ($DCCl_3$) included a sharp methylene doublet (J = 8.5 Hz), an equally sharp methine triplet (J = 8.5 Hz) at low field (δ 4.76), and a rather

sharp hydroxyl singlet not coupled to this triplet. This suggested a five-membered ring and showed that no secondary hydroxyl was present, pointing to **5** as the only plausible structure. Oxidation of **1***c* similarly but with a trace of *p*-toluenesulfonic acid added to the reaction medium gave a different non-crystallized product, identified as **6***b*. The n.m.r. spectrum ($DCCl_3$) of this compound showed multiple signals for the methylene group, and a vague methine resonance (δ 3.84) strongly coupled also to a hydroxyl proton. When the secondary hydroxyl signal was removed with D_2O, the CH_2CH signals formed a clear ABX pattern. This was interpreted as indicating a six-membered ring.

These results are in accord with mechanistic considerations of the reactions involved. The peracid must attack the olefinic bond of the C_5 side chain of **1***c*, transforming it into an epoxide. Subsequent cyclization in neutral or basic medium would be expected to proceed by S_N2 mechanism, and take place at the less sterically hindered carbon of the epoxide bridge, giving **5**. An acid-catalyzed epoxide ring fission should, on the other hand, produce a carbonium ion which would be most favorably located at the tertiary carbon, so that ring closure in this case would produce a six-membered heterocycle.

Condensation of **5** with malonic acid in pyridine–aniline gave a carboxylic acid, m.p. 220–221°, which fluoresced a brilliant blue in u.v. light and had n.m.r. and u.v. spectra consistent with 3-carboxycolumbianetin (**4***a*). Decarboxylation of this acid in boiling quinoline, in presence of copper powder, yielded (±)-columbianetin (**4***b*), m.p. 168–169° [lit. 170–171° (5)], identical in its u.v. and n.m.r. spectra, and also in its chromatographic behavior, with natural (+)-columbianetin obtained by hydrolysis of columbianetin angelate isolated from roots of *Lomatium columbianum* (1).

Condensation of **6***b* similarly gave a carboxylic acid, m.p. 223–223.5°, with brilliant blue fluorescence. Its u.v. and n.m.r. spectra were consistent with 3-carboxylomatin (**3***b*). Decarboxylation of this compound in copper/quinoline afforded

(±)-lomatin (**3***a*), m.p. 163–165.5° [lit. 165.5–7.0° (9)], with spectral properties identical with those described for (+)-lomatin (4). This is the first total synthesis of lomatin.

The advantages of these synthetic routes are three: first, the sequences are short and the overall yields reasonably high; second, the method permits optical resolution at all stages, particularly at the carboxylic acid stage; third, and of particular interest to this laboratory, carbon-14 can be conveniently introduced in the malonic acid condensation.

A synthesis of osthenol (**2***b*) from **1***c* also seemed feasible, either by reaction with sodium acetate and acetic anhydride, or via the carboxylic acid **2***a*. This last compound was obtained without difficulty with malonic acid in pyridine–aniline, but its decarboxylation was attended by ring closure, yielding dihydroseselin (**3***c*) (6). Reaction of **1***c* with sodium acetate and acetic anhydride under the conditions described (6) for the synthesis of 7-demethylsuberosin (**2***c*) gave none of the expected osthenol acetate. The synthesis of osthenol reported (10, 11) while this work was in progress would seem to be an effective alternative.

Experimental

All melting points are uncorrected. The n.m.r. spectra were measured with a Varian model HA-100 Spectrometer. All proton assignments below are supported by signal integration. Tetramethylsilane was the reference standard. *2,4-Dihydroxybenzaldehyde (**1***a*)* was purchased from Eastman Organic Chemicals, and *3-hydroxy-3-methyl-1-butene* and *m-chloroperoxybenzoic acid* from Aldrich Chemical Co.

*Compounds **1***b, c, and d*

Compound **1***a* (50 g) in 300 ml dioxan was added to a stirred fresh solution of 40 g 3-hydroxy-3-methyl-1-butene and 25 ml BF_3 etherate in 200 ml dioxan, and stirring was continued for 2.5 h at room temperature. Ether (2500 ml) was added and the resulting solution extracted with water (3 × 1000 ml). The remaining organic layer was dried (Na_2SO_4) before evaporation to dryness. The crystalline residue was extracted with six 100-ml portions of pentane or hexane, which dissolved the reaction products and left behind most unchanged starting material. After removal of the solvent, the mixed products were adsorbed upon 50 g silicic acid (Mallinckrodt 100 mesh, used as received) and chromatographed on a column of 450 g more silicic acid prepared either in ether–hexane (1:1) or in ethyl acetate – hexane (1:9). Fractions of 20 ml were continuously collected. In development with ether–hexane, fractions 30–40 contained mostly **1***d*, 41–50 mostly **1***b*, and 53–66 **1***c*. Later fractions gave a little **1***a*. All products crystallized on standing in the collection tubes. In development with ethyl acetate – hexane, fractions 12–23 contained **1***d*; 68–117 **1***b* (development with 15% EtOAc after fraction 80, 20% after 92, 25% after 120, 100% after 145); 118–128 mixed **1***b* and *c*; 129–165, **1***c*. Higher fractions held unchanged **1***a*.

Each compound was recrystallized once from benzene–hexane.

Compound **1***b*, (yield 6–9 g), colorless rods, m.p. 140.5–141.0° [lit. 113–116° (6)].

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.9; H, 6.8. Found: C, 69.9; H, 6.8.

λ_{max}(EtOH) 237, 281, and 324 nm; λ_{max}(EtOH/KOH) 255 and 343 nm. The n.m.r. signals ($DCCl_3$) at δ 1.76–1.80 (singlets, 2 vinyl methyls); 3.28 (doublet, J = 7 Hz, CH_2); 5.26 (triplet, J = 7 Hz, =CH); 6.19 (singlet, 4-OH). This peak and one at 11.23 (2-OH) disappeared on shaking the sample with D_2O; 6.34 (singlet, H-3); 7.20 (singlet, H-6); 9.66 (singlet, CHO).

Compound **1***c*, (yield 2–4 g), colorless rods, m.p. 117–120°.

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.9; H, 6.8. Found: C, 69.6; H, 6.8.

λ_{max}(EtOH) 235, 287, and 320 (sh) nm. The n.m.r. signals ($DCCl_3$): δ 1.76 (singlet, vinyl CH_3); 1.82 (singlet, vinyl CH_3); 3.42 (doublet, J = 7 Hz, CH_2); 5.25 (triplet, J = 7 Hz, =CH); 6.15 (singlet, 4-OH); 6.45 (doublet, J = 8 Hz, H-5); 7.28 (doublet, J = 8 Hz, H-6); 9.66 (singlet, CHO); 11.74 (singlet, 2-OH). Shaking with D_2O eliminated the hydroxylic signals. Irradiation at the frequency of the δ 5.25 proton collapsed also the CH_2 signal and the methyl signals to sharp singlets; irradiation at δ 7.28 collapsed the doublet at 6.45.

Compound **1***d*, (yield 6–8 g), along colorless needles, m.p. 113–117° [lit. 120–121° (6)].

Anal. Calcd. for $C_{17}H_{22}O_3$: C, 74.3; H, 8.1. Found: C, 73.8; H, 8.0.

λ_{max}(EtOH) 228, 236 sh, 278, and 327 (sh). The n.m.r. signals at δ 1.75–1.85 (12H, 4 methyls): 3.26 and 3.40 (doublets, J = 7 Hz, 2 methylenes); 5.23 and 5.27 (triplets, J = 7 Hz, 2 =CH); 6.30 (singlet, 4-OH); 7.09 (singlet, H-6); 9.64 (singlet, CHO); 11.60 (singlet, 2-OH).

*Alternate Methods for **1***c and d*

To a solution of 2,4-dihydroxybenzaldehyde (13.8 g) in 100 ml dry methanol was added 100 ml methanol containing dissolved sodium metal (4.6 g). The solvent was evaporated at once at reduced pressure and the residual light-tan disodium salt was dried, first by evaporation from ethanol–benzene and then by standing 1 h at 120°. Yield 18.2 g (100%).

This salt (9.0 g) and 1-bromo-3-methyl-2-butene (12.5 g) (13) were put into 250 ml benzene and heated under reflux for 4 h, then cooled and shaken with a mixture of ether and cold dilute acid. The organic layer was washed with water, dried and freed of solvent, leaving a dark semi-solid mass. This was chromatographed on silicic acid as described above to yield 1.1 g (10.6%) **1***c* and 1.0 g (7.4%) **1***d*, along with a larger quantity of unchanged starting aldehyde.

*Derivatives of **1***b*

*(a) Compound **6***a*

Compound **1***b* (1 g) was boiled 30 min in 50 ml 30% alcohol containing 2 ml H_2SO_4. The alcohol was evaporated and the aqueous suspension remaining was extrac-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ted with 100 ml ether. After washing with water, the ether solution was dried (Na_2SO_4), treated with 10 ml hexane, and allowed to evaporate overnight. The deposited crystals of 2,2-dimethyl-7-hydroxychroman-6-aldehyde (**6***a*) (0.9 g), m.p. 103–104° from benzene [lit. 104° (7)], gave n.m.r. signals ($DCCl_3$) at δ 1.35 (singlet, 2 methyls); 1.80 (triplet, J = 6.5 Hz, CH_2); 2.72 (triplet, J = 6.5 Hz, benzylic CH_2); 6.28 and 7.16 (singlets, H-3 and -6); 9.63 (singlet, CHO); 11.53 (singlet, 2-OH).

(b) Dihydroxanthyletin

The above aldehyde (0.3 g) was kept for 16 h with 0.6 g malonic acid in 0.7 ml pyridine and 0.1 ml aniline, with occasional warming. The mixture was poured into ice/3 *N* HCl and the yellow precipitate filtered, giving 0.35 g crude 3-carboxydihydroxanthyletin (**7***b*), m.p. 140–158°; recrystallization from alcohol gave crystals, m.p. 158–159° [lit. 158–159° (7)].

λ_{max}(EtOH) 252, 262, and 356 nm. The n.m.r. signals (d_6-DMSO) at δ 1.72 (singlet, 2 methyls); 2.18 and 3.16 (triplets, J = 6.5 Hz, 2 adjacent CH_2's); 6.07 and 6.98 (singlets, H's of central ring); and 8.97 (singlet, H-4 of pyrone ring). The carboxyl proton was very broad, *ca.* δ 12–13.

The acid (0.15 g) was decarboxylated as described below for the preparation of columbianetin, giving 0.09 g dihydroxanthyletin (**7***a*), m.p. 122–123° from aqueous alcohol [lit. 124–125° (6)]. The mixed m.p. with authentic material, prepared by acid treatment of 7-demethylsuberosin (12), was undepressed, and the spectra were indistinguishable.

λ_{max}(EtOH) 249, 258, and 326 nm. The n.m.r. signals ($DCCl_3$) at δ 1.36 (singlet, 2 methyls); 1.83 and 2.81 (triplets, J = 6.5 Hz, 2 adjacent CH_2's); 6.17 and 7.54 (doublets, J = 9.5 Hz, pyrone ring protons); 6.71 and 7.14 (singlets, central ring protons).

Derivatives of **1***c*

(a) 2-Hydroxy-3-(3-methyl-2-butenyl)-4-benzyloxybenzaldehyde (Method 1)

Compound **1***c* (200 mg) was benzylated with phenyldiazomethane (8) in boiling ether. Gas chromatography of the reaction mixture showed a main component which matched (retention time, n.m.r. spectrum) the 4-benzyl ether (**1***f*).

(b) 2-Hydroxy-3-(3-methyl-2-butenyl)-4-benzyloxybenzaldehyde (Method 2)

The sodium salt of 4-benzyloxy-2-hydroxybenzaldehyde was prepared by treatment of the phenol **1***e* (15.5 g) in 100 ml methanol with 1.62 g sodium dissolved in 200 ml methanol, followed by rapid removal of the methanol and oven-drying of the product (15.6 g, 95%). The powdered salt was suspended in 300 ml dry benzene and refluxed 4 h with 7.5 g 3-methyl-1-chloro-2-butene. The filtered solution was evaporated to a syrup and dissolved in ether. This solution was adsorbed on 20 g silicic acid and chromatographed on a further 180 g silicic acid. Fractions of 20 ml were collected. Development with 1:9 ether–hexane gave 0.2 g **1***g*, m.p. 91–94.5° (fractions 40–43), 1.6 g **1***f*, m.p. 71.5–72.5° (fractions 46–53), and 2.6 g unchanged starting aldehyde (fractions 55 and onwards).

Anal. Calcd. for $C_{19}H_{20}O_3$ (**1***f*): C, 77.0; H, 6.8. Found: C, 76.8; H, 6.8.

The n.m.r. spectrum ($DCCl_3$) showed signals at δ 1.7 (singlets, 2 vinyl methyls); 3.41 (doublet, J = 7 Hz, CH_2 of butenyl chain); 5.16 (singlet, benzyl CH_2); 5.24 (triplet, J = 7 Hz, =CH); 6.58 and 7.30 (doublets, J = 8.5 Hz, H-5 and -6 of phenolic ring); 7.40 (singlet, phenyl); 9.70 (singlet, CHO); 11.46 (singlet, 2-OH).

The n.m.r. spectrum of **1***g* was similar to that of **1***f* except that the methyl signals were separated (δ 1.64, 1.74) and aromatic singlets at δ 6.48 and 7.25 replaced the doublets at 6.58 and 7.30.

(c) 3-Carboxyosthenol (2a)

Compound **1***c* (70 mg) and 120 mg malonic acid were warmed together 2 h at 50–60° in 1 ml 10% aniline in pyridine. After standing overnight the mixture was poured into 20 ml ice-cold 10% HCl; the yellow precipitate (50 mg, m.p. 180–204°) was filtered, washed with water, then chromatographed on a small column of Polyclar AT powder (General Aniline and Film Corporation), developing with increasing strengths of aqueous methanol. 3-Carboxyosthenol emerged as a brilliant blue-fluorescing band, melting at 209–212° after recrystallization from aqueous alcohol.

Anal. Calcd. for $C_{15}H_{14}O_5$: C, 65.7; H, 5.2. Found: C, 65.5; H, 5.2.

λ_{max}(EtOH) 262, 299 (sh), and 354 nm. The n.m.r. signals (d_6-DMSO) at δ 1.67 and 1.82 (singlets, 2 methyls); 3.40 (doublet, J = 7 Hz, CH_2); 5.18 (triplet, J = 7 Hz, =CH); 6.94 and 7.62 (doublets, J = 9 Hz, H-6 and -5 of coumarin system); 8.66 (singlet, H-4); 10.6–11.0 (broad singlet, 7-OH); the carboxyl proton was very broad, near δ 12–13.

(d) Dihydroseselin (3c)

Compound **2***a* (6 mg) was heated 5 min at 230–235° in 0.5 ml fresh quinoline containing a little copper powder. The cooled solution was diluted with 10 ml ether, decanted from the copper metal, and washed first with dilute HCl then twice with water. The blue-fluorescing solution was chromatographed on silicic acid, developing with ether. The major fluorescent band was dihydroseselin, co-chromatographing with authentic material and having the same spectral properties: λ_{max}(EtOH) 248, 258, 327 nm, unchanged by either $AlCl_3$ or NaOH.

The n.m.r. signals ($DCCl_3$) at δ 1.25 (singlet, 2 methyls); 1.83 and 2.88 (triplets, J = 7 Hz, 2 adjacent methylenes); 6.15 and 7.55 (doublets, J = 9.5 Hz, H-3 and -4 of coumarin ring system); 6.67 and 7.15 (doublets, J = 9 Hz, H-6 and -5 of coumarin ring system). No osthenol could be detected in the reaction mixture. Repeated attempts at decarboxylation of **2***a* in Cu–quinoline, using lower and higher temperatures, or in ethylene glycol, gave similar results. By heating *in vacuo* below 270°, 3-carboxyosthenol could be sublimed; above 270° a mixture containing some dihydroseselin (but no osthenol) was produced.

(±)-2,3-Dihydro-2-(1-hydroxy-1-methylethyl)-4-hydroxybenzofuran-5-aldehyde (5)

Compound **1***c* (0.5 g) in 20 ml chloroform was treated with 0.5 g technical (85%) *m*-chloroperoxybenzoic acid in 20 ml chloroform. After 24 h the solution was washed with dilute bicarbonate, then with water, and evaporated to a syrup. Gas chromatography showed a single component with n.m.r. signals ($DCCl_3$) at δ 1.24 and 1.36

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(singlets, methyls); 1.82 (singlet, alcoholic OH); 3.12 (doublet, J = 8.5 Hz, CH_2); 4.76 (triplet, J = 8.5 Hz, —CH); 6.45 and 7.35 (doublets, J = 8.5 Hz, H-5 and -6); 9.70 (singlet, CHO); 11.74 (singlet, 2-OH). Removal of the hydroxyl signals by shaking the sample with D_2O did not alter the shape or position of the —CH triplet.

(±)-3-Carboxycolumbianetin (4a)

The aldehyde **5** (1.4 g) was kept 24 h with 1.2 g malonic acid in 5 ml pyridine and 0.5 ml aniline, then the solution was poured slowly into ice-cold 10% HCl (50 ml) and the resulting solution or suspension was continuously extracted with ether. This extract was passed through a column of silicic acid developing with ethyl acetate–hexane. The product, 0.3 g white crystals of m.p. 220–221°, was dried at 120° overnight.

Anal. Calcd. for $C_{15}H_{14}O_6$: C, 62.1; H, 4.9. Found: C, 62.2; H, 4.9.

λ_{max}(EtOH) 263 and 353 nm. The n.m.r. signals (d_6-DMSO) at δ 1.33 and 1.36 (singlets, methyls); 2.79 (doublet, CH_2); 3.81 (triplet, —CH); 5.2 (broad singlet, alcoholic OH); 6.83 and 7.67 (doublets, J = 9 Hz, H-6 and -5); 8.70 (singlet, H-4). The carboxyl proton was very broad at δ 12–13.

(±)-Columbianetin (4b)

Compound **4***a* (30 mg) was refluxed 10 min with 30 mg copper powder in 1 ml fresh dry quinoline. The cooled solution was then diluted with 15 ml ethyl acetate and 15 ml ether, decanted from the copper, shaken with two portions of 3 *N* HCl, washed with two portions of water, and dried over Na_2SO_4. Evaporation of the clear yellow solution gave 18 mg crude (±)-columbianetin, m.p. 164–167°, raised to 168–169° by recrystallization from chloroform–hexane [lit. 170–171° (5)]. Direct comparison of the product with authentic (+)-columbianetin showed no differences in chromatographic behavior (paper chromatography, three systems; g.l.c.) or in u.v. and n.m.r. spectra.

λ_{max}(EtOH) 251, 262, and 327 nm. The n.m.r. signals ($DCCl_3$) at δ 1.25 and 1.37 (singlets, methyls); 1.75 (singlet, OH); 3.30 (doublet, J = 8 Hz, CH_2); 4.77 (triplet, J = 8 Hz, CH); 6.17 and 7.58 (doublets, J = 9.5 Hz, H-3 and -4 respectively of coumarin ring system); 6.72 and 7.22 (doublets, J = 9.0 Hz, H-6 and -5).

(±)-2,2-Dimethyl-3,5-dihydroxychroman-6-aldehyde (6b)

Compound **1***c* (0.6 g) and *p*-toluenesulfonic acid (0.01 g) in 20 ml $HCCl_3$ were treated with 85% *m*-chloroperoxybenzoic acid (0.6 g) in 15 ml $HCCl_3$ and kept 18 h at room temperature. Work-up as for **5** above gave a light brown syrup. After chromatography on silicic acid a colorless viscous syrup (0.45 g) was obtained which, although chromatographically homogeneous, still could not be crystallized. It showed n.m.r. signals ($DCCl_3$) at δ 1.46 (singlet, two methyls); 1.73 (broad singlet?, OH); 2.70 and 2.94 (doublets of doublets, J_{AB} = 16 Hz, —CH_2); 3.84 (after removal of coupled HO, doublet of doublets, J_{AX} = 5, J_{BX} = 6 Hz, —CH); 6.46 and 7.27 (doublets, J = 9 Hz, aromatic H-5 and -6); 9.66 (singlet, CHO) and 11.75 (singlet, 2-HO).

(±)-3-Carboxylomatin (3b)

The above aldehyde (0.35 g) was kept 24 h with malonic acid (0.5 g) in 1.5 ml pyridine containing a little aniline. The mixture was poured in 25 ml cold 3 *N* HCl and extracted with chloroform. The chloroform solution was washed once with water then dried and evaporated, leaving 0.28 g pale yellow crystals, m.p. 223–223.5° from methanol.

Anal. Calcd. for $C_{15}H_{14}O_6$: C, 62.1; H, 4.9. Found: C, 62.1; H, 4.9.

The n.m.r. signals (d_6-DMSO) at δ 1.29 and 1.32 (singlets, methyls); 2.70 and 2.99 (doublets of doublets, J_{AB} = 16 Hz, CH_2); 3.77 (doublet of doublets, J_{AX} = 5, J_{BX} = 6 Hz, —CH); 5.31 (broad singlet?, OH); 6.83 and 7.66 (doublets, J = 8.5 Hz, aromatic H-6 and -5); 8.70 (singlet, H-4); 12–13 (very broad, carboxyl).

(±)-Lomatin (3a)

Decarboxylation of **3***b* as for 3-carboxycolumbianetin gave (±)-lomatin in 30–50% yield, m.p. 163–165.5° from benzene [lit. m.p. 165.5–167.0° (9)].

λ_{max}(EtOH) 246, 256, and 325 nm. The n.m.r. signals ($DCCl_3$) at δ 1.35 and 1.41 (singlets, methyls); 2.0 (broad singlet, alcoholic OH); 2.92 and 3.14 (doublets of doublets, J_{AB} = 17 Hz, —CH_2); 3.89 (doublet of doublets, J_{AX} = 5.5, J_{BX} = 6 Hz, —CH); 6.21 and 7.60 (doublets, J = 9.5 Hz, H-3 and -4 respectively); 6.76 and 7.23 (doublets, H-6 and -5 respectively); all in agreement with literature values (4).

Thanks are extended to Mr. W. Haid for the elemental analyses, to Mr. M. Mazurek for the n.m.r. spectra, and especially to Mr. B. K. Bailey for skillful technical assistance throughout. I am also indebted to Professor A. Kjaer (Technical University of Denmark, Lyngby, Denmark) for helpful advice.

Conformational Analysis of Trimethylene Sulfites. The Importance of Vicinal Unshared Electron Pairs[1]

GORDON WOOD, JOHN M. MCINTOSH, AND MAURICE H. MISKOW[2]
Department of Chemistry, University of Windsor, Windsor, Ontario

Received June 16, 1970

Dipole moments are reported for trimethylene sulfite and 11 alkyl derivatives in a variety of solvents (C_6H_{12}, CCl_4, C_6H_6, dioxan). The variation of dipole moment with solvent for one of the 5-*t*-butyltrimethylene sulfite isomers is confirmed, but this behavior is not shown by the other compounds. This latter fact is used to rule out rapid chair–chair interconversion for these compounds. Recent ultrasonic absorption experiments are reinterpreted in the context of vicinal electron pair interactions and their effect on conformational analysis of sulfites and similar six-membered compounds. The result is a general scheme which is consistent with available information and which we believe is preferable to analysis of these compounds by analogy with cyclohexane.

On a mesuré, dans quelques solvants (C_6H_{12}, CCl_4, C_6H_6, dioxane), les moments polaires du sulfite de triméthylène et de 11 dérivés alkylés. Nous avons confirmé que le moment polaire de l'un des *tert*-butyl-5 sulfite de triméthylène varie avec le solvant; cette variation n'est pas observée avec les autres composés. Ce dernier fait est utilisé pour exclure la possibilité d'une interconversion chaise–chaise rapide entre ces composés. Des résultats récents d'absorption ultrasonique sont réinterprétés dans le contexte d'interactions entre des paires d'électrons vicinaux et de leurs effets sur l'analyse conformationnelle des sulfites et des composés cycliques à six chaînons de nature similaire. Le résultat est un schéma général qui est consistant avec les informations disponibles et qui, nous le croyons, est préférable à une analyse de ces composés par analogie avec le cyclohexane.

Canadian Journal of Chemistry, 49, 1202 (1971)

Introduction

Much data has been reported on the conformations of substituted trimethylene sulfites since the initial attempt by Arbouzov (1) to assign a conformation to the parent ring system, but no clear picture of the shapes of these compounds has emerged. Although trimethylene sulfites are usually assumed to undergo rapid chair–chair interconversion at room temperature, all our attempts to find a coalescence of signals in n.m.r. spectra have been unsuccessful. While this result by itself could indicate the presence of only one chair form in measurable amounts (anancomeric system), dipole moment data will be presented here which rules out that possibility for at least some of the sulfites. The lack of coalescence temperature between -100 and $+30$ °C for the molecules[3] is sufficient to show that the barrier to ring inversion must lie either substantially above or substantially below the usual cyclohexane barrier of 10.3 kcal/mol.[4] We shall attempt to show that only the former is consistent with all the facts. Recently ultrasonic relaxation studies have been interpreted in terms of chair–chair equilibria for several trimethylene sulfites (2). We suggest that the analysis of the data obtained in these experiments errs by neglecting the effect of vicinal electron pairs.

Our aim is to present, point by point, the evidence which leads us to conclude that the presently held concepts about the conformation of trimethylene sulfites and some related molecules need revision and to develop a new model consistent with all the facts known at this time.

Results and Discussion

Dipole Moments and Solvent Dependence

The dipole moments were calculated by the method of Guggenheim (3) and are presented in Table 1. The values in parentheses were obtained by van Woerden and Havinga (4) and the agreement is satisfactory, considering the different methods of calculation. In keeping with a previous observation (4*b*), these dipole moments permit important conclusions on conformation to be made. In particular, the influence of a polar solvent on an equilibrium between two forms of different dipole moment is such that the form of higher moment is favored. This shift in equilibrium results in a higher (average) dipole moment.

[1]Presented in part at the Organic Symposium of the Chemical Institute of Canada, London, Ontario, September, 1970.

[2]Recipient of NRCC Scholarships, 1966–1970.

[3]Results of our n.m.r. experiments will be reported later.

[4]For a signal separation of 0.5 p.p.m., a coalescence temperature below -100 °C corresponds to a barrier < 8.5 kcal/mol; a temperature above $+30$ °C to a barrier > 15 kcal/mol. Differences in signal separation have only a small effect on these values.

¶From ref. 4*a*.

Several of these compounds have dipole moments corresponding at least approximately to a chair form with axial S=O[5] (compounds **1, 2, 4, 10, 11**). The only molecule with a moment which clearly corresponds to a chair with equatorial S=O is compound **6**.[6] This molecule has been assigned this conformation (5, 6) and recent n.m.r. evidence supports this assignment.[7] Compounds **3** and **8** must also have large amounts of this form or a non-chair form with similar geometry at the sulfite end of the molecule. Our analysis requires that the latter be the case.

The variation of dipole moment with solvent for compound **12** (4*a*) has been confirmed by measurement in two additional solvents. The difference in dipole moment between dioxane and cyclohexane solutions is 0.61 D which is well outside the experimental error and much larger than the corresponding change (0.16 D) for the other (rigid ?) isomer, compound **11**. The behavior exhibited by compound **12** is expected for a molecule existing as interconverting conformations with substantially different dipole moments (4*a* and references therein). In this situation the conformation of higher moment is favored in the more polar solvent. *None of the other compounds studied show enough variation of dipole moment with solvent to implicate a conformational equilibrium with certainty*, although some of them are borderline, *e.g.*, compound **8**.

Compound **9** has a dipole moment of intermediate value which is constant and it therefore seems likely that this compound exists in a non-chair form almost exclusively. Compounds **5** and **7** have moments near 3.9 D which implies either a distortion of the S=O axial chair or a non-chair form. Since both of these molecules have the same axial methyl – axial S=O interaction in the chair form, it is not surprising that they have similar moments, but it is not possible on this basis to decide between the chair and non-chair alternatives.[8]

The general constancy of the dipole moments in various solvents (except for compound **12**) even for compounds whose moments deviate considerably from the values expected for chair forms makes it highly unlikely that any of these

[5]Calculations give 3.4 D for trimethylene sulfite, see ref. 4*b*.
[6]The dipole moment for this form has been estimated as 5.0–5.2 D by H. F. van Woerden, private communication.
[7]Private communication from Professor R. E. Lack, University of Sydney, Sydney, Australia.
[8]Compound **5** has been assigned as existing as 70% chair and 30% non-chair (7). This result fits very well the general scheme to be developed later in this paper.

compounds exist as equilibrium mixtures of conformations with large differences in dipole moment. *In particular, with the possible exception of compound* ***12****,*[9] *none of these compounds exist as equilibrium mixtures of two chair conformations.* Where equilibria do exist, they probably involve chair and non-chair forms with similar moments.

In the remainder of this discussion an attempt will be made to reconcile the conclusions from the dipole moment study with other information available from conformation studies of cyclic sulfites and related molecules.

Ultrasonic Absorption and Conformational Equilibria

Sulfite barriers of 5–7 kcal/mol ($\Delta H^{\ddagger}$, more stable to less stable) are typical of the ultrasonic data. The assignment of these barriers to the chair–chair interconversion process depends on an interpretation of other data (8), chiefly spectral (2), which is less than compelling. In fact, all such interpretations to date implicitly use cyclohexane as the model for six-membered ring behavior.

The most relevant experimental evidence on the nature of the barrier being measured in the ultrasonic work arises from a comparison of the latter with low temperature n.m.r. results on related systems. For example, we have recently determined the ring inversion barrier for 5,5-dimethyltrimethylene sulfate (9). The n.m.r. result is 8.1–8.4 kcal/mol in contrast to the ultrasonic value of 4.6–6.2 kcal/mol for the related 4-methyltrimethylene sulfate. We prefer to handle this anomaly in the way that a similar one was handled for a 1,3-dioxane, namely by assigning the lower barrier observed in the ultrasonic work to a chair – non-chair interconversion (10).

A different kind of difficulty has arisen with compounds having two identical chair forms. Chair–chair interconversion cannot cause ultrasonic absorption for such a system (10), and yet relaxation has been observed. Once again, the assumption of a chair – non-chair equilibrium has been made.

Finally, ultrasonic absorption measurements on 4-phenyl-1,3-dioxan gave results unexpected for a chair–chair equilibrium (11). The most serious discrepancy was the large negative entropy associated with conversion of the less stable to the more stable form. That fact, coupled with the large $-\Delta G^{\circ}$ value expected for 4-axial substituents on this ring (12) can readily be accommodated by assignment of the less stable form to a non-chair conformation.

In conclusion, we suggest that the trimethylene sulfites which have been shown by ultrasonic measurements to exist as a conformational equilibrium (as little as 1% of minor conformer can be detected (8)) have a non-chair conformation of energy comparable to the preferred chair form. According to this notion, compounds which fail to give a relaxation result are limited to a single chair or non-chair conformation. Compound **9** and possibly **7** are examples of the latter and 5-nitro-5-methyltrimethylene sulfite (2) is presumably an example of the former. Compounds in our dipole moment study that have been studied by ultrasonics are noted in Table 1 along with the result.

The nature of the data from the ultrasonic experiment is such that one cannot use it to prove *any* structural assignments. Our claim is simply that considerable evidence can be brought forward from a re-evaluation of this data to support our interpretation of conformational behavior in these systems. The next section will show that there exists a large body of information on the influence of vicinal electron pairs on rotational barriers and conformation which is also consistent with our interpretation.

Vicinal Unshared Electron Pairs and Barriers to Rotation

The transition state for ring inversion in cyclohexane is considered to be the half-chair (13). In other six-membered ring compounds the minimum energy path for ring inversion may involve a twist or other form, but regardless of the form of the transition state, rotation about single bonds of the ring must accompany the process. Indeed, the barrier to ring inversion represents, in large part, the torsional energy required for rotation about these bonds (13, 14). Thus, the barrier of 10.3 kcal/mol in cyclohexane (15) should be related in part to the 3.4 kcal/mol about the C—C bond in propane (16),[10] and a ring containing single bonds with higher barriers to rotation would be expected to have a higher barrier to inversion.[11]

[9]Since compound **12** shows a constant n.m.r. spectrum from −100 to +180 °C, it is probable that it also fits the scheme proposed later, in spite of its dipole moment behavior.

[10]The choice of propane over ethane or butane for a model is an arbitrary one.

[11]There seems to be no dispute with this principle, see ref. 2, p. 314 and ref. 17. Our disagreement with ref. 2 involves only the choice of suitable acyclic models.

Rotational barriers about single bonds between atoms carrying unshared electron pairs have been measured (16, 18–21) and calculated (22–26) for a large variety of compounds. These barriers are generally of the order of 10 kcal/mol, a value seldom reached by the most hindered ethane derivatives lacking vicinal electron pairs. Although these high barriers may not be wholly resultant from vicinal electron pair interactions (18*b*, 19, 21, 25), all results thus far indicate these interactions make a most important contribution. A comprehensive paper by Wolfe and co-workers reduces the wealth of data and calculations now available on this point to two simple rules (26).

There is also abundant evidence that one or more bonds of this sort in a six-membered ring increase the barrier to ring inversion, in spite of the reduction in rotation barrier for neighboring bonds where only one atom has unshared electron pairs (27).

Thus, it seems to us that for trimethylene sulfites (with unshared electron pairs on three adjacent atoms) the choice between a high (>15 kcal/mol) and a low (<8.5 kcal/mol) barrier to ring inversion can be made with some confidence. The only conclusion compatible with these arguments is that the barrier to ring inversion is high and, further, that interactions of vicinal electron pairs are a major cause of this barrier as well as other conformational properties. The strong preference of the exocyclic S=O bond for the axial position is probably best understood in these terms.[12] Equatorial disposition of S=O would give rise to an arrangement which corresponds to an energy maximum for molecules of this sort ($\theta = 120°$, see Fig. 1 and ref. 28).

Two-fold Rotational Barriers and Minimum Energy Conformations

Attention is drawn by Wolfe *et al.* (26) to an important feature of their calculation of barriers for bonds with vicinal unshared electron pairs; *viz*, the total energy curves for 360° rotation about these bonds show only two maxima and two minima. Perhaps the clearest example of this can be seen by comparison of the calculated barriers for hydrogen methyl sulfoxide and its carbanion (28*c*).[13] Figure 1 shows a sketch combining these results with the corresponding curve for ethane. Note that CH_3SHO has an ethane-like barrier with the three maxima and three minima shifted about 20° to the right. The carbanion has had two of these maxima and the minimum between them ($\theta = 80$–$200°$) replaced by a single maximum ($\theta = 130°$), as well as other smaller shifts. When one considers that the conformational preference for the chair over non-chair forms in cyclohexane is equated with the preference of the staggered over the eclipsed conformation in ethane, it becomes clear that arbitrary assignment of the chair as preferred conformation in six-membered rings containing one or more bonds with vicinal unshared electron pairs is unjustified. The curve for $^-CH_2SHO$ shows energies of 4.4, 12.8, and 0 kcal/mol for the conformations corresponding to staggered ethane. Thus, in six-membered rings with vicinal electron pairs the staggered conformation characteristic of a perfect chair *may* correspond to an energy minimum, *but it also may correspond to the highest energy on the rotation curve or any intermediate value.*

Because of the increased height and, therefore, importance of these two-fold barriers we conclude that the preference for chair forms should decrease with the introduction of one or more bonds of this type. In fact, there is already experimental evidence for twist form preference in some of these molecules. One well-documented case involves 3,3,6,6-tetramethyl-1,2,4,5-tetrathian (29) where the twist form is preferred by 0.5–1 kcal/mol in the various activation parameters. The small entropy difference between the chair and twist forms of this molecule probably reflects the reduced flexibility of non-chair form in these systems. Several recent communications on phosphorus analogues of sulfites also implicate twist forms and high ring inversion barriers for these compounds (30–33).

The current view that trimethylene sulfite prefers the chair form, based mainly on X-ray data (34) may well be correct. However, the possibility of relatively low energy non-chair forms in solution seems to us to be strong. The n.m.r. work of Maroni and Cazaux referred to earlier (7), dipole moment data presented here, and our interpretation of the ultrasonic absorption data of Wyn-Jones may be cited in support

[12]No direct measure of this preference exists. Acid equilibration of compounds **4** and **6** gives values of 2.6 kcal/mol in CCl_4 and 1.7 kcal/mol in CH_3CN. However, persistent association of these sulfites (5) in dilute solution may influence these results.

[13]For comment on recent experimental work on related molecules, see ref. 26.

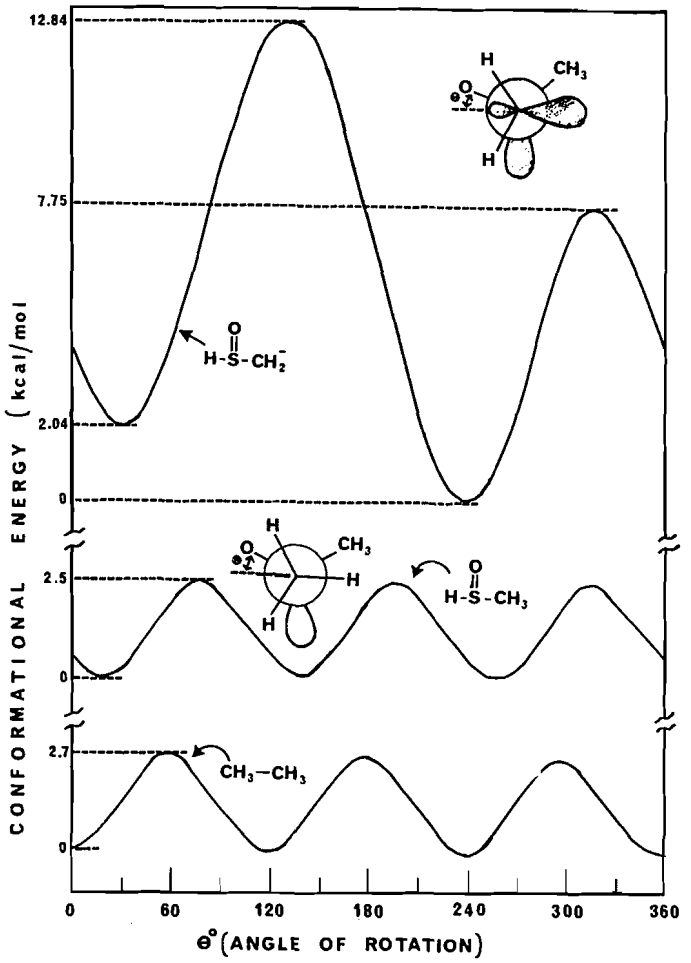

FIG. 1. Variation of the total energy of ethane, hydrogen methyl sulfoxide, and its carbanion as a function of rotation about the C—C or C—S bond (θ).

of this position. Further, it seems likely that steric interactions are capable of changing relative energy levels of sulfite conformations drastically. For example, it seems likely that compound **9** is predominantly non-chair.

Summary and Conclusions

The application of existing notions on trimethylene sulfite conformations to ultrasonic absorption data has led to an interpretation that contradicts a number of conformational studies documenting the importance of unshared electron pairs on adjacent atoms.

In this paper an attempt has been made, using the above results and new data on the sulfites, to define normal behavior for trimethylene sulfites with emphasis on the influence of electron pairs on sulfur and oxygen. This analysis leads to a coherent picture in which trimethylene sulfites have high barriers to chair–chair interconversion, low energy non-chair forms, and a strong preference for axial S=O. No conflict with previously reported facts has been uncovered, and the ultrasonic absorption experiments emerge as an important probe for chair to non-chair equilibria in these systems.

While we feel our conclusions are consistent with the data available at this time, we do not wish to imply that we have proven our contentions beyond any doubt. We offer our model as a possible solution to the difficulties encountered in viewing certain six-membered rings as close

relatives of cyclohexane in the hope that it will inspire more definitive experiments. Current work in this laboratory is directed toward that end.

Experimental

The n.m.r. spectra were obtained on a JEOL JNM-C60S or C60HL using TMS as internal standard.

Synthesis of Sulfites

The best synthetic method for the preparation of these sulfites was found to be the thionyl chloride – pyridine method. This gave not only a good yield of sulfites, but also the highest yield of the less stable isomers. The following procedure for 4-methyl-trimethylene sulfite is typical.

To 45 g (0.50 mol) 1,3-butanediol, dissolved in 300 ml dry benzene and 150 ml dry pyridine, was added dropwise with stirring and external cooling 44 ml thionyl chloride (0.60 mol) in 100 ml benzene over a period of 3 h. After filtering off the salt formed and neutralizing with bicarbonate, the organic layer was separated and washed with 0.1 *N* HCl, water, and dried over $MgSO_4$. After filtration and concentration on a rotary evaporator, the sulfites were collected by g.l.c. using either an 8 ft × 0.50 in. 10% DEGS (LAC 728) on 60–80 Diatoport W with an F and M 720, or a 14–19 ft × 3/8 in. 20% DEGS on 40–60 Chromosorb W with a Varian 712 Autoprep. All new compounds gave satisfactory elemental analyses and isomeric purity was in all cases greater than 99% by g.l.c.

Dipole Moments

Dipole moments were calculated by the method of Guggenheim (3) from dielectric constants determined on a Wissenschaftlich-Technische Werkstatten (Germany) Dipolemeter DMO1 at 20 °C. Solvents were spectrograde and dried over Linde molecular sieve type 4A. The determination equation is:

$$\mu^2 = 27kT/4\pi N_L \cdot 1/d_1(\varepsilon_1 + 2)^2 \cdot (a_\varepsilon + a_n) \cdot M_2$$

where

k = Boltzmann constant
N_L = Lohschmidt's number
d_1 = solvent density
ε_1 = solvent dielectric constant
M_2 = solute molecular weight
a_ε = slope of line $(\varepsilon_{12} - \varepsilon_1)$ *vs.* w_2
a_n = slope of line $(n^2_{12} - n_1^2)$ *vs.* w_2
ε_{12} = solution dielectric constant
n_{12} = solution refractive index
n_1 = solvent refractive index
w_2 = solute weight fraction $(m_2/m_1 + m_2)$

At 20 °C the first term is 1.433×10^{-37}

Slopes were determined from a least squares plot on an IBM 1620 Mk II and μ reproducibility was generally better than 0.1 D.

Sulfite Equilibrations

Solutions (1 *M* in sulfite with 100 l BF_3–etherate per 3 ml solution) initially on each side of equilibrium were stirred at room temperature in sealed vials for 2–10 weeks, neutralized with K_2CO_3 and gas chromatographed on a 6 ft × 0.25 in. Carbowax 20M on 60–80 Porapak S. Area ratios were measured by planimeter and corrected for response ratios determined with a standard mixture under identical conditions. Calculations were done according to Eliel and Reese (35) taking T as 298 °K.

NOTE ADDED IN PROOF: Similar conclusions to some of those drawn here are contained in a recent paper by Wucherpfennig (36).

Effect of Solvent Upon the Vicinal Proton Coupling Constants of Complex Substituted Ethanes. II. Anomalous Results for 1-Phenyl-1,2,2-trihaloethanes[1]

W. F. Reynolds and D. J. Wood
Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received September 9, 1970

The n.m.r. spectra of 11 tetra-substituted ethanes have been obtained in a number of solvents. Changes in the vicinal coupling constants of 1-phenyl-1,2,2-trihaloethanes with solvent do not fit the electrostatic model for solvent effects. It is concluded that the theory breaks down because solute–solvent hydrogen bonding specifically favors the *trans* rotamers of these compounds. The conditions under which the theory would be expected to break down are also discussed in more general terms.

Les spectres r.m.n. de 11 éthanes tetra-substitués ont été obtenus dans un certain nombre de solvants. Des changements, avec le solvant, des constantes de couplage vicinales des phényl-1 trihalo-1,2,2 éthanes ne peuvent être accomodés avec le modèle électrostatique des effets de solvant. Il en est conclu que la théorie ne tient pas parce que des ponts hydrogènes entre le solvant et le soluté favorisent le rotamère *trans* de ces composés. Les conditions où la théorie ne serait pas appropriée sont aussi discutées en termes plus généraux.

Canadian Journal of Chemistry, **49**, 1209 (1971)

Introduction

For substituted ethanes containing two or more polar groups, the fractional population of the most polar rotational isomer (rotamer) normally increases on going from the gas phase to a polar or polarizable medium (1). Observed differences for the rotationally averaged vicinal n.m.r. coupling constant(s) of the same compound in different solvents have been interpreted as due to changes in rotamer population (2–4). More recently, Abraham *et al.* have developed an electrostatic theory for the solvent reaction field (5), which enables one to calculate the energy difference between rotamers of a disubstituted ethane as a function of solvent dielectric constant, ε, and the energy difference in the gas phase. It can also be used to calculate vicinal coupling constants for the individual rotamers from changes in rotationally averaged vicinal coupling constants with solvent. The theory has been modified to allow for the presence of three or more dipolar substituents (6) and solvent–solute dipole–dipole interactions (7). It has been successfully used to predict differences between rotamer energy levels in a number of simple substituted ethanes in which two of the three rotamers have degenerate energy levels (8).

We have been interested in the problem of estimating relative rotamer energy levels of more complex substituted ethanes where all three rotamers have different energy levels and where gas phase energy differences are generally not known. We have shown that relative rotamer energy levels for 1-phenyl-1,2-dibromoethane can be correctly deduced from changes of vicinal coupling constants with ε and that reasonable values of relative rotamer energy levels for 1-phenyl-1,2-dibromopropanes can be deduced from the variation of vicinal coupling constants with ε and temperature (9). However, this approach will only be valid if the compounds investigated obey the electrostatic theory (5). In order to test the limits of applicability of the theory to more complex substituted ethanes, we have extended our investigation to include a large number of tetra-substituted ethanes, including 1-phenyl-1,2,2-trihaloethanes, 1-phenyl-1,2-dichloropropanes and 1,1,2-trihalopropanes. The results of these investigations are reported here.

Experimental

1-Phenyl-1,2,2-trichloropropane was produced as a by-product (20% yield) during the chlorination of styrene in CH_2Cl_2. It was separated and purified by v.p.c. Similarly, 1-(*p*-tolyl)-1,2,2-trichloroethane was produced from 4-methylstyrene. 1-Phenyl-1,2,2-tribromoethane was prepared by the addition of Br_2 to *trans*-β-bromostyrene in CH_2Cl_2. The solid product (m.p. 34°) was purified by low temperature recrystallization from methanol.

Bromination of *trans*-β-chlorostyrene in CH_2Cl_2 gave a 52–48 mixture of the two isomeric 1-phenyl-1,2-dibromo-2-chloroethanes. The products could not be separated by v.p.c. or fractional distillation because of their very similar physical properties. Therefore the mixture was purified by v.p.c. and n.m.r. data were obtained using the mixture. Chlorination of *trans*-β-bromostyrene

[1]For Part I, see ref. 9.

in CH_2Cl_2 gave an 80–20 mixture of the two isomeric 1-phenyl-1,2-dichloro-2-bromoethanes with the major product having the larger coupling constant. The corresponding reaction of *cis*-β-bromostyrene gave a 33–67 mixture of the same products. The isomers could not be separated and the two mixtures were purified by v.p.c. The n.m.r. spectra of both mixtures were recorded for each solvent. In every case, coupling constants for a given compound agreed within experimental error, suggesting that solute–solute interactions were unimportant. Assignment of each pair of isomers as *erythro* and *threo* is considered in the Discussion.

Erythro- and *threo*-1-phenyl-1,2-dichloropropane were prepared by addition of Cl_2 to *trans*-1-phenylpropene in CCl_4. The two liquid products were obtained in nearly equimolar quantities. They were separated and purified by v.p.c. 1,1,2-Tribromo- and 1,1,2-trichloropropane were obtained commercially and purified by v.p.c.

All halogenation reactions were carried out in the dark, using 0.3 M solutions of styrenes. The styrenes used in this investigation were obtained commercially and were used without further purification. All products were characterized by n.m.r. and mass spectra. Solvents were dried with appropriate drying agents and distilled in an N_2 atmosphere before use.

The n.m.r. spectra were recorded on a Varian HA-100 spectrometer operating in frequency sweep mode (ambient temperature 30°). Procedures followed were identical to those reported previously (9).

Solution dielectric constants were measured with a W.T.W. DKO3 dielectric constant apparatus with the cell thermostatted at 30°. The v.p.c. purifications were carried out using a Varian Aerograph Autoprep 700 gas chromatograph. Mass spectra were obtained with a C.D.C. 21490 mass spectrometer.

Results

(*b*) Expanded plot of J_{AB} *vs.* $(\varepsilon - 1)/(2\varepsilon + 1)$ for 1-phenyl-1,2,2-tribromoethane.

ethanes were analyzed as AB spectra. Results for room temperature measurements are given in Table 1 and Fig. 1. Results for variable temperature experiments for 1-phenyl-1,2,2-tribromoethane are given in Fig. 2.

The substituted propyl groups for the 1-phenyl-1,2-dichloropropanes and 1,1,2-trihalopropanes gave ABC_3 spectra. As previously reported (9), the splittings of the A and C protons corresponded, within 0.01 Hz, with $|J_{AC}|$ and $|J_{BC}|$. Therefore, the coupling constants were measured directly from these splittings. Values of the vicinal coupling constants are given in Table 2.

Results for 1-(*p*-tolyl)-1,2,2-trichloroethane are given in Table 3. The AA'BB' ring proton spectra were analyzed by an AB approximation. Assignment of ortho and meta protons was based upon the observation of greater long range coupling to the protons ortho to the methyl group (10) and was confirmed by a double resonance experiment in which the methyl group was decoupled.

The r.m.s. error for measurements of coupling constants was always less than 0.05 Hz. It is assumed that coupling constants are accurate within this value.

Rotamers for the various compounds included in this investigation are illustrated in Fig. 3.

Discussion

It is difficult to unambiguously assign pairs of *erythro* and *threo* compounds in the 1-phenyl-1,2,2-trihaloethane series. The actual assignments given are based upon the results of empirical energy calculations (11) similar to those of Scott and Scheraga (12). Pairs of compounds were assigned by assuming that the compound with the larger vicinal coupling constant (J_{AB}) corresponded to the compound with the larger fractional population of the *trans* rotamer. The assignments are believed to be correct since they correspond to predominant *cis* addition of chlorine and *trans* addition of bromine to ethylenic bonds, in agreement with previously reported results for the halogenation of 1-phenylpropene (13). It should be emphasized, however, that the following discussion would not be changed even if one or more of the assignments were incorrect since it is concerned with the anomalous solvent dependence of the vicinal coupling constants of these compounds and not primarily with the relative stabilities of rotamers.

averaged coupling constants of 1-phenyl-1,2,2-trihaloethanes is unusual (see Fig. 1*a*). The J_{AB} value decreases slightly or remains essentially constant on changing from solvents of low to intermediate ε but increases significantly in solvents of higher ε (particularly acetone and dimethylsulfoxide). Previous investigations of simpler substituted ethanes have revealed either a regular increase or a regular decrease in vicinal coupling constants with increasing ε for the solvents used in this investigation (8), although anomalous results have been noted for aromatic and hydroxylic solvents. Results of previous investigations have also been in general agreement with predictions of the electrostatic theory. However, as shown below, this theory does not predict the increase of J_{AB} for 1-phenyl-1,2,2-trihaloethanes in polar media.

Assuming staggered conformations for the three rotamers of 1-phenyl-1,2,2-tribromoethane and C—Br, H—C and C—phenyl bond dipole moments of respectively 1.48, 0.4 (14), and 0.35 D,[2] the predicted dipole moments of rotamers **1**, **2**, and **3** (see Fig. 3) are respectively 1.13, 2.08, and 3.11 D. According to the electrostatic theory, rotamer **3** would be stabilized relative to rotamers **1** and **2** by 0.33 and 0.23 kcal/mol respectively on going from the gas phase to carbon tetrachloride solution and by 0.52 and 0.35 kcal/mol on going from carbon tetrachloride to acetone solution (for details of calculations see Appendix). These predictions are not significantly altered if

one considers deviations from staggered conformations of as much as 15° or if one uses only C—Br group dipole moments in place of C—Br, H—C and C—phenyl bond dipole moments. Therefore, according to the electrostatic theory, the fractional population of rotamer **1** should decrease with increasing ε, leading to a decrease in J_{AB}. The same prediction would be made for all of the other 1-phenyl-1,2,2-trihaloethanes included in this investigation since C—Cl and C—Br bond dipole moments are only slightly different.

The electrostatic theory has recently been modified to include solvent–solute dipole–dipole interactions (7). However, inclusion of a term of this type would lead to the prediction of even greater stability of rotamer **3** (and a correspondingly smaller value of J_{AB}) in polar media

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

(an effect of this type has been demonstrated experimentally for 1,1,2-trichloroethane (7)). Therefore, it must be concluded that neither the simple nor the modified electrostatic theory can explain the observed increase of J_{AB} for 1-phenyl-1,2,2-trihaloethanes in acetone and dimethylsulfoxide.

(b) Evidence for Existence of Specific Hydrogen Bonding Interactions

As shown in Table 1, J_{AB} for 1-phenyl-1,2,2-trichloroethane is nearly independent of concentration in chloroform and acetone over a concentration range from 0.15 to 0.60 *M*. Consequently, it is improbable that anomalous results can be explained in terms of specific solute–solute interactions.

An alternate explanation, which we favor, is that specific hydrogen bonding occurs between the protons of 1-phenyl-1,2,2-trihaloethanes (either involving the ethyl protons or phenyl protons, *vide infra*) and strong hydrogen bonding solvents such as acetone and dimethylsulfoxide and that this hydrogen bonding favors the *trans* rotamer relative to the other rotamers. A similar explanation has been offered to account for the failure of the electrostatic theory to predict accurate rotamer energy differences for 1-chloro-1,2-dibromo-1-iodoethane in polar solvents (16).

In order to test the possibility of specific hydrogen bonding, 1-phenyl-1,2,2-tribromoethane was investigated in a number of additional solvents which were chosen because their hydrogen bonding properties did not parallel their dielectric constants. Assuming that CCl_4, $CDCl_3$, and $(CH_3)_3CCl$ are "normal" solvents, the order of magnitude of deviation of J_{AB} is acetonitrile < tetrahydrofuran < acetone < dimethylsulfoxide (see Fig. 1*b*). This parallels the hydrogen bonding abilities of these solvents as measured by association constants with phenol (17, 18), but is totally unrelated to ε. The large value of J_{AB} in tetrahydrofuran is particularly suggestive of hydrogen bonding in view of the relatively low ε for the tetrahydrofuran solution. Ethanol shows no tendency to stabilize the *trans* rotamer. This may indicate that ethanol preferentially hydrogen bonds to the halogen atoms.

Variable temperature measurements for 1-phenyl-1,2,2-tribromoethane in carbon disulfide, chloroform, and acetone provide support for the suggestion of specific hydrogen bonding in acetone. The J_{AB} value has a much larger negative temperature coefficient in acetone than in the other two solvents. When J_{AB} is plotted as a function of ε at different temperatures (Fig. 2), it is seen that J_{AB} increases rapidly with ε at low temperatures but that the plot becomes flatter as the temperature is increased, *i.e.* the solvent dependence of J_{AB} becomes closer to the predictions of the electrostatic theory at higher temperatures.

This is precisely the behavior which one would expect if the *trans* rotamer were being favored by specific hydrogen bonding in acetone. The extent of hydrogen bonding should decrease with increasing temperature. The negative temperature coefficient for J_{AB} in the other solvents is not surprising. Since rotamer **1** has a smaller total of steric and dipolar interactions than the other two rotamers, it should be the most stable rotamer. This is supported by the relatively large value of J_{AB} in all solvents and by empirical energy calculations (11). Consequently, the fractional population of rotamer **1** would be expected to increase with decreasing temperature, leading to an increase in J_{AB}. There will be a compensating change in each solvent due to the increase in ε with decreasing temperature, but the plots of J_{AB} *vs.* $(\varepsilon - 1)/(2\varepsilon + 1)$ at different temperatures indicate that the former effect predominates.

The chemical shift data for 1-phenyl-1,2,2-tribromoethane suggest specific hydrogen bonding to the protons of the substituted ethyl group. In acetone, H_A (see Fig. 3) shifts to high field by approximately 0.34 p.p.m. (relative to internal tetramethylsilane) when the temperature is increased from $-52°$ to $+78°$. Corresponding shifts in chloroform and carbon disulfide are 0.06 and -0.04 p.p.m. The large shifts in acetone are consistent with hydrogen bond breaking. At room temperature, H_A for 1-phenyl-1,2,2-tribromoethane shifts 0.12 p.p.m. to low field on going from carbon tetrachloride to *t*-butyl chloride but by 0.38, 0.52, 0.62, and 0.93 p.p.m. on going from carbon tetrachloride to acetonitrile, tetrahydrofuran, acetone, and dimethylsulfoxide, respectively. Similar, although smaller, shifts are noted for H_B and for the other compounds investigated (see Table 1).

It can be seen from the above discussion that the chemical shift and coupling constant data for 1-phenyl-1,2,2-tribromoethane are all consistent with the suggestion that basic hydrogen-bonding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

solvents form hydrogen bonds with 1-phenyl-1,2,2-trihaloethanes, preferentially stabilizing the *trans* rotamers **1**, **4**, or **7**.

(c) General Discussion of Conditions for Breakdown of Electrostatic Theory

As stated in the Introduction, the primary purpose of this investigation was to establish the limitations of the application of the electrostatic theory to complex substituted ethanes. On the basis of available evidence, it would appear that di- and tri-substituted ethanes (with at least two halogen substituents) obey the simple (5) or modified (7) theory. Our results suggest that the theory may break down in the case of tetra-substituted ethanes in hydrogen-bonding media and should be used with caution in these systems.

One possible explanation for these observations is that in di- and tri-substituted ethanes all rotamers are hydrogen-bonded to a roughly equal extent while in tetra-substituted ethanes the *trans* rotamer is specifically favored by hydrogen bonding to ethyl C—H protons, possibly for steric reasons. The coupling constant data for 1-phenyl-1,2,2-trihaloethanes (Table 1 and Fig. 1) indicate that steric factors may be important in determining preferential stabilization of the *trans* rotamer. For example, the change in J_{AB} on going from *t*-butyl chloride to dimethylsulfoxide is only 0.27 Hz for 1-phenyl-1,2,2-trichloroethane while it is 0.82 Hz for 1-phenyl-1,2,2-tribromoethane. Average values for the bromodichloro and chlorodibromo compounds are respectively 0.36 and 0.71 Hz.

On the basis of the above explanation, one would expect the probability of breakdown of the theory to increase as the number of electron-withdrawing groups increases, due to increased hydrogen bonding. The evidence concerning this point is ambiguous. The electrostatic theory gives at least qualitatively correct predictions for meso-2,3-dibromobutane (7), *erythro-* and *threo-*1-phenyl-1,2-dibromo- (9) and dichloropropanes (Table 2) and 1,1,2-trihalopropanes (Table 2) while it breaks down for 1-phenyl-1,2,2-trihaloethanes. Three 1,1,2,2-tetrahaloethanes have been investigated. In both 1-chloro-1,2-dibromo-1-iodoethane (16) and 1,1,2,2-tetrafluoroethane (19), the electrostatic theory underestimates the stability of the *trans* rotamer in polar solvents. However, in both cases the deviations probably are less than the possible errors in the calculation. The theory gives good results for 1,1,2,2-tetrachloroethane (20). Consequently, it must be concluded that there is conclusive evidence for the breakdown of the electrostatic theory only in the case of 1-phenyl-1,2,2-trihaloethanes.

An alternative explanation involves specific hydrogen bonding of the solvent with phenyl protons. We have obtained some evidence that the phenyl group may be involved in specific hydrogen bonding. In non-polar solvents, the phenyl proton spectrum of each 1-phenyl-1,2,2-trihaloethane was essentially a single peak but in basic hydrogen bonding solvents a two proton multiplet appeared at slightly lower field. In order to investigate this phenomenon, we synthesized 1-(*p*-tolyl)-1,2,2-trichloroethane. The pattern of chemical shifts for this compound (see Table 3) is consistent with hydrogen-bonding to the phenyl protons. The protons ortho to the trihaloethyl group are shifted to a greater extent than the meta protons.

It is possible that hydrogen bonding may favor the *trans* rotamer simply by increasing the effective size of the phenyl group. On the basis of total steric and dipolar interactions, the *trans* rotamer (**1**, **4**, or **7**) and one of the *gauche* rotamers (**2**, **5**, or **8**) should be favored over the other *gauche* rotamer. The phenyl group is in a less sterically hindered environment than the favored *gauche* rotamer (see Fig. 3). Consequently an increase in size of the phenyl group should favor the *trans* rotamer.

However, in view of the bulk of the trihaloethyl group, it is surprising that the solvent should hydrogen bond to a greater extent to the ortho protons than to the meta protons. It has previously been reported that in 1-methyl-4-X-benzenes (where X was a polar group), acetone preferentially hydrogen bonded to the protons ortho to the methyl group (10*a*). Examination of molecular models suggests an alternate, although highly speculative, explanation for the low field shift of the ortho phenyl protons and, in part, for the increased stability of the *trans* rotamer (**1**, **4**, or **7**). In this rotamer, the β proton (H_A) and one of the ortho protons tend to align in a manner which allows them to simultaneously hydrogen bond to the same solvent molecule. No similar arrangement is possible with the *gauche* rotamer (**2**, **5**, or **8**) since the β proton is *trans* to the phenyl group in this rotamer.

It would obviously be useful to determine more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

conclusively the reasons for the break-down of the electrostatic theory. Low temperature investigations, in which individual rotamers are observed, would be particularly useful in this respect. Our spectrometer cannot, at present, reach sufficiently low temperatures to "freeze out" individual rotamers but it is hoped to modify it to carry out experiments of this type.

In the absence of more definite information, our tentative conclusion is that the electrostatic theory probably breaks down in the case of 1-phenyl-1,2,2-trihaloethanes in polar media because of specific hydrogen bonding to the phenyl groups. However, the possibility that the breakdown is at least in part due to hydrogen bonding to the ethyl C—H protons also cannot be ruled out.

Conclusions

(*1*) Changes in the vicinal coupling constants of 1-phenyl-1,2,2-trihaloethanes with solvent cannot be explained by the electrostatic theory of solvent effects.

(*2*) Chemical shift and coupling data support the postulate that the *trans* rotamers of 1-phenyl-1,2,2-trihaloethanes are preferentially stabilized by hydrogen bonding in basic hydrogen bonding solvents.

(*3*) The preferential stabilization may be due to hydrogen bonding to either ethyl or phenyl protons or to some combination of both effects.

Appendix

The radius of the molecular cavity for 1-phenyl-1,2,2-tribromoethane was estimated by assuming that the difference in molar volume between 1-phenyl-1,2,2-tribromoethane and 1,1,2-tribromoethane was equal to that between 1-phenyl-1-bromoethane and bromoethane. The estimated molar volume and radius of the molecular cavity were respectively 168.4 cm^3 and 4.055 Å. The refractive index, n, was estimated as 1.617, using additive molar refraction parameters (21).

Bond dipole moments used in the calculation of rotamer dipole moments are listed in the discussion. The X—C—C and X—C—X (X ≡ Br or C_6H_5) angles were fixed at 111.5° and H—C—C angles at 109.5°. The following bond lengths (Å) were used: C—C = 1.54, C—C_6H_5 = 1.52, C—Br = 1.94, C—H = 1.11. Due to the completely non-spherical shape of the molecule, the quadrupole moment for each rotamer was calculated choosing the mid-point of the ethyl C—C bond as the origin. Since the calculation should be carried out with the geometrical center of the molecule as the origin, this may have introduced some error, particularly for the *gauche* rotamers (6). However, any significant change in the origin for rotamer **3** would result in an increase in the relatively small value (see below) for the quadrupolar reaction field parameter q_3 and a predicted greater stability for this rotamer.

The calculated values for the dipolar and quadrupolar reaction field parameters (5) are: $k_1 = 0.27_6$, $k_2 = 0.93_5$, $k_3 = 2.08_2$, $h_1 = 1.47_2$, $h_2 = 0.91_2$, $h_3 = 0.24_3$ kcal/mol. These values are generally smaller than previously calculated values for haloethanes (8). This is due to the significantly larger molar volume of this compound and to the use of bond dipole moments in place of group dipole moments.

The above values for k, h, and n lead to eqs. 1 and 2 for the rotamer energy differences (5);

$$[1]\quad \Delta E_{3-1}{}^{s} = \Delta E_{3-1}{}^{g} - [1.806X/(1 - 0.700X)] + [3.687X/(5 - X)]$$

$$[2]\quad \Delta E_{3-2}{}^{s} = \Delta E_{3-2}{}^{g} - [1.147X/(1 - 0.700X)] + [2.007X/(5 - X)]$$

where $\Delta E^g \equiv$ energy difference in the gas phase $\Delta E^s \equiv$ energy difference in a solution of dielectric constant ε, and $X \equiv (\varepsilon - 1)/(2\varepsilon + 1)$ (5). Insertion of solution dielectric constants into eqs. 1 and 2 yields the energy changes quoted in the discussion.

Structure of the Second Coordination Sphere of Transition Metal Complexes. II. Substituted Anilines as Ligands

D. R. EATON, H. O. OHORODNYK, AND LINDA SEVILLE
Department of Chemistry, McMaster University, Hamilton, Ontario

Received[1] January 26, 1970

The role of substituted anilines as second coordination sphere ligands of cobalt(II) complexes has been investigated. Chemical shifts of the ligand nuclear magnetic resonance (n.m.r.) spectra arising from pseudo-contact interaction with the paramagnetic cobalt complex have been utilized for this purpose. It has been found that in each case the aniline preferentially occupies a position perpendicular to the three fold symmetry axis of the complex and tends to be aligned with the amino group directed towards the cobalt atom. Electron withdrawing substituents para to the amino group enhance the second coordination sphere binding and electron donating substituents diminish it. These results are consistent with the idea that the structure of the second coordination sphere is determined by electrostatic interaction with the negatively charged ligands comprising the first coordination sphere. There is competition between aniline molecules and solvent molecules for a position in the second sphere with the solvent competing with increasing effectiveness in the series carbon tetrachloride, benzene, and methylene chloride.

Le rôle des anilines substituées comme ligands de la seconde sphère de coordination des complexes du cobalt(II) est étudié. Les déplacements chimiques des spectres r.n.m. du ligand produits par les interactions de pseudo-contact avec le complexe paramagnétique du cobalt ont été utilisés à cette fin. On a trouvé que dans chaque cas l'aniline occupe préférentiellement une position perpendiculaire à l'axe de symétrie ternaire du complexe, et tend à s'aligner sur le groupe aminé en direction de l'atome de Cobalt. Des substituants-accepteur d'électrons en position para du groupe aminé augmentent la force de liaison de la seconde sphère de coordination, et des substituants-donneur d'électrons diminuent la force en question. Ces résultats sont en accord avec l'idée que la structure de la seconde sphère de coordination est déterminée par des interactions électrostatiques avec les ligands chargés négativement qui composent la première sphère de coordination. Il y a compétition entre les molécules d'aniline et les molécules du solvant pour une position en seconde sphère, l'efficacité de cette compétition du solvant croissant dans l'ordre de tétrachlorine de carbon, benzène et chlorure de méthylène.

Canadian Journal of Chemistry, 49, 1218 (1971)

Introduction

In the first paper in this series (1, and references therein) a method for studying the structure of the second coordination sphere of transition metal complexes based on pseudo contact interactions between a paramagnetic metal complex and protons on the complexing ligand was described. In the system studied it was demonstrated that aniline and pyridine interacted with the metal complex in preference to the solvent, that the enthalpy change involved in the formation of such a second sphere complex was of the order of 2 or 3 kcal/mol, and that there was a definite preferred geometry for the resulting complex. The present experiments were designed to investigate the effect of changes in the electronic nature of the ligand on the structure of the second sphere complexes. For this purpose the complexing of a number of substituted anilines has been investigated. The tentative conclusion reached in the first paper was that electrostatic attraction between the negatively charged nitrogen atoms surrounding the cobalt ion and the second coordination sphere ligand provided the binding energy for the complex. If this is correct, para substitution of the aniline with an electron withdrawing ligand should enhance the binding and para substitution with an electron donating ligand should diminish it. Data pertinent to this point are reported in the present paper.

Results

Co(II) trispyrazoylborate ($Co[HBpz_3]_2$) (2) was again used as the complexing agent. The structure of this compound and the preferred orientation of an aniline molecule in the second coordination sphere is shown in Fig. 1. Previously we have used carbon tetrachloride as an "inert" solvent. Limited solubility of some of the substituted anilines restricts the use of this solvent but data has been obtained for *p*-anisidine, *N*,*N*-dimethyl *p*-phenylenediamine, and *p*-aminobenzotrifluoride. The design of the experiments was similar to that developed in the earlier paper (1). Initially the chemical shifts of the aniline protons were measured in the presence of both Co(II) trispyrazoylborate and Zn(II) trispyrazoylborate. These latter two compounds are structurally

[1]Revision received December 3, 1970.

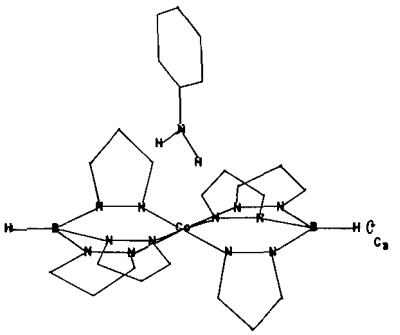

FIG. 1. Geometry of Co(II) trispyrazoylborate and preferred orientation of complexing aniline molecule.

TABLE 1. Aniline shifts in the presence of zinc and cobalt complexes*

Substituent	Position	Co shift	Zn shift
p-CF_3	Ortho	54	2
	Meta	26	1
	NH_2	47	14
p-OCH_3	Ortho	34	5
	Meta	15	3
	NH_2	32	1
p-$N(CH_3)_2$	Ortho	28	4
	Meta	17	7
	NH_2	27	12

*Data refer to shifts observed in 0.08 M solutions of $Co[HBpz_3]_2$ and $Zn[HBpz_3]_2$, respectively, in carbon tetrachloride. All shifts are in Hz and are to high field. Ortho and meta refer to the position with respect to the NH_2 group.

similar and differ only in the paramagnetism of the cobalt compound. The data of Table 1 show that the shifts of the aromatic protons of p-aminobenzotrifluoride in the presence of zinc complex are indeed small compared with those in the presence of cobalt complex and hence that the pseudo contact interaction is dominant. These shifts will be determined by the relationship

$$\Delta\nu = \frac{-D(3\cos^2\theta - 1)}{r^3}(g_{\parallel} - g_{\perp})$$

where r is the distance between the metal atom and the nuclear dipole under consideration, θ is the angle between the principal axis of the molecule and the vector joining the metal to the ligand nucleus, D is a constant, and $g_{\parallel}$ and $g_{\perp}$ are the principal values of the **g** tensor. It is the presence of the factor $(3\cos^2\theta - 1)/r^3$ which provides information on the geometry of the second coordination sphere complex. The D value for $Co[HBpz_3]_2$ is known (3) and it is therefore possible to use the pseudo contact shifts to obtain information on the geometry of the complex. However, for the purposes of the present paper it suffices to note that positive values of $\Delta\nu$ (*i.e.* high field shifts) correspond to negative values of $3\cos^2\theta - 1$ and hence that θ has values around $\pi/2$ and that the $1/r^3$ dependence of the shifts determines that the ligand protons closest to the cobalt will be shifted most. The situation for p-anisidine and N,N-dimethyl-p-phenylenediamine is somewhat less clear cut since the shifts with the cobalt compound are smaller and those with the zinc compound larger, but it is still apparent that pseudo contact effects make the main contribution to the shifts.

The aromatic protons of the anilines were assigned by reference to the mono substituted compounds which have been analyzed previously (4). Thus the ortho protons of p-anisole are found at lower field than those of aniline, hence it is deduced that the lower field resonance in p-anisidine arises from the protons ortho to the OCH_3 (meta to the NH_2) and the higher field resonance from those ortho to the NH_2. Similarly the protons ortho to the NH_2 of dimethylphenylenediamine are also assigned to higher field. At 100 Mc/s the aromatic protons of trifluorobenzoaniline are well separated and the chemical shifts can be measured directly. For p-anisidine and N,N-dimethylphenylenediamine the chemical shifts are of the same order as the larger spin–spin coupling constant and these were treated as AB spectra using the analytical expressions of Pople, Schneider, and Bernstein (5).

It has been shown previously (1) that for a model involving association between the aniline (L) and cobalt complex (X) of the simple type $X + L \rightleftharpoons XL$ with equilibrium constant K, providing the exchange between free and associated L is fast on the n.m.r. time scale, the observed shifts will be given by

$$[1] \qquad \Delta\nu_{obs} = \frac{K[X]\Delta\nu_0}{1 + K[X]}$$

where $\Delta\nu_0$ is the shift of the complexed ligand. It is apparent from this equation that providing $K[X] \ll 1$, a plot of $\Delta\nu_{obs}$ *vs.* [X] will be linear. This was found to be the case for aniline and also appears to hold for substituted anilines. Typical plots of $\Delta\nu_{obs}$ *vs.* [X] are shown in Fig. 2 and the derived slopes x are collected together in Table 2.[2]

It has also been shown that the temperature dependence is determined by the equation

TABLE 2. Experimental results in carbon tetrachloride*

Substituent	x (Hz) Ortho	Meta	NH_2	x_{ortho}/x_{meta}	y (kcal) Ortho	Meta	Hammett σ	Dipole moment (D)
p-H(ref. 1)	500	240	532	0.48	−2.5	−2.3	0.0	1.55
p-CF_3	740	343	889	0.46	−3.5	−3.7	0.55	4.28
p-$N(CH_3)_2$	360	214	—	0.59	−2.7	−2.5	−0.60	1.43
p-OCH_3	410	189	—	0.46	—	−2.1	−0.27	1.82

*From eq. 1 it is apparent that the slope x can be formally identified with the product $K\Delta\nu_0$ and from eq. 2 that the slope y similarly corresponds to ΔH. However, as has been discussed previously (1) these parameters do not have any rigorous thermodynamic significance since they represent only average values for a range of possible geometries rather than definitive data for a complex of well defined structure. We have therefore avoided the use of the symbols K and ΔH which have specific thermodynamic connotations. It remains true though, that x is a measure of the extent of second coordination sphere interaction even though we cannot distinguish between the effect of more molecules being complexed or the same number being more tightly bound and that y, although a complex average, is a measure of the difference in energy between a metal complex/aniline and a solvent/aniline environment.

$$[2] \quad \ln \Delta\nu_{obs} = \frac{-\Delta H}{RT} + \frac{\Delta S}{R} + \ln [X] + \ln \Delta\nu_0$$

Before applying this equation it is necessary to make an appropriate correction for the Curie law temperature dependence of $\Delta\nu_0$. This was effected by measuring the temperature dependence of the pyrazoyl protons of $Co[HBpz_3]_2$ and multiplying the observed aniline shifts at temperature T by the ratio of pyrazoyl shift at temperature T to that at a standard temperature (25 °C) in the manner described previously. A typical plot of $\ln \Delta\nu_{corr}$ *vs.* $1/T$ is shown in Fig. 3 and the measured slopes of these plots, y, are given in Table 2.[2] The agreement between the values obtained from the ortho and meta protons is seen to be quite good and with some allowance for possible systematic errors we obtain the values -3.6 ± 0.5 kcal for the *p*-CF_3 compound, -2.6 ± 0.2 kcal for the *p*-$N(CH_3)_2$ compound and -2.1 ± 0.6 kcal for the *p*-OCH_3 compound.

It would obviously be desirable to extend these measurements to a wider range of substituted anilines but this requires a change of solvent. Preliminary experiments indicated that the results obtained are very solvent dependent. Thus methylene chloride is a very suitable solvent for a wide range of anilines but in all cases the addition of $Co[HBpz_3]_2$ leads to no significant pseudo-contact shifts. It must be concluded either that the anilines cannot compete favorably with the methylene chloride in the solvation of the cobalt

complex or that solvation of the aniline by the methylene chloride is too strong to allow preferential complexing with the $Co[HBpz_3]_2$. It is these factors of course which enhance the solubility of the cobalt complex or the anilines and it is apparent that meaningful results can only be obtained with a restricted range of solvents. Methylene chloride has a dipole moment comparable to that of aniline so it is perhaps not surprising that it is an equally efficient solvating agent.

It has been found that benzene has some advantages as a compromise solvent. A rather wide range of anilines are soluble but this advantage is to some extent off-set by the small shifts observed which is reflected in the lower accuracy of the derived parameters. In Table 3 the shifts of the ortho and meta protons of a number of anilines in carbon tetrachloride and benzene (C_6D_6) are shown to illustrate the magnitudes of the shifts observed. That the reduced shifts are caused at least in part by competition between the solvent and the aniline for positions in the second coordination sphere of the cobalt complex is illustrated by the shift in the position of the resonance of the residual hydrogen in the deuterated benzene with increasing concentration of cobalt complex which is clearly apparent in the spectra of Fig. 4. With increasing complex concentration the benzene resonance moves to high field showing that the solvent molecule competes with the aniline for a position perpendicular to the symmetry axis of the molecule as illustrated in Fig. 1. Analysis of the data follows the method previously outlined and values of x and y are contained in Table 4.

Discussion

Consider first the results in carbon tetrachloride. We might first note that the basic geometry of the second coordination sphere complex is unchanged by substitution on the aniline. All pseudo-contact shifts are to high field showing that the approach of the aniline is perpendicular to the three-fold symmetry axis of the $Co[HBpz_3]_2$. In each case the shift of the ortho proton is greater than that of the meta proton indicating that the amino end of the molecule is directed towards the cobalt. The ratio of the meta to ortho shifts is within experimental error identical for the p-H, the p-CF_3, and the p-OCH_3 derivatives (0.47, 0.46, and 0.46, respectively). The only other ratio which is available for comparison is that involving the amino protons. These protons are broadened to a greater extent than the aromatic protons by the addition of the paramagnetic complex and only in the case of the p-CF_3 derivative did it prove possible to measure their position with any degree of certainty. The observed x ratio of 1.20 agrees reasonably well with that of 1.07

previously reported for the unsubstituted anilines. It is concluded therefore that the geometries of the second sphere complexes formed by the above three compounds are closely similar.

The case of the p-$N(CH_3)_2$ derivative is less clear cut. The only ratio available for comparison is that of meta:ortho and the value of 0.59 is significantly different from those obtained for the compounds previously discussed. This compound has the smallest dipole moment of any of the molecules in this series and it might be argued that the second coordination sphere complex will have the least rigid structure. It has previously been pointed out that restricted tumbling or libration of the aniline will tend to make the shifts of different protons more nearly equal and the above observation could be rationalized on this basis.

It is apparent that qualitatively the expectation that electron withdrawing substituents on the aniline will enhance the binding of the second sphere ligands and electron donating substituents will diminish it is upheld. This is perhaps most clearly seen by noting the correlation between the x values for the protons ortho to the amino group and the Hammett σ values (6) for the substituent. Thus for the p-CF_3, p-H, p-OCH_3, and p-$N(CH_3)_2$ derivatives the ortho x values are 740, 462, 410, and 360 Hz, respectively, and the Hammett σ values are $+0.55$, 0.00, -0.27, and -0.60. It might also be noted that the dipole moments of these four compounds (7) are 4.28, 1.55, 1.82, and 1.43 D, respectively. The most plausible interpretation is that increasing positive charge on the amino group leads to stronger electrostatic interaction with the neighboring negatively charged nitrogens. Thus the idea of an electric "double layer" surrounding the metal ion with the first sphere ligands oriented with their negative ends towards the positive metal ion and the second sphere ligands oriented with their positive ends towards the metal ion receives additional support. It might next be asked whether the increasing x with electron withdrawing substituents is due to a change in K, the equilibrium constant, or a change in $\Delta\nu_0$, reflecting a contraction of the second coordination sphere due to tighter binding. However, as has been discussed previously, due to the relatively long time scale of the n.m.r. experiment it is not meaningful to try to separate these factors on the basis of the present type of experiment. We can only conclude that the average environment of the aniline involves increased interaction with the cobalt complex when an electron withdrawing substituent is present and can say nothing about the detailed kinetic processes which give rise to this average. It is possible to obtain a measure of the enthalpy changes for the formation of the second sphere complexes by studying the temperature dependences of the n.m.r. shifts. The values obtained of -3.6, -2.4, -2.1, and -2.6 kcal for the p-CF_3, p-H, p-OCH_3, and p-$N(CH_3)_2$ derivatives do not show a pronounced systematic variation with the donor ability of the substituent. These numbers represent the differences between the interaction energy of an aniline molecule with surrounding solvent molecules and with the $Co[HBpz_3]_2$ molecule. Since both of these quantities will vary with the substituent and the measured quantity is probably a small difference between two relatively large numbers it is perhaps not surprising that the data do not show a well defined trend.

The data obtained in deuterobenzene serve to compliment the carbon tetrachloride data discussed above. A rather wider range of anilines can be examined but the data are less accurate due to the smaller shifts and the more restricted temperature range available. In some cases there is also a problem of overlap from the resonance of the residual hydrogen in the solvent. The parameters given in Table 5, particularly the y values, are therefore somewhat less precise than those obtained in carbon tetrachloride. They do, however, serve to illustrate a number of points.

First of all it may be noted that all values of x are less than those obtained in carbon tetrachloride by a factor of about two. However, for the compounds for which there are data in both solvents the ratios of the ortho to meta shifts agree quite well. This includes the reproduction of an anomalously high value for N,N'-dimethylphenylenediamine. Taken together with the fact that there is a significant high field shift of the solvent resonance these observations suggest that the structure of the second sphere complexes is much the same in both solvents but that the competition between solvent and aniline molecules for a second sphere position is less favorable to the aniline when benzene is the solvent. This effect is of course reinforced by the known interaction between benzene and aniline. Data have also been obtained for two additional electron withdrawing substituents, p-NO_2 and p-CN, and

these show the expected behavior of stronger complex formation. In both cases the meta:ortho ratios are lower than for aniline and by an argument analogous to that developed for the *p*-$N(CH_3)_2$ this could be interpreted as implying that the second sphere complex structures are more rigid due to stronger binding. Arguments developed previously showed that either a smaller metal-to-amino nitrogen distance or a diminution in the tendency of the aniline molecule to tumble would lessen this meta-to-ortho ratio. Complexing with *m*-nitro aniline was also examined. In this case the shifts were all relatively small and it seems reasonable that steric factors are becoming important. The *y* values obtained are all of the expected order of magnitude and it would probably be unwise to attach too much significance to variations within the series.

The results of the present paper can be summarized as follows. The second sphere coordination complexes formed between substituted anilines and $Co[HBpz_3]_2$ have the same basic geometry as that previously found for aniline itself. Stronger complexes are formed if the substituent is electron withdrawing than if it is electron donating. This is consistent with the idea that the structure of the second sphere is determined by electrostatic interaction with the negatively charged first sphere ligands. The observation that the non-polar benzene molecule can also participate in the second sphere suggests that induced dipolar forces must also be considered. It is also apparent that steric factors will probably be important. An interesting implication of the present results is that if second sphere complexing does indeed play an important part in the mechanism of ligand substitution processes the electronic factors which tend to favor second sphere complexing and hence more facile substitution will tend to make the molecule less satisfactory as first sphere ligand. Such a result has interesting implications for the coupled ligand exchange reactions which constitute the cyclic mechanisms found in homogeneous catalysis. Experimental investigations in this area are underway and will be reported in subsequent papers in this series.

Experimental

The n.m.r. spectra were obtained on a Varian HA 100 spectrometer. The proton shifts were measured relative to tetramethylsilane used as an internal calibrant to obviate the need for susceptibility corrections. Cobalt and zinc trispyrazoyl borates were prepared by Dr. S. Trofimenko in a manner described previously and other chemicals were obtained commercially.

A number of experiments were carried out to investigate the possible effects of impurities in the anilines. Several were purified by vacuum distillation. This procedure had no appreciable effect on the observed shifts. It was also demonstrated that the maximum change in line position obtained by saturating the solutions with water was of the order of 1 Hz.

The authors are indebted to Dr. S. Trofimenko of the Central Research Department, E. I. Du Pont de Nemours and Co., Wilmington, Delaware for gifts of cobalt and zinc trispyrazoyl borates and to the National Research Council of Canada for financial support of this research.

The Motion of Guest Molecules in Clathrate Hydrates[1]

D. W. DAVIDSON
Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received September 25, 1970

The reorientation of molecules encaged in hydrates of structures I and II is controlled mainly by the cage geometry and the electrostatic fields of the water molecules. Departure from spherical symmetry of the short-range interactions between the guest molecule and the water molecules which form the cages leads to preferred orientations which become increasingly occupied at low temperatures. A modified Lennard–Jones potential energy calculation shows the preferred positions of Cl_2 to lie off-center and close to the equatorial plane of the tetrakaidecahedral cage with the Cl atoms near the axial planes of symmetry. In an attempt to account for the remarkable reorientational freedom of polar guest molecules, the electrostatic fields of the water molecules are treated in detail. It is shown that the geometry of the cages causes the sum of the fields of the cage water dipoles to almost vanish at points near the cage center, but that this is not true of the resultant quadrupolar fields. It is suggested that the quadrupolar fields are also relatively small because the hydrogen bonding to four neighbors considerably reduces the quadrupole moment of the water molecule. The orientational disorder of the water molecules results in a wide distribution of resultant electrostatic fields in different cages. This appears to be the origin of the great width of the dielectric absorption observed at low temperatures in tetrahydrofuran hydrate and of the wide temperature range of variation of the proton magnetic resonance (p.m.r.) line width in tetrahydrofuran deuterate.

La réorientation des molécules encagées dans des hydrates de structures I et II est principalement contrôlée par la géométrie de la cage et les champs électrostatiques des molécules d'eau. L'écart à la symétrie sphérique des intéractions à courte distance entre les molécules d'eau qui forment les cages et la molécule qui y est emprisonnée conduit à des orientations préférentielles qui deviennent plus fréquentes à basse température. Un calcul d'énergie potentiel de Lennard–Jones modifié montre que les positions préférentielles de Cl_2 sont décentrées et proches du plan équatorial de la cage tetrakaidecahedrale avec les atomes de Cl proches des *plans axiaux* de symétrie. Dans une tentative de rendre compte de la liberté remarquable de réorientation des molécules polaires emprisonnées, les champs électrostatiques des molécules d'eau sont traités en détail. On montre que la géométrie des cages entraînent la somme des champs dus aux dipôles aqueux de la cage à presque s'annuler en des points proches du centre de la cage, mais ceci n'est pas vrai des champs quadrupolaires résultants. On suggère que les champs quadrupolaires sont aussi relativement petits parce que la liaison hydrogène avec quatre voisins réduit considérablement le moment quadrupolaire de la molécule d'eau. Le désordre d'orientation des molécules d'eau entraîne une distribution étendue des champs électrostatiques résultant dans les différentes cages. Ceci apparaît être à l'origine de la grande largeur d'absorption diélectrique observée aux basses températures dans l'hydrate de tétrahydrofurane et du grand intervalle de température de variation de la largeur de raie r.m.p. dans le deuterate de tétrahydrofurane.

Canadian Journal of Chemistry, 49, 1224 (1971)

I. Introduction

This report is intended to serve as an introduction to a number of others in which the results of dielectric and wide-line nuclear magnetic resonance (n.m.r.) studies of the motions of a variety of molecules encaged in clathrate hydrates of von Stackelberg's structures I and II (1) will be presented. The first of these describes the dielectric properties of cyclobutanone hydrate and follows (2).

Among clathrate substances the clathrate hydrates are unique in the variety of cage geometries present and in the variety of guest molecules which may be incorporated in them (3). The lattices are ices in the sense that they consist of 4-coordinated hydrogen-bonded water molecules. In hydrates of structures I and II the hydrogen-bonded O---O---O angles are distorted from the tetrahedral angle by only, on average, 3.7 (4) and 3.0° (5), respectively (Table 1). The orientations of the water molecules, at least at relatively high temperatures, are disordered, as is shown by their dielectric relaxation. The disorder is not necessarily complete, as it is in cubic and hexagonal ices: that is, each of the six hydrogen-bonded orientations at each site may not be of equal average stability. But unlike the case of ice III (6), complete ordering is not possible within the unit cells which have been defined for the oxygen atoms. Indeed, any extensive degree of ordering is prevented by the correlations between neighboring water molecules which are required for full hydrogen bonding within the five- and six-membered rings of water molecules. Some of the consequences of this disorder are considered below (Section III).

The four cages which occur in hydrates of structures I and II are shown in Fig. 1. They con-

sist of 20 to 28 water molecules, each hydrogen-bonded to three neighbors within the cage wall and to a fourth neighbor outside the cage. The latter lies approximately on the extension of the line joining the center of the cage to the cage water molecule to which it is hydrogen-bonded. Distances from the cage centers of the water molecules which form the cages are given in Table 1, as given by the X-ray studies of the structure I hydrate of ethylene oxide (4) and the structure II double hydrate of tetrahydrofuran and hydrogen sulfide (5). In terms of these distances the most spherical cage is the large cage of structure II which shows a variation of no more than 2% in cage radius. In the large cage of structure I the variation is 14%.

It is significant that the formation of almost spherical cages in these and other related (3) hydrate structures is accompanied by no great distortion of the O---O---O angles from tetrahedral (Table 1) and by no great difference between the lattice energies and that of hexagonal ice (7, 8). A simple model suggests the geometrical reasons for this.

We suppose the O---O bonds between a water molecule and three of its neighbors a distance l away to make tetrahedral angles with one another. These four oxygen atoms then lie on an element

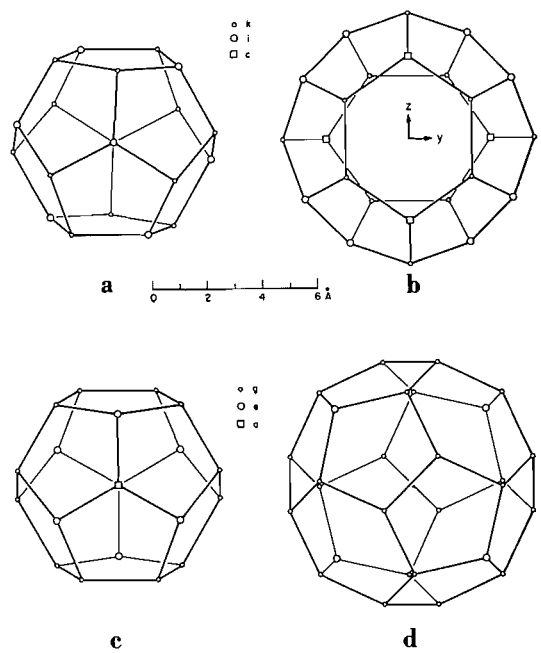

FIG. 1. The small and large cages of structure I (*a* and *b*) and of structure II (*c* and *d*) hydrates, viewed along an axis of greatest symmetry. The point group symmetries are respectively, $m3$, $\bar{4}2m$, $3m$, and $\bar{4}3m$. Literal identification of the non-equivalent oxygen sites follows the notation of *The International Tables for X-ray Crystallography* for space groups *Pm3n* and *Fd3m*.

of surface of a sphere whose center lies on the axis of 3-fold symmetry. A real cage consisting of an integral number of water molecules cannot of course be constructed in this way. However, if it be imagined that elements of the cage surface are so constructed, and to each molecule is assigned an appropriate element of surface area in the form of an equilateral spherical triangle bounded by the great circles which are the normal bisectors of the three bonds of each water molecule, it is found that each water molecule of this idealized cage occupies a fraction 1/24.09 of the area of the sphere. In structures I and II the cages are formed of 20, 24, and 28 water molecules. The model further leads to a cage radius of 3/2 l, or 4.14 Å for $l = 2.76$ Å as in hexagonal ice. This is only a few hundredths Å less than the mean cage radii found (Table 1) in structures I and II, in each of which the mean l is 2.79 Å. Thus it appears that the existence of cages is made possible and their general size determined by the tendency of water molecules to bond tetrahedrally, along with the circumstance that the angles in pentagonal and hexagonal faces need not depart greatly from the tetrahedral angle. A further requirement is, of course, that faces and edges be shared by cages in a way that permits formation of a unit cell. This is not possible if only one kind of cage is present (3).

The actual clathrate structure formed is determined by the nature of the guest molecule, particularly by its size (1, 3). With the exception of bromine (9) and various amines (3), which form clathrate hydrates of distinct and possibly unique structures, and of molecules which interact strongly and specifically with water to form, like ammonia and hydrogen chloride, stoichiometric hydrates, non-electrolyte molecules lying between about 3.8 (argon) and 6.5 Å (cyclobutanone) in maximum diameter form clathrate hydrates of structures I or II. Cyclopropane (10, 11) and trimethylene oxide (12) under suitable conditions can form either. The diameters of these molecules (5.3 to 5.5 Å) are intermediate between those of the small molecules which form hydrates of type I exclusively and of the larger molecules which form type II. The upper limit to the size of molecules which form each structure roughly agrees with the "free diameter" of the larger cage obtained by subtracting the van der Waals radius of the water molecule (1.45 Å) from the appropriate "average distance to center" given in Table 1. Complete occupancy of the smaller cages is approached for molecules less than about 5.0 Å in diameter, although partial occupancy is possible for somewhat larger molecules like chlorine and ethylene oxide (13). The larger cages of each structure seem generally to be almost completely occupied.

The absence of any strong interaction of a specific nature between individual water molecules and the guest molecule is clear not only from the prevalence of iso-structural hydrates for a wide variety of type of guest molecule but also by the exceptional degree of rotational mobility of the guest molecules. Reorientation rates of the order of 10^{10} s^{-1} and above at temperatures as low as 90 °K have been shown by microwave dielectric studies of ethylene oxide, tetrahydrofuran, and acetone hydrates (14, 15). The extent to which free rotation is approached at high temperatures is as yet uncertain. In their thermodynamic treatment (7) Platteeuw and van der Waals assumed that at 0 °C the rotational partition function of small guest molecules like methane was the same as that of the gas. Parsonage and Staveley (16) found a roughly gas-like contribution to the specific heat above 150 °K from the rotation of methane in the β-quinol clathrate in which the cages are approximately the same size, as, if less symmetric than, the pentagonal dodecahedral hydrate cages. Interaction with the cage walls, however, may well be expected to eliminate any possibility of a line structure in the microwave region associated with free molecular rotation.

The energy of a guest molecule depends on its position and orientation within the cage as determined by three major contributions: (*i*) short-range interactions between the guest and water molecules due to London dispersion and orbital overlap forces, and longer range interactions of guest molecules (*ii*) with the electrostatic fields of the water molecules and (*iii*) with the (mainly) dipolar fields of guest molecules in neighboring cages. Proper evaluation of each of these contributions is generally difficult but some conclusions may be drawn from the approximate analysis which follows.

II. Short Range Interactions with the Lattice Molecules

Monatomic Guests

The position-dependence of the energy of rare gas molecules in structure I cages and in the small cages of structure II has recently been considered by Barrer and Edge (8). The interaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

energy was taken as the sum of the pair-wise Lennard–Jones interactions between the rare gas atom k and individual water molecules i

$$[1] \qquad V_k = C_k \sum_i \left[\frac{1}{2}\left(\frac{r_{0k}}{r_{ik}}\right)^{12} - \left(\frac{r_{0k}}{r_{ik}}\right)^{6} \right]$$

where i included 1244 water molecules for structure I and 146 for structure II. The separation r_{0k} of minimum pair energy $-C_k/2$ was taken (8) as the sum of the van der Waals radii of the water molecule (1.40 Å for the oxygen atom) and of the rare gas atom. The enthalpies of encagement calculated with values of C_k obtained from the expressions of London, Slater and Muller, and Slater and Kirkwood were compared with those determined experimentally from the variation with temperature of the Langmuir equilibrium constant $K = \theta/(p(1 - \theta))$, which describes the degree of cage occupancy θ in terms of rare gas pressure p, for the small cages of chloroform structure II hydrate. There was best approximate agreement with the C_k values of Slater and Kirkwood. The "experimental" C_k values derived for chloroform double hydrates were used for calculation of the potential energies of the rare gases in the two cages of structure I.

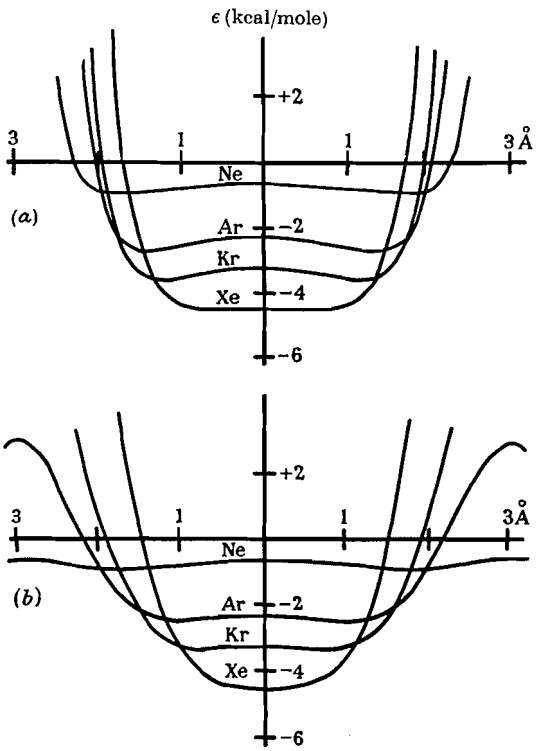

FIG. 2. Lennard–Jones potential energy of rare gas molecules (with London C_k) in the tetrakaidecahedron as a function of displacement from the center along a line (*a*) in the equatorial plane, (*b*) along the polar $\bar{4}$ axis. From ref. 8.

Figure 2 shows the variation of potential energy within the large cages of structure I along two directions through the cage center. For argon and krypton the energy hump at the center amounts to several hundred calories per mole. The directional dependence of the energy apparent for this cage is much less in the smaller cages of either structure and a small central energy maximum occurs only for argon (8).

Diatomic Guests

For homonuclear diatomic molecules the electrostatic fields of the water molecules may again be neglected to good approximation. (The orientation-dependent energies involve these electrostatic fields principally through the anisotropy of the polarizability and the quadrupole moment of the guest molecule. For magnitudes of field and field gradient of the order of those obtained later (Section III) both energies are less than 0.1 kcal/mol.)

Attempts to take the asymmetries of diatomic and polyatomic guest molecules into account for purposes of estimating clathrate hydrate dissociation pressures have been made by McKoy and Sinanoglu (17), who used a Kihara potential function (18) to represent the interaction between a guest molecule and an oxygen atom of water. As in earlier applications of the Lennard–Jones 12–6 potential by van der Waals and Platteeuw (19), the Lennard–Jones–Devonshire method of integrating the interactions with the oxygen atoms over the surface of a sphere of mean cage radius was adopted. The resulting form of the potential function (Fig. 3 for example) has a higher and broader central maximum than in the Lennard–Jones case, the effect being more pronounced for the pseudo-diatomic ethane molecule than for nitrogen and oxygen. The smearing-out of the cage oxygen atoms removes the orientation dependence of the energy and the potential function, having been effectively averaged over all orientations, becomes a function only of the position of the center of mass. Nevertheless, the results suggest that molecules of ethane, which according to Fig. 3 have an energy about 0.5 kcal/mol higher at the cage center than at positions 0.9 Å away, should tend at low temperatures to lie considerably off-center with the

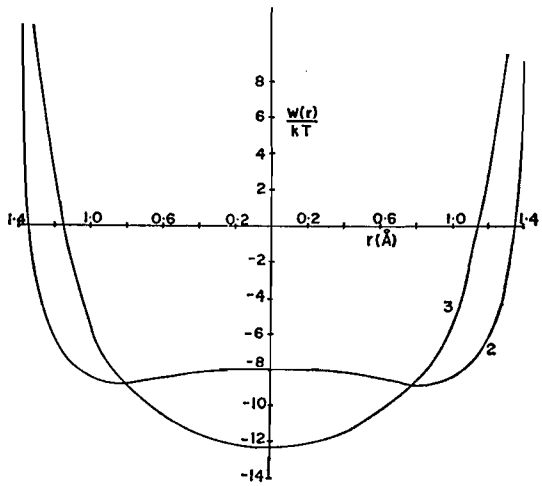

FIG. 3. Spherically symmetric (3) Lennard–Jones and (2) Kihara potential of ethane at 0 °C. From ref. 17.

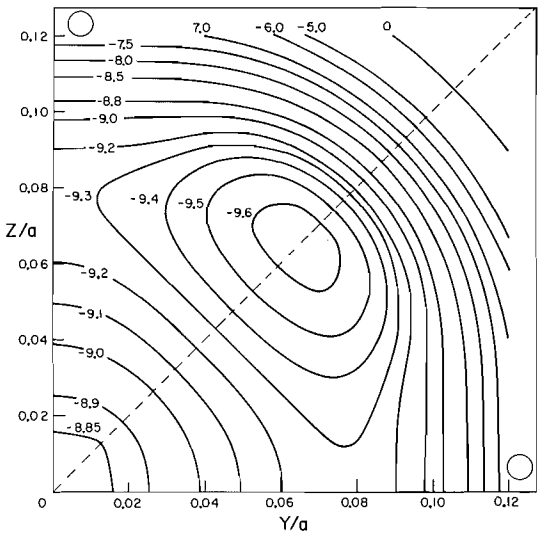

FIG. 4. Equipotential lines for center of mass of Cl_2 in the equatorial plane of the tetrakaidecahedron. The circles mark the positions of least energy of the Cl atoms.

methyl groups in van der Waals contact with cage water molecules. A similar tendency for other diatomic molecules to "stick" at low temperatures to the walls in off-center positions and therefore to experience finite barriers to reorientation is to be expected.

The case of chlorine hydrate is considered in more detail since some information about the X-ray structure factor of encaged chlorine is available (20). We represent the guest–host interaction in the large structure I cage by the superposition of two Lennard–Jones potential functions (eq. 1), one for each chlorine atom, and thereby neglect the presence of the bond. The value of r_{0k} was taken as 3.2 Å and the coordinates of the oxygen atoms from (4). The r_{ik}'s were expressed in terms of the coordinates of the center of mass of the chlorine molecule and the two angular coordinates specifying the direction of the chlorine bond (length = 1.988 Å). The right-handed coordinate system was that of Fig. 1(*b*).

The Lennard–Jones sum over the two chlorine atoms and the 24 water molecules of the cage wa found to have an absolute minimum at $x = 0$, $y = z = 0.065\,a$ (where the cubic lattice parameter $a = 12.1$ Å (20)), $\theta = 91.5°$ (measured from the $+x$ direction), and $\phi = 135°$ (measured from the $+y$ direction) and at three other equivalent positions generated by reflexion in the xy and xz symmetry planes. This energy is scarcely changed by a slight rotation to bring the molecule into the yz plane ($\theta = 90°$). The energy contours in one quadrant of this equatorial plane are shown in Fig. 4, where the numbers are the van der Waals sums as yet unmultiplied by the energy C_k. The potential defined at each point of the figure is for the value of ϕ at which the energy is a minimum. This value is 90° for points along the y axis, 0° along the z axis, and is usually but not always roughly defined by the direction of the equipotential line.

The value of C_k may be estimated from the heat of formation of chlorine hydrate from ice and gaseous chlorine, $\Delta H_h = -6.5 \pm 0.5$ kcal/mol at 0 °C (21). If the lattice energy is not appreciably affected by the presence of guest molecules, the heat of formation of $Cl_2 \cdot nH_2O$ is

$$[2] \qquad \Delta H_h = n\Delta H_0 + \Delta H_i$$

where ΔH_0 is the heat of formation of the empty lattice from ice and ΔH_i is the heat of intercalation of chlorine from the gas. We adopt Barrer and Edge's (8) average value of ΔH_0 for the rare gas hydrates, *viz.* 0.35 kcal/mol, and somewhat arbitrarily, in view of the range of composition of chlorine hydrate which has been reported (13), take $n = 6.6$. This is tantamount to complete occupancy of the larger cages and about half occupancy of the smaller cages. Since there are three times as many large as small cages in the lattice, only about 14% of the chlorine molecules occupy small cages and little error is introduced by ignoring the difference between the heats of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

intercalation in the two cages, which is not likely to be great. We thus estimate $\Delta H_i = -8.8$ kcal/mol at 0 °C. This is related to the potential minimum $V_{min} = -9.64\ C_k$ of Fig. 4 approximately by

$$[3] \qquad \Delta H_i = V_{min} + 3RT/2$$

where the small zero-point energy of encaged chlorine has been neglected and $3RT/2$ refers to the excess of the enthalpy of translation and rotation of the encaged molecule over that of the gas, it being assumed that the encaged molecule makes the classical contribution from 5 translational and rotational vibrations. C_k then becomes 1.0 kcal/mol, with an uncertainty of perhaps 0.2 kcal/mol. This appears to be a reasonable value for the chlorine atom in Cl_2: the "experimental" value for argon was found (8) to be 0.93 kcal/mol.

The numbers on the equipotential lines of Fig. 4 may then be read, approximately, as kcal per mol.

The three-dimensional equipotential surfaces in the vicinity of the potential minimum are roughly ellipsoids with two principal axes in the equatorial plane in the direction of, and perpendicular to, the diagonal, and the third axis in the x direction. The approximately quadratic dependence on displacement in these three directions (particularly poor in the first case) gives 40, 23, and 27 cm^{-1} for the ground state translational oscillation frequencies. In a similar way the frequencies of rotational oscillation about the equilibrium orientation at (0, 0.065a, 0.065a) are found to be 18 cm^{-1} for rotation about the diagonal (variation of θ from 91.5°) and 28 cm^{-1} for rotation about the x axis (variation of ϕ from 135°).

Only at very low temperatures are the chlorine molecules in their ground oscillation states. With increase of temperature the motions become increasingly anharmonic and the molecules increasingly able to cross the ~300 cal/mol barriers separating the four regions of the potential minimum. The chlorine electron density, which at very low temperatures is concentrated in the vicinity of positions about 1.5 Å from the cage center along the y and z axes (*cf.* circles in Fig. 4), should as the temperature rises tend to become smeared out in a diffuse roughly circular ring.

The model gives a *relative* minimum of energy

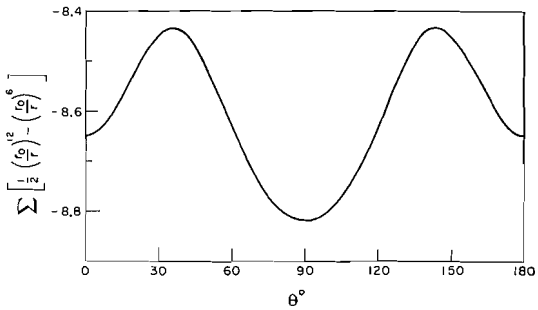

FIG. 5. Dependence of energy of Cl_2 centered in the cage on polar angle (θ); $\phi = 0$.

(−8.65 kcal/mol) when the axis of the chlorine molecule is aligned with the x axis and the center of mass is at the cage center. In Fig. 5 the energy is plotted *vs.* the polar angle, the center of mass being at the cage center, and ϕ is 0. (For each value of θ, the energy has equivalent minima at $\phi = 0, \pi/2, \pi, \ldots$; the energies at odd multiples of $\pi/4$ are as much as 100 cal/mol higher.) The axial configuration is about 1 kcal/mol less favorable than the configurations of least energy, in agreement with Pauling and Marsh's conclusion (20) that it could not account for the observed X-ray line intensities at 4 °C.

Pauling and Marsh made structure factor calculations for three other cases in which the center of mass coincided with the cage center. In these, the orientations were (*i*) distributed isotropically over a sphere, (*ii*) weighted by $\cos^2(\pi/2 - \theta)$ toward the equatorial plane, and (*iii*) confined to the equatorial plane. The best fit to the rather inaccurate observed intensities was found for (*ii*), with (*iii*) almost as good. This high-temperature result agrees with the present model with regard to electron density. We note, however, that the van der Waals model shows that the center of mass is not in general near the cage center and that reorientation of the chlorine molecule is accompanied by translation.

Rather similar results are expected for other nonpolar molecules like ethane and ethylene which resemble chlorine in size and shape. A more spherical but still off-center distribution is expected for smaller molecules like nitrogen and oxygen in the small as well as the large cages. Bromine, which is about 0.6 Å longer than chlorine, was first considered (1, 19) to partly occupy the larger structure I cages and its composition ($Br_2 . 8.47H_2O$) was the basis of a method of determining the difference in μ-potential be-

For personal use only.

tween the empty structure I lattice and ice (19). Allen and Jeffrey (22) found, however, that bromine forms a structurally distinct tetragonal hydrate which contains 15-hedral as well as 12- and 14-hedral cages and has a composition of $Br_2 \cdot 8.6H_2O$ if the two largest cages are completely and exclusively occupied. A detailed structure has not been given but it may be suggested that the bromine molecule tends to be aligned along the long axis of 3-fold symmetry of the 15-hedron and to occupy nearly central positions in the equatorial plane of the 14-hedron.

Polyatomic Guests

The presence of hexagonal rings in the larger cages of both structures (Fig. 1) must contribute a degree of orientation dependence to the energy of many guest molecules, if only because atoms or atomic groups of the guest molecule which approach these rings may experience van der Waals contact with six water molecules rather than five. The "hole" in the center of a hexagonal ring is some 0.8 Å larger than in a pentagonal ring and may be partly penetrated by atoms of suitable size. Thus it is possible that in its most stable configuration in the large structure I cage the molecule of carbon dioxide is aligned with the polar axis of the cage. It is almost certain that the stable configurations of the large carbon tetrachloride molecule (known to form only a double structure II hydrate with hydrogen sulfide (23, 24) or other "help gas" (25) to occupy the small cages) are those in which the chlorine atoms are orientated toward the centers of the tetrahedrally disposed hexagonal rings. A relatively large barrier to rotation is probably present. Similar conclusions apply to neopentane, for which a clathrate hydrate appears not to have been reported, and, to a lesser degree, to isobutane, chloroform, and other molecules of similar geometry.

Oxygen atoms in guest molecules appear to be small enough to approach particularly close to the hexagonal faces if permitted to do so by adjacent groups. McMullan and Jeffrey (4) found that at −25 °C about one-half of the ethylene oxide molecules in large type I cages appeared to occupy the two "equilibrium" configurations shown in Fig. 6. Other ethylene oxide molecules appeared to occupy disordered positions somewhat displaced and rotated from the "equilibrium" ones. The possibility of additional disorder, including interchange of positions of the oxygen atom and a methylene group, was also suggested (4).

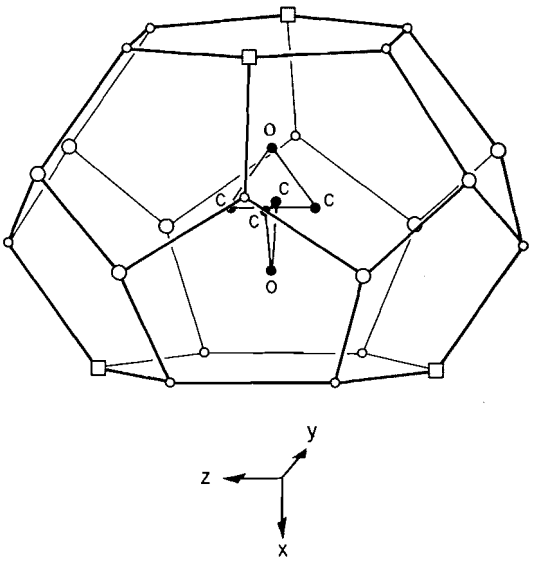

FIG. 6. Ethylene oxide in the two preferred positions in the tetrakaidecahedron suggested by ref. 4.

Tentative attempts were made to determine the configurations of greatest stability of ethylene oxide by using an expanded form of eq. 1 with individual values of r_{0k} and C_k chosen to represent the interaction of the cage oxygen atoms with the carbon, oxygen, and hydrogen atoms of ethylene oxide. Although the obvious inadequacies of this procedure give little quantitative meaning to the energies obtained, some conclusions are not sensitive to the particular parameters chosen.

The results failed to establish any preference for the axial configurations of Fig. 6. Many configurations of comparable and greater stability were found in which the molecule lay somewhat inclined to the equatorial plane. Even among axial configurations, increased stability resulted from translation of the ethylene oxide molecule along the $\bar{4}$ axis of the cage so as to bring the oxygen atom appreciably nearer to the adjacent hexagon. The results also showed no reason for the particular orientations about the axis shown in Fig. 6: these orientations were slightly less stable than those rotated by 90°.

The need for some reinterpretation of the X-ray results is also suggested by the rapid reorientation of the ethylene oxide dipole at temperatures down to 90 °K for which an "activation energy" of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

only 0.5 kcal/mol has been found (14, 15). Moreover, at temperatures comparable to that of the X-ray study, the narrow proton resonance line of ethylene oxide deuterate (26) is indistinguishable from that expected for rapid isotropic rotation; that is, all intramolecular interproton vectors effectively average to zero in about 10^{-5} s.

In their X-ray study of the double hydrate of tetrahydrofuran and hydrogen sulfide at −20 °C, Mak and McMullan (5) found a spherically-symmetric distribution of electron density around the center of the 16-hedron, a result consistent (3) with either "free rotation" or the 12-fold orientational disorder required by the $\bar{4}3m$ symmetry of the cage. In the single hydrate of tetrahydrofuran the dipole reorientation rate is 15 GHz at 90 °K and increases at higher temperatures with an activation energy of *ca.* 0.3 kcal/mol (14, 15). Although the rotation is not free, the barriers to rotation are certainly comparable with kT at relatively high temperatures. At very low temperatures the dominant tetrahydrofuran configurations may well be those in which the oxygen atoms "point" toward the centers of the hexagonal rings.

III. Electrostatic Fields of the Water Molecules

The electrostatic field of the dipole moment of a *single* isolated water molecule an average cage radius away amounts to 44, 32, and 25 kesV/cm for the 12-, 14-, and 16-hedral cage, respectively. The corresponding energies of alignment of the ethylene oxide (μ = 1.90 D) and tetrahydrofuran (1.63 D) dipoles in their large cages are −980 and −590 cal/mol, respectively. Since the orientations of the water molecules are disordered, the resultant fields near the cage centers of the 20 to 28 water dipoles, each with six possible orientations consistent with full hydrogen bonding, should be expected to show wide variation according to the details of the cage configuration. The initial expectation is for fields which range from nearly zero to fields many times as great as the field of a single water molecule.

That large fields are not generally present, however, is shown by the dielectric results. The mean activation energies for orientation of ethylene oxide and tetrahydrofuran are less than 1 kcal/mol. For these and such other polar guest molecules (27) as trimethylene oxide (12), propylene oxide (12), dihydrofuran (12), acetone (28), and dioxolane (29) in structure II hydrates and methyl chloride (30) in structure I, the contribution of the guest molecule to the permittivity shows no significant departure at temperatures down to 77 to 100 °K from that expected for isotropic rotation, or the equivalent contribution to the permittivity from reorientation between two or more symmetrically disposed sites of the same energy. The electrostatic fields of the water molecules therefore appear to introduce no great anisotropy at high temperatures. One reason for this, as is shown below, is the almost complete cancellation of the dipolar fields of the water molecules at sites near the cage centers.

Dipolar Fields in an Idealized Cage Model

We suppose, as before, that the oxygen atoms of each water molecule and three of its neighbors are arranged tetrahedrally on the surface of a sphere of radius r. The fourth neighbor lies outside the sphere in the fourth tetrahedral direction which is also the direction of the position vector of the original molecule with respect to the cage center. The hydrogen bonding conforms to the Bernal–Fowler rules. The dipole moment of each water molecule is located on the oxygen atom and is resolved into two components m_{OH} along the O---O bonds to which hydrogen atoms are contributed.

For a cage of n water molecules, the $2n$ OH moments consist of $3n/2$ "internal" moments lying between the water molecules of the cage and $n/2$ moments lying external to the cage. The resulting field at the center of the cage is

$$[4]\quad \boldsymbol{E}(D) = \sum_{j=1}^{3n/2} [3(\boldsymbol{p}_j \cdot \boldsymbol{r}_j)\boldsymbol{r}_j - \boldsymbol{p}_j] + \sum_{k=1}^{n/2} [3(\boldsymbol{p}_k \cdot \boldsymbol{r}_k)\boldsymbol{r}_k - \boldsymbol{p}_k]$$

in units of m_{OH}/r^3. Here $\boldsymbol{p}_j$ is the unit vector in the direction of the jth internal moment located at $\boldsymbol{r}_j$ and k subscripts refer to external moments and positions (see Fig. 7).

Since $\boldsymbol{p}_k = \boldsymbol{r}_k$, the second sum becomes

$$[5]\quad \boldsymbol{E}_{ext} = 2 \sum_{k=1}^{n/2} \boldsymbol{r}_k$$

and, since $\boldsymbol{p}_j \cdot \boldsymbol{r}_j = -\frac{1}{3}$, the first

$$[6]\quad \boldsymbol{E}_{int} = -\sum_{j=1}^{3n/2} (\boldsymbol{r}_j + \boldsymbol{p}_j)$$

For tetrahedral angles the moment pointing from

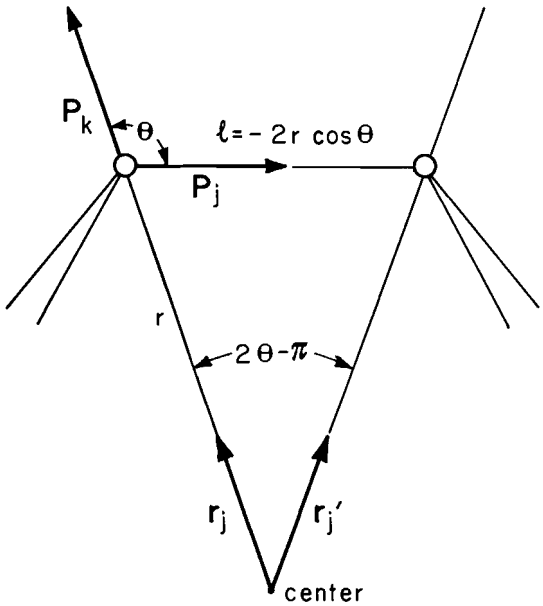

FIG. 7. Geometric model. θ is the tetrahedral angle, or, for the regular dodecahedron, 110° 54.3′.

site j to j' (Fig. 7) is $\boldsymbol{p}_j = 3(\boldsymbol{r}_{j'} - \boldsymbol{r}_j)/2$ and

$$[7] \qquad \boldsymbol{E}_{\text{int}} = \frac{1}{2}\sum_{j=1}^{3n/2} \boldsymbol{r}_j - \frac{3}{2}\sum_{j'=1}^{3n/2} \boldsymbol{r}_{j'}$$

The summation over j is taken once for each oxygen atom which has an external moment ($j = k$) and twice for each atom which does not ($j \neq k$). Thus

$$\sum_{j=1}^{3n/2} \boldsymbol{r}_j = \sum_{k=1}^{n/2} \boldsymbol{r}_k + 2\sum_{\substack{j=1 \\ j\neq k}}^{n/2} \boldsymbol{r}_j = -\sum_{k=1}^{n/2} \boldsymbol{r}_k$$

since the sum over all distinct sites

$$\sum_{k=1}^{n/2} \boldsymbol{r}_k + \sum_{\substack{j=1 \\ j\neq k}}^{n/2} \boldsymbol{r}_j = 0$$

(This condition does not follow from the model alone, but is fulfilled for all the actual cages.) Similarly, the summation over j' in eq. 7 occurs twice for $j' = k$, otherwise only once, and

$$\sum_{j'=1}^{3n/2} \boldsymbol{r}_{j'} = \sum_{k=1}^{n/2} \boldsymbol{r}_k$$

Substitution in eq. 7 gives

$$[8] \qquad \boldsymbol{E}_{\text{int}} = -2\sum_{k=1}^{n/2} \boldsymbol{r}_k$$

and addition of eq. 5

$$[9] \qquad \boldsymbol{E}(D) = 0$$

It is worth noting that this result is a consequence of the Bernal–Fowler rules and the tetrahedral bonding and is independent of the particular configuration of the water molecules. On the other hand, the vector sum of the dipole moments of the cage water molecules is

$$P = 4m_{\text{OH}}\sum_{k=1}^{n/2} \boldsymbol{r}_k$$

and does depend on this configuration.

In a discussion of the enthalpies of formation of clathrate hydrates, Glew suggested (31) that the attractive energy between guest and cage water molecules derives predominantly from short-range dispersion forces, since the cage symmetry and hydrogen bonding of the water molecules effectively reduce the dipole moments of the water molecules to zero. While providing support for Glew's main conclusion, the present treatment shows that it is based on the mutual cancellation of the *fields* of the dipoles.

Dipolar Fields in the Regular Dodecahedral Cage

Small resultant dipolar fields are to be expected for real cages in which the angles depart somewhat from tetrahedral. The idealized model may be slightly generalized to the case in which the three O---O directions on the cage surface make a common angle θ with the positive position vector (Fig. 7). With the other conditions as before, it is easily shown that

$$[10] \quad \boldsymbol{E}(D) = \frac{(1-\cos\theta)(1+3\cos\theta)}{\cos\theta}\sum_{k=1}^{n/2} \boldsymbol{r}_k$$

in units of m_{OH}/r^3. The value of the field now depends on the distribution of external OH groups over the cage. Since P is now

$$-(1-\cos\theta)(\cos\theta)^{-1} m_{\text{OH}}\sum_{k=1}^{n/2} \boldsymbol{r}_k$$

$$[11] \qquad \boldsymbol{E}(D) = -(1+3\cos\theta)\boldsymbol{P}/r^3$$

the proportionality factor being small for θ close to tetrahedral.

The pentagonal dodecahedral cages ($n = 20$) of structures I and II are slightly distorted from regular dodecahedra (32) for which θ is 110° 54.3′. For this value of θ

$$[12] \quad E(D) = 0.268 \frac{m_{OH}}{r^3} \sum_{k=1}^{10} r_k = -0.0705 \frac{P}{r^3}$$

The sum of the r_k's may take on all values from 0 to 4.91, the maximum value corresponding to the unlikely case that all ten external OH groups lie in the same half of the dodecahedron. Even the maximum dipolar field, 1.116 m_{OH}/r^3, is only 0.68 as large as the field of a single water dipole.

In order to find the distribution of dipolar fields in the regular dodecahedron, cage configurations were generated by assigning at random a hydrogen atom to either end of the thirty internal O---O bonds, excluding configurations which violated the Bernal–Fowler rules. The resulting distribution of fields for 4000 configurations is shown in Fig. 8, where $|E|$ is in units of m_{OH}/r^3. Without regard to direction, the number of distinct fields found was 71. Zero field occurred 25 times, the maximum field only twice. The median field was 0.44 m_{OH}/r^3 or 11.8 kesV/cm if m_{OH} is obtained from the dipole moment of the gas-phase water molecule, 1.84 D. (If a reaction-field enhanced dipole moment is assumed, the fields are increased in proportion.) The energy of alignment in this median field of a central dipole moment of 1 D (*e.g.*, hydrogen sulfide) is only −0.17 kcal/mol. The asymmetry introduced into the potential energy of the guest molecules by the dipolar fields therefore becomes important only at low temperatures, provided the molecular dipole is located close to the cage center.

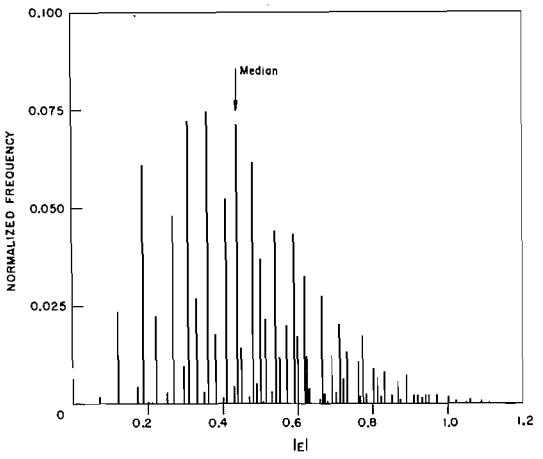

FIG. 8. Distribution of electrostatic fields for 4000 cage configurations of the regular dodecahedron. The fields are in units of m_{OH}/r^2 ($\cong$19 kesV/cm).

Quadrupolar Fields

Since, for geometric reasons, there is a high degree of mutual cancellation of dipolar fields, it is necessary to consider the fields of the higher moments of the charge distribution of the water molecules. Of these the quadrupolar fields are expected to be the most important.

In the coordinate system shown in Fig. 9 the only non-zero elements of the quadrupole moment tensor of the isolated water molecule are $Q_{xx}(=\int \rho(x,y,z)x^2 dv)$, Q_{yy}, and Q_{zz}. Here $\rho(x,y,z)$ is the charge density in the element of volume dv with coordinates x,y,z with respect to the oxygen nucleus as origin. For water molecules located and properly oriented in a lattice at sites where the symmetry is C_{2v} (or, as for tetrahedral symmetry, have C_{2v} as a factor group) the off-diagonal elements likewise vanish. In the clathrate hydrates, as in the ices (with the exception of Ic), most of the disordered orientations (except statistically) do not conform to the site symmetry with respect to O atoms and the quadrupole moment contains off-diagonal elements. These are expected to be small, however, since the local symmetry is approximately tetrahedral, and will be ignored.

The quadrupole potential at a point $r(x,y,z)$ with respect to the oxygen atom is

$$[13] \quad V(Q) = -\frac{1}{2r^3} \sum_{\alpha} Q_{\alpha\alpha}(1 - 3\alpha^2/r^2)$$

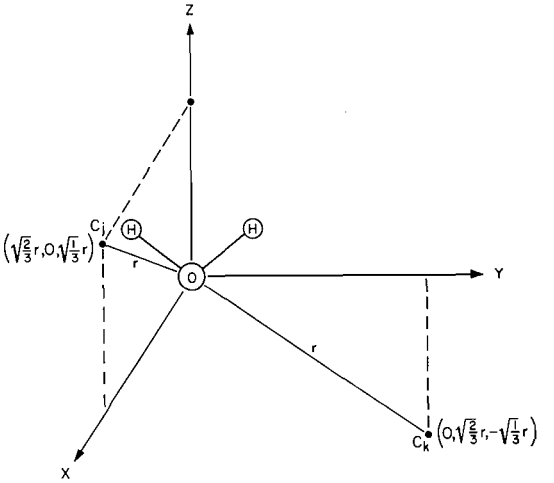

FIG. 9. Oxygen-centered coordinate system. C_j and C_k are the cage centers for tetrahedral O---O---O angles when both OH groups lie in the cage and when one OH group lies outside, respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with $\alpha = x$, y, and z. The field in the α direction may be written

$$[14]\quad E_\alpha(Q) = -(\partial V/\partial\alpha) = \frac{3\alpha}{2r^5} \times \left[Q_{\alpha\alpha}(-3 + 5\alpha^2/r^2) + \sum_{\alpha'} Q_{\alpha'\alpha'}(-1 + 5\alpha'^2/r^2) \right]$$

where $\alpha' \neq \alpha$. Again, we express the quadrupolar fields in terms of the components in the directions of the donor O---O bonds and position vectors of the oxygen atoms with respect to the cage center.

For a water molecule with two internal OH groups, the cage center, in the coordinate system of Fig. 9, is at $(\sqrt{\frac{2}{3}}r, 0, \sqrt{\frac{1}{3}}r)$, where the field is

$$[15]\quad \boldsymbol{E}_j(Q) = E_x\boldsymbol{i} + E_z\boldsymbol{k} = E_{pj'}\boldsymbol{p}_{j'} + E_{pj''}\boldsymbol{p}_{j''} + E_{rj}\boldsymbol{r}_j$$

The unit vectors are

$$\boldsymbol{p}_{j'} = \sqrt{\tfrac{2}{3}}\boldsymbol{j} + \sqrt{\tfrac{1}{3}}\boldsymbol{k}$$
$$\boldsymbol{p}_{j''} = -\sqrt{\tfrac{2}{3}}\boldsymbol{j} + \sqrt{\tfrac{1}{3}}\boldsymbol{k}$$
$$\boldsymbol{r}_j = -\sqrt{\tfrac{2}{3}}\boldsymbol{i} - \sqrt{\tfrac{1}{3}}\boldsymbol{k}$$

whence

$$[16]\quad E_{pj'} = E_{pj''} = -\tfrac{1}{2}(\sqrt{\tfrac{3}{2}}E_x - \sqrt{3}E_z)$$
$$E_{rj} = -\sqrt{\tfrac{3}{2}}E_x$$

From eqs. 16 and 14

$$E_{pj'} = E_{pj''} = \frac{3}{2r^4}(Q_{xx} - Q_{zz})$$
$$E_{rj} = -\frac{1}{2r^4}(Q_{xx} - 3Q_{yy} + 2Q_{zz})$$

and by summation of eq. 15 over the $n/2$ "internal" sites

$$[17]\quad \boldsymbol{E}_{\text{int}}(Q) = \frac{9}{4r^4}(Q_{xx} - Q_{zz})(\sum \boldsymbol{r}_{j'} + \sum \boldsymbol{r}_{j''}) + \frac{1}{2r^4}(-10Q_{xx} + 3Q_{yy} + 7Q_{zz})\sum \boldsymbol{r}_j$$

Here, as before, we have used $\boldsymbol{p}_{j'} = (3/2)(\boldsymbol{r}_{j'} - \boldsymbol{r}_j)$, $\boldsymbol{p}_{j''} = (3/2)(\boldsymbol{r}_{j''} - \boldsymbol{r}_j)$, where $\boldsymbol{r}_{j'}$ and $\boldsymbol{r}_{j''}$ are the unit position vectors of the oxygen atoms which "receive" OH groups.

In the coordinate system of a water molecule with an external OH group the cage center is at $(0, \sqrt{\frac{2}{3}}r, -\sqrt{\frac{1}{3}}r)$ (Fig. 9). Since $E_x = 0$, there is no component of field perpendicular to the plane of $\boldsymbol{r}_k$ and $\boldsymbol{p}_{k'}$

$$[18]\quad \boldsymbol{E}_k(Q) = E_y\boldsymbol{j} + E_z\boldsymbol{k} = E_{pk'}\boldsymbol{p}_{k'} + E_{rk}\boldsymbol{r}_k$$

where

$$E_{pk'} = \tfrac{1}{2}(\sqrt{\tfrac{3}{2}}E_y + \sqrt{3}E_z)$$

and

$$E_{rk} = -\tfrac{1}{2}(\sqrt{\tfrac{3}{2}}E_y - \sqrt{3}E_z)$$

From [14]

$$E_{pk'} = \frac{3}{2r^4}(-Q_{yy} + Q_{zz})$$
$$E_{rk} = \frac{1}{2r^4}(3Q_{xx} - 4Q_{yy} + Q_{zz})$$

which, with $\boldsymbol{p}_{k'} = \frac{3}{2}(\boldsymbol{r}_{k'} - \boldsymbol{r}_k)$ and eq. 18 gives, for the sum over the $n/2$ external sites,

$$[19]\quad \boldsymbol{E}_{\text{ext}}(Q) = \frac{9}{4r^4}(-Q_{yy} + Q_{zz})\sum \boldsymbol{r}_{k'} + \frac{1}{4r^4}(6Q_{xx} + Q_{yy} - 7Q_{zz})\sum \boldsymbol{r}_k$$

The total quadrupolar field at the cage center $\boldsymbol{E}(Q)$ is the sum of eqs. 17 and 19. In addition to $\sum \boldsymbol{r}_j = -\sum \boldsymbol{r}_k$, as before, we have $\sum \boldsymbol{r}_{j'} + \sum \boldsymbol{r}_{j''} + \sum \boldsymbol{r}_{k'} = \sum \boldsymbol{r}_k$, since these three sums together include all $n/2$ internal sites once and all $n/2$ external sites twice. With these substitutions

$$[20]\quad \boldsymbol{E}(Q) = \frac{5}{4r^4}[-7(Q_{zz} - Q_{xx}) + (Q_{zz} - Q_{yy})]\sum \boldsymbol{r}_k + \frac{9}{4r^4}[(Q_{zz} - Q_{xx}) + (Q_{zz} - Q_{yy})]\sum \boldsymbol{r}_{k'}$$

There is thus no general geometric tendency for mutual cancellation of quadrupolar fields. However, since each k' is a nearest neighbor of some k, there is a statistical correlation between $\sum \boldsymbol{r}_{k'}$ and $\sum \boldsymbol{r}_k$. Not only may some $\boldsymbol{r}_{k'}$'s be identical with $\boldsymbol{r}_k$'s but they may occur twice.

Octupolar Fields

The field at the cage center due to the octupole moments of the water molecules may be similarly derived for the tetrahedral model. Again in the coordinate system of Fig. 9, the non-vanishing elements of the octupole moment tensor are R_{zzz}, R_{zxx}, and R_{zyy}, in terms of which the potential energy is

$$[21]\quad V(\text{O}) = \frac{z}{2r^5}\sum_\alpha (R_{zzz} - 3R_{z\alpha\alpha})\left(1 - \frac{5\alpha^2}{r^2}\right)$$

with $\alpha = x, y$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The procedure of the last section leads to the simple result

$$[22] \quad \boldsymbol{E}(\mathrm{O}) = -\frac{14\sqrt{3}}{9r^5}\left[\sum_{\alpha}(R_{zzz} - 3R_{z\alpha\alpha})\right]\sum \boldsymbol{r}_k$$

Statistical Evaluation of Fields in the Tetrakaidecahedra

It is of interest to compare the predictions of the tetrahedral model with the fields calculated for actual cages. For this purpose, random 14-hedral cage configurations were generated for oxygen atom sites given by McMullan and Jeffrey (4) for ethylene oxide hydrate. Two protons were assigned randomly to those of the four O---O bonds of each water molecule which did not already bear a proton at the other end. If three bonds bore such a proton, or if the resulting assignment led to more than $12(=n/2)$ external protons, the entire process of assignment was restarted. The order of assignment of protons to water molecules was also random.

After generation of a cage configuration which conformed to the Bernal–Fowler rules, the axes of a coordinate system for each water molecule were determined to accord with Fig. 9. The coordinates of the 24 molecules outside the cage and directly hydrogen-bonded to it were included in the program to define the directions of the external bonds. The fields of the individual dipole, quadrupole, and octupole moments were found (from eqs. 4, 14, and differentiation of eq. 21) in the molecular coordinate system, transformed to a cage-fixed coordinate system, and summed over the 24 molecules. The resultant dipole moment of the cage was also found.

We illustrate the results for the following choice of moments: $\mu = 1.84 \times 10^{-18}$ e.s.u. cm; $Q_{xx} = -6.56$, $Q_{yy} = -5.18$, $Q_{zz} = -5.51 \times 10^{-26}$ e.s.u. cm^2; $R_{zzz} = -2.75$, $R_{zxx} = -1.08$, $R_{zyy} = -0.50 \times 10^{-34}$ e.s.u. cm^3. These quadrupole and octupole moment elements were calculated from relatively primitive wavefunctions by Glaeser and Coulson (33) and were used by Coulson and Eisenberg (34) to calculate the electrostatic field at the site of a water molecule in ice.

The distribution of magnitude of the dipolar field at the cage center given by 85 cage configurations is shown in the lower histogram of Fig. 10. As for the regular dodecahedron, the resultant dipolar fields are relatively small, the mean field (13.6 kesV/cm) being only 43% of the

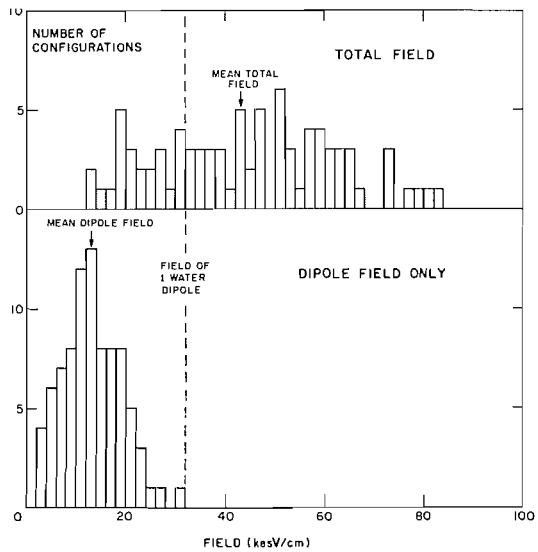

FIG. 10. Distribution of central fields for 85 configurations of the tetrakaidecahedron. The mean resultant dipole moment of the 24 water molecules was 6.93 μ.

dipolar field of a single water molecule. The energy of alignment of ethylene oxide in this mean field is −0.37 kcal/mol.

The field distribution when the fields of the quadrupoles and octupoles are added to those of the dipoles for the same configurations is also shown in Fig. 10. The distribution is considerably broadened and shifted to higher fields, the mean field being now more than three times as large as before. The increase is entirely the effect of the quadrupoles, since the contribution of the octupoles was found, in almost all cases, to slightly reduce the contribution of the quadrupoles. This is consistent with eqs. 20 and 22 (for the tetrahedral model). The latter now becomes $\boldsymbol{E}(\mathrm{O}) = 0.31 \sum \boldsymbol{r}_k$ kesV/cm. Since the resultant dipole moment of the cage molecules is $2\sqrt{3}\mu\sum \boldsymbol{r}_k$ for the tetrahedral model, and the mean value of this resultant was found to be 6.93 μ for the configurations of Fig. 10, the mean value of $\sum \boldsymbol{r}_k$ may be estimated to be about 2.0 and the mean octupolar field to be only about 0.62 kesV/cm. The actual mean field due to octupoles was found to be 3.0 kesV/cm and, like the resultant dipolar field, reflects departure from the tetrahedral model.

Since eq. 20, unlike eqs. 9 and 22, does not rely heavily on mutual cancellation effects implicit in the tetrahedral model, it is expected to give a reasonable estimate of the quadrupolar field of

TABLE 2. Calculated and experimental quadrupole moment elements ($\times 10^{26}$ e.s.u. cm^2) of water with respect to the O atom as origin

Workers	Reference number	Q_{xx}	Q_{yy}	Q_{zz}

*Experimental values.

the real cage. With $\overline{\sum r_k} = 2.0$ again, the mean contribution of the first term of eq. 20 is 55 kesV/cm, considerably greater than the 37 kesV/cm found for the actual mean quadrupolar field for the 85 configurations. Thus the term in $\sum r_{k'}$ reduces the contribution of the first term, as expected from a positive correlation between the directions of $\sum r_k$ and $\sum r_{k'}$ and the opposite signs of the factors in square brackets. We note too that for the moments assumed the signs of the coefficients of $\sum r_k$ in eqs. 20 and 22 are opposite.

A statistical tendency for the dipolar fields to favor the x direction (the $\bar{4}$ symmetry axis of the cage) was shown. The x component of this field averaged 36% higher than the y and z components which, for the 85 configurations considered, were the same to within 0.5%. After the quadrupolar and octupolar fields were added the mean preference for the x direction was reduced to 19%.

The mean dipolar field was found to be 68% higher at a point displaced 0.5 Å along the x axis than at the center, the major difference being in its x component. The total field however averaged only 2% higher.

Effect of Electrostatic Fields on Dielectric Properties

It is evident that the presence of a broad distribution of electrostatic fields and field directions within the cages will lead to a highly variable perturbation of the potential energy function which describes the short-range interactions. The symmetry imposed by cage geometry is removed and, at least at low temperatures, the reorientation should become distinguishable from isotropic reorientation. The contribution of the guest molecules to the permittivity should fall as, with fall of temperature, orientations favored by the electrostatic fields become increasingly populated at the expense of those which are not. The decline would be expected to cover a wide range of temperature because of the distribution of fields in different cages.

The barriers to reorientation ("activation energies") are also field-dependent and the distribution of fields should be reflected by a wide distribution of reorientation rates. Dielectric relaxation of the guest molecules should depart appreciably from Debye behavior.

It is difficult to make these qualitative conclusions more quantitative in the absence of an adequate knowledge of the charge distribution of the water molecule in the hydrate lattice, *i.e.* in an ice-like environment. The enhancement over the value of the gas-phase dipole moment may be reasonably estimated as the moment induced by the reaction field (Coulson and Eisenberg found $\mu = 2.60$ D in ice (34)), but the effect of the hydrogen bonding on the quadrupole moment, potentially the largest contributor to the field, is difficult to estimate.

Some recently calculated quadrupole moment elements are given in Table 2, together with an "experimental" value derived (35) from the magnetic moment tensor and the anisotropy of the magnetic susceptibility tensor obtained from analysis of the hyperfine microwave Zeeman spectrum. All the values listed are for the isolated water molecule, the calculated values having been obtained from a variety of electronic wave functions, of which those of refs. 38, 39, and 40 are presumably the most accurate. Where necessary the quadrupole moment elements have been converted from the Buckingham (41) form to the form which describes the second moment of the charge distribution, the origin has been shifted from the center of mass to the oxygen nucleus to conform with the present treatment, and axes have been transformed to conform to Fig. 9.

It is apparent that substitution of more recent gas-phase values for the quadrupole moment elements of Glaeser and Coulson will generally raise the resultant fields shown in Fig. 10 by a factor of between 2 and 3. The mean field is then about 100 kesV/cm and the energy of alignment of the ethylene oxide dipole at the cage center is about −3 kcal/mol. Dielectric and n.m.r. results for ethylene oxide hydrate at low temperatures have yet to be reported, but it seems quite clear that the high-temperature properties (14, 15, 26) are inconsistent with the presence of orientation-dependent energies of this magnitude. The second moment of the charge distribution of the water molecule in the hydrate lattice therefore appears to be much less anisotropic than in the gas.

Fields in the Hexakaidecahedra

The distribution of electrostatic fields in the more symmetrical large cages of structure II is shown in Fig. 11 for 241 randomly-generated configurations. The procedure was the same as for the 14-hedra, with modifications appropriate to a cage of 28 water molecules located at sites given by Mak and McMullan's X-ray analysis (5) of the structure II double hydrate of tetrahydrofuran and hydrogen sulfide.

The mean dipolar field (14.9 kesV/cm) was slightly larger than within the 14-hedra, the mean total field and resultant dipole moment slightly smaller.

Again, as expected, the resultant field is statistically a minimum at the cage center. For any given cage configuration, however, the position of minimum total field is diplaced from the cage center by, on average, some 1.45 Å. Only about 25% of the positions of least dipolar field were displaced from the center by more than 0.7 Å.

Figure 12 shows the variation of the *mean* field with displacement from the center along the directions of the mid points of the hexagons. The same 69 configurations were used for evaluation of the mean fields due to dipole moments (1.84 and 2.60 D) alone and with the multipole moments of Glaeser and Coulson (33) or Arrighini *et al.* (40) also included. It is apparent that the dipolar fields in general depend more on position within the cage than do the "total" fields and that for the quadrupole moment elements assumed, there is a strong tendency for the quadrupolar fields to reduce the increasing dipolar contributions with increase of off-center displacement.

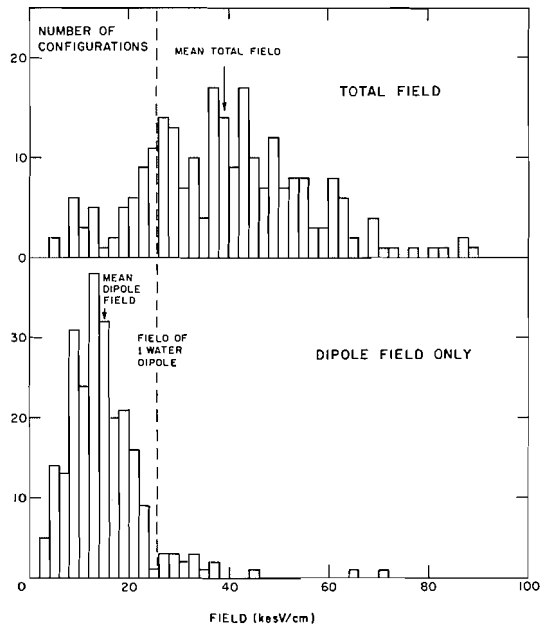

FIG. 11. Distribution of central fields for 241 configurations of the hexakaidecahedron. The mean resultant dipole moment was 6.89 μ.

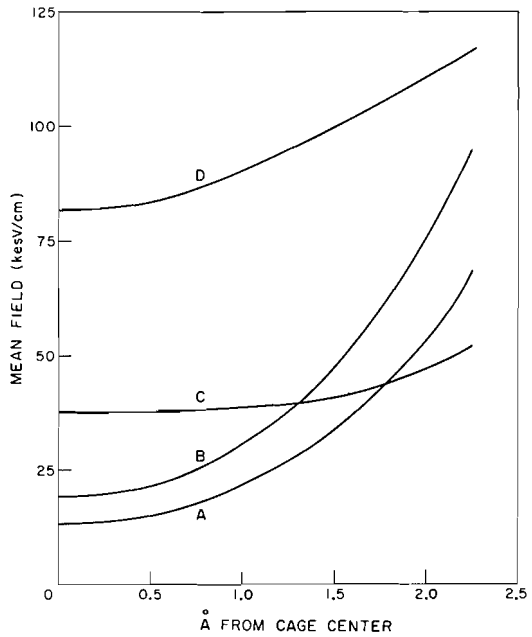

FIG. 12. Variation of mean fields with displacement along the 3-fold axes of the 16-hedra for *A*, μ = 1.84 D; *B*, μ = 2.60 D; *C*, μ = 1.84 D and higher moments of Glaeser and Coulson; *D* = 1.84 D and higher moments of Arrighini *et al.*

For personal use only.

As long as the dipolar guest molecule has the ability to rotate it will be most stable where the field is largest. As it moves out from the center, however, the short-range repulsive forces eventually determine which orientations with respect to the field are possible. A model in which a molecular dipole is constrained by geometry to four mutually tetrahedral directions is considered in Section V.

IV. Interactions between Guest Molecules

The only interactions between adjacent guest molecules likely to contribute appreciably to the orientation-dependent energy are dipole–dipole interactions.

The centers of nearest-neighbor large cages in structure I lie on lines extending in 3 orthogonal directions, adjacent centers being 6.0 Å apart. There is a preference for parallel alignment of guest dipoles along the lines of centers, especially if the dipoles are constrained by geometry to point along these lines, as Fig. 6 suggests for ethylene oxide and may possibly be the case for trimethylene oxide at low temperatures. The energy of interaction between guest dipoles is affected by the presence of polarizable water molecules. If an isotropic polarizability α of 1.44 Å^3 is assigned to a water molecule, the reaction field of the dipoles induced in the water molecules of the cage enhances the dipole moment of a central ethylene oxide molecule ($\alpha = 4.8$ Å^3) by 0.11 D. Moreover, the field at the site of one guest molecule due to an adjacent parallel guest dipole is reduced by more than one-third by the fields of the dipoles induced in the 24 water molecules of the adjacent cage. (This shielding effect is equivalent to an effective permittivity of 1.6 for the medium between adjacent guest dipoles.) The energy of parallel alignment of an ethylene oxide molecule with a neighbor is then -350 cal/mol. If only parallel or anti-parallel alignment is permitted, the one-dimensional Ising model gives $\frac{1}{2}[1 + \tanh(350/RT)]$ for the probability of parallel alignment of a pair of adjacent molecules, or 0.91 at 150 °K. This leads to a chain of about 8 parallel dipoles in average length at this temperature and predicts a considerable enhancement of the permittivity.

No such enhancement has been found for ethylene oxide (14, 15) or trimethylene oxide (12) hydrates. This result does not conclusively show the absence of geometric preference for orientations along the polar axis of the cage since the electrostatic fields of the water molecules are in general larger than that of a neighboring guest, at most 12 kesV/cm for ethylene oxide. Even so, for such preferred orientations the statistical short range order should be great enough to give an appreciable dielectric increment.

Within the structure II hydrates interaction between the guest molecule dipoles is of minor importance. The lattice formed by centers of the large cages possesses simple tetrahedral symmetry. It is not certain whether any net statistical correlation of dipole directions is to be expected for this lattice. In any event the interaction energy between neighboring tetrahydrofuran molecules, with shielding, is no more than 110 cal/mol, which corresponds to a field of 5.1 kesV/cm at one molecule due to the other.

V. A Model of Guest Molecule Relaxation in Structure II Hydrates

An attempt is now made to make the previous discussion more quantitative by introducing a definite model to which to relate the dielectric results. The model is applied to structure II hydrates where the dipole–dipole interactions between guest molecules are assumed small enough to be neglected.

The simplest model that takes advantage of the tetrahedral symmetry of the large type II cages is the one which assumes that, in the absence of electrostatic fields of water molecules, there are four tetrahedrally disposed preferred orientations of equal energy. In the case of tetrahydrofuran these could be the orientations in which the oxygen atoms approach the hexagonal rings, that is, the dipole moment points toward the cage center along the line joining it to the center of a hexagon. We wish to find the temperature variation of the contribution of reorienting guest molecules to the permittivity when the symmetry is disturbed by the fields of the water molecules.

Consider first a collection of N cages per cm^3, all with identical configurations. The populations of the four orientations are given by $N_i(\mathrm{O})$, where

$$\sum_{i=1}^{4} N_i(\mathrm{O}) = N$$

In the presence of an applied field $\boldsymbol{E}_e$ there is a small adjustment of populations which now become $N_i(e)$ at equilibrium. For E_e small in com-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

parison with kT/μ the four quotients of the form

$$\frac{N_i(\mathrm{e})}{N_i(\mathrm{O})(1 + \mu l_i E_\mathrm{e}/kT)}$$

may be equated to one another, which, along with

$$\sum_{i=1}^{4} N_i(\mathrm{e}) = N$$

leads to

[23] $$N_i(\mathrm{e}) = N_i(\mathrm{O}) \times \left[1 + \frac{\mu E_\mathrm{e}}{NkT} \sum_{j \neq i} N_j(\mathrm{O})(l_i - l_j)\right]$$

where l_i is the direction cosine between dipole orientation i and $\boldsymbol{E}_\mathrm{e}$. The polarization is

[24] $$P = \mu \sum_i l_i[N_i(\mathrm{e}) - N_i(\mathrm{O})] = \frac{\mu^2 E_\mathrm{e}}{kT} \sum_i \left[l_i N_i(\mathrm{O}) \sum_{j \neq i} \frac{N_j(\mathrm{O})}{N} (l_i - l_j)\right]$$

which for a polycrystalline sample yields an average polarization

[25] $$\bar{P} = \frac{\mu^2 E_\mathrm{e}}{kT} \sum_i \left[N_i(\mathrm{O}) \sum \frac{4N_j(\mathrm{O})}{9N}\right] = \frac{4}{9} \frac{\mu^2 E_\mathrm{e}}{kT} \sum_i N_i(\mathrm{O}) \left\{\frac{N - N_i(\mathrm{O})}{N}\right\}$$

since $\overline{l_i^2} = 1/3$ and $\overline{l_i l_j} = -1/9$, the latter for tetrahedral angles. This is the analogue of the Debye equation for an applied field E_e at the sites of the dipoles and reduces to the Debye case for all $N_i(\mathrm{O}) = N/4$.

After averaging over the distribution of electrostatic fields of the water molecules in different cages eq. 25 becomes

[26] $$\bar{\bar{P}} = \frac{4N\mu^2 E_\mathrm{e}}{9mkT} \sum_{n=1}^{m} \sum_i p_{in}(1 - p_{in})$$

where n specifies one of the m randomly generated cage configurations and p_{in}, the probability of orientation i within a cage of configuration n, is given by

[27] $$p_{in} = \frac{\exp(\boldsymbol{\mu}_i \cdot \boldsymbol{E}_{in}/kT)}{\sum_j \exp(\boldsymbol{\mu}_j \cdot \boldsymbol{E}_{jn}/kT)}$$

$\boldsymbol{E}_{in}$ being the cage electrostatic field at the site of orientation i.

The field $\boldsymbol{E}_\mathrm{e}$ is a consequence of the applied external field but is not equal to it. If all four orientations in each cage are equally probable the contribution to the dielectric constant from reorientation of guest molecules is not

[28] $$\Delta\varepsilon = \frac{4\pi N\mu^2}{3kT}$$

as given by eq. 26 with $\boldsymbol{E}_\mathrm{e}$ set equal to the external field, since the cavity and reaction fields are neglected and the contribution to the permittivity therefore considerably underestimated. A better representation is in terms of the Onsager equation (eq. 3 of ref. 2), especially, as discussed in the accompanying paper (2), if allowance is made for the enhanced polarizability of the guest molecule. For brevity we do not repeat the development here but simply note that modification of eq. 5 of ref. 2 by replacing the factor $\mu^2/3$ appropriate to high temperatures by the factor

$$(4\mu^2/9m) \sum_n \sum_i p_{in}(1 - p_{in})$$

appropriate to the present model at all temperatures leads to

[29] $$\frac{(\varepsilon_{02} - 1)(2\varepsilon_{02} + 1)}{3\varepsilon_{02}} = \frac{(\varepsilon_{\infty 2} - 1)(2\varepsilon_{\infty 2} + 1)}{3\varepsilon_{\infty 2}} + \frac{16\pi N\mu^2}{9mkT} \cdot \frac{1 + f(\alpha^* - \alpha)}{(1 - f\alpha^*)(1 - f\alpha)} \times \sum_{n=1}^{m} \sum_{i=1}^{4} p_{in}(1 - p_{in})$$

where ε_{02} is the permittivity of the hydrate which includes the contribution from reorientation of guest molecules but not of water molecules, $\varepsilon_{\infty 2}$ is the permittivity at frequencies too high for any reorientational contribution, α is the "normal" polarizability of the guest molecule, and α^* is the enhanced polarizability introduced in (2). The latter is related to the relatively large value of $\varepsilon_{\infty 2}$, which is found to be 3.47 for tetrahydrofuran hydrate at 4 °K, where reorientation makes no appreciable contribution to the permittivity at frequencies in the kHz region.

We have taken $\alpha = 7.9$ Å^3 and $\alpha^* = 16$ Å^3 (2) for tetrahydrofuran and applied eq. 29 with an effective cage radius $a = 3.4$ Å in $f = 2(\varepsilon_{02} - 1)/[(2\varepsilon_{02} + 1)a^3]$. The probabilities defined by eq. 27 were varied in two ways: by varying the assumptions made about the dipole and multipole moments of the water molecules, and by allowing the position of the dipole moment of the tetra-

For personal use only.

hydrofuran molecule (that is, the point at which $\boldsymbol{E}_{in}$ was evaluated) to move from the cage center along the directions towards the mid-points of the hexagons. It is apparent that the dipole moment of tetrahydrofuran should be displaced from the center of mass toward the oxygen atom. Without a detailed knowledge of the charge distribution its proper position cannot be defined but it may be assumed to be close to a point lying on the axis bisecting the C—O—C bond and removed from the oxygen atom by about half the projection of an OC bond on this axis. If the center of mass lies at the cage center the dipole moment is then located about $0.04a$ away. Fields have been evaluated at positions $0.04a$, $0.08a$, and $0.12a$ from the cage center along the lines to the centers of the hexagons. The latter two positions correspond to increasing approach of the oxygen ends of the molecules to the hexagonal rings in conformity with the likely geometric preference for such positions.

In Fig. 13 the results of preliminary measurements of ε_{02} of tetrahydrofuran hydrate at low temperatures and of the earlier measurements (12) at higher temperatures are shown as a heavy solid line. The value of ε_{02} passes through a very broad maximum of 6.3 near 50 °K and falls off at an accelerating rate at lower temperatures. It proved impossible to estimate adequately this static permittivity below about 20 °K because the orientational relaxation became too slow. The dashed line joining the ε_{02} curve at low temperatures represents 1 kHz results through this dispersion region.

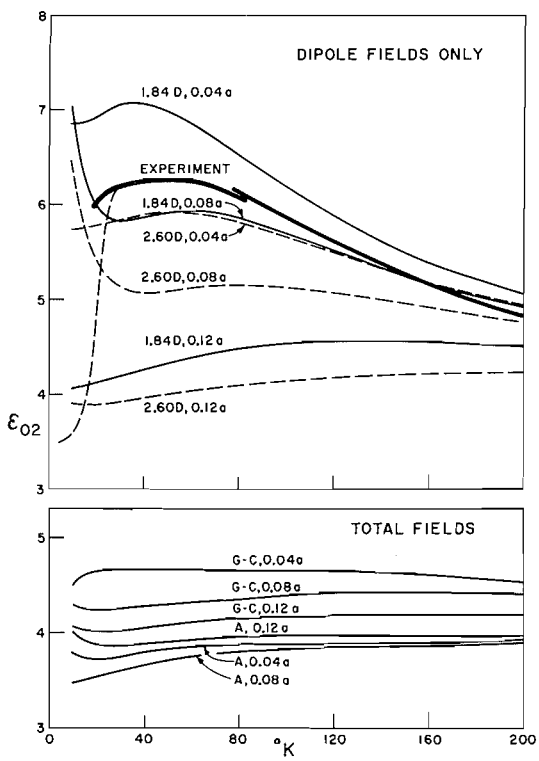

FIG. 13. Experimental and calculated ε_{02} *vs.* temperature curves of tetrahydrofuran hydrate.

The other curves of Fig. 13 represent various calculated values of ε_{02}, all for the same 70 randomly generated cage configurations. The curves in the upper part of the figure were calculated for dipole moments alone, two extreme values of the dipole moment, 1.84 and 2.60 D (34), being assumed. The lower curves include, besides the contribution of dipole moments of 1.84 D, quadrupole and octupole moment contributions using the smallest (Glaeser and Coulson) and largest (Arrighini *et al.*) quadrupole moments of Table 2. These curves are slightly depressed if the dipole moment is taken as 2.60 D.

It is apparent that the inclusion of any reasonable gas-phase quadrupole moment elements leads to dielectric constants which are much lower than the experimental ones. The agreement is much better when the fields are assumed to arise from dipole moments alone.

The model is obviously a very crude one. The rise in ε_{02} at the lower end of some curves as temperature goes down is contributed by only a few of the 70 configurations and would probably disappear for a more statistically significant number of configurations. We have neglected the possibility that guest molecules may occupy other than the orientational sites specified, that they may move to positions where the energy is more favorable, that the cavity and reaction fields are sensitive to displacement of the dipole moment from the center of the cage, and that the cage configurations may not be random. Most of these assumptions will lead to some under-estimation of ε_{02}. On the other hand the factor $f\alpha^*$ may be too large, especially at high temperatures. No great significance can therefore be attached to the particular choice of moments and sites which agrees best with experiment. However it is difficult to escape the qualitative conclusion that the second moment of the charge distribution of the water molecule in the hydrate lattice (and by

inference in ices and liquid water) is much more symmetrical than it is in the isolated water molecule.

VI. Distribution of Reorientation Rates

We conclude by offering some evidence of the variability of the electrostatic fields in different cages. Figure 14 shows the frequency-dependence of the dielectric absorption in tetrahydrofuran hydrate at liquid hydrogen temperature. The points at which $\varepsilon'' = \varepsilon''_{max}/2$ differ by a factor of 10^4 in frequency compared with the factor of ~ 14 characteristics of a Debye curve for a single relaxation time. Such a width corresponds to a very broad distribution of relaxation times at this low temperature, in qualitative agreement with the expectation of a wide variability of barrier heights resulting from the effects of the electrostatic fields. The same explanation seems appropriate to the proton magnetic resonance line width of tetrahydrofuran deuterate, shown in Fig. 15 as the square root of the second moment. This undergoes a very gradual change from its rigid lattice value at the lowest temperatures to the value characteristic of isotropic rotation at much higher temperatures.

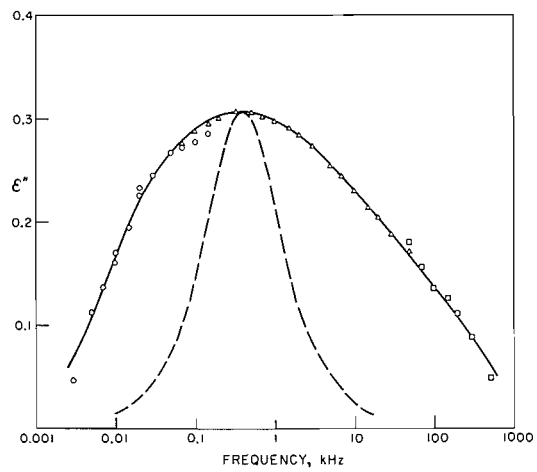

FIG. 14. Dielectric absorption in tetrahydrofuran hydrate at 20.4 °K.

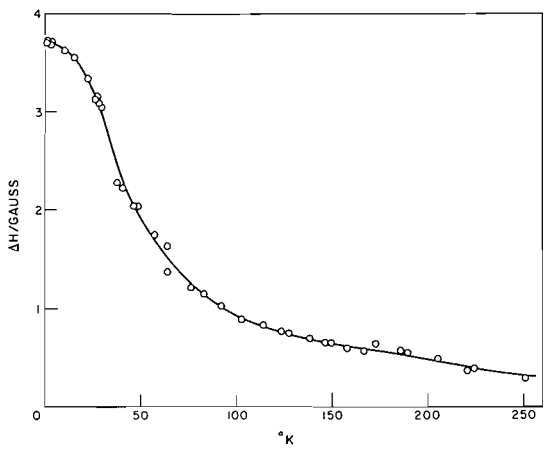

FIG. 15. Line width of the proton resonance line (as square root of the second moment) of $C_4H_8O \cdot 17.4D_2O$.

I am indebted to B. Morris for the low temperature dielectric measurements of tetrahydrofuran hydrate, to S. K. Garg for the n.m.r. measurements of tetrahydrofuran deuterate, and to M. Bedard for some of the calculations.

A Clathrate Hydrate of Cyclobutanone: Dielectric Relaxation of the Host and Guest Molecules[1]

B. MORRIS AND D. W. DAVIDSON
Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received September 25, 1970

A low-frequency dielectric study of $(CH_2)_3CO \cdot 17H_2O$ shows a water absorption region characteristic of a structure II clathrate hydrate which melts congruently at 0.0 °C. The relatively low Arrhenius energy of 6.5 kcal mol^{-1} is similar to that of acetone hydrate, for which new results are given. At low temperatures reorientation of encaged cyclobutanone molecules gives a very broad absorption region and a contribution to the static permittivity which falls with decrease of temperature. These properties are attributed to the effects of the electrostatic fields of the orientationally-disordered water molecules which form the cages. Such fields distort the tetrahedral symmetry of the cages to an extent which varies greatly from cage to cage. The high permittivity (~ 3.6) at 4.2 °K probably arises from rotational oscillations at frequencies near 20 cm^{-1} of the guest molecules in shallow potential minima. This enhancement of polarizability removes the difficulty previously noted in the applicability of the Onsager cavity model to structure II hydrates. The dipole moment of cyclobutanone in cyclohexane solution was found to be 2.78 ± 0.02 D.

Une étude diélectrique à basse fréquence de $(CH_2)_3CO \cdot 17H_2O$ montre un domaine d'absorption par l'eau caractéristique de la structure II de l'hydrate de clathrate ayant une fusion congruente à 0.0 °C. L'énergie d'Arrenius relativement basse de 6.5 kcal mol^{-1} est semblable à celle de l'hydrate d'acétone pour lequel on donne de nouveaux résultats. Aux basses températures la réorientation des molécules de cyclobutanone encagées donne une très large région d'absorption et contribue à la permitivité statique qui tombe quand la température décroit. Ces propriétés sont attribuées aux effets des champs électrostatiques des molécules d'eau en état de désordre d'orientation qui forment les cages. De tels champs introduisent une distorsion dans la symétrie tétrahédrique des cages qui varie beaucoup d'une cage à l'autre. La haute permitivité (~ 3.6) à 4.2 °K vient probablement des oscillations rotationnelles à des fréquences proches de 20 cm^{-1} des molécules prisonnières à des minima de potentiel peu profonds. Cette accuentation de polarisabilité fait disparaître la difficulté notée précédemment dans la possibilité d'appliquer le modèle de cavité d'Onsager aux hydrates de structure II. On a trouvé que le moment dipolaire de la cyclobutanone dans une solution de cyclohexanone est 2.78 ± 0.02 D.

Canadian Journal of Chemistry, 49, 1243 (1971)

Reference has already been made (1) to the dielectric evidence that cyclobutanone (CB) forms a clathrate hydrate of von Stackelberg's structure II (2), evidence since confirmed by powder X-ray examination (3).

Here we present the results of a dielectric study of the reorientation of both the lattice water molecules and the encaged cyclobutanone molecules. The dielectric properties of the lattice are compared with those of other structure II hydrates, including acetone hydrate (4), for which some new experimental data are presented. In previous studies (5, 6), the absorption by guest molecules in several clathrate hydrates was found to occur at microwave frequencies at 90 °K and above. In the present study the measurements have been made at temperatures sufficiently low that the absorption by cyclobutanone molecules occurs at low-radio and audio frequencies where it may be accurately defined.

[1]NRCC No. 11764.

Experimental Methods

Hydrate samples were prepared in dielectric cells by cooling solutions of cyclobutanone (< 0.2% impurity, mainly 2-butanone, by flame-detection vapor phase chromatography) in conductivity water. Compositions of the six samples studied varied between 16.7 and 17.5 mol of water per mol of cyclobutanone, *i.e.*, bracketed the 17:1 mole ratio of the ideal structure II hydrate with all large cages filled. Simple thermal analysis having shown that the hydrate formed and decomposed congruently at 0.0°, samples were conditioned for several hours at temperatures between −10 and −20° before measurements were started.

Two samples of acetone hydrate were conditioned for several days near −30°. This hydrate has an incongruent melting point at −20°. Its slow formation from ice and acetone-rich liquid was followed by the changes in the dielectric behavior of the system.

Most measurements above 77 °K were made with the 5 pF, stainless steel, three-terminal, coaxial cell and temperature control and measurement previously described (7). Capacitance and conductance were measured at frequencies between 0.01 and 700 kHz.

At lower temperatures the brass cell used was of the "split cylinder" type designed by Swenson and Cole (8) to minimize the development of gaps from thermal con-

traction of the sample. The guarded electrode assembly was held parallel to the high potential electrode by screws through the Teflon discs which formed the top and bottom of the cell. The cell was mounted in a copper can lined with a thin sheet of Teflon and threaded to a stainless steel supporting tube through which passed the coaxial Microdot leads from the electrode and the thermocouple leads. The assembly was supported within an Andonian Associates Cryogenic Dewar from a top plug, with leads brought out through vacuum seals. The sample thickness was 2.5 mm, sample volume 2.5 cm^3, and cell constant about 1 pF. Normally, after initial measurements at liquid helium temperature, the helium was vaporized and the vaporization heater and throttle control of the helium flow adjusted to maintain a heating rate of $\sim 0.1°$ per min. Measurements were made during heating at a number of fixed frequencies. Temperatures were measured by a copper–constantan thermocouple mounted in the cell and referred to liquid helium temperature.

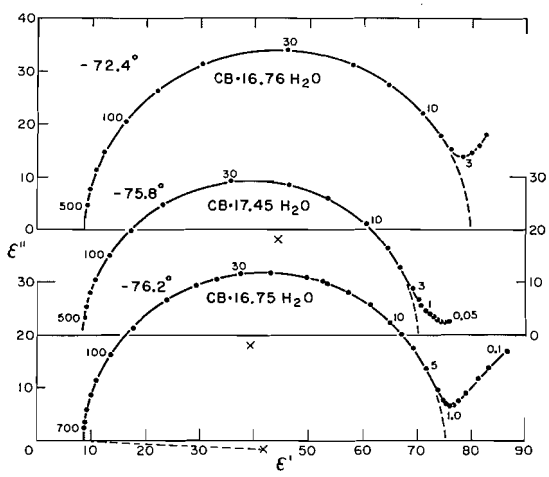

FIG. 1. Complex permittivity loci of various samples of cyclobutanone hydrate near −75°. Numbers on loci are frequencies in kHz.

Results

Absorption and Dispersion Associated with Water Molecules

Cyclobutanone Hydrate

Examples of a complex permittivity plots associated with relaxation of the hydrate lattice are given in Fig. 1 for three samples of somewhat different composition at temperatures near −75°. The CB·17.45H_2O sample clearly shows a region of extra absorption and dispersion at low frequencies which we attribute to the presence of a small quantity of ice. This feature is present in the loci of this sample at other temperatures but never evident in the loci of the other samples. It serves to fix the composition of the hydrate close to the ideal composition CB·17H_2O. The bottom locus is for a sample in the low-temperature cell.

The shapes of the loci are similar to those previously found (9) for the structure II hydrates of tetrahydrofuran, dihydrofuran, propylene oxide, trimethylene oxide, and 1,3-dioxolane (10) and appear to be characteristic of the type II lattice. They conform approximately to Cole–Cole arcs (with $\alpha = 0.03$ for the loci of Fig. 1) except at relatively high frequencies.

Representative dispersion parameters for a few of the 38 loci measured are given in Table 1. As before (9, 10), the mean relaxation time τ_0, static permittivity ε_0, and width parameter α refer to the Cole–Cole arc that "best" fits the locus, while $\varepsilon_{\infty 1}$ is the high-frequency intercept with the ε' axis, which is approached at right angles (*cf.* Fig. 8 below).

Values of the static permittivity for CB·16.76-H_2O measured in the high temperature cell were within a few permittivity units of those previously reported for dioxolane hydrate (11) and other isostructural hydrates (10) and are believed to represent the proper hydrate permittivities to about ±5%. The reasons for preferring a slight excess of hydrate-former in the sample have been dis-

cussed (9). Measured permittivities of samples containing excess water were lower at low temperatures, probably because of the presence of gaps and cracks. The results for CB·17.45H_2O are consistent with parallel air gaps constituting a few parts per thousand of the interelectrode separation (11).

Relaxation times are plotted in Fig. 2. The lower values for CB·17.45H_2O at low temperatures again reflect the presence of air gaps. Application of a correction of the form (11)

$$[1] \qquad \tau_0 = \left[\frac{\varepsilon_0(\text{true})}{\varepsilon_0(\text{exp})}\right]^{\frac{1}{1-\alpha}} \tau_0(\text{exp})$$

brings these points close to the line drawn in Fig. 2, which is described by

$$[2] \qquad \log_{10} \tau_0 = A + 1418/T$$

with $A = -12.395$.

Acetone Hydrate

New dielectric measurements of acetone hydrate were made primarily to check the static permittivity values found in the early study (4) which subsequent work with other structure II hydrates suggests are too low. Figure 3 is typical of the new loci obtained. Although better defined than before, the somewhat larger values of ε_0 are still considerably lower than expected for completely homogeneous samples.

The freezing point data of Benjamin (12) clearly

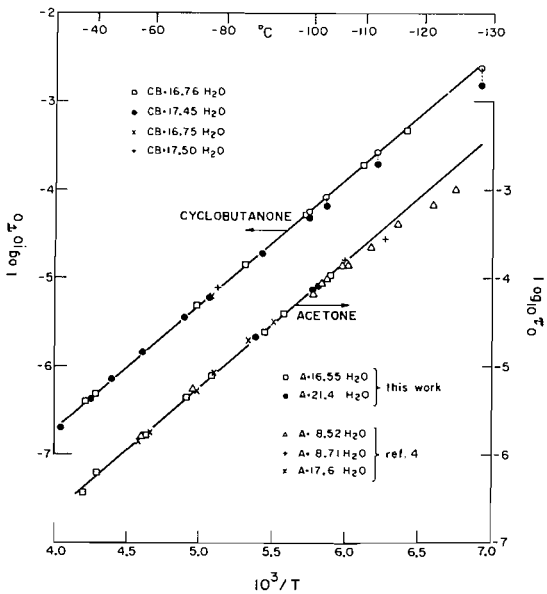

FIG. 2. Relaxation times of cyclobutanone and acetone hydrates.

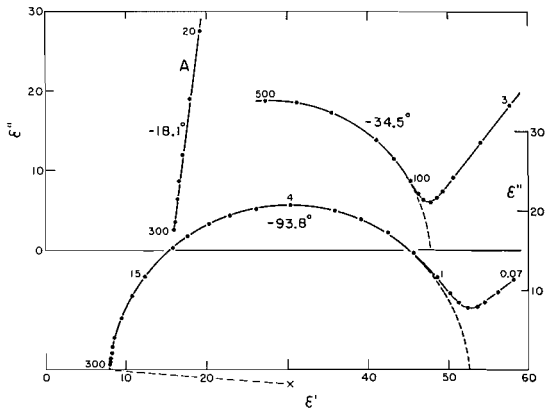

FIG. 3. Complex permittivity loci of $(CH_3)_2CO$·16.55H_2O. *A* is above the decomposition temperature of acetone hydrate.

show a change of slope at about −19° and 16.5 mol% acetone of the type characteristic of incongruent hydrate formation. At the composition of the ideal hydrate (5.6 mol% acetone) ice freezes at −5°. Hydrate therefore normally forms from ice and acetone-rich liquid by a process which is limited by the ability of the acetone to penetrate the hydrate crust as it forms on the ice. (The slowness of formation of argon and nitrogen hydrates has a similar cause (11).) Thus a sample containing 25% excess water after three days of conditioning at −30° still showed, by a small inflection in the high-frequency permittivity at the eutectic temperature, the presence of a trace of unreacted acetone.

The changes in ε' at a fixed frequency found when samples were slowly heated through the regions of the eutectic and decomposition temperatures identified these temperatures as −96.8 ± 0.4 and −19.8 ± 0.2°, respectively.

It appears that the main reason for the relatively low values of ε_0 (and of $\varepsilon_{\infty 1}$, see below) of acetone hydrate is the presence of irregular voids in the sample which result from the 4 to 5% contraction associated with the formation of hydrate from ice and acetone-rich liquid.

Relaxation times from the new measurements of acetone hydrate are plotted in Fig. 2, along with the earlier data (4). No attempt has been made to correct the results for the presence of gaps. Such a correction would raise the relaxation times somewhat, but the assumption that the effect of all the void space may be represented by a parallel air gap of uniform thickness seems unjustified in this instance.

The temperature-dependence of the water re-

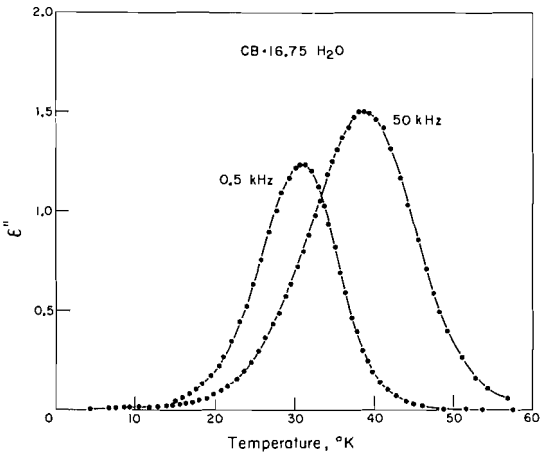

FIG. 4. Dielectric absorption of encaged cyclobutanone.

TABLE 2. Temperatures T_m of maximum loss ε_m'' at fixed frequencies f

f	ε_m''	T_m(°K)	ε' at T_m
10 Hz	~0.72	25.8	8.16
0.5 kHz	1.24	31.0	8.75
1.0 kHz	1.29	31.8	8.75
5 kHz	1.36	34.5	8.74
10 kHz	1.40	35.4	8.43
50 kHz	1.50	38.5	8.50

laxation times of acetone and cyclobutanone hydrates are very similar. At temperatures down to −106° these times for acetone hydrate average 18% higher and the best data may be described by eq. 2 with $A = -12.323$.

Dielectric Absorption by Cyclobutanone

The dielectric loss associated with reorientation of cyclobutanone in its cages is illustrated in Fig. 4. The absorption curves are very much broader than single relaxation-time Debye curves, as is evident from the extent of the overlap between the two curves for frequencies which differ by a factor of 100. In Table 2 the temperature at which ε'' reaches its maximum value is listed for a number of frequencies. The corresponding rate plot is linear between 30 and 40 °K, with the activation energy 1.44 kcal/mol. The slope appears to become smaller below 30°.

The variation with temperature of the contribution to the permittivity of reorienting cyclobutanone molecules is shown in Fig. 5. At the high-temperature end the values plotted are $\varepsilon_{\infty 1}$, the limiting permittivities on the high-frequency side of the water dispersion region. At low temperatures, down to 29 °K, the static permittivities of the cyclobutanone dispersion region, ε_{02}, are plotted. Also shown are dispersion curves at a number of fixed frequencies.

At high temperatures the variation of $\varepsilon_{\infty 1}$ is consistent with that expected (dashed curve) for an orientational contribution $\varepsilon_{02} - \varepsilon_{\infty 2}$ which is proportional to $1/T$. This behavior is characteristic of isotropic rotation or of reorientation between sites of about the same energy. Below about 150 °K departures become evident and $\varepsilon_{\infty 1} = \varepsilon_{02}$ passes through a flat maximum at about 45 °K and at lower temperatures begins to fall sharply. There is clearly a gradual depopulation of less stable orientational states over a large temperature range as energy differences between different orientations become more pronounced in comparison with kT.

The absorption and dispersion curves are so broad that they cannot be adequately defined at a fixed temperature by the frequency range available. However, it is possible to construct a Cole–Cole diagram (Fig. 6) using the reduced parameters $\varepsilon_r'' = \varepsilon''/(\varepsilon_{02} - \varepsilon_{\infty 2})$ and $\varepsilon_r' = (\varepsilon' - \varepsilon_{\infty 2})/(\varepsilon_{02} - \varepsilon_{\infty 2})$ measured at a number of temperatures. The resulting locus illustrates the extreme broadness of the absorption and its very slow fall at relatively high frequencies. Some absorption is still detectable at audio frequencies at 4.2 °K.

Discussion

Relaxation of Water Molecules in Structure II Hydrates

Although the shapes of the absorption–dispersion curves associated with reorientation of the water molecules in structure II hydrates appear to be insensitive to the nature of the guest molecule, the actual relaxation times and activation energies are dependent on the guest species. As Table 3 shows, there is no apparent correlation between the relaxation times τ_0 or the Arrhenius energies E_A and the estimated (3) maximum van der Waals diameter d of the guest or the lattice parameter a. There is a trend toward decrease of τ_0 and E_A with increase of dipole moment μ of the guest molecule, but no simple dependence on μ is suggested by these data nor by the results of study of the type II hydrates of CCl_3F ($\mu = 0.5$ D) and $CHCl_2F$ (1.3 D), for which E_A values as great as or greater than the value for ice (13.25 kcal/mol (13)) have been reported (14). (The relaxation times for these hydrates, however, may

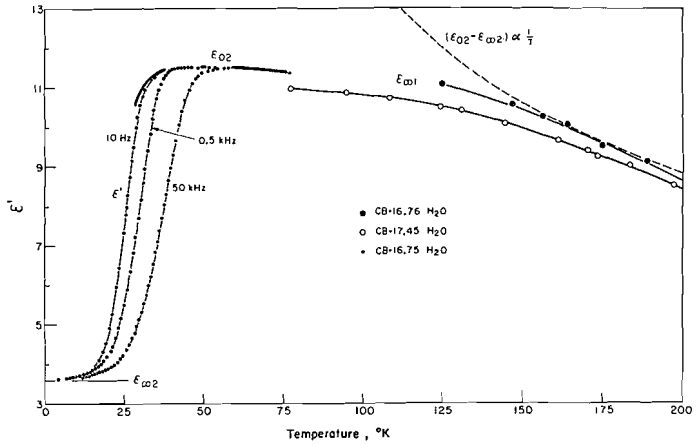

FIG. 5. Temperature dependence of $\epsilon_{\infty 1} = \epsilon_{02}$ and dispersion in cyclobutanone hydrate at low temperatures. Points O have been corrected for estimated series gaps.

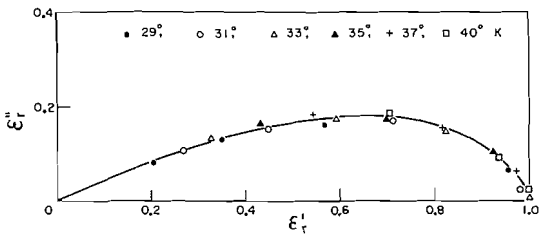

FIG. 6. Reduced complex permittivity plot for cyclobutanone hydrate for various temperatures between 29 and 40 °K.

have been affected by the presence of ice and incomplete filling factors: the loci (14) are much broader than found for other type II hydrates.)

As has been suggested elsewhere (11), it is possible that the relatively fast relaxation of the hydrates of ethers and ketones may be due to the occasional formation of hydrogen bonds between oxygen atoms of guest molecules and water molecules of the cage, with consequent injection of Bjerrum defects of the L type into the lattice. The listed values of τ_0 and E_A are not well correlated with the "strength" of hydrogen bonding between an OH group and an ethereal or ketonic oxygen atom as determined by infrared OH group frequency shifts and p.m.r. chemical shifts of, for example, phenol in solution (15). For the encaged molecules, however, the molecular geometry may well modify the extent of the proposed hydrogen bonding by affecting the distance and angle of approach of the oxygen atoms to the water molecules. This geometric factor should favor the formation of hydrogen bonds to the ketones over those to the ethers and to trimethylene oxide more than to propylene oxide, as required for consistency with the experimental data. It is also possible that molecular geometry may play a more general role by determining the nearness of approach and extent of electrostatic perturbation of the lattice by polar groups of the guest molecule.

When the relaxation time measurements of clathrate hydrates are extended to sufficiently low temperatures a fall in the slope of the log τ_0 *vs.* $1/T$ line is commonly found. Approximate temperatures and corresponding relaxation times at which these departures from linearity become significant are given in columns 7 and 8 of Table 3. Three reasons for this low-temperature behavior may be suggested.

The effect of the development and opening of cracks and gaps in the sample with decreasing temperature leads for the Cole–Cole arc approximation to a reduction in measured relaxation time given (11), at most, by eq. 1 above. This effect is tied to a negative departure from the expected linearity of ϵ_0 in $(1/T)$. It seems capable of accounting for the behavior of τ_0 of cyclobutanone and acetone hydrates at low temperatures (Fig. 2).

Another spurious effect may arise from the presence of "impurity" centers which give rise to extrinsic Bjerrum defects in numbers which dominate at low temperatures those intrinsic to the lattice. This is almost certainly the origin of the greatly reduced slope found for most samples of ice at low temperatures (16). It may determine the relaxation times of the structure I lattices of argon and nitrogen hydrates (11) prepared under

§See Appendix.

high pressures of gas and relaxation times of the structure II hydrates of ethers (9, 10) which, at the lowest temperatures of measurement, are of the order of ten times as small as those given by extrapolation of the high-temperature behavior. This difference is much too great to be given by eq. 1.

A fall in effective activation energy at low temperatures may be characteristic of the lattice itself when some orientations become stabler than others by energies which are appreciable in comparison with kT. Such a process will be accompanied by a pronounced fall in ε_0 such as that observed during the gradual ordering transformation of ice III to ice IX (17). No appreciable change of slope of the log τ_0 *vs.* $1/T$ curve occurs during this transformation, however (17). It is unlikely that the curvature observed in the relaxation rate plots of water in the clathrate hydrates is due to this mechanism.

Contribution of Guest Molecules to the Permittivity

At relatively high temperatures this contribution is expected to be nearly proportional to the square of the dipole moment of the guest molecule. This is confirmed by Fig. 7, where $\varepsilon_{\infty 1} = \varepsilon_{02}$ at −105° is plotted *vs.* μ^2 for a series of eight structure II hydrates. The temperature is chosen for experimental convenience (9). It is also sufficiently high that any departure from isotropy of the rotation appears not to be great enough to appreciably affect the contribution to ε_{02}. In general

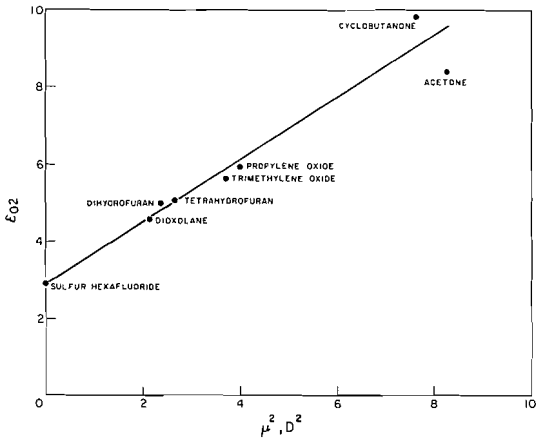

FIG. 7. ε_{02} at −105 °C *vs.* (dipole moment)² of guest molecules in structure II hydrates.

the values of ε_{02} are uncertain to at least 0.10. This uncertainty arises not from inability to fix the high-frequency limit of the permittivity of the water dispersion region for a given sample: Figure 8 illustrates how well this value may be defined. The main uncertainty arises from small air pockets and gaps and from possible traces of solid hydrate-former and ice in the sample. Such inclusions act to reduce the measured permittivity, as already discussed for acetone hydrate, in which the reduction is especially large.

It was previously pointed out (9, 10) for the hydrates of the cyclic ethers that the experimental values of ε_{02} were higher than those calculated from the Onsager theory if the radius of

the Onsager cavity were taken to coincide with the free radius of the hydrate cage. With experimental estimates now available of $\varepsilon_{\infty 2}$ values for cyclobutanone and tetrahydrofuran hydrates, a reassessment of the Onsager model is possible.

Modification of the Onsager Model to Include Rotational Oscillations

With oxygen atoms of the water molecules at positions given by Mak and McMullan's study (19) of the tetrahydrofuran – hydrogen sulfide double hydrate and with an average lattice parameter of 17.18 Å at −105° (Table 3), one finds, for the large cage, 12 oxygen atoms at 4.68 Å, 12 at 4.60 Å, and 4 at 4.69 Å from the cage center. If the van der Waals radius of oxygen is 1.45 Å, the nearly spherical cage has a mean free radius of 3.20 Å.

We write the Onsager equation in the form (ref. 20, p. 191)

$$[3]\quad \frac{(\varepsilon_{02}-1)(2\varepsilon_{02}+1)}{3\varepsilon_{02}} = \frac{(\varepsilon_\infty{}^0-1)(2\varepsilon_\infty{}^0+1)}{3\varepsilon_\infty{}^0} + \frac{4\pi N_M \alpha_M}{1-f_M\alpha_M} + \frac{4\pi N_M \mu_M{}^2}{3kT(1-f_M\alpha_M)^2}$$

where $\varepsilon_\infty{}^0$ is the dielectric constant of the hypothetical empty lattice at frequencies too high for reorientation of the water molecules and N_M, α_M, μ_M, and f_M are, respectively, the number density, polarizability, dipole moment, and reaction field factor of the guest molecule. We take $\varepsilon_\infty{}^0 = 2.83$ as derived by equating the first term on the r.h.s. of eq. 3 to the product of the corresponding term for hexagonal ice (with $\varepsilon_\infty = 3.10$) by the ratio of the number densities of water molecules in hydrate and ice. This value is more consistent with the results (21) for the hydrate of nonpolar SF_6 than the somewhat higher value previously (9) assumed.

In the Onsager model the reaction field factor $f_M = 2(\varepsilon_{02}-1)/[a^3(2\varepsilon_{02}+1)]$ refers to a polarizable dipole located at the center of a spherical cavity of radius a, surrounded by a continuum of dielectric constant ε_{02}. For $a = 3.2$ Å, the free radius of the cage, values of ε_{02} from eq. 3 are listed in the third column of Table 4. The values of polarizabilities (mostly from sodium D molar refractions) used are also given in Table 4. All large cages are assumed occupied and $N_M = 1.59 \times 10^{21}$. It is seen that for polar guest molecules the derived values of ε_{02} are consistently and appreciably smaller than the measured values (column 5). Formally, the agreement may be greatly improved by allowing a to assume smaller values: column 4 gives ε_{02} for $a = 2.8$ Å.

Such a value for the cavity radius is however, unrealistically small. In applications of the Onsager equation to liquids a is invariably defined

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

by $4\pi a^3/3 = V/N$, where V is the molar volume of the liquid. The cavity radius is then larger than the radius of close-packed spheres which occupy the same volume. In liquid acetone, for which the Onsager equation fits the data well (ref. 20, p. 324), the value of a so defined is 3.04 Å at 0 °C. Similar values are obtained for other hydrate-forming liquids: for example $a = 3.18$ Å for liquid tetrahydrofuran at 22 °C. It is clear that for the molecules enclathrated in type II hydrates, with their exceptional degree of rotational mobility, values of a should be considerably larger than for the liquids. The free radius of the cage should be a *lower* limit to the proper value of a.

At the same time it may be noted that at very low temperatures, where guest-molecule reorientation makes no contribution to the permittivity, $\varepsilon_{02} = \varepsilon_{\infty 2}$ and

$$[4] \quad \frac{(\varepsilon_{\infty 2} - 1)(2\varepsilon_{\infty 2} + 1)}{3\varepsilon_{\infty 2}} = \frac{(\varepsilon_{\infty}{}^{0} - 1)(2\varepsilon_{\infty}{}^{0} + 1)}{3\varepsilon_{\infty}{}^{0}} + \frac{4\pi N_M \alpha_M}{1 - f_M \alpha_M}$$

Equation 4 predicts for cyclobutanone hydrate, with $a = 3.2$ Å and the polarizability in Table 4, a value of $\varepsilon_{\infty 2}$ of 3.08. The experimental value of the permittivity at 4.2 °K is about 3.6. This large value can be reconciled with the Onsager model (or any other reasonable model) only if the polarizability of the encaged molecule is greatly enhanced, to something like 18 Å^3. In a similar way it is found that the normal polarizability of tetrahydrofuran accounts for an $\varepsilon_{\infty 2}$ value of only 3.09 for its hydrate. The experimental value of 3.47 requires a polarizability of about 16 Å^3.

This enhanced polarizability probably arises mainly from the rotational oscillations of the encaged molecules around their equilibrium positions, oscillations of large amplitude expected to occur at far infrared frequencies. The increase in refractive index corresponding to the enhanced permittivity may be related (22) to the integrated infrared absorption. If the gross simplification is made that there is only one doubly-degenerate oscillation giving rise to a band of intensity proportional to $(\partial\mu/\partial Q)^2 \approx \mu^2 \sin^2\theta/(I\theta^2) \approx \mu^2/I$, where I is the moment of inertia corresponding to an angular displacement θ, it is found that the oscillation frequency is of the order of 20 cm^{-1} for both cyclobutanone and tetrahydrofuran. Actually, a great variety of depths and shapes of potential minima is expected from the wide distribution of fields and field directions in different cages (18) and broad structureless absorption is to be expected in the far infrared region.

It is to be noted that the contribution to the polarizability from rotational oscillation of the guest molecule is at right angles to the direction of the dipole moment of a molecule which possesses an axis of symmetry. The reaction field therefore increases the dipole moment by $1/(1 - f_M\alpha_M)$ where α_M may not differ much from the "normal" polarizability in Table 4. On the other hand the cavity field is increased on the average by $1/(1 - f_M\alpha_M{}^*)$, where $\alpha_M{}^*$ includes the contribution from rotational oscillations. For this case the Onsager equation takes the form

$$[5] \quad \frac{(\varepsilon_{02} - 1)(2\varepsilon_{02} + 1)}{3\varepsilon_{02}} = \frac{(\varepsilon_{\infty 2} - 1)(2\varepsilon_{\infty 2} + 1)}{3\varepsilon_{\infty 2}} + \frac{4\pi N_M \mu_M{}^2}{3kT} \cdot \frac{1 + f_M(\alpha_M{}^* - \alpha_M)}{(1 - f_M\alpha_M{}^*)(1 - f_M\alpha_M)}$$

If a is again taken to be 3.2 Å, eq. 5 is found to over-estimate ε_{02} of cyclobutanone and tetrahydrofuran hydrates. Such a result is to be expected since the assumption that the medium may be represented as a continuum of permittivity ε_{02} beyond the free radius ignores the structural details. The innermost shell of neighbors consists only of water molecules whose effective permittivity is less than ε_{02}. It is necessary to compensate for this by allowing a to assume somewhat larger values. That the value of a necessary to fit the observed value of ε_{02} of cyclobutanone hydrate is about 3.6 Å and that for tetrahydrofuran hydrate 3.4 Å agrees with this interpretation.

It thus appears that the inclusion of the relatively large contributions to the polarizability from low-frequency rotational oscillations in the Onsager equation leads to a satisfactory representation of the high-temperature values of ε_{02}.

Reorientation of Cyclobutanone Molecules

The very broad audio-frequency absorption associated with reorientation of guest molecules occurs at higher temperatures for cyclobutanone than for tetrahydrofuran. The temperatures of maximum absorption at 1 kHz, for example, are 31.8 and 21.6 °K, respectively, "corresponding" temperatures which are roughly proportional to the Arrhenius energies of 1.44 (between 30 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

40 °K) and 1.06 kcal/mol (between 18 and 25 °K). At these low temperatures the guest molecules appear to be undergoing restricted rotation between preferred orientations of unlike energy since the values of ε_{02} are small fractions of those given for an orientational contribution proportional to $1/T$ (Fig. 5). There is an increasing loss of population of unfavorable orientations with decrease of temperature. At the same time the absorption becomes broader, as shown by, for example, the data plotted in Fig. 6.

In these circumstances the interpretation of the experimental Arrhenius energy is far from straight-forward. One may perhaps infer that its larger value for cyclobutanone results from greater length of the molecule along its polar axis and the nearer approach of the oxygen atom to the center of a hexagonal ring of water molecules than is the case for tetrahydrofuran (18).

There appears to be a close similarity between the shapes of the absorption–dispersion curves (in frequency terms) of the two hydrates when compared at corresponding temperatures. Compared at temperatures where the 1 kHz absorption is greatest, for example, the ratio $\varepsilon_m''/(\varepsilon_{02} - \varepsilon_{\infty 2})$ is between 0.16 and 0.17 for both guests. It is suggested (18) that the shapes are mainly the result of variation from cage to cage of the electrostatic fields $\boldsymbol{E}$ of the orientationally-disordered water molecules. These fields modify the tetrahedral symmetry of the cages by introducing orientation-dependent energies of the form $-\boldsymbol{\mu}\cdot\boldsymbol{E}$ which lead, *inter alia*, to a distribution of barriers to reorientation, the spread of barrier heights being proportional to the dipole moment of the guest and therefore larger by a factor of about 1.7 for cyclobutanone ($\mu = 2.78$ D, see Appendix) than for tetrahydrofuran (1.63 D). For relaxation times of the simple form

$$\tau = \tau_0 \exp(\Delta E_A/RT)$$

the distributions of times will be similar when the distributions of $\Delta E_A/T$ are similar, that is, at temperatures which are about 1.7 times as high for cyclobutanone as for tetrahydrofuran. That these distributions are roughly the same at temperatures which differ by a factor of 1.5 provides a crude confirmation of the model.

Appendix

Dipole Moment of Cyclobutanone

This moment has been reported (23) from measurements of benzene solutions to be 2.76 D. Because of the relatively large values of ε_{02} found for cyclobutanone hydrate (Fig. 7), it appeared that new measurements in a more inert solvent would be worthwhile. From dielectric constant and refractive index measurements at 25 °C of five solutions in the weight fraction range between 0.0016 and 0.011 of cyclobutanone in cyclohexane Guggenheim's method (24) gave 2.78 ± 0.02 D. Because of possible solvent effects even in cyclohexane, however, it is not certain that the proper (*i.e.*, dilute gas phase) dipole moment of cyclobutanone is less than that of acetone. Figure 7 also suggests that the value for dihydrofuran (1.54 D) measured in benzene solution may be too low by as much as 0.1 D.

Photochlorination of Perfluorocyclobutene

Z. R. Alberto, J. J. Cosa, C. A. Vallana, and E. H. Staricco

Departamento de Fisico-Química, Instituto de Ciencias Químicas, Universidad Nacional de Córdoba, Ciudad Universitaria, Córdoba, Argentina

Received October 19, 1970

The kinetics in the gas phase of the photochemical reaction between perfluorocyclobutene and chlorine was studied between 10 and 70 °C. The system was irradiated with light of 4360 Å. The rate of photochlorination was measured under full and intermittent light. The Arrhenius parameters for the reaction:

$$C_4F_6Cl + Cl_2 \rightarrow C_4F_6Cl_2 + Cl$$

are: $A_3 = (2.9 \pm 1.1) \times 10^8$ l mol^{-1} s^{-1} and $E_3 = 4.64 \pm 0.03$ kcal/mol and for

$$2\ C_4F_6Cl \rightarrow \text{Inactive products}$$

the constant rate value is: $k_4 = (7.23 \pm 4.3) \times 10^8$ l mol^{-1} s^{-1}.

On a étudié, entre 10 et 70° la cinétique en phase gazeuse de la réaction photochimique du perfluorocyclobutène avec le chlore; le système était irradié à 4360 Å. On a mesuré la vitesse de chloruration photochimique avec irradiation contenue et intermittente. Les paramètres d'Arrhénius pour la réaction

$$C_4F_6Cl + Cl_2 \rightarrow C_4F_6Cl_2 + Cl$$

sont: $A_3 = (2.9 \pm 1.1) \times 10^8$ l mol^{-1} s^{-1} et $E_3 = 4.64 \pm 0.03$ kcal/mol et pour la réaction

$$2\ C_4F_6Cl \rightarrow \text{Produits inactifs}$$

la constante de vitesse est: $k_4 = (7.23 \pm 4.3) \times 10^8$ l mol^{-1} s^{-1}.

Canadian Journal of Chemistry, 49, 1252 (1971)

Introduction

The addition of atoms or radicals to olefins has been subject to a rather extensive study (1–3). Less interest, however, has been devoted to processes involving cyclic olefins. Recently, the addition of CF_2Cl radicals to cyclic fluoroolefins has been studied (4). Also chlorine atoms produced photochemically have been added to perfluorocyclohexene (5). It was found that this reaction follows the well known chain chlorination mechanism (eqs. 1–4) (6) where A stands for the olefin and ACl for the chloroalkyl radical.

[1] $$Cl_2 + h\nu \rightarrow 2Cl$$

[2] $$A + Cl \rightarrow ACl$$

[3] $$ACl + Cl_2 \rightarrow ACl_2 + Cl$$

[4] $$2ACl \rightarrow \text{Inactive products}$$

Hence, it would be interesting to examine the behavior of other cyclic olefins such as perfluorocyclobutene (PFCB) and perfluorocyclopentene (PFCP).

Taking into account the above mechanism the rate law for these olefin reactions could be represented by eq. 5 where $k_0 = k_3/k_4^{1/2}$ and I_a is the

[5] $$\text{Rate} = k_0 \cdot Cl_2 \cdot I_a^{1/2}$$

absorbed light intensity.

In order to elucidate the influence of the ring structure on the kinetic parameters it is important to get the individual values of k_3 and k_4 at different temperatures. To accomplish this the intermittent light technique was used.

The present work deals with the kinetics of photochlorination of perfluorocyclobutene under steady and intermittent light.

Experimental

The reactor was a cylindrical quartz reaction vessel of 94.8 ml in volume. The other experimental arrangements have already been described (5). Light measurements and temperature control were also made as previously.

The experiments with intermittent light were performed at 30 and 60 °C following the suggestions given by Burnett and Melville (7). A 90° metal sector was used to cut the light beam off at its narrowest cross section. A set of synchronous a.c. motors at constant velocity was used for slow sector speeds. A low voltage d.c. motor connected to a power supply was used for high sector speeds and the rotation speed controlled electronically (8).

The PFCB from Pierce Chemical Company was sublimated several times in vacuum. Its purity was tested chromatographically with two different columns (Silica Gel and Halocarbon oil columns 10 and 30 ft long respectively) at room temperature, and no impurities were detected. After purification it was stored in a trap cooled with liquid air.

Cylinder chlorine was distilled trap-to-trap in vacuum five times between −78 and −135 °C, only the middle fraction being collected.

The CO_2 from a cylinder was dried by passage through sulfuric acid and then sublimated under vacuum at low temperature.

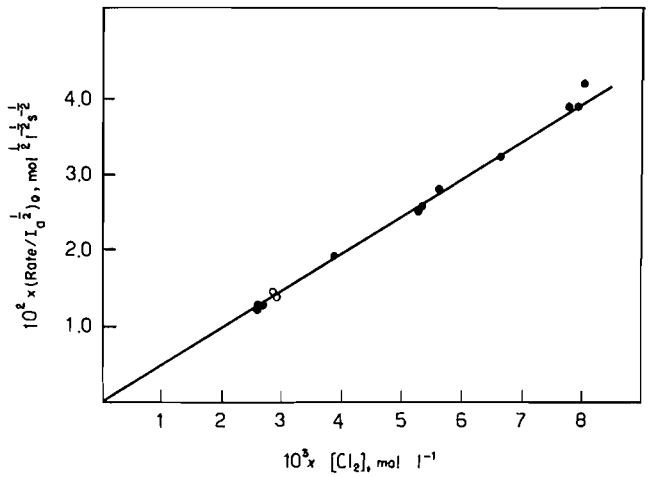

FIG. 1. Initial rate/$I_{abs}^{1/2}$ *vs.* initial pressure of Cl_2. ○, Runs with addition of 400 Torr CO_2. Temperature, 30 °C and pressure of C_4F_6, 50 Torr.

All samples were exhaustively degassed before using. Runs were always made up to 25% conversion under continuous light and up to 5% with intermittent light.

Results

(A) Experiments with Full Light

Preliminary observations at 30 °C showed the existence of a dark reaction less than 3% of the photochlorination rate. Therefore, all runs were performed in a darkened room. Under this condition experiments were reproducible and no dark reaction was observed at any temperature.

The analysis of products by gas chromatography and i.r. showed the existence of only one compound identified as 1,2-dichlorohexafluorocyclobutane. In addition, the i.r. spectrum showed that it was over 80% the *trans* isomer (9).

To test the eq. 5, the dependence upon rate of chlorine, olefin, total pressure, and light intensity was determined. An average value of the rate constant for each run was calculated assuming that the rate eq. 5 was valid at any moment through the course of the reaction within the studied range. The standard deviation of k for each run was less than 5% including some runs made up to 50% conversion. Initial rates given in all plots were calculated using that rate constant and the initial chlorine pressure.

The incident light intensity was changed in a series of runs using neutral glasses of known transmission and the rate was measured at different intensities. Chain termination by mutual interaction of radicals was also verified in experiments with the rotating sector (see below). The rate was found to be proportional to the square root of I_a as previously suggested.

In order to check the chlorine pressure effect the rate was measured at constant PFCB pressure and temperature. The rate was proportional to the first power of chlorine pressure within the whole range of pressure studied (25–150 Torr). Data are given in Fig. 1.

A plot of rate/$I_a^{1/2}$ *vs.* PFCB concentration at constant Cl_2 pressure and olefin between 25 and 150 Torr, given in Fig. 2, shows that the rate does not depend on olefin pressure.

Experiments with CO_2 as inert gas indicated that the total pressure does not have any effect on the rate at olefin pressure above 25 Torr (Fig. 1).

Hence, the results obtained with continuous light confirm the suggestion that the rate is proportional to the square root of I_a and to the first power of chlorine.

From experimental data, k_0 was found to be $4.989\ l^{1/2}\ mol^{-1/2}\ s^{-1/2}$ at 30 °C. With k_0 values at 10, 20, 30, 40, 50, 60, and 70 °C, obtained from similar plots to Fig. 1, an Arrhenius plot was made (Fig. 3). From this plot the kinetic parameters were obtained by the least squares method, being $E_0 = 4.64 \pm 0.03$ kcal/mol and $A_0 = (1.08 \pm 0.08) \times 10^4\ l^{1/2}\ mol^{-1/2}\ s^{-1/2}$. The incident light intensity was 1.4908×10^{-8} einstein $l^{-1}\ s^{-1}$.

(B) Experiments with Intermittent Light

The condition $\rho = 1 \pm 0.02$ at high sector speed was checked before and after a series of runs. Here ρ is the ratio between twice the rate with

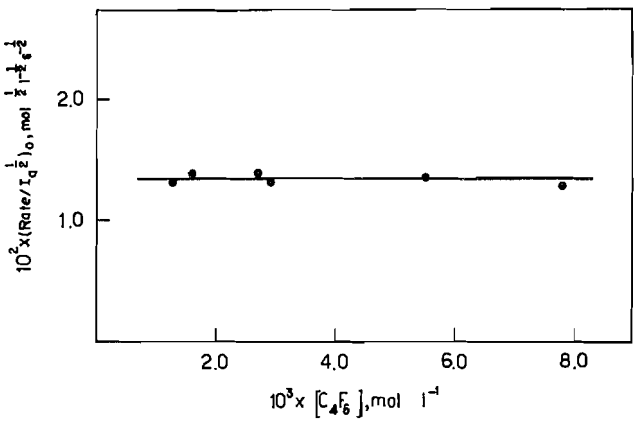

FIG. 2. Initial rate/$I_{abs}^{1/2}$ *vs.* initial pressure of C_4F_6. Temperature, 30 °C; pressure of Cl_2, 50 Torr.

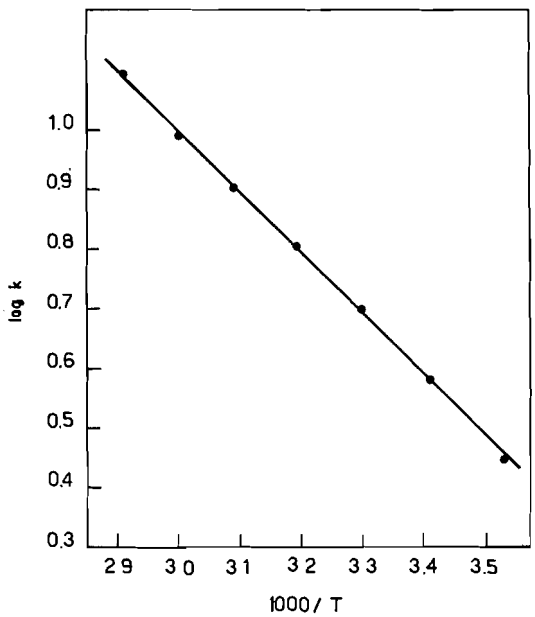

FIG. 3. Arrhenius plot; k in $mol^{-1/2}\ l^{1/2}\ s^{-1/2}$ of the overall reaction.

intermittent light to that with continuous light and it must be one when a 90° sector is used if rate is proportional to $I_a^{1/2}$. This ratio was also taken as a criterion of purity for reactants. When this condition was not fulfilled, the runs were rejected and the reactants purified again.

The plots of ρ *vs.* $\log_{10} \lambda I_0^{1/2}$ at 30 and 60 °C are shown in Fig. 4, where λ is the flash period. When the experimental plots are compared with the theoretical one, the value of $\log_{10} \lambda I_0^{1/2}$ was read off corresponding to the point at which $\log_{10} m = 0$, therefore $\lambda = \tau$. Since $\tau = \frac{1}{2}(k_4 I_a)^{-1/2}$, k_4 was obtained.

The value of k_4 appears independent of the temperature, within the experimental error. Hence, E_4 was taken as zero and the apparent activation energy E_0 assigned to E_3.

From the experimental plots follows that k_4 and therefore $A_4 = (7.23 \pm 4.3) \times 10^8$ l mol^{-1} s^{-1}. With this value and the overall reaction parameter A_0, A_3 results $(2.9 \pm 1.1) \times 10^8$ l mol^{-1} s^{-1}.

Discussion

The addition of inert gases showed that the vibrationally excited ACl radical formed in eq. 2 (2), because of the complexity of that radical, is deactivated in the pressure range used in the present work.

On the assumption that the apparent activation energy of 5.1 kcal/mol for perfluorocyclohexene (PFCH) arises as a result of a repulsive effect between the ring and the chlorine molecule (5), the 4.6 kcal/mol obtained with perfluorocyclobutene could account for the same effect. The difference may be justified by the smaller ring size or by a less electronic density on the carbon atom bearing the unpaired electron in PFCH.

With k_4 value (11) and k_0 (5), for PFCH, A_3 was evaluated as 3.1×10^8 l mol^{-1} s^{-1}. It appears that A_3 for PFCH and PFCB (3.1×10^8 and $2.9 \pm 1.1 \times 10^8$ respectively) are lower than A_3 for chloroethylenes as could be expected in a first approach, from the fact that cyclic radicals should have a more restricted zone of attack by Cl_2 molecule than alkyl radicals.

Regarding the k_4 value in the chloroethylene series (10) one could point out that k_4 decreases as the degree of substitution by chlorine atoms

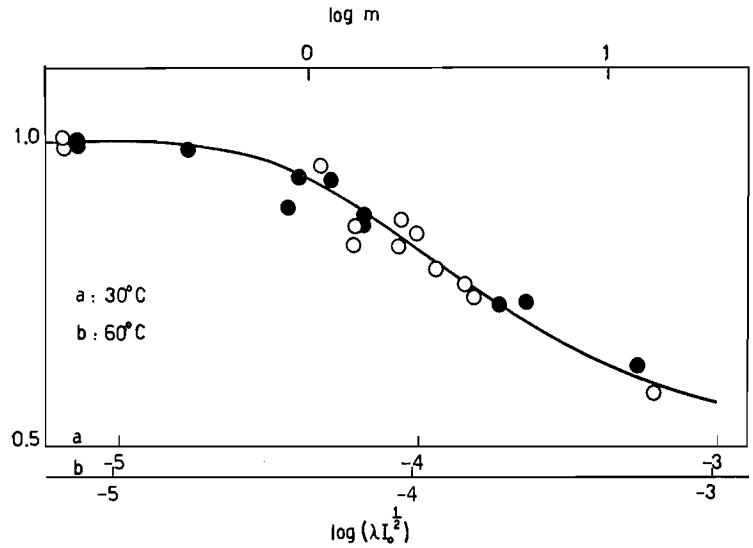

FIG. 4. Rotating sector curve: ρ *vs.* $\log_{10}$ ($\lambda I_0^{1/2}$); pressure of Cl_2, 100 Torr; pressure of C_4F_6, 50 Torr; ○ 30 °C; ●, 60 °C.

increases. In the present case it was found that k_4 is comparable with the smaller value of that series ($k_4 = 5 \times 10^8$ l mol^{-1} s^{-1} for C_2Cl_5) but slightly greater than the recently reported for $C_6F_{10}Cl$ (2.5×10^8 l mol^{-1} s^{-1}) (11).

It should be interesting to seek the value of k_4 in the chlorination of perfluorocyclopropene and perfluorocyclopentene because it likely would lead to an insight into the eventual trend of these values for a comparative set of cyclic olefins.

Nuclear Magnetic Resonance Study of Ring Inversion in Cycloheptene

MAURICE ST-JACQUES AND CAMBYSE VAZIRI
Department of Chemistry, University of Montreal, Montreal, Quebec

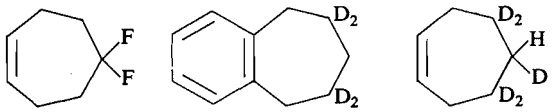
Received November 26, 1970

The p.m.r. spectrum of 4,4,5,6,6-pentadeuteriocycloheptene (**3**) has been studied down to −171 °C. Analysis of the spectral change below −160 °C yielded a $\Delta F^{\ddagger}$ value of 5.0 kcal/mol at −165 °C. Possible energy profiles for the ring inversion of cycloheptene are discussed.

On a étudié le spectre r.m.p. du pentadeuterio-4,4,5,6,6 cycloheptène (**3**) jusqu'à −171 °C. L'analyse des changements spectraux en bas de −160 °C permet d'évaluer à 5.0 kcal/mol la valeur du $\Delta F^{\ddagger}$ à −165 °C. Différents profils énergétiques pour l'interconversion du cycloheptène sont discutés.

Canadian Journal of Chemistry, 49, 1256 (1971)

Ring inversion has been studied in several seven-membered cyclic compounds (1). Out of the compounds investigated, 5,5-difluorocycloheptene (**1**) and 4,4,6,6-tetradeuteriobenzocycloheptene (**2**) have a carbon ring skeleton closely related to cycloheptene and yet the free energy barriers ($\Delta F^{\ddagger}$) to ring inversion are significantly different, being 7.4 (2)[1] and 10.9 kcal/mol (3) respectively.



1 **2** **3**

We wish to report the results of a p.m.r. study of 4,4,5,6,6-pentadeuteriocycloheptene (**3**) which shows that $\Delta F^{\ddagger}$ for ring inversion is appreciably lower for this parent compound than for **1** and **2**.

Results and Discussion

Compound **3** was prepared from 4-cycloheptenone (4)[2] by the following sequence of reactions: (*1*) base-catalyzed exchange of α-protons by deuterium atoms, (*2*) reduction with lithium aluminum deuteride, and (*3*) reaction of the alcohol with *p*-toluenesulfonyl chloride and reduction with lithium aluminum hydride.

The deuterium decoupled 100 MHz p.m.r. spectrum at 25 °C of **3** in a mixture of vinyl chloride and chlorodifluoromethane (85:15 by volume) consists of a singlet at δ 1.680 (proton on C-5), a multiplet centered at δ 2.10 (methylene protons on C-3, and -7), and a lowfield multiplet due to the olefinic protons. Figure 1 shows the behavior of the two upfield bands as the temperature is decreased. The upfield singlet broadens and splits into a doublet whose upfield component is clearly visible at δ 1.40, the lowfield component

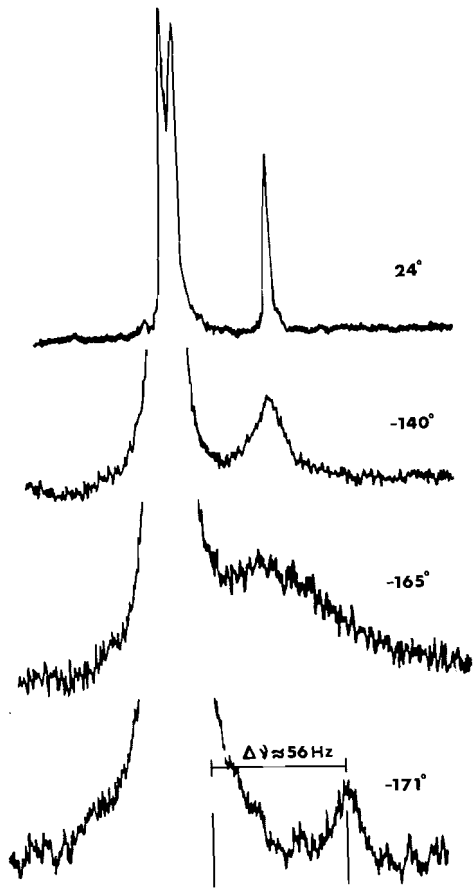


FIG. 1. The 100 MHz p.m.r. deuterium decoupled spectra of the high field peaks of **3** at several temperatures.

[1]The $\Delta F^{\ddagger}$ value was calculated from the data at −165 °C (2).

[2]We are very thankful to Professor G. Descotes for sending us a sample of this compound.

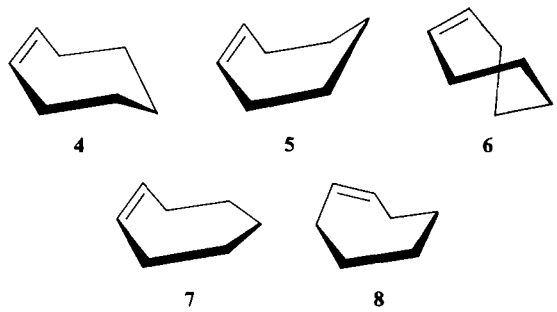
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

being under the intense band centered at about δ 2.10 which has broadened but not changed appreciably. The coalescence temperature (T_c) for this spectral change is estimated to be −165 °C. Since the chemical shift of the C-5 singlet changes by only 0.1 Hz from +25 to −140 °C, it is possible to assume that at −171 °C this peak has split into a doublet symmetrically disposed about δ 1.68 thus fixing the position of the downfield component at δ 1.96 as indicated with a line in Fig. 1. The chemical shift difference (Δν) at −171 °C is then about 56 ± 5 Hz, the uncertainty being due to the broadness of the lines because of increased viscosity and the closeness to T_c. This value is comparable to the 0.43 p.p.m. observed for the C-5 protons of **2** (3).

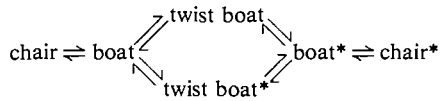
The rate constant (k, in s^{-1}) at T_c for the process of conformational interconversion responsible for the spectral change may be obtained from the relationship, $k = \pi\Delta\nu/\sqrt{2}$ (5). From $k = 124$ s^{-1}, a value of $\Delta F^{\ddagger}$ equal to 5.0 ± 0.3 kcal/mol was calculated using the Eyring equation (1) with a transmission coefficient of one-half (this value will be justified later in the discussion of the interconversion mechanism). The error in $\Delta F^{\ddagger}$ was estimated from the maximum uncertainties in T_c (±3 °C) and in Δν(±5 Hz). Since the spectra of **3** are not suitable for obtaining k with any accuracy over a reasonable range of temperature, it has not been possible to obtain values for $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (1). However once the interconversion mechanism and the geometry of the transition state are known, it is possible to obtain a fair estimate for $\Delta S^{\ddagger}$ from symmetry contributions (1). We will now consider this aspect of the problem.

Although it has generally been assumed (1) that the most stable conformation of cycloheptene is a chair (**4**), the literature is somewhat ambiguous on this question. Semiempirical strain energy calculations by Allinger and coworkers (6) favor a boat form **5** whereas the results of similar calculations by Favini and co-workers (7) argue for a chair form. Experimentally, p.m.r. results[3] (8) for the benzocycloheptene system strongly favor the chair. It is therefore highly probable that the stable conformation of **3** is also a chair.

[3]The p.m.r. spectra of 2,3-benzocyclohepten-1,4-diol (*8a*) at room temperature and 5,5-dimethylbenzocycloheptene at −52 °C (*8b*) were interpreted in terms of a chair. The p.m.r. results in preparation from our laboratory on deuterated derivatives of benzocycloheptene indicate clearly that the seven-membered ring is a chair.



Our p.m.r. study therefore indicates that there are two equivalent (chair) forms in equilibrium which are separated by an energy barrier of 5.0 kcal/mol. A proposed itinerary for chair interconversion was described as involving the conformation changes described in Scheme 1 (9) (the asterisks indicated inverted conformations).



SCHEME 1

The free energy profile corresponding to this mechanism can take two limiting forms as shown in Fig. 2. Since Favini's results predict the correct stable conformation for cycloheptene, we have assumed that their calculated stabilities for the boat and twist boat forms are such that the latter is the least stable. The rate determining transition

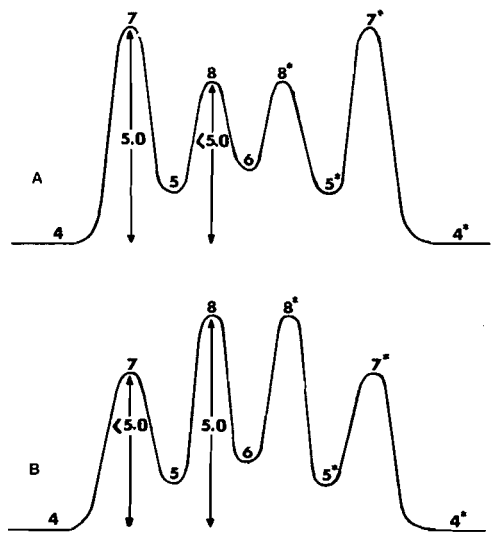


FIG. 2. Possible free energy profiles for the interconversion of cycloheptene chair forms. The asterisks indicate inverted conformations.

For personal use only.

state could be the one for the chair to boat change (**4** → **5**, curve A); in this case the transition state is approximated by conformation **7** which contains five carbon atoms in an essentially planar arrangement. The other possibility (curve B) involves the transition state for the boat to twist boat pseudorotation for which conformation **8** has been proposed by Favini *et al.* (7). In that paper, the energy difference between **4** and **8** has been calculated as 5.6 kcal/mol, a value not incompatible with our p.m.r. result of 5.0 kcal/mol. It is very unfortunate that the energy of conformation **7** was not calculated by these workers. Other calculations for cycloheptane (10), however, have suggested that the barrier to pseudorotation is ordinarily lower than that of a symmetrical process as the change **4** → **5** through **7**. Furthermore, p.m.r. results (9) on cycloheptene derivatives containing two or three sulfur atoms instead of the C-4, -5, and -6 methylene groups have shown that the barrier to pseudorotation is appreciably smaller than chair-to-boat process (for 1,2-benzo-4,5,6-trithio-1-cycloheptene the values were found to be about 10 and 17.4 kcal/mol respectively) although for these compounds both barriers are much higher than the 5.0 kcal/mol observed for cycloheptene. It therefore appears that the energy profile B (Fig. 2) would represent a behavior different from other related systems. In addition, it is difficult to rationalize the barrier differences for **1**, **2**, and **3** by means of this profile. On the other hand, profile A (Fig. 2) offers a more comprehensive rationale for all cycloheptene derivatives through a consideration of substituent and structural effects on the energy of the transition state **7** in the rate determining step as will be discussed next.

Although fluorine substitution has been widely used (2, 11–16) to obtain information on the barrier to conformational interconversion, no comprehensive explanation has been advanced to account for the differences between fluorinated and non-fluorinated compounds. For example, perfluorocyclohexane has a lower $\Delta F^{\ddagger}$ barrier (~0.4 kcal/mol) than cyclohexane (12, 17) while for perfluorocyclohexene it is larger (~1.3 kcal/mol) than cyclohexene (16, 18). Similar differences have also been observed when only one or two fluorine atoms are present in the molecule. For example, 1,1-difluorocyclohexane and 4,4-dimethyl-1,1-difluorocyclohexane (12) have lower $\Delta F^{\ddagger}$ values than cyclohexane (17) and 1,1-dimethylcyclohexane (19) (9.7, 10.2, 10.3, and 11.1 kcal/mol respectively). For 4-fluorocyclohexene (20) the barrier has been found to be essentially equal to that for cyclohexene. In the cyclohexane series, steric interactions in the ground state chair conformation were used to rationalize the results whereas increased torsional energy in the transition state was invoked for halogenated cyclohexene derivatives (20). Solvent variations where possible have shown that these differences were not due to solvent effects (12, 14).

Any attempt to explain the higher barrier for **1** over **3** must consider steric, torsional, and electrostatic interactions. If steric (nonbonded) interactions were mainly responsible for the difference, we would expect the barrier to be lower since the larger size of fluorine would tend to destabilize the ground state chair conformation through axial-like H—F repulsion. Since the opposite is observed, this factor cannot be the sole or main contribution to the difference unless it leads to a larger destabilization of the transition state.

The replacement of the C-5 methylene protons by fluorine atoms is expected to increase the torsional energy to rotation about the C_4—C_5 and C_5—C_6 bonds only slightly if at all as suggested from a comparison of the barriers to methyl rotation in propane (3.4 kcal/mol)(21) and 2,2-difluoropropane (3.4–3.8 kcal/mol)(22). Electrostatic interactions would be manifested through increased dipole–dipole repulsion resulting from a decrease in the F—C—F angle accompanying a widening of the C_4—C_5—C_6 angle in reaching the rate determining transition state. An analogous repulsion has been considered as a possible reason for the much greater stability of 7,7-dicyanonorcaradiene over its cycloheptatriene form (~17 kcal/mol) (23).

The calculations by Favini *et al.* (7) indicate that the C-5 angle is about the same in **4** and **8** while torsional energy is lower and nonbonded energy is larger for **8**. If **8** were the transition state for ring inversion the larger $\Delta F^{\ddagger}$ for **1** would necessarily be due to a steric destabilization of this conformation. However an examination of Fieser models show that the only serious nonbonded interaction is between the interior C-4 and -7 protons, the H—F distances not being significantly shortened. It therefore appears that the fluorine atoms at C-5 would not raise the energy of conformation **8** appreciably over that expected for the parent compound. But since the nonbonded potential function for H—F

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

interaction is not available, we cannot be absolutely sure.

Profile A, with **7** as the rate determining transition state is better able to rationalize the 2.4 kcal/mol increase in energy for the inversion of **1** over **3**. The "flipping" of C-5 to reach **7** causes a slight (if any) increase in torsional energy and an increase in F—F repulsion because of the increase in the C_4—C_5—C_6 angle during this transition.

Incorporating the double bond of the cycloheptene ring into a benzene ring as in **2** raises the barrier by about 5.9 kcal/mol (3). The reason for this increase is not quite clear but appears to be related in part to the greater energy required to bend the C_1—C_2—C_3 and C_2—C_1—C_7 angles inward as Fieser models indicate they must to reach the transition state **7**. The origin of this effect is not obvious but is thought to depend in part on the magnitude of these angles in the chair conformation of both types of molecule. These angles are not known for these seven-membered rings but the values of 127° determined for naphthalene tetrachloride by X-ray analysis (24) and of 123.5° obtained for cyclohexene (25) from electron diffraction and microwave spectroscopy suggest that they should be larger in **2** than in **3**. (It is to be noted here that the 120° angles used by Favini *et al.* (7) are probably too small.) The larger deformation associated with the bending of bonds in **2** might account for part of the difference. Another contributing factor might be associated with differing facility for in-plane bending of the C_2—C_3 and C_1—C_7 bonds without introducing appreciable non-planarity into the C_3—C_2—C_1—C_7 part of the molecule (out-of-plane bending). Thus the constraint imposed by the aromatic ring is believed to increase the energy requirement of the in-plane distortions required to reach conformation **7**.

It is therefore reasonable that profile A is correct. The value to be chosen as the transmission coefficient in the Eyring equation for the calculation of $\Delta F^{\ddagger}$ depends on the inversion pathway (16–18, 26). The presence of the metastable intermediates (**5** and **6**) suggests that its value should be one-half to allow for the possibility that a molecule having once overcome the barrier **7** may return back to the initial chair and not go to an inverted chair. The p.m.r. experiment records only the complete inversion of the chair conformation.

Contributions to the entropy of activation ($\Delta S^{\ddagger}$) from differences in vibrational and rotational partition function are expected to be small and positive for ring inversion in similar classes of compounds in inert solvents (1, 16–18, 26) and for cyclohexane, a very accurate $\Delta S^{\ddagger}$ was found to be close to that calculated from symmetry considerations (17). For cycloheptene, the symmetry number (1) and the statistical weight of conformations **4** and **7** are equal since they both belong to the same symmetry group (C_s). The contribution of symmetry to $\Delta S^{\ddagger}$ is therefore $R\ln 1 = 0$ so that $\Delta F^{\ddagger}$ and $\Delta H^{\ddagger}$ are expected to be essentially equal, probably within experimental errors. Such a contention is supported by the determination of $\Delta S^{\ddagger} = -0.2 \pm 2$ e.u. for **1** (2) whose inversion mechanism is undoubtedly the same as that of cycloheptene. The energy difference between **4** and **8** must consequently be less that 5.0 kcal/mol and may turn out to be significantly smaller that the 5.6 kcal/mol calculated by Favini *et al.* (7). Our conclusion is not necessarily contradictory with the qualitative aspect of Favini's calculations. Our results indicate that the energy calculated for **8** is too high and it is highly probable that had the energy of **7** been calculated, its value would have been higher than **8** and qualitatively in accord with curve A. More comprehensive and accurate calculations for the conformations of the maxima and minima (**4** to **8**) of the energy profiles of Fig. 2 seem desirable in order to supply the missing thermodynamic parameters necessary to define completely the energetics of the mechanism of cycloheptene inversion. The results and discussion of this paper provide the necessary check value to lend credibility to such a calculation.

Finally, the results obtained for cycloheptene permit a comparision of the flexibility of the fundamentally important six-, seven-, and eight-membered cycloalkenes. Cyclohexene (18) and cycloheptene have comparable $\Delta F^{\ddagger}$ barriers (5.3 and 5.0 kcal/mol respectively) whereas *cis*-cyclooctene shows two p.m.r. spectral changes at low temperature characterized by $\Delta F^{\ddagger}$ values of 8.2 and 5.8 kcal/mol (27). *trans*-Cyclooctene is rigid on the p.m.r. time scale (28) and its conformation has recently been determined by Manor and co-workers (29).

Experimental

The v.p.c. analyses and separations were carried out on a Varian-Aerograph A90-P3 instrument using ¼ in. columns.

Routine analytical p.m.r. spectra were recorded on a JEOL C-60H spectrometer operating at 60 MHz in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

external lock mode. The variable temperature p.m.r. spectra were recorded on a JEOL JNM-4H-100 spectrometer operating at 100 MHz using a 5% of **3** in a mixture of vinyl chloride and chlorodifluoromethane (85:15, v:v), m.p. −160 °C for both. A small quantity of tetramethylsilane was added and the sample was degassed and sealed. Temperatures were monitored by means of a JEOL temperature control unit model JES-VT-3 and read off a calibration chart obtained with a thermocouple inside a solvent-containing dummy n.m.r. tube. Checks on the accuracy of the calibration curve were made repeatedly and are believed accurate to within ±2 °C. Deuterium decoupling was effected by means of the JEOL Hetero Spin Decoupler model JNM-SD-HC.

2,2,7,7-Tetradeuterio-4-cycloheptenone

4-Cycloheptenone (4) was purified by v.p.c. on carbowax at 170 °C and 0.75 g (0.0068 mol) was added to a solution of 3.0 g of potassium carbonate in 30 ml of deuterium oxide. After 5 h of reflux, the organic material was extracted with ether, dried over magnesium sulfate, and stripped of its ether. The p.m.r. spectrum of the product in deuteriochloroform showed two multiplets at δ 2.43 and 5.95 which integrated for four and two protons respectively, thus indicating essentially complete deuteration next to the carbonyl group.

1,2,2,7,7-Pentadeuterio-4-cycloheptenol

The above deuterated ketone (0.72 g, 0.0062 mol) in 10 ml of anhydrous ether was added to 0.30 g of lithium aluminum deuteride (Fluka ⩾ 99% deuterium) in 10 ml of ether. The mixture was stirred for 1 h at room temperature and then the excess deuteride was decomposed with dilute sulfuric acid. The ether phase was separated, washed with a saturated solution of sodium bicarbonate, water, and dried over magnesium sulfate. The v.p.c. analysis on a silicone fluid, Dow 550 (15%) column at 170 °C indicated that the product, stripped of its ether, was entirely reduced to the alcohol. The p.m.r. spectrum of this compound showed peaks centered at δ 2.12 (multiplet, 4 protons), 2.62 (singlet, one proton), and 5.87 (multiplet, two protons).

4,4,5,6,6-Pentadeuteriocycloheptene (3)

p-Toluenesulfonyl chloride (1.25 g, 0.0065 mol) freshly crystallized from petroleum ether was slowly added to a solution 0.72 g (0.0061 mol) of the above alcohol in 12 ml of dry pyridine. After standing for 48 h at 0 °C, water was added and the solution was extracted three times with 20 ml of ether; the organic phase was then washed successively with 2 *N* hydrochloric acid, a solution of sodium bicarbonate and water. After drying over magnesium sulfate, the ether was evaporated.

The above tosylate (0.200 g, 0.0007 mol) was dissolved in 10 ml of dry tetrahydrofuran (freshly distilled) and this solution was added to a suspension of 0.150 g of lithium aluminum hydride in 10 ml of tetrahydrofuran. After 20 h of reflux, the excess hydride was decomposed with dilute sulfuric acid. Petroleum ether was added; the organic phase was separated and extracted three times with water and then dried over magnesium sulfate and the ether was stripped.

The v.p.c. analysis of the product on carbowax at 80 °C allowed the identification of the peak corresponding to **3** from a comparison with authentic cycloheptene. The deuterated cycloheptene **3** was then collected by v.p.c. on this same column.

The p.m.r. spectrum of this compound in carbon disulfide showed peaks at δ 1.65 (broad singlet, one proton), 2.10 (multiplet, four protons), and 5.70 (multiplet, two protons).

Identically prepared deuterated cycloheptene was used to prepare a sample for the low temperature study.

We are grateful to the National Research Council of Canada for financial assistance and to the Quebec Ministry of Education for a scholarship (France-Québec) to C. V.

The Effect of Sulfurhexafluoride on the Photochemistry of Aqueous Solutions[1]

R. C. RUMFELDT
Department of Chemistry, University of Windsor, Windsor, Ontario

Received July 6, 1970

The effect of SF_6 as a specific scavenger for e_{aq}^- in the photolysis of aqueous solutions has been studied. The photolysis of aqueous solutions of I^- with 2537 Å light and Br^-, Cl^-, and SCN^- with 1849 Å light containing $[SF_6] = 1.4 \times 10^{-3}$ *M* results in the formation of F^-, the yields of which are $\phi(F^-) = 1.38 \pm 0.05$, 1.98 ± 0.05, 2.40 ± 0.08, and 2.07 ± 0.05, respectively. By comparison with $\phi(N_2)$ from N_2O saturated solutions the relationship $\phi(e_{aq}^-) = \phi(F^-/6)$ was confirmed. Assuming the same ratio, $\phi(e_{aq}^-)$ for pure H_2O and aqueous HPO_4^{2-} with 1849 Å radiation and $[SF_6] = 2.4 \times 10^{-4}$ is 0.013 ± 0.002 and 0.30 ± 0.07, but these are considered minimum values due to the low concentration of SF_6. Despite these yields HPO_4^{2-} could be used as buffer in 1849 Å photolysis due to its low extinction at this wavelength.

On a étudié l'effet de SF_6 comme intercepteur spécifique des e_{aq}^- lors de la photolyse de solutions aqueuses. La photolyse de solutions aqueuses (contenant $[SF_6] = 1.4 \times 10^{-3}$ *M*) de I^- à 2537 Å et de Br^-, Cl^-, SCN^- à 1849 Å conduit à la formation de F^- avec des rendements respectifs de $\phi(F^-) = 1.38 \pm 0.05$, 1.98 ± 0.05, 2.40 ± 0.08 et 2.07 ± 0.05. Par comparaison avec les $\phi(N_2)$ mesurés à l'aide de solutions saturées de N_2O, on a pu confirmer que $\phi(e_{aq}^-) = \phi(F^-/6)$. En faisant l'hypothèse que ce rapport reste le même, les valeurs respectives de (e_{aq}^-) pour l'eau pure et HPO_4^{2-} aqueux à 1849 Å et $[SF_6] = 2.4 \times 10^{-4}$ sont de 0.013 ± 0.002 et 0.30 ± 0.07. En dépit de ces rendements, HPO_4^{2-} pourrait être utilisé comme tampon pour des photolyses à 1849 Å à cause de son faible coefficient d'extension à cette longueur d'onde.

Canadian Journal of Chemistry, 49, 1262 (1971)

Introduction

The irradiation of aqueous solutions of a variety of anions with light of short wavelength has been shown to produce solvated electrons (e_{aq}^-) as a primary product (1–3). Although flash photolysis (4, 5) has been used to identify e_{aq}^-, the principal technique in its quantitative measure has been the use of N_2O as a scavenger in the reaction

$$[1] \quad e_{aq}^- + N_2O \rightarrow N_2 + O^-(+H_2O \rightleftharpoons OH + OH^-)$$

From reaction 1 it is easily seen that $\phi(N_2)$ should give a quantitative measure of $\phi(e_{aq}^-)$, provided that there are no competing solutes or N_2 producing reactions.

When the photolyzing light is of wavelength 1849 Å, a direct photodissociation of N_2O can occur

$$[2] \quad N_2O + h\nu\,(1849\ Å) \rightarrow N_2 + O$$

with the result that a distinction must be made between N_2 formed via reactions 1 and 2.

The molecule SF_6 is also known to react rapidly with e_{aq}^- (6) with the proposed stoichiometry being

$$[3] \quad e_{aq}^- + SF_6 \rightarrow SO_4^{2-} + 6F^- + 8H^+$$

Since otherwise SF_6 is assumed to be extremely inert, reaction 3 represents a useful alternate to the use of N_2O as a specific scavenger of e_{aq}^-. Furthermore, it was found that SF_6 does not have any strong absorption bands in the region of 1849 Å. Thus, SF_6 should not undergo direct photodissociation at 1849 Å and any F^- formed would be the result of scavenging such as in reaction 3.

The potential of SF_6 as a specific scavenger in the quantitative measure of e_{aq}^- depends on the assumptions that e_{aq}^- is the only precursor to F^- and that the ratio 1:6 between e_{aq}^- and F^- given in reaction 3 is valid. It is the purpose of this investigation to examine these assumptions as well as to test the utility of SF_6 as an electron scavenger in photochemical systems.

The quantum yields of e_{aq}^- from the photolysis of I^-, Br^-, and Cl^- have previously been measured (1, 2) and provide a useful series with which to test SF_6. The pseudohalides, CN^- and SCN^-, have also been included to provide a broader range of conjugate radicals. While SF_6 does not react even with hydrogen atoms (6) (suggesting that its reactions are kinetically controlled), the possibility existed that the pseudohalogens through their antibonding π-orbitals might react with SF_6. Although there was no evidence of such reactions, some interesting effects were observed with the SCN^- system.

Experimental

Materials

The solutions were prepared with water which had been distilled from acid dichromate in a stream of oxygen over a hot platinum filament, condensed and redistilled from alkaline permanganate, and maintained under constant reflux over alkaline permanganate.

The salts KCl, KBr, KI, KCN, KSCN, and $Na_2HPO_4 \cdot 12H_2O$ were reagent grade and were used without further purification. The gases N_2O and SF_6 (The Matheson Company) were purified by repeated trap-to-trap distillations, stored in the vacuum system, and redistilled several times just prior to use.

Apparatus and Procedures

The standard photolysis vessel consisted of a cylindrical quartz cell 20 mm in depth to which was attached a 100 ml degassing bulb and a 10 mm pathlength spectrophotometer cell. The solutions were pipetted into the vessel through a side arm to which a stopcock could be joined for connecting to the vacuum system. After thorough deaeration, the solutions were equilibrated with the desired partial pressure of SF_6 or N_2O. Since the pressure of the additive gases was measured with a mercury manometer, the solutions were protected from contamination by mercury vapor by placing a trap (CO_2–acetone with N_2O and ice-salt slurry with SF_6) between the manometer and the reaction vessel.

Since SF_6 is only slightly soluble in H_2O (7), relatively high partial pressures were required to obtain millimolar concentrations and a high pressure cell was used for these experiments. This cell consisted of a heavy walled Pyrex cup and sidearm which were enclosed in a brass jacket. A quartz window was sealed on to the top of the cup by an O-ring and held tightly in place by a threaded metal cap which screwed over the window on to the brass jacket. A stopcock with a threaded Teflon tap was attached to the sidearm to close the system. This cell could withstand at least 15 atm internal pressure without leaking. The gas to be added to the cell was first measured in a calibrated bulb then distilled into the reaction vessel and the concentration of the gas in solution calculated from the solubility of SF_6 and the PV data with due corrections made for the volume of solution.

The photochemical lamp was a model PCQ011S low pressure mercury grid lamp (Ultra-Violet Products, Inc., San Gabriel, California). For irradiations with the 2537 Å line, the cells were immersed in a constant temperature water bath (25 ± 0.5 °C) with the radiation passing through a quartz window. When the desired line was 1849 Å, the cell was first brought to 25 °C in the bath, dried, and irradiated. Due to the brevity of the irradiation times and the proximity of the ambient temperature to 25 °C, the temperature of the solution under these conditions was assumed to be 25 ± 2 °C. Both cells contained magnetic stirring bars and all solutions were vigorously stirred during irradiation.

The intensity of the 2537 Å line was determined using the ferrioxalate actinometer (8), first with a water filter then replacing it with a degassed aqueous KI filter and measuring the difference. The approximate intensity was 4×10^{-4} einstein l^{-1} min^{-1}, the exact value depending on the particular cell and conditions employed. A deaerated solution of N_2O was used as the actinometer for the 1849 Å line. Following the work of Dainton and Fowles (9), the primary quantum yield of N_2 ($\phi_{N_2}{}^0$) was assumed to be unity and was related to the measured yield ($\phi(N_2)$) by the relationship

$$\phi(N_2) = \phi_{N_2}{}^0 \frac{\varepsilon_{N_2O}[N_2O]}{\varepsilon_{N_2O}[N_2O] + \Sigma_{H_2O}}$$

where $\varepsilon_{N_2O} = 60\ M^{-1}\ cm^{-1}$ and $\Sigma_{H_2O} = 1.8\ cm^{-1}$. The approximate intensity of the 1849 Å was 1.3×10^{-5} einstein l^{-1} min^{-1}.

Gaseous products were analyzed by removal from the reaction cell by successive freeze–pump–thaw cycles and injection into a Varian model 1521-B gas chromatograph employing a molecular sieve 13X column.

Fluoride and cyanide were measured by means of Orion specific ion electrodes with an Orion model 801 meter. The calibration curves were obtained using standardized solutions in reagent blanks. In the case of CN^- the solutions were made 0.1 N in NaOH to prevent hydrolysis. Due to the low yields sulfate was only measured qualitatively using the $BaSO_4$ turbidity technique.

Spectra were obtained using a Beckman DK-1A Far U.V. recording spectrophotometer. At wavelengths below 2000 Å the monochromator and cell compartment were vigorously purged with high purity N_2 to eliminate light absorption by atmospheric gases. Cells with a pathlength of 0.028 or 0.0074 cm were used in the region 2000 to 1700 Å to reduce absorption by the solvents H_2O and D_2O, thereby minimizing the slitwidth and the effects of scattered light. Using the 0.028 cm pathlength cell the slitwidth could be maintained at less than 0.1 mm to 1800 Å after which it increased to 0.5 mm at 1750 Å with a maximum value of 1.0 mm at the 1700 Å cutoff. Essentially the same values were obtained using the 0.0074 cm cell; however, the 0.028 cm cell was used preferentially as it provided greater ease in handling.

Results

(a) KI–SF_6 with 2537 Å Radiation

The only products on irradiation with 2537 Å light of solutions containing $[KI] = 5 \times 10^{-3}\ M$ and $[SF_6]$ in the range 1×10^{-4} to $1.4 \times 10^{-3}\ M$ were F^-, H^+, and $SO_4{}^{2-}$ with no $I_2(I_3{}^-)$ being formed. Beyond a yield of $[F^-] = 1 \times 10^{-4}\ M$, the F^- yields showed a nearly continuous curvature with irradiation time. While buffering the solution after irradiation caused an increase in the F^- yield, buffering with $10^{-3}\ M$ Na_2HPO_4 prior to irradiation resulted in even higher F^- yields which were now linear with irradiation time (Fig. 1). The variation of $\phi(F^-/6)$ from the buffered solutions with $[SF_6]$ is shown in Fig. 2 with the maximum value being $\phi(F^-) = 1.38 \pm 0.05$. Whereas $SO_4{}^{2-}$ was detected it could not be determined quantitatively due to the low concentration.

(b) Irradiation with 1849 Å Light

The spectra of $2.4 \times 10^{-4}\ M$ aqueous SF_6 showed no absorption bands in the region 3000 to

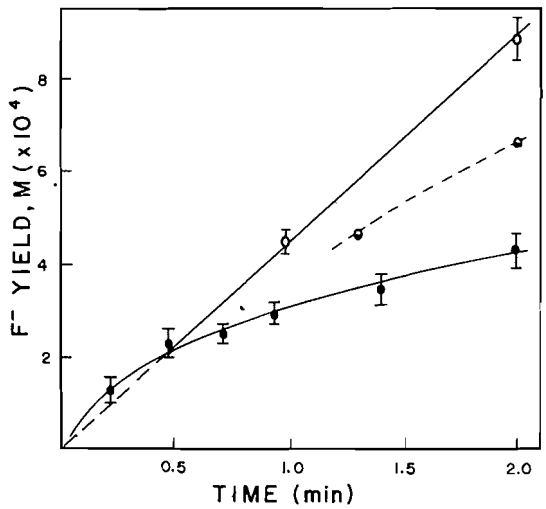

FIG. 1. The dependence of F^- yield on the time of irradiation with 2537 Å light of intensity 4.25×10^{-4} einstein l^{-1} min^{-1} for solutions containing [KI] = 5×10^{-3} M and [SF_6] = 2.4×10^{-4} M; ● unbuffered solutions, ◒ post-irradiation buffering, and ○ pre-irradiation buffering.

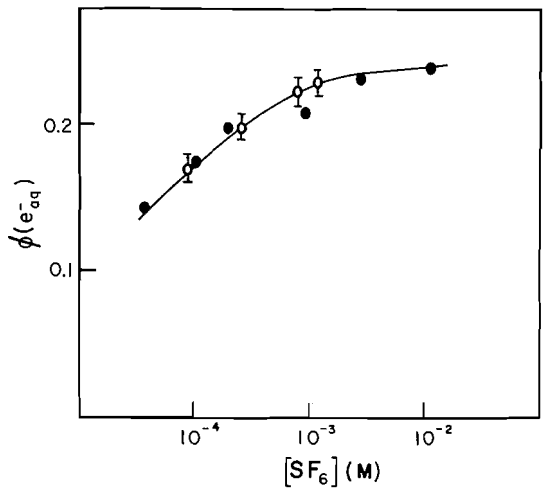

FIG. 2. The variation of $\phi(e_{aq}^-)$ with SF_6 concentration: ○, $\phi(e_{aq}^-) = \phi(F^-/6)$ using buffered solutions; ●, $\phi(e_{aq}^-) = \phi(N_2)$ where $[SF_6] = k_2/k_3[N_2O]$ to account for the difference in scavenging efficiencies and using $k_2/k_3 = 0.57$ (6).

1700 Å. Although irradiation with 2537 Å light of aqueous SF_6 produced no F^-, using the 1849 Å line caused the formation of a low yield of F^- corresponding to $\phi(F^-) = 0.08 \pm 0.01$. No other products could be detected. Since SF_6 is transparent to 1849 Å light, the F^- must arise by the reactions of SF_6 with a product of the photolysis of the solvent H_2O, presumably e_{aq}^- for which $0.2 < \phi(e_{aq}^-) < 0.4$ for pure H_2O has been reported (10).

When salt solutions are illuminated with 1849 Å light only a fraction of the incident light is absorbed by the anion with the remainder being absorbed by the solvent water. Therefore, eq. 1 has been used to calculate the quantum yields due to the photolysis of the solute anions.

$$[4] \qquad \phi'(A) = \phi(A)\frac{\varepsilon_S[S]}{\varepsilon_S[S] + \Sigma_{H_2O}}$$

$\phi'(A)$ is the yield based on the total light intensity, $\phi(A)$ is the yield if all the light had been absorbed by the solute (S), ε_S is the extinction coefficient of the solute, and $\varepsilon_S[S]/(\varepsilon_S[S] + \Sigma_{H_2O})$ gives the fraction of the total light intensity absorbed by the solute. Unless otherwise indicated, all the quantum yields have been calculated this way. The values of ε_S employed are given in Table 1. It can be seen that with the salt concentrations employed, the F^- yield resulting from photolysis of H_2O would be reduced to the magnitude of the experimental error and thus can be neglected.

(i) Buffered and Unbuffered KCl and KBr Solutions

In order to employ HPO_4^{2-} as a buffer in the photolysis of Cl^- and Br^-, it was necessary to establish the absence of a significant inner filter effect by the HPO_4^{2-}. Furthermore photolysis of HPO_4^{2-} by wavelengths shorter than 2000 Å has been shown to produce e_{aq}^- (13), however, $\phi(e_{aq}^-)$ is uncertain since the value appears to differ depending on the choice of scavenger (14).

The spectrum of aqueous Na_2HPO_4 was recorded over the region 3000 to 1700 Å and when plotted as a function of frequency showed a single weak asymmetric band with $\lambda_{max} = 1830$ Å for which $\varepsilon = 575 \pm 50$ M^{-1} cm^{-1}. At the

$[SF_6] = 2.4 \times 10^{-4}\ M$	2.0 ± 0.2	1.26 ± 0.05	—
$[SF_6] = 1.4 \times 10^{-3}\ M$	—	2.07 ± 0.05	—

*Quantum yields have been calculated from linear yield *vs.* time plots.

photolyzing wavelength $\lambda = 1849$ Å, $\varepsilon = 500 \pm 50\ M^{-1}\ cm^{-1}$ and at $\lambda = 2537$ Å there was no appreciable absorption; these values being in good agreement with previously published data (15). Thus, at $10^{-3}\ M$ the HPO_4^{2-} would contribute only 0.5 OD units per cm of solution suggesting its feasibility as a buffer in 1849 Å photolyses.

Irradiation of solutions containing only $[HPO_4^{2-}] = 10^{-3}\ M$ and $[SF_6] = 2.4 \times 10^{-4}\ M$ results in a total yield of F^- corresponding to $\phi(F^-) = 0.45 \pm 0.09$, of which 0.06 units would be due to H_2O photolysis. Applying the light fraction correction to the residue, $\phi(F^-) = 1.8 \pm 0.4$ would be the value associated with the photolysis of HPO_4^{2-}. As is discussed later, further corrections should be made before this value can be related to any primary process. In any event, in the presence of $5 \times 10^{-3}\ M$ Cl^- or Br^-, the HPO_4^{2-} would absorb only 2.3 and 0.74% respectively of the incidental light, thus reducing the F^- yield from HPO_4^{2-} below the level of the experimental error. For these solutions when $[SF_6] = 2.4 \times 10^{-4}\ M$, $\phi(F^-) = 1.30 \pm 0.2$ for Cl^- and $\phi(F^-) = 1.0 \pm 0.1$ for Br^-. The relatively large error arises from the poor electrode response under these conditions. As an alternate, the same systems were repeated without the buffer and the irradiation times maintained sufficiently short so that $[F^-]$ did not exceed $5 \times 10^{-5}\ M$. Good linear yield–time plots were obtained from which $\phi(F^-) = 1.34 \pm 0.05$ and 2.40 ± 0.08 for Cl^- at $[SF_6] = 2.4 \times 10^{-4}$ and $1.4 \times 10^{-3}\ M$, respectively. For Br^- solutions where $[SF_6] = 2.4 \times 10^{-4}$ and $1.4 \times 10^{-3}\ M$, $\phi(F^-) = 1.1 \pm 0.05$ and 1.98 ± 0.05, respectively.

(ii) KCN

Due to hydrolysis, aqueous solutions of KCN are quite alkaline and it is essential to use a reagent blank in the F^- calibration curve since OH^- interferes with the F^- measurement. The F^- yields for $[CN^-] = 2 \times 10^{-2}\ M$ and $[SF_6] = 2.4 \times 10^{-4}\ M$ are linear with time. After correcting the yields for the anticipated contribution by photolysis of OH^-, the yield associated with photolysis of CN^- corresponds to $\phi(F^-) = 0.50 \pm 0.05$ where the error limit here refers only to the reproducibility.

(iii) KSCN

Irradiation of $[SCN^-] = 5 \times 10^{-3}\ M$ either deaerated, air saturated or with the solutes N_2O or SF_6 results in the formation of sulfur and CN^- with $\phi(CN^-)$ being independent of the total integrated absorbed intensity up to 2.5×10^{-4} einstein/l. The yield data are summarized in Table 2. Since some oxides of sulfur are known to interfere with CN^- determinations, some of the SF_6–SCN^- photolyte was mixed with a standardized CN^- solution with no deviation from the calibration curve being observed.

Discussion

The published values (1, 2) of $\phi(e_{aq}^-)$ for Cl^- and Br^- at 1849 Å and I^- at 2537 Å systems are 0.43, 0.34, and 0.23, respectively. Comparing these values with the F^- yield for the same systems using $[SF_6] = 1.4 \times 10^{-3}\ M$ it can be seen that $\phi(F^-/6) = \phi(e_{aq}^-)$.

While the rate constant for the reaction of e_{aq}^- with SF_6 has been measured (6), neither the exact reaction nor reaction sequence leading to the formation of $6F^-$ and SO_4^{2-} have been established. However, a parallel mechanism to that proposed for the γ-radiolysis of SF_6 solutions is given below

$$[5] \qquad X_{aq}^- + h\nu \rightarrow X + e_{aq}^-$$

$$[6] \qquad e_{aq}^- + SF_6 \rightarrow SF_6^- \rightarrow SF_5\cdot + F^-$$

$$[7] \qquad SF_5\cdot + X^- \rightarrow SF_4 + F^- + X$$

$$[8] \qquad SF_4 + H_2O \rightarrow SOF_2 + 2F^- + 2H^+$$

$$[9] \qquad SOF_2 + X_3^- + 3H_2O \rightarrow SO_4^{2-} + 2F^- + 3X^- + 6H^+$$

or alternately to reaction 8

[10] $SOF_2 + 2H_2O \rightarrow SO_3^{2-} + 2F^- + 4H^+$

[11] $SO_3^{2-} + X_3^- + H_2O \rightarrow SO_4^{2-} + 3X^- + 2H^+$

An important product of these reactions is H^+ since it will compete with SF_6 for e_{aq}^- to form H-atoms which do not react with SF_6. Likewise, H^+ reacts with F^- to form the weak acid HF to which the specific ion electrode is insensitive, thus further reducing the yield of F^-. The combination of these effects accounts for the pronounced curvature of the F^- yields and, while the latter effect is offset by post-irradiation buffering, both effects are suppressed by photolyzing buffered solutions.

Reaction 8 is stoichiometrically equivalent to reactions 9 and 10 and for the halide systems no distinction can be made. For other systems which may lack a sufficiently strong oxidizing agent reaction 9 may replace reaction 8 for which $\phi(e_{aq}^-) = \phi(F^-/6) = \phi(X_3^-)$. It is also possible since reaction 9 is reported to be slow (16) that the reaction sequence may terminate at reaction 7 for which $\phi(e_{aq}^-) = \phi(F^-/4) = \phi(X_3^-)$; however, there is no evidence for such a case either in the systems reported here or those studied by radiation chemistry (6).

In the HPO_4^{2-}, CN^-, or pure H_2O systems where a SO_4^{2-} yield could not be established, the relationship $\phi(e_{aq}^-) = \phi(F^-/6)$ is speculative. Furthermore, because of the relatively low concentrations of SF_6 used, these yields would not be expected to represent more than 60 to 70% of the scavengable yield of e_{aq}^- (17). Although the HPO_4^{2-} system was examined primarily to determine its suitability as a buffer in the 1849 Å photolysis of Cl^- and Br^-, applying the rough correction suggested above leads to a value of $\phi(e_{aq}^-)$ for HPO_4^{2-} of between 0.4 and 0.5. This value clearly supports the yield $\phi(e_{aq}^-) = 0.506$ reported by Halmann and Platzner (14) using N_2O rather than the lower yield of 0.14 determined by the same authors using CH_3OH.

For the SCN^- systems, although SO_4^{2-} could not be determined, since $\phi(F^-/6) = 0.35 \pm 0.02$ for $[SF_6] = 1.4 \times 10^{-3}$ and $\phi(N_2) = 0.33 \pm 0.02$ for $[N_2O] = 2.0 \times 10^{-2}$, the relationship $\phi(F^-/6) = \phi(e_{aq}^-)$ appears valid.

A corollary to the establishment of $\phi(e_{aq}^-) = \phi(F^-/6)$ is the exclusion of any reactions between SF_6 and the various radicals produced in these systems. This supports the conclusion that SF_6 is a specific scavenger of e_{aq}^-.

The formation of e_{aq}^- has been observed in the flash photolysis of SCN^- (4, 5) and the coincidence in $\phi(e_{aq}^-)$ for Br^- and SCN^- might seem consistent with the similarities in their absorption spectra. On the other hand, from a detailed study of the spectral region from 2750 to 2000 Å, Gusarsky and Treinin (18) assigned the absorption band at 2200 Å as CTTS and were supported in their assignment by the reported formation of e_{aq}^- on irradiation with 2288 Å light (19); however, the yield was very small ($\phi(e_{aq}^-) = 0.05$). While this seems to present a disagreement with the results observed here, it can be seen from Fig. 3 that the 2200 Å band does not appear to extend to 1849 Å nor does the broad asymmetric high frequency band extend to 2288 Å. Thus, the apparent discrepancy may only be the result of producing two different excited states by the two different exciting wavelengths. If in fact this is the case, then the apparent wavelength dependence of the yield of e_{aq}^- would not seem unreasonable.

In any event, if intersystem crossing is neglected, only the high frequency part of the SCN^- spectrum will contribute significantly to the absorption of the 1849 Å radiation. The asymmetry of the band suggests that more than one electronic transition is contained within this absorption band and the resultant excited states could then correlate with the photochemical processes

[12a] $SCN^- + h\nu\,(1849)\,Å \rightarrow S + CN^-$

[12b] $SCN^- + h\nu\,(1849)\,Å \rightarrow SCN\cdot + e_{aq}^-$

These reactions which have also been proposed (5) in the flash photolysis of SCN^- suggest a modification to eq. 1 since in effect reaction 12*a* is competing with 12*b* for the incident radiation via an intramolecular inner filter effect. Thus, the true quantum efficiency ($\phi^0(e_{aq}^-)$) would be given by

$$[13]\quad \phi(e_{aq}^-) = \phi^0(e_{aq}^-)\frac{\varepsilon'[SCN^-]}{\varepsilon_{SCN^-}[SCN^-] + \Sigma_{H_2O}}$$

where ε' is the extinction coefficient at 1849 Å of the absorption band leading to the excited state involved in reaction 12*b*. Consequently, $\phi^0(e_{aq}^-)$ may be substantially larger than the mean observed value of $\phi(e_{aq}^-) = 0.34$. Similar conclusions would also apply to the CN^- system and, in general, should be considered before interpreting $\phi(e_{aq}^-)$ for complex ions.

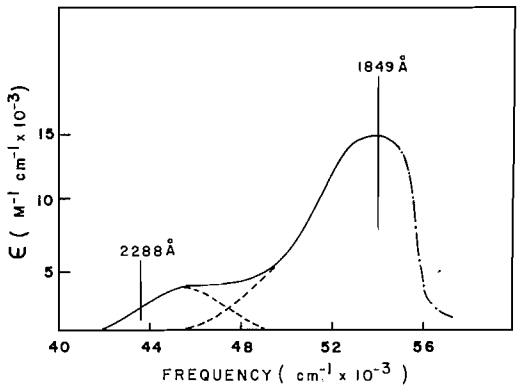

FIG. 3. The spectrum of KSCN in H_2O. The solid line represents the observed spectrum (mean of eight), the broken line (–·–) indicates the region of poor resolution due to increasing slit width and the dashed lines were calculated assuming a Gaussian shape for the band at 45 500 cm^{-1}.

The same considerations when applied to $\phi(CN^-)$ requires that reaction 12*a* cannot be the only source of CN^- and that the SCN produced must also lead to CN^-. This is supported by the difference in $\phi(CN^-)$ between the deaerated and N_2O system where the increase in $\phi(CN^-)$ is equal to $\phi(N_2)$. The use of N_2O in both the pulse radiolysis (20) and flash photolysis (5) of SCN^- solutions causes an increase in the species $(SCN)_2^-$.

[1] $e_{aq}^- + N_2O \rightarrow N_2 + O^- (+H_2O \rightleftharpoons OH + OH^-)$

[14] $OH + SCN^- \rightarrow OH^- + SCN$

[15] $SCN\cdot + SCN^- \rightarrow (SCN)_2^-$

The decay of the species $(SCN)_2^-$ in N_2O saturated systems is reported to be first order in the flash photolysis system whereas it is second order by pulse radiolysis. While the discrepancy between the two systems cannot presently be explained, CN^- could be the decay product in the first case by

[16] $2H_2O + (SCN)_2^- \rightarrow SCN^- + SO_2 + CN^- + 4H^+$

and in the second case by

[17] $(SCN)_2^- + (SCN)_2^- \rightarrow (SCN)_2 + 2SCN^-$

[18] $(SCN)_2 + 4H_2O \rightarrow 2SO_2 + 2CN^- + 8H^+$

In addition, Dogliotti and Hayon (5) have also proposed the reaction

[19] $S + SCN^- \rightarrow S_2 + CN^-$

The speculative nature of these reactions does not encourage a detailed interpretation of $\phi(CN^-)$. In particular, the anomalously high value for $\phi(CN^-)$ in the SF_6 system suggests the possibility that a more complex mechanism may be operative and further experimental data is required to resolve these problems.

The author wishes to acknowledge the assistance of Mr. R. K. Singal in performing the high pressure experiments and to Mr. J. L. Batiste for his assistance in resolving the SCN^- spectra.

Collisional Deactivation Rates of $N_2^+(B^2\Sigma_u^+)$

G. I. MACKAY AND R. E. MARCH
Department of Chemistry, Trent University, Peterborough, Ontario

Received September 24, 1970

Electron beam excitation of nitrogen was utilized to produce ions in the zeroth and first vibrational levels of the $B^2\Sigma_u^+$ state. The rate constants for the collisional deactivation of electronically excited N_2^+, for each of N_2 and NO, were determined individually for the $v' = 0$ and $v' = 1$ vibrational levels of the $N_2^+(B^2\Sigma_u^+)$ state. Charge transfer is the most probable mode of deactivation.

L'excitation de l'azote par un faisceau d'électrons a été utilisé pour produire des ions de niveau vibrationnels zéro et un de l'état $B^2\Sigma_u^+$. Pour N_2 ainsi que NO, les constantes de vitesse de désactivation par collision de N_2^+ excité électroniquement, ont été déterminées individuellement pour les niveaux vibrationnels $v' = 0$ et $v' = 1$ de l'état $N_2^+(B^2\Sigma_u^+)$. Le transfert de charge est le mode le plus probable de désactivation.

Canadian Journal of Chemistry, 49, 1268 (1971)

Measurements of a large number of ion–molecule reactions have been reported by Ferguson *et al.* (1) in recent years. While their experiments involved ground state ions exclusively some work has been reported (2) in which the reacting molecule may be excited. In this work we report the rate constants at room temperature for the collisional deactivation process (in which charge-transfer is energetically favored)

$$[1] \qquad NO + N_2^+(B^2\Sigma_u^+) \rightarrow NO^+ + N_2 \qquad k_1$$

where the nitrogen ion is electronically excited and is in either the ground vibrational level or in the first excited vibrational level. No attempt was made to ascertain the identities of the products.

Experimental[1]

A differentially-pumped beam of electrons, accelerated to 20 keV through an orifice 0.022 in. in diameter, was directed into a known mixture of nitrogen and nitric oxide in a flow system, perpendicular to the direction of flow. The beam current was maintained at a constant value of approximately 1 mA; fluctuations greater than $\pm 1\%$ could not be detected with the Keithley 601 electrometer once a reliable filament had been installed. The flow rate of each component was determined from the decrease in pressure of a known volume of gas; a calibrated McLeod gauge was used for the total pressure. An image of the slit of the spectrometer at a magnification of unity was formed at the axis of the beam using a combination of lens and front surfaced mirror. Direct observation of the first negative system (1N) of nitrogen in the beam was made with a SPEX 1700-II Czerny-Turner spectrometer. The spectrometer was equipped with a 100 mm × 100 mm grating (1200 lines/mm) blazed at 3000 Å. The spectrum was scanned in the first order with a Servo-Tek wavelength scanning control. The spectrometer, associated external optics, chopper, and detector were mounted on a movable platform which was operated by a 1 mm pitch screw to facilitate alignment with the central core of the beam. The beam diameter was 0.15 cm. The signal was detected with an EMI 6256S photomultiplier tube and amplified by an Ortec 486 Amplifier-Pulse Height Analyzer coupled with an Ortec 441 Linear Ratemeter. The output was recorded on a Leeds and Northrup Speedomax W Azar Recorder. The signal intensity was taken as the integrated area of an entire vibrational band.

[1]A complete description of the apparatus is given in the M.Sc. thesis of G. I. Mackay (11).

Results and Discussion

Electronically excited N_2^+, in the $B^2\Sigma_u^+$ state which lies some 3.1 eV above that of the ground state molecular ion, is produced by electron impact;

$$[2] \qquad N_2 + e^- \rightarrow N_2^+(B) + 2e^- \qquad k_2$$

where k_2 is an effective rate constant for the formation of $N_2^+(B)$ ions in a particular vibrational level, v'. The effects of secondary electron excitation are small at the pressures used here and are minimized by the optical arrangement in which the fluorescent beam is brought to a focus parallel to the spectrometer entrance slit rather than perpendicular to it. Removal of excited molecular ions may be effected by

(*i*) spontaneous emission of radiation (1N) which results in the production of nitrogen ions in the $X^2\Sigma_g^+$ state.

$$[3] \qquad N_2^+(B) \rightarrow N_2^+(X) + h\nu\,(1N) \qquad k_3$$

Bennett and Dalby (3) have measured the mean lifetime corresponding to the (0,0) band at 3914 Å as $6.53 \pm 0.22 \times 10^{-8}$ s. The rotational temperature of the 3914 Å band was 298 °K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(*ii*) de-excitation by ground state nitrogen molecules, presumably through a charge transfer process

[4] $N_2^+(B) + N_2 \rightarrow N_2^+(X) + N_2 \quad k_4$

and

(*iii*) de-excitation by nitric oxide molecules, again presumably through a charge transfer process

[1] $N_2^+(B) + NO \rightarrow NO^+ + N_2 \quad k_1$

It was anticipated that k_1 would not differ considerably from the rate constant involving ground state ions (4).

[5] $N_2^+(X) + NO \rightarrow NO^+ + N_2 \quad k_5$

where $k_5 = 30(+6, -18) \times 10^{10}\ l\ s^{-1}$

In pure nitrogen, the steady state equation for the intensity of any given vibrational band of the 1N system, $I_{v',v''}$ is of the form

$$[6] \qquad \frac{1}{I_{v',v''}} = \frac{1}{k_2 i[N_2]} + \frac{k_4}{k_2 k_3 i}$$

where i is the electron beam current. Thus a plot of $1/I_{v',v''}$ *vs.* $1/[N_2]$, such as is shown in Fig. 1 (curve *a*), should yield a straight line of slope, $S_{N_2} = 1/k_2 i$ and intercept, $i_{N_2} = k_4/k_2 k_3 i$.

In the presence of nitric oxide, reaction 1 must be taken into account and thus

$$[7] \qquad I_{v',v''} = \frac{k_2 k_3 i[N_2]}{k_3 + k_4[N_2] + k_1[NO]}$$

When the total concentration of nitrogen and nitric oxide is kept constant, *i.e.*

$$[8] \qquad [N_2] + [NO] = C$$

eq. 7 may be re-arranged to yield

$$[9] \qquad \frac{1}{I_{v'v''}} = \frac{k_4 - k_1}{k_2 k_3 i} + \frac{k_3 + k_1 C}{k_2 k_3 i[N_2]}$$

A plot of $1/I_{v',v''}$ *vs.* $1/[N_2]$ at constant total pressure of mixtures of nitrogen and nitric oxide yields a straight line of slope, $S_{NO} = (k_3 + k_1 C)/k_2 k_3 i$ and intercept, $i_{NO} = (k_4 - k_1)/k_2 k_3 i$. It is readily seen that

$$[10] \qquad k_1 = \frac{k_3}{C}\left(\frac{S_{NO}}{S_{N_2}} - 1\right)$$

and k_1 was determined for a number of values of C. The rate constant for any given vibrational state of $N_2^+(B)$ in reaction 1 can be determined from observation of the emission from that given state. Thus reaction 1 can be expanded to include individual vibrational levels

$[1,v'=0]$ $N_2^+(B)_{v'=0} + NO \rightarrow NO^+ + N_2$

$[1,v'=1]$ $N_2^+(B)_{v'=1} + NO \rightarrow NO^+ + N_2$

etc.

In practice, it was possible to observe only the (0,0), (1,0), and (1,2) vibrational bands due to interference from the second positive (2P) system of nitrogen, and other minor background features excited by the electron beam.

In Figs. 1 and 2 are shown the linear relationship between $1/I_{v'v''}$ and reciprocal nitrogen

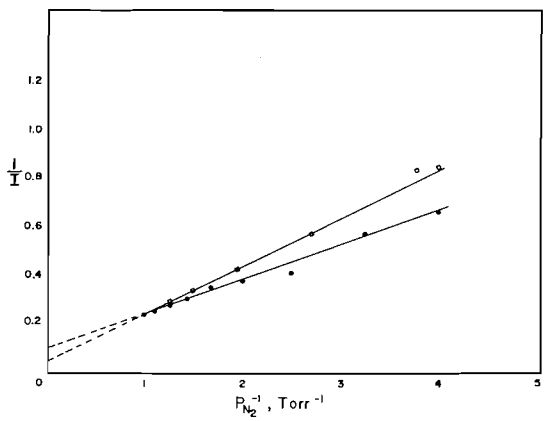

FIG. 1. Plot of the reciprocal intensity (arbitrary units) of the (0,0) band of the N_2 1N system *vs.* reciprocal nitrogen pressure, (*a*)●, pure nitrogen; (*b*) NO added, ○, $C = 1$ Torr; (*c*) NO added, ◇, $C = 0.9$ Torr; (*d*) NO added, △, $C = 0.8$ Torr.

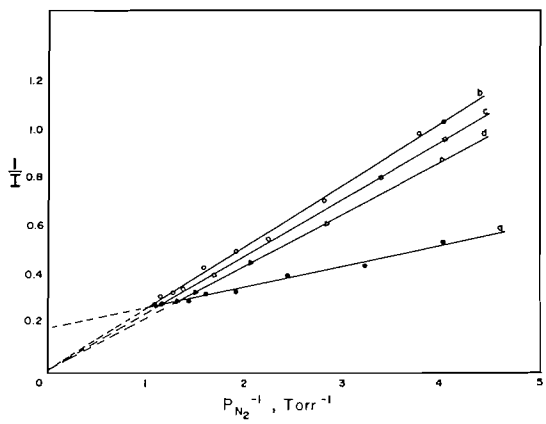

FIG. 2. Plot of the reciprocal intensity (arbitrary units) of the (1,0) band of the N_2 1N system *vs.* reciprocal nitrogen pressure. Pure nitrogen, ●; NO added, ◇, $C = 1$ Torr.

pressure up to a pressure of 1 Torr, for the $v' = 0$ and $v' = 1$ levels, respectively. The straight lines represent the least-squares curve fit of the points which are the experimental data. At a given pressure, nitrogen was partially replaced by successive amounts of nitric oxide. A series of curves, each originating from the pure nitrogen line, was then obtained. Values for k_1, calculated from each curve, are shown in Table 1. The mean value for $k_{1,v'=0}$ was $46 \pm 9 \times 10^{10}$ l s^{-1}, based on Bennett and Dalby's value for k_3. The rate constant for deactivation of $N_2^+(B)$ by nitric oxide agrees quite well with the value for charge transfer from $N_2^+(X)$ obtained by Ferguson *et al.*, though it lies at the upper limit of their range.

In the determination of $k_{1,v'=1}$, two vibrational bands (1,0) and (1,2) were monitored, and the results are shown also in Table 1; a mean value of $k_{1,v'=1} = 14(+6, -3) \times 10^{10}$ l s^{-1} was obtained. The radiative lifetime for the (1,0) and (1,2) bands was taken to be 7.58×10^{-8} s based on the value of Jeunehomme (5). The values of $k_{1,v'=1}$ are less accurate than those for $k_{1,v'=0}$ due to the diminished intensity of the $v' = 1$ bands. The rate constant is lower for the excited nitrogen ion with a single vibrational quantum than that for the vibrationally unexcited one. Schmeltekopf *et al.* (2) have reported enhancement of the rate constant for a vibrationally excited neutral in the ion–atom interchange reaction

$$[11] \qquad O^+ + N_2(v) \rightarrow NO^+ + N$$

No enhancement was observed in our case with a vibrationally excited ion; on the contrary, as shown above a decrease was noted.

A value for the rate constant $k_{4,v'=0}$ (for the de-excitation reaction of nitrogen ions with nitrogen molecules) may be estimated crudely in three ways:

TABLE 1. Mean values of the rate constant k_1 for N_2^+ in the $v' = 0$ and $v' = 1$ vibrational levels

Total pressure (Torr)	$k_{1,v'=0}$ (l s^{-1} × 10^{-10})	$k_{1,v'=1}$ (l s^{-1} × 10^{-10})	
1.00	47	14*	13†
0.90	41		
0.80	46		
0.70	44		
0.60	48		

*Mean value derived from the (1,0) band of the N_2^+ 1N system.
†Mean value derived from the (1,2) band of the same system.

(*i*) In the excitation of pure nitrogen, the ratio of the intercept to slope $i_{N_2}/S_{N_2} = k_4/k_3$. It was calculated, thus, from the data in Fig. 1 that $k_{4,v'=0} \approx 42 \times 10^{10}$ l s^{-1}.

(*ii*) On extrapolation of the nitric oxide curves to zero (such a procedure invokes negative concentrations of nitric oxide!), comparison may be made of the resulting common intercept with that for pure nitrogen, *i.e.* $i_{NO}/i_{N_2} = 1 - k_1/k_4$. The uncertainty in the value for i_{NO}, in this work, is too large to justify even a crude estimate.

(*iii*) Equation 7 may be rearranged to predict a linear plot of $1/I_{v'v''}$ *vs.* [NO] at constant [N_2]; the data are obtained from any vertical line on Fig. 1. The slope of this plot $S'_{NO} = k_1/(k_2k_3i[N_2])$. Now $i_{N_2} = k_4/k_2k_3i$, therefore

$$\frac{k_1}{k_4} = \frac{S'_{NO}}{i_{N_2}}[N_2]$$

The data present a range for $(k_1/k_4)_{v'=0}$ of from 1.1 to 1.4, corresponding to the minimum and maximum values for S'_{NO}. For the vibrationally excited ion $(k_1/k_4)_{v'=1}$ was found to be approximately 0.6. These ratios for k_1/k_4 were evaluated independently of k_3. One may then substitute the above values for $k_{1,v'=0}$ and $k_{1,v'=1}$ (based on the lifetimes of the $v' = 0$ and $v' = 1$ states, respectively) and show that, whereas the rate constant for deactivation by nitric oxide is decreased by a factor of 3 on the acquisition of a single vibrational quantum, the corresponding rate constant for deactivation by nitrogen molecules is decreased by a factor of 1.5 only.

As shown in Table 2, Brocklehurst and Downing (6), in two experiments using X-ray excitation and 50 keV electron excitation of nitrogen at 770 Torr, obtained values for $k_{4,v'=0} = 24 \pm 9 \times 10^{10}$ l s^{-1}, while Mitchell (7) reports a value for $27 \pm 3 \times 10^{10}$ l s^{-1} obtained by soft X-ray excitation in the pressure range 0.3–600 Torr. This is in fair agreement with the values obtained in this work which was carried out at low pressures and with 20 keV electron excitation.

The observation that $k_{1,v'=0}$ is slightly greater than k_5 may be accounted for by favored Franck–Condon transitions to vibrationally excited states of the $A^3\Sigma$ molecule. It has been shown (8, 9) that reaction 5 may yield molecules in the $A^3\Sigma_u^+$ state. Transitions from the N_2^+ $X^2\Sigma_g^+$ and $B^2\Sigma_u^+$ states to the $A^3\Sigma$ state

of nitrogen are compatible with the application of the Franck–Condon principle, and the spin-conservation rule is not violated. Reaction 5 is near-resonant while reaction 1 is exothermic by $\geqslant 3.1$ eV.

Little can be said of the mechanism of deactivation to explain the diminution of the rate constants for the vibrationally excited ions. No other results are available for the variation of quenching of ions with v'. Some data are available (10) for the molecular state $C^3\Pi_u$ where a 3-fold enhancement of the quenching constant is observed between $v' = 0$ and 1. There is, however, little reason to expect similar behavior for quenching of charged species. An attempt is being made to obtain more precise data for this species as it is an important constituent of the upper atmosphere.

The authors gratefully acknowledge the financial support of the National Research Council of Canada, Imperial Oil Limited (Canada) and one of us (G.I.M.), the Province of Ontario for a Graduate Fellowship.

Removal of Wood Components During Chlorite Delignification of Black Spruce

P. A. AHLGREN[1] AND D. A. I. GORING

Physical Chemistry Section, Pulp and Paper Research Institute of Canada and Chemistry Department, McGill University, Montreal, Quebec

Received October 14, 1970

The pattern of component removal has been studied for black spruce during delignification by acidified sodium chlorite at 70 °C. Special emphasis was placed on the determination of the acid soluble portion of lignin remaining in the sample.

It was found that the chlorite procedure is selective in removing lignin only during the first 60% of delignification. At later stages of delignification some glucomannan is dissolved. A so-called holocellulose of 70% yield is thus composed of about 40% cellulose, 13% glucomannan and galactan, 12% xylan and other carbohydrates, and 5% lignin (all based on the original wood).

On a étudié la séquence de dissolution des différents composés de l'épinette noire durant la délignification par chlorite de sodium acidifié, à 70 °C. On s'est occupé surtout de suivre la mise en solution de la lignine par détermination de la teneur résiduelle en lignine de la fibre après la cuisson.

Durant une première étape de délignification le traitement au chlorite est sélectif pour la lignine seulement. Lorsque 60% de la lignine est éliminé, le glucomannan commence à se dissoudre et on trouve qu'un holocellulose de rendement 70% est composé d'environ: 40% cellulose, 13% glucomannan et galactan, 12% xylan et autres carbohydrates ainsi que 5% de lignine (les pourcentages étant basés sur la masse originale du bois).

Canadian Journal of Chemistry, 49, 1272 (1971)

Introduction

Although the chlorite method is widely used for the preparation of holocellulose few attempts have been made to study quantitatively the pattern of component removal. Previous investigations (1–3) were inadequate as few intermediate stages of delignification were reported and the degree of delignification was not determined accurately. That acidic chlorite does not leave the carbohydrate portion of the wood intact is suggested by the observed decrease in DP of the cellulose (4), as well as the observed decrease in carbohydrate yield toward the end of the delignification (3–5).

The main purpose of the present work was to establish quantitatively the degree to which acidic chlorite treatment at 70 °C is selective in removing lignin from spruce wood. A secondary purpose was to determine which polysaccharides and how much of them dissolved during the delignification.

The delignification was followed by Klason analysis of the remaining lignin. It has long been recognized that this procedure does not account for all the lignin in the sample. The analysis must be complemented by a determination of that part of the lignin soluble in the sulfuric acid used to hydrolyze the carbohydrates. High values have been reported for the amount of acid-soluble lignin in samples produced by the chlorite process (3, 6). In order to ensure accuracy in the measurement of the degree of lignin removal, special care was taken in determining acid-soluble lignin at various stages of chlorite treatment.

Previous investigators have isolated glucose and mannose from chlorite liquors (7–9). In the present work, the sugar composition of samples treated to different extents was determined in order to characterize quantitatively the loss of various types of carbohydrates during the chlorite process.

Materials and Methods

Wood

Black spruce (*Picea mariana*) whole wood was used in three forms: (*1*) 2 × 2 × 5 mm matchstick chips; (*2*) 0.3 mm thick longitudinal shavings cut to about 3 mm in the fiber direction; (*3*) 40–60 mesh meal from dry Wiley milling. The Klason lignin content of the samples was 27.8 ± 0.2% (n = 7, 95% confidence limits). The samples were extracted with hot water before chlorite treatment.

Chloriting Procedure

Chlorite treatment was done according to the procedure of Wise *et al.* (5) as adapted by Timell (10). The initial chemical charge was 0.3 g sodium chlorite and 0.1 ml glacial acetic acid per g of dry wood. The liquor to wood ratio was 15:1 and the temperature was 70 °C. Batches of 2 g of wood were treated for different lengths of time. At hourly intervals a fresh charge of chemicals was added without withdrawal of any liquor. The time required with

[1]On leave from Swedish Forest Products Research Laboratory (STFI), Stockholm, Sweden.

For personal use only.

this procedure was 2 h 10 min and 7 h to reach 50 and 90% lignin removal respectively.

Lignin Determination

The Klason lignin analyses were done according to Tappi T 13m-54 for wood and Tappi T 222m-54 for the chlorite-treated samples.

The acid soluble portion was estimated spectrophotometrically by measuring the absorbance of the Klason hydrolysates in the u.v. Similar results were obtained when the measurements were made at 240 and 280 nm but the measurements at 240 nm gave greater precision because of the higher absorbance of the lignin at this wavelength.

There are several indications that the amount of acid-soluble lignin from untreated softwoods is sufficiently small to be neglected (3, 11, 12). The observed absorbance of a Klason hydrolysate from spruce wood is most probably due to carbohydrate degradation products of the furan type, such as furfural and hydroxymethylfurfural (3). Therefore it has been assumed in the present work that the portion of the absorbance in the acid soluble fraction of the treated samples due to non-lignin is equal to the absorbance of the Klason hydrolysate from untreated wood and the appropriate correction made. This correction for carbohydrate degradation products corresponded to less than 1% acid soluble lignin on wood. Lignin concentrations were then calculated from the corrected absorbances using an absorptivity of 30 l/g cm at 240 nm determined by Campbell and McDonald (6) for the acid soluble lignin from chlorited spruce wood.

Carbohydrate Determination

In the hydrolysates from Klason lignin analysis, the glucose contents were determined by the glucose–oxidase method (13, 14). The relative sugar compositions of the hydrolysates were determined by g.l.c. of the alditol acetates, essentially according to the method reported by Sjöström *et al.* (13, 15).

Results and Discussion

Figure 1 shows the results obtained for the acid soluble lignin at various Klason lignin contents. Each point is an average of the data from two separate hydrolyses (mean deviation ±0.1% lignin on wood). Noteworthy is the high level of the acid soluble lignin, in agreement with earlier findings (3, 6). A maximum is reached at about 50% delignification in agreement with the behavior found for other processes (11, 16).

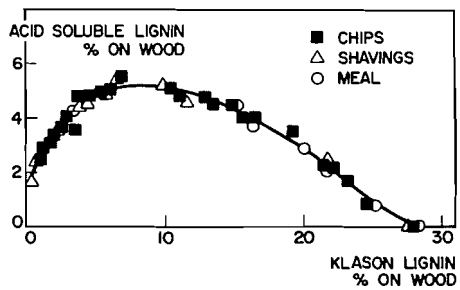

FIG. 1. The amount of acid-soluble lignin from chlorite treated spruce wood measured spectrophotometrically at different stages of delignification.

The removal of components during the course of chlorite delignification is shown in Fig. 2. The hot water extraction dissolved about 2% of the wood, giving a starting point at 98% yield. The total yield is determined from eq. 1.

$$[1]\quad \text{Yield} = \frac{\text{Oven-dried wt. of washed sample after treatment}}{\text{Oven-dried weight of original wood}} \times 100$$

The non-lignin yield is calculated by subtracting from the total yield the amount of lignin remaining in the sample (determined as insoluble Klason lignin plus the u.v.-estimated acid soluble lignin, Fig. 1). The total carbohydrate content of the samples is assumed to be the non-lignin yield. In order to facilitate use of the data by others, smoothed values from the curves in Figs. 1 and 2 are compiled in Table 1.

From Fig. 2, it is evident that acidic chlorite treatment dissolves only lignin during the first 60% of delignification. On further treatment, the non-lignin yield decreases, indicating that lignin-removal is accompanied by a loss of carbohydrates. In passing it is worth noting that, as the wood contains about 28% lignin and 2% water-soluble extractives in totally selective delignification, a residue obtained in 70% yield should be constituted entirely of carbohydrate. However, it was found that at 70% yield the carbohydrate content of the residue was only 93%, the loss being compensated for by the retained lignin.

The question then arises as to which of the

TABLE 1. The lignin contents of holocelluloses at different degrees of delignification

Delignification (%)	Klason lignin (% on wood)	Acid soluble lignin (% on wood)	Total yield (%)
0	27.8	0	100
10	23.2	1.7	95.4
20	19.2	3.1	92.5
30	15.4	4.2	89.7

70	4.0	4.4	77.4
80	2.1	3.4	72.3
85	1.3	2.8	69.0
90	0.6	2.1	64.6
92.5	0.3	1.8	61.3

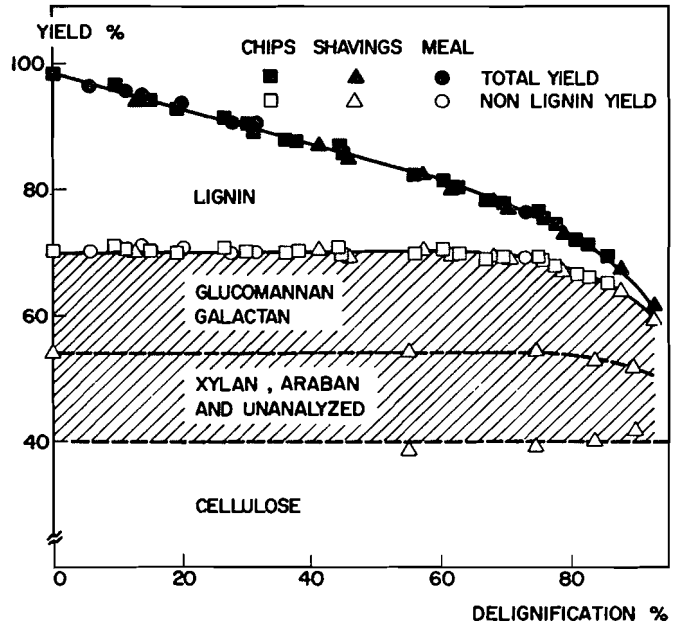

FIG. 2. Yield of the major wood components during chlorite treatment of spruce at different stages of delignification.

TABLE 2. Sugar composition of holocelluloses at different yields

Holocellulose yield (%)	Anhydrosugars from holocellulose (% on wood)				
	Glucose	Arabinose	Xylose	Mannose	Galactose
97.9	—	1.1	5.9	10.2	2.2
82.7	42.4	0.8	5.9	10.7	1.5
75.4	43.0	0.8	5.7	9.8	1.3
70.2	43.7	0.8	6.3	8.6	1.3
65.1	44.7	0.7	5.7	7.4	0.7

wood carbohydrates are lost in the later stages of the delignification. Bublitz (7), Meier (8), and Thompson *et al.* (9) have all found that the polysaccharide fraction isolated from chlorite liquors contains galactose, glucose, and mannose. Only small amounts of arabinose and xylose were found in the chlorite liquor. As seen in Table 2 this is in reasonable agreement with the analysis of the carbohydrates remaining in the chlorite treated samples; there is a well-defined decrease in mannose and galactose with decrease in yield, while xylose and arabinose remain constant. The glucomannan content of the samples in Table 2 was estimated by assuming the value of 2.6 for the ratio mannose/glucose (17). Glucose not in glucomannan was taken to be cellulose; the remainder was assumed to be xylan and other sugars. In Fig. 2 the non-lignin portion has been subdivided into carbohydrate fractions by means of the data in Table 2. The fractions are cellulose, xylan plus other sugars (partly unanalyzed), and glucomannan plus galactan. This graphical representation illustrates clearly that the predominant loss in carbohydrates towards the end of the chlorite process is in glucomannan and galactan.

It has been suggested that hemicelluloses are difficult to extract from softwoods because of the protective action of lignin (18, 19). If this is so, the present results imply that removal of about 60% of the lignin is necessary before the carbohydrate fraction is exposed. A possible reason for preferential retention of xylan could be that in acidic processes the glucomannan is easily dissolved whereas the xylan is resistant to hydrolysis unless the p*H* is very low (20). A similar prefer-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ential removal of glucomannan has been noted by Erikson and Samuelson (21) in the bisulfite cooking of spruce wood.

At this stage we may comment on the excellent agreement between the analyses shown in Figs. 1 and 2 for the different forms of wood used. The agreement extends over the entire range of delignification studied. An average minimum dimension of the wood meal was about 0.04 mm compared with 0.3 mm for the shavings and 2 mm for the chips. Evidently in this range of dimensions there is a negligible effect of particle size on the chemistry of chlorite delignification and carbohydrate solubilization.

Concluding Remarks

Many physicochemical studies have been made of the important commercial pulping processes (22–27), but interpretation is often difficult because of the simultaneous removal of lignin and hemicellulose from the wood (20). The present investigation has shown that the chlorite process is selective in removing lignin from spruce wood during the first 60% of delignification. Beyond this point small quantities of glucomannan are dissolved together with the lignin. There is no doubt, however, that the selectivity of the chlorite procedure is much greater than conventional pulping processes and offers advantages for studies of physicochemical effects of "pure" delignification.

Subsequent research will deal with the dimensional changes of the cell wall, the macromolecular properties of the lignin, and the porous structure of the cell wall developed during chlorite delignification.

It is anticipated that a comparison of the results of such work with the corresponding behavior in kraft and sulfite pulping will further elucidate the physicochemical phenomena which are important in chemical pulping.

A ^{19}F Nuclear Magnetic Resonance Study of Halogen Exchange between Antimony Pentafluoride and Inorganic Chlorides. Complexes of Antimony and Arsenic Pentafluorides with Carbonyl Fluoride

J. BACON, P. A. W. DEAN, AND R. J. GILLESPIE
Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 31, 1970

^{19}F nuclear magnetic resonance (n.m.r.) has been used to study the reactions occurring in the systems $SbCl_5$–SbF_5–SO_2ClF, SO_2Cl_2–SbF_5–SO_2ClF, COF_2–SbF_5–SO_2ClF, COF_2–AsF_5–SO_2ClF, and COClF –SbF_5–SO_2ClF. Ionization occurs in $SbCl_5$–SbF_5–SO_2ClF, yielding antimony chloro- and chlorofluorocations and antimony polyfluoroanions. Donor–acceptor complexes are formed between SbF_5 and SO_2Cl_2, COF_2 or COClF at low temperatures and also between AsF_5 and COF_2. In all the complexes the ligand is oxygen-bonded. At higher temperatures halogen exchange and ionization occurs in SO_2Cl_2–SbF_5–SO_2ClF and COClF–SbF_5–SO_2ClF giving SO_2ClF and COF_2 complexes, respectively, together with antimony cations and polyfluoroanions. The alkyl chloride – SbF_5 reaction is also shown to give chlorine-containing cations of antimony.

La r.m.n. du ^{19}F a été utilisée pour l'étude des réactions se produisant dans les systèmes $SbCl_5$–SbF_5–SO_2ClF, SO_2Cl_2–SbF_5–SO_2ClF, COF_2–SbF_5–SO_2ClF, COF_2–AsF_5–SO_2ClF et COClF–SbF_5–SO_2ClF. Une ionisation se produit dans $SbCl_5$–SbF_5–SO_2ClF conduisant à la formation de cations chloro- et chloro-fluoroantimoine et d'anions polyfluoro antimoine. Des complexes donneur–accepteur sont formés entre SbF_5 et SO_2Cl_2, COF_2 et COClF à basses températures et aussi entre AsF_5 et COF_2. Dans tous les complexes le ligand est lié à l'oxygène. A plus haute température des échanges d'halogènes et des ionisations se produisent dans SO_2Cl_2–SbF_5–SO_2ClF et COClF–SbF_5–SO_2ClF donnant respectivement des complexes de SO_2ClF et COF_2 avec des cations d'antimoine et des anions polyfluorés. Il est démontré que la réaction entre un chlorure d'alkyle et SbF_5 donne cations de l'antimoine contenant du chlore.

Canadian Journal of Chemistry, 49, 1276 (1971)

As part of a continuing study of the chemistry of antimony pentafluoride, we have used ^{19}F n.m.r. to investigate its interaction with $SbCl_5$, SO_2Cl_2, COClF, and COF_2, generally in sulfuryl chlorofluoride as solvent, and we have used our results for these systems as a basis for reinterpretation of the alkyl chloride – SbF_5 reaction.

^{19}F n.m.r., electrical conductivity, and viscosity measurements have previously been made on homogeneous liquid phase mixtures of SbF_5 and $SbCl_5$, and the complexity of the system demonstrated (1). On addition of $SbCl_5$ to SbF_5, both the viscosity and specific electrical resistance dropped precipitously, reaching a minimum at a F/Sb ratio of *ca.* 3.5. The results for the fluorine-rich part of the system were interpreted in terms of the equilibrium [1] which involves ionization and formation of a polyfluoroanion or mixture of polyfluoroanions.

$$[1]\quad 4SbCl_5 + (5n+1)SbF_5 \rightarrow 5SbCl_4^+ + 5Sb_nF_{5n+1}^-$$

Definitive ^{19}F n.m.r. spectra of the polyfluoroanions were not observed, however, presumably due to the relatively high temperatures ($> -10°$) necessary to prevent crystallization in the system. More recent work (2–4) has shown that temperatures of $-60°$ or below are necessary to slow down the fluorine exchange of the polyfluoroanions to the point where fine structure is observed in the ^{19}F n.m.r. spectrum.

Results and Discussion

SbF_5–$SbCl_5$ Solutions in SO_2ClF

At room temperature the fluorine-on-antimony region of the ^{19}F n.m.r. spectrum of a solution with $SbCl_5/SbF_5/SO_2ClF = 1/4.45/21.8$ was a single broad line due to fluorine exchange. At low temperatures, however, fine structure was observed. Figure 1 shows the 94.1 MHz ^{19}F n.m.r. spectrum of the F-on-Sb region at $-106°$. The doublet *C* at ϕ104.0 can be attributed to the four equivalent fluorines in the 1:1 complex $SbF_5.SO_2ClF$; this resonance has previously been observed (5) at ϕ105.1. The quintet resonance expected for the single axial fluorine of this species is not observed but is expected to lie under the intense quintet *H*. Comparison with a previous study (4) of *t*-BuF–SbF_5–SO_2ClF and $(n\text{-Bu})_4NSbF_6$–SbF_4–SO_2ClF shows that resonances *B*, *D*, *E*, *F*, and *H*, arise mainly from fluorines F_3, F_5, F_2, F_4, and F_1, respectively, of the *cis*-$Sb_3F_{16}^-$ anion **1**. However, the

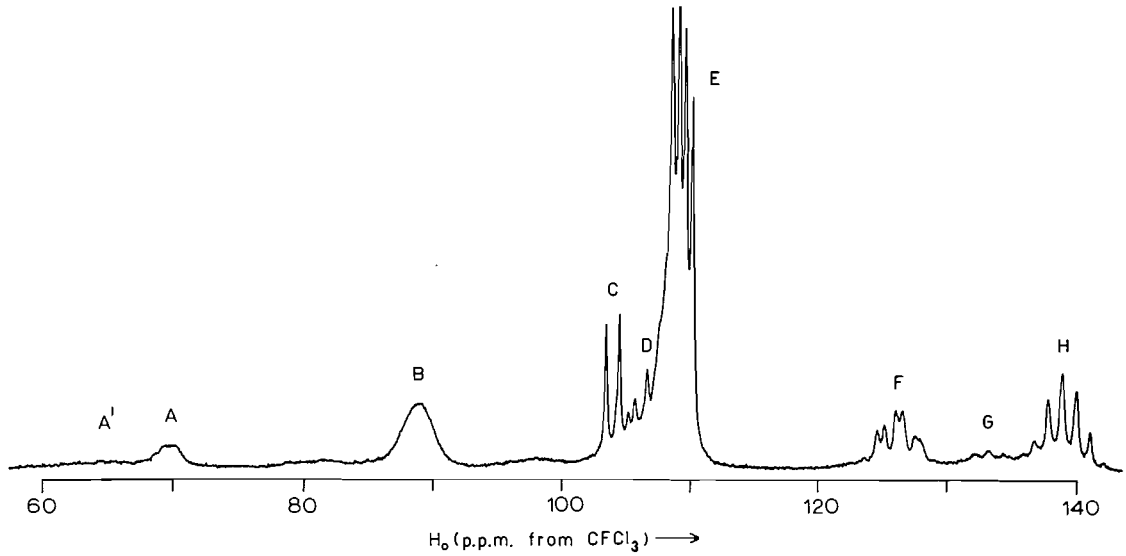

FIG. 1. The 94.1 MHz ^{19}F n.m.r. spectrum (F-on-Sb region only) of a solution with $SbCl_5/SbF_5/SO_2ClF$ = 1/4.45/21.8, at −106°.

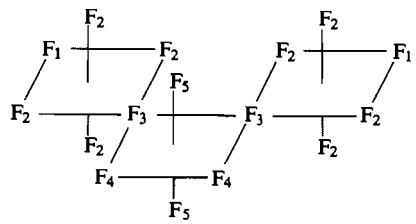
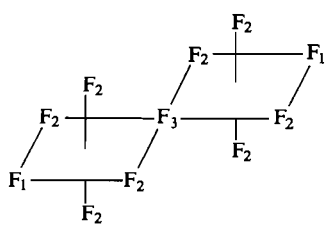
broad quintet *G*, from F_1 of the $Sb_2F_{11}^-$ anion (**2**) can also be seen at ϕ133.4, and the asymmetry of the double-doublet *E* must be caused



1

by partial overlap with the double-doublet resonance expected for F_2 of this anion. Likewise a minor part of the intensity of the resonance *B* is from F_3 of $Sb_2F_{11}^-$.



2

In the previous study (4) of the formation of the polyfluoroanions $Sb_nF_{5n+1}^-$ in SO_2ClF, it was shown that with increasing SbF_5 concentration $Sb_2F_{11}^-$ and then $Sb_3F_{16}^-$ are formed and are followed by the formation of both $Sb_4F_{21}^-$ and $SbF_5.SO_2ClF$, *i.e.*, $Sb_4F_{21}^-$ is solvolyzed to some extent according to the equation

$$Sb_4F_{21}^- + SO_2ClF \rightleftarrows Sb_3F_{16}^- + SbF_5.SO_2ClF$$

whereas solvolysis of $Sb_2F_{11}^-$ and $Sb_3F_{16}^-$ is negligible. Thus the observation of a small amount of $SbF_5.SO_2ClF$ in the spectrum in Fig. 1 indicates that a small amount of $Sb_4F_{21}^-$ is also formed.

The resonance *A*, at ϕ69.8, is not due to a polyfluoroanion or an SbF_5–SO_2ClF complex, and it seems most likely, therefore, that it arises from a fluorine-containing cation. There is a suggestion of a broad resonance *A'* to low field of *A* which is difficult to see in Fig. 1, but which is somewhat clearer in other spectra (*e.g.* it occurs at *ca.* ϕ65 in Fig. 2(*b*)).

In the fluorine-on-sulfur region of the ^{19}F n.m.r. spectrum, an intense sharp line due to the solvent is seen, together with another less intense sharp signal +396 Hz from the solvent line. The latter arises from SO_2ClF in $SbF_5.SO_2ClF$ (5), consistent with the observation of the remainder of the spectrum of this species in the F-on-Sb region.

Our results clearly support earlier evidence (1) for ionization in $SbCl_5$–SbF_5. It is unlikely, however, that the cation is solely $SbCl_4^+$ as indicated by reaction 1, since we observe ^{19}F

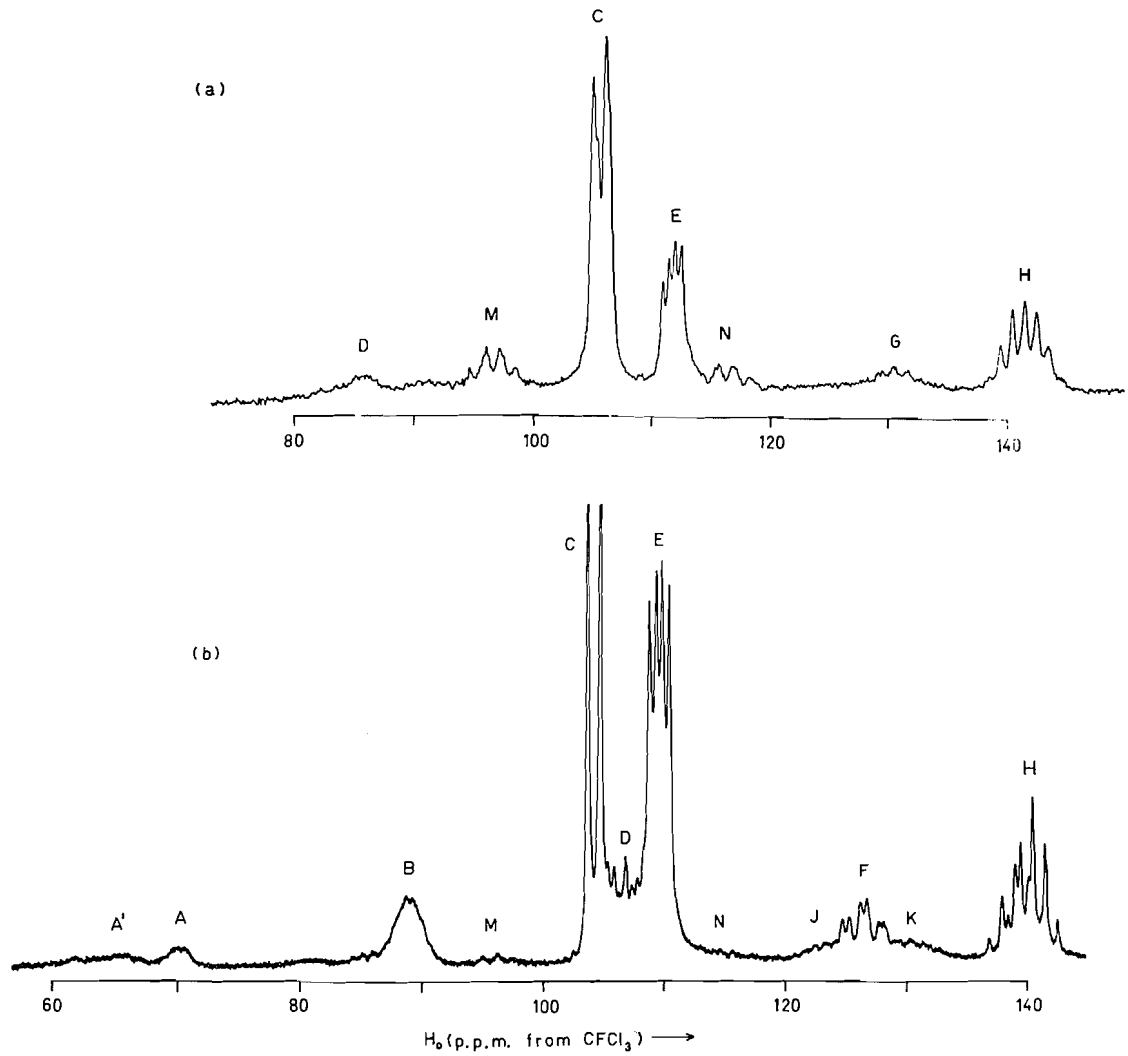

FIG. 2. The 94.1 MHz ^{19}F n.m.r. spectra (F-on-Sb region only) of a solution with $SO_2Cl_2/SbF_5/SO_2ClF$ = 1/1.61/5.09: (*a*) −75° spectrum after being kept at −23° or below; (*b*) −100° spectrum after standing at room temperature for 10 min.

n.m.r. signals which are very probably due to cationic species. We note that, assuming complete reaction according to [1], the stoichiometry of the solution leads to a value of 3.36 for n, the average number of antimony units in the polyfluoroanions. The n.m.r. spectrum in Fig. 1 shows that the amount of $SbF_5.SO_2ClF$, and presumably therefore also $Sb_4F_{21}^-$, is very small, suggesting a somewhat lower value for n. Reactions such as 2 and 3 produce chlorofluoro

[2] $3SbCl_5 + (5n + 2)SbF_5 \rightarrow 5SbCl_3F^+ + 5Sb_nF_{5n+1}^-$

[3] $2SbCl_5 + (5n + 3)SbF_5 \rightarrow 5SbCl_2F_2^+ + 5Sb_nF_{5n+1}^-$

cations and the occurrence of these would be consistent with the observation of ^{19}F n.m.r. signals from cations. The positions of *A* and *A'*, to relatively low applied fields, also support the suggestion that they arise from chlorofluoro species: the resonances of such species commonly lie to lower fields than those of their fully fluorinated analogs (6). If only reaction 2 occurred and this reaction was complete, the value of n would be 2.27 and similarly reaction 3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

would lead to a value of 1.18 for n in the present solution; as noted above the observed spectrum shows $n \sim 3$. Thus reactions 2 and 3 appear to occur only to a minor extent. Our observations suggest the formation of a mixture of cationic species including $SbCl_4^+$ (which is probably the predominant cation) and chlorofluorocations of the type $SbCl_{4-n}F_n^+$. We tentatively assign resonance A' to $SbCl_3F^+$ and A to $SbCl_2F_2^+$. (The more chlorinated of the two species is expected to have a resonance at lower field (6).) The fluorine resonances of these cations are broad presumably due to relatively slow quadruple relaxation of the antimony nucleus in the quite symmetrical tetrahedral environment of the cations. A reasonable first step in the reaction of $SbCl_5$ and SbF_5 would be

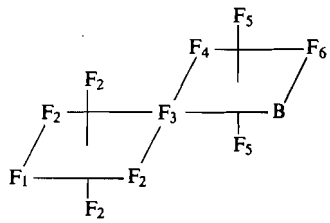
$$SbCl_5 + nSbF_5 \rightarrow SbCl_4^+ + Sb_nF_{5n}Cl^-$$

but the reaction route from this initial cation-producing step to the final formation of the observed polyfluoroanions, $Sb_nF_{5n+1}^-$, must be complex.

SbF_5–SO_2Cl_2 Solutions in SO_2ClF

A solution of SbF_5 in SO_2Cl_2, allowed to stand for several hours at room temperature, provided good evidence for halogen exchange. Whilst it was not possible to attain low enough temperatures for observation of fine structure in the fluorine-on-antimony region of the ^{19}F n.m.r. spectrum, the room temperature spectrum showed a single line at $\phi - 99.9$ which is due to SO_2ClF.

A solution of composition $SO_2Cl_2/SbF_5/SO_2ClF = 1/1.61/5.09$ was prepared at low temperatures and homogenized at $-23°$. On cooling, a white solid quickly came out of the solution. It was possible, however, by rapid recording, to obtain the ^{19}F n.m.r. spectrum of the solution whilst crystallization was occurring. When the solution was cooled to $-75°$, the fluorine-on-sulfur region of the 94.1 MHz spectrum showed a sharp line from the bulk solvent and a second line due to $SbF_5.SO_2ClF$ 384 Hz upfield of the solvent line. The fluorine-on-antimony region of the spectrum is shown in Fig. 2(*a*). Though the resolution is not good owing to the conditions under which the spectrum was obtained, there are some features of interest. The signal C is comprised of two overlapping doublets at $\phi \sim 105.1$ and $\phi \sim 105.5$. One of these arises from the four equatorial fluorines in $SbF_5.SO_2ClF$, and the other must be due to the analogous fluorines in a 1:1 complex with oxygen-bonded SO_2Cl_2. The two quintets expected for these species make up part of the complex resonance H which is centered at $\phi \sim 142$. Because of the closeness of the chemical shifts we cannot make a definite assignment of either of the two AX_4 spectra to one or the other of the two possible species. In addition to the signals from the 1:1 complexes, the spectrum also shows the complex spectrum E, D, M, N, G previously shown (5) to be characteristic of neutral 2:1 SbF_5:base complexes of the type **3**. Signals E, D, M, N, and G at ϕ111.4, 85.1, 96.0, 115.9, and 130.4 are due to the fluorines F_2, F_3, F_5, F_6, and F_4, respectively. The signal



3

arising from F_1 is expected to occur in the region of H. The chemical shifts in the spectrum of the 2:1 complex are close to those reported (5) for $(SbF_5)_2.SO_2ClF$. Nevertheless, it seems unlikely that the latter species is formed, for the following reasons: (*i*) no signal attributable to SO_2ClF in $(SbF_5)_2.SO_2ClF$ is seen in the F-on-S region, whereas in SbF_5/SO_2ClF solutions of comparable dilution this signal is easily observed under the same conditions; (*ii*) in the F-on-Sb region E is a multiplet whereas in all comparable SbF_5/SO_2ClF solutions E was found to be a single line at the same temperature; (*iii*) SO_2Cl_2 is more basic than SO_2ClF: a complex $SbCl_5.SO_2Cl_2$ has been isolated at room temperature (7), whereas we have found no evidence from ^{19}F n.m.r. spectra for $SbCl_5$–SO_2ClF complexes even at very low temperatures. It is, therefore, more probable that E, D, M, N, G is the spectrum of a 2:1 SbF_5:SO_2Cl_2 complex; this spectrum is expected to resemble closely that of the analogous SO_2ClF complex. In this context it is noteworthy that the chemical shifts of the four equivalent fluorines in the 1:1 complexes $SbF_5.SO_2ClF$ and $SbF_5.SO_2Cl_2$ are very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

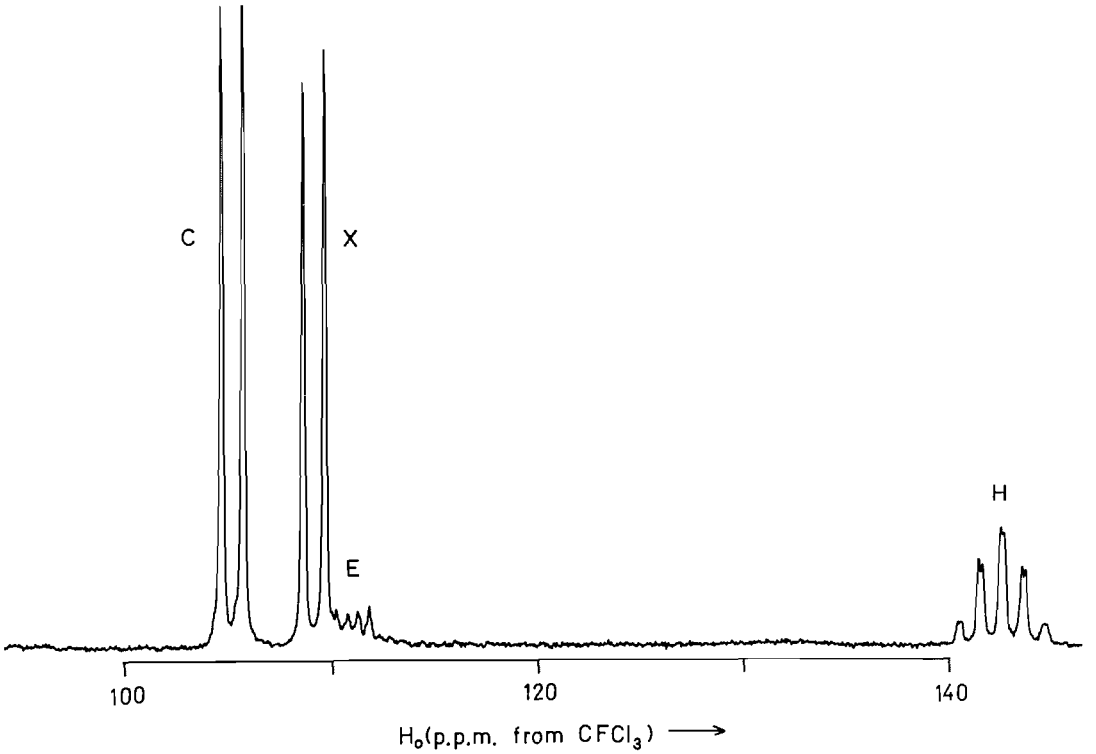


FIG. 3. The 94.1 MHz ^{19}F n.m.r. spectrum (F-on-Sb region only) of a solution with $COF_2/SbF_5/SO_2ClF$ = 1/2.17/10.0, at −100°.

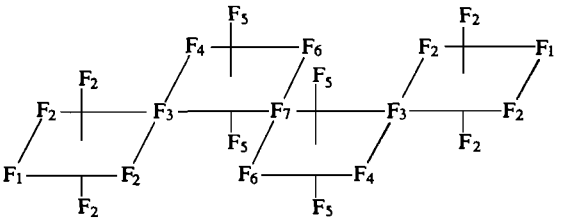
similar: this chemical shift is as sensitive as any in either the 1:1 or 2:1 complexes to change in the donor (4).

The solution can be warmed to room temperature briefly and recooled with no change in the ^{19}F n.m.r. spectrum, but when it is allowed to stand at room temperature for 10 min, crystallization no longer occurs on cooling. The −100° 94.1 MHz ^{19}F n.m.r. spectrum at this time is as shown in Fig. 2(*b*). It differs considerably from the spectrum in Fig. 2(*a*) and there is a very obvious similarity to the spectrum in Fig. 1, the only apparent differences being the increased intensity of the doublet *C* due to $SbF_5.SO_2ClF$ in Fig. 2(*b*), and the apparent absence of any peaks due to $Sb_2F_{11}^-$ in this spectrum. In addition the resonances *J* and *K* are now seen on the low and high field sides of the signal *F*; these two resonances have previously been tentatively assigned (4) to fluorines F_6 and F_4 of *cis-cis*-$Sb_4F_{21}^-$ (**4**).

The small multiplets *M* and *N* can be assigned to F_5 and F_6 of $(SbF_5)_2.SO_2ClF$ (**3**). (These signals persist for weeks and hence cannot be due to the complex $(SbF_5)_2.SO_2Cl_2$, which, as noted above, has a very similar spectrum to $(SbF_5)_2.SO_2ClF$.)



4

From the results above it is clear that in the cold solutions, donor–acceptor complexes of SbF_5 with O-bonded SO_2Cl_2 are formed. On warming, halogen exchange occurs, the SO_2Cl_2 being converted to SO_2ClF, and the chlorofluoro antimony species simultaneously formed ionize in a manner analogous to that which occurs in $SbCl_5$–SbF_5–SO_2ClF (reactions 1–3).

SbF_5–COF_2 Solutions in SO_2ClF

Fine structure is observed in the ^{19}F n.m.r. spectra of SbF_5–COF_2 solutions in SO_2ClF at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

low temperatures. Figure 3 shows the fluorine-on-antimony region of a spectrum obtained from a solution with $COF_2/SbF_5/SO_2ClF$ = 1/2.17/10.0, when cooled to −100°. In addition to this spectrum and the solvent line, two lines are observed at +376 and +269 Hz from the solvent line (relative areas 10.5 and 1, respectively) which are attributable (5) to SO_2ClF bound in 1:1 and 2:1 complexes with SbF_5, and a relatively sharp singlet (half width ~18 Hz) is also seen at ϕ −2.1.

In the F-on-Sb region, the doublet *C* (chemical shift ϕ105.3; J_{F-F} = 98 Hz) is due to $SbF_5.SO_2ClF$, as is the more intense (lower field : ϕ142.5) of the two overlapping quintets *H*. The second doublet, X, (chemical shift ϕ109.2; J_{F-F} = 98 Hz) and the higher field (ϕ142.6) quintet constitute an AX_4 spectrum which must be due to a complex $SbF_5.OCF_2$, in which the carbonyl fluoride acts as a donor through oxygen. The multiplet *E* arises from the fluorines F_2 of the 2:1 complex $(SbF_5)_2.SO_2ClF$ (**3**), the observation of this spectrum being consistent with the presence of the line +269 Hz from the solvent line. In solutions with greater SbF_5/COF_2 ratios, larger amounts of SO_2ClF complexes occur, but we did not observe any spectrum attributable to a 2:1 SbF_5:COF_2 complex.

The singlet at ϕ −2.1 has an area half that of the doublet X and so results from the fluorine in the bound COF_2. At −65°, where fine structure is being lost in the F-on-Sb region, no signal is observed which could be due to F-on-C. (We presume it becomes too broad to see.) At higher temperatures the signal reappears, and at 25° is again quite sharp (~ 45 Hz half width) with a chemical shift ϕ14.3, much closer to the position of the signal from free COF_2 in SO_2ClF (ϕ19.6 in dilute SO_2ClF solution at −100°). The temperature dependent behavior of the F-on-C resonance shows increasing dissociation of $SbF_5.OCF_2$ with increasing temperature; the dissociation is incomplete even at 25°, however, since there is still a significant difference between the chemical shift of the COF_2 in the presence and absence of the pentafluoride at this temperature.

No change was observed in the n.m.r. spectra of the solutions even after standing for long periods at room temperature. Other than producing changes in resolution due to viscosity changes, changes in concentration were without significant effect on the spectra.

AsF_5–COF_2 Solutions in SO_2ClF

No fine structure was observed in the −100° ^{19}F n.m.r. spectrum of a solution with composition $COF_2/AsF_5/SO_2ClF$ = 1/2.0/4.0. In addition to the solvent line, a quite sharp (~ 16 Hz half width) signal from fluorine-on-arsenic was seen at ϕ49.4, together with a resonance due to COF_2 at ϕ5.2 (~ 12 Hz half width). The observation of a relatively sharp ^{19}F n.m.r. line from AsF_5 in the presence of a weak base has been shown (8) to indicate complex formation. By comparison with SbF_5–COF_2–SO_2ClF (above), the low field shift of the F-on-C signal relative to free COF_2, is also consistent with complexed COF_2 being present. This low field shift is not as great as in $SbF_5.OCF_2$, however, showing that complexing of the COF_2 by AsF_5 is most probably incomplete even at −100°.

As the temperature of the solution is increased there is a steady increase in the chemical shift of the F-on-C resonance (*e.g.* ϕ12.1 at −51°, 20.4 at 24°).

At room temperature the chemical shift is the same within experimental error as that of free COF_2 showing complete dissociation of the AsF_5–COF_2 complex (or complexes). Similar behavior is observed with AsF_5 and the weak base SOF_2 (8).

SbF_5–COClF in SO_2ClF Solution

A sample having $COClF/SbF_5/SO_2ClF$ = 1/2.9/3.1 was prepared by allowing COClF to distil into a cold (−63°) solution of SbF_5/SO_2ClF. A considerable amount of white solid formed immediately which could not be redissolved even at −23°. Outside the fluorine-on-antimony region, the 94.1 MHz fluorine spectrum of the supernatant liquid at −80° gave no resonance for COClF (ϕ −57.7 at 25° in SO_2ClF solution), but signals were observed at ϕ −2.1 and ϕ +17.7 (relative areas ~ 2 and 1) which, by comparison with $SbF_5/COF_2/SO_2ClF$ (above), can be attributed to co-ordinated and free COF_2. In addition, lines were observed from the solvent, and from SO_2ClF co-ordinated in $SbF_5.SO_2ClF$.

The fluorine-on-antimony region of the spectrum was complicated, but similar to Figs. 1 and 2(*b*). It showed resonances attributable to $SbF_5.SO_2$ (impurity), $SbF_5.SO_2ClF$, $(SbF_5)_2.SO_2ClF$, $Sb_2F_{11}^-$, and *cis*-$Sb_3F_{16}^-$. Also observed was a doublet (J_{F-F} ~ 95 Hz) centered on ϕ108.8 in the position expected for the signal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

from the four equivalent fluorines in $SbF_5.OCF_2$ (see above). This resonance partly overlapped the signal from F_5 of *cis*-$Sb_3F_{16}^-$.

When a much more dilute solution was prepared ($COClF/SbF_5/SO_2ClF$ = 1/2.0/27) dissolution was complete at −63°. The −95° ^{19}F n.m.r. spectrum of this solution showed two equally intense doublet–quintet (AX_4) spectra. The first of these (chemical shifts: X, ϕ105.1; A, ϕ141.0, J_{F-F} = 96 Hz) arises from $SbF_5.SO_2ClF$ for which shifts of ϕ105.1 and ϕ141.8 are known (5). The second (chemical shifts: X, ϕ110.0; A, ϕ142.5, J_{F-F} = 96 Hz) cannot be due to $SbF_5.OCF_2$, since no signal from co-ordinated COF_2 was observed, and it must, therefore, show the presence of the complex $SbF_5.OCClF$. In agreement with this assignment, a resonance with intensity one quarter that of the ϕ110.0 doublet was observed at ϕ −59.9: this must result from co-ordinated COClF. This resonance is not seen in the spectrum of the sample having $COClF/SbF_5/SO_2ClF$ = 1/2.9/3.1 because all the COClF was converted to COF_2 in that solution. As for $SbF_5.SO_2Cl_2$ and $SbF_5.SO_2ClF$ (see earlier), the ^{19}F n.m.r. spectra of $SbF_5.OCClF$ and $SbF_5.OCF_2$ are very similar.

It is clear that, as in the case of SO_2Cl_2 and SbF_5, simple donor–acceptor behavior between SbF_5 and oxygen-bonded COClF occurs at low temperatures. At higher temperatures, however, halogen exchange occurs, the chlorofluoro-antimony species so produced ionizing in the manner demonstrated earlier for $SbCl_5/SbF_5$ to give a mixture of polyfluoroanions and chlorine-containing cations.

The Reaction of Alkyl Chlorides with SbF_5

Alkyl chlorides react with SbF_5 in SO_2 to produce carbonium ions (9) but there has been some controversy over the fate of the chlorine in this reaction. Olah *et al.* (9) suggested that the anion produced was SbF_5Cl^-. In a previous paper (3) we showed by ^{19}F n.m.r. that the anion was, in fact, $Sb_2F_{11}^-$, excess SbF_5 combining with the solvent to give $SbF_5.SO_2$; we suggested that the chlorine was present in some neutral species such as $SbF_4Cl.SO_2$ which precipitated from solution. Commeyras and Olah (10) used ^{19}F n.mr. to study the effect of adding HCl or alkyl chlorides to SbF_5/FSO_3H. The n.m.r. spectra of the solutions were complicated but very similar to those produced by adding HF or alkyl fluorides to SbF_5/FSO_3H. The authors therefore concluded that in the chloride solutions halogen exchange certainly occurred leading to anions of the type SbF_6^- and $Sb_2F_{11}^-$ more or less chlorine substituted, although they did not observe any n.m.r. signals assignable to these species. In view of the complex nature of the halogen exchange reaction occurring between SbF_5 and $SbCl_5$, SO_2Cl_2, or COClF, we have re-examined the evidence relating to the reaction of alkyl chlorides with antimony pentafluoride.

At −80° the 56.4 MHz ^{19}F n.mr. spectra of SO_2 solutions in which *t*-BuCl/SbF_5 = 1/5.5 or *t*-BuF/SbF_5 = 1/3.8 are very similar in the region above ϕ90 (3). Careful examination showed, however, that whilst in the latter mixture no signal was observed below ϕ90, the former shows two small broad singlets (half width 120 Hz) at ϕ71.8 and 79.9. At −50° the 56.4 MHz ^{19}F n.m.r. spectrum of the solution with $SbF_5/FSO_3H/HCl$ = 0.799/1/0.72 given in the work of Commeyras and Olah (10) also shows a low field broad line (ϕ ~ 84), which the authors labelled *H'* but did not comment on. The results given earlier, of our investigations into other systems which involve halogen exchange, provide evidence that the relatively low field lines observed in these two cases should be attributed to chlorofluorocations of antimony. Assigning these resonances to particular chlorofluoro-cations is somewhat difficult, as there may be a solvent dependence of the chemical shifts of the cations in the three solvents SO_2ClF, SO_2, and FSO_3H. We have previously reported solvent effects on the chemical shifts of the anions SbF_6^- and $Sb_2F_{11}^-$ in several systems (4). If we assume similar solvent effects in these anions and the chloro-fluoro-cations, then we can expect the difference in chemical shift between a particular cation and one of the anions, say $Sb_2F_{11}^-$, to be constant. The resonance in the fluorine spectrum of the solution having $SbF_5/FSO_3H/HCl$ = 0.799/1/0.72 which Commeyras and Olah label *H'* lies 31 p.p.m. below the "double-doublet" resonance of the eight equivalent fluorines of $Sb_2F_{11}^-$ in the same spectrum. The resonance at ϕ79.9 in the fluorine spectrum of our *t*-BuCl/SbF_5/SO_2 sample is 30 p.p.m. below the double-doublet resonance of $Sb_2F_{11}^-$ in the same spectrum, and can therefore be assigned to the same species. The resonance at ϕ71.8 in the spectrum of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

t-BuCl/SbF_5/SO_2 is 38 p.p.m. below the double-doublet resonance, while resonance *A* in Fig. 1 of this work is about 39 p.p.m. below the same resonance in that spectrum, suggesting the same species in the two spectra. Since we expect that the resonances of the more highly chlorine-substituted cations will occur at lower field (6), the above analysis suggests that the SbF_5/FSO_3H/HCl solution of Commeyras and Olah contains $SbClF_3^+$ (ϕ84), that our *t*-BuCl/SbF_5/SO_2 solution contains $SbClF_3^+$(ϕ79.9) and $SbCl_2F_2^+$ (ϕ71.8), and that our $SbCl_5$/SbF_5/SO_2ClF solution contains $SbCl_2F_2^+$ (ϕ69.8) and $SbCl_3F^+$ (ϕ65).

We conclude that the reaction of alkyl chlorides with SbF_5 is more complicated than previously suspected. The reaction may be regarded as occurring in two steps: firstly, halogen exchange between the chloride and SbF_5 to give the alkyl fluoride together with antimony chloro- or chlorofluorocations and polyfluoroanions, and secondly, reaction of the alkyl fluoride with the polyfluoroanions to yield a carbonium ion and smaller polyfluoroanions.

Conclusions

Ionization occurs in $SbCl_5$/SbF_5 mixtures in SO_2ClF, polyfluoroanions, $Sb_nF_{5n+1}^-$, and chlorine-containing cations ($SbCl_4^+$ and probably $SbCl_3F^+$ and $SbCl_2F_2^+$) being formed. Evidence for ionization in mixtures of the pentachloride and pentafluoride has been given previously (1), but the nature of the ionization was not established with certainty.

At low temperatures both SO_2Cl_2 and COClF form donor–acceptor adducts (through oxygen) with SbF_5 in SO_2ClF, but at higher temperatures, halogen exchange and ionization occur, producing SO_2ClF and COF_2 adducts, together with a mixture of antimony cations and polyfluoroanions. It is not clear whether the low temperature complexes are intermediates in the halogen exchange process.

Both arsenic and antimony pentafluorides form donor–acceptor complexes with carbonyl fluoride in SO_2ClF. In contrast to the reactions of many acyl fluorides with SbF_5 (11), no ionization occurs in these solutions even at room temperature.

A re-examination of the evidence relating to the reaction of alkyl chlorides with SbF_5 shows that reaction to be more complex than hitherto supposed. In addition to carbonium ions and polyfluoroanions of antimony, chloro- and chlorofluorocations are among the reaction products.

Experimental

Nuclear Magnetic Resonance Spectra

These were obtained as described in earlier work (4).

Materials

Sulfuryl chlorofluoride was prepared by the method of Seel and Riehl (12). This and SbF_5 were purified as described previously (4). Sulfuryl chloride (Eastman Organic Chemicals) and antimony pentachloride (J. T. Baker Chemical Co.) were purified by vacuum fractionation. Carbonyl chlorofluoride (Ozark-Mahoning Co.) was vacuum distilled twice before use; the purified material showed only one ^{19}F n.m.r. resonance. The carbonyl fluoride (Matheson of Canada Ltd.) showed only one ^{19}F n.m.r. signal and was used without purification.

Sample Preparation

The basic methods of sample preparation have been described in earlier papers (3–5). For SbF_5/$SbCl_5$/SO_2ClF, SbF_5/SO_2Cl_2/SO_2ClF, and SbF_5/COF_2/SO_2ClF, the antimony compounds were added from all glass syringes to suitably adapted n.m.r. tubes under an inert atmosphere. Sulfuryl chloride was transferred in preweighed amount using a standard vacuum line; known amounts of SO_2ClF and/or COF_2 were added to the samples by gaseous volume. SbF_5/COClF/SO_2ClF samples were prepared by a method directly analogous to that used previously (4) for SbF_5/*t*-BuF/SO_2ClF mixtures. Low temperature homogenization of samples was achieved by stirring or shaking, the temperature being maintained by use of a suitable slush bath.

We thank the National Research Council of Canada for generous financial assistance. One of us (J.B.) thanks the National Research Council of Canada for the award of a studentship.

Formation of Lower Nitro Alkanes by Vapor Phase Nitration of Cyclic Hydrocarbons

C. MATASA
IMNR Research Institute, Bucharest, Romania

AND

H. B. HASS
95 Fernwood Road, Summit, New Jersey

Received[1] July 17, 1969

Vapor-phase nitration of cyclohexane and cyclohexyl nitrite produces primary nitro alkanes, the yield of which decreases with decreasing number of carbon atoms. Both their structure and relative ratios of formation lead to the conclusion that they are formed from 1-pentyl radical, which in turn is formed from cyclohexoxyl radical. The intermediate phases are radical reactions already known from the vapor-phase oxidation of hydrocarbons.

La nitration en phase gazeuse du cyclohexane et du nitrite de cyclohexyle conduit à des nitroalcanes primaires avec des rendements qui diminuent lorsque le nombre d'atomes de carbone diminue. La structure et les quantités relatives de produits obtenus tendent à supposer que ces composés sont formés à partir du radical pentyle-1 qui proviendrait lui-même du radical hydroxycyclohexyle-1. Les phases intermédiaires seraient des réactions radicaliques déjà connues pour l'oxydation en phase gazeuse des hydrocarbures.

Canadian Journal of Chemistry, 49, 1284 (1971)

Introduction

The study of the formation of lower nitro alkanes produced by the nitration of a hydrocarbon (also called degradation nitro alkanes) is of interest from both theoretical and industrial point of view. It is well known that all the nitromethane and nitroethane now produced industrially are obtained by the nitration of propane. Different mechanisms have been proposed for the formation of these nitro derivatives by nitration of acyclic hydrocarbons under conditions where thermal cracking is avoided but none has been proved beyond doubt.

Omitting some mechanisms which have been previously rejected, *i.e.* the intermediate formation of alpha nitro acids (1), the oxidation or nitration of nitro derivatives initially formed, the addition of nitric acid to the hydrocarbon with the formation of a complex which is decomposed into nitro derivatives and alcohols (2), the following mechanisms are now considered as probable: (*A*) Breaking of the C—C bond of the hydrocarbon with simultaneous formation of two nitro derivatives (2)

$$R{-}CH_2{-}CH_3 + 2NO_2 \rightarrow R{-}CH_2{-}NO_2 + CH_3{-}NO_2$$

(*B*) Decomposition of alkyl nitrites with formation of nitric oxide and alkoxy radicals, the latter being decomposed to a lower alkyl radical and formaldehyde (3)

$$R{-}CH_2{-}CH_2\cdot + NO_2 \rightarrow R{-}CH_2{-}CH_2{-}ON{=}O$$
$$\xrightarrow{-NO} R{-}CH_2{-}CH_2O\cdot \rightarrow R{-}CH_2\cdot + CH_2O$$

(*C*) The intermediate formation of vicinal dinitro alkanes which react further to give aldehydes and lower nitro alkanes (4)

$$R{-}CH_2{-}CH_3 + 2NO_2 \rightarrow R{-}CHNO_2{-}CH_2NO_2 + 2HNO_2$$
$$R{-}CHNO_2{-}CH_2NO_2 \rightarrow R{-}CH{=}CHNO_2 + HNO_2$$
$$R{-}CH{=}CHNO_2 + H_2O \rightarrow RCHO + CH_3NO_2$$

The application of these mechanisms to the nitration of the branched or cyclic hydrocarbons can eliminate some possibilities. In fact, if for the linear hydrocarbons the formation of lower nitro alkanes can be explained by any of the foregoing mechanisms, for branched hydrocarbons, *e.g.* for neopentane, the two compounds which are identified, nitromethane and 2-nitro-2-methylpropane (5), lead to the *A* mechanism.[2]

The application of this mechanism to the nitration of cyclic hydrocarbons suggests the formation of α-ω-dinitro alkanes but these

[1]Revision received December 16, 1970.

[2]These products can also be explained, however, by mechanism *B* on the assumption that acetone rather than formaldehyde is the co-product (note added by Hass).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

products have not been previously identified. For a long time it was considered that during the nitration of cyclic hydrocarbons in vapor phase, no opening of the ring took place, the lower nitro alkanes were not formed. (2, 6). Hass has repeated this assertion in his nitration rules. However, the presence of lower nitro alkanes in the reaction products obtained by the nitration of cyclic hydrocarbons was subsequently reported by some researchers. Quilico and Fusco (8) first reported that a mixture of nitro alkanes was obtained by the nitration of cyclohexane. Later the formation of nitropentane and nitrobutane was reported from the same nitration by Yasui and Yamada (9). The explanation for this has not been stated precisely.

In the following we propose to present the mechanism by which these lower nitro derivatives are obtained. We have considered cyclohexane to be the most appropriate hydrocarbon for this purpose because of the equivalence of its carbon atoms and the absence of strain in the ring.

Experimental

Raw Materials

Cyclohexane

A 99.8% cyclohexane, obtained by vapor-phase hydrogenation of benzene, was subjected to refining by sulfuric acid, washing with aqueous alkali, and then rectified.

Nitric Acid

Fifty percent analytical grade HNO_3 was used.

Cyclohexyl Nitrite

A 98% pure product was obtained from 99.5% cyclohexanol following Hunter and Marriott (11). The characteristics of the product were D_4^{20}, 0.990; n_D^{20} = 1.4430.

The Apparatus

The apparatus used is shown in Fig. 1. During a first series of experiments, nitric acid and liquid cyclohexane were introduced into the reactor using pumps made of stainless steel (Cr 18%, Ni 9%, Mn 2%, Si 1%), provided with polytetrafluoroethylene diaphragms. To prevent thermal decomposition of nitric acid before entering the reactor, the feed pipe was provided with an air-cooled jacket. The air flowing through the jacket was used to homogenize the bath surrounding the reactor, composed of a eutectic mixture of KNO_3 and $NaNO_3$. After evaporation and preheating at 400 °C by means of a stainless steel coil, cyclohexane was introduced at the base of the reactor where it met the nitric acid. The reactor (12), in the form of a truncated cone of stainless steel, was provided at its base with several U-tubes forming a thermosiphon system necessary to heat the inner salt bath composed also of an equimolar mixture of KNO_3 and $NaNO_3$. These melted salts were injected into the free

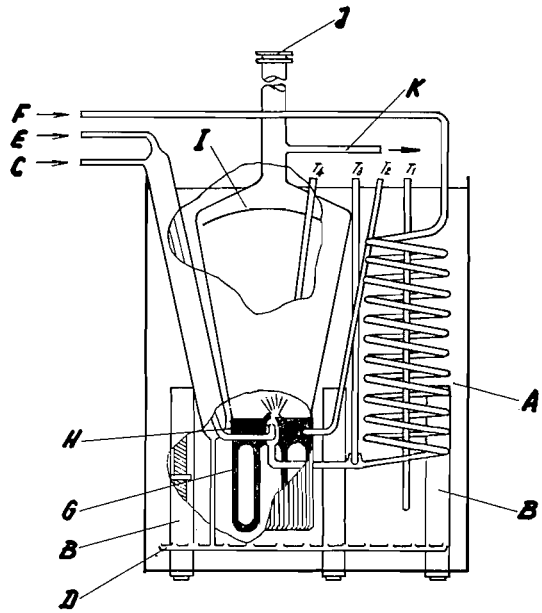

FIG. 1. The apparatus: *A*, molten salt thermostat; *B*, heating elements; *C*, air inlet for tube E cooling and molten salt agitation; *D*, perforated coil for air bubbling in the thermostat; *E*, nitric acid inlet; *F*, cyclohexane inlet; *G*, thermosiphon for heating molten salts; *H*, coaxial nozzles; *I*, baffles for separation of molten salt droplets; *J*, relief valve; *K*, outlet for reaction products.

space of the reactor through a concentric system of three nozzles. The first two were required for the cyclohexane and the nitric acid and the third for the salt.

The molten salt dispersion thus obtained acted as a heat transfer agent and, due to its wall effect, the oxidative chain reactions were greatly limited, at the same time having no effect on the nitration. The salts were then separated from the gases and returned on the wall to the thermosyphon system. The effluent gases were condensed and cooled to 5 °C by a brine condenser.

In a second series of experiments cyclohexyl nitrite was introduced together with nitric acid through the jacketed pipe. No cyclohexane was supplied.

(A) Cyclohexane Nitration

The nitration was carried out at 400 °C and atmospheric pressure; the reaction time was 1–1.1 s and the molar ratio cyclohexane/nitric acid was 2/1.

The condensate separated into two layers, the lower layer composed of water, some oxidation and nitration products, and a small quantity of nitric acid; the upper one composed of unreacted cyclohexane and the major part of the nitration and oxidation products. It was neutralized with a solution of 5% Na_2CO_3, washed and dried with anhydrous Na_2SO_4; the resulting solution of Na_2CO_3 and the aqueous layer were mixed together, adjusted to neutrality and extracted with ethyl ether. The residue obtained after distillation of the ether from the extract was added to the neutralized organic layer; the resulting mixture was extracted with a solution of

TABLE 1. Comparison of amounts of product of recovery

Product submitted to extraction with 10% NaOH solution	Acid used for recovery of nitro compounds	Refractive index of nitro compounds		Recovery, % by volume
		Before extraction	After extraction	
Pure nitrocyclohexane	10% H_2SO_4	1.4605	Impure	40–50
" "	95% CH_3COOH	1.4605	1.4603	96–97
" "	CO_2(gas)	1.4605	Nitrocyclohexane cannot be recovered	
90% Cyclohexane + 10% nitrocyclohexane	95% CH_3COOH		1.4600	95
Organic layer from cyclohexane nitration	95% CH_3COOH		1.4575–1.4535	96

10% $NaHCO_3$ to remove the fatty acids without solubilizing the nitro derivatives. The aqueous alkaline solution obtained as extract was subsequently extracted with ethyl ether; the ether layer was distilled and the residue added to the raffinate.

The organic mixture, freed from aliphatic acids, was then treated with a 10% aqueous solution of NaOH to convert the nitro derivatives to their salts, which were extracted in the aqueous layer. This was treated further with acetic acid to release the nitro derivatives; for a better separation NaCl was added. The tests performed showed a better recovery of nitrocyclohexane than those previously reported (over 95% *vs.* 74%) (14). An attempt to decompose the sodium salt of nitrocyclohexane with CO_2 did not succeed at atmospheric pressure. To the nitro derivatives thus obtained 1% boric acid was added, the mixture being subjected to a rectification at atmospheric pressure. The water and separate organic layer were continuously removed, the organic layer returned to the still and the aqueous layer extracted with ether to recover traces of organics which were added to the main part. The nitro compounds were distilled in an adiabatic column of the Podbielniak type having 10 theoretical plates. Nitromethane and nitroethane were distilled at atmospheric pressure, the higher homologs at 25 mm over nitrogen.

(B) Nitration of Cyclohexyl Nitrite

The nitration was carried out under the same conditions as for cyclohexane, the molar ratio of cyclohexyl nitrite to nitric acid being 2:1. The product was worked up in the manner already described.

Results

Table 1 presents a comparison of recovery obtained by extraction with NaOH and the subsequent treatment with acids of pure nitrocyclohexane, its synthetic mixtures and of the organic layers obtained by nitration. The following lower nitro alkanes were obtained by rectification of the nitration products of either cyclohexane or cyclohexyl nitrite: 1-nitropentane, 1-nitrobutane, 1-nitropropane, and nitroethane. Small quantities of nitromethane were found in the nitration product of cyclohexane.

Table 2 presents the relative weight range between the nitro alkanes obtained in both nitrations as well as their properties. In addition, a color identification was done with Meyer's reagent.

Discussion

The fact that primary nitro alkanes comprise almost the entire fraction of lower nitro alkanes obtained in the nitration of cyclohexane, and that the ratios of formation from two homologs are near halves for each decrease of one carbon atom (see Table 2) indicate that all these products are derived from 1-pentyl radical, initially formed by mechanism *B*.

The radical 1-pentyl can arise from the radical cyclohexoxyl, whose formation from cyclohexyl nitrite can readily be deduced.

This hypothesis is confirmed by the nitration of cyclohexyl nitrite in which both the identity and the ratios of lower nitro alkanes are the same as in the nitration of cyclohexane. Except for the mononitro alkanes already discussed,

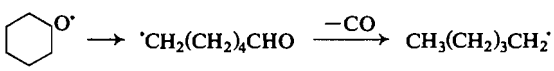
no other nitrogen-containing compounds were found in the distillate.

It is now possible to eliminate mechanisms *A* and *B* for the nitration of cyclohexane. The breakdown mechanism of the cycle can now be explained on the basis of literature on the vapor-phase oxidation of cyclohexane. The rupture of the ring of the cyclohexane radical with formation of 1-pentyl radical requires only 1.7 kcal/mol (15). The formation of 1-pentyl radical from cyclohexoxyl radical has already been described (16), the decomposition occurring through the intermediate formation of the radical shown.



Such intermediates are commonly formed in the decomposition of hydroperoxides. This decarbonylation can probably take place after an internal hydrogen abstraction, as in other cases described even for cyclohexane derivatives (15), studies which were carried out using labeled oxygen in the cyclohexane oxidation have shown that nearly all the carbon oxide formed results from carbonyl compounds (17).

Another route can be the oxidation of the cyclohexoxyl radical or of carboxylic intermediates, followed by a decarboxylation (as described by Tipper for lower alkyl radical formation in cyclopentane oxidation) (18). In the case of cyclohexane nitration this route seems less probable due to the relatively small quantities of carbon dioxide which can be formed. It is interesting to show that the preceding arguments are supported also by the nitration of other substances having weak bonds. In these cases the nitro alkanes which can be formed are principally the primary ones.

This fact is confirmed by the results obtained by Hass and Hudgin (19) in the nitration of *n*-butyl ether. Both the structure of the nitro alkanes formed and their relative ratios show that the 1-butyl radical was initially formed.

The traces of secondary nitropentane which were found in the reaction mixture can arise from a vapor-phase isomerization of the 1-pentyl radical.

Examination of the foregoing data shows that for vapor-phase nitration of cyclo alkanes the formation of lower nitro alkanes can be explained by mechanism *B*, with the aid of certain radical reactions already known from oxidation studies.

Infrared and Raman Spectroscopic Studies of Solid Alkali Metal Nitrites

M. H. BROOKER[1] AND D. E. IRISH
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received July 2, 1970

Infrared and Raman spectra of solid $LiNO_2.H_2O$, $LiNO_2$, $NaNO_2$, KNO_2, and $CsNO_2$ are presented and discussed. Pronounced changes in the spectra of $LiNO_2.H_2O$ during dehydration to anhydrous $LiNO_2$ are interpreted as evidence for an ordered distribution of NO_2^- ions over two non-equivalent sites (akin to linkage isomerism) in anhydrous $LiNO_2$. The frequencies of the internal modes of the nitrite ion shift to lower values with increasing cation size. Vibrational bands due to nitrate ion present as an impurity are assigned.

Les spectres infrarouge et Raman des $LiNO_2.H_2O$, $LiNO_2$, $NaNO_2$, KNO_2 et $CsNO_2$ sont présentés et discutés. Les changements prononcés qui se produisent dans les spectres pendant la déshydratation du sel $LiNO_2.H_2O$ à $LiNO_2$ sont interprétés comme preuve d'une distribution ordonnée des ions NO_2^- sur deux sites non équivalents (véritable isomérisme de liaison) dans le sel anhydre $LiNO_2$. Les fréquences des modes internes de l'ion nitrite sont abaissées lorsque la dimension du cation augmente. Les bandes vibrationnelles dues à l'ion nitrate présent comme impureté sont assignées.

Canadian Journal of Chemistry, 49, 1289 (1971)

Introduction

An interest in the vibrational spectra of concentrated electrolyte solutions and in N—O vibrations of ions similar to nitrate (1) has recently caused us to focus attention on metal nitrites, many of which are extremely water soluble. When interpreting data for concentrated solutions and melts, knowledge about the probe ion in static, cationic environments is an asset. Although $NaNO_2$ has been extensively studied and KNO_2 to a lesser extent (2–17), no systematic comparison including other alkali metal nitrites has been reported. In this study Raman spectra and multiple internal reflectance (m.i.r.) infrared spectra of powders have been obtained. The m.i.r. technique is particularly useful for disclosing features of intense absorption bands, the positions of which are not distorted by contributions from longitudinal optical (l.o.) modes or Christiansen filter effects (18). An interesting consequence of this study has been the observation of spectral changes on dehydration of the lithium nitrite monohydrate which can be attributed to a reorientation of nitrite ions into an ordered distribution over two non-equivalent orientations in the coordination sphere of the lithium (linkage isomerism).

The nitrites of lithium, potassium, and caesium are extremely hygroscopic. Lithium nitrite crystallizes from aqueous solution as a monohydrate which may be dehydrated at 110 °C but is reported to decompose at 200 °C before melting at 225 °C (19). The solid potassium and caesium nitrites take the form of unmanageable plastics with variable amounts of water; however, definite hydrates of these salts are not known (19, 20). Sodium nitrite, on the other hand, forms well defined single crystals. The discovery by Strijk and MacGillavry (21) of the ferroelectric phase transition in $NaNO_2$ prompted considerable infrared (12–15) and Raman (16, 17) spectral studies, most of which have been performed on single crystals and concerned with various phenomena associated with order–disorder ferroelectrics.

An important consideration prior to the measurement of the physical properties of nitrites must be sample purity. The assay of commercial reagent grade KNO_2 varies from 89 to 97% nitrite; even $NaNO_2$ seldom exceeds 98% minimum nitrite assay. Usual impurities are H_2O, OH^-, Cl^-, CO_3^{2-}, and NO_3^-; of these the NO_3^- is most serious. Potassium nitrite is known to form a solid solution with NO_3^- and consequently is extremely difficult to purify (19, 22, 23). In infrared studies of nitrite-doped alkali halides, vibrational bands due to NO_3^- were also observed (9–11). Kato and Rolfe (9) reported inability to obtain an infrared spectrum of NO_2^- in an alkali halide pellet without also observing vibrational bands due to NO_3^-. Sato *et al.* (12) observed the ν_2 vibration of NO_3^- *ca.* 840 cm^{-1} in the infrared spectrum of single crystal $NaNO_2$.

In a recent publication (23), bands present in the spectrum of KNO_2 which previously had

*The Raman intensity ratio of bands at 810 and 829 cm^{-1} is within experimental error of the predicted ratio 0.00413 on the basis of natural isotopic abundance of ^{18}O. Abbreviations: s, strong; m, medium; w, weak; sp, sharp; br, broad; sh, shoulder; v, very.

been incorrectly attributed to the NO_2^- ion perturbed by ionic interactions were reassigned to NO_3^- present as an impurity. Infrared and Raman methods of analyses for small amounts of NO_3^- in NO_2^- were advanced. Evidence for NO_3^- impurity in nitrite complexes has also been reported (24). Vibrational bands due to NO_2^- are thus assigned with full knowledge of NO_3^- impurity.

Experimental

Chemicals used were all high purity reagent grade. KNO_2 and $NaNO_2$ were Baker and Adamson 95 and 98% minimum nitrite assay, respectively. $Ba(NO_2)_2$ was supplied by Alfa Chemicals and listed at 97–99% nitrite assay. British Drug House reagent grade K_2SO_4, Cs_2SO_4, and AnalaR Li_2SO_4 were used as received. $NaNO_2$ and $Ba(NO_2)_2$ were recrystallized from aqueous solution. KNO_2 was purified by the ion exchange method of Ray (20), using Dowex 3-X8, 50–100 mesh anion exchange resin. Pure KNO_2 was also prepared by stoichiometric addition of K_2SO_4 to $Ba(NO_2)_2$ followed by filtration to remove insoluble $BaSO_4$. $LiNO_2$ and $CsNO_2$ were prepared in a similar manner from Li_2SO_4 and Cs_2SO_4. The potassium, lithium, and caesium salts were subsequently recrystallized from aqueous solution. The lithium salt crystallizes as the stable monohydrate, $LiNO_2.H_2O$. Anhydrous $LiNO_2$ was obtained by carefully drying the hydrate in the oven at 110 °C. Reconversion to the hydrate occurred slowly if the sample was left open to the atmosphere. The removal of 1 mol of water was confirmed by weight loss. $LiNO_2$, $NaNO_2$, KNO_2, and $CsNO_2$ were dried and stored in an oven at 110 °C. $LiNO_2.H_2O$ was used as recrystallized from aqueous solution. Analyses for nitrate by methods described previously (23) gave NO_3^- to NO_2^- ion ratios of 0.0054, 0.0031, 0.001, and 0.0002 for $CsNO_2$, $LiNO_2$, KNO_2, and $NaNO_2$, respectively. The solid powders except for $LiNO_2.H_2O$ were loaded into the sampling devices while still in the oven, sealed and allowed to cool in a desiccator over P_2O_5.

Raman spectra, excited by the 4358 Å mercury line of a "Toronto" lamp were obtained from powdered samples in a thermostated (25 °C) conical cell sealed from the atmosphere and were recorded on a Cary 81 spectrophotometer as described previously (25). Raman spectra from powders in a sealed capillary tube, excited by the 4880 Å line of the Spectra Physics 141 Argon ion laser, were recorded on the Jarrell-Ash model 25-300 Raman spectrometer. Frequency agreement between the two methods was excellent. Spectra recorded on the Jarrell-Ash instrument were obtained at the ambient temperature of the sample compartment (25 °C). Similarities between spectra recorded by both methods indicate no evidence of heating or decomposition of the samples by the laser beam. Further, the invariance of the relative intensities of nitrate and nitrite bands indicates that the samples were stable even in the laser beam. Spectra recorded on the Jarrell-Ash instrument were superior in quality. Vibrational bands of low intensity were only detected by the laser Raman method.

Infrared spectra were obtained from powdered solids pressed against the surface of a KRS-5 prism cut with a face angle of 60° and placed in the Wilks-model 9 m.i.r. attachment. Multiple internal reflectance spectra were recorded with a Beckman IR-9 operated at 3 times the "standard" program slits. The double beam mode was employed with some reference beam attenuation. Infrared spectra were recorded at the temperature of the infrared beam *ca.* 30 °C. The sample compartment of the IR-9 was purged with dry air and desiccated with P_2O_5. The extreme weakness of the water vapor bands *ca.* 1600 cm^{-1} attested to the dryness of the sample compartment. Infrared spectra were also recorded of Nujol mulls of $LiNO_2.H_2O$, anhydrous $LiNO_2$, and solids at intermediate stages of dehydration as well as for the other nitrites. Frequencies obtained by the two different infrared methods were identical in the 800–900 cm^{-1} region. In the 1200–1500 cm^{-1} region, bands due to the mulling agents complicated the infrared spectra and caused considerable uncertainty in the nitrite frequencies. The frequencies measured by m.i.r. methods are reported for this region since they are more reliable. The uncertainties for the reported infrared and Raman frequencies are expected to be ± 1 cm^{-1} for sharp peaks (ν_1 and ν_2) and ± 5 cm^{-1} for broad bands (ν_3).

Results

Infrared m.i.r. spectra of the solid alkali metal nitrites are shown in Fig. 1. A portion of the Raman spectrum of $NaNO_2$ is shown in Fig. 2. Portions of the infrared and Raman spectra of $LiNO_2.H_2O$, $LiNO_2$, and a partially dehydrated

sample of the salt are also shown (Fig. 3). Vibrational frequencies are collected in Tables 1 and 2. Except for anhydrous $LiNO_2$, the internal vibrations of the nitrite ion give rise to only three nearly coincident infrared and Raman bands.

Vibrational frequencies shift to lower values with increasing cation mass (Tables 1, 2). The symmetric stretching vibration $\nu_1(A_1)$, *ca.* 1330 cm^{-1}, is intense and polarized (*e.g.* see refs. 5, 16, 17, 23) in the Raman spectrum; it is weak in the infrared spectrum. The antisymmetric stretching vibration $\nu_3(B_2)$, *ca.* 1230 cm^{-1}, exhibits strong infrared absorbance but in the Raman spectrum the intensity is low. In the infrared spectra ν_3 absorbs strongly and masks ν_1 in the spectra of KNO_2 and $CsNO_2$ (Fig. 1). Dehydration of $LiNO_2.H_2O$ is accompanied by intensity decrease for bands at 1710, 1310, 857, 134, and 92 cm^{-1}, and intensity increase for bands at 1360, 1273, 872, 842, 335, 310, 170, and 86 cm^{-1} while bands at 1352, 126, and 70 cm^{-1} appear relatively constant (Fig. 3, Table 1). The dehydration process and the spectroscopic manifestations were observed to be reversible even after several dehydrations and no decomposition of nitrite was apparent.

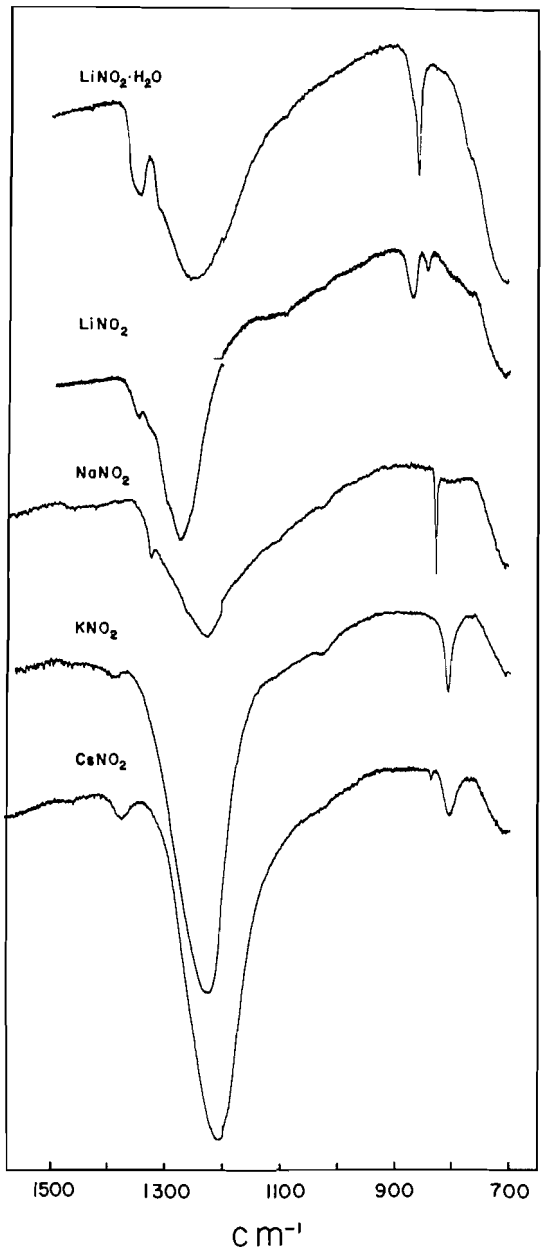

FIG. 1. Photographs of m.i.r. infrared spectra obtained from powdered-solid phase $LiNO_2.H_2O$, $LiNO_2$, $NaNO_2$, KNO_2, and $CsNO_2$.

Discussion

Weak bands *ca.* 835 and 1380 cm^{-1} in the infrared spectra and *ca.* 1050 cm^{-1} in the Raman spectra are due to the $\nu_2(A_2'')$, $\nu_3(E')$, and $\nu_1(A_1')$ modes, respectively, of NO_3^- present as an impurity (23). The frequencies are similar to but not exactly those found for the solid alkali metal nitrates (25, 26). Band intensities are in agreement with the known NO_3^- concentration in the alkali metal nitrite salt. It is possible that NO_3^- contributes to the band *ca.* 1350 cm^{-1} in the infrared spectrum of the lithium salts but it is extremely unlikely to be sole cause of this band. Note that a comparison of spectra of the lithium salts to the caesium salt (Fig. 1) provides a way to estimate the intensity of the NO_3^- band in $LiNO_2$.

The data for Na, K, and Cs nitrites are collected in Table 1 for comparison purposes. Assignments for $NaNO_2$ have previously been made (15, 17). Since the crystal is orthorhombic, space group C_{2v}^{20}–Im_2m_1 with two molecules per unit cell but one molecule per primitive cell (27–30) and since the nitrite ion is on a C_{2v} site, factor group analysis predicts three internal modes $2A_1(I,R) + B_2(I,R)$ and six external modes $A_1(I,R)$, $A_2(R)$, $2B_1(I,R)$, $2B_2(I,R)$. In the absence of crystal data to support any major departure from this analysis for K and Cs nitrites, the internal mode assignments (which are also the "free" ion assignments) are adopted for all

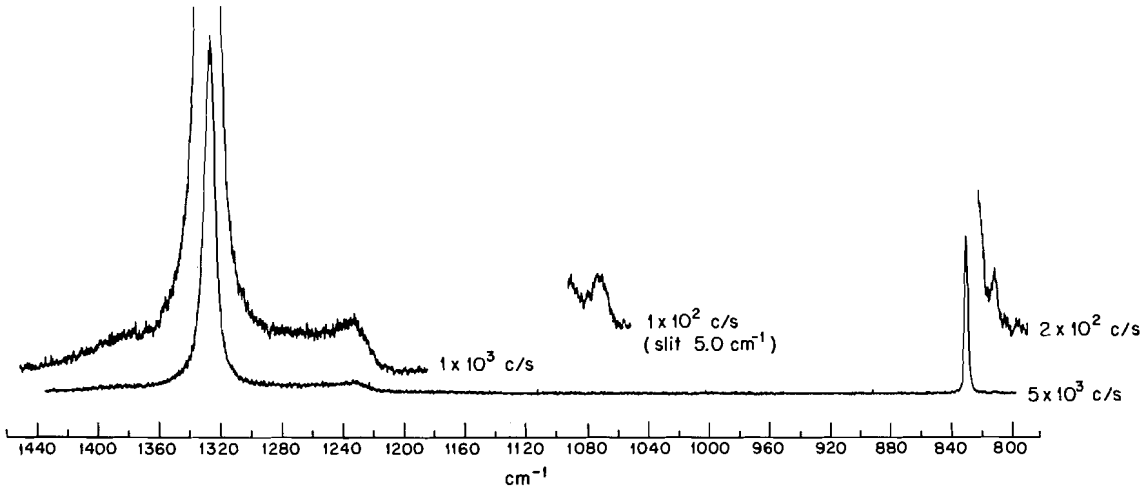

FIG. 2. A portion of the Raman spectrum of $NaNO_2$ obtained on the Jarrel-Ash model 25-300 Raman spectrometer after excitation with the 4880 Å Argon ion line. Slit width 2.0 cm^{-1} except where noted. Weak bands at *ca.* 810 and 1050 cm^{-1} are due to $^{14}N^{16}O^{18}O^-$ and NO_3^-, respectively.

the crystals except $LiNO_2$. The external modes of $NaNO_2$ observed in this work reproduce those in the literature; they are 122 (vs, sp), 155 (m), 164 (sh), 186 (w), and 222 (w). One point arising from the $NaNO_2$ study bears emphasis. The $\nu_3(B_2)$ mode is very broad in the Raman, peaking at 1232 cm^{-1} and extending to *ca.* 1360 cm^{-1} (Fig. 2). Tramer (5) and Tsuboi *et al.* (17) have observed that Raman frequency shifts for this band depend on the orientation of the single crystal. These authors proposed that the effect was due to the presence of a transverse optical mode (t.o.) at 1230 cm^{-1} and a longitudinal optical mode (l.o.) at 1360 cm^{-1}, in agreement with infrared reflectance studies (15). The true infrared absorption frequency corresponding to a normal mode of vibration is considered to be the frequency of the t.o. maximum, which is usually measured by thin film transmission techniques for which the l.o. mode is theoretically inactive (31). It has been recently shown (18) that the m.i.r. technique also provides a spectrum in which the activity of the l.o. mode is either absent or so low that it has no effect on the frequency of the band

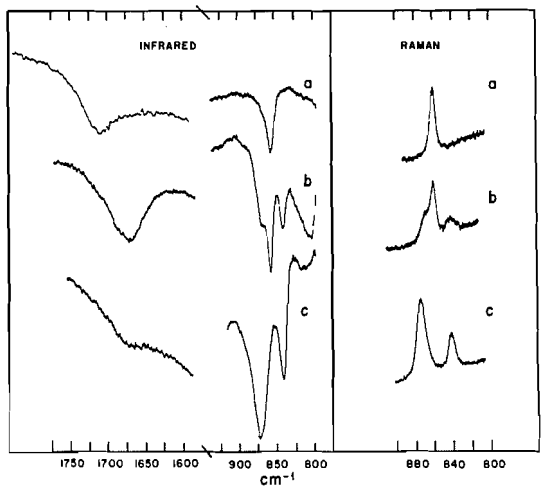

FIG. 3. Photographs of portions of infrared and Raman spectra of $LiNO_2.H_2O$ at various stages of dehydration: (*a*) $LiNO_2.H_2O$; (*b*) $LiNO_2.H_2O$ partially dehydrated; (*c*) $LiNO_2$ anhydrous. Infrared spectra were recorded as Nujol mulls between AgBr plates. Raman spectra were recorded on the Jarrel-Ash model 25-300 Raman spectrometer after excitation with the 4880 Å Argon ion line.

maximum, which corresponds identically to the t.o. frequency, provided $\theta \gg \theta_c$. The same cannot be said for single internal reflectance studies, specular reflection, or regular transmission studies when the incident radiation has non-normal incidence on a sample surface (31). This point is illustrated by the data for $NaNO_2$. Our m.i.r. frequency for ν_3 is $1230 \pm 5\ cm^{-1}$, identical to the t.o. frequencies independently determined by specular reflection (15) and Raman techniques (5, 17).

Zeigler (32) reported a face-centered monoclinic crystal for KNO_2 similar to $NaNO_2$ with space group C_s^3 and NO_2^- on a C_s site. However, Tanisaki and Ishimatsu (33) recently reported a trigonal structure for KNO_2. The latter authors concluded from the absence of superlattice reflections that there was a disordered arrangement of NO_2 groups. The absence of any lattice vibrations in the Raman spectrum of KNO_2 (Table 1) would be in accord with large-scale disorder in solid KNO_2. We have found that KNO_2 does not produce well formed crystals but acts rather as an unmanageable plastic. $CsNO_2$ resembles KNO_2 in physical appearance and properties. Crystallographic data for $CsNO_2$ are inconclusive. Ferrari *et al.* (20) reported that $CsNO_2$ forms a body-centered cube but lack of a sufficient number of reflections prevented determination of atomic positions. Raman and infrared spectra for KNO_2 and $CsNO_2$ are very similar (Fig. 1) (Table 1). Since no lattice bands can be found in the Raman spectrum of $CsNO_2$, it would appear that $CsNO_2$ also has a disordered crystal structure. It would be interesting to know if the apparent disorder in KNO_2 and $CsNO_2$ crystals is impurity induced or a real property of the room temperature crystal phase. However, the preparation of ultra-pure KNO_2 and $CsNO_2$ appears to be a formidable task.

Significant frequency discrepancies between the infrared and Raman frequencies for the ν_3 peaks (Table 1) are difficult to rationalize. It is possible that contributions from the l.o. component of ν_3 have shifted the Raman peak to higher frequencies. Weston and Brodasky (4) reported striking changes in the appearance of the ν_3 infrared peak which depended on the mulling procedure employed. Spectral variations of this type can be caused by contributions from the l.o. mode which becomes active when the incident beam propagates in an orientation other than parallel to the optic axis (31). Failure to observe similar effects in our m.i.r. spectra further support our claim that l.o. contributions are minimal.

Zeigler (32) reported that $LiNO_2.H_2O$ crystallized in a pseudo-orthorhombic monoclinic cell with 4 molecules per unit cell. The complete crystal structure was never determined. No crystallographic structural evidence exists for $LiNO_2$.

Appearance of the band at *ca.* $842\ cm^{-1}$ in the infrared spectrum of anhydrous $LiNO_2$ (Figs. 1, 3) was first suspected to be due to the $\nu_2(A_2'')$ nitrate vibration, but this explanation was ruled out for several reasons. The bands at 842 and $872\ cm^{-1}$ are both infrared and Raman active; if the band at $842\ cm^{-1}$ was $\nu_2(A_2'')$ of nitrate, it would not be Raman active (25, 26). The intensity ratio of bands at 842 and $872\ cm^{-1}$ is similar in both Raman and infrared and is much too large (on the basis of NO_3^- analysis above) for the band at $842\ cm^{-1}$ to be due to nitrate impurity. Finally, in the infrared spectrum of $LiNO_2.H_2O$ no band is visible at *ca.* $840\ cm^{-1}$ (Figs. 1, 3).

Dehydration of $LiNO_2.H_2O$ produces significant changes in the nitrite bending region at *ca.* $850\ cm^{-1}$ (Fig. 3). On conversion of $LiNO_2.H_2O$ to the anhydrous form, the bands at *ca.* 842 and $872\ cm^{-1}$ increase together at the same rate and at the expense of the band at $857\ cm^{-1}$.

A band at *ca.* 1700 cm^{-1} assigned to the bending mode of the water of hydration decreases in both frequency and relative absorbance as the sample is dehydrated. The loss of weight on dehydration of $LiNO_2.H_2O$ corresponds to the loss of 1 mol of water.

A nondegenerate vibration may be split in two ways, each of which requires more than one molecule per primitive cell. (*a*) Coupling between identical normal modes of vibration of molecules in the unit cell gives rise to correlation field splitting (34, 35). (*b*) The ordered distribution of molecules over sets of non-equivalent sites will give rise to a number of bands equal to the number of distinct sites occupied. Correlation field splittings are typically of the order of 5 cm^{-1} except for normal modes with very large dipole derivatives (34, 35). The 30 cm^{-1} separation between the two bands in the ν_2 region of $LiNO_2$ is considered too large to be due to correlation field splitting. On the other hand, the presence of two distinct sites will result in a pair of bands with separation that depends on the dissimilarity of the static fields at the occupied sites. In certain nitrate crystals where the nitrate ion is known to occupy two distinct sites, pairs of bands separated by 15 to 30 cm^{-1} have been observed in regions of the nondegenerate vibrations and interpreted in terms of a two site effect (36–38).

In studies of inorganic nitrite complexes, Goodgame and Hitchman (39) and Hathaway and Slade (40) have assigned bands above 860 cm^{-1} to ONO type vibrations of either a nitrito linkage or a bridged ligand. The presence of both low and high frequency vibrations in the deformation region has been used by these authors as a criterion for two types of nitrite bonding. The low frequency bands are attributed to nitro (bonding through nitrogen); whereas, the high frequency bands arise from nitrito (bonding through oxygen) linkages. In anhydrous lithium nitrite, it appears that two different environments are available to the nitrite ion. Different sites can be created by an asymmetric arrangement of nitrite ions about the lithium ions. From infrared and Raman intensity considerations, it appears that the site responsible for the band at 872 cm^{-1} is twice as plentiful as the one responsible for the 842 cm^{-1} band. One could argue that nitrito linkages are twice as plentiful as nitro. The nitrite is probably not specifically linked or bonded to the lithium. The nitrito, nitro terminology is used merely to suggest that the band at 872 cm^{-1} is associated with a nitrite site with short Li—O distances; whereas the band at 842 cm^{-1} is associated with a nitrite site with short Li—N distances. If a strongly covalent nitrito linkage was actually present (as in nitrito complexes of cobalt), one would anticipate a decrease in the symmetric stretching frequency (41–43); in fact, the symmetric stretching frequency does not shift. In the hydrate, only one band is present in the deformation region which would indicate that the nitrite ions lie on a single site.

The infrared and Raman spectra of $LiNO_2.H_2O$ and $LiNO_2$ differ in many respects other than those discussed above (Table 2). Changes in the lattice region are difficult to explain without a more detailed study of a single crystal. A shoulder *ca.* 1360 cm^{-1} on the ν_1 vibration in the Raman spectrum of $LiNO_2$ may reflect a doubling of the symmetric stretching vibration for reasons analogous to those discussed for the deformation region but this region is very complicated (*cf.* ref. 24).

Occasionally it was possible to detect a weak band in the 800 cm^{-1} region approximately 20 cm^{-1} removed from the ν_2 nitrite ion fundamental (Fig. 2, Table 1). This band may be due to either isotopic species $^{15}N^{16}O_2^-$ or $^{14}N^{16}O^{18}O^-$; expected intensity ratios based on natural isotopic abundances are 0.00366 and 0.00413, respectively. Sato *et al.* (12) assigned a band at $\sim(\nu_2 - 20)$ cm^{-1} in the $NaNO_2$ spectrum to the $^{15}N^{16}O_2^-$ species; however, ^{15}N isotopic substitution studies (2, 4, 9) have firmly established that the ν_2 mode of NO_2^- shifts only 5 cm^{-1} on ^{15}N substitution. Kato and Rolfe (9) have assigned a band at $(\nu_2 - 21)$ cm^{-1} to the $^{14}N^{16}O^{18}O^-$ species. There can be little doubt that this latter assignment is correct.

NOTES

Mass Spectra of the Hydroxyindole-3-carboxylic Acids and the Hydroxyskatoles[1,2]

ROSANGELA MARCHELLI,[3] W. D. JAMIESON, S. H. SAFE, O. HUTZINGER, AND R. A. HEACOCK
Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received November 4, 1970

The electron impact fragmentations of the 4-, 5-, 6-, and 7-hydroxyskatoles and the 4-, 5-, 6-, and 7-hydroxyindole-3-carboxylic acids have been studied. The spectra of the four isomeric hydroxyskatoles are virtually indistinguishable, due to substituent randomization of the [M] and [M-1] ions. In the case of the hydroxyindole-3-carboxylic acids, loss of H_2O from the molecular ion is characteristic of the 4-isomer but initial loss of $\cdot OH$ from the molecular ion is the most important reaction of the other three isomers.

On a étudié la fragmentation sous l'impact d'électrons, des hydroxy-4, -5, -6, ou -7 skatoles et des acides hydroxy-4, -5, -6, ou -7 indolecarboxyliques-3. Les spectres des quatre hydroxyskatoles isomériques sont virtuellement indiscernables du à la randonisation des substituants dans les ions [M] et [M-1]. Dans le cas des acides hydroxyindolecarboxyliques-3, la perte d'eau est caractéristique de l'isomère 4 mais une perte initiale de $\cdot OH$ de la part de l'ion moléculaire est la réaction principale pour ces trois autres isomères.

Canadian Journal of Chemistry, 49, 1296 (1971)

The electron impact-induced fragmentations of indoles, substituted indoles (1–11), and oxindoles (12–14) have been extensively investigated. Marx and Djerassi (15) have shown that with [1-^{13}C]-*N*-methylindole considerable skeletal rearrangement involving the exocyclic methyl group occurs prior to formation of the [M-(H + HCN)] ion. Similar observations using deuterated oxindoles (12–14) also indicate considerable H/D randomization.

In the present study the mass spectra of several biologically important isomeric hydroxyskatoles and hydroxyindole-3-carboxylic acids have been investigated to determine if differences in their mass spectra would be useful for identification purposes and to study their respective fragmentation pathways.

4-, 5-, 6-, and 7-Hydroxyskatoles

The mass spectrum (Fig. 1) and fragmentation pattern (Scheme 1) for 4-hydroxyskatole are shown and are remarkably similar to the data obtained from the 5-, 6-, and 7-isomers. The constancy of the relative abundance of the [M], [M-H], [M-H-28], and [M-H-29] species (Table 1) shows that the differences in the primary ion spectra are small. One exception being that for the 7-isomer a slightly more intense [M-H-18] ion is observed. Inspection of the high resolution spectra confirmed that for all four isomers the reaction *m/e* 146 → 118 is primarily due to expulsion of CO (80–95%) rather than $H_2CN\cdot$ (5–20%), a fragment commonly lost in the breakdown of indoles (*cf.* ref. 6).

Using the kinetic approach (*cf.* refs. 16–18) it was of interest to compare ["metastable" ion]/[daughter ion] ratios for the *m/e* 147 $\xrightarrow{-H\cdot}$ 146 and 146 $\xrightarrow{-CO}$ 118 reactions of the isomeric hydroxyskatoles (Table 1). Strong "metastable" ions at *m/e* 145.0 (m_1*) and 95.4 (m_2*) respectively are observed for the above reactions in all four isomeric hydroxyskatoles; moreover the [m_1*]/[*m/e* 146] and [m_2*]/[*m/e* 118] ratios are all similar. The results indicate that under electron impact the molecular ions and [M-1] ions for the 4-, 5-, 6-, and 7-hydroxyskatoles have similar energy distributions which suggests substituent randomization in these ions. These results indicate why the spectra of the isomers are virtually indistinguishable.

The extent and mechanism of substituent randomization has not been ascertained since the mechanism of carbon and hydrogen scram-

bling in aromatic systems is not yet fully established (*cf.* ref. 19).

4-, 5-, 6-, and 7-Hydroxyindole-3-carboxylic Acids

The mass spectral fragmentation patterns of the isomeric hydroxyindole-3-carboxylic acids are more complex than those of the corresponding hydroxyskatoles. The spectra of the 5-, 6-, and 7-isomers are similar to each other (*e.g.* 5-isomer, Fig. 2), except that for the 5-isomer the *m/e* 133 ion (100%) is much more intense than the same ion in the 6- (20%) and 7- (8%) isomers. Thermal decarboxylation of the hydroxyindole-3-carboxylic acids, prior to ionization, is probably an important factor here. The fragmentation patterns (Scheme 2) for the 5-, 6-, and 7-isomers show two main pathways featuring initial loss of ·OH and decarboxylation. The reaction *m/e* 177 $\xrightarrow{-OH\cdot}$ 160 yields an intense "metastable" ion at *m/e* 144.7 (m_3*) and the [m_3*]/[*m/e* 160] ratios for the 5-, 6-, and 7-isomers are identical (1.4×10^{-3}). As with the skatole derivatives the kinetic approach for the above reaction suggests substituent randomiza-

tion has occurred because the molecular ions of the 5-, 6-, and 7-isomers have similar internal energies and energy distributions.

The mass spectrum (Fig. 3) and breakdown pattern (Scheme 3) of 4-hydroxyindole-3-carboxylic acid are in contrast to those of the other isomers. As a result of the 3,4-peri-interaction between the carboxyl and hydroxy substituents the initial loss of ·OH is entirely suppressed by the formation of an $[M\text{-}H_2O]$ ion. Thus with the mass spectra of the isomeric hydroxyindole-3-carboxylic acids only that of the 4-isomer is significantly different to the others due to the above-mentioned peri-interaction. In the case of the hydroxyskatoles, the methyl group, in place of the carboxyl group in the 3-position, prevents this interaction with the result that the mass spectra of the isomeric hydroxyskatoles are virtually indistinguishable. In the case of the hydroxyindole-3-carboxylic acids however, high resolution measurement of the ions at *m/e* 104, 105, and 106 indicated that the components of these doublets varied in relative abundance and that this depended on the isomer (see Table 2). Also an unusually abundant doubly charged ion at $[M\text{-}H_2O]$ was present in the spectrum of the 7-isomer. This information allows differentiation

TABLE 2. Nature and relative abundance of some doublet ions

Ion		Isomer*			
m/e	Formula	4-	5-	6-	7-
106	C_7H_6O	—	4	S	1

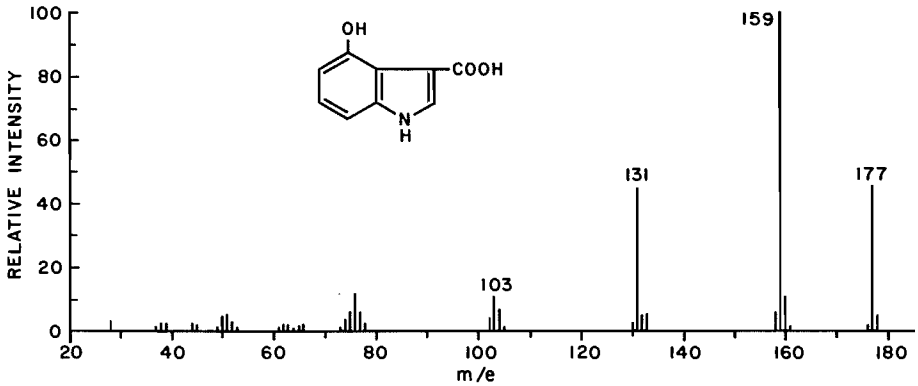

FIG. 3. Mass spectrum of 4-hydroxyindole-3-carboxylic acid.

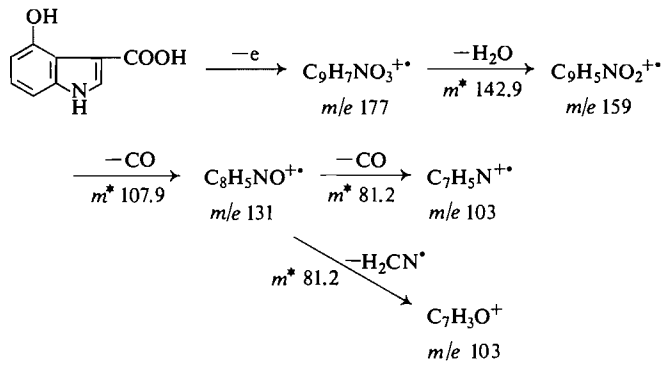

SCHEME 3

of these isomers. The above results indicate some of the difficulties in the way of structural identification of isomeric hydroxyindoles by mass spectrometry.

Experimental

Materials

The hydroxyindole-3-carboxylic acids (20) and hydroxyskatoles (21) were prepared by methods described in the literature.

Methods

Mass spectral data were obtained with a Dupont/CEC 21-110B double-focussing instrument equipped with an electron-impact ion source and fitted to record data either by photoplate (Ilford Q2 emulsion) or electrical detection.

The 70 eV spectra of the 4-, 5-, 6-, and 7-hydroxyindole-3-carboxylic acids were recorded at ionization chamber temperatures of: 4-, 203°; 5-, 196; 6-, 236; 7-, 223. The 70 eV mass spectra of the 4-, 5-, 6-, and 7-hydroxyskatoles were recorded with sample temperatures in the range 50–66° and block temperatures in the range 153–157°.

The authors wish to thank D. J. Embree, who recorded the mass spectra.

An Aspect of the Scope of the Phosphonic Acid Bis Amide – Carbonyl Method in the Synthesis of Exocyclic Olefins

J. BRYAN JONES AND PETER W. MARR
Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received November 16, 1970

The synthesis of cyclohexylidene derivatives by condensation of α-lithiocyclohexylphosphonic acid bis(dimethylamide) with some carbonyl compounds has been studied. The desired olefin was obtained when the carbonyl moiety was an aldehyde but, probably for steric reasons, not when ketones were used.

On a étudié la synthèse de cyclohexylidènes substitués obtenus par condensation de composés carbonylés avec la bis(diméthylamide) de l'acide α-lithiocyclohexylphosphonique. Les oléfines désirées peuvent être obtenues lorsque le composé carbonylé est de nature aldéhydique; toutefois les composés attendus ne sont pas obtenus, probablement pour des raisons stériques, lors des essais de condensation de cétones.

Canadian Journal of Chemistry, 49, 1300 (1971)

During the course of some studies on non-steroidal potential androgens the need arose for olefin intermediates of the general structure **1**. Tetrasubstituted olefins of this type are not easily prepared and routes involving elimination reactions (1) were not considered suitable for steroid-like polycyclic compounds owing to the probability of double bond migration (2) under the vigorous reaction conditions required. Attention was therefore concentrated on the possibility of preparing the series of compounds **1** by condensation of the appropriate Wittig or related reagent with cyclohexanones.

Although the Wittig reaction has been used successfully to effect the preparation of alkylidene alkanes (3) attempts to condense cyclohexylidenetriphenylphosphorane with cyclohexanone did not produce any of the required olefin **1**, R = H.[1] The related phosphonamide route to tetrasubstituted and other recently described olefins (4, 5) was also evaluated. The required cyclohexylphosphonic acid bis(dimethylamide) starting material was prepared but disappointingly its α-lithioderivative **2** and cyclohexanone could not be induced to react to give any cyclohexylidenecyclohexane (**1**, R = H).[1]

The use of carbocyclic phosphonamide derivatives, such as **2**, in olefin synthesis has not previously been reported and it was recognized that steric factors might be interfering with the formation of the intermediate β-hydroxyphosphonamide adducts.[2] Accordingly a limited study on the scope and limitations of the cyclohexylphosphonamide reagent **2** in olefin synthesis was carried out.

The results obtained, which are generalized in Scheme 1, show that reactions of **2** with alde-

[1]The g.l.c. analysis of the reaction mixture prior to working-up showed only the presence of unchanged starting materials.

[2]That α-lithioisopropylphosphonic acid bis(dimethylamide), for which qualitatively similar steric factors obtain, reacted readily with benzophenone (4) was confirmed by repeating the literature experiment. However, condensation of the lithioisopropylphosphonamide with cyclohexanone did not go well and a 17% (by g.l.c., 15% isolated) yield only of isopropylidenecyclohexane was obtained.

Les oléfines désirées peuvent être obtenues lorsque le composé carbonylé est de nature aldéhydique; toutefois les composés attendus ne sont pas obtenus, probablement pour des raisons stériques, lors des essais de condensation de cétones.

Canadian Journal of Chemistry, 49, 1300 (1971)

During the course of some studies on non-steroidal potential androgens the need arose for olefin intermediates of the general structure **1**. Tetrasubstituted olefins of this type are not easily prepared and routes involving elimination reactions (1) were not considered suitable for steroid-like polycyclic compounds owing to the probability of double bond migration (2) under the vigorous reaction conditions required. Attention was therefore concentrated on the possibility of preparing the series of compounds **1** by condensation of the appropriate Wittig or related reagent with cyclohexanones.

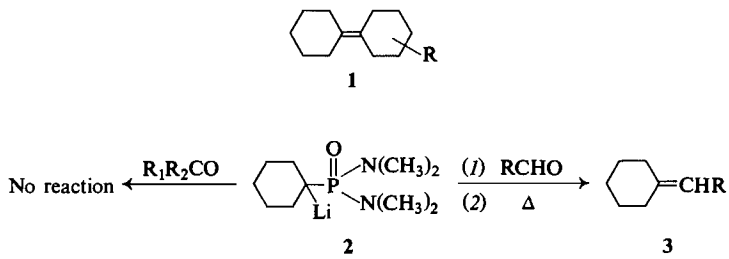
Although the Wittig reaction has been used successfully to effect the preparation of alkylidene alkanes (3) attempts to condense cyclohexylidenetriphenylphosphorane with cyclohexanone did not produce any of the required olefin **1**, R = H.[1] The related phosphonamide route to tetrasubstituted and other recently described olefins (4, 5) was also evaluated. The required cyclohexylphosphonic acid bis(dimethylamide) starting material was prepared but disappointingly its α-lithioderivative **2** and cyclohexanone could not be induced to react to give any cyclohexylidenecyclohexane (**1**, R = H).[1]

The use of carbocyclic phosphonamide derivatives, such as **2**, in olefin synthesis has not previously been reported and it was recognized that steric factors might be interfering with the formation of the intermediate β-hydroxyphosphonamide adducts.[2] Accordingly a limited study on the scope and limitations of the cyclohexylphosphonamide reagent **2** in olefin synthesis was carried out.

The results obtained, which are generalized in Scheme 1, show that reactions of **2** with alde-

[1]The g.l.c. analysis of the reaction mixture prior to working-up showed only the presence of unchanged starting materials.

[2]That α-lithioisopropylphosphonic acid bis(dimethylamide), for which qualitatively similar steric factors obtain, reacted readily with benzophenone (4) was confirmed by repeating the literature experiment. However, condensation of the lithioisopropylphosphonamide with cyclohexanone did not go well and a 17% (by g.l.c., 15% isolated) yield only of isopropylidenecyclohexane was obtained.



SCHEME 1

hydes[3] can occur to give ~40–60% yields of alkenes such as **3** but that no olefinic products could be detected[1] when a representative structural range of ketones[4] was used as the carbonyl moiety.

Experimental

Cyclohexylphosphonic Acid Bis(dimethylamide)

Chlorocyclohexane (30 g, 0.25 mol), phosphorous trichloride (68.7 g, 0.5 mol), and aluminum trichloride (68 g, 0.5 mol) were mixed (in that order) with stirring at 0° (6). After stirring for 20 min, methylene chloride (900 ml) was added and the solution cooled to −20°. Water (92 ml) was then added slowly with stirring and when the precipitate formed had coagulated (1 h), the mixture was filtered and the filtrate was rotary evaporated. The cyclohexylphosphonic dichloride (42 g) so obtained was added slowly with stirring to a cooled (0°) solution of dimethylamine (68 g, 1.5 mol) in diethyl ether (400 ml) (7). The mixture was stirred at 20° for a further 2 h and was then filtered and the filtrate dried ($MgSO_4$) and evaporated. Chromatography of the crude product on Florisil with methanol–acetone (1:1) elution followed by distillation yielded *cyclohexylphosphonic acid bis(dimethylamide)*, b.p. 118°/0.45 Torr, as a hygroscopic white solid (13.2 g): i.r. ($CHCl_3$) 1295 cm^{-1} (P=O); p.m.r. ($CDCl_3$) δ 1.2–1.8 (broad, 11H, C_6H_{11}) and 2.60 and 2.75 p.p.m. (two s, 12H, $[N(CH_3)_2]_2$).

Anal. Calcd. for $C_{10}H_{23}N_2OP$ (mol. wt. 218.1548): C, 55.03; H, 10.62; N, 12.83; P, 14.19. Found (218.1547 (mass spectrum)): C, 54.47; H, 10.69; N, 12.50; P, 14.20.

General Procedure for Reaction of α-Lithiocyclohexyl Phosphonic Acid Bis(dimethylamide) (2) with Aldehydes (1)

A solution of *n*-butyl lithium in hexane (9.9 ml, 1.6 *M*, 16.2 mmol) was added with stirring under dry nitrogen to cyclohexylphosphonic acid bis(dimethylamide) (3.51 g, 16.2 mmol) in dry tetrahydrofuran (80 ml) at −40°. After further stirring of the yellow solution at −40° for 1 h, the aldehyde (16.2 mmol) was added dropwise and the mixture kept at −40° for 30 min and then at 20° for a further 20 min. Water (2 ml) was added and the mixture concentrated by rotary evaporation. The residue was extracted with diethyl ether (60 ml) and the ether solution washed with water (4 × 10 ml), dried ($MgSO_4$), and evaporated. The resulting β-hydroxyphosphonamide was then heated under reflux in benzene (60 ml) in the presence of silica gel G (12 g) for 12 h. The mixture was filtered, the silica gel washed with diethyl ether (30 ml), and the combined organic solution washed with water (15 ml). Evaporation of the dried ($MgSO_4$) solution afforded an oil which was chromatographed on Florisil with petroleum ether (b.p. 30–60°) elution. Distillation (spinning band) of the product was used as the final purification step. All compounds obtained showed single peaks when analyzed by g.l.c. on a 3% SE-30 column. Following the above procedure *n*-butylidenecyclohexane[5] (**3**, R = C_3H_7), b.p. 35°/1.4 Torr, was obtained from 1-butanol in 38% yield; 1-cyclohexylidene-2-butene[5] (**3**, R = $CH{=}CHCH_3$), b.p. 47°/1.3 Torr (lit. (8) b.p. 66.5°/6 Torr) from 2-butenal in 48% yield, and benzylidenecyclohexane[5] (**3**, R = C_6H_5), b.p. 59°/0.08 Torr (lit. (9) b.p. 76°/0.05 Torr) from benzaldehyde in 57% yield.

Isopropylidenecyclohexane

Isopropylidenecyclohexane was obtained in 15% yield by the above general procedure from α-lithioisopropylphosphonic acid bis(dimethylamide) prepared *in situ* as described by Corey and Kwiatkowski (4), and cyclohexanone. The i.r. spectrum was identical with that reported previously (11); p.m.r.[6] ($CDCl_3$) δ 1.55 (broad s, 6H, C-3,4,5 CH_2), 1.66 (s, 6H, $=C(CH_3)_2$) and 2.20 p.p.m. (broad s, 4H, C-2,6 CH_2).

Mol. Wt. Calcd.: 124.1252. Found (mass spectrum): 124.1251.

The generous support of the National Research Council of Canada and the award (to P.W.M.) of an Ontario Government Fellowship are gratefully acknowledged.

Polysaccharides of the Red Alga *Rhodymenia pertusa* Part II. Cell-Wall Glucan; Proton Magnetic Resonance Studies on Permethylated Polysaccharides[1]

J. N. C. WHYTE AND J. R. ENGLAR
Fisheries Research Board of Canada, Vancouver Laboratory, 6640 N.W. Marine Drive, Vancouver 8, British Columbia

Received November 5, 1970

The cell-wall polysaccharide from *R. pertusa* has been shown, by g.l.c., mass spectrum, and p.m.r. studies on the methylated derivative, to consist of β-(1 → 4)-linked-D-glucopyranose residues. The assessment of anomeric configuration in polysaccharides by p.m.r. spectroscopy is illustrated by the spectra of methylated amylose and cellulose. The preparation of anilides for mass spectral analysis of sugars is suggested.

On a démontré par c.p.g., spectre masse, et par des études de r.m.n. du proton de dérivés méthylés que les polysaccharide des parois cellulaires de *R. pertusa* sont constitués de résidus de D-glucopyranose liés suivant la relation β-(1 → 4). La détermination par r.m.n. de la configuration anomérique des polysaccharides est démontrée grâce aux spectres de l'amylose et de la cellulose méthylée. Il est recommandé pour l'analyse des sucres par spectrométrie de masse, de préparer leur anilide.

Canadian Journal of Chemistry, **49**, 1302 (1971)

Few structural studies on the cell-wall glucans of Rhodophyceae have been presented (1). The residue from aqueous extraction of the red alga *Rhodymenia pertusa* (2) gave mainly glucose on hydrolysis and when successively treated with acid, alkali, and chlorine water furnished an insoluble glucan which was purified by dissolution and reprecipitation from cuprammonium hydroxide solution.

The constituent sugar was characterized as 2,3,4,6-tetra-*O*-acetyl-*N*-(*p*-nitrophenyl)-β-D-glucopyranosylamine which provided a mass spectrum with a parent peak at *m/e* 468 (11% of the base peak *m/e* 43), the A series of ions (3) and an ion at mass 180 which was derived from the rearrangement involving the transfer of the acetyl group on O-2 to the nitrogen of the glycosidic linkage in a manner analogous to the electron impact fragmentation of nucleosides (4). The abundance of the molecular ion in the spectrum of this *N*-glycoside, which is absent in corresponding *O*-glycoside spectra, indicates a possible use of anilides in the mass spectral analysis of oligosaccharides (5).

Treatment of the glucan with the Hakomori reagents (6) afforded a methylated derivative ($[\alpha]_D$ −15°, OCH_3 45.6%) a portion of which was hydrolyzed, reduced, and acetylated to yield partially methylated alditol acetates subsequently analyzed by g.l.c. and mass spectrometry (7). The methylated polymer contained 2,3,4,6-tetra- and 2,3,6-tri-*O*-methyl-D-glucose in the molar proportions of 1:110, providing evidence for a structure of linear (1 → 4)-linked-D-glucopyranose residues with a degree of polymerization (d.p.) of 110–120; a d.p. value of 120 was obtained from viscosity measurements of the derived nitrated polymer (8).

The p.m.r. spectra of the methylated derivatives of the glucan from *R. pertusa* and potato amylose in benzene-d_6: chloroform-*d* (6:1) are

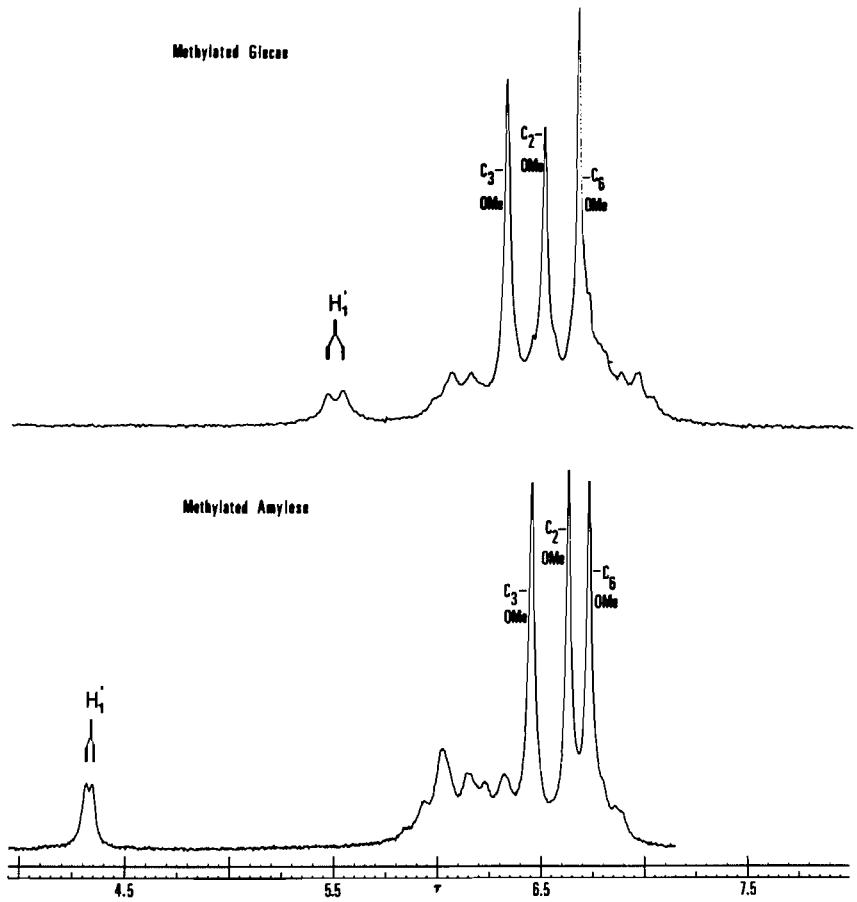

FIG. 1. The p.m.r. spectra (100 MHz) in benzene-d_6:chloroform-d (v/v 6:1) of the methylated derivatives of: Glucan from *R. pertusa* (top) and amylose from potato.

illustrated in Fig. 1. Devoid of the shielding effects of the methoxyl groups, the anomeric protons at the glycosidic linkages resonated to lower field than the remaining annular protons. The signals at τ 4.32 and 5.53 were assigned to the anomeric protons of the α- and β-linked linear polyglucans respectively and this was substantiated by the resonance of the proton at C-1 of the non-reducing moiety of methyl hepta-*O*-methyl-α- and β- maltoside and methyl hepta-*O*-methyl-α- and β-cellobioside at τ 4.29, 4.34 and 5.59 and 5.60 respectively. The spacings of 3.6 Hz for the doublet at τ 4.32 and 7.0 Hz for that at 5.53 are consistent with a *gauche* and *trans*-diaxial interaction between H-1 and -2 of the α- and β-linked glucose residues respectively. The signals at τ 6.44, 6.62, and 6.72 in the spectrum of methylated amylose (mol. wt. *ca.* 106 000) and τ 6.32, 6.51, and 6.68 in the spectrum of the methylated glucan (mol. wt. *ca.* 33 000) were ascribed (9) to the methoxyl groups at C-3, -2, and -6, respectively.

The anomeric configuration in this cell-wall β-(1 → 4)-linked glucan (cellulose) was verified chemically by the isolation of cellobiose and cellotriose as products of acetolysis. Callose, an insoluble β-(1 → 3)-linked glucan, reported to exist in the red seaweeds *Bangia* and *Porphyra* (10) was not evident as a polymer in *R. pertusa*.

The spectrum, Fig. 2, derived from a mixture (1:9, w/w) of methylated α-(1 → 4): β-(1 → 4)-linked glucan exhibited signals at τ 4.4 and 5.54 for the α- and β-anomeric protons and provided an integrated value of 9.5% content of α-linked residues. Together with the assessment of the overall anomeric configuration of the glycosidic linkages in polysaccharides (which is normally determined by isolation and characterization of

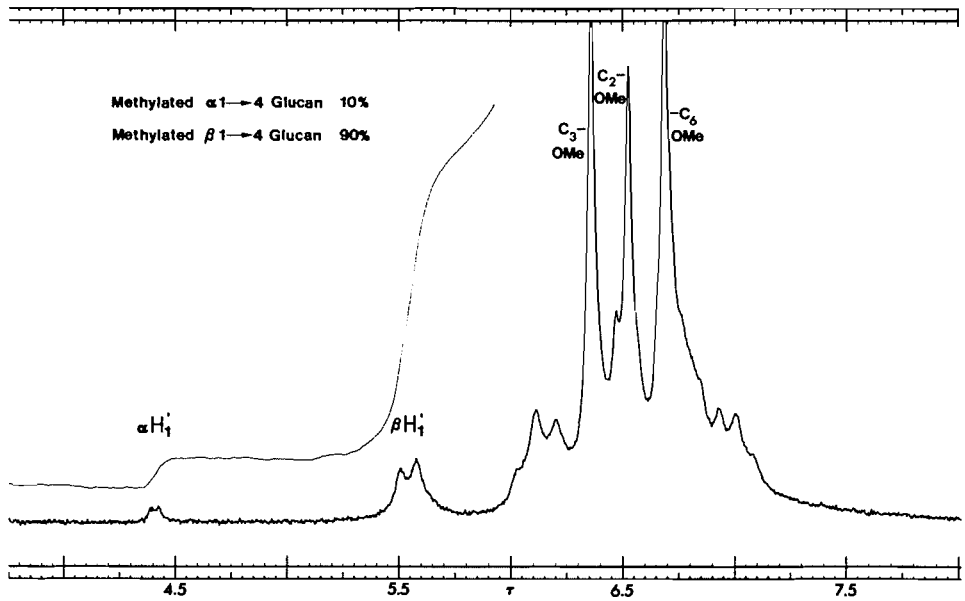

FIG. 2. The p.m.r. spectrum (100 MHz) in benzene-d_6: chloroform-d (v/v 6:1) of methylated α-(1 → 4): β-(1 → 4)-linked glucans (w/w 1:9).

partial depolymerization products), the p.m.r. spectra of methylated polysaccharides have provided for a distinction between α-linked branched and linear polyglucans (2). The insolubility or highly viscous nature of many polysaccharides in water preclude p.m.r. studies in deuterium oxide to assess anomeric configuration and the peracetylated derivatives have the disadvantage that the acetoxyl groups deshield the protons on C-2 and -3 into the region of the p.m.r. spectrum associated with the anomeric protons (11).

Experimental

The p.m.r. spectra were obtained with a Varian HA 100 spectrometer, τ values are relative to tetramethylsilane. The mass spectra were obtained with a Nuclide spectrometer. The g.l.c. was carried out on a column (170 × .45 cm) containing (w/w) 0.2% poly (ethylene glycol adipate), 0.2% poly (ethylene glycol succinate), and 0.4% silicone XF1150.

The residue (70 g) from aqueous extraction of the alga was treated with aqueous sulfuric acid (1%, 90°, 0.5 h), aqueous sodium hydroxide (1% under N_2, 6h), washed with water, resuspended in chlorine water (12 h) and the procedure repeated. After dialysis for 4 days, the slurry was freeze-dried to yield an insoluble polysaccharide (8 g; ash, 4.9%) which gave only glucose on hydrolysis.

The polysaccharide was dissolved in cuprammonium hydroxide solution (500 ml) then centrifuged to yield a siliceous residue and a centrifugate which on acidification with hydrochloric acid precipitated the polysaccharide (6.06 g; ash, 0.5%). The purified product (20 mg) was dissolved in sulfuric acid (72%, 0.2 ml, 1 h) then water (2.3 ml) was added and the solution heated at 100° for 6 h. The phenol – sulfuric acid estimation (12) of the hydrolysate gave 86.9% carbohydrate as glucose; cotton cellulose under the same conditions provided 88% carbohydrate as glucose. The hydrolysate of a sample of the polymer (50 mg) on treatment with *p*-nitroaniline followed by acetylation yielded 2,3,4,6-tetra-*O*-acetyl-*N*-(*p*-nitrophenyl)-β-D-glucopyranosylamine, m.p. and mixed m.p. 182–183°, $[\alpha]_D$ −101° (*c*, 1.0 in $CHCl_3$), which provided a mass spectrum with major peaks at *m/e* 468 (11%), 331 (10%), 169 (23%), 180 (11%), and 43 (100%). Nitration of the crude polysaccharide afforded a derivative which in ethyl acetate gave $[\eta] = 0.9$ corresponding to a d.p. of 120. The glucan (400 mg) was methylated with successive treatments of methyl sulfinyl carbanion and methyl iodide to give a product which was fractionated by dissolution in boiling mixtures of chloroform – light petroleum. The main fraction (420 mg, OCH_3 = 45.6%, $[\alpha]_D$ − 15° (*c*, 1.0 in benzene) was soluble in chloroform – light petroleum (1:4). A portion of the methylated polysaccharide (10 mg) was hydrolyzed with 90% formic acid for 1 h at 100° followed by 0.25 *M* sulfuric acid for 12 h at 100°, subsequently neutralized, the sugars converted into alditol acetates and analyzed by g.l.c. and mass spectrometry. Two fractions T_G 1.0 and 2.6 were shown to be chromatographically and mass spectrometrically identical to 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-glucitol and 1,4,5-tri-*O*-acetyl-2,3,6-tri-*O*-methyl-D-glucitol in the molar proportions of 1:110. Methylated amylose, $[\alpha]_D$ + 212° (*c*, 1.0 in $CHCl_3$), OCH_3 45.5%, prepared and analyzed in a similar manner, contained 2,3,4,6-tetra- and 2,3,6-tri-*O*-methyl-D-glucose in the molar proportion 1:421.

A portion of the crude glucan (3 g) was stirred in a mixture of acetic anhydride (20 ml), acetic acid (20 ml), and concentrated sulfuric acid (2 ml) for 72 h. Separation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of the acetolysis products and deacetylation with barium methoxide yielded a mixture of mono- and oligomers (2.5 g) which were separated by chromatography on charcoal. The sugar (400 mg) eluted with water containing 5% ethanol, recrystallized from aqueous ethanol m.p. mixed m.p. 225°, $[\alpha]_D$ + 35° (*c*, 1.0 in H_2O) was identical to 4-*O*-β-D glucopyranosyl -D-glucose. Elution of the column with water containing 10% ethanol yielded a sugar (50 mg) recrystallized from aqueous ethanol m.p. and mixed m.p. 206° $[\alpha]_D$ + 21° (*c*, 1.0 in H_2O) which was identical to *O*-β-D-glucopyranosyl-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 4)-D-glucose.

Methyl hepta-*O*-methyl α-D-maltoside provided a p.m.r. spectrum in benzene-d_6: chloroform-*d* (6:1 v/v) with signals at τ 5.33, H-1 ($J_{1,2}$ = 3.6 Hz), 4.29, H-1′ ($J_{1',2'}$ = 3.6 Hz) and the corresponding β-glycoside exhibited signals at τ 5.92, H-1 ($J_{1,2}$ = 7.6 Hz) and 4.34, H-1′ ($J_{1',2'}$ = 3.6 Hz). Methyl hepta-*O*-methyl α- and β-cellobioside exhibited nomeric signals for the α-glycoside at τ 5.31, H-1 ($J_{1,2}$ = 3.6 Hz), 5.59, H-1′ ($J_{1',2'}$ = 7.3 Hz) with the corresponding β-glycoside signals at τ 5.88, H-1 ($J_{1,2}$ = 7.5 Hz) and 5.60, H-1′ ($J_{1',2'}$ = 7.3 Hz). The spectrum of 2,3,4,6-tetra-*O*-methyl-α-D-glucose in the solvent mixture exhibited 4-OMe signals at τ 6.76 (C-6), 6.67 (C-2), 6.54 (C-4), and 6.40 (C-3); the spectrum of the corresponding methyl glycoside was in accord with Gagnaire (9).

The authors are indebted to Mr. J. Love for p.m.r. and mass spectral analysis.

Kinetic Isotope Effects in the Radiation-induced Oxidation of Alcohols by Hydrogen Peroxide in Aqueous Solution

C. E. Burchill and G. F. Thompson[1]

Department of Chemistry, University of Manitoba, Winnipeg 19, Manitoba

Received October 15, 1970

By using selectively deuterated alcohols it is demonstrated that abstractions from both α and β positions of 2-propanol and ethanol contribute to the overall mechanism for the radiation-induced chain oxidation of these alcohols by hydrogen peroxide. Kinetic isotope effects are measured for abstraction of H by OH from 2-propanol and ethanol at both α and β positions and for the H atom transfer reaction from the alcohol to the β radical. The chain oxidation of methanol shows no primary kinetic isotope effect on substitution of CD_3OH.

On a démontré, en utilisant des alcools deutérés sélectivement, que des abstractions faites en position α et en position β du propanol-2 et de l'éthanol contribuent au mécanisme global de l'oxydation, en chaîne et induite par des radiations, de ces alcools par le peroxyde d'hydrogène. On a mesuré les effets isotopiques cinétiques pour l'enlèvement de H· par des ·OH du propanol-2 et de l'éthanol aux positions α et β et pour la réaction de transfert de H· de l'alcool au radical β. L'oxydation en chaîne du méthanol ne présente aucun effet isotopique lorsqu'on lui substitue du CD_3OH.

Canadian Journal of Chemistry, 49, 1305 (1971)

The radiation-induced oxidation of several aliphatic alcohols by hydrogen peroxide has recently been investigated in these laboratories (1*a*, *b*). On the basis of the observed dependence of *G*(acetone) and $G(-H_2O_2)$ on alcohol concentration, Burchill and Ginns proposed eqs. 1–8 as a mechanism for the chain oxidation of 2-propanol by hydrogen peroxide (1*a*).

$$H_2O \rightsquigarrow e_{aq}^-, H, OH, H_2O_2, H_2, H_3O^+$$

[1] $$e_{aq}^- + H_2O_2 \rightarrow OH^- + OH$$

of the acetolysis products and deacetylation with barium methoxide yielded a mixture of mono- and oligomers (2.5 g) which were separated by chromatography on charcoal. The sugar (400 mg) eluted with water containing 5% ethanol, recrystallized from aqueous ethanol m.p. mixed m.p. 225°, $[\alpha]_D$ + 35° (*c*, 1.0 in H_2O) was identical to 4-*O*-β-D glucopyranosyl -D-glucose. Elution of the column with water containing 10% ethanol yielded a sugar (50 mg) recrystallized from aqueous ethanol m.p. and mixed m.p. 206° $[\alpha]_D$ + 21° (*c*, 1.0 in H_2O) which was identical to *O*-β-D-glucopyranosyl-(1 → 4)-*O*-β-D-glucopyranosyl-(1 → 4)-D-glucose.

Methyl hepta-*O*-methyl α-D-maltoside provided a p.m.r. spectrum in benzene-d_6: chloroform-*d* (6:1 v/v) with signals at τ 5.33, H-1 ($J_{1,2}$ = 3.6 Hz), 4.29, H-1′ ($J_{1',2'}$ = 3.6 Hz) and the corresponding β-glycoside exhibited signals at τ 5.92, H-1 ($J_{1,2}$ = 7.6 Hz) and 4.34, H-1′ ($J_{1',2'}$ = 3.6 Hz). Methyl hepta-*O*-methyl α- and β-cellobioside exhibited nomeric signals for the α-glycoside at τ 5.31, H-1 ($J_{1,2}$ = 3.6 Hz), 5.59, H-1′ ($J_{1',2'}$ = 7.3 Hz) with the corresponding β-glycoside signals at τ 5.88, H-1 ($J_{1,2}$ = 7.5 Hz) and 5.60, H-1′ ($J_{1',2'}$ = 7.3 Hz). The spectrum of 2,3,4,6-tetra-*O*-methyl-α-D-glucose in the solvent mixture exhibited 4-OMe signals at τ 6.76 (C-6), 6.67 (C-2), 6.54 (C-4), and 6.40 (C-3); the spectrum of the corresponding methyl glycoside was in accord with Gagnaire (9).

[6] $\alpha + H_2O_2 \rightarrow (CH_3)_2CO + H_2O + OH$

[7] $\beta + (CH_3)_2CHOH \rightarrow (CH_3)_2CHOH + \alpha$

[8] $2\alpha \rightarrow$ 2,5-Hexanediol or other products

An expression for G(acetone) may be derived using the usual steady-state assumptions, eqs. 9, 10.

$$[9]\quad G(\text{acetone}) = \left[G_H \left\{ \frac{k_2}{k_5} \left(\frac{k_4 + k_5}{k_2 + k_3} \right) \right\} + \frac{k_4}{k_5} (G_{e_{aq}^-} + G_{OH}) \right] + \left(1 + \frac{k_4}{k_5} \right) k_7 \times \left(\frac{G_{e_{aq}^-} + G_H + G_{OH}}{2k_8 \cdot D} \right)^{1/2} [\text{2-propanol}]$$

where D is the dose rate in units of 6.023×10^{25} eV l^{-1} s^{-1}.

$$[10]\quad G(-H_2O_2) = G(\text{acetone}) + G_{e_{aq}^-} - G_{H_2O_2}$$

If $(CH_3)_2CDOH$ is substituted for $(CH_3)_2CHOH$, reactions 2, 4, and 7 would be expected to show a normal primary kinetic isotope effect if they are, in fact, hydrogen atom transfer reactions. Equation 9 predicts that this would lead to a decrease in both the slope and the intercept of a plot of G(acetone) as a function of alcohol concentration. Similarly, if $(CH_3)_2CHOH$ is replaced by $(CD_3)_2CHOH$, reactions 3 and 5 should show a primary kinetic isotope effect leading to an increase in both the slope and the intercept of the concentration dependence of G(acetone).

Burchill and Ginns have shown that the radiation-induced peroxidation of ethanol (1*b*) is very similar to that of 2-propanol and may be described by a reaction scheme analogous to eqs. 1–8. Hence selective deuteration of ethanol should have effects comparable to those outlined above for 2-propanol.

In the case of methanol, which has no β carbon, it was found (1*b*) that the results were adequately rationalized by a mechanism employing only one alcohol-derived radical. This simpler reaction scheme is outlined in eqs. 11–14. Equation 15 predicts that the first order consumption of peroxide under irradiation will be essentially identical for CH_3OH and CD_3OH, assuming that neither reaction 13 or 14 involves H atom transfer from a C—H bond.

[11] $H + CH_3OH \rightarrow H_2 + \dot{C}H_2OH$

[12] $OH + CH_3OH \rightarrow H_2O + \dot{C}H_2OH$

[13] $\dot{C}H_2OH + H_2O_2 \rightarrow H_2CO + H_2O + OH$

[14] $2\,\dot{C}H_2OH \rightarrow$ ethylene glycol or $H_2CO + CH_3OH$

$$[15]\quad \frac{-d[H_2O_2]}{dt} = (G_{e_{aq}^-} - G_{H_2O_2})D + k_{13} \left[\frac{(G_{e_{aq}^-} + G_H + G_{OH})D}{2k_{14}} \right]^{1/2} [H_2O_2]$$

In order to verify the mechanisms proposed above we have carried out a study of the radiation-induced peroxidation of three 2-propanols ($(CH_3)_2CHOH$, $(CH_3)_2CDOH$, and $(CD_3)_2CHOH$), three ethanols (CH_3CH_2OH, CH_3CD_2OH, and CD_3CH_2OH), and two methanols (CH_3OH and CD_3OH).

Experimental

2-Propanol (Fisher Certified Reagent), ethanol (Canadian Industrial Alcohols, absolute), methanol (Fisher Certified Reagent), and hydrogen peroxide (Fisher Reagent, 30%, unstabilized) were used without further purification. The following partially deuterated alcohols, all of guaranteed 99% isotopic purity, supplied by Merck, Sharp and Dohme were used as received: 2-d_1 2-propanol ($(CH_3)_2CDOH$); 1,1,1,3,3,3,-d_6 2-propanol ($(CD_3)_2CHOH$); 1,1-d_2 ethanol (CH_3CD_2OH); 2,2,2-d_3 ethanol (CD_3CH_2OH); and d_3 methanol (CD_3OH). Water was redistilled from alkaline $KMnO_4$ and then from acidic $K_2Cr_2O_7$ solution. Analytical reagents were of reagent grade and were used without further treatment.

Two milliliters aliquots of the solutions in 5 ml Pyrex bulbs were degassed by four freeze–pump–thaw cycles and irradiated at an average dose rate of 1.32×10^{19} eV l^{-1} s^{-1} using a ^{60}Co Gammacell 220 source (Atomic Energy of Canada, Ltd.). Dose rates were estimated using the Fricke dosimeter (2) and assuming $G(Fe^{3+}) = 15.6$. Absorbed dose rates in experimental solutions were assumed to be proportional to their electron densities.

Acetone was determined spectrophotometrically using salicylaldehyde (3), and hydrogen peroxide by the triiodide method (4).

Results

Acetone formation yields for a constant initial hydrogen peroxide concentration of 0.01 *M* and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

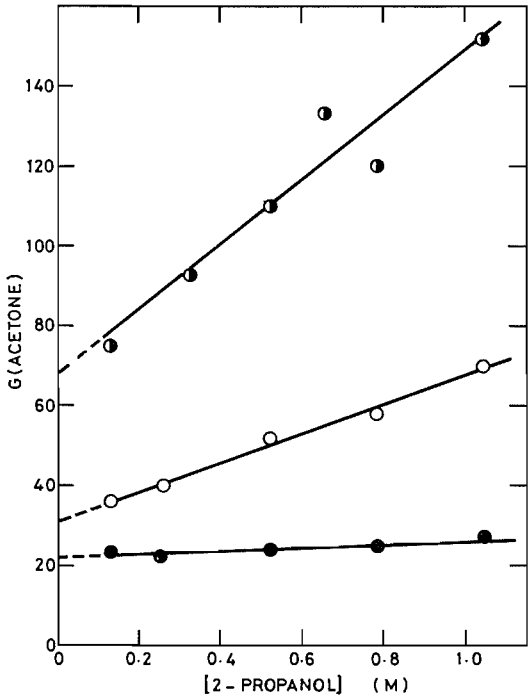

FIG. 1. Radiation-induced oxidation of 2-propanols by hydrogen peroxide in aqueous solution. Initial $[H_2O_2] = 0.01\ M$. Dose rate = 1.32×10^{19} eV l^{-1} s^{-1}. ◑ $(CD_3)_2CHOH$; ○ $(CH_3)_2CHOH$; ● $(CH_3)_2CDOH$.

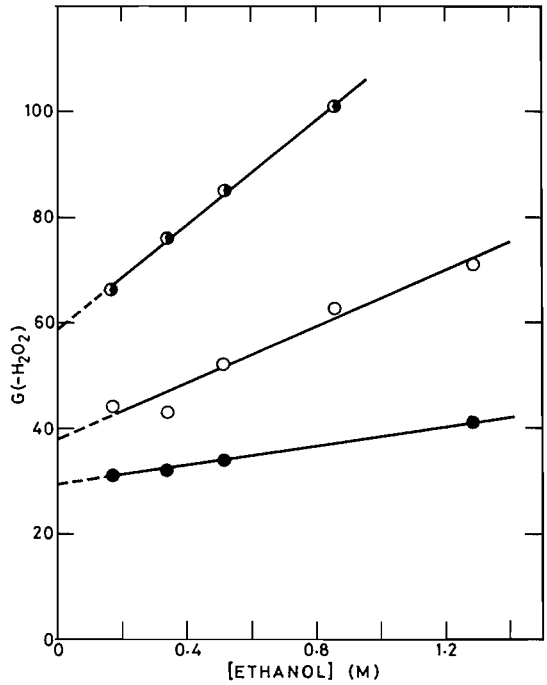

FIG. 2. Radiation-induced reduction of hydrogen peroxide by ethanols in aqueous solution. Initial $[H_2O_2] = 0.02\ M$. Dose rate = 1.32×10^{19} eV l^{-1} s^{-1}. ◑ CD_3CH_2OH; ○ CH_3CH_2OH; ● CH_3CD_2OH.

various concentrations of the three 2-propanols are shown in Fig. 1. The essential equivalence of acetone formation and peroxide consumption reported previously for $(CH_3)_2CHOH$ (1*a*) was found to hold also for the partially deuterated alcohols. Thus for solutions 0.131 *M* in alcohol and 0.01 *M* in H_2O_2, *G*(acetone) = 23.6 and $G(-H_2O_2) = 20.8$ for $(CH_3)_2CDOH$, and *G*(acetone) = 74.5 and $G(-H_2O_2) = 76.9$ for $(CD_3)_2CHOH$. For all three 2-propanols, *G*(acetone) is a linear function of alcohol concentration over the range 0.13–1.05 *M*. The slopes and extrapolated intercepts of the best-fit straight lines are given in Table 1.

The variation of the peroxide destruction yields with ethanol concentration for solutions of the three ethanols is shown in Fig. 2. The initial concentration of hydrogen peroxide was 0.02 *M* in each case. In the case of CH_3CH_2OH and CH_3CD_2OH, $G(-H_2O_2)$ increased linearly with increasing alcohol concentration over the range 0.17–1.28 *M* but for CD_3CH_2OH the yield leveled off above 0.9 *M* and was significantly less at 1.28 *M*. The slopes and extrapolated intercepts obtained from the linear portions of the curves are given in Table 2.

When methanol is the oxidizable substrate the reduction of hydrogen peroxide under irradiation shows a first-order dependence on peroxide concentration. Apparent first-order rate constants for peroxide removal have been determined for four different alcohol concentrations for both CH_3OH and CD_3OH. The results obtained are given in Table 3.

TABLE 1. Slopes and intercepts calculated for the lines of Fig. 1

0.741	1.01	1.11
1.24	1.00	1.12

Discussion

It is apparent from Figs. 1 and 2 that selective deuteration of the alcohol has essentially the same effects on the radiation-induced chain oxidation of 2-propanol and ethanol by hydrogen peroxide. In both cases deuteration at the α position causes a marked decrease in both the slope and intercept of the yield *vs.* alcohol concentration plot whereas the opposite effect is observed on deuteration of the β position.

The effects are in excellent qualitative agreement with those predicted in the introduction on the basis of eq. 9 and thus provide further strong evidence in favor of the mechanism proposed by Burchill and Ginns (1*a*, *b*). Furthermore, the large increase in the chain yield observed on β deuteration of either 2-propanol or ethanol is, *per se*, a direct indication of the involvement of the β position in the reaction scheme.

The lack of significant effect observed on deuteration of the methyl group of methanol is evidence that reaction 13 (and its analogue, [6], for 2-propanol and ethanol) does not involve rupture of a C—H bond as a rate-determining process and is in accord with the prediction previously made on the basis of eq. 15.

In the case of 2-propanol and ethanol it is possible to estimate the magnitudes of the primary hydrogen kinetic isotope effects for reactions 4, 5, and 7 from the data of Tables 2 and 3. Assuming that secondary isotope effects are unimportant, it may be seen from eq. 9 that the ratio of the intercepts or the ratio of the slopes for $(CD_3)_2CHOH$ and $(CH_3)_2CHOH$ will give essentially $k_{5(H)}/k_{5(D)}$ while the ratio of the intercepts for $(CH_3)_2CHOH$ and $(CH_3)_2CDOH$ will be approximately $k_{4(H)}/k_{4(D)}$ and the ratio of their slopes will be

$$\left(\frac{k_{5(H)} + k_{4(H)}}{k_{5(H)} + k_{4(D)}}\right)\frac{k_{7(H)}}{k_{7(D)}}$$

For more precise values of the kinetic isotope effects it is necessary to assume specific values for the primary free radical yields, $G_{e_{aq}^-}$, G_{OH}, and G_H, the kinetic isotope effects on reactions 2 and 3, and the rate constant ratio k_2/k_3. This calculation is, however, very insensitive to the particular values chosen. The following values were assumed for the primary yields in irradiated aqueous solution as being more applicable to solutions containing appreciable scavenger concentrations than those previously assumed by Burchill and Ginns (1*b*):

$$G_H + G_{e_{aq}^-} = 3.18$$

$$G_{OH} = 2.72$$

$$G_{H_2O_2} = 0.68 \quad (5)$$

$$G_H = 0.55 \quad (6)$$

k_2/k_3 was taken as 20 for 2-propanol and as 10.5 for ethanol (7). Anbar and Meyerstein (8) have obtained a value of 7.5 ± 1 for $k_{2(H)}/k_{2(D)}$ and this figure has also been assumed for $k_{3(H)}/k_{3(D)}$. This value is somewhat less than that obtained by Vacek and von Sonntag (9) for hydrogen abstraction from $(CH_3)_2CHOH$ and $(CD_3)_2CDOH$ by hydrogen atoms. However, reactions 2 and 3 are not involved in chain propagation, with the result that the magnitudes of the isotope effects calculated for [4] and [5] are almost independent of the particular value assumed. The same values were assumed also for the isotope effects on reactions 2 and 3 for ethanols.

The results of these calculations are given in Table 4. The uncertainties quoted are probable deviations based on the scatter of the points from the best-fit lines in Figs. 1 and 2. Several comments should be made regarding the results. The values of k_4/k_5 given in Table 4 are somewhat different from those previously calculated (1*a*, *b*). For 2-propanol this simply reflects the different choice of primary yields used in calculation but with ethanol there was a significant difference in the observed reaction yields for the undeuterated alcohol from those reported earlier (1*b*) although the concentration dependence was similar. It was observed that the reduction of H_2O_2 in the presence of ethanol tended to become somewhat non-linear with dose at larger conversions. An average G value calculated from a non-linear yield-dose curve varies with the extent of the reaction and this may, in part, account for the

TABLE 4. Rate constants and rate constant ratios for H atom abstraction reactions from 2-propanol and ethanol. Values of k_4/k_5 and k_7 from previous work (1*a*, *b*) are included

	Rate constant ratio	Rate constant (M^{-1} s^{-1})
2-Propanol	$k_4/k_5 = 5.2 \pm 0.1 (6.2)$ (1*a*)	$k_4+k_5 = 1.4\times10^9$ (7)
	$k_{5(H)}/k_{5(D)} = 2.08\pm0.12$ (intercept)	$k_5 = 2.3\times10^8$
	$= 2.15\pm0.16$ (slope)	
	$k_{4(H)}/k_{4(D)} = 1.38\pm0.05$	$k_4 = 1.2\times10^9$
	$k_{7(H)}/k_{7(D)} = 7.3 \pm 1.5$	$k_7 = 51\pm2(53\pm10)$ (1*a*)
		(assuming $2k_8 = 2\times10^9$)
Ethanol		
	$k_4/k_5 = 6.0 \pm 0.2 (8.2)$ (1*b*)	$k_4+k_5 = 1.1\times10^9$ (7)
	$k_{5(H)}/k_{5(D)} = 1.55\pm0.06$ (intercept)	$k_5 = 1.6\times10^8$
	$= 2.28\pm0.20$ (slope)	
	$k_{4(H)}/k_{4(D)} = 1.24\pm0.04$	$k_4 = 9\times10^8$
	$k_{7(H)}/k_{7(D)} = 2.9 \pm 0.3$	$k_7 = 33\pm3(16\pm3)$ (1*b*)
		(assuming $2k_8 = 2\times10^9$)

differences. The difference in initial yields observed with ethanol is also reflected in a significantly higher value of k_7 reported for ethanol in this work. For ethanol the kinetic isotope effect calculated for reaction 5 differs by more than the estimated precision depending upon whether it is calculated from the slope or intercept ratio in Fig. 2. This is a further indication that the reliability of the calculated parameters for ethanol may be significantly poorer than the precision estimates given.

It is a feature of both the 2-propanol and ethanol systems that

$$\frac{k_{4(H)}}{k_{4(D)}} < \frac{k_{5(H)}}{k_{5(D)}} < \frac{k_{7(H)}}{k_{7(D)}}$$

which is the reverse order of the magnitudes of the specific rate constants. This is in agreement with the qualitative picture that if an atom is transferred from one site to another in a rate-determining step there will be a normal primary kinetic isotope effect observed if the bond strength to the atom (and hence the zero-point energy) is decreased in the transition state relative to that in the initial state. If the bond is not significantly weakened in forming the transition state (a situation corresponding to a small activation energy) the isotope effect will be small whereas if the bond is very weak in the transition state (corresponding to a large activation energy) the kinetic isotope effect will be large. Hence for a series of analogous reactions, such as abstraction of hydrogen atoms from C—H bonds by free radicals, the kinetic hydrogen isotope effects are expected to be in the reverse order of their activation energies (and their rate constants.)

Photolysis of 4-Methyl 3-Hexanone and 2-Methoxy 3-Pentanone in Hydrocarbon Solution

L. P-Y. LEE, B. MCANENEY, AND J. E. GUILLET
Department of Chemistry, University of Toronto, Toronto, Ontario

Received January 7, 1970[1]

Studies of the photolysis of 4-methyl 3-hexanone and the iso-electronic 2-methoxy 3-pentanone have been made in hydrocarbon solution using light of wavelength 313 nm. The latter compound gives only Norrish type II products with a quantum yield of 0.19 ± .01. The former gives a predominance of type I products with a total quantum yield of 0.23 ± .01 and the quantum yield for type II is reduced to 0.10 ± .01. The predominant type I reaction appears to involve α-scission to give an ethyl and a 2-methyl butyryl radical, which suggests a "cage effect". It is suggested that the reason for the suppression of the type I reaction in 2-methoxy 3-pentanone is the greater ease of γ-hydrogen abstraction due to the presence of the oxygen atom in a six-membered transition state.

On a étudié la photolyse en solution dans des hydrocarbures à 313 mm, de la méthyl-4 hexanone-3 et de la méthoxy-2 pentanone-3 qui lui est iso-électronique. Ce dernier composé ne donne, avec un rendement quantique de 0.19 ± 0.01, que des produits provenant d'une réaction de Norrish de type II. Par ailleurs le premier conduit de préférence à des produits de type I avec un rendement quantique de 0.23 ± 0.01 alors que le rendement quantique des produits de type II n'est que de 0.10 ± 0.01. La formation d'une quantité prépondérante de composés de type I semble impliquer une session α conduisant à des radicaux éthyle et méthyl-2 butyryle qui suggérerait un "effet de cage". On croit que le fait de la réaction de type I ne se produit pas provient de ce que dans la méthoxy-2 pentanone-3 l'hydrogène γ est enlevé plus facilement dû à la présence d'oxygène dans l'état de transition à six chaînons.

Canadian Journal of Chemistry, 49, 1310 (1971)

A considerable body of evidence (1–3) now supports the role of a cyclic six-membered transition state in the Norrish type II photoelimination reaction of aliphatic ketones containing hydrogen in the γ-position. It appeared to us of interest to determine if the substitution of a hetero atom such as oxygen for a methylene in the cyclic ring would alter the quantum yields for the various photochemical processes. Accordingly, we have studied the photolysis of two ketones, 4-methyl 3-hexanone and 2-methoxy 3-pentanone. The structure of the two ketones is identical except that in the latter compound an oxygen atom replaces a methylene group.

Srinivasan (4) has shown that the photolysis of methoxyacetone at 313 nm in the vapor phase leads to the formation of acetone and formaldehyde as the major products. Since these are the products expected from the type II reaction, it seemed likely that a similar reaction would occur for 2-methoxy 3-pentanone. The quantum yield of acetone obtained by Srinivasan was 0.32 as compared with 0.22 for 2-pentanone obtained by Ausloos and Rebbert (5). This was considered to be an indication that the presence of the hetero atom in the cyclic transition state increased the probability of the type II reaction. Similar results will be shown in the present work.

In other analogous studies, a series of alkoxy acetophenones was investigated by Turro and Lewis (6) and it was shown that only the type II products and the cyclic oxetanol were formed, the total quantum yield being unity for the sum of the two processes. However, Yates and Szabo (7) who studied a number of alkyl and aryl alkoxy ketones in the liquid phase, report that only a very low yield of cyclic product was formed in the photolysis of methoxy acetone and 1-methoxy-3,3-dimethyl-2-butanone. On this basis they concluded that formation of the cyclic compound was considerably less probable in aliphatic ketones than in the analogous aromatic ketones containing an α-alkoxy group.

Experimental

2-Methoxy 3-pentanone and 4-methyl 3-hexanone were synthesized from the appropriate acid chlorides by reaction with diethyl cadmium by the method of Cason and Prout (8). The crude reaction products were purified on a preparative gas chromatograph and are estimated to be better than 99.8% pure by v.p.c. analysis. 2-Methyl butyraldehyde was prepared by reaction of 2-butyl magnesium chloride with methyl formate. The compounds were identified by their u.v. and n.m.r. spectra.

Product analysis was made by gas chromatography using a Perkin–Elmer 800 Gas Chromatograph. The irradiation products were identified by the identity of their retention times on two different columns using authentic samples of the suspected compound as reference. The solvent used for the photolysis was *n*-undecane which had

been chromatographically purified and an internal standard (tetradecane) was used for quantitative work. Photolysis experiments were carried out both under nitrogen and in a cell sealed under vacuum.

The photolysis apparatus consisted of a medium pressure Mercury arc (B.T.H. type ME/D), a quartz lens, a solution filter, an interference filter, a heating block, and a quartz photolysis cell and photomultiplier all mounted rigidly on an optical bench. The system is similar to that described by Hartley and Guillet (3). The 3130 Å wavelength line was isolated by the use of a Carl Zeiss U.V.–P.I.L. line filter with a λ_{max} equal to 315 with a 70 Å half-width. The photolysis cell was a 1 mm path length quartz cell sealed to a side arm containing a quartz to pyrex graded seal. The cell was heated in an aluminum block the temperature of which was maintained constant by a circulating oil bath from a Lauda K-2 ultra thermostat. The light beam intensity was monitored by an RCA IP-28 photomultiplier tube whose response was calibrated against a uranyl oxalate actinometer.

Results and Discussion

The absorption spectra of the two ketones are shown in Fig. 1. Both ketones show the characteristic low intensity absorption of the $n \rightarrow \pi^*$ transition in the 250–330 mμ region. However, the band for the methoxy ketone has a somewhat higher molar extinction coefficient and shows a red shift. This red shift is due to the substitution of the methoxy group for an ethyl group. It can be attributed to a lowering of the energy level of the π^* antibonding orbital of the carbonyl group by the contribution of the lone pair electrons on the ether oxygen, which permits further delocalization of the electron over a four atom system (as for example in a conjugated diene). The n level of the non-bonding electrons localized on the carbonyl oxygen will not be affected to the same degree by the presence of the ether oxygen. Hence the energy corresponding to the $n \rightarrow \pi^*$ transition is reduced, and λ_{max} is shifted to longer wavelengths.

The analytical results for the photolysis of the two ketones in undecane solution are summarized in Table 1 and the quantum yields in Table 2. Each analysis was run in triplicate and the results are estimated to be precise to $\pm 1\%$ and accurate to $\pm 5\%$. It is clear from this table that the presence of the oxygen atom has changed markedly the photochemistry of the two ketones. The only products identified in the photolysis of 2-methoxy 3-pentanone are 3-pentanone and formaldehyde which constitute the type II products formed by the reaction shown in Scheme 1. Careful inspection of the gas chromatographic data indicated no other products exceeding 5% of the 3-pentanone. The total quantum yield for the type II process at 23 °C was 0.19. The almost total elimination of type I products is quite remarkable.

On the other hand the products isolated from the photolysis of 4-methyl 3-hexanone indicate a predominance of type I products even at the low

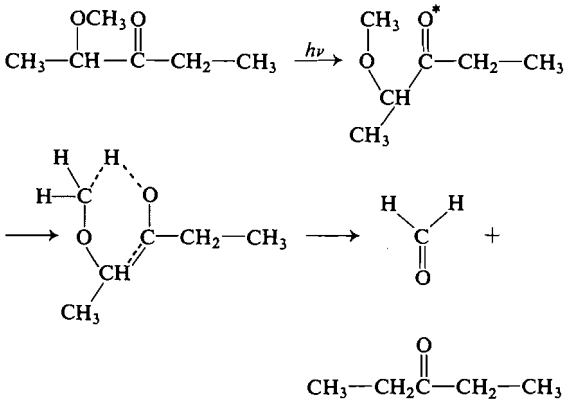

SCHEME 1

temperature of the experiment. The observed products can be explained by reaction Scheme 2. Smaller peaks which were tentatively identified as various combination products of radicals formed by the type I process were shown by the gas chromatograph, but the amounts observed were considerably smaller than for any of the compounds listed above.

Several conclusions can be drawn from these data. In the first place, it is interesting to note that the type I cleavage of the ethyl group is favored by a factor of 10 to 1 over cleavage of the isobutyl group. Since the bond strength of the carbon bond on the ethyl group would be expected to be greater than that of the isobutyl group, one might conclude that the reason for the higher efficiency for the cleavage of the smaller radical is due to a smaller "cage effect". In essence the smaller radical has a greater probability of escaping from the adjacent fragment and the quantum yield for scission of this bond is therefore higher.

The other factor of interest is that the quantum yield for the type I process is nearly double that for the type II process in this ketone whereas in the case of the methoxy ketone, practically no type I products were identified at all and the quantum yield for the type II process was double that for 4-methyl 3-hexanone. It is possible that the reason for the increased quantum yield for the type II reaction in 2-methoxy 3-pentanone is a greater ease in the formation of the six-membered transition state, and that this formation must compete with whatever state gives rise to the free radical type I split. Alternatively, one may argue that the six-membered ring is formed readily in both cases and the proportion of reaction into the type II photoelimination (as opposed to the type I) will depend on the relative ease of proton abstraction. This is suggested by the results of Wagner and Kamppainen (9) who estimate that the rate constant for γ-hydrogen abstraction in methoxy acetophenone is 230 times that in propiophenone.

In the case of both ketones a careful inspection of the chromatograms showed no product in the region where the cyclic oxetanol or cyclobutanol derivatives would be expected. It is estimated that unless these products are very unstable during the analysis, they could not amount to more than 5% of the yields of the major type I and type II products. This low yield of the cyclic derivative for aliphatic ketones corroborates the results of Yates and Szabo (7) with similar ketones.

The unusual distribution of the type I split in 4-methyl 3-hexanone suggests that perhaps a major mechanism for the dissipation of excited state energy involves the dissociation of the molecule into free radicals which lose some of their excess excitation energy by collision with the solvent and then recombine in the "cage". It would appear that this might represent a fairly efficient method for the conversion of the energy

The Silver–Calcium System

A. N. CAMPBELL AND W. H. W. WOOD
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received November 4, 1970

The Ag–Ca system has been reinvestigated over the composition range 50–100 atomic% Ca, by differential thermal analysis and high temperature X-ray powder diffraction. Our results are in good agreement with those of Alexander *et al.* (1) and those of Pascal *et al.* (2) in the region 50–59 atomic% Ca, but the peritectic claimed by Alexander *et al.*, lying at 50% Ca and 598 °C, appears not to exist, according to our DTA and X-ray results. Here and elsewhere our results substantiate those of Pascal *et al.* We also find that the compound $AgCa_3$ is formed peritectically, and not congruently as suggested by Alexander *et al.*

Le système Ag–Ca a été réexaminé dans le domaine des compositions 50–100% at. Ca, par les techniques d'analyse thermique différentielle et de diffraction X de poudres à températures élevées. Nos résultats sont en accord avec ceux de Alexander et coll. (1) et ceux de Pascal et coll. (2) dans la région 50–59% at. Ca; cependant nos résultats d'ATD et de rayons-x ne confirment pas l'existence d'une réaction péritectique à 50% Ca et 598 °C, telle que rapportée par Alexander et coll. De façon générale, nos résultats s'accordent avec ceux de Pascal et coll. Nous trouvons de plus que le composé $AgCa_3$ est formé par une réaction péritectique et non pas, tel que suggéré par Alexander et coll., de façon congruente.

Canadian Journal of Chemistry 49, 1315 (1971)

Introduction

The equilibrium diagram of the system Ag–Ca is well established for the most part. The original work is that of Baar (3), whose results have been confirmed by Alexander *et al.* (1) and by Pascal *et al.* (2) as far as the region from 0 to 50 atomic% Ca is concerned. On the basis of DTA results only, Alexander *et al.* suggested the occurrence of a peritectic lying at 59 atomic% Ca and 598 °C, and that the compound $AgCa_3$, whose existence is not disputed, is produced from the melt with congruent freezing. Pascal *et al.* (2) working in the range 50–100% Ca failed to confirm the conclusions of Alexander *et al.* The aim of the present work was to settle these disputed points, using both DTA and X-ray powder photography.

Experimental

Materials

Silver, obtained from the Matheson, Coleman and Bell Company, was 99.999% pure. Calcium from Dominion Magnesium Ltd., was supplied with the following spectrographic analysis: N_2 = 0.0057%, Fe = 0.0008%, Mg = 0.10%, Al = 0.007%, and Mn = 0.013%.

The alloys were homogenized in a Leco induction furnace (Model 521) but some modifications were necessary to prevent oxidation. Stirring of the molten sample was assumed to have been sufficiently accomplished by the eddy currents established by the induction furnace. Microscopic examination and chemical analysis by the Volhard method for silver showed a variation in composition of up to 1% Ca between top and bottom sections. This variation in composition was undoubtedly due to the burning off of calcium at the top of the alloy, during the homogenization process. Accordingly, the tube in which the alloys were homogenized was purged several times with purified argon, before heating, and a final positive pressure of about 5 cm Hg maintained over the alloy during homogenization.

Zircon crucibles were found to be satisfactory for alloys with low calcium content but they were attacked by alloys containing more than 30% Ca. We, therefore, changed to boron nitride crucibles for all our definitive work. There appears to be no interaction between these alloys and boron nitride.

Experimental details of our DTA and X-ray work are to be found in a previous publication (4).

Results and Discussion

As noted by Alexander *et al.* (1), the liquidus points were fairly consistent but the solid state arrests were not very reproducible, both from alloy to alloy and also for successive thermal analyses of the same alloy. This is probably due to slight contamination of the alloy by the crucible.

We found no evidence for the existence of the peritectic claimed by Alexander *et al.* (1) at 59% Ca and 598 °C. In this region, our results confirm those of Pascal *et al.* (2). Between the compound Ag_3Ca_5 and pure Ca, Alexander *et al.* has suggested the existence of two eutectics, with $AgCa_3$ forming congruently at 75% Ca. This, however, is inconsistent with their own suggestion of a maximum at 77.5% Ca. Admittedly, the curve is very flat between 75 and 80% Ca and, were it not for the extreme sensitivity of our DTA method, we

should be inclined to leave it as an open question whether $AgCa_3$ forms peritectically or congruently. The matter is of no great moment but, obviously, if a maximum were to exist, it must lie at 75% Ca, since this is the composition of the compound itself. In our opinion, the compound $AgCa_3$ forms incongruently at 475 °C, at the composition of the compound. Our results are to be found in Table 1.

TABLE 1

Composition (at % Ca)	Temperature (°C) Liquidus	Solidus

X-Ray photographs were taken with the high temperature camera, above and below 598 °C, the temperature suggested by Alexander *et al.* as that of a peritectic, but we found no evidence of the existence of any phase other than AgCa, above 555 °C, the temperature at which Ag_3Ca_5 is formed peritectically. On the basis both of DTA and X-ray work, we conclude that the peritectic proposed by Alexander at 59% Ca and 598 °C, does not exist.

Photolysis of Thiolane Vapor[1]

SILVIA BRASLAVSKY AND JULIAN HEICKLEN
Department of Chemistry and Center for Air Environment Studies, The Pennsylvania State University, University Park, Pa. 16802

Received October 26, 1970

The photolysis of thiolane vapor ($\overline{CH_2CH_2CH_2CH_2S}$) was studied at room temperature with 2139 Å radiation. The major product was C_2H_4, whose quantum yield decreased as the pressure was increased. Next in importance were 1-C_4H_8, C_3H_6, and C_2H_6. Also produced were CH_4, *c*-C_3H_6, 1,3-C_4H_6, CH_2CHSH, $\overline{CH_2CH_2S}$, 1-C_4H_9SH, H_2, C_3H_8, *n*-C_4H_{10}, *c*-C_4H_8, polymer, and an unstable product tentatively identified as 1-butene-1-thiol. All products were initial products of the reaction. Experiments with added C_3H_6 showed the absence of sulfur atoms. The results are interpreted in terms of two excited states and an intermediate which might be the diradical $\cdot CH_2CH_2CH_2CH_2S\cdot$.

La photolyse de vapeur de thiolane, ($\overline{CH_2CH_2CH_2CH_2S}$) a été étudiée à la température de la pièce à 2139Å. Le produit principal de la réaction est C_2H_4 dont le rendement quantique diminue inversement avec la pression. Les produits formés avec une importance moindre étaient le butène-1, C_3H_6 et C_2H_6. Les composés suivants: CH_4, C_3H_6, butadiène-1,3, CH_2CHSH, $\overline{CH_2CH_2S}$, butanethiol-1, H_2, C_3H_8, *n*-C_4H_{10}, *c*-C_4H_8, polymère et un produit instable qui pourrait être le butène-1-thiol-1 sont aussi formés. Tous ces produits étaient des produits initiaux de la réaction. Des expériences supplémentaires au cours desquelles du C_3H_6 avait été ajouté ont permis de démontrer l'absence d'atome de soufre. Les résultats sont expliqués en termes de deux états excités et d'un intermédiaire qui pourrait être le diradical $\cdot CH_2CH_2CH_2CH_2S\cdot$.

formation of an intermediate which reacts with a second molecule to produce S_2 and hydrocarbon products. In both studies sulfur atoms were found to be absent. In this paper we report some results on the room-temperature photolysis of thiolane vapor ($\overline{CH_2CH_2CH_2CH_2S}$) with 2139 Å radiation.

There are two previous reports of the photolysis of thiolane. In a brief study Haines *et al.* (3) reported the products when liquid samples of $\overline{CH_2(CH_2)_nCH_2S}$ (n = 1 to 3) were irradiated with a mercury arc. For thiolane, the major products reported were C_2H_4 and H_2. A more detailed study of the photodecomposition of thiirane vapor ($\overline{CH_2CH_2S}$) and thiolane vapor irradiated with 2537 Å radiation was reported by Sidhu (4). In both cases $S(^3P)$ atoms were detected by episulfide formation in the presence of olefins. A primary process involving ring opening and leading to diradicals was proposed in both systems. Heavy molecular weight molecules were also produced in the presence of olefins which were explained as coming from the adduct of sulfur-bearing radicals with the olefins. When 10 Torr of pure thiolane was irradiated at 2537 Å, the products were 1-C_4H_9SH, 1-C_4H_8, C_3H_6, and c-C_3H_6 in the ratio of 3.6 to 1, equal amounts of C_2H_4 and $\overline{CH_2CH_2S}$, hydrogen, and polymer. The C_2 and C_3 hydrocarbons were about of equal importance. Furthermore c-C_4H_8 was absent. In the liquid phase the products were the same but their quantum yields were small.

Thiolane absorption is very weak at 2537 Å, but a strong transition occurs below 2350 Å, possibly involving two electronically excited states (5). With 2139 Å irradiation the major product is C_2H_4. Next in importance are 1-C_4H_8, C_3H_6, and C_2H_6. Minor products included CH_4, c-C_3H_6, 1,3-C_4H_6, CH_2CHSH, $\overline{CH_2CH_2S}$, and 1-C_4H_9SH. Traces of H_2, C_3H_8, n-C_4H_{10}, and c-C_4H_8 (cyclobutane) were produced. A very unstable product was also found which, according to its retention time and its high instability, was tentatively identified as 1-butene-1-thiol, an isomer of thiolane. A white polymer also formed. A careful search was made for H_2S, CS_2, C_2H_2, 2-C_4H_8, and i-C_4H_8, but these compounds were not found as products. (H_2S and CS_2 were also absent in the photolysis of thietane (2).) The effect of extent of conversion was studied and it was found that all the product quantum yields were invariant to exposure times between 10 and 60 min. Thus all the products are primary products of the photolysis.

With 2139 Å radiation, the products included those reported at 2537 Å, as well as several others. Furthermore the ratio C_3H_6 to c-C_3H_6 is about the same at both wavelengths. Three significant differences at the two wavelengths are: (*1*) the C_2 and C_3 hydrocarbons were of about equal importance at 2537 Å, whereas at 2139 Å, the amount of C_2H_4 was in great excess, (*2*) the ratio of $[C_2H_4]$ to $[\overline{CH_2CH_2S}]$ greatly exceeded unity with 2139 Å, whereas it was about one at 2537 Å, and (*3*) an experiment in which 9 Torr of thiolane was photolyzed at 2139 Å in the presence of 3 Torr of propylene produced neither propylene episulfide nor propanethiol, thus indicating the absence of sulfur atoms (6), contrary to the results at 2537 Å where $S(^3P)$ was found. Furthermore with 2139 Å radiation the quantum yields of 1,3-C_4H_6 and the sulfur bearing products remained unchanged in the presence of C_3H_6. Thus intermediates which react readily with C_3H_6 are not important in this system.

It is of interest to note that the photodecomposition of the electronically similar oxolane molecule ($\overline{CH_2CH_2CH_2CH_2O}$) with radiation principally at 1942 and 1973 Å gives similar products (7). The major products in that system were CO, H_2, CH_4, C_2H_6, C_2H_4, C_3H_6, c-C_3H_6, C_3H_8, and CH_2O. Minor products included C_4H_{10}, 2-C_4H_8, and 1,3-C_4H_6.

Table 1 lists the quantum yields for the more important gas-phase products at pressures between 0.78 and 11.6 Torr and absorbed intensities, I_a, between 10.8 and 48 $\times$ 10^{11} quanta/cc s. The yields for 1-C_4H_9SH and the product tentatively identified as 1-butene-1-thiol varied erratically between 0 and $\simeq$ 0.1. When one was present and important, so was the other. $\Phi\{C_2H_4\}$ drops measureably as the pressure (and I_a) is enhanced. Presumably this drop results from pressure quenching of the precursor, since intensity effects were absent in the thiophene and thietane systems (1, 2). The CH_4 yield rises with pressure and I_a, but the quantum yields of the other products show no marked trend with the experimental parameters, though the results are quite scattered due to the low quantum yields and the attendant analytical difficulties.

Since $\Phi\{C_2H_4\}$ is pressure quenched and the other gas-phase products are not, two electronically excited states of thiolane (designated Th* and Th**) are indicated, as was proposed in the

photolysis of thietane vapor (2). One electronically excited state produces C_2H_4, and the primary steps can be represented by

[1] $\quad Th^* \rightarrow C_2H_4 + \cdot C_2H_4S\cdot$

[2] $\quad Th^* + Th \rightarrow 2Th$

Th* might be formed by direct absorption of the 2139 Å radiation or might result from internal conversion of Th**. On the other hand Th* cannot be a precursor for Th** since the products arising from Th** show no pressure dependence; reaction 2 cannot produce Th**, but it might produce polymer. The fate of the $\cdot C_2H_4S\cdot$ fragment is uncertain. In this system $\Phi\{C_2H_4\}$ greatly exceeds $\Phi\{\overline{CH_2CH_2S}\} + \Phi\{CH_2CHSH\}$, contrary to the results at 2537 Å where the two quantities are about the same. In this system the $\cdot C_2H_4S\cdot$ fragment probably either polymerizes or produces more C_2H_4 via

[3] $\quad 2\cdot C_2H_4S\cdot \rightarrow 2C_2H_4 + S_2$

Reactions 1–3 lead to the result

$$[4] \quad (\Phi\{C_2H_4\})^{-1} = (1 + k_2[Th]/k_1)/2\alpha$$

where α is the fraction of the light absorbed which leads to Th* formation. However, if reaction 3 is negligible then

$$[5] \quad (\Phi\{C_2H_4\})^{-1} = (1 + k_2[Th]/k_1)/\alpha$$

Figure 1 is a plot of $(\Phi\{C_2H_4\})^{-1}$ *vs.* [Th]. The data points are fitted by a straight line of slope 0.20 $Torr^{-1}$ and intercept 1.2. The ratio of slope to intercept gives $k_2/k_1 = 0.17$ $Torr^{-1}$. The intercept yields a value for α of either 0.42 if reaction 3 is important or 0.83 if reaction 3 is negligible.

The CH_4 yield increases with pressure suggesting that reaction 2 might lead to CH_4 part of the time. The C_3 hydrocarbon products could be produced directly by decomposition of Th**. However, the C_4 hydrocarbon products cannot be produced in this way, since sulfur atoms were shown to be absent. In order to explain the absence of both sulfur atoms and a pressure effect, it is necessary that Th** revert to some intermediate, possibly $\cdot CH_2CH_2CH_2CH_2S\cdot$, which can react with unexcited thiolane to produce S_2 and the C_4 hydrocarbon products.

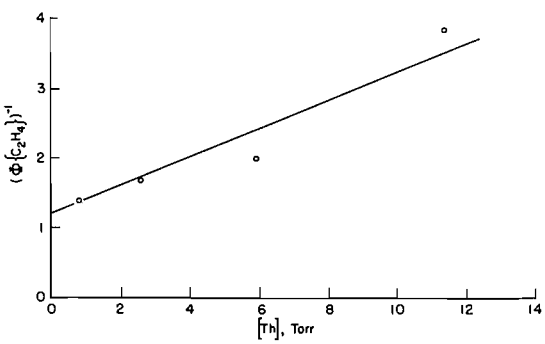

FIG. 1. Plot of the reciprocal ethylene quantum yield *vs.* thiolane pressure in the photolysis of thiolane vapor at 2139 Å and room temperature.

Experimental

Thiolane was obtained from Eastman Organic Chemicals. It contained two impurities (< 200 p.p.m.) which were removed by preparative gas chromatography using a 20 ft long column packed with 10% tricresyl phosphate on Chromosorb G, operating at 60 °C with a He flow rate of 60 cc/min. Furthermore the thiolane was distilled at −90 °C before each run. Matheson Co. Instrumental Grade C_3H_6 and C.P. grade O_2 were used without purification. The C_3H_6 showed no impurities, and the O_2 contained only traces of N_2.

The reaction vessel, radiation source, vacuum system, and HBr actinometry have been described previously (1). The extinction coefficient of thiolane at 2139 Å was found on a Cary 14 spectrophotometer to be 1.9×10^{-2} $Torr^{-1}$ cm^{-1} (to base 10). The absorbed radiation was obtained by comparison to the H_2 yield from HBr irradiations at matched absorbances. Since polymer formation was observed after long irradiations, air was admitted to the reaction vessel and heated with an oxygen torch to about 500 °C after each run to remove the polymer.

The products were analyzed with a Gow-Mac Model No. 40-05D gas chromatograph utilizing a thermistor detector and 1/4-in. diameter columns. The identification of the hydrocarbon products and 1-C_4H_9SH was made by adding an authentic commercial sample to the reaction products and checking the chromatographic retention time on two different columns. These products were also calibrated directly. H_2 was identified by collecting the gas noncondensable at −196 °C and passing it through a chromatograph using a Porapak Q column with Ar as a carrier gas. To identify CH_2CHSH and $\overline{CH_2CH_2S}$, these compounds were prepared from the photolysis of OCS in the presence of C_2H_4 (6). Both compounds gave retention times corresponding to products of the reaction. Furthermore the product with the same retention time as CH_2CHSH was collected and the identification confirmed by mass spectroscopy.

For complete analysis of the products three runs were performed under similar experimental conditions. From one run the gases noncondensable at −130 °C were collected with a Toepler pump, and analyzed on a 20 ft Porapak Q column at 0 °C using a He flow rate of 60 cc/min for 20 min after which the flow rate was increased to 110 cc/min. In this way CH_4, C_2H_4, and C_2H_6 were measured.

In a second run the C_3 and C_4 hydrocarbons were analyzed on a 40 ft column packed with 15% dimethyl-

sulfone on Chromasorb G at 0 °C with a He flow rate of 43 cc/min. The sulfur compounds were analyzed in the third run using a 2 ft column packed with 10% tricresyl phosphate on Chromasorb G at room temperature with a He flow rate of 43 cc/min.

Pyrolysis of Oxime Carbonates: Novel Conversion of Aldehydes into Nitriles under Mild Conditions

J. M. PROKIPCAK AND P. A. FORTE
Department of Chemistry, University of Guelph, Guelph, Ontario

Received January 8, 1971

A new synthesis of nitriles is reported based on the pyrolysis of oxime carbonates.

On rapporte une nouvelle synthèse des nitriles qui fait appel à la pyrolyse de carbonates d'oximes.

Canadian Journal of Chemistry, 49, 1321 (1971)

Recently there have been reports for preparing nitriles using dialkyl hydrogen phosphonates (1), 3-chloro-1,2-benzisothiazole-*S*,*S*-dioxide (2), and chlorothionoformate (3) derivatives of oximes. Other methods generally used involve more vigorous fragmentation of oxime esters under a variety of conditions (4). We wish to report a new relatively mild method of effecting this conversion of aldehydes to nitriles without use of any acidic or basic reagents.

Various aldoximes **1** which were readily available from the aldehydes were treated with phenyl chloroformate to yield the desired oxime carbonate **2**. Thermal decomposition of these oxime carbonates produced high yields of the corresponding nitriles. A typical transformation is depicted in Scheme 1.

The method seems applicable to both aliphatic and aromatic systems. A summary of our results to date is given in Table 1.

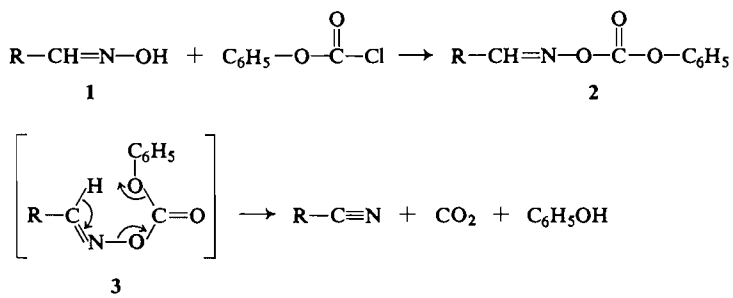
Although the mechanistic details of the reaction are not yet understood, a possible six-centered transition state **3** could be involved.

TABLE 1. Preparation and pyrolysis* of oxime carbonates†

Starting oxime	Melting point of oxime carbonate (°C)	Yield of nitrile (%)
anti-p-Nitrobenzaldoxime	151 (dec)	90
syn-p-Chlorobenzaldoxime	115	90
syn-Benzaldoxime	83	85
syn-p-Methylbenzaldoxime	91	90
syn-p-Methoxybenzaldoxime	115 (dec)	85

*All decompositions were carried out at approximately 100–110°.

†Structure of carbonate is 
Further work on the synthetic scope as well as the mechanistic aspects of this reaction is now underway and will be reported in due course. The reaction itself has possible synthetic use because of the relatively mild temperatures required to effect the conversion, excellent yields of the nitriles, and no use of any acidic or basic reagents.



SCHEME 1.

All the oximes used were prepared by standard routes. The general experimental procedure is illustrated for the preparation of the carbonate of *syn*-anisaldoxime and its subsequent thermal breakdown. To a cooled (0°), stirred solution of *syn*-anisaldoxime (25.3 g, 0.17 mol) in 250 ml anhydrous ether containing 14 ml (0.18 mol) pyridine was added slowly 28.4 g (0.18 mol) of phenyl chloroformate. The resultant mixture was stirred for 10 h at room temperature and then poured on ice water (1000 ml). The ether layer was removed and the aqueous layer extracted with 800 ml methylene chloride. The combined organic extracts were washed with water, dried over sodium sulfate, and the solvent evaporated to yield the crude oxime carbonate. Recrystallization from hexane–chloroform gave 36.0 g (79%) of pure carbonate, m.p. 118° which had the following spectral data: ($CHCl_3$) 1759 (C=O stretch), 1259–1190 (ester C—O stretch), and 1024 cm^{-1} (C—O—C stretch); n.m.r. ($CDCl_3$) δ (p.p.m.) 8.44 (1H singlet, imino hydrogen H—C(=N)—) 7.84–6.92 (9H multiplet centered at 7.38, aromatic), 3.84 (3H singlet, phenyl CH_3—O—).

Anal. Calcd. for $C_{15}H_{13}NO_4$: C, 66.41; H, 4.83; N, 5.11. Found: C, 66.63; H, 4.76; N, 5.28.

The oxime carbonate (7.46 g, 0.028 mol) was then placed in a flask and heated until a steady stream of CO_2 evolved (110°). Then the reaction became very exothermic and external heating was discontinued. After CO_2 evolution had ceased, the resultant material was dissolved in 150 ml benzene. The benzene layer was extracted with 5% NaOH (3 × 50 ml), water (2 × 100 ml), and dried over sodium sulfate. The benzene was removed *in vacuo* yielding an oil which crystallized from hexane–chloroform. The pure nitrile (3.1 g, 85%) had a m.p. 59.0–61.0° (reported (5), 61–62°) and its spectral data (i.r. and n.m.r.) was consistent with the assigned structure.

The authors wish to thank the National Research Council of Canada for financial support of this research and for a NRCC Scholarship awarded to P. A. Forte.

Coordination Compounds of Olefins with Anhydrous Silver Tetrafluoroborate. VI. Complexes with Vinyl Chloride and Vinyl Fluoride[1]

H. W. QUINN AND R. L. VANGILDER

Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received February 27, 1970[2]

The stability of the complexes $AgBF_4 \cdot 2$ vinyl chloride and $AgBF_4 \cdot 2$ vinyl fluoride has been determined and compared with that of $AgBF_4 \cdot 2$ propylene. The much lower stability of the halo-olefin complexes has been attributed partly to weaker interaction of these less basic olefins with the silver ion and partly to configurational restrictions imposed upon the complexed halo-olefin molecules as a result of their higher permanent dipole moment.

On a déterminé les stabilités des complexes de $AgBF_4 \cdot 2$ chlorure de vinyle et $AgBF_4 \cdot 2$ fluorure de vinyle et on les a comparées avec celle de $AgBF_4 \cdot 2$ propylène. La stabilité beaucoup plus faible des complexes des olefines halogénées est attribuée en partie à une intéraction plus faible de ces oléfines moins basiques avec les ions d'argent et aussi en partie aux restrictions configurationnelles imposées aux molécules d'oléfines halogénées du au fait qu'elles ont des moments polaires plus élevés.

Canadian Journal of Chemistry, 49, 1323 (1971)

Introduction

Earlier studies of the interaction of solid silver tetrafluoroborate with propylene and some other gaseous mono-olefins (1, 2) have indicated that the stability of the π complexes (1) produced is dependent upon olefin basicity. In order to compare propylene with some less basic olefins a study has been made of the stability of the 1:2 silver tetrafluoroborate complexes of propylene, vinyl chloride, and vinyl fluoride. Equilibrium dissociation pressure–temperature data for the complexes have been determined experimentally over the temperature range -40 to 20 °C. From these the change in the values of the thermodynamic functions for complex dissociation has been calculated. A determination has been made also of the change which occurs in the frequency of the double bond stretching vibration in the olefin when the $AgBF_4$ complex is formed.

[1]Dow Chemical of Canada, Limited, contribution no. 181.

[2]Revision received August 31, 1970.

Experimental

Materials

Vinyl chloride and vinyl fluoride were Matheson C. P. grade with 99.9% purity.

Propylene and 1-pentene were Phillips Pure Grade (99%) and Phillips Research Grade (99.99%), respectively.

Anhydrous $AgBF_4$ was purchased from Peninsular Chemical Research Incorporated.

1,2-Dichloroethane was Dow Chemical of Canada material of 99.99% purity.

Preparation of Complexes

(a) $AgBF_4 \cdot 2$ (1-Pentene)

The $AgBF_4$ (2.0109 g, 10.328 mmol) under petroleum ether was transferred to a Pyrex vapor pressure cell. The petroleum ether was pumped off and the system thoroughly evacuated. The anhydrous $AgBF_4$ was exposed to 1.4515 g (20.697 mmol) liquid 1-pentene at 50 °C to yield the liquid 1:2 complex (3). The complex was distributed as a thin uniform layer on the wall of the vapor pressure cell, crystallized by cooling to room temperature, and the 1-pentene subsequently removed by pumping for 48 h. This procedure yields a thin layer of $AgBF_4$ on the cell wall which equilibrates more rapidly with olefin than does a thick deposit of $AgBF_4$ at the bottom of the cell.

TABLE 1. Dissociation equilibrium data

Complex	Dissociation pressure equation*		Temperature range (°C)	Dissociation pressure at 0 °C (Torr)
	A	*B*		
$AgBF_4 \cdot 2C_3H_6$	8.8258 ± 0.00001	2274.2 ± 14.0	+2.27 to +16.68	3.18

*$\log P$ (Torr) $= A - B/(273.15 + t\ °C)$.

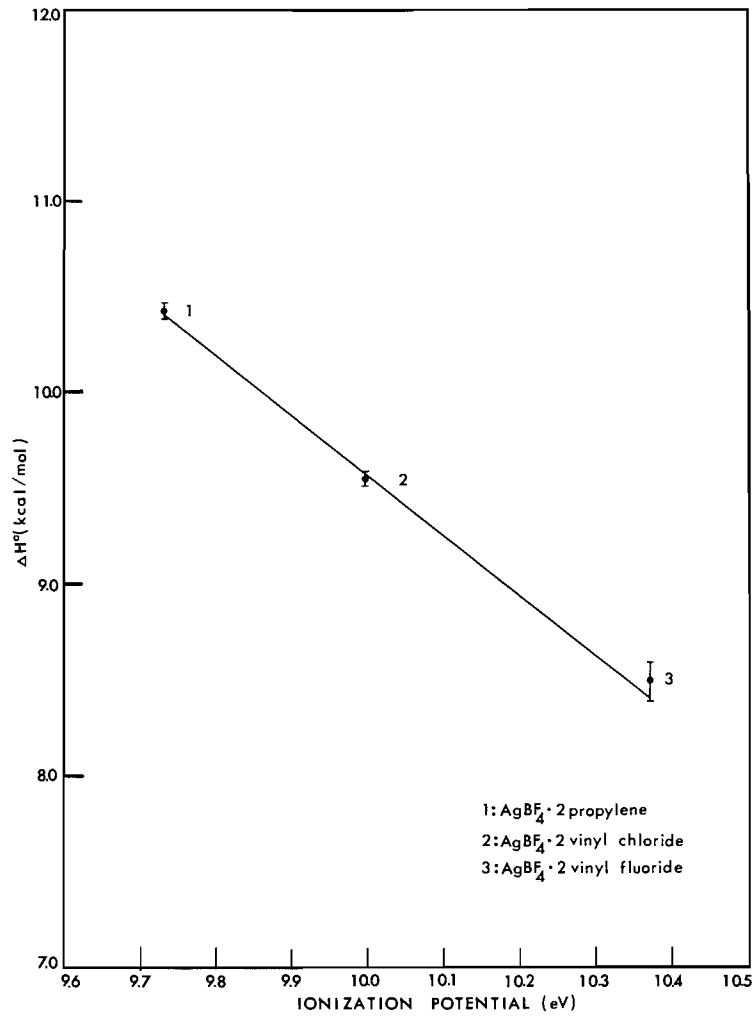

FIG. 1. Enthalpy change – olefin ionization potential correlation.

(b) $AgBF_4 \cdot 2$ Vinyl Chloride

The above described sample of anhydrous $AgBF_4$ was exposed at −22 °C to vinyl chloride (initial pressure 580 Torr). After 2 days the quantity of olefin in the cell was 1.3239 g (21.182 mmol), yielding the system $AgBF_4 \cdot 2$ 2.05 vinyl chloride.

(c) $AgBF_4 \cdot 2$ Vinyl Fluoride

After removal of the vinyl chloride, the same sample of anhydrous $AgBF_4$ was exposed at −45 °C to vinyl fluoride (initial pressure 690 Torr). After 4 days the quantity of olefin in the cell was 1.0339 g (22.456 mmol), yielding the system $AgBF_4 \cdot 2.17$ vinyl fluoride.

(d) $AgBF_4 \cdot 2$ Propylene

After removal of the vinyl fluoride, the same sample of $AgBF_4$ was exposed at ambient temperature to propylene (initial pressure 760 Torr). After 4 days the propylene

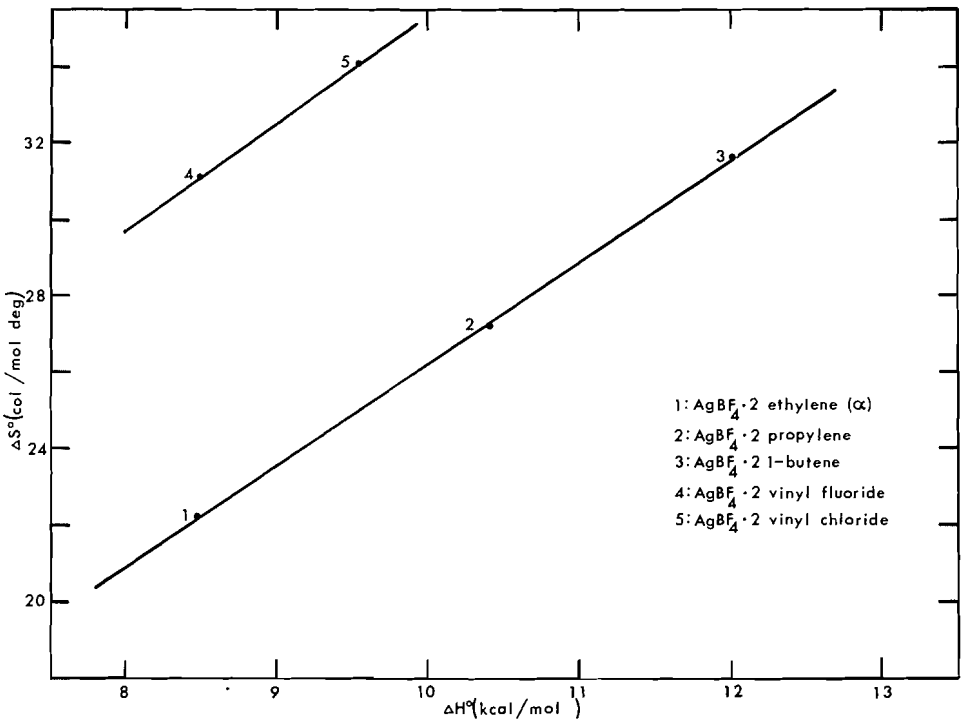

FIG. 2. Plot of entropy change *vs.* enthalpy change. Data for ethylene and 1-butene complexes taken from ref. 1.

uptake was 0.8580 g (20.428 mmol) yielding $AgBF_4 \cdot 1.98C_3H_6$.

The olefin uptake was determined gravimetrically. The discrepancy between the quantity of olefin in the cell and that expected for the 1:2 complex is attributable to the olefin still in the gas phase when the cell was removed for weighing. This excess was removed prior to determination of the dissociation pressure.

Pressure was measured with a Texas Instruments Fused Quartz Precision Pressure Gauge, Model 140A, operating within the range 0–1000 Torr with a sensitivity of 0.01 Torr. The temperature of the gauge capsule was controlled at 35 °C while the envelope of the capsule was continuously evacuated with a mercury diffusion pump backed by an oil pump.

The temperature dependence of the complex dissociation pressure was determined for vinyl chloride and vinyl fluoride complexes in the range −10 to −40 °C and for the propylene complex between 0 and +20 °C. The sample cell was evacuated for about 1 min between measurements after lowering the temperature to a point where the vapor pressure of the complex was very low.

After determination of the stability data for the 1:2 complex, the olefin content of the system was lowered to produce a 1:1 ratio of $AgBF_4$: olefin and another stability point was determined. The similarity of the dissociation pressure to that previously observed for the 1:2 complex ruled out the possibility of lower complexes.

Infrared Studies

A 10% solution of anhydrous $AgBF_4$ in 1,2-dichloroethane was exposed at −20 °C to vinyl chloride or vinyl fluoride (700 Torr) for 24 h. A Research and Industrial Instruments Company variable temperature i.r. unit, V-LTJ, equipped with an absorption cell, FH-01 Ag, was then used with a Beckman IR-9 Spectrophotometer to obtain the i.r. spectra of the solutions at −15 °C.

Results and Discussion

The dissociation pressure and resulting thermodynamic data for the three complexes are presented in Tables 1 and 2. The constants, *A* and *B*, for the dissociation pressure equation were determined by a least squares fit of five to nine

experimental points. The thermodynamic values for the propylene complex are slightly different from those reported earlier (1). The present data are considered to be the more accurate.

Upon complexation of the olefins, the shifts to lower frequency for the double bond stretching vibrations are 55 (2), 53, and 47 cm^{-1} for propylene, vinyl chloride, and vinyl fluoride respectively.

From the data of Table 2 it is obvious that the order of complex stability for the three olefins studied is $AgBF_4 \cdot 2C_3H_6 \gg AgBF_4 \cdot 2C_2H_3Cl > AgBF_4 \cdot 2C_2H_3F$. The stability of the corresponding ethylene complex, $AgBF_4 \cdot 2C_2H_4$ (α) (1), lies between those for propylene and vinyl chloride. The much lower stability of the vinyl chloride and vinyl fluoride complexes results both from smaller enthalpy and larger entropy changes upon interaction of these olefins with the silver salt.

As has been found earlier with a series of hydrocarbon olefins (1), there is a linear dependence, Fig. 1, of $\Delta H°$ on the ionization potential (4) of the olefin indicating a linear increase of $\Delta H°$ with increasing olefin basicity. The slope of this plot may be indeed a measure of the dependence of the coordinate bond energy upon the olefin basicity.

The shift to lower frequency, $\Delta\nu_{C=C}$, for the double bond stretching vibration in the olefin reflects the extent of perturbation of the double bond by the silver ion (2). The approximately linear variation of $\Delta H°$ with $\Delta\nu_{C=C}$ is then a further indication that the difference between the $\Delta H°$ values for the different olefins in this series is a measure of the difference between the coordinate bond energies.

The complexes of the hydrocarbon olefins (1) show a linear variation of $\Delta S°$ with $\Delta H°$ indicative of a progressive limitation of the freedom of the olefin with increasing silver ion – olefin interaction. On this plot, Fig. 2, the points for the vinyl fluoride and vinyl chloride complexes lie, however, far from the line for the hydrocarbon olefins because of their large $\Delta S°$ values and may lie, in fact, on another line essentially parallel to that for the hydrocarbon olefins.

Physical properties of the olefin such as molar volume and polarizability (5) are very similar for vinyl fluoride and ethylene and for vinyl chloride and propylene. Consequently, the larger $\Delta S°$ values for the halo-olefin complexes must be attributable to configurational limitations imposed upon the complexed molecule in addition to those determined by the strength of the coordinate bond and the size or shape of the molecule.

One physical characteristic of the halo-olefins which differs markedly from that of the hydrocarbon olefins is the permanent dipole moment (C_3H_6, 0.366; C_2H_3Cl, 1.445; C_2H_3F, 1.43 D (6)). As a result of their large dipole moment relative to those of ethylene and propylene, the complexed vinyl fluoride and vinyl chloride molecules will experience a greater ion–dipole interaction with the silver ion as well as a greater dipole–dipole interaction with other complexed molecules than do those of the hydrocarbon olefins. These additional interactions will further restrict the freedom of the complexed halo-olefin and will be reflected in higher $\Delta S°$ values for complex formation. Figure 3 provides an indication of the dependence of $\Delta S°$ on the dipole

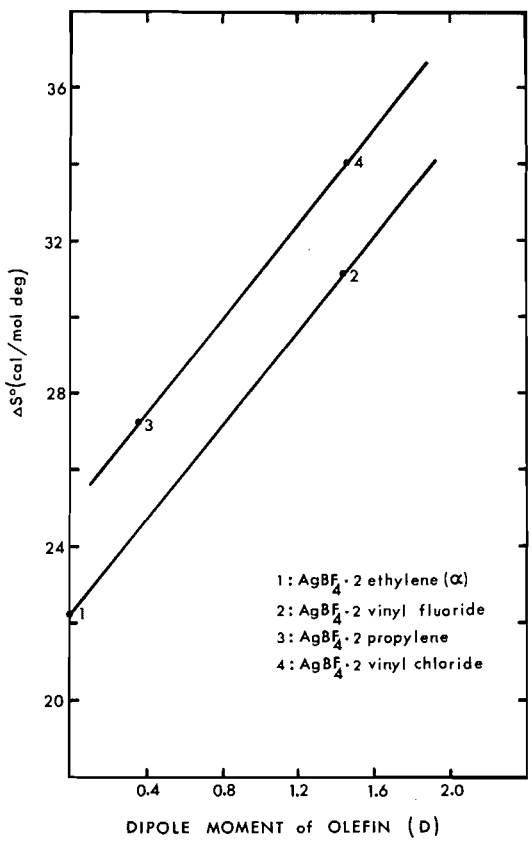

FIG. 3. Entropy change – dipole moment correlation.

moment of the olefin molecule for each pair of olefins with similar molar volume.

For olefins with relatively large dipole moments such as vinyl fluoride or vinyl chloride, the $\Delta S°$ for complex formation can be represented then by the two-term expression, $\Delta S° = C(\Delta H°) + D$ (dipole moment). The constant C is the slope of the line, ($\Delta S° = 2.627\ \Delta H° - 0.044$, by least squares), representing the hydrocarbon olefins in Fig. 2, while the constant D is the slope of either line in Fig. 3. Using the slope of the line for the ethylene and vinyl fluoride complexes, $D = 6.207$, one can calculate for the vinyl chloride complex a $\Delta S°$ value of 34.02 cal deg^{-1} mol^{-1} which compares very favorably with that, 34.06 cal deg^{-1} mol^{-1}, obtained directly from the equilibrium dissociation data.

The much lower stability of the vinyl chloride than of the propylene complex is due then both to the lower basicity of the halo-olefin which results in a weaker metal–olefin bond and to the presence of a much larger dipole moment in the halo-olefin which results in a larger entropy change; the latter effect is the larger. With vinyl fluoride, the reduced complex stability with respect to propylene is about equally attributable to reduced olefin basicity and to the effect of the dipole moment while the reduced stability with respect to ethylene results almost completely from the dipole moment effect.

The authors wish to acknowledge the contribution of A. R. McDowell, Analytical Laboratory, Dow Chemical of Canada, who has determined the i.r. spectra of the complexes.

Chemical Shift. V. Further Studies on the Long-range Shielding Effects of the C—H and C=O Bonds

J. W. ApSimon and H. Beierbeck[1]

Department of Chemistry, Carleton University, Ottawa, Canada

Received November 9, 1970

The long-range shielding effects of the C=O and C—H bonds were reexamined by the method described in part IV of this series, with the objective of resolving the discrepancies between some of the conclusions presented and earlier findings by Zürcher. The C—H bond magnetic anisotropy was treated as a variable and found to be small enough to be negligible. Upon omission of this term, both electrostatic and magnetic anisotropy effects had to be invoked to account for the shielding effects of the carbonyl group.

The necessary geometric quantities were calculated from atomic coordinates for androsterone, as determined by X-ray crystallography, and freely rotating methyl groups were approximated by superpositions of 24 conformations of the group. The results were in essential agreement with those obtained with the use of geometric factors computed as described in part IV.

La méthode décrite dans notre travail précédent (4ème partie) est utilisée pour réexaminer l'effet de blindage à longue distance des liaisons C=O et C—H; le but de ce travail était de trouver une explication qui permettrait de concilier quelques-unes des conclusions présentées et des données rapportées précédemment par Zürcher. On a traité l'anisotropie magnétique du lieu C—H comme une variable et on a trouvé qu'elle est suffisamment faible pour être négligée. Si l'on omet ce terme des calculs ayant comme but d'évaluer les effets de déblindage du groupe carbonyle on doit ensuite faire intervenir les effets d'anisotropie magnétique et électrostatique.

Les quantités géométriques nécessaires ont été calculées à partir des coordonnées atomiques de l'androstanone telles que déterminées par cristallographie de rayons-X; on a simulé les groupes méthyles en rotation libre par superposition de 24 conformations de ce groupe. Les résultats obtenus sont généralement en accord avec ceux obtenus en utilisant les facteurs géométriques calculés par la méthode décrite dans la section IV de cette série.

Canadian Journal of Chemistry, 49, 1328 (1971)

Introduction

In part IV of this series (1–4) the derivation of values for the shielding parameters of the ketonic C=O bond was described. Chemical shifts were predicted in good agreement with experiment and with earlier calculations by Zürcher (5) for the same group of model compounds. However, our conclusions differed in two aspects from Zürcher's results. We did not find any preferred position for the (coincident) magnetic and electric dipole representing the carbonyl group. More importantly it appeared that, in contrast to Zürcher's findings, the electrostatic shielding effect of the carbonyl group was only of minor importance if not negligible. Apart from our simplified version of methyl groups the only difference in assumptions concerned the magnetic anisotropy $\Delta\chi_{xz}$(CH) of the C—H bond. We used a value of 7.54 for $\Delta\chi_{xz}$(CH),[2] derived previously (see note added in proof, ref. 2), whereas the latter author assumed the C—H bond to be practically magnetically isotropic and omitted this term in his calculations. Since this difference in the assumed values for $\Delta\chi_{xz}$(CH) must be responsible for the conflicting results and in the light of recent evidence (8) supporting Zürcher's view that the C—H bond is magnetically isotropic it was decided to repeat the calculations of Part IV (4), firstly treating $\Delta\chi_{xz}$(CH) as a variable, in the hope of confirming one or the other value, and secondly omitting in turn the terms for the C—H bond anisotropy effect and that for the electrostatic effect of the C=O group, in order to compare their relative importance.

[1]Taken from the M.Sc. thesis of H. Beierbeck, Carleton University, Ottawa, Canada, April, 1970.

[2]All shielding parameters are quoted in units: $\times 10^{-30}$ cm^3/molecule.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It also appeared useful to study the reproducibility of the C—H and C=O shielding parameters using geometric quantities obtained from atomic coordinates derived from X-ray crystallographic data and by the use of a more realistic methyl group model (5). Comparison of values obtained by these routes with those of part IV (4) (use of Dreiding models and methyl hydrogen approximation) would then give indication of the expected variations in shielding parameters on the use of approximate conformational data.

Results and Discussion

As in part IV (4) the change in chemical shift of a methyl group upon substitution of CH_2 by C=O is assumed to be due to two shielding mechanisms. The magnetic anisotropy effects of the C=O and C—H bonds are given by eqs. 1*a* and 1*b*[3] (4, 6).

$$[1a]\quad \delta^{M}(CO) = \Delta\chi_{yx}(CO)\,\langle(1 - 3\cos^2\theta_y)/3R^3\rangle + \Delta\chi_{zx}(CO)\,\langle(1 - 3\cos^2\theta_z)/3R^3\rangle$$
$$= \Delta\chi_{yx}(CO)\,\langle g_1{}^{M}(CO)\rangle + \Delta\chi_{zx}(CO)\,\langle g_2{}^{M}(CO)\rangle$$

$$[1b]\quad \delta^{M}(CH) = \Delta\chi_{xz}(CH)\,\langle(1 - 3\cos^2\theta_x)/3R^3\rangle$$
$$= \Delta\chi_{xz}(CH)\,\langle g^{M}(CH)\rangle$$

Equations 2*a* or 2*b*, depending on the methyl group model used (*vide infra*), are the expressions for the electrostatic shielding effect of the C=O bond (4, 7).

$$[2a]\quad \delta^{E}(CO) = K(CO)\,\langle\cos\omega(3\cos\phi\cos\theta_x - \cos\alpha)/R^3\rangle$$
$$= K(CO)\,\langle g^{E}(CO)\rangle$$

$$[2b]\quad \delta^{E}(CO) = K(CO)\,\langle(2\cos\theta_x\cos\phi + \sin\theta_x\cos\psi)/R^3\rangle$$
$$= K(CO)\,\langle g^{E}(CO)\rangle$$

The geometric quantities are defined in Fig. 1, $\Delta\chi_{yx}(CO)$, $\Delta\chi_{zx}(CO)$, and $\Delta\chi_{xz}(CH)$ are the magnetic anisotropies and $K(CO)$ is a proportionality constant descriptive of the electric screening effect. The angle brackets denote averages over the possible conformations of the rotating methyl groups. Thus, the change in chemical shift for a methyl group substitution of CH_2 by C=O is given by eq. 3 (4)

$$[3]\quad \Delta\delta = \Delta\chi_{yx}(CO)\,\langle g_1{}^{M}(CO)\rangle + \Delta\chi_{zx}(CO)\,\langle g_2{}^{M}(CO)\rangle + K(CO)\,\langle g^{E}(CO)\rangle$$
$$- \Delta\chi_{xz}(CH)[\langle g^{M}(CH_\alpha)\rangle + \langle g^{M}(CH_\beta)\rangle]$$

Two changes were introduced in the computation of the necessary geometric quantities. Firstly, in addition to measurements on Dreiding models, X-ray structural data were used.[4,5] The carbon coordinates for androsterone (9) seemed a suitable representation of the androstane backbone. The coordinates for the ring protons and carbonyl oxygens were derived using standard bond lengths and angles.

In the calculations of the oxygen coordinates it had to be assumed that the C—(C=O)—C and C—(CH_2)—C ring fragments are the same. In fact the valency angles increase from *ca.* 110°

[3]The corresponding terms in ref. 4 are:
$\langle g_1{}^{M}(CO)\rangle \equiv f(\theta_1 R_1)$
$\langle g_2{}^{M}(CO)\rangle \equiv f(\theta_1 R_1 \gamma_1)$
$\langle g^{E}(CO)\rangle \equiv f(R_1\omega\beta\psi\phi)$
$\langle g^{M}(CH_\alpha)\rangle \equiv f(\theta_2 R_2)$
$\langle g^{M}(CH_\beta)\rangle \equiv f(\theta_3 R_3)$

[4]Dr. Samek has informed us that his group at the Czechoslovak Academy of Sciences, Prague, is using a similar approach.

[5]Although conformational data from the solid state are used, the close agreement between geometric factors (Table 1) and shielding parameters (Table 4), obtained with X-ray data for six different steroids (Table 1, footnote *), supports the view that different packing in crystals does not seriously affect the molecular geometry.

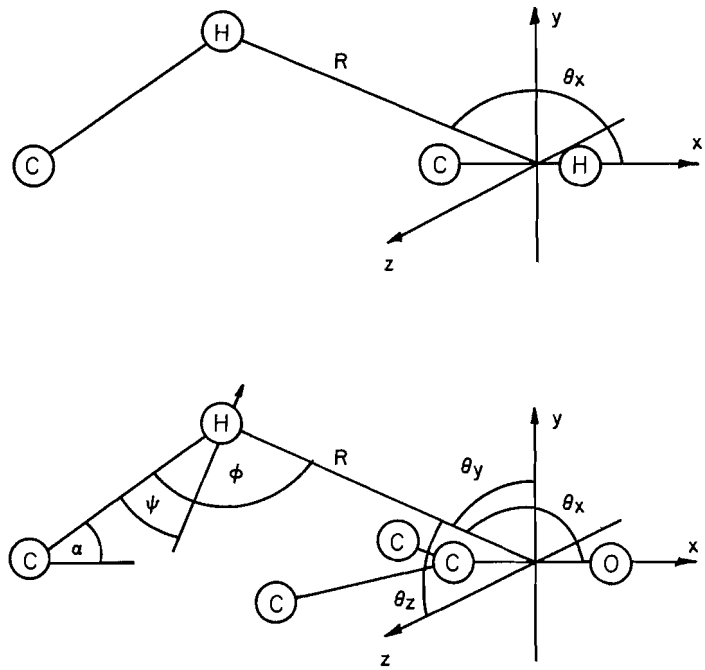

FIG. 1. Definition of geometric quantities.

in the saturated compound to about 116° in the ketones. However, this assumption does not seem to affect the results seriously. In Table 1, geometric factors and differences between calculated and experimental shifts are given for case 11/19, *i.e.*, the effect of substitution of CH_2 by CO in position 11 on the chemical shift of the C-19 methyl group. Carbonyl oxygen positions were calculated with the carbon coordinates for six different steroids, but in the last three cases the C—(CO)—C fragments were part of 11-keto steroids. The variations in geometric factors and calculated shifts between the two groups are of the same magnitude as the variations within both groups.

Secondly two methyl group models were compared. In one, the methyl shifts were represented by the effects at the center of the circle of rotation of the methyl hydrogens. In this case, eq. 2*a* was used and the angle brackets indicate that an average methyl proton position was assumed.

In a second series the shielding was approximated by the average of the shift increments at each of 72 points around the circle, 5° apart. In this case the electric field effect was expressed by eq. 2*b*, derived previously (4), and the angle brackets signify that the enclosed geometric quantities are averages of 72 values.

In order to separate changes in shielding parameters due to changes of the methyl group model from changes with the source of the skeletal coordinates, four series of geometric factors were derived, XR, XA, MR, and MA. The X and M stand for X-ray data and molecular models respectively, R and A denote the type of methyl group model that was employed (R = rotating methyl; A = average proton position (1–4)). Within each of these four series of geometric factors the C—H and C═O dipole positions were varied in steps of 0.2 Å. The geometric quantities from set XR are collated in Table 2; Table 3 shows a comparison of geometric factors from the four series XR, XA, MR, and MA.

Least squares calculations were carried out initially with the 22 equations derived from the methyl shifts in 5α,14α androstane and its monoketo derivatives, varying C═O and C—H point dipole positions independently. Again, it was found that the shielding effect of the C-11 keto

group on the C-19 methyl protons was anomalous. The corresponding equation was therefore excluded from further calculations.

The original suggestion to account for this discrepancy (4) was conformational disparity between the 11-ketone and androstane, caused by nonbonded interactions between the C-1 protons and the C-11 carbonyl oxygen. However, the six steroids in Table 1 do not show a distortion of either the A or the C ring large enough to produce additional downfield shifts of 0.3 p.p.m. More likely causes are van der Waals' deshielding and hindered rotation of the C-19 methyl group (also suggested by Zürcher (5)) and failure of the point dipole approximation. The distance of closest approach of the carbonyl oxygen and the C-19 methyl hydrogens is 2.2 to 2.4 Å as compared to the next shortest distance of *ca.* 3 Å in the case of the 1-ketone.

Conformational disparity, however, seems to be the reason for the large error in the prediction of the effect of the C-17 carbonyl group on the C-18 methyl hydrogens. Introduction of the C-17 C=O bond shifts the energy minimum along the pseudorotation path of the D ring relative to its position in the saturated ring (15). This change from one conformation to the other most likely contributes to the chemical shift of the C-18 methyl group. This case was also excluded from further calculations.

The least squares analyses were repeated with the remaining 20 equations, varying C—H and C=O dipole positions independently. The standard deviation between calculated and experimental shifts showed a minimum for a C=O dipole location at the bond center, but there was no preferred C—H dipole location. The

values for $\Delta\chi$(CH) were small for all points along the C—H bond, *e.g.*, 3.1 for the point 0.8 Å from carbon. The standard deviation remained practically unchanged when the term in $\Delta\chi_{xz}$(CH) was omitted and there were only small changes in the C=O bond shielding parameters. Thus, it is fairly certain that the C—H bond anisotropy is indeed small and normally it seems justified to set it equal to zero.

The electrostatic shielding effect of the C=O bond was found to be equally important as its anisotropy effect. The chemical shifts could not be accounted for by the use of only the anisotropy effects or only the electric field effect terms, in accord with Zürcher's findings (5). Thus, it appears that the conflicting conclusions regarding the C=O dipole location and the significance of the electrostatic screening mechanism were indeed due to the use of different C—H bond anisotropy values.

In contrast the use of geometric quantities obtained from measurements on molecular models and the simplifying assumptions concerning the actual methyl hydrogen positions, led to conclusions in general agreement with results obtained using more accurate conformational data. Although the results obtained with set XR of geometric factors have to be considered to be the best, the other parameters do not differ very much (Table 4) and they predict the chemical shifts equally well (Table 5).

Experimental

The steroids used were obtained as described in ref. 4. Calculations were performed on the SIGMA 7 computer at Carleton University. Programs are available upon request.

We thank Mrs. J. Lemke and Mr. S. Scharf for expert technical assistance, the National Research Council of Canada for generous financial support, and the Ontario Government for a Graduate Fellowship (H.B.).

Received November 9, 1970

The calculation of chemical shift values by the method used in parts I–V (1–5) has been extended to a derivation of the shielding effects of the ethylene–ketal and –thioketal groups. For these studies ketal and thioketal derivatives of monoketoandrostanes were prepared. The chemical shifts of the C-18 and -19 methyl protons in these compounds are reported for the solvents $CDCl_3$, CCl_4 and benzene.

Representing both groups by point dipoles, values for the anisotropies and for *K*, a parameter descriptive of the electric field effect, were derived for various, coincidental, locations of the magnetic and electric dipoles along the symmetry axes of the two groups.

La méthode de calculs des déplacements chimiques développée dans nos communications I–V (1–5) a été étendue à la dérivation des effets de blindage provoqués par les groupes éthylène–cétals et –thiocétals. Afin de mener ces études à bien on a préparé des dérivés cétals et thiocétals de monocétoandrostanes. On rapporte les déplacements chimiques des protons des méthyles en C-18 et -19 de ces composés lorsqu'ils sont en solution dans le $CDCl_3$, CCl_4 et le benzène.

On a représenté les deux groupes par des dipoles ponctuels et il a été alors possible d'évaluer pour divers sites des dipoles électriques et magnétiques qui coincident le long des axes de symétrie des deux groupes, des valeurs pour leur anisotropie et pour *K*, un paramètre descriptif de l'effet de champ électrique.

Canadian Journal of Chemistry, 49, 1335 (1971)

Preceding papers in this series (1–5) have described the derivations of values for the long range shielding parameters of C—C, C—H, C=C, and C=O bonds. In this paper we report the results of the extension of the method to the ethylene–ketal **1** and –thioketal **2** groups.

1 **2**

We became interested in these groups in connection with our studies of the C=O bond shielding effect. Since only changes in chemical shifts upon exchange of one group by another can be predicted, it is necessary to have a reference group for every functional group of interest. In the studies of the C=O bond shielding effects (4–6) the substitution CO/CH_2 was used, *i.e.*, the parent hydrocarbon served as reference. In the general case, however, ketal or thioketal derivatives are more readily available. Therefore an understanding of the shielding effects of these groups could be of considerable value for structural assignments concerning the keto group.

One paper on the long-range shielding effects of the ketal groups has appeared recently in the literature (7). These workers estimated the shift increments due to the substitution of CH_2 by the ethylene–ketal group from the sum of the anisotropy effects (8) of the component bonds plus the electric field effect (9) of the total group. Values for the anisotropies for the C—C and C—O bonds were taken from the literature (10, 11), the C—H bonds were assumed to be magnetically

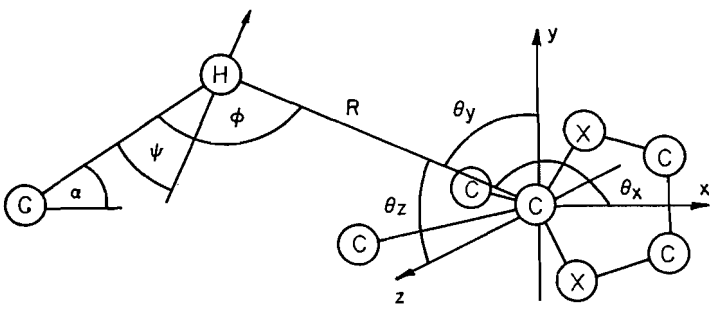

FIG. 1. Definition of geometric quantities.

isotropic. The electric field effect was assumed to arise from a point dipole, with the dipole moment of the group located at its center of gravity. Experimental shifts for C-18 and -19 methyl groups in 12 steroidal ketals, representing seven different situations, were quoted. Calculated shifts were given for three cases, in two cases agreement with experiment was satisfactory.

In the present study we attempted to treat the ketal and thioketal groups as point magnetic and electric dipoles as in the case of the carbonyl group. If average planarity is assumed, the two groups have the same symmetry as the C=O bond. Therefore, the same geometric quantities could be used that had previously been derived in the course of our studies of the C=O bond shielding effect (5). The requisite experimental data were derived from the chemical shifts of the C-18 and -19 methyl groups in ketal and thioketal derivatives of monoketoandrostanes, made in this laboratory (Table 1).

As in the case of the carbonyl group (4, 5) changes in chemical shift were assumed to be due to anisotropy effects δ^M (8) and to electric field effects δ^E (9), as defined by eqs. 1 and 2.[2]

The geometric quantities are defined in Fig. 1, $\Delta\chi_{yx}$ and $\Delta\chi_{zx}$ are the magnetic anisotropies in the yx and zx planes respectively, and K is a proportionality constant, descriptive of the

*Estimated from $\Delta\delta(\text{Ke/CO}) = \Delta\delta(\text{Ke/CH}_2) - \Delta\delta(\text{CO/CH}_2)$. Dipole positions: Ke at carbon, CO 0.6 Å from carbon.
†From direct least squares fit to $\delta(\text{Ke/CO})^{obs}$. Both dipoles at carbon.

electric field effect. Electric and magnetic dipoles were assumed to coincide. Their positions were varied along the symmetry axes in steps of 0.2 Å.

Shielding parameters for the ketal (thioketal) group were derived in two ways, namely by predicting the effect of the substitutions of either CH_2 or of C=O by the ketal (thioketal) group. With the abbreviations Ke = ketal, S = thioketal, Ke/CO = substitution of C=O by the ketal group, etc., eqs. 3 and 4 can be written,

$$[3]\quad \delta(\text{Ke/CH}_2) = \delta^M(\text{Ke}) + \delta^E(\text{Ke}) - \delta^M(\text{CH}_2)$$
$$= \Delta\chi_{yx}(\text{Ke})\langle g_1{}^M(\text{Ke})\rangle + \Delta\chi_{zx}(\text{Ke})\langle g_2{}^M(\text{Ke})\rangle + K(\text{Ke})\langle g^E(\text{Ke})\rangle$$
$$- \Delta\chi(\text{CH})[\langle g(\text{CH}_\alpha)\rangle + \langle g(\text{CH}_\beta)\rangle]$$

$$[4]\quad \delta(\text{Ke/CO}) = \delta^M(\text{Ke}) + \delta^E(\text{Ke}) - \delta^M(\text{CO}) - \delta^E(\text{CO})$$
$$= \Delta\chi_{yx}(\text{Ke/CO})\langle g_1{}^M(\text{CO})\rangle + \Delta\chi_{zx}(\text{Ke/CO})\langle g_2{}^M(\text{CO})\rangle$$
$$+ K(\text{Ke/CO})\langle g^E(\text{CO})\rangle$$

plus two analogous equations for the thioketal group.

Equation 4 was written in an attempt to use coincidental C=O and Ke(S) dipole positions. The actual center of gravity of the ketal group is *ca.* 1 Å from carbon, compared to 0.6 Å for the keto group. The shielding parameters obtained by employing eq. 4 are differences between the parameters for the Ke(S) and the C=O group. The use of two different dipole locations involves too many variables to promise reasonably accurate predictions of chemical shifts. Least squares calculations of δ(Ke/H) and δ(S/H), using eq. 3, again (5) showed little dependence of the standard deviation between calculated and experimental shifts on the C—H dipole position. Values obtained for the C—H bond anisotropy were small in agreement with previous results (5). In view of the nature of the other assumptions it seemed justified to ignore this term.

A plot of the standard deviation between calculated and experimental shifts $\delta(\text{Ke/CH}_2)$ and $\delta(\text{S/CH}_2)$ *vs.* the dipole positions had a minimum at the steroidal carbon, but there was only a slight increase of σ as the dipoles were moved out along the symmetry axes. Table 2 shows the differences between calculated and experimental shifts; the

[5] $$\Delta\delta(\mathrm{Ke/CO}) = \Delta\delta(\mathrm{Ke/CH_2}) - \delta(\mathrm{CO/CH_2})$$

since

[6] $$\delta(\mathrm{Ke/CO})^{\mathrm{obs}} = \delta(\mathrm{Ke/CH_2})^{\mathrm{obs}} - \delta(\mathrm{CO/CH_2})^{\mathrm{obs}}$$

corresponding shielding parameters are given in Table 3.

An estimate of the errors Δ(Ke/CO) of predictions of δ(Ke/CO) may be obtained from eq. 5.

Analogous expressions hold for $\Delta\delta$(S/CO). Alternatively the shifts δ(Ke/CO) and δ(S/CO) may be calculated by a direct least square fit to experimental shifts, using eq. 4. In this case, too, the steroidal carbon was found to be the best dipole location. Calculated shifts and shielding parameters are collated in Tables 2 and 3.

It is doubtful whether these shielding parameters have any physical significance. The point dipole approximation is certainly inadequate in this case and the electric center of gravity is not at the steroidal carbon atom. Only five of the experimental shifts δ(Ke/CO) in the 5 α series were larger than 10 Hz and these represent only two truly different situations, since substituents in the 2, 4, and 6 positions and those in the 3 and 7 positions are practically equivalently oriented with respect to the C-19 methyl group. In addition, it is likely that the 1,3-diaxial interactions between the methyl groups and the C—O (C—S) bonds are severe enough to cause substantial deformations in the steroid skeleton and to give rise to van der Waals shielding effects.

Total Synthesis of 4-*O*-Methyl-DL-lyxose and 4-Deoxy-DL-ribose. Further Evidence of the Stereoselective Hydroxylation of Double Bonds by Osmic Acid

R. M. SRIVASTAVA[1] AND R. K. BROWN

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received December 7, 1970

Methyl 4-*O*-methyl-α-DL-lyxopyranoside (**6**) and methyl 4-deoxy-β-DL-*erythro*-pentopyranoside (**3**) were obtained in excellent yield as the sole isolable products of the reaction of osmic acid in pyridine on *cis*-2,5-dimethoxy-5,6-dihydro-2*H*-pyran (**2**) and 2-methoxy-5,6-dihydro-2*H*-pyran (**1**), respectively. Hydrolysis of **6** and **3** gave respectively 4-*O*-methyl-DL-lyxose (**9**) and 4-deoxy-DL-ribose (**8**).

The attack on the double bond of **1** and **2** occurs nearly completely if not exclusively from the unhindered side, remote from the substituent. These results indicate that **1** must be predominantly in the conformation in which the C-2 alkoxy group is *quasi* axial.

Le 4-*O*-méthyl-α-DL-lyxopyranoside de méthyle (**6**) et le déoxy-4 β-DL-*érythro*-pentopyranoside de méthyle (**3**) ont été obtenus avec un excellent rendement et comme seuls produits de la réaction entre l'acide osmique dans la pyridine et respectivement le diméthoxy-2,5-dihydro-5,6 2*H*-pyranne-*cis* (**2**) et le méthoxy-2 dihydro-5,6 2*H*-pyranne (**1**). L'hydrolyse de **6** et de **3** conduit respectivement au 4-*O*-méthyl DL-lyxose (**9**) et au déoxy-4 DL-ribose (**8**).

L'attaque de la double liaison de **1** et de **2** se produit presque complètement sinon complètement par le côté le moins empêché, à savoir celui le plus éloigné du substituant. Ces résultats impliquent que **1** doit être sous une conformation dans laquelle le groupe alcoxy en position 2 est *quasi* axial.

Canadian Journal of Chemistry, 49, 1339 (1971)

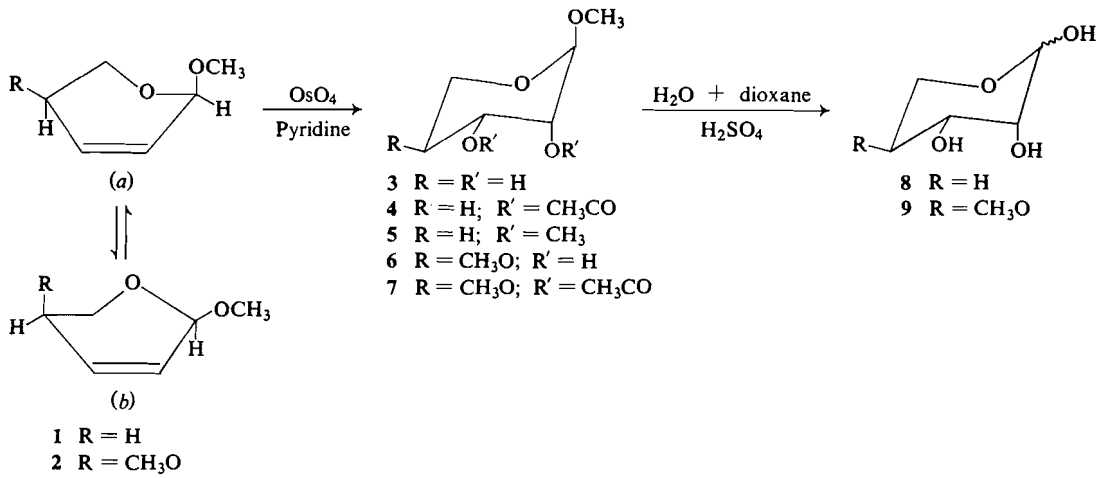
A recent report from this laboratory has described the stereoselective attack of osmic acid on the double bond of the bicyclo compound 1,6-anhydro-3,4-dideoxy-β-DL-*erythro*-hex-3-enopyranose to produce, after hydrolysis, both α,β-DL-allose and α,β-DL-galactose (1). As part of a program aimed at the total syntheses of monosaccharides, and also to determine whether the stereoselective attack by osmic acid could be extended to 2-alkoxydihydropyrans, the reaction of osmic acid on both 2-methoxy-5,6-dihydro-2*H*-pyran (**1** in Scheme 1) and *cis*-2,5-dimethoxy-5,6-dihydro-2*H*-pyran (**2** in Scheme 1) was investigated. This report describes the results obtained.

The reactions performed and the products obtained are summarized in Scheme 1.

By the improved procedure (2), the reaction of osmic acid with **1** gave a nearly quantitative yield of crude material whose 100 MHz p.m.r. spectrum showed the presence of only one anomeric proton signal. Distillation of this crude material provided methyl 4-deoxy-β-DL-*erythro*-pentopyranoside (**3**) in 93% yield. The 100 MHz p.m.r. spectrum of **3** agreed with the structure designated. The 100 MHz p.m.r. spectrum of its diacetate **4** when analyzed with the aid of double irradiation, fully confirmed that the configuration and conformation was that indicated by **4**. Hydrolysis of **3** with aqueous dioxane containing sulfuric acid gave 4-deoxy-DL-ribose (**8**) in 77% yield. The 100 MHz p.m.r. spectrum of **8** in D_2O showed at first only one anomeric proton signal as a doublet at τ 5.09 ($J \approx 5$ Hz). When the solution had stood for a period of 24 h a second doublet appeared in the anomeric proton region at τ 5.36 ($J \approx 1.7$ Hz) thus indicating that the α anomer was now present in the ratio β:α = 1.0:0.42 as shown by the integrated areas of the signals.

The reaction of osmic acid with **2** gave a nearly quantitative yield of crude material which showed only two spots on a t.l.c., one barely discernible. Distillation of this crude substance gave methyl 4-*O*-methyl-α-DL-lyxopyranoside (**6**) in 84% yield as the sole insoluble product. The i.r. spectrum of **6** in carbon tetrachloride showed a narrow band at 3600 cm^{-1} and a broad absorption band, 3260–3540 cm^{-1}. An extensively diluted solution gave an i.r. spectrum with only one narrow band at 3590 cm^{-1}, indicative of the absence of intramolecular hydrogen bonding. The 100 MHz p.m.r. spectrum of **6** in pyridine-d_5 showed the anomeric proton signal as a doublet ($J \approx 2.8$ Hz) centered at τ 5.05 in agreement with the configura-

[1]Postdoctoral Fellow, 1968–1970. Presently at the Department of Chemistry, University of Windsor, Windsor 11, Ontario.



SCHEME 1

tion and conformation shown by **6**. Spin decoupling experiments provided no further corroboration of the structure proposed. However, the 100 MHz p.m.r. spectrum of the crystalline di-*O*-acetyl derivative **7** agreed with the proposed structure and spin decoupling experiments corroborated that **7** was in fact methyl 2,3-di-*O*-acetyl-4-*O*-methyl-α-DL-lyxopyranoside.

Hydrolysis of **6** with aqueous dioxane containing sulfuric acid afforded 4-*O*-methyl-DL-lyxose **9** as a viscous sirup in 75% yield. The 100 MHz p.m.r. spectrum of **9** in D_2O, after it had stood at room temperature for 16 h, showed two anomeric proton signals as doublets at τ 4.72 ($J \approx 5$ Hz) and 4.83 ($J \approx 1.5$ Hz) in the area ratio of 1.0:0.37, indicative of a mixture of the β and α anomers respectively. Final corroboration that **9** was indeed the structure indicated was obtained by the observation that the 100 MHz p.m.r. spectrum of **9** in D_2O was identical to that of authentic 4-*O*-methyl-D-lyxose.

It is clear that for both **1** and **2**, the attack by osmic acid on the double bond occurs nearly if not completely exclusively from the side remote from the substituent at C-2 and -4 and thus provides further evidence that the preferred direction of attack by osmic acid on a double bond of this six-membered ring structure is determined by steric factors. In this respect it is similar to the effect of substituents in directing the attack of peroxy acids on the double bond of 3-substituted cyclohexenes (3). This steric effect is readily discerned in either of the conformations *a* and *b* of compound **2** (Scheme 1). However, only in conformation *a* does compound **1** show such steric opposition by the C-2 methoxy group to the approach of osmic acid to the double bond on the same side of the ring occupied by the substituent. In conformation **1***b*, the double bond of compound **1** is readily accessible from either side of the ring. The fact that such a high proportion (84% at least) is obtained of the product resulting from attack of the double bond *trans* to the C-2 methoxy group indicates that compound **1** must prefer to a very large degree the conformation *a* in which the C-2 methoxy group is in the *quasi* axial orientation. It is well known that 2-alkoxytetrahydropyrans prefer that chair conformation in which the alkoxy group is axial. This phenomenon is known as the "anomeric effect" (4–6). This phenomenon is thought to be due to the polar character of the C_2—OCH_3 bond and the C_6—O_1 or C_2—O_1 bond of the 2-alkoxytetrahydropyran ring system (6–9). The similarity in these structural features of compound **1** leads to the reasonable assumption that the anomeric effect should be operative here also and thus conformer *a* would be preferred to conformer *b*. The great preponderance of attack by osmic acid on the side of the double bond remote from the C-2 methoxy group lends further support for this view.

Experimental

Boiling points and melting points are uncorrected. The b.p. of the viscous sirup was obtained in a sublimation apparatus. The lower end of this apparatus was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

dipped into an oil bath and slowly heated. When the sirup started to deposit on the cold finger, the bath temperature was recorded as the b.p.

Elemental analyses were made by Mrs. Darlene Mahlow and Mrs. Andrea Dunn of this Department.

The 60 MHz p.m.r. spectra were made by Mr. R. Swindlehurst on a Varian A-60 spectrometer at 35 ± 1°. The 100 MHz p.m.r. spectra and spin decoupling experiments were done by Mr. Glen Bigam and associates of this Department, using a Varian HR-100 MHz instrument at 33 ± 1°. Unless otherwise specified, deuteriochloroform was the solvent used, with tetramethylsilane as internal or external reference. The couplings reported have been estimated from the spacings on the spectrum and are therefore approximate values.

The t.l.c. was done with Silica Gel G (E. Merck and Co.) as adsorbent. Iodine vapor was used to detect the spots.

Solvents were removed by rotary evaporator under vacuum unless otherwise stated.

*Methyl 4-O-Methyl-*α*-*DL*-lyxopyranoside (6)*

Osmium tetroxide (1.0 g, 3.39 mmol) in 4 ml of dry pyridine (2) was added to a solution of 0.563 g (3.90 mmol) of *cis*-2,5-dimethoxy-5,6-dihydro-2*H*-pyran (**2**) (10) in 9 ml of pyridine at room temperature. The solution was stirred for 20 h at room temperature and then treated with a solution of 1.8 g of sodium bisulfite in a mixture of 20 ml of pyridine and 30 ml of water and then stirred for an additional 4 h. The orange solution was extracted with methylene chloride (6 × 25 ml) and the extract dried (K_2CO_3) and filtered. The drying agent was washed with methylene chloride. The combined methylene chloride solutions were freed from solvent at room temperature under vacuum and gave 0.65 g of a sirup which showed two spots on a t.l.c. (solvent, 10% methanol in chloroform). Distillation at 70° at 0.05 mm gave 0.51 g (73%) of **6** as a colorless sirup.

Anal. Calcd. for $C_7H_{14}O_5$: C, 47.19; H, 7.92. Found: C, 46.99; H, 7.72.

The aqueous portion left after methylene chloride extraction was further extracted continuously for 48 h with methylene chloride and provided, after purification, 80 mg (11.4%) more of **6**. The t.l.c. of this pure material showed only one spot.

The i.r. spectrum in carbon tetrachloride showed a narrow band at 3600 (OH) and a broad band at 3260–3540 cm^{-1} (bonded OH). In highly dilute solution only one narrow band at 3590 cm^{-1} occurred (unbonded OH).

The 100 MHz p.m.r. spectrum in pyridine-d_5 showed a doublet ($J \sim 2.8$ Hz) at τ 5.05.

*Methyl 2,3-Di-O-acetyl-4-O-methyl-*α*-*DL*-lyxopyranoside (7)*

A solution of **6** (0.51 g, 2.86 mmol) in 2.5 ml of dry pyridine and 2.5 ml of acetic anhydride was warmed for 0.5 h at 60° and then stirred overnight at room temperature. The bulk of the pyridine and excess acetic anhydride was removed by fractional distillation under vacuum (5–6 mm) at room temperature. The residual liquid in 10 ml of chloroform was treated with 10 ml of cold 3 *N* aqueous ammonium hydroxide and the resulting solution then extracted with chloroform (5 × 25 ml). The chloroform extract was dried (Na_2SO_4), filtered, and freed from solvent. The residual sirup crystallized from chloroform–hexane; yield, 515 mg (69%), m.p. 79–82°, raised to 81–82.5° by two recrystallizations.

Anal. Calcd. for $C_{11}H_{18}O_7$: C, 50.38; H, 6.92. Found: C, 50.50; H, 6.87.

The i.r. spectrum in chloroform showed a strong band at 1750 cm^{-1} (—CO_2—).

The 100 MHz p.m.r. spectrum showed the anomeric proton signal at τ 5.41 (doublet, $J \sim 2.0$ Hz) and a multiplet (2H) at 4.79 due to H-2 and -3. Irradiation of the nucleus of H-1 at τ 5.41 resulted in loss of a small coupling in the multiplet at τ 4.79. Double irradiation of H-1 (τ 5.41) and H-4 (∼τ 6.36) produced an AB pattern for the signal of H-2 and -3 at τ 4.79 which appeared as a rather broad singlet. The loss of a large coupling in the signal at τ 4.79 due to this double irradiation shows that H-3 and -4 are *trans* diaxially disposed.

*4-O-Methyl-*DL*-lyxose (9)*

A solution of **6** (0.1 g, 0.56 mmol) in 1.2 ml of *p*-dioxane and 3 ml of 1.5% aqueous sulfuric acid was refluxed for 4 h, then cooled, neutralized with barium carbonate, and filtered. The solid was washed with a 1:1 mixture of *p*-dioxane and water (4 × 3 ml). The combined filtrate and washings were freed from solvent and gave 80 mg of crude viscous sirup. Distillation provided 69 mg (75%) of colorless sirup boiling at 80° at 0.07 mm.

Anal. Calcd. for $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 43.94; H, 7.45.

The 100 MHz p.m.r. spectrum (tetramethylsilane as external reference) of a solution of **9** in D_2O after standing for 16 h, showed two anomeric proton signals at τ 4.72 (doublet, $J \sim 5$ Hz) and 4.83 (doublet, $J \sim 1.5$ Hz) in the area ratio of 1.0:0.37. Both the 60 and 100 MHz p.m.r. spectra of **9** were identical to those of authentic 4-*O*-methyl-D-lyxose.

*Methyl 4-Deoxy-*β*-*DL*-erythro-pentopyranoside (3)*

The reaction of osmic acid with **1** (11) was carried out essentially as described above for the formation of **6** except that after decomposition of the osmate ester the solution was extracted continuously with methylene chloride. The extract was then worked-up as described for the isolation of **6**. The crude product, obtained in almost quantitative yield, gave a 100 MHz p.m.r. spectrum whose amplified anomeric proton signal region gave only one anomeric proton signal, a doublet at τ 5.40 ($J \sim 4.0$ Hz). Distillation of the crude product in a sublimation apparatus afforded a colorless, viscous liquid in 93% yield, b.p. 72° at 1.5 mm. This showed a single spot on t.l.c. (5% methanol in chloroform).

Anal. Calcd. for $C_6H_{12}O_4$: C, 48.64; H, 8.16. Found: C, 47.92, 48.27; H, 7.85, 8.16.

An ether solution, cooled in ice, gave an hygroscopic solid, m.p. 49–51.5°.

The 100 MHz p.m.r. spectrum of the viscous oil showed the anomeric proton (H-1) signal as a doublet at τ 5.39 ($J \sim 4.0$ Hz). Irradiation of H-1 caused a collapse of the triplet (total $J \sim 7.5$ Hz) for H-2 at τ 6.38 to a doublet ($J \sim 3.5$ Hz). A one-proton multiplet at τ 5.97 with total width ∼16 Hz remained unaffected. This, as well as its

splitting pattern indicated that this multiplet at τ 5.97 was due to H-3.

*Methyl 4-Deoxy-2,3-di-O-acetyl-β-*DL*-erythro-pentopyranoside (4)*

Compound **3** (0.4 g) was converted to its diacetate **4** by the same procedure used to prepare the diacetate 7 above. Crystals (505 mg, 81%) from methylene chloride – hexane, m.p. 80–82.5°, raised to 82–83.5° by two recrystallizations.

Anal. Calcd. for $C_{10}H_{16}O_6$: C, 51.72; H, 6.94. Found: C, 51.53; H, 6.71.

The i.r. spectrum (Nujol mull) showed a strong band at 1750 cm^{-1} (—CO_2—).

The 100 MHz p.m.r. spectrum gave a triplet at τ 4.97 ($J \sim 2.5$–3.0 Hz) for H-2 and an eight-line multiplet for H-3 at 4.75 with total width $\simeq$ 19 Hz. Irradiation of H-1 at τ 5.36 (doublet, $J \sim 2.5$ Hz) caused the triplet for H-2 at 4.97 to change to a doublet ($J \sim 3.0$ Hz) thus corroborating the location of the H-2 signal. A slight sharpening of the eight-line multiplet at τ 4.75 occurred. This multiplet can be accommodated only if H-3 is axial. This information clearly confirms the structure and conformation of this diacetate as shown by **4**.

*Methyl 4-Deoxy-2,3-di-O-methyl-β-*DL*-erythro-pentopyranoside (5)*

Compound **3** was methylated by the following modification of the published general procedure (12). A solution of **3** (0.37 g, 2.5 mmol) in 5 ml of dry 1,2-dimethoxyethane (DME) was added dropwise over a period of 15 min to a stirred slurry of sodium hydride (0.15 g, 6.2 mmol) in 5 ml of dry DME containing 1 ml of methyl iodide (an excess). The mixture was stirred overnight at room temperature, then diluted with 50 ml of ether and filtered. The solvent was removed by fractional distillation. The residue was distilled in a two-bulb apparatus and gave 0.21 g (48%) of a colorless oil, b.p. 95° (oil bath temperature) at 11 mm, $n_D^{27.5}$, 1.4394.

Anal. Calcd. for $C_8H_{16}O_4$: C, 54.53; H, 9.15. Found: C, 54.68; H, 9.06.

The i.r. and 60 MHz p.m.r. spectra were consistent with the structure as shown by **5**.

*4-Deoxy-*DL*-ribose (8)*

Hydrolysis of **3** was carried out by the same procedure used above to hydrolyze **6**. From 200 mg of **3** there was obtained 175 mg of crude product. Distillation in a sublimation apparatus gave 139 mg (76.8%) of a semisolid, b.p. 74–76° (oil bath temperature) at 0.09 mm.

Anal. Calcd. for $C_5H_{10}O_4$: C, 44.77; H, 7.51. Found: C, 44.68; H, 7.57.

The i.r. spectrum (neat) showed a strong broad band at 3360 (OH) and two weak bands at 1720 (C=O) and 1650 cm^{-1} (unknown).

The 60 MHz p.m.r. spectrum in D_2O, with tetramethylsilane as external reference, was taken after the solution had stood at room temperature for a short time and showed one anomeric proton signal at τ 5.09 (doublet for H-1, $J \simeq 5$ Hz). The spectrum, obtained this time at 42° after the solution had stood for 24 h, showed two anomeric proton signals as doublets, one at τ 5.1 and the other at 5.36. Expansion of these signals to a sweep width of 100 Hz gave $J \simeq 5.2$ and $J \sim 1.7$ Hz respectively with the signals in the area ratio of 1.0:0.42.

The authors thank the National Research Council of Canada for financial support throughout the course of this work.

Particular thanks are given to Professor N. A. Hughes, Department of Organic Chemistry, The University of Newcastle upon Tyne, England, for kindly supplying us with a sample of 4-*O*-methyl-D-lyxose.

Synthesis of 2,3,6,7,8,9-Hexahydro-1*H*-cyclohepta[*gh*]phenalene

A. FISCHER AND D. R. A. LEONARD
Department of Chemistry, University of Victoria, Victoria, British Columbia

AND

D. A. R. HAPPER
Department of Chemistry, University of Canterbury, Christchurch, New Zealand

Received September 2, 1970

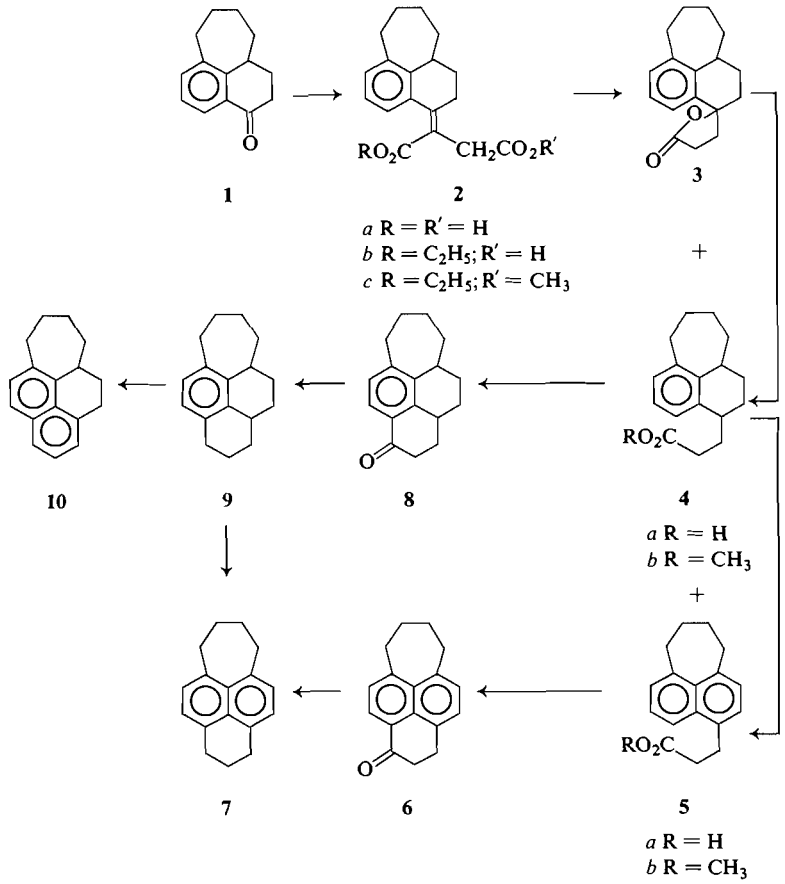
2,3,6,7,8,9-Hexahydro-1*H*-cyclohepta[*gh*]phenalene (**7**) has been prepared via the tricyclic ketone 3-oxo-1,2,3,7,8,9,10,10*a*-octahydrocyclohepta[*de*]naphthalene (**1**) and the tetracyclic ketone 1-oxo-2,3,6,7,8,9-hexahydro-1*H*-cyclohepta[*gh*]phenalene (**6**). Conversion of the tricyclic ketone **1** into 1-oxo-1,2,3,3*a*,5,5*a*,6,7,8,9-decahydro-4*H*-cyclohepta[*cd*]phenalene (**8**) and reduction of this tetracyclic ketone to 1,2,3,3*a*,5,5*a*,6,7,8,9-decahydro-4*H*-cyclohepta[*cd*]phenalene (**9**), followed by aromatization, gave 5,5*a*,6,7,8,9-hexahydro-4*H*-cyclohepta[*cd*]phenalene (**10**) (73%) together with the desired isomeric 2,3,6,7,8,9-hexahydro-1*H*-cyclohepta[*gh*]phenalene (**7**) (23%).

On a préparé l'hexahydro-2,3,6,7,8,9 1*H*-cyclohepta[*gh*] phénalène (**7**) en utilisant la cétone tricyclique, oxo-3 octahydro-1,2,3,7,8,9,10,10*a*-cyclohepta[*de*]naphtalène (**1**), et la cétone tétracyclique, oxo-1 hexahydro-2,3,6,7,8,9 1*H*-cyclohepta[*gh*]phénalène (**6**) comme intermédiaires. La transformation de la cétone tricyclique **1** en oxo-1 décahydro-1,2,3,3*a*,5,5*a*,6,7,8,9, 4*H*-cyclohepta[*cd*]phénalène (**8**) suivie d'une réduction de cette cétone tétracyclique en décahydro-1,2,3,3*a*,5,5*a*,6,7,8,9, 4*H*-cyclohepta[*cd*]-phénalène (**9**) et d'une aromatisation de ce dernier conduit à 73% de l'hexahydro-5,5*a*,6,7,8,9, 4*H*-cyclohepta[*cd*]phénalène (**10**) aux côtés de 23% de l'hydrocarbure (**7**) désiré.

Canadian Journal of Chemistry, 49, 1343 (1971)

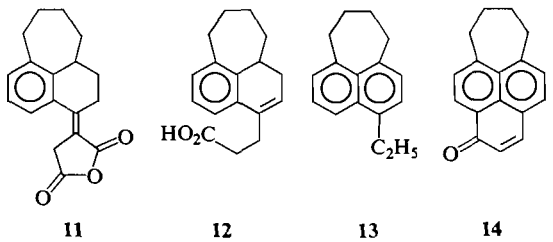
2,3,6,7,8,9-Hexahydro-1*H*-cyclohepta[*gh*]phenalene (**7**) (Scheme 1) was synthesized for comparative studies with its homolog 1,2,3,4,7,8,9,10-octahydrodicyclohepta[*de*,*ij*]naphthalene (**1**). The Stobbe condensation of the tricyclic ketone 3-oxo-1,2,3,7,8,9,10,10*a*-octahydrocyclohepta[*de*]-naphthalene (**1**) with diethyl succinate gave the *exo* olefinic half-ester 3-carbethoxy-3-(1′,2′,3′,7′,8′,9′,10′,10′*a*-octahydrocyclohepta[*de*]naphthalen-3′-ylidene)propionic acid (**2***b*). Acid-catalyzed hydrolysis and concurrent decarboxylation of the half-ester (**2***b*) produced the lactone of 3-(3′-hydroxy-1′,2′,3′,7′,8′,9′,10′,10′*a*-octahydrocyclohepta[*de*]naphthalen-3′-yl)propionic acid (**3**) together with 3-(1′,2′,3′,7′,8′,9′,10′,10′*a*-octahydrocyclohepta[*de*]naphthalen-3′-yl)propionic acid (**4***a*) and 3-(7′,8′,9′,10′-tetrahydrocyclohepta[*de*]naphthalen-3′-yl)propionic acid (**5***a*). On refluxing in acetic acid with red phosphorous and iodine, the lactone **3** was converted into a mixture of the octahydro acid **4***a* and tetrahydro acid **5***a*. The mixture of acids **4***a* and **5***a* was converted into a mixture of the methyl esters **4***b* and **5***b* by treatment with diazomethane. The octahydro ester **4***b* component of the mixture was dehydrogenated and essentially pure tetrahydro ester **5***b* was obtained by heating the mixture with palladium-on-charcoal. Treatment of the ester **5***b* with anhydrous hydrogen fluoride brought about ring closure and gave an excellent yield of 1-oxo-2,3,6,7,8,9-hexahydro-1*H*-cyclohepta[*gh*]phenalene (**6**). Clemmensen reduction of the ketone **6** gave the desired hexahydrocyclohepta[*gh*]phenalene **7**, obtained in 49% overall yield from the ketone **1**.

Structure **2***b* was assigned to the Stobbe product on the basis of the n.m.r. spectrum which showed a singlet for an acid proton at τ 0.04 and insignificant absorption in the vinyl proton region. Attempts to crystallize the half-ester were not successful. On methylation with diazomethane, the methyl ethyl ester **2***c* was obtained. Hydrolysis of the half-ester **2***b* gave the diacid **2***a*. Sublimation of the diacid gave the anhydride **11** which, like the half-ester and di-ester, showed no vinyl proton absorption in the n.m.r. spectrum. The anhydride **11** had an u.v. absorption maximum at 308 mμ, indicative of the C_6H_3—C=C—CO_2 conjugated system and supporting the *exo* assignment of the double bond. Formation of only the *exo* olefinic half-ester in the Stobbe reaction of the tricyclic ketone **1** may be



SCHEME 1

contrasted with the predominant formation of the *endo* olefinic half-ester when benzosuberone was the substrate (1). The implication is that in a seven-membered ring with a fused benzo substituent there is a steric preference for an *endo* rather than an *exo* double bond.



Hydrolysis–decarboxylation of the half-ester was expected to lead to a mixture of the lactone **3** and its isomeric olefinic acid **12**. The olefinic acid **12** could be detected as its methyl ester, after methylation with diazomethane of a sample of the reaction mixture isolated after a reaction of short duration. However, only the lactone **3** and the disproportionation products, **4***a* and **5***a*, of the olefinic acid were obtained from the reactions of extended period. The tetrahydro acid **5***a* was much less soluble than the octahydro acid **4***a* and almost pure acid **5***a* crystallized out from the hydrolysis mixture, as was shown by methylation with diazomethane and v.p.c. of the ester mixture. There is a considerable gain in resonance energy as a result of the disproportionation reaction. In the hydrolysis–decarboxylation of the Stobbe product from benzosuberone no disproportionation was observed (1) because the seven-membered ring cannot be aromatized. From the hydrolysis–decarboxylation followed by hydrogen fluoride-catalyzed ring closure of the Stobbe product from 1-

tetralone Johnson *et al.* (2) obtained 2,3,3*a*,4,5,6-hexahydro-1*H*-phenalen-1-one in addition to the expected tetrahydrophenalenone. They recognized the hexahydrophenalenone as being a disproportionation product, although they were not able to isolate the dehydrogenated counterpart. They were also unable to determine whether the acid disproportionated before ring closure, or whether the tetrahydrophenalenone itself disproportionated. However, the acid was known to disproportionate on distillation.

Small amounts of the ketone **8** and the hydrocarbon **13** were isolated as the neutral fraction from the products of reduction of the lactone **3**. These compounds are likely to have been formed by acid-catalyzed ring closure of acid **4***a* and by decarboxylation of acid **5***a* respectively. In the hydrolysis–decarboxylation of the half-ester **2***b* the products, which include **4***a* and **5***a*, are refluxed in acid solution for a lengthy period and under these conditions ring closure and decarboxylation are likely. The ketone **8** and the hydrocarbon **13** were present (v.p.c.) in the neutral (lactone) fraction from hydrolysis–decarboxylation reaction and it is possible that the samples isolated from after reduction of the lactone were actually formed in the previous (hydrolysis–decarboxylation) reaction.

An attempt to form acid **5***a* by aromatization of acid **4***a* led to considerable decarboxylation resulting in the formation of hydrocarbon **13**. The ester **4***b* was much less prone to decarbomethoxylation during aromatization. Similar observations were made by Newman and O'Leary (3) for the aromatization of 5,6,7,8-tetrahydro-2-naphthylacetic acid and its methyl ester. The ester **5***b* was much more soluble in hydrogen fluoride than the acid **5***a* and was therefore much more suitable as a substrate for the ring closure reaction to give the ketone **6**. When the condensation of the ester **5***b* with hydrogen fluoride was carried out for reaction times longer than 3 h or when polyphosphoric acid was used as the condensing agent, the ketone **6** was contaminated with the enone **14**. With polyphosphoric acid the enone **14** was the major product and a considerable amount of tar was also formed. The ketone **6** was also readily dehydrogenated to enone **14** with dichlorodicyanoquinone. In the closure of 3-(1′naphthyl)propionic acid with hydrogen fluoride Fieser and Gates (4) obtained 6% of the product of closure in the 2′ position as well as the dihydrophenalenone, the product of closure in the 8′ (*peri*) position. We did not observe any of the product of closure in the 2′ position from the tetrahydrocycloheptanaphthalen-3′-ylpropionate, **5***b*. The alicyclic ring activates the 4′ (*peri*) position more than the 2′ and thus enhances the 4′ closure.

The Clemmensen reduction of the ketone **6** to give the desired hydrocarbon **7** was conducted for a short time since prolonged treatment of either **6** or **7** with acid led to formation of enone **14** and its subsequent dimerization.

In the preparation of 1,2,3,4,7,8,9,10-octahydrodicyclohepta[*de*,*ij*]naphthalene the fourth (seven-membered) ring was constructed before the second six-membered ring was aromatized. This was necessary since ring closure would have otherwise preferentially occurred in this second aromatic ring and a cycloheptaphenanthrene system formed. Initially, we attempted to follow the same sequence for the preparation of the cycloheptaphenalene **7**. Ring closure of the ester **4***b* with polyphosphoric acid gave the ketone **8** in excellent yield. Clemmensen reduction of the ketone **8** gave the hydrocarbon **9**. Dehydrogenation of hydrocarbon **9**, by heating with palladium-on-carbon gave as major product (73%) the hydrocarbon **10** together with a lesser amount (23%) of the desired hydrocarbon **7**. The ketone **8** was dehydrated and dehydrogenated, by heating palladium-on-carbon, to the same mixture of hydrocarbons. The hydrocarbons **7** and **10** were separated by chromatography on alumina.

Experimental

The u.v. spectra were determined on a Unicam S.P. 800 spectrometer. The i.r. spectra were determined on a Perkin–Elmer model 337 spectrometer calibrated with polystyrene. The n.m.r. spectra were determined on a Varian HA-60-IL spectrometer using tetramethylsilane as internal standard. Mass spectra were determined on an AEI MS-902 instrument. Microanalyses were by Dr. A. D. Campbell, University of Otago, Dunedin, New Zealand. Melting points are uncorrected.

3-Carbethoxy-3-[1′,2′,3′,7′,8′,9′,10′,10′a-octahydrocyclohepta[de]naphthalen-3′-ylidene]propionic Acid (2b)

3-Oxo-1,2,3,7,8,9,10,10*a*-octahydrocyclohepta[*de*]-naphthalene (**1**) (10.0 g, 0.05 mol) and diethyl succinate (13.05 g, 0.075 mol) were added under 1 atm of nitrogen to a slurry of potassium *t*-butoxide (0.055 mol) which had been prepared by stirring potassium shavings (2.15 g) with dry *t*-butyl alcohol until all the potassium had dis-

For personal use only.

solved. After heating under reflux for 40 min the solution was stood at room temperature for 24 h before being acidified with hydrochloric acid. The solvent was removed and the residue taken up in ether. The ether solution was washed with water, the product half-ester extracted into bicarbonate, and the bicarbonate solution washed. The product was extracted back into ether from the acidified bicarbonate solution and the ethereal solution dried. After removal of the ether the half-ester **2***b* (13.42 g, 82%) was obtained: i.r. 1710 cm^{-1} (conjugated ester C=O and acid C=O); n.m.r. (CCl_4) τ 0.04 (s, 1, CO_2H), 3.05 (m, 3, C_6H_3), 5.9 (q, 2, J = 7 Hz, $CO_2CH_2CH_3$), 6.45 (m, 2, C=C—CH_2CO_2H), 6.7–7.7 (5, $CH_2C_6H_3CH$ and CH_2C=C—CO_2), 7.7–8.7 (8, alicyclic CH_2), 9.0 p.p.m. (t, J = 7 Hz, CH_2—CH_3).

Methyl 3-Carbethoxy-3-(1′,2′,3′,7′,8′,9′,10′,10′a-octahydrocyclohepta[de]naphthalen-3′-ylidene)-propionate (2c)

The half-ester **2***b* (3.4 g) was treated with excess diazomethane, allowed to stand overnight at 5°, and the solvent then evaporated. The residue was taken-up in petroleum ether and chromatographed on neutral alumina (100 g, Brockmann activity II), using petroleum ether as solvent. The v.p.c. analyses on a 5 ft SE30 column of the crude di-ester showed that two compounds were present in an 80:20 ratio. These two compounds were not separated by the column chromatography nor by subsequent distillation. It is suggested that the two compounds are geometrical isomers with the carbethoxy group being *cis* to the aromatic ring in one case and *trans* in the other. The diester **2***c* had b.p. 176–178°/0.05 mm, i.r. 1740 and 1705 cm^{-1} (ester C=O); n.m.r. (CCl_4) τ 3.0 (m, 3, C_6H_3), 6.0 (q, 2, J = 7 Hz, $CO_2CH_2CH_3$), 6.35 (s, 3, CH_3O), 6.5 (m, 2, C=C—CH_2CO_2), 6.7–8.8 (13), 9.0 p.p.m. (t, J = 7 Hz, CH_2CH_3); mass spectrum (70 eV) *m/e* (relative intensity) 342.1832 (20, $M_r(^{12}C_{21}{}^{1}H_{26}{}^{16}O_4)$ = 342.1831), 311 (14, $C_{20}H_{23}O_3$), 310 (8), 298 (9), 297 (60), 296 (100), 282 (13), 268 (99), 264 (40).

1′,2′,3′,7′,8′,9′,10′,10′a-Octahydrocyclohepta[de]-naphthalen-3′-ylidenesuccinic Acid (2a)

The half-ester **2***b* (1.02 g) was dissolved in methanol (50 cm^3) and a solution of potassium hydroxide (50 g) in water (50 cm^3) was added and the mixture stirred for 1 week. The methanol was evaporated and the residue was taken up in water and acidified. The diacid **2***a* was extracted with benzene–ether, dried over magnesium sulfate, and concentrated to yield a light yellow crystalline solid (0.64 g). The acid was converted to the sodium salt which was recrystallized from water. The salt was converted back into the acid which was recrystallized from benzene; m.p. 173.7–174.0°; i.r. (KBr) 2700–2500 and 940 (acid OH), 1705 (acid C=O), 1680 (conjugated acid C=O), 1655 cm^{-1} (C=C); mass spectrum (70 eV) *m/e* (relative intensity) 300.1369 (9, $M_r(^{12}C_{18}{}^{1}H_{20}{}^{16}O_4)$ = 300.1362), 283 (17), 282 (84, $C_{18}H_{18}O_3$), 255 (19), 254 (100, $C_{17}H_{18}O_2$), 239 (5), 238 (12), 237 (10), 236 (9).

1′,2′,3′,7′,8′,9′,10′,10′a-Octahydrocyclohepta[de]-naphthalen-3′-ylidenesuccinic Anhydride (11)

Vacuum sublimation of the diacid **2***a* at 120–155°/0.005 mm gave as a white crystalline sublimate the octahydronaphthalenylidenesuccinic anhydride **11**: m.p. 165.2–165.4°; u.v. max (95% C_2H_5OH) 204 (ε 1560), 215 (shoulder, ε 1100), 235 (ε 660), 307 mμ (ε 1000 m^2 mol^{-1}); i.r. (Nujol) 1845, 1775, 1232 cm^{-1} (anhydride C=O); n.m.r. ($CDCl_3$) τ 2.43 (q, 1, 4′-*H*), 2.83 (m, 2, 5′-*H* and 6′-H), 6.33 (s, 2, C=C—CH_2CO_2), 7.2 (b, 3, CHC_6H_3-CH_2), 7.6 (b, 2, CH_2C=C—CO_2), 8.3 p.p.m. (b, alicyclic CH_2); mass spectrum (70 eV) *m/e* (relative intensity) 282.1249 (85, $M_r(^{12}C_{18}{}^{1}H_{18}{}^{16}O_3)$ = 282.1257), 255 (19), 254 (100), $C_{17}H_{18}O_2$), 238 (9, $C_{17}H_{18}O$), 237 (10), 236 (8), 226 (5), 225 (7), 211 (16), 210 (26), 209 (39), 208 (20), 207 (9).

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.57; H, 6.42. Found: C, 76.69; H, 6.42.

The Hydrolysis–Decarboxylation of the Half-ester 2b; Methyl 3-(1′,2′,3′,7′,8′,9′,10′,10′a-Octahydrocyclohepta[de]naphthalen-3′-yl)propionate (4b); the Lactone of 3-(3′-Hydroxy-1′,2′,3′,7′,8′,9′,10′,-10′a-octahydrocyclohepta[de]naphthalen-3′-yl)-propionic Acid (3)

The half-ester **2***b* (13.3 g) was refluxed with a solution of concentrated hydrochloric acid (100 cm^3), acetic acid (200 cm^3), and water (150 cm^3). Isolation of the product after 48 h indicated that the hydrolysis–decarboxylation was incomplete[1] and the heating under reflux was continued with a fresh solution of the hydrochloric acid – acetic acid – water for an additional 72 h. More hydrochloric acid (50 cm^3) was added after 24 h and again after 48 h of the second reflux period. The acidic solution was concentrated, benzene was added, and the mixture filtered to remove the highly insoluble cycloheptanaphthalenylpropionic acid **5***a* (3.4 g, 33%). The benzene layer was separated, extracted with sodium carbonate solution, dried, and evaporated to give the lactone **3** (1.8 g, 17%) as a gum. The sodium carbonate solution was acidified and extracted with benzene. From this benzene solution (3.8 g, 36%) of an acidic gum was isolated.

The combined acid fractions (7.9 g) which contained mainly the tetrahydro **4***a* and octahydro **5***a* cycloheptanaphthalenylpropionic acids were taken up in a solution of ether (100 cm^3) and benzene (100 cm^3). Diazomethane (0.07 mol) in ether (200 cm^3) was added, with stirring to the solution at 0°. The mixture was stirred for 2 h, stood at 5° for 12 h, and the ether evaporated. The residue was taken-up in benzene (5 cm^3) and placed on a column of alumina (300 g deactivated with 50% acetic acid (18 cm^3)). Elution with petroleum ether (900 cm^3) gave, after discarding the initial fraction (300 cm^3) methyl octahydrocycloheptanaphthalenylpropionate **4***b* (2.2 g); i.r. (film) 1740 cm^{-1} (ester C=O); mass spectrum (70 eV) *m/e* (relative intensity) 272 (41, $M_r(C_{18}H_{24}O_2)$ = 272), 241 (17, $C_{17}H_{21}O$), 240 (22), 199

[1]A sample of the acid fraction of the incompletely reacted material was esterified with diazomethane and subjected to chromatography on alumina. The second fraction (5% of the total esters) obtained from the column contained, as the major component, an ester (i.r. 1735 cm^{-1}) which on v.p.c. on an SE30 column had retention time between that of the esters **4***b* and **5***b* and which had M_r = 270. This was presumably the methyl ester of the olefinic acid **12**.

(23), 198 (83), 186 (22), 185 (100), 158 (26). Further elution with petroleum ether (1800 cm^3) and then benzene (1200 cm^3) gave mixtures of the octahydro **4***b* and tetrahydro esters **5***b* (4.8 g). The ester mixtures were analysed by v.p.c. on an SE30 column and by mass spectrometry.

The neutral lactone fraction was recrystallized (×2) from ether–petroleum ether and sublimed (×2). The lactone **3** had m.p. 119.5–119.8°; i.r. (Nujol) 1775 cm^{-1} (lactone C=O), mass spectrum (70 eV) *m/e* (relative intensity) 256.1411 (59, $M_r(^{12}C_{17}{}^1H_{20}{}^{16}O_2)$ = 256.1463), 238 (1), $C_{17}H_{18}O$), 212 (24, $C_{16}H_{20}$), 202 (16), 201 (100), 183 (21), 169 (18), 158 (41).

Anal. Calcd. for $C_{17}H_{20}O_2$: C, 79.65; H, 7.87. Found: C, 79.91, H, 7.89.

3-(1′,2′,3′,7′,8′,9′,10′,10′a-Octahydrocyclohepta[de]-naphthalen-3′-yl)propionic Acid (4a)

The ester **4***b* (1 g) in methanol (50 cm^3) was stirred with sodium hydroxide (50 g) in water (50 cm^3) for 5 days. The methanol was evaporated, the solution acidified, and extracted with benzene. The benzene solution was dried and the solvent evaporated. The residual gum was recrystallized (×2) from methanol–water and sublimed at 120–125°/0.005 mm; m.p. 135–136.5°; i.r. (Nujol) 1705 cm^{-1} (acid C=O); n.m.r. (CCl_4) τ 1.6 (b, 1, CO_2H), 3.23 (s, 3, C_6H_3), 7.3 (b, $CH_2C_6H_3(CH)CHCH_2CH_2CO_2H$), 8.3 p.p.m. (b, alicyclic and aliphatic CH_2); mass spectrum (70 eV) *m/e* (relative intensity) 258.1615 (79, $M_r(^{12}C_{17}{}^1H_{22}{}^{16}O_2)$ = 258.1620), 240 (5), 230 (8), 217 (9), 216 (9), 212 (20), 199 (16), 186 (29), 185 (100).

Anal. Calcd. for $C_{17}H_{22}O_2$: C, 79.03; H, 8.59. Found: C, 78.94; H, 8.59.

The Reduction of Lactone 3

The lactone **3** (5.6 g) was heated under reflux for 24 h with a mixture of glacial acetic acid (125 cm^3), red phosphorous (7.5 g), iodine (2.5 g), and water (5 cm^3). The hot reaction mixture was filtered and added to water (400 cm^3) containing sufficient sodium bisulfite to reduce the iodine. The aqueous solution was extracted with benzene–ether and the benzene–ether solution then extracted with 10% sodium carbonate solution. The carbonate solution was acidified and extracted with benzene–ether. This benzene–ether solution was washed with water and concentrated to 200 cm^3. Diazomethane (0.04 mol) in ether (100 cm^3) was added and the mixture left to stand at 5° for 24 h. The solvent was evaporated and the ester taken up in benzene and filtered through a column of alumina (100 g). Removal of the benzene gave the ester **4***b* (4.1 g, 79%).

The benzene–ether solution containing the non-acidic portion of the reaction product was dried and the solvent removed to yield 0.6 g of a gum shown by comparison of retention times with authentic samples (*vide infra*) to be composed of approximately equal parts of ketone **8** and 3-ethyl-7,8,9,10-tetrahydrocyclohepta[*de*]naphthalene (**13**).

Methyl 3-(7′,8′,9′,10′,-Tetrahydrocyclohepta[de]-naphthalen-3′-yl)propionate (5b) and 3-Ethyl-7,8,9,10-tetrahydrocyclohepta[de]naphthalene (13)

A sample (12.7 g) of the mixed esters **4***b* (80%) and **5***b* (20%) was heated under 1 atm of nitrogen with 30% palladium-on-carbon (0.8 g) in a Claisen flask fitted with a cold finger and placed in a silicone-oil bath. Hydrogen evolution started at 240°, reached a maximum at 270° and continued for 8 h as the temperature was raised to 300°. The v.p.c. analysis after heating for 3.5 h, at which time the temperature had reached 275°, showed only the octahydro **4***b* (22%) and tetrahydro **5***b* (78%) esters. The product was isolated by taking it up in benzene, filtering off the catalyst, and evaporation of the solvent. The v.p.c. analysis of the crude product showed the presence of the tetrahydro ester **5***b* (95%) and its de-ethoxycarbonylation product, 3-ethyl-7,8,9,10-tetrahydrocyclohepta[*de*]naphthalene (**13**) (5%). Chromatography on alumina (300 g deactivated with 50% acetic acid (18 cm^3)) using petroleum ether then benzene as eluants gave a mixture (2.1 g) of **13** (25%) and **5***b* (75%) and then pure ester **5***b* (9.9 g).

The ester **5***b* was distilled: b.p. 160–170°/0.2 mm; i.r. (film) 1735 cm^{-1} (ester C=O); n.m.r. (CCl_4) τ 2.29 (q, 1, 4′-*H*), 2.93 (m, 2, 5′-*H* and 6′-*H*), 3.03 (s, 2, 1′-*H* and 2′-*H*), 6.50 (s, 3, CH_3O), 6.9 (b, 6, $C_{10}H_5CH_2$), 7.4 (m, 2, CH_2CO_2), 8.1 p.p.m. (b, 4, alicyclic CH_2); mass spectrum (70 eV) *m/e* (relative intensity) 268.1468 (100, $M_r(^{12}C_{18}{}^1H_{20}{}^{16}O_2)$ = 268.1463), 240 (15), 237 (14), 208 (17), 196 (31), 195 (99), 181 (19), 179 (21), 165 (40).

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.56; H, 7.51. Found: C, 80.34; H, 7.70.

Further chromatography of the hydrocarbon-ester fraction on alumina, using petroleum ether as eluant, gave the hydrocarbon **13** (0.5 g) which was finally distilled: b.p. 120–122°/0.2 mm; n.m.r. (CCl_4) τ 2.23 (q, 1, 4-*H*), 2.87 (m, 2, 5-*H* and 6-*H*), 2.98 (s, 2, 1-*H* and 2-*H*), 6.8 (b, 4, $C_{10}H_5(CH_2)_2C_2H_4$) 7.0 (q, 2, J = 7 Hz, $CH_3CH_2C_{10}H_5$), 8.0 (b, 4, alicyclic CH_2), 8.69 p.p.m. (t, 3, J = 7 Hz, CH_3CH_2); mass spectrum (70 eV) *m/e* (relative intensity) 210.1405 (100, $M_r(^{12}C_{16}{}^1H_{18})$ = 210.1408), 196 (33), 195 (98), 182 (27), 181 (92), 179 (29), 178 (25), 167 (40), 166 (38), 165 (97), 153 (30), 152 (46).

*5,5a,6,7,8,9-Hexahydro-4H-cyclohepta[cd]phenalene (**10**)*

The decahydrocycloheptaphenalene **9** (0.2 g) was heated under an atmosphere of nitrogen with 30% palladium-on-carbon (0.02 g) at 300° for 4 h. The product was taken up in benzene, the catalyst filtered off, and the benzene evaporated. The v.p.c. and mass spectral analysis of the residue showed that it was a mixture of unchanged

decahydro compound **9** (4%) and the isomeric hexahydrocycloheptaphenalenes 7 (23%) and **10** (73%). When the decahydrophenalenone **8** (0.2 g) was heated with palladium-on-carbon under the conditions described the product consisted of unreacted ketone **8** (7%) and the hexahydrocycloheptaphenalenes **7** (24%) and **10** (69%).

The combined products from the two dehydrogenations (0.31 g) were taken up in benzene (0.5 cm^3) and chromatographed on alumina (10 g of activity I). The more symmetrical hexahydrocyclohepta[*gh*]phenalene was eluted first with petroleum ether. Further elution with petroleum ether and with 5% benzene – petroleum ether gave the hexahydrocyclohepta[*cd*]phenalene contaminated with the *gh*-isomer. The impure *cd*-isomer was rechromatographed. The final fractions from the second column were recrystallized (×2) from methanol and then sublimed at 65–70°/0.005 mm to give the pure hexahydrocyclohepta[*cd*]phenalene **10** as a white powder: m.p. 73.3–74.3°; u.v. max (95% C_2H_5OH) 236 (ε 2000), 271 (shoulder, ε 360), 281 (s, ε 600), 292 (ε 720), 297 (s, ε 640), 303 (s, ε 550), 311 (s, ε 310), 315 (s, ε 200), 325 (ε 140), 330 mμ (s, ε 80 m^2 mol^{-1}); n.m.r. (CCl_4) τ 2.83 (m, 5, $C_{10}H_5$), 7.03 (b, 5, $C_{10}H_5CH$, $C_{10}H_5CH_2$), 8.15 p.p.m. (b, 8, alicyclic CH_2); mass spectrum (70 eV) *m/e* (relative intensity) 222.1397 (100, $M_r(^{12}C_{17}{}^1H_{18})$ = 222.1408), 207 (4), 193 (17), 181 (13), 179 (12), 178 (11), 165 (41).

Anal. Calcd. for $C_{17}H_{18}$: C, 91.84; H, 8.16. Found: C, 91.65, H, 8.33.

Hindered Rotation and Intramolecular Hydrogen Exchange in *N*-Phenyl-*o*-hydroxybenzylamines[1]

S. Brownstein, E. C. Horswill, and K. U. Ingold
Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received November 2, 1970

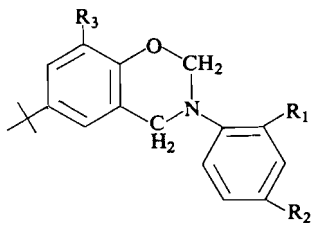
Non-equivalence of the benzylic hydrogens was found in several *N*-phenyl-ortho-hydroxybenzylamines and, where possible, activation parameters were calculated for the processes causing non-equivalence. Hindered rotation about the aromatic carbon–nitrogen bond was the rate determining process with an ortho-*t*-butyl group on the aniline ring. Exchange of phenolic and amino hydrogens was studied over a range of temperature and concentration. Both intermolecular and intramolecular exchange were observed. The latter may be the first example of such a process to be studied by n.m.r.

On a trouvé que les hydrogènes benzyliques de plusieurs *N*-phényl ortho-hydroxybenzylamines sont non-équivalents; dans certains cas, on a pu calculer les paramètres d'activation des processus causant cette non équivalence. On a établi que dans les cas où l'aniline possède un groupe *t*-butyle en position ortho, l'empêchement à la rotation libre autour du lien reliant le carbone aromatique et l'azote est le facteur déterminant la vitesse de réaction. On a de plus étudié à diverses températures et à diverses concentrations, l'échange des hydrogènes des groupes amino et phénols; on a observé que l'échange peut se faire soit par une réaction intermoléculaire soit par une réaction intramoléculaire. Ce dernier procédé pourrait être le premier exemple d'une telle réaction à être observé par r.m.n.

Canadian Journal of Chemistry, **49**, 1350 (1971)

Introduction

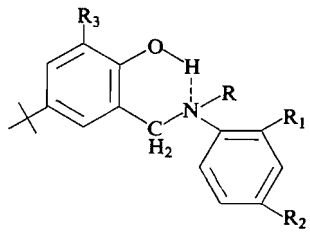
Proton resonance spectroscopy has frequently been used to study hindered rotation about nominally single bonds in organic compounds (1–4). The barrier to rotation about formally single carbon–nitrogen bonds has in most cases been attributed to some partial double bond character. We have previously shown (5) that for ortho-alkylphenyl substituted 1,3-benzoxazines, **1**, the barrier to rotation about the aromatic carbon–nitrogen bond, $\Delta H^{\neq}$, increases with increasing bulk of the ortho-substituent, R_1. Inhibition to free rotation in these cases must therefore arise from steric effects.



1

	$\Delta H^{\neq}$ kcal/mol
a R_1 = Me; R_2 = R_3 = H	<8.9
b R_1 = Pr^i; R_2 = H; R_3 = Me	10.8
c R_1 = R_2 = R_3 = Bu^t	16.9

ortho-Hydroxybenzylanilines, **2**, are structurally related to the benzoxazines, the six-membered heterocyclic ring being produced by an intramolecular hydrogen bond. In these compounds there are four processes which could



2

produce magnetic non-equivalence of the benzylic protons. When the phenyl ring is symmetrically substituted (*i.e.*, R_1 = H) non-equivalence could arise from hindered inversion about nitrogen (6, 7), or from hindered rotation about the benzyl–nitrogen bond (8), or by a slow inversion of the heterocyclic ring so as to produce quasi-axial and quasi-equatorial benzylic hydrogens. However, in this last case, the values of $\Delta H^{\neq}$ could not be greater than the strength of the OH---N hydrogen bond (probably ~4 kcal/mol). Finally, non-equivalence could arise from hindered rotation about the aromatic carbon–nitrogen bond if the aromatic group is asymmetrically substituted (*i.e.*, **2** with $R_1 \neq$ H).

Provided the ortho-hydroxybenzylanilines do not have an additional substituent on the nitrogen atom (*i.e.*, provided R = H in structure **2**) there is an additional process that can be studied by n.m.r., namely proton exchange between the amino hydrogen and the phenolic hydrogen. There are two possible mechanisms for such an exchange, an intermolecular reaction involving two molecules of **2** or an intramolecular reaction involving only a single molecule of **2**. In the present work we have observed both processes. The intramolecular exchange is of particular interest because it appears to be the first example of such a reaction. That is, although there have been several n.m.r. studies of intermolecular proton exchange between hydroxyl and amino groups (9) we have only been able to find one example of even an apparent intramolecular exchange. Sheinblatt (10) has reported that in water at 21° $k_f = 75\ s^{-1}$ for the reaction,

$$CH_3\overset{+}{N}H_2CH_2COO^- \underset{}{\overset{k_r}{\rightleftharpoons}} CH_3NHCH_2COOH$$

However, proton exchange is believed to occur via a water molecule solvent bridge (10) and therefore this reaction is only pseudo-intramolecular.

Experimental

Proton resonance spectra were obtained at 100 MHz on a Varian Associates HA100D spectrometer. Sample temperatures were controlled with a Varian Associates V-4343 temperature controller. The temperatures were measured by monitoring the voltage drop across the platinum sensing element of the temperature controller, which had been calibrated with variable temperature spectra of a standard methanol sample. Chemical shifts are reported as p.p.m. to low field of tetramethylsilane as internal reference. Rate constants were obtained by comparison of theoretical and experimental spectra as reported previously (5). All activation parameters were obtained from a least squares fit of the data and quoted errors are standard deviations. The solvent is carbon disulfide unless otherwise specified. All samples were prepared on a vacuum line using vigorously dried materials and should not contain any water or molecular oxygen.

Compounds **2***a*, *b*, and *e* were prepared as described previously (11).

*N-(3,5-Di-tert-butyl-2-hydroxybenzyl)-N-methylaniline (**2***c*)

A mixture of 2,4-di-*tert*-butylphenol (4.12 g, 20 mmol), *N*-methylaniline (2.14 g, 20 mmol), barium hydroxide octahydrate (0.18 g), and formalin solution (1.65 ml, 22 mmol) was stirred and heated in a bath at 94° for 1 h. The solid product was dissolved in 50 ml benzene, washed with 2 *N* HCl and with water and then dried over sodium sulfate. Vacuum removal of the solvent left a syrup which rapidly crystallized as beige prisms (5.61 g) m.p. 55–75°. Recrystallization from 95% ethanol yielded 3.98 g of product m.p. 87–92°. Further recrystallization gave an analytical sample, m.p. 89.5–91.1°.

Anal. Calcd. for $C_{22}H_{31}NO$: C, 81.18; H, 9.60; N, 4.30. Found: C, 81.10; H, 9.69; N, 4.22.

*N-(3,5-Di-tert-butyl-2-hydroxybenzyl)-ortho-toluidine (**2***d*)

Similar treatment of 3.1 g (15 mmol) 2,4-di-*tert*-butylphenol, 1.6 g (15 mmol) *o*-toluidine, 0.18 g barium hydroxide octahydrate, and 1.22 ml (16 mmol) formalin solution gave, after work-up, 4.39 g of crude solid. Recrystallization from hexane–benzene gave colorless, fluffy, needles, m.p. 149.5–151°.

Anal. Calcd. for $C_{22}H_{31}NO$: C, 81.18; H, 9.60; N, 4.30. Found: C, 81.32; H, 9.75; N, 4.27.

Results and Discussion

Hindered Rotation

The structural formulae of the compounds studied and the chemical shifts for the various types of protons are given in Fig. 1. The assignments of the *o*- and *p*-*tert*-butyl group chemical shifts were made by analogy with other similar compounds and cannot be considered to be definitely proven. Non-equivalent methylene protons could be observed in compounds **2***a* at room temperature and in the other four compounds at low temperatures.

The process causing equivalence of the methylene protons of **2***a* has $\Delta H^{\ddagger}_{298} = 14.1 \pm 0.9$ kcal/mol and $\Delta S^{\ddagger}_{298} = -11 \pm 14$ e.u. in tetrachloroethylene as the solvent. A plot of the experimental results is shown in Fig. 2. The activation parameters are sufficiently close to those of the correspondingly substituted benzoxazine, **1***c*, ($\Delta H^{\ddagger}_{298} = 16.9 \pm 0.3$ kcal/mol, $\Delta S^{\ddagger}_{298} = 0.4 \pm 0.2$ e.u. (5)) that we can be reasonably sure that the same process is being examined in both cases, *viz.*, hindered rotation about the aromatic carbon–nitrogen bond. Since $\Delta H^{\ddagger}_{298}$ for **2***a* is so much greater than the strength of the hydrogen bond which holds the heterocylic ring rogether, it is clear the non-equivalence of the methylene protons does not in fact require a six-membered ring incorporating the methylene protons and the nitrogen atom. That is, it can be confidently predicted that *N*-benzyl-*N*-methyl-*o*-*t*-butylaniline will also exhibit non-equivalent methylene protons and that $\Delta H^{\ddagger}$ for the process causing their equivalence will be somewhere around 16 kcal/mol.

Non-equivalent methylene protons were also observed in compound **2***b* which is similar to **2***a* except for the replacement of the amino methyl group by a hydrogen atom. However, in **2***b* the

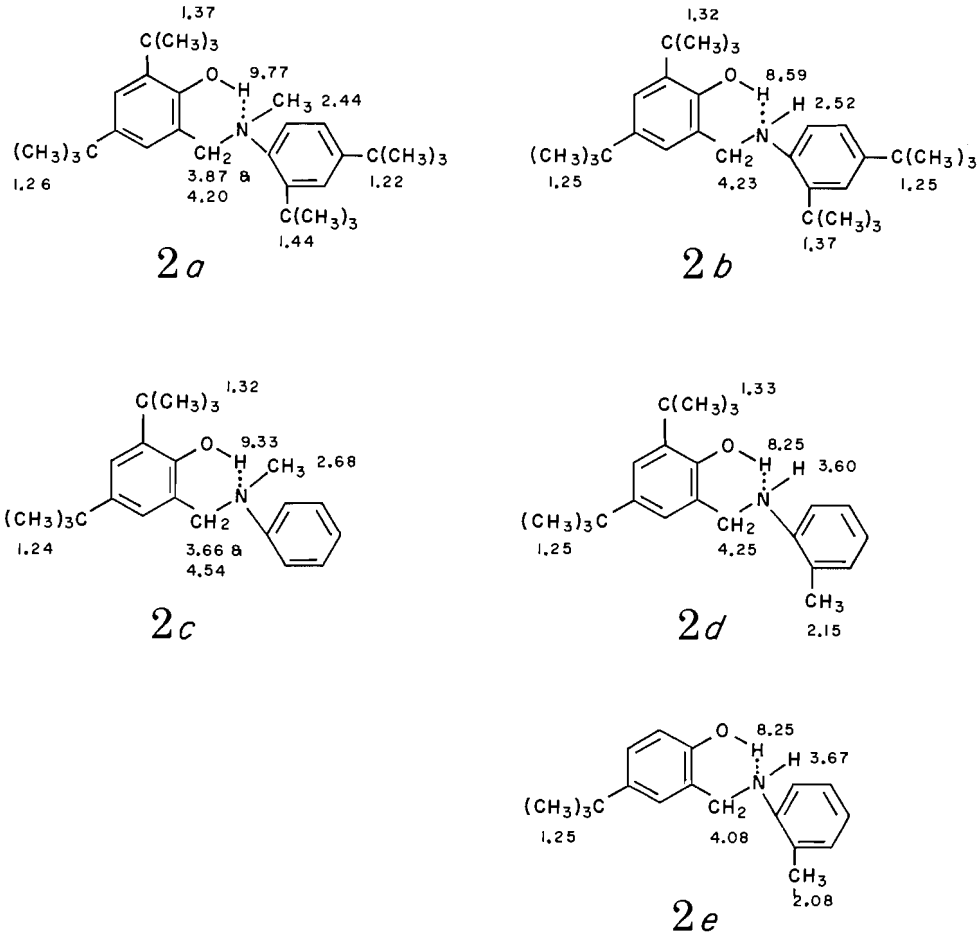

FIG. 1. Structural formulae and chemical shifts of some *N*-phenyl-*o*-hydroxybenzylamines.

chemical shift difference between the methylene protons is so small that accurate rates could not be measured.

Compound **2***c*, which does not have any ortho-substituent on the aniline ring, exhibited non-equivalent methylene protons at low temperatures. The process causing equivalence for this compound in CF_2Cl_2 solvent had $\Delta H^{\ddagger}_{298} = 6.1 \pm 0.5$ kcal/mol and $\Delta S^{\ddagger}_{298} = -12 \pm 12$ e.u. (see Fig. 2). Three possible causes of non-equivalence for compounds of this type were described in the Introduction, inversion at nitrogen, inversion of the ring, and rotation around the benzyl carbon–nitrogen bond. Of these we are inclined to disfavor inversion at nitrogen since we could find no evidence for non-equivalent methylene protons in *N*-benzyl-*N*-methylaniline even at temperatures below those required for non-equivalence with **2***c* (8). The barrier to rotation should be larger for **2***c* than for *N*-benzyl-*N*-methylaniline because of the ortho-hydroxy group, but the barrier to inversion is probably similar.

Non-equivalent methylene protons were observed in compounds **2***d* and **2***e* at low temperatures but, as with **2***b*, the chemical shift difference was too small for rate constants to be calculated. It would appear that an *N*-methyl substituent is necessary to give appreciable chemical shifts.

Hydrogen Exchange

The phenolic and amino hydrogen atoms in compounds **2***b*, *d*, and *e* undergo exchange since for each compound the signals due to these two protons undergo comparable changes in shape as the temperature is altered. The hydroxyl proton line was used for rate measurements since the

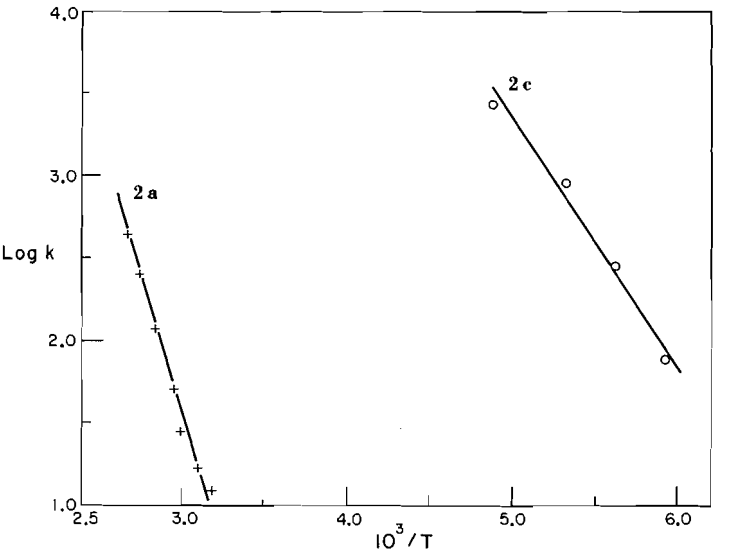

FIG. 2. The temperature variation for the rate of magnetic averaging of the methylene protons.

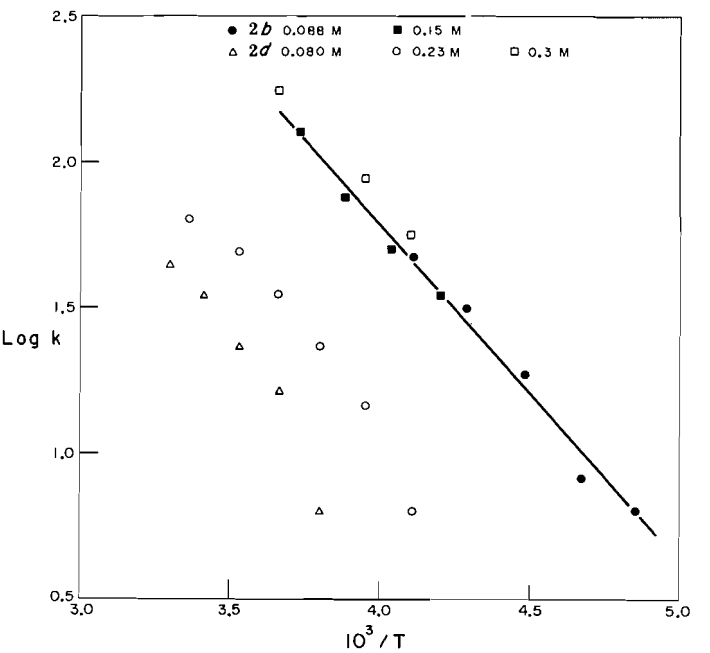

FIG. 3. The concentration and temperature dependence of the exchange of hydroxyl and amino protons.

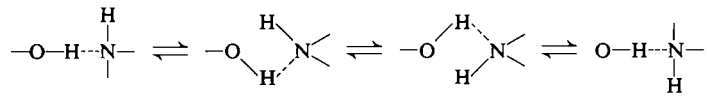
amino hydrogen gave a broadened line in the slow exchange limit because of proton–nitrogen spin coupling. The solubility of compound **2***e* in CS_2 at low temperatures was unfortunately too low for accurate rate measurements but exchange rates were measured for **2***b* and *d* over a range of temperature and concentration. First order rate constants were calculated from the reciprocal of the measured lifetimes and have been plotted as their logarithms against the reciprocal of the temperature in Fig. 3. For compound **2***b* the rate constants are independent of concentration which indicates a unimolecular process, *i.e.*, an intramolecular hydrogen exchange. An excellent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

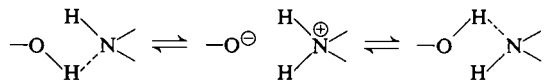


linear Arrhenius plot is obtained from which is calculated $\Delta H^{\ddagger}_{298} = 4.7 \pm 0.2$ kcal/mol and $\Delta S^{\ddagger}_{298} = -29 \pm 7$ e.u. for the exchange. In contrast, with **2***d* the rate constants at a particular temperature increase with increasing concentration of **2***d* which indicates the occurrence of a bimolecular or higher order process.[2] The Arrhenius plots with this compound show some evidence of curvature.

Space-filling molecular models indicate that the amino hydrogen in **2***b* (and in **2***d* and *e*) can approach fairly close to the phenolic oxygen if the angle formed by the O—H---N hydrogen bond is decreased to ~120° from its optimum 180°. In this configuration it is not unreasonable to suppose that the phenolic and amino hydrogens of **2***b* should change places.

The large negative entropy of activation for this exchange is indicative of a reaction requiring a highly constrained transition state.

From the data in Fig. 3 it is clear that with **2***d* the intermolecular exchange swamps out any intramolecular exchange at concentrations of **2***d* $\geqslant$ 0.08 *M*. This can be accounted for by the lesser steric hindrance of the reaction center in **2***d* compared with **2***b*. However, the question remains as to why **2***d* does not have a residual intramolecular exchange occurring at a rate comparable to the intramolecular rate with **2***b*. That is, why are the apparent rate constants at 0.08 *M* [**2***d*] not greater than the rate constants found with **2***b* (7). The only explanation that has occurred to us which might account for the ten-fold or more faster intramolecular exchange of **2***b* relative to **2***d* is based on the polar effect of the aniline ring's para-*t*-butyl group in compound **2***b*. The transition state for intramolecular exchange probably involves a significant degree of charge separation and, in fact, proton transfer from oxygen to nitrogen prior to that from nitrogen to oxygen is a distinct possibility. A reaction that involved



such an intermediate or transition state would be very sensitive to the acidity of the phenolic proton and to the basicity of the nitrogen atom. The *t*-butyl group at the para-position of the aniline ring (R_2) in compound **2***b* is electron donating and hence should accelerate the intramolecular exchange relative to the rate of intramolecular exchange in **2***d*. Our attempt to check this explanation by studying a compound with increased acidity of the phenolic hydrogen, as in compound **2***e*, was frustrated by the material's insolubility at low temperatures.

To judge by our present limited results, intramolecular proton transfers are very sensitive both to polar and to steric effects. It is therefore perhaps not so surprising that one has not, apparently, been previously observed.

[2]The rate constants at 0.23 *M* [**2***d*] are about twice those found at 0.08 *M* indicating a reaction order somewhat less than 2. However, the rate constants at 0.3 *M* are about ten times as great as those at 0.08 *M* indicating an order greater than 2.

Methyl Glycosidation and Methyl Thioglycosidation of Some Fully Chlorosulfated Pentopyranosyl Chlorides Using Sodium Iodide as a Catalyst[1]

H. J. JENNINGS

Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada

Received November 2, 1970

The treatment of α- and β-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) and the corresponding α-D-*lyxo* derivative with a catalytic quantity of sodium iodide in methanol solution resulted in the removal of the chlorosulfate groups and rapid methanolysis of the anomeric chlorine atoms. The methanolysis proceeded with predominant inversion in each case (80–90%), independent of the orientation of the C-2 substituent. In the presence of sodium methyl mercaptide, however, thioglycosides having an inverted configuration were produced from 1,2-*cis* chlorides, and thioglycosides having an unchanged anomeric configuration were formed from 1,2-*trans* chlorides. It is proposed that all these glycosidations occur via a free pentopyranosyl chloride intermediate, and that under the basic conditions of thioglycosidation a 1,2-anhydro intermediate is formed from 1,2-*trans* chlorides.

Le traitement des chloro-1 trichlorosulfate-2,3,4 α- et β-D-xylopyranose et α-D-lyxopyranose par des quantités catalytiques d'iodure de sodium en solution dans le méthanol conduit à une solvolyse rapide des groupes chlorosulfates et des atomes de chlore attachés aux carbones anomériques. Dans chaque cas, la méthanolyse se produit principalement (80–90%) avec inversion et ceci quelle que soit l'orientation du substituant en position 2. Toutefois, lorsque ces réactions sont effectuées en présence du sel de sodium du méthanethiol, la stéréochimie de la réaction dépend de l'orientation présente dans les composés de départ; la réaction des chlorures ayant la configuration *cis*-1,2 procède avec inversion alors que celle des dérivés *trans*-1,2 se produit avec rétention. On croit que toutes ces réactions conduisant à des glucosides se produisent par l'intermédiaire d'un chloro-1 pentopyranose; pour ce qui est des thioglucosides formés en milieu alcalin à partir de chlorures trans-1,2; ils proviendraient d'un dérivé anhydro-1,2 intermédiaire.

Canadian Journal of Chemistry, 49, 1355 (1971)

In earlier experiments it has been demonstrated that chlorosulfate groups can be removed from chlorosulfated glycoside derivatives by treatment with sodium iodide in aqueous methanol (1). This reaction is very rapid and regenerates the hydroxyl groups with retention of configuration. When glycosyl chlorides containing chlorosulfate groups were treated with sodium iodide in aqueous acetone the reaction involved in addition, hydrolysis of the anomeric chlorine atom, to give the free glycose (2, 3). It was of interest to study this reaction on chlorosulfated glycosyl chlorides using methanol as the solvent, to ascertain whether methyl glycosidation would occur under these conditions. As in some previously described dechlorosulfations (1, 4), barium carbonate was added in these reactions in order to neutralize hydrochloric acid and so to prevent, as much as possible, the formation of chloro–deoxy derivatives by displacement of chlorosulfate groups, and to minimize anomerization of the glycosides produced.

The reaction of β-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) (1) gave good yields of a mixture of methyl α- and β-D-xylopyranosides. The methyl α-D-anomer (3) was shown to constitute approximately 90% of the mixture (g.l.c. analysis), and was isolated and characterized as its triacetate. Thus the methyl glycosidation of **1** occurs predominantly with inversion of configuration and similar results were obtained with α-D-anomeric chlorides. Both the α-D-anomer of **1** and its α-D-*lyxo* epimer yielded mixtures of methyl pyranosides in which the products of inversion (β-D-anomers) preponderated to the extent of approximately 80%, as indicated by p.m.r. spectroscopy. The fact that the methanolysis in both of these cases proceeded largely with inversion of the anomeric configuration indicates that the configuration at C-2 has little influence on the stereochemical course. It is interesting to note that when the reaction of **1** was carried out in the absence of sodium iodide, the methanolysis was not so rapid and only a very small amount of a methyl glycoside could be detected (p.m.r. spectroscopy). This seems to indicate that iodide ions assist in the displacement of the anomeric chlorine atom, either

SCHEME 1

directly, or by the prior removal of the chlorosulfate groups, or possibly by a combination of these two modes. Our results provide no evidence for a direct action of iodide ions upon the anomeric center, but we do have evidence to suggest that the chlorosulfate groups of these glycosyl chloride derivatives are removed prior to methanolysis, and it is probable that a free glycopyranosyl chloride (2) is generated as a highly reactive intermediate in the solvolytic process (see Scheme 1). This evidence will be discussed below. Certainly the removal of the C-2 chlorosulfate group would contribute to a more rapid solvolysis as it has been demonstrated that the removal of a non-participating trichloroacetate group from the C-2 position of a glucopyranosyl chloride derivative does considerably enhance the rate of solvolysis (5). This has been attributed to a decrease in steric hindrance at the anomeric center (5), although the importance of the contribution of electronic factors has also been clearly demonstrated (6). It is also probable that the removal of the C-3 and -4 chlorosulfate groups from **1** would further assist in the solvolytic process, as it has been demonstrated that other groups besides the one situated at C-2 of glycopyranosyl halides do have some effect on the relative rates of anomeric exchange reactions (7, 8).

Some evidence for the formation of **2** was obtained when **1** was treated under reaction conditions similar to those described above except for the introduction of sodium methyl mercaptide. The addition of barium carbonate was omitted in this case as sufficient base was used to neutralize all the acid produced in this reaction. Sodium iodide was still employed for the rapid removal of the chlorosulfate groups because although sodium methoxide, too, will remove these groups, it will produce cyclic sulfate or epoxy derivatives from vicinal chlorosulfates (1). The β-D chloride (1) gave good yields of crystalline methyl 1-thio-β-D-xylopyranoside (5), which was also synthesized by the treatment of 2,3,4-tri-*O*-acetyl-α-D-xylopyranosyl bromide with potassium methyl mercaptide (9) for comparative reasons. Thus, in contrast to the previous results on the methyl glycosidation of **1**, the thioglycosidation proceeded with complete retention of configuration. This was confirmed since the only other detectable reaction product was in fact a small quantity of methyl β-D-xylopyranoside, estimated as approximately 10% of the crude reaction mixture. Obviously methoxide must compete with methyl mercaptide to a limited extent in this glycosidation process. Retention of configuration in the thioglycosidation of **1** can be explained on the basis that the reaction proceeds via a 1,2-anhydro intermediate **4** which is probably formed by the action of base on **2**. This would require that the C-1 and -2 groups of the original pentopyranosyl chloride derivative should be *trans* disposed as in **1**. Support for

this explanation was obtained when the thioglycosidation of α-D-lyxopyranosyl chloride 2,3,4-tri(chlorosulfate) also yielded products of complete retention of configuration. Methyl 1-thio-α-D-lyxopyranoside and methyl α-D-lyxopyranoside were the only two detectable products of the reaction (p.m.r. and g.l.c. analysis), the former constituting approximately 90% of the crude reaction product. Methyl 1-thio-α-D-lyxopyranoside was isolated crystalline from the crude reaction mixture and was assigned the α-D-configuration by virtue of its high positive specific rotation.

A similar methyl thioglycosidation procedure has been performed which proceeds through a 1,2-anhydro intermediate when 3,5-di-*O*-benzoyl-D-arabinofuranosyl chloride was treated with sodium methyl mercaptide (10). Also, a structural analogue of **2** having an anomeric fluorine atom has been isolated which on treatment with sodium methoxide yielded methyl β-D-xylopyranoside, presumably also via intermediate **4** (11). Although this evidence does not prove conclusively that all the chlorosulfate groups are removed prior to epoxide formation, nevertheless it does prove that the C-2 chlorosulfate group is, as this would be a requirement for such a retention (12). Also it would seem reasonable to assume that both the C-3 and -4 chlorosulfate groups would be removed at a rate comparable to that of the C-2 chlorosulfate group.

Further evidence in support of the formation of the 1,2-anhydro intermediate **4** was obtained when α-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) was treated with sodium methyl mercaptide by an identical procedure to that used with its β-D-anomer **1**. The reaction produced two glycosidic products which were shown to be identical to those produced with **1** (g.l.c. analysis), and the major component was isolated crystalline and was characterized as methyl 1-thio-β-D-xylopyranoside. Thus the thioglycosidation occurs with predominant inversion of configuration with the α-D-anomer of **1** because the 1,2-*cis* arrangement of the anomeric chlorine and C-2 chlorosulfate group is sterically unfavorable for the formation of a 1,2-anhydro intermediate (12).

It is of interest to note that although no substantial quantity of free glycose was detected in any of the crude reaction products (g.l.c. analysis), it is nevertheless probable that water does play some role in the dechlorosulfation procedure. Although the precise mechanism is not known, mechanisms have been proposed which all involve the attack of iodide ion on the chlorosulfate group to liberate iodine and sulfur dioxide (13). In our reactions, only a catalytic quantity of iodide ion was used (approximately 0.1 mol equiv.), which would require that the iodide ion must be regenerated for complete dechlorosulfation. This is probably accomplished by the iodine oxidation of the liberated sulfur dioxide (or sulfite) to sulfur trioxide (or sulfate). This reaction requires the presence of water and is similar to the one utilized in the method of Karl Fischer for the estimation of water in methanol (14). It is probable that sufficient water is available in the reagent grade methanol to satisfy these requirements but not enough to compete extensively as a nucleophile at the anomeric center.

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected, and optical rotations were measured at 21 ± 3°. Solutions were concentrated below 50° under diminished pressure. An F and M (model 420) chromatograph was used for g.l.c. and the column packings used were (*a*) 10% Carbowax 6000 on Chromosorb W, 100–120 mesh at 165°, and (*b*) 10% neopentylglycol sebacate on Gas Chrom A, 100–120 mesh at 180°. Relative amounts of the separated components were estimated by triangulation of the peaks on the g.l.c. The p.m.r. spectra were obtained from a Varian A60A spectrometer using the following solvents (*i*) deuteriochloroform with tetramethylsilane (τ 10.0) as the identical standard and (*ii*) deuterium oxide with 3-(trimethylsilyl)-propanesulfonic acid sodium salt (τ 10.0) as the internal standard. Barium carbonate was dried over phosphorus pentoxide under vacuum and "Anachemia" reagent grade methanol was used in all these experiments.

Methyl 2,3,4-Tri-O-acetyl-α-D-xylopyranoside

Crystalline β-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) (**1**) (2 g, 0.0043 mol) (15) was dissolved in methanol (100 ml) and anhydrous barium carbonate (20 g) was added to the solution with continuous stirring. A solution of sodium iodide (0.07 g) (0.00046 mol) in methanol (5 ml) was then added to the mixture which caused an immediate evolution of iodine. The iodine (yellow coloration) rapidly disappeared and the reaction mixture was stirred for a further 15 min before being filtered. The clear filtrate was then concentrated to dryness and the residue was acetylated using pyridine and acetic anhydride. The inorganic salts were then removed by partitioning the acetylation mixture between chloroform and water and the chloroform layer was then washed with dilute sulfuric acid, water, and sodium bicarbonate solution. The chloroform solution was then dried over anhydrous sodium sulfate, filtered, and concentrated to a syrup (1.2 g) which rapidly crystallized.

Recrystallization of the crude acetate from ethanol gave crystals (0.95 g, 69%) of $[\alpha]_D$ +118° (*c*, 3.7 in chloroform) and m.p. 84° undepressed on admixture with authentic methyl 2,3,4-tri-*O*-acetyl-α-D-xylopyranoside (16). The p.m.r. spectrum of the crude acetylated product in solvent *i* was almost identical to that of authentic methyl tri-*O*-acetyl-α-D-xylopyranoside (methoxy singlet at τ 6.60) indicating a high yield of the methyl α-D-anomer. This was confirmed when a small quantity of the crude acetate was deacetylated (sodium methoxide) and the deacetylated product was trimethylsilylated and injected onto column *a*. Two components were detected with identical retention volumes to those of the trimethylsilyl derivatives of authentic samples of methyl α- and β-D-xylopyranosides. The amount of methyl α-D-anomer was estimated as 90%.

The above reaction was repeated and the reaction mixture was stirred for an identical period of time except that the addition of sodium iodide was omitted in this case. The mixture was filtered and the filtrate was poured into chloroform solution. The chloroform solution was washed with water, dried, and concentrated to a syrup. A p.m.r. spectrum of the syrupy product in solvent *i* was almost identical to the original β-D-chloride **1** except for a very small methoxy singlet at τ 6.50 indicating that only a negligible amount of methyl glycosidation had occurred.

Methyl 2,3,4-Tri-O-acetyl-β-D-xylopyranoside

Crystalline α-D-xylopyranosyl chloride 2,3,4-tri(chlorosulfate) (0.6 g) (15) was treated in methanol solution with sodium iodide and barium carbonate, and the product was acetylated by identical procedures used for **1**. The syrupy acetate (0.4 g) slowly crystallized and recrystallization from ethanol gave crystals (0.1 g, 24%) of $[\alpha]_D$ −59.6° (*c*, 1.0 in chloroform) and m.p. 116–118° undepressed on admixture with authentic methyl 2,3,4-tri-*O*-acetyl-β-D-xylopyranoside. A p.m.r. spectrum of the crude acetate in solvent *i* indicated two methoxy singlets at τ 6.52 (methyl β-D-anomer) and 6.60 (methyl α-D-anomer). Integration of these signals indicated that the amount of methyl β-D-anomer present in the mixture was approximately 80%.

Methyl β-D-Lyxopyranoside

α-D-Lyxopyranosyl chloride 2,3,4-tri(chlorosulfate) (1.5 g) (15) was treated in methanol solution with sodium iodide and barium carbonate, and the product was acetylated by identical procedures used for **1**. A p.m.r. spectrum of the syrupy acetate (0.9 g) in solvent *i* indicated two methoxy singlets at τ 6.54 (methyl β-D-anomer) and 6.58 (methyl α-D-anomer). These signals were assigned by comparison with the p.m.r. spectrum of an authentic mixture of methyl 2,3,4-*O*-acetyl-α- and β-D-lyxopyranosides in solvent *i*. Integration of these signals indicated that the amount of methyl β-D-anomer present in the mixture was approximately 80%. The syrupy acetate was deacetylated (sodium methoxide) and following deionization with Amberlite I.R. 120 (H^+ form) ion-exchange resin was concentrated to a syrup which crystallized. Recrystallization from propan-2-ol gave needles (0.25 g, 47%) of $[\alpha]_D$ −127° (*c*, 0.25 in water) and m.p. 115–116° undepressed on admixture with an authentic sample of methyl β-D-lyxopyranoside.

Methyl 1-Thio-β-D-xylopyranoside

Crystalline **1** (2 g, 0.0043 mol) was dissolved in methanol (25 ml) and the solution was quickly added to a previously prepared solution of sodium iodide (0.07 g, 0.00046 mol) and methyl mercaptan (5 ml) in 0.35 *M* sodium methoxide in methanol (100 ml). During the addition the solution was continuously stirred and was cooled in an ice-bath. A yellow coloration (iodine) was formed instantaneously on the addition of **1** which rapidly disappeared leaving a colorless solution. The solution then began to deposit inorganic salts. The reaction mixture was stirred for 45 min and was then neutralized with a few drops of dilute sulfuric acid (aqueous). The inorganic salts were removed by filtration and the filtrate was passed through Amberlite I.R. 120 (H^+ form) and Duolite A4 (OH^- form) ion-exchange resins. The eluate was concentrated to a syrup (1.1 g) which rapidly crystallized and recrystallization from ethanol gave colorless plates (0.38 g, 50%) of m.p. 162–164° and $[\alpha]_D$ −69° (*c*, 1.0 in water).

Anal. Calcd. for $C_6H_{12}O_4S$: C, 40.00; H, 6.67; S, 17.80. Found: C, 40.29; H, 6.82; S, 17.70.

These physical constants are in fairly good agreement with those quoted for authentic methyl 1-thio-β-D-xylopyranoside (9) and the m.p. of the above crystalline compound was undepressed on admixture with an authentic sample prepared essentially as described by Zinner *et al.* (9). The p.m.r. spectrum of the crystals in solvent *ii* indicated a methylthio singlet at τ 7.79 (3 protons) and an anomeric doublet at 5.60 (1 proton) with a spacing of 7.9 Hz. The g.l.c. analysis using column *b* of the trimethylsilylated crude product from the deionized eluate indicated two components with relative retention volume of 1.0:2.5. The faster minor component had an identical retention volume to that of the trimethylsilyl derivative of methyl β-D-xylopyranoside and the slower major component (estimated as 90% of the mixture) had an identical retention volume to that of the trimethylsilyl derivative of authentic methyl 1-thio-β-D-xylopyranoside above.

α-D-Xylopyranosyl chloride 2,3,4-tri(chlorosulfate) (2 g) (15) was treated with sodium iodide in sodium methyl mercaptide solution and the product was isolated by an identical procedure used for **1**. The product was a syrup (0.5 g) which crystallized and the crude product was shown to be a mixture of two components identical to those produced under the same reaction conditions by **1** (g.l.c. analysis) except that the methyl 1-thio-β-D-xylopyranoside constituted only 70% of the mixture in this case. Recrystallization (two times) of the crude product from ethanol gave crystals (0.1 g, 13%) of m.p. 162–164°, undepressed on admixture with authentic methyl 1-thio-β-D-xylopyranoside obtained above.

Methyl 1-Thio-α-D-lyxopyranoside

Crystalline α-D-lyxopyranosyl chloride 2,3,4-tri(chlorosulfate) (2 g) (15) was treated with sodium iodide in sodium methyl mercaptide solution and the product was isolated by identical procedures used for **1**. The product was a syrup which crystallized and a p.m.r. spectrum of the crude product in solvent *ii* indicated a methylthio singlet at τ 7.86 and a methoxy singlet at 6.62. The g.l.c. analysis using column *b* of the trimethylsilylated crude product indicated two components with relative retention times of 1.0:2.8. The faster minor component had

an identical retention volume to the trimethylsilyl derivative of methyl α-D-lyxopyranoside and the major slower component constituted 90% of the mixture. Recrystallization from chloroform – propan-1-ol gave crystals (0.3 g, 40%) of m.p. 120–122° and $[\alpha]_D$ +123° (*c*, 0.9 in water).

Anal. Calcd. for $C_6H_{12}O_4S$: C, 40.00; H, 6.67; S, 17.80. Found: C, 40.18, H, 6.72; S, 17.67.

The crystals did not reduce Fehlings' solution and a p.m.r. spectrum of the crystals in solvent *ii* indicated a methylthio singlet at τ 7.86 (3 protons) and an anomeric doublet at 5.09 (1 proton) with a spacing of 4.6 Hz.

The author wishes to thank Mrs. A. Martin for technical assistance and Mr. A. E. Castagne for determination of the microanalyses and the p.m.r. spectra.

Tricyclic Unsaturated Hydrocarbons

R. H. WIGHTMAN, (Miss) R. J. WAIN, AND D. H. LAKE[1]
Department of Chemistry, Carleton University, Ottawa, Canada

Received December 7, 1970

Some new unsaturated tricyclic hydrocarbons have been synthesized using a sequence of some general usefulness.

De nouveaux hydrocarbures tricycliques insaturés ont été synthétisés utilisant une série de réactions qui pourraient s'avérer d'utilisation générale.

Canadian Journal of Chemistry, 49, 1360 (1971)

Introduction

Polycyclic unsaturated systems containing chiefly non-six-membered rings represent an area of organic chemistry currently full of theoretical interest (1) and synthetic challenges (2). From the synthetic point of view we wish to report a generally useful sequence which has provided us with several new tricyclic compounds containing a bicycloalkeno–benzenoid system. The compounds should serve as excellent precursors to test chemically the theoretical predictions (1) concerning stability and/or aromaticity of similar carbon skeletons containing more unsaturations. The general scheme is outlined in Scheme 1. Additionally, slight variations in the synthetic sequence (3*a*) or modification (3*b*) of the final products (*i.e.* **4***a–d*, **5***b–d*) would give other ring systems of potential interest in this expanding field.

Results and Discussion

The Synthetic Sequence

The pinacol reaction leading to the diols **1***a–d* is well-documented (4), even in the mixed series, *i.e.* preparation of **1***c* (5). Since we were primarily interested in the product from this "mixed-pinacol" reaction much of our effort was devoted to separation and characterization of the products **1***c*–**4***c* in this series.[2]

The mixed pinacol reaction gave a somewhat variable yield of products **1***a* (~10%), **1***b* (~40%), **1***c* (~50%); however, it was possible to obtain analytical samples of the mixed diol (1*c*), either by preparative t.l.c. or careful sublimation of the diol mixture. No useful methods were found for separation of preparative quantities of the diols, hence the mixture was carried through the next step.

Dehydration of the diols was accomplished with phosphorus oxychloride in pyridine (4, 6) to minimize possible rearrangements. Due to the varying instability of the dienes,[3] no rigorous attempt was made to purify them. However, separation of the diene mixture **2***a–c* could readily be accomplished by g.l.c. and preparative-scale g.l.c. techniques were employed at this stage. The individual dienes were then immediately allowed to react with maleic anhydride (4) to yield Diels–Alder adducts, **3***a–c*. Product distribution at the diene stage did not correspond exactly to that of the diol mixture, presumably due to the differences in stabilities of the various dienes.

Transformation of the anhydrides **3***a–d* into the corresponding aromatic products was accomplished by heating with a slight excess of phosphorus pentoxide, P_2O_5, or excess 10% palladium-on-charcoal. The synthesis of **4***a*, originally prepared via an alternate route (8), has already been reported using the P_2O_5 method (7*a*), while a similar "aromatization" was accomplished using Pd/C (7*b*). Treatment of **4***a* with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) produced the dihydro-*as*-indacene (**6**) as indicated by comparison with the reported n.m.r. data (9). This final reaction was not further investigated,

[1]Taken in part from the thesis submitted by D.H.L. in partial fulfillment of the requirements of the M.Sc. degree at Carleton University, Ottawa, Canada, 1969. Present address: Cambrian College of Applied Arts and Technology, Sudbury, Ontario.

[2]No attempt had been made to characterize **1***c* and **2***c* by the original author (5).

[3]Stability of the dienes increases with ring size. We have an indication that the decomposition involves cycloaddition of oxygen and subsequent cleavage to keto-alcohols.

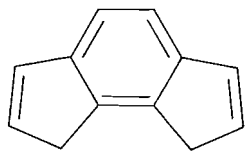
SCHEME 1

since the chemistry of the system has already been elegantly investigated by Katz and coworkers (9). However, this method is a significantly simpler approach to **4***a* (21% overall yield in four steps from cyclopentanone after our modification of the P_2O_5 treatment). Also, it serves to illustrate how benzenoid products can be used in quest of the more interesting compounds containing additional unsaturations.



6

The reaction of **3***d* with phosphorus pentoxide usually yieded two hydrocarbons, easily separable by g.l.c. and partially separable by column chromatography. The minor constituent (*ca.* 10–20%), m.p. 133–135°, was identified as bicyclo-octeno-[*a*,*d*]-benzene (**5***d*) by comparison with an authentic sample[4] obtained via an unambiguous synthesis (10). The major product, m.p. 83–85°, has been characterized as the hitherto unknown bicyclo-octeno-[*a*,*c*]-benzene (**4***d*). Combustion analysis and mass spectral data established the empirical formula; n.m.r. data (two aromatic, eight benzylic, and 16 methylenic protons) indicated the functionality and i.r. and u.v. comparisons (*vide infra*) corroborated the correct isomeric designation.

The identification of **4***c* and **5***c* has been noted (11), albeit in milligram quantities and via a rather lengthy synthesis (12) which favors the linear[5] isomer **5***c*. Our sequence now makes available synthetically useful amounts of the potentially more interesting[6] angular isomer **4***c*. In our sequence the hydrocarbon mixture obtained by "aromatization" of **3***c* with P_2O_5 appears to contain approximately 90% of **4***c* and 10% of **5***c* as judged by i.r. and u.v. comparisons of reported values.

Treatment of the anhydride **3***b* with P_2O_5 at elevated temperatures produced a mixture of two hydrocarbons from which a crystalline solid, m.p. 140°, could easily be isolated. This product was identified as bicyclohepteno-[*a*,*d*]-benzene (**5***c*), primarily on the basis of strong i.r. bands in the region 860–900 cm^{-1} and comparative u.v. data. Once again the empirical formula was ascertained by mass spectrum and combustion analysis, while the three gross structural features (two aromatic, eight benzylic, and 12 methylenic protons) were clearly distinguishable in the n.m.r. The ratio of the two components varied greatly, depending on the duration and temperature of the P_2O_5 treatment. Removal of **5***c* was almost complete after several crystallizations and g.l.c. investigation showed that the mother liquors contained essentially the second compound which could be obtained as a solid, m.p. 54°. This product was identified as bicyclohepteno-[*a*,*c*]-benzene (**4***c*).[7] Structure proof was again dependent on combustion analysis plus mass spectral and n.m.r. data for the gross structure, while i.r. and u.v. data (*vide infra*) were necessary to identify the substitution pattern.

The Isomers: Formation and Characterization

The formation of the linear isomer, often in appreciable quantities from **3***b* with P_2O_5, was somewhat puzzling and frustrating at first. However, this isomerization, which had not previously been noted (7*a*), appears to be yet another example of the acid-catalyzed rearrangement of polyalkylated benzenes (16). Much work has been reported over the years on the *s*-octahydroanthracene : *s*-octahydrophenanthrene equilibrium under a variety of acidic conditions (*e.g.*, H_2SO_4, $AlCl_3$, HF/BF_3). A recent paper (17) suggests that the most plausible mechanism involves protonation of the ring system followed by rearrangement via a spiro-carbonium ion intermediate (similar to the dienone–phenol rearrangement). It seems quite probable, there-

[4]We thank Professor F. Sondheimer for kindly providing a sample and other relevant data.

[5]Angular and linear designate 1,2:3,4- and 1,2:4,5-substitution patterns respectively.

[6]Several unsuccessful attempts to prepare the fully unsaturated hydrocarbon derived from the linear isomer **5***c* have been reported (13*a*, *b*). Recently, however, it has been calculated that the non-benzenoid hydrocarbon containing the angular system **4***c* is more favorable (14*a*, *b*).

[7]Although very incomplete data were reported and only the melting points agree, it seems possible that our sample is the same as that reported by Rosenfelder and Ginsburg (15) via a completely different route. Unfortunately, Professor Ginsburg has no sample of his product (personal communication).

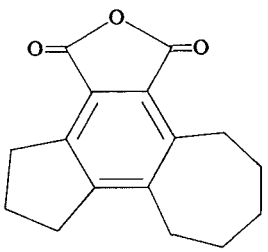
fore, that some rearrangement would be occurring under the conditions of the P_2O_5 experiments. Although not useful as a large-scale preparative method, it is interesting to note that isomerically pure angular hydrocarbons could be obtained if the corresponding anhydrides were treated under non-acidic conditions, *e.g.*, heating with excess Pd/C. Thermal reaction of **3***c* with catalytic amounts of Pd/C merely produced the aromatic anhydride **7**.[8]



7

Proof of structure of the new aromatic hydrocarbons required a complete spectral investigation. The mass spectra of each pair of isomers exhibited fairly intense molecular ions and all other significant *m/e*'s were the same. The n.m.r. spectra could not be used to distinguish isomers; the only potentially useful value (the chemical shift of the singlet representing two aromatic protons) varied slightly but no significant trends were observed. The most useful values were the strong i.r. bands ascribed to out-of-plane C—H deformation vibrations of the hydrogens on the benzene ring (18). Good agreement with the values quoted was found: for the angular isomers a range of 830–800 cm^{-1} (two adjacent hydrogens), and for the linear isomers a range of 890–850 cm^{-1} (one isolated hydrogen). Another useful trend was noticed when comparing the u.v. spectra of various pairs of isomers. Although the λ_{max} were not always identical, the linear isomer invariably exhibited a larger extinction coefficient (ε) than the angular isomer. Finally, it was noted that the linear isomer always had the higher melting point.

In addition to making available several precursors for potential non-benzenoid aromatic hydrocarbons, this study has provided the missing compounds in an interesting series of tetraalkylated benzenes. Much spectroscopic information was unavailable in this series and we have repeated the syntheses of the 5–5 linear (**5***a*) (16) and 5–6 linear (21) compounds for a more complete comparison. Table 1 summarizes the pertinent information.

[8]The aromatization of anhydrides such as **3***c* can be readily accomplished (4, 7*b*) while similar decarboxylations involving prolonged heating with metals (Zn, Cu, Pd/C) have been previously noted (7*b* and refs. therein). Excess Pd/C appears to accelerate the latter process but no kinetic studies were attempted at this time.

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. The n.m.r. spectra were obtained on a Jeolco C-60 spectrometer and are expressed in p.p.m. (τ) from internal tetramethylsilane in deuterochloroform. The i.r. spectra (ν_{max} in cm^{-1}) were measured on a Perkin–Elmer 237B or 257 spectrophotometer either as solutions or liquid film, and u.v. spectra [λ_{max} in nm (ε)] were recorded with a Cary 14 or Perkin–Elmer 202 instrument. Mass spectra were obtained from an MS12 spectrometer (AEI). The g.l.c. was performed on Hewlett–Packard (F and M) instruments. Analytical investigations were performed on a Model 402 equipped with flame-ionization detector, helium carrier gas (50 ml/min), and a glass column (6′ × ¼″) packed with six-ring polyphenyl ether (PPE – 5% on Chromosorb W 80/100 mesh). For preparative separations a Model 776 was used with a stainless steel column (80″ × 3/4″) packed with UCW98 (2% on Chromosorb W 60/80 mesh) and nitrogen carrier gas (400 ml/min). Temperatures and retention times are noted as required. The t.l.c. was accomplished using Silica gel G (0.25 mm layers) on glass plates. Microanalyses were performed by Organic Microanalyses (Dr. C. Daesslé), Montreal, Quebec.

The preparation of some of the starting materials (**1***a, b, d* and **3***a, b, d*) has been adequately described elsewhere (4). Therefore the "mixed" series (**1***c*–**3***c*) will be used as the experimental example (5).

Preparation of "Mixed" Diols (1a–c)

To a well-stirred mixture of coarse aluminum powder (100 g, 3.7 mol) in dry benzene (600 ml), was added a solution of cycloheptanone (276 g, 2.46 mol), cyclopentanone (206 g, 2.46 mol), and mercuric chloride (46 g, 0.17 mol) in dry benzene (600 ml). The mixture was stirred and heated at reflux for 6 h, then cooled. Extra benzene (600 ml) then water (250 ml) was added dropwise and the stirred mixture was again heated for 3 h before being cooled and filtered. The solid was thoroughly washed with hot benzene and the combined organic filtrates were dried (anhydrous sodium sulfate). After removal of the solvent, the thick, residual oil was dissolved in a minimal amount of petroleum ether (b.p. 30–60°) and upon cooling, white crystals (m.p. 64–68°) slowly formed. Further concentration of the mother liquors eventually produced a total yield of 189 g (35%). The t.l.c. (30% ethyl acetate : 70% benzene) showed three spots with R_f values of 0.19, 0.31, and 0.42. Preparative t.l.c. or slow sublimation (90°/0.1 mm Hg) produced three crystalline solids (approximate ratio 1:5:4). The

Preparation of Bicyclic Dienes (2a–c)

Essentially the method of Greidinger and Ginsburg (4) was followed. Thus the mixture of diols (189 g), excess phosphorus oxychloride (150 g), and dry pyridine (1500 ml) was stirred at room temperature for 0.5 h, then heated under reflux for 6 h. The pyridine was removed under reduced pressure, the residue dissolved in ice–water (4 l) and stirred for 2 h. This mixture was extracted with hexane (3 × 300 ml) and the combined organic extracts were washed successively with 5% aqueous hydrochloric acid (2 × 300 ml), 5% aqueous sodium bicarbonate (2 × 300 ml), water (1 × 300 ml), and saturated aqueous sodium chloride (1 × 200 ml) before drying (anhydrous sodium sulfate) and removing solvent. The yield of crude oily dienes was 153 g. Separation was achieved by repeated 8 ml injections on a preparative scale g.l.c. instrument at 165°. Yields of components were as follows: **2***a* (8.5 g), **2***b* (62.7 g), **2***c* (34.2 g), mixture of **2***b* and **2***c* (6.9 g).

Preparation of Anhydrides (3a–c)

The dienes were immediately dissolved in hexane, treated with excess maleic anhydride, and heated under reflux for several hours, as outlined by Greidinger and Ginsburg (4). The reaction mixture was dissolved in benzene and excess maleic anhydride removed by water extraction. After drying (anhydrous sodium sulfate) and removing the solvent, the residue was recrystallized from hexane. Thus, (*i*) **2***a* (8.5 g, 0.063 mol) and maleic anhydride (17.6 g, 0.180 mol) gave **3***a* (13.5 g, 92%), m.p. 103°; reported m.p. 104° (4). (*ii*) Compound **2***b* (62.7 g, 0.33 mol) and maleic anhydride (128 g, 1.3 mol) gave **3***b* (75 g, 80%), m.p. 157°; reported m.p. 158° (4); (*iii*) Compound **2***c* (34.2 g, 0.21 mol) and maleic anhydride (72 g, 0.74 mol) gave **3***c* (43.3 g, 62%), m.p. 135–137°. Spectra: i.r. 1850 and 1775 (anhydride); n.m.r. 6.65 (2H, d), 7.0–9.2 (18H, m).

Anal. Calcd. for $C_{16}H_{20}O_3$: C, 73.85; H, 7.70. Found: C, 73.91; H, 7.62.

Preparation of Aromatic Hydrocarbons.

The aromatic hydrocarbons were prepared by heating the corresponding anhydrides with a slight excess of phosphorus pentoxide at elevated temperatures (7*a*) for short periods of time (*ca.* 2–5 min). Our method involved mixing the two components in an elongated flask connected to a Hickman-type still and air condenser. The flask was briefly inserted into a preheated furnace (350°) and following a somewhat vigorous reaction, the distillate was collected. Filtration through a short column of silica gel (using petroleum ether as eluant) was usually sufficient to rid the product of any colored impurities.

The following reactions were carried out:

(*i*) **3***a* (3.5 g, 0.017 mol) and phosphorus pentoxide (3.0 g, 0.021 mol) gave a colorless oil (1.67 g, 65%) which formed white needles, m.p. 40°; reported for **4***a*, m.p. 40° (8, 9).

(*ii*) Compound **3***b* (5.0 g, 0.0192 mol) and phosphorus pentoxide (3.5 g, 0.021 mol) gave a colorless oil (2.50 g, 70%). Crystallization from methanol/ether produced **5***b*, white crystals, m.p. 139–140°. Spectra: n.m.r. 3.15 (2H, s, aromatic H), 7.0–7.5 (8H, m, benzylic H's) and 8.0–8.6 (12H, m —CH_2's); i.r. and u.v. (see Table 1) indicated a 1,2:4,5 tetra-substitution pattern; mass spectrum, molecular ion *m/e* 214.

Anal. Calcd. for $C_{16}H_{22}$: C, 89.72; H, 10.28. Found: C, 89.72; H, 10.28.

From the mother liquors could be isolated a second compound **4***b*, m.p. 53–54°. Spectra: n.m.r. 3.22 (2H, s, aromatic H's), 7.0–7.5 (8H, m, benzylic H's), and 8.0–8.6 (12H, m —CH_2's); i.r. and u.v. (see Table 1) consistent with a 1,2:3,4-substitution pattern; mass spectrum, molecular ion *m/e* 214.

Anal. Calcd. for $C_{16}H_{22}$: C, 89.72; H, 10.28. Found: C, 89.75; H, 10.21.

Analytical g.l.c. at 175° showed the two components to have retention times of 10.0 (**4***b*) and 11.5 min (**5***b*). The linear:angular ratio of approximately 1:3 in the reaction mixture could be changed dramatically in favor of the linear isomer by prolonging the contact time with phosphorus pentoxide.

(*iii*) The usual reaction between **3***c* (5.0 g, 0.019 mol) and phosphorus pentoxide (3.5 g, 0.025 mol) produced after column chromatography a colorless oil (2.98 g, 86%). The n.m.r., i.r., and u.v. comparisons with reported values (see Table 1) indicated that this material was composed of **4***c* and **5***c* (approximately 9:1 in favor of the angular isomer). The g.l.c. analysis at 175° showed only one (slightly unsymmetrical) peak with a retention time of 4.5 min.

(*iv*) The preparation of **3***d* was precisely as outlined by Greidinger and Ginsburg (4). The reaction of **3***d* (5.0 g, 0.016 mol) and phosphorus pentoxide (2.5 g, 0.018 mol) produced, after the usual work-up, a white crystalline residue (3.2 g, 80%). The g.l.c. analysis indicated two components with retention times at 175° of 21.3 and 25.7 min. The two compounds could be separated by column chromatography (silica gel) and crystallization (methanol/ether) and were identified as **5***d* and **4***d* respectively (ratio of approximately 1:5). Our linear isomer **5***d* had m.p. 135° and mixture m.p. 135° with an authentic sample[6] while all spectral data were in complete agreement with literature values. Compound **4***d* (white needles) had m.p. 83–85° and the following spectra: n.m.r. 3.10 (2H, s, aromatic H's), 7.0–7.5 (8H, m, benzylic H's) and 8.0–8.6 (16H, m, —CH_2's); i.r. and u.v. (see Table 1) indicated a 1,2:3,4-substituted benzene ring; mass spectrum, molecular ion *m/e* 242.

Anal. Calcd. for $C_{18}H_{26}$: C, 89.27; H, 10.73. Found: C, 89.20; H, 10.59.

Alternate Preparation of 4c

A mixture of **3***c* (500 mg, 0.0019 mol) and 10% palladium-on-charcoal (700 mg) was heated at 350° for a few

[9]Oxidation with lead tetraacetate and treatment with 2,4-dinitrophenylhydrazine showed two spots on t.l.c. corresponding to the 2,4-dinitrophenylhydrazones of cyclopentanone and cycloheptanone.

minutes. After evolution of gas (*ca.* 5 min) the mixture was cooled, filtered, and rinsed with ether. The filtrate was evaporated to dryness to yield an oily residue (300 mg, 85%) which was rendered colorless by filtration through a short column of silica gel. Spectroscopic examination (especially i.r. and u.v.) indicated isomerically pure **4***c* and g.l.c. comparison was identical with a sample prepared via the phosphorus pentoxide method.

Preparation of **7**

When a mixture of **3***c* (500 mg, 0.0019 mol) and 10% palladium-on-charcoal (100 mg) was treated in a manner similar to that outlined above, there was obtained a solid residue (400 mg, 80%). Crystallization from ethanol yielded white crystals of **7**, m.p. 199–201°. Spectra: i.r. (Nujol mull) 1835 and 1775 (aromatic anhydride).

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.98; H, 6.24. Found: C, 74.67; H, 6.45.

Preparation of **6**

A solution of **4***a* (300 mg, 0.002 mol) and DDQ (1.0 g, 0.004 mol) in benzene (50 ml) was heated under reflux for 24 h. Hexane (100 ml) was added to precipitate phenolic by-products and the residue, after filtration and evaporation, was subjected to column chromatography on alumina (Woelm, neutral, activity I). Elution with hexane yielded a slightly colored viscous oil. The n.m.r. comparisons with a published spectra (9) indicated the presence of **6** (extra bands in the 3.0–4.0 τ region). The g.l.c. studies showed the sample to contain some starting material.

We wish to thank the National Research Council of Canada for generous financial support and the Ontario Department of University Affairs for a studentship (D.H.L.).

We wish to thank Professor J. W. ApSimon for assistance in obtaining the mass spectra and Mr. G. K. Diedrich and Mr. R. J. Sampson for technical assistance.

Some Aspects of the Mass Spectra of *N*-Nitrosamines

J. W. ApSimon and J. D. Cooney[1]
Department of Chemistry, Carleton University, Ottawa, Canada

Received November 26, 1970

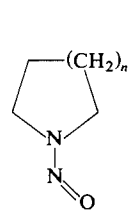
The mass spectra of seven cyclic *N*-nitrosamines were examined for characteristic fragmentation patterns. Accurate mass measurements on three of the compounds indicated that the M-17 and M-30 peaks resulted from molecular ion losses of •OH and •NO respectively. The loss of •OH was rationalized in terms of a McLafferty-type rearrangement.

On a examiné les spectres de masse de sept *N*-nitrosoamines cycliques afin de déterminer s'il existe des modes de fragmentations caractéristiques. Des mesures précises des masses de trois de ces composés ont permis de mettre en évidence que les fragments de masses M-17 et M-30 résultent respectivement de la perte de •OH et •NO par l'ion moléculaire. La perte de •OH peut être rationalisée en faisant intervenir un réarrangement du type préconisé par McLafferty.

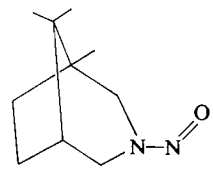
Canadian Journal of Chemistry, 49, 1367 (1971)

Several researchers have reported the mass spectra of dialkyl-*N*-nitrosamines (1–3) and dibenzyl-*N*-nitrosamines (3, 4) but little mass spectral data have been presented on cyclic *N*-nitrosamines (3). Schroll *et al.* (3) obtained the mass spectra of *N*-nitrosazacyclohexane and *N*-nitrosomorpholine and accurate mass measurements on the latter compound indicating molecular ion loss of •NO. In the course of another problem we had cause to determine the mass spectra of seven cyclic *N*-nitrosamines and some interesting facets of their fragmentation pathways are reported here.[2]

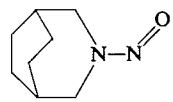
The compounds studied were the cyclic series **1** (n = 1–5), *N*-nitrosocamphidine (**2**), and *N*-nitroso-3-azabicyclo[3.2.2]nonane (**3**).



1
$n = 1$–5



2



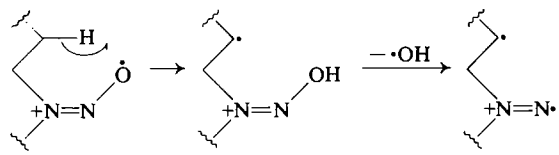
3

Two processes interested us in this study, the molecular ion loss of fragments of mass 17 and mass 30. Intuitively, these would be expected to be loss of •OH (5, 6) and •NO, respectively and this was confirmed by the accurate mass measurements summarized in Table 1.

Loss of •OH

Schroll *et al.* (3) had also noticed the loss of •OH from *N*-nitrosodi-*n*-propylamine but not from the di-*n*-butyl, diethyl or dimethyl derivatives. Examination of Collin's data (1) revealed an M-17 fragment for each of these compounds. These data are summarized in Table 2. A reasonable mechanism for •OH loss can be written as in Scheme 1 (7) assuming a preference for a six-membered McLafferty-type rearrangement (8) with transfer of a hydrogen atom β to the amine nitrogen.[3]

Fragments representing the expected loss of olefin from a McLafferty-type rearrangement



Scheme 1

[1]Taken from the M.Sc. thesis of J. D. Cooney, Carleton University, Ottawa, Canada, April, 1970. Present Address: Textile Chemistry Section, Division of Chemistry, National Research Council of Canada, Ottawa, Canada.

[2]We purposely refrain from extrapolation to more complete fragmentation patterns in the absence of deuterium labels and further accurate mass measurements. Those fragmentations mentioned are supported by metastable peaks.

[3]Attempts are in progress to confirm this by synthesis of specifically deuterated *N*-nitrosamines.

TABLE 1. Accurate mass measurements

Compound	Species	Calculated mass	Measured mass
	M^+	114.0793	114.0793
	M-OH	97.0766	97.0763
	M-NO	84.0813	84.0798
	M^+	156.1263	156.1251

were also observed for each of the dialkyl-*N*-nitrosamines examined by Collin (1) and a possible mechanism is illustrated in Scheme 2.

Generally speaking a large loss of •OH was accompanied by a small loss of olefin and *vice versa* (9) suggesting two pathways for molecular ion fragmentation involving hydrogen atom transfer.

In some respects the data in Table 2 support the contention of a six-membered process for transfer of a β-hydrogen, thus *N*-nitrosodi-*n*-propylamine and *N*-nitrosodi-*n*-butylamine have larger M-17 peaks than the other aliphatic cases since a weaker C—H bond (10) was broken during transfer of a secondary hydrogen. A preference of approximately 7:1 for secondary hydrogen abstraction over primary hydrogen abstraction is apparent from comparison of % total ionization (T.I.) values for *N*-nitrosodi-*n*-propylamine and *N*-nitrosodiethylamine. Preference for secondary

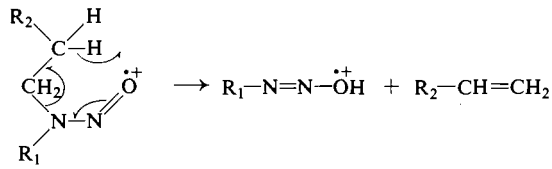
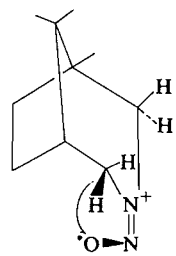


SCHEME 2

hydrogen abstraction has also been observed in the McLafferty rearrangement of ketones (11). The loss of •OH from *N*-nitrosodimethylamine is very small since this requires breakage of a stronger C—H bond as well as a strained five-membered ring process with transfer of a primary hydrogen. Since submission of this paper, a communication (12) has appeared on the dialkyl-*N*-nitrosamine molecular ion loss of •OH employing ion cyclotron resonance.

In the cyclic cases (see Table 2), *N*-nitrosoazacyclopentane (**1**, $n = 1$) shows very little •OH loss, perhaps a reflection of the geometrical restraints on hydrogen transfer by a five-membered process. We can also support a similar mechanism for loss of •OH for *N*-nitrosoazacyclohexane (**1**, $n = 2$), but in this more flexible system the oxygen can approach the hydrogen to be transferred much more readily (13). The loss of •OH from *N*-nitrosoazacycloheptane (**1**, $n = 3$) is fairly efficient (1.1% T.I.) since the medium ring system is more flexible and a six-membered arrangement is possible. The loss of •OH from *N*-nitrosoazacyclooctane (**1**, $n = 4$) and *N*-nitrosoazacyclononane (**1**, $n = 5$) (0.41 and 0.31% T.I. respectively) is not as large as anticipated for these more flexible systems, a possible reason being the higher efficiency of competing reactions.

From examination of the molecular models of *N*-nitrosocamphidine and *N*-nitroso-3-azabicyclo[3.2.2]nonane, it appears that tertiary hydrogen abstraction via a six-membered process is unlikely, thus the large M-OH peaks (0.64 and 0.60% T.I. respectively) probably result from secondary hydrogen abstraction (α to the amine nitrogen). If we extrapolate from the ground state molecular models to the excited state, the ease of hydrogen abstraction becomes apparent since in the case of *N*-nitrosoazacyclopentane and *N*-nitrosoazacyclohexane a five-membered ring process cannot attain coplanarity whereas in *N*-nitrosocamphidine and *N*-nitroso-3-azabicyclo-[3.2.2]nonane such a process is readily obtained. The planar process **4** is more efficient because it has a shorter oxygen to α-hydrogen distance which appears to be the critical factor in hydrogen atom transfer (13).



4

Loss of •NO

The accurate mass measurements (Table 1) indicate that the M-30 peak of three of the cyclic *N*-nitrosamines was due to the expected molecular ion loss of •NO. The ability to lose •NO (Table 3, % T.I. column) would be expected to indicate the relative strengths of the N—N bond. A large M-NO peak would indicate a weaker N—N bond and predominance of resonance form **5** while a small M-NO peak would indicate a stronger N—N bond and a larger contribution from resonance form **6**. In a similar manner the

size of the molecular ion and M-17 peaks should also be indicative of the N—NO bond strength. Consideration of the size of the M^+, M-17, and M-30 peaks in Tables 2 and 3 suggests that stronger N—NO bonds are present in *N*-nitrosoazacycloheptane, *N*-nitroso-3-azabicyclo[3.2.2]-nonane, and *N*-nitrosocamphidine. The possibility of differing contributions from **5** and **6** influencing the fragmentation pattern is supported by the observation that a small M-30 peak is accompanied by a large M-17 peak and *vice versa*.

Accurate mass measurement on the M-32 peak of *N*-nitrosoazacyclopentane indicated loss of H_2NO. Metastable peaks confirmed molecular ion loss of ·NO and then H_2.

M-59 Peak of N-Nitroso-3-azabicyclo[3.2.2]-nonane (3)

The accurate mass measurement (Table 1) on the M-59 peak of *N*-nitroso-3-azabicyclo[3.2.2]-nonane indicated molecular ion loss of CH_3N_2O. Metastable peaks suggested fragmentation by loss

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of •NO, HCN, then H_2 in sequence. A possible process resulting in a stable allylic cation as the final M-59 fragment is illustrated in Scheme 3 (*cf.*, however, footnote 2). Metastable peak analysis also indicated a similar fragmentation process for *N*-nitrosoazacyclopentane, *N*-nitrosoazacyclohexane, and *N*-nitrosoazacycloheptane.

Other Fragments

It would not be opportune to discuss other fragments deeply but in this series there are some general similarities which would bear further study.

The base peak varies from compound to compound but in all spectra intense peaks were present at *m/e* 41, 42 (possibly $CH_2{=}N^+{=}CH_2$ (5)), and 55. Very few similarities to the parent amine spectra were noted (9).

Experimental

The *N*-nitrosamines were prepared by nitrosation of the parent amine with HNO_2 made *in situ* (14, 15) and showed all requisite spectral and analytical properties for the structures quoted. The mass spectra were determined with an Atlas CH 4 mass spectrometer operating at 70 eV and a source temperature of 180–250 °C. Most of the spectra were repeated on both an AEI MS-12 and a Thomson–Houston mass spectrometer. The mass spectra are available from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada. A typical mass spectrum of a cyclic *N*-nitrosamine is shown in Fig. 1. Accurate mass measurements were determined on an AEI MS-902 mass spectrometer by interpolation using an internal fluorinated mass marker with an error of less than 10 p.p.m. unless otherwise indicated.

We thank the National Research Council of Canada for generous financial assistance (grant in aid J.W.A. and study leave J.D.C.). J.W.A. thanks the administrators of the C. D. Howe Foundation for a fellowship, Professors Ourisson, Institut de Chimie, Strasbourg, France, and G. W. Kenner, University of Liverpool, Liverpool, England, for their hospitality and use of facilities. Mr. J. Barclay and his associates, University of Liverpool, kindly obtained the accurate mass measurements. Dr. R. F. Pottie, Division of Chemistry, National Research Council of Canada, Ottawa, Canada, is thanked for the Atlas CH 4 mass spectra and many helpful discussions.

Quelques imino-4 thiophènes particulièrement stables[1]

RÉAL LALIBERTÉ ET GEORGES MÉDAWAR
Département de Chimie, Laboratoires de Recherche Ayerst, Montréal, Québec

Reçu le 1 décembre, 1970

La réaction des dérivés sodés d'hydrazides des acides amino-3 cyano-2 mercapto-3 acryliques avec certains dérivés halogénés a donné des dérivés imino-4 thiophènes stables que nous avons caractérisés à l'i.r., à l'u.v., et au r.m.n.

Reaction between sodium salts of 3-amino-2-cyano-3-mercapto acrylhydrazides and two halocompounds resulted in the formation of some 4-iminothiophenes that were found to be quite stable. Their i.r., u.v., and n.m.r. spectra are described here together with one of their tautomeric forms obtained after acetylation.

Canadian Journal of Chemistry, **49**, 1372 (1971)

Introduction

Dans une publication récente (1) nous avons suggéré la formation d'imino-4 thiophènes se réarrangeant rapidement en amino-4 thiophènes lors de la réaction de dérivés sodés d'hydrazides des acides amino-3 cyano-2 mercapto-3 acryliques (**3**) avec des α-halocétones pour donner des hydrazides d'acides diamino-2,4 acyl-5 thiophène carboxyliques-3. Ces aminothiophènes sont d'une grande stabilité et leur examen à l'i.r. et au r.m.n. n'a pas permis de déceler de forme imine tautomérique soit en position 4 soit en position 2. La possibilité qu'ont ces amines de former des ponts hydrogènes avec les carbonyles adjacents ainsi que la contribution des azotes à l'aromaticité du thiophène nous ont semblé suffisant pour expliquer la grande stabilité du système. Comme la synthèse décrite est très souple et permet de modifier ces thiophènes nous avons essayé de dissocier ces deux facteurs pour évaluer leur importance relative. C'est ainsi que nous avons réussi à éliminer l'un des carbonyles et à obtenir quelques molécules aussi stables que les premières mais sous une forme différente.

Synthèse

La réaction de l'isothiocyanate de phényle (**1**) avec les hydrazides de l'acide cyano-2 acétique (**2**) en présence d'un équivalent d'éthylate de sodium dans l'éthanol donne les dérivés sodés d'hydrazides des acides amino-3 cyano-2 mercapto-3 acryliques (**3**) utilisés *in situ* comme produit de départ (schéma 1). Ils réagissent avec un dérivé halogéné convenable pour donner des thiophènes portant en 5 soit un groupe méthyle **12** soit un groupe phényle **8**. Dans le premier cas on fait réagir le dérivé sodé **3** avec un peu moins d'un équivalent de bromo-3 butanone dans l'éthanol sous reflux pendant quelques heures. La condensation s'accompagne de l'élimination du groupe acétyle de telle sorte qu'on obtient directement l'hydrazide de l'acide anilino-2 dihydro-4,5 imino-4 méthyl-5 thiophène carboxylique-3 (**12**) après addition sur le nitrile du carbanion **11** formé dans les conditions utilisées.

Pour introduire un groupe phényle on fait réagir le produit de départ **3** avec l'α-bromophénylacétate d'éthyle (**4**). Dans ce cas il n'y a pas d'élimination spontanée de la fonction ester de sorte qu'on obtient après addition sur le nitrile du carbanion **6** un imino-4 thiophène disubstitué en position 5 ne pouvant pas se tautomériser. L'acide chlorhydrique à 20% à chaud provoque l'élimination de la fonction ester pour donner l'hydrazide de l'acide anilino-2 dihydro-4,5 imino-4 phényl-5 thiophène carboxylique-3 (**8**) après addition de carbonate de sodium et extraction avec l'acétate d'éthyle.

Il est à noter que dans ce cas il n'y a pas hydrolyse du groupe hydrazide ou de la fonction imine. Celle-ci est donc très stable. Elle a aussi résisté à plusieurs essais d'acétylation avec l'anhydrique acétique. Cependant l'anhydride de l'acide trifluoracétique forme un trifluoracétamide en position 4 avec déplacement de la double liaison vers le cycle, pour donner un thiophène aromatique. Dans ce cas il y a simultanément formation de l'amide trifluoré du groupe aniline en 5 et le produit que l'on obtient est en fait le méthyl-5(*N*-phényltrifluoracéta-

mido)-2 trifluoracétamido-4 *N*-pipéridinothiophène carboxamide-3 (**13**).

Spectroscopie

L'aromatisation du système que l'on vient de décrire confirme la structure des iminothiophènes. On obtient des indications additionnelles en examinant les spectres i.r. et de r.m.n. des produits décrits dans le tableau 1.

On y voit immédiatement que l'i.r. dans le $CHCl_3$ montre une bande imine caractéristique à $3480 \pm 10\ cm^{-1}$. Cette bande est fine et peut être repérée facilement. On notera qu'elle est la même pour les produits **7***a* et **7***b* dont la structure est évidente et les imines **8***a* et **12***a*. On trouve aussi dans l'i.r. les deux bandes NH amides à 3340–3250 et 3270–3170 cm^{-1} ainsi que les bandes carbonyles à $1632 \pm 3\ cm^{-1}$. Le spectre du produit **12***b* a été fait dans le Nujol et présente des caractéristiques normales pour ce milieu. Les spectres de r.m.n. montrent une bande à 640–620 Hz attribuée à l'imine et deux bandes amines entre 560–420 et entre 385 et 320 Hz. Toutes les trois sont faciles à reconnaître parce qu'elles sont échangeables ce qui permet d'établir avec certitude le nombre de NH réel. La formation du trifluoracétamide modifie ce tracé et ce produit **13** montre deux bandes amides à 650 et 535 Hz. De plus l'imide **8***a* montre un singulet à 310 Hz pour H-5 et les imines **12***a* et **12***b* montrent chacune un quartet à 250–252 Hz ($J = 7$). Ce couplage ne peut s'expliquer que par la structure proposée.

Conclusion

Il est donc évident que l'équilibre imine–amine en -4 auquel nous avons fait allusion plus haut est possible comme le démontre les formes extrêmes **12** et **13** que nous décrivons ici. Il est tout aussi évident que l'aromaticité du thiophène est un facteur secondaire contribuant à la stabilité de ces molécules vu que des produits comme **8***a* et **12***a* n'existent que sous la forme imine non-aromatique. Ceci est d'autant plus surprenant que l'on pourrait s'attendre à ce que la présence d'un phényle en -5 favorise la forme amine en ajoutant à la conjugaison comme semblent le faire certains carbonyles déjà décrits (1).

Partie expérimentale

Remarques générales

Les spectres i.r. sont faits dans le $CHCl_3$ sur spectrophotomètre Perkin–Elmer 225. Les spectres u.v. sont pris dans l'éthanol sur spectrophotomètre Perkin–Elmer 350. Les spectres de r.m.n. ont été enregistrés sur un appareil Varian A-60-A en utilisant le tétraméthylsilane comme référence interne. Les positions sont exprimées en Hz. Les points de fusion sont pris au microscope chauffant Reichert.

N,N-Diméthylhydrazide de l'acide cyano-2 acétique (2a)

Nous avons utilisé les conditions décrites par Howard *et al.* (2).

Cyano-2 N-pipéridino acétamide (2b)

On laisse à température ambiante un mélange équimoléculaire de cyano-2 acétate d'éthyle et d'amino-1 pipéridine. Après 4 jours on filtre le solide obtenu et on le cristallise de l'isopropanol. On obtient ainsi un solide jaunâtre (65%) fondant à 131–132°. A l'i.r. il montre des bandes à 3210, 3080, 2260, et 1670 cm^{-1}.

Anal. Calc. pour $C_8H_{13}N_3O$: C, 57.46; H, 7.84; N, 25.13. Trouvé: C, 57.48; H, 7.88; N, 25.25.

Sel de sodium du N,N-diméthylhydrazide de l'acide anilino-3 cyano-2 mercapto-3 acrylique (3a)

On ajoute un équivalent du *N,N*-diméthylhydrazide de l'acide cyano-2 acétique **2** à une solution refroidie de sodium (0.1 mol) dans 300 ml d'éthanol sec. On ajoute ensuite un équivalent d'isothiocyanate de phényle et on chauffe la solution sous reflux pendant 1 h.

Sel de sodium de l'anilino-3 cyano-2 mercapto-3 N-pipéridinoacrylamide (3b)

On le prépare comme ci-haut en utilisant le cyano-2 *N*-pipéridino acétamide **2***b*.

N,N-Diméthylhydrazide de l'acide anilino-2 carbéthoxy-5 imino-4 phényl-5 dihydro-4,5 thiophène carboxylique-3 (7a)

On ajoute à la solution dans l'éthanol du sel de sodium **3***a* un peu moins d'un équivalent de α-bromophénylacétate d'éthyle **4** et on chauffe pendant 1 h. On acidifie avec quelques ml d'acide acétique puis on filtre. On évapore l'éthanol, on reprend à l'acétate d'éthyle puis on lave. On évapore à nouveau et on reprend dans l'isopropanol pour obtenir un solide que l'on précipite du benzène par addition d'hexane et que l'on cristallise du benzène seul. Il est blanc (45%) et fond à 83–85°. A l'i.r. il montre l'ester à 1725 cm^{-1} et une bande intense à 1578 cm^{-1}. L'u.v. montre un maximum à 305 (ε 19 700). Le groupe $N(CH_3)_2$ parait à 164 Hz dans le r.m.n.

Anal. Calc. pour $C_{22}H_{24}N_4O_3S$: C, 62.25; H, 5.70; N, 13.20; S, 7.50. Trouvé: C, 61.91; H, 5.79; N, 12.83; S, 7.55.

Anilino-2 carbéthoxy-5 dihydro-4,5 phényl-5 thiophène N-pipéridinocarboxamide-3 (7b)

On le prépare comme 7*a* en utilisant le dérivé sodé **3***b*. On le précipite du benzène par addition d'hexane et on le cristallise du méthylcyclohexane. Le solide blanc (35%) fond à 101–103°. L'i.r. montre l'ester à 1725 et une bande intense à 1575 cm^{-1}. L'u.v. montre un maximum à 300 (ε 19 200).

Anal. Calc. pour $C_{25}H_{28}N_4O_3S$: C, 64.64; H, 6.08; N, 12.06; S, 6.88. Trouvé: C, 64.94; H, 5.83; N, 12.28; S, 6.67.

N,N-Diméthylhydrazide de l'acide anilino-2 dihydro-4,5 imino-4 phényl-5 thiophène carboxylique (8a)

On obtient en traitant 3 g de 7*a* par 60 ml d'acide

chlorhydrique à 20% sous reflux pendant 2 h. On neutralise avec Na_2CO_3 et on reprend à l'acétate d'éthyle. Après lavage on évapore le solvant et on cristallise le résidu du benzène et de l'isopropanol. C'est un solide blanc (75%) qui fond à 191–193°. L'i.r. montre une bande intense à 1575 cm^{-1}. L'u.v. donne un maximum à 291 (ε 20 000). Le r.m.n. donne un singulet à 159 Hz pour le $N(CH_3)_2$.

Anal. Calc. pour $C_{19}H_{20}N_4OS$: C, 64.76; H, 5.72; N, 15.90; S, 9.08. Trouvé: C, 64.98; H, 6.24; N, 15.94; S, 8.96.

*N,N-Diméthylhydrazide de l'acide anilino-2 dihydro-4,5 imino-4 méthyl-5 thiophène carboxylique-3 (**12a**)*

On l'obtient en gardant sous reflux pendant 2 h le dérivé sodé **3***a* avec un peu moins d'un équivalent de bromo-3 butanone. On refroidit, on ajoute un peu d'acide acétique et on évapore. On dissout le résidu dans l'acétate d'éthyle, on lave, on sèche, et on évapore. On cristallise le produit du benzène et de l'isopropanol. Le solide est blanc (45%) et fond à 197–200°. L'u.v. montre un maximum à 289 (ε 21 350).

Anal. Calc. pour $C_{14}H_{18}N_4OS$: C, 57.92; H, 6.25; N, 19.30; S, 11.01. Trouvé: C, 57.97; H, 6.40; N, 19.07; S, 10.81.

*Anilino-2 dihydro-4,5 imino-4 méthyl-5 thiophène N-pipéridinocarboxamide (**12b**)*

On l'obtient en gardant sous reflux pendant 2 h le dérivé sodé **3***b* avec un peu moins d'un équivalent de bromo-3 butanone. On refroidit, on ajoute un peu d'acide acétique et on évapore. On dissout le résidu dans l'acétate d'éthyle, on lave puis on évapore à nouveau pour obtenir un solide jaune qu'on lave avec de l'isopropanol, et que l'on cristallise du méthanol. Il est blanc (55%) et fond à 275°. L'u.v. donne un maximum à 280 (ε 22 800).

Ion Association Effects on Nuclear Magnetic Resonance Parameters of Aromatic Ions. II. The Anions of Carbazole and 4,5-Methylenephenanthrene[1]

RICHARD H. COX
Department of Chemistry, University of Georgia, Athens, Georgia 30601

Received November 2, 1970

The ^1H n.m.r. spectra of carbazole nitranion, 4,5-methylene- and 9,10-dihydro-4,5-methylenephenanthrene carbanions with various alkali metal cations have been analyzed in terms of chemical shifts and coupling constants. Chemical shifts of the anions depend upon cation and solvent and are related to the type of ion pairs present. The ^7Li n.m.r. data indicate that Li is associated with the nitrogen of carbazole nitranion whereas with the 4,5-methylenephenanthrene carbanions, Li appears to be located in the π-cloud of the anions and associated equally with all carbons in the anion. The results are discussed in terms of the types of ion pairs present and the association of cation with anion.

On a analysé les spectres r.m.n. de proton du nitranion du carbazole et des carbanions des méthylène-4,5 et dihydro-9,10 méthylène-4,5 phénanthrènes en présence de divers cations de métaux alcalins et l'on a pu évaluer les déplacements chimiques et les constantes de couplage. Il a été démontré que les déplacements chimiques des anions varient avec le cation et le solvant et sont reliés avec le type de paires d'ions présents. Les données concernant les spectres r.m.n. du ^7Li indiquent que le Li est associé avec l'azote du nitranion du carbazole tandis que dans le cas des carbanions des méthylène-4,5 phénanthrènes, il semble que le Li se trouve dans le nuage d'électrons π des anions et qu'il est associé également avec tous les carbones de l'anion. On discute les résultats en termes des types de paires d'ions qui sont présents et de l'association entre le cation et l'anion.

Canadian Journal of Chemistry, **49**, 1377 (1971)

Introduction

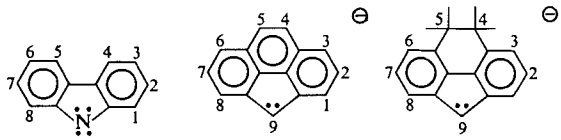
Of all the factors given by Schaefer and Schneider (2) which affect aromatic proton chemical shifts ion association effects have been the least investigated. The effect of counterion on the proton spectrum of the pyridinium cation was interpreted in terms of ion pair formation which reduces the π-electron polarization in the pyridinium ion (3). Although the effect of cation on the n.m.r. spectra of aromatic anions has been reported in a few cases, the results have not been discussed to any extent. Cation was reported to have no effect on the n.m.r. spectrum of triphenylmethyl carbanion (4). The protons of cyclopentadienyl (2) and cyclononatetraenyl (5) anions are more shielded with lithium than with other alkali metal cations. However, the protons of 1-phenylallyl anion are less shielded with lithium than with either sodium or potassium (6). In order to more clearly define the effect of counterion and ion association on chemical shifts of aromatic ions, we have undertaken an extensive investigation of the n.m.r. spectra of aromatic ions.

Recently, we reported the effect of cation and temperature on the proton n.m.r. spectrum of fluorenyl carbanion (1). In THF, the protons were found to be shielded in the order Li > Rb > K > Na. Furthermore, at -70 °C the spectrum of fluorenyl sodium became identical with that of fluorenyl lithium at room temperature. The effect of cation was interpreted in terms of polarization of charge in the aromatic anion by the cation. The anomalous shielding with lithium and the temperature dependence with sodium is consistent with a change in the type of ion pair formed with these cations. From the effect of cation, solvent, and temperature on the absorption spectrum of fluorenyl carbanion, Smid and co-workers (7, 8) have clearly shown that fluorenyl carbanion exists in solution in equilibrium with two types of ion pairs (contact and solvent-separated). Since the n.m.r. results are consistent with the absorption data, we suggested that n.m.r. spectroscopy may be used to study ion pairing of aromatic anions. Recently, we have learned of another investigation where n.m.r. has been used to study equilibrium between ion pairs of similar carbanions. It appears, on the basis of n.m.r. shifts and their behavior with cation and temperature, that carbanions may be divided into three classes: (*1*) those which exist as solvent-separated ion pairs, (*2*) those which exist as contact ion pairs, and

[1]For Part I, see ref. 1.

(*3*) those which exist as rapidly equilibrating mixtures of contact and solvent-separated ion pairs (9).

We have extended our previous investigations and wish to report the effect of cation and solvent on the n.m.r. parameters of the anions of carbazole (**1**) and 4,5-methylenephenanthrene (**2** and **3**). The carbazole nitranion is of interest since it permits examination of possible differences in bonding between nitranions and carbanions with a given cation. Since the 4,5-methylenephenanthrene system forms both a $4n$ (**2**) and $4n + 2$ (**3**) π-electron anion upon alkali metal reduction (10), the relationship between the number of π-electrons in the anion and the effect of cation on the chemical shifts may be examined. The results are discussed in terms of bonding between cation and anion.



1 **2** **3**

Experimental

Carbazole and 4,5-methylenephenanthrene of commercial origin were used without further purification. Samples were prepared using vacuum-line techniques in the "onion-dome" cells as described previously (10). Solvents were stored over sodium benzophenone ketyl and were transferred to the n.m.r. tube under vacuum. A final concentration of 0.4 *M* for the starting hydrocarbon was used. Tetramethylsilane was added (3%) as internal reference and lock signal source. No impurity peaks were detected in any of the spectra of the starting hydrocarbons.

Proton n.m.r. spectra were obtained on a Varian Associates HA-100 spectrometer operating in the field-sweep mode. A probe temperature of 29 °C was used. Calibration of the spectra was by the usual frequency difference technique. Final line positions used in the calculation of the chemical shifts and coupling constants were obtained as the average of two upfield and two downfield scans. A scan width of 50 Hz was employed with a sweep time of 1000 s.

The ^{7}Li n.m.r. spectra were obtained on the HA-100 spectrometer operating in the HR mode at 38.8 MHz. Calibration of the spectra was by the usual side-band technique using an external reference of aqueous LiCl. The reported chemical shifts are the average of two upfield and two downfield scans. No attempt was made to correct the ^{7}Li chemical shifts for bulk susceptibility differences. Such effects are usually smaller than 0.1 p.p.m.

The *in situ* alkali metal reductions of carbazole and 4,5-methylenephenanthrene were carried out by allowing the respective hydrocarbon solution to remain in contact with the metal mirror until n.m.r. signals from either the methylene or N—H protons in the starting hydrocarbon were no longer detectable. At this point there was essentially complete conversion of the starting hydrocarbons to their respective anions. Both the phenanthrenide (**2**), and 9,10-dihydrophenanthrenide (**3**) anions are formed in each case with 4,5-methylenephenanthrene (11)[2] (Fig. 1). Carbazole nitranion is the only detectable anion in the reduction of carbazole (Fig. 2). Identical conditions (concentration and temperature) were used for the reductions of a given hydrocarbon so that with a given solvent, any differences in the spectra of the anions are due to the effect of cation.[3]

The proton n.m.r. spectra were analyzed in terms of chemical shifts and coupling constants with the aid of the computer program LAOCN3 (12). Chemical shifts were assigned on the basis of comparisons with the shifts of fluorenyl carbanion (1, 2) and substituted fluorenyl and carbazole anions (13). The chemical shifts are considered to be accurate to within ±0.1 Hz. Coupling constants for these anions have been previously reported (10). Neither cation nor solvent have any effect on the coupling constants within experimental error (±0.1 Hz).

Results and Discussion

Carbazole

The chemical shifts of carbazole nitranion are dependent upon the cation (Table 1). In THF, the protons are shielded in the order Rb > K > Na. With lithium as the counterion, carbazole nitranion was not soluble in THF at these concentrations. The order of shielding observed in THF is similar to that observed for fluorenyl (1) and 1-phenylallyl (6) carbanions. However, in the better cation-solvating solvent (14) DME, the protons are shielded in the reverse order (Li > Na > K). With potassium the chemical shifts are identical to within 1 Hz in both solvents.

Several features of the data in Table 1 are in contrast to those reported for fluorenyl carbanion (1). Firstly, the effect of cation on the shifts of fluorenyl carbanion was approximately identical

[2]Polarographic reduction of 4,5-methylenephenanthrene also produces both **2** and **3** (11).

[3]While it is true that solvent affects the ratio of ion pairs present in solution (7), there is no evidence to indicate that solvent affects the type of anions formed upon alkali metal reduction. In fact the n.m.r. spectra show that identical anions are formed in each case. The relative amounts of the two anions in the case of 4,5-methylenephenanthrene are dependent upon the solvent. With potassium, the ratio of **2** to **3** is 1.95:1 and 2.50:1 in THF and diethyl ether, respectively. This difference reflects the effect of solvent on the rate of proton transfer from 4,5-methylenephenanthrene to the 4,5-methylenephenanthrene radical anion (10).

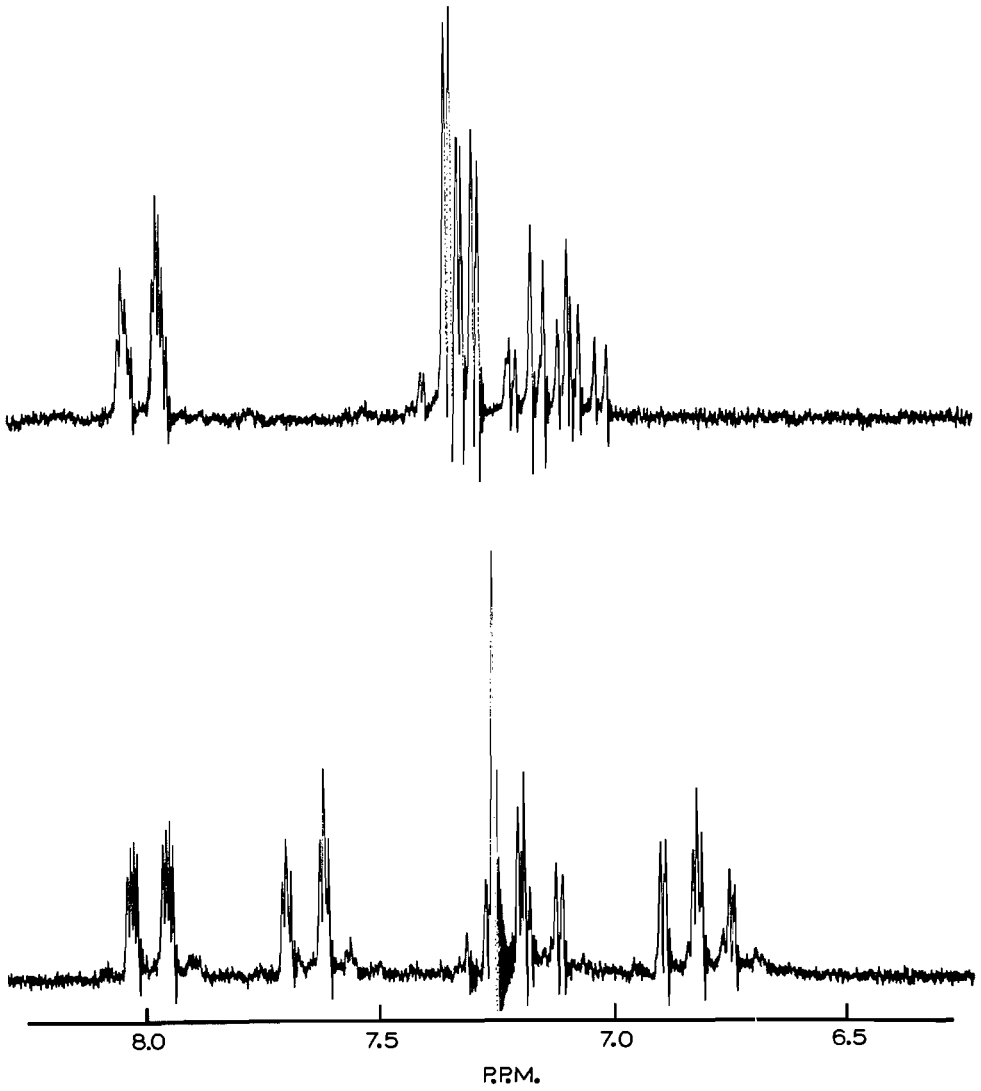

FIG. 1. Upper trace, the 100 MHz n.m.r. spectrum of 4,5-methylenephenanthrene in THF-d_8; lower trace, the 100 MHz n.m.r. spectrum of **2** and **3** with sodium in THF-d_8. The peaks at 1.7 and 3.5 p.p.m. are due to residual THF.

for all protons (~20 Hz). In THF, the total change in chemical shift with cation for the protons of carbazole nitranion is: H_1, 21; H_2, H_3, and H_4, 8 Hz. In DME the change is H_1, 23; H_2, 10; H_3 and H_4, 3 Hz. Secondly, the ^{7}Li chemical shift for fluorenyl lithium in diethyl ether was reported to be 6.2 p.p.m. upfield from an aqueous lithium chloride reference (15). The ^{7}Li chemical shift for lithium carbazole nitranion in DME is 0.13 p.p.m. downfield from lithium chloride. The differences in the observed ^{7}Li and ^{1}H shifts reflect the differences in the overall electronic structure of the carbanion and nitranion and hence, the bonding of cation to these two anions.

In the carbanion, the pair of electrons are in a p orbital and are delocalized throughout the carbon system. However, two pairs of electrons are donated to the system by nitrogen in the nitranion. The electronic structure about nitrogen in carbazole nitranion should be similar to that of pyrrole. Thus, a crude model for the electronic structure about nitrogen in carbazole nitranion

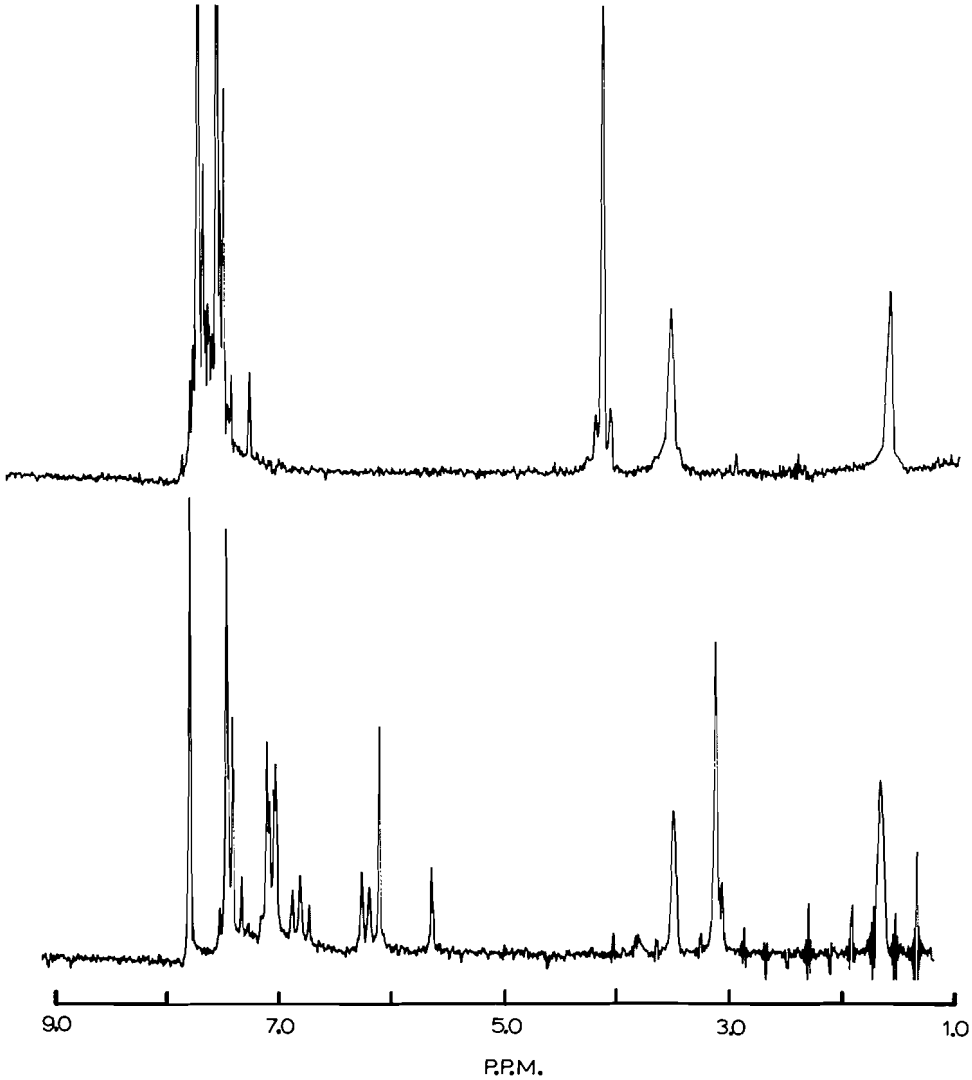

FIG. 2. Upper trace, the 100 MHz n.m.r. spectrum of carbazole in THF; lower trace, the 100 MHz n.m.r. spectrum of carbazole nitranion with sodium in THF. The sharp singlet at 7.24 p.p.m. is due to benzene impurity.

has one pair of electrons in a p orbital on nitrogen which are delocalized throughout the system and the second pair of electrons in an orbital (probably sp^2) orthogonal to the π-system. Using this model for the nitranion, one would expect the electrostatic interactions between carbazole nitranion and cation to be stronger than those between fluorenyl carbanion and cation. Furthermore, since the excess charge is located partially in a sigma orbital on nitrogen, the cation influences the chemical shifts of the six-membered ring protons largely through inductive effects which are thought to be attenuated rapidly and to be smaller than resonance or π-effects (16). The larger variation exhibited by H_1 with cation in the nitranion compared to the other protons is consistent with this model. The ^7Li chemical shift is also consistent with the above model. It was suggested with fluorenyl lithium that lithium was located in the π-cloud of the anion and hence, the upfield ^7Li shift was due to the shielding of the aromatic anion. The ^7Li shift observed for carbazole ni-

§Overlapping with solvent.

tranion suggests that lithium is strongly associated with nitrogen and is not located in the π-cloud of carbazole nitranion.

Even though the cation is associated with nitrogen, the degree of association is dependent upon both cation and solvent. In THF, the protons are shielded with cation in the order expected on the basis of polarizability of the cation (17). Since the chemical shifts of carbazole nitranion with potassium are identical in both THF and DME, the degree of association of potassium with nitrogen must be the same in both solvents (9). However, with sodium and lithium in DME, the protons of carbazole nitranion are more shielded, especially H_1, than with potassium indicating a difference in association of sodium and lithium with nitrogen than with potassium and nitrogen. On the basis of the shielding observed with cation and solvent (1, 9), it appears that contact ion pairs are formed in THF whereas with sodium and lithium in DME, an appreciable fraction of solvent-separated ion pairs are formed (18).

4,5-Methylenephenanthrene

The chemical shifts of both **2** and **3** are dependent upon the cation (Table 2) in a manner similar to that reported for fluorenyl carbanion (1). In THF, the protons of **2** and **3** are shielded in the order Li > Rb > K > Na. However, the effect of cation is smaller for **2** and **3** (~12 Hz) than for fluorenyl carbanion. From studies of the effect of temperature, cation, and solvent on the absorption spectrum of **2**, it was concluded that **2** forms both contact and solvent-separated ion pairs (19). The fraction of solvent-separated ion pairs in THF at 0° was reported to be: Li, 0.80; Na, 0.15; K, 0.0; and Cs, 0.0. Although the presence of **3** (10, 11) in solution was not considered by these investigators (18), their overall conclusions are probably correct.

The increased shielding observed for **2** and **3** with lithium, compared to the other cations, (Table 2) clearly indicates a larger separation between cation and anion (less distortion of charge in the anion) and is consistent with an appreciable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

amount of solvent-separated ion pairs present in solution. With sodium the n.m.r. data are not consistent with the absorption data (19). At least three factors could be responsible for this difference: (*a*) the two investigations were conducted at different concentrations, (*b*) the two investigations were conducted at different temperatures, and (*c*) the n.m.r. data are characteristic of the average population in solution. It has been shown from u.v. data that the fraction of solvent-separated ion pairs is not dependent upon the concentration (10^{-2} to 10^{-3} *M*) (20). Similar studies of the n.m.r. spectrum of sodium triphenylmethanide over the concentration range of 1.5–7.6 $\times$ 10^{-1} *M* also show that concentration does not affect the ratio of ion pairs formed (9). Lowering the temperature causes a shift in the equilibrium which favors the solvent-separated ion pair (7, 8, 19). Therefore, it is reasonable that less than 15% of solvent-separated ion pairs are present in the present investigation since it was conducted at a higher temperature. The time scale for the interconversion between solvent-separated and contact ion pairs has been shown by e.s.r. studies on related radical anions (21, 22) to be of the order of 10^{-8} s. Therefore, the n.m.r. data represent the population average and hence, are probably characteristic of the contact ion pair present in greater concentration.

The effect of solvent on the chemical shifts of **2** and **3** with potassium was investigated. In the less basic solvent (14) diethyl ether, the protons of **2** and **3** are less shielded than in THF. Similar shifts to lower field upon changing to a less basic solvent have been observed for fluorenyl lithium (15) and 1-phenylallyl sodium and potassium (6). Since both **2** and **3** with potassium exists as contact ion pairs (19), the downfield shift reflects a decrease in ionic character of the anion–cation interaction upon changing to a less basic solvent.

The ^{7}Li n.m.r. spectra of **2** and **3** are quite revealing concerning the location of lithium with respect to the anions. In THF, the ^{7}Li chemical shift is 2.20 p.p.m. upfield from external aqueous lithium chloride. Furthermore, only a single peak is observed indicating that either there is fast exchange of lithium between the two carbanions relative to the n.m.r. time scale or the ^{7}Li shift is accidentally the same for **2** and **3**. The upfield ^{7}Li shift indicates that lithium is located in the π-cloud of the carbanions similar to fluorenyl lithium (15). Although the ^{1}H chemical shifts of **2** and **3** indicate that there is a greater attraction between cation and anion with sodium, potassium, and rubidium than with lithium, the observation that all protons of **2** and **3** are affected to approximately the same extent by cation indicates that sodium, potassium, and rubidium are also located in the π-clouds of the carbanions.

Concluding Remarks

The major difference in the bonding of cation to carbazole nitranion, compared to fluorenyl carbanion is the association of cation with nitrogen in **1**, whereas with fluorenyl carbanion the cation appears to be associated with all carbons in the molecule. Even though the cation is associated with nitrogen in **1**, the degree of association is both cation and solvent dependent. In DME, the results suggest that with lithium and sodium, carbazole nitranions form an appreciable fraction of solvent-separated ion pairs.

The results for the carbanions of 4,5-methylenephenanthrene (**2** and **3**) clearly show that the number of π-electrons has no effect on the type of ion pairs formed since the effect of cation is identical for both **2** and **3**. Furthermore, the results with sodium suggest that the fraction of solvent-separated ion pairs must be greater than 0.15 before deviations to the order of shielding with cation (1) will be observed.

Finally, the use of ^{7}Li n.m.r. to determine the locations of the cation with respect to the anion complements the proton data and allows a more complete picture to be drawn concerning the bonding between cation and anion and hence, the effect of ion association on n.m.r. chemical shifts.

A historical and mechanistic review of the Wohl–Ziegler reaction (allylic bromination by *N*-bromoamides and imides) is presented as an introduction to the present work, a re-examination of the reaction of *N*-bromoacetamide (NBA) with some olefins. The reaction has been found to lead not to allylic bromination but, rather, to 2-bromo-*N*-bromoacetimidates, a new class of compounds. The stoichiometry of the reaction is: olefin + 2 NBA → adduct + acetamide. The process appears to occur in two stages, *viz.*, a free radical reaction of NBA with itself to form *N,N*-dibromoacetamide (NDBA), followed by ionic addition of NDBA to the double bond. Hofmann's synthesis of NDBA has been repeated; the compound reacts rapidly with cyclohexene to give the same adduct **10** as does NBA. A variety of stereochemical and selectivity data suggest that this is an ionic addition.

The chemical transformations of 2-bromo-*N*-bromoacetimidates under thermal, acidic, and basic conditions are discussed.

Comme introduction au présent travail qui est un réexamen de la réaction de la *N*-bromoacétamide avec quelques oléfines, nous présentons une revue historique et mécanistique de la réaction de Wohl–Ziegler (bromuration allylique par des *N*-bromoamides et imides). On a trouvé que la réaction ne conduit pas à la bromination allylique mais plutôt aux bromo-2 *N*-bromoacétimidates, une nouvelle classe de composés. La stoichiométrie de la réaction est: oléfine + 2 NBA → composé d'addition + acétamide. Le processus semble se produire en deux temps à savoir une réaction radicalique de la NBA sur elle-même pour conduire à la *N,N*-dibromoacétamide (NDBA) suivie d'une addition ionique de la NDBA à l'alcène. La synthèse de Hofmann de la NDBA a été repétée; ce composé réagit rapidement avec le cyclohéxène et conduit au produit **10** qui est aussi obtenu sous l'action de la NBA. La stéréochimie et la sélectivité de cette réaction suggèrent que l'addition est ionique.

On discute aussi des transformations chimiques que subissent les bromo-2 *N*-bromoacétamidates sous l'influence de la chaleur, des acides, et des bases.

Canadian Journal of Chemistry, 49, 1384 (1971)

Historical Introduction

In 1919, A. Wohl reported (1) that a mixture of 10 g of tetramethylethylene and 16 g of *N*-bromoacetamide (NBA), allowed to stand overnight in 36 ml of ether and then distilled, afforded in 16% yield a bromine-containing fraction, b.p. 60–90° at 15 mm. This liquid decolorized permanganate and contained 46.3% of bromine ($C_6H_{11}Br$ requires 49.0% bromine). A mixture of 50 g of trimethylethylene and 100 g of NBA, allowed to stand for one day and then vacuum distilled, afforded 10 g of an oil, b.p. 49–52.5° at 13.5 mm, which decolorized permanganate and contained 67.6% of bromine (C_5H_9Br requires 53.6%, and $C_5H_8Br_2$ requires 70.1% bromine). On the basis of these results, Wohl formulated the latter substance as an unsaturated dibromide, $C_5H_8Br_2$, and the product from tetramethylethylene as an unsaturated monobromide, $C_6H_{11}Br$, the reaction in this instance being described by eq. 1. A mechanism was proposed which involved exchange of bromine for an allylic hydrogen within a 1:1 olefin-NBA complex. The possibility that this complex

[1] $Me_2C{=}CMe_2 + CH_3CONHBr \rightarrow Me_2C{=}CMeCH_2Br + CH_3CONH_2$

might be an intermediate in an addition–elimination sequence was considered, and rejected on the grounds that HBr, rather than acetamide, ought to have been eliminated from such an adduct.

When equal amounts of NBA and trimethylethylene were mixed in ether at low temperature, the sparingly soluble NBA slowly dissolved and a viscous oil precipitated. The supernatant solution was then found to contain only traces of olefin and NBA. Wohl recognized that the viscous oil was an addition compound, but

[1]This work was presented, in part, at the 50th Canadian Chemical Conference, Toronto, Ontario, June 1967.

For personal use only.

apparently believed that its formation was not related to the reactions which produced the unsaturated dibromide.

In a second paper in 1921 (2), Wohl and Jaschinowski extended this work to the substrates crotonic acid, ethyl β-ethoxycrotonate, ethyl β-ethoxycinnamate, propylene, allyl alcohol, allyl bromide, and methyl phenylacetylene. In each case the reactants were stirred in ether or acetone at room temperature or below until a negative starch–iodide test was obtained; products were then isolated by vacuum distillation and characterized by bromine analysis. Carbon and hydrogen analyses were recorded for the products from the enol ethers and from allyl alcohol. In all cases, the distilled sample subjected to analysis represented only a small fraction of an obviously complex mixture; in several cases the analytical data were not compatible with a simple molecular formula.

Wohl and Jaschinowski observed that 2 mol equiv of NBA reacted with 1 mol equiv of crotonic acid to produce a *mono*bromocrotonic acid. They also observed some yellow crystals in the reaction with propylene. Neither of these observations was followed up. Ethylene, acetylene, ethyl cinnamate, cinnamic acid, cinnamaldehyde, maleic acid, and fumaric acid did not react with NBA. Styrene gave styrene dibromide.

It is evident from this summary of Wohl's experimental work that, although some reaction does take place between certain olefins and NBA, unequivocal evidence for allylic bromination was not obtained. It is not surprising, therefore, that the next reference to this work appeared only in 1941 (3). An attempt to convert β-cyclogeranic acid to 3-bromo-β-cyclogeranic acid was not successful.

In 1942 (4), Ziegler and his co-workers presented the results of a systematic study, prompted by Wohl's work, of the reactions of alkenes with *N*-halo compounds. *N*-Bromoacetamide was not included in the study because "*die von Wohl mitgeteilten Ergebnisse auf einem nicht eben glatten Reaktionsverlauf schliessen lassen*". In Ziegler's work the unique ability of *N*-bromosuccinimide (NBS), in refluxing carbon tetrachloride, to effect allylic bromination was discovered and exploited. The synthetic implications of this discovery were very clear and, by 1948 (5), at least 100 examples had been reported. Djerassi's review, subtitled "The Wohl–Ziegler Reaction", left the impression that Wohl's work had been overlooked because of a failure to emphasize its practical implications, and the description "Wohl–Ziegler reaction" is taken to mean allylic bromination by *N*-bromoamides and imides, including NBA and NBS. Although allylic bromination by NBA has often been assumed since the appearance of the first review, in no case do the experimental descriptions indicate that an allylic bromide was ever isolated and characterized. Indeed, the work reported here was also founded on the assumption that allylic bromination by NBA does exist; and a close examination of Wohl's papers was not made until it had become clear (6) that this assumption is incorrect.

Introduction to the Present Work

That allylic bromination by NBS is a radical chain reaction is evident from the catalytic effect of peroxides, other radical sources, and u.v. light, the retarding properties of oxygen and other typical radical inhibitors (7), and kinetic studies (8). In allylic bromination of cyclohexene, initiated by decomposition of azobisisobutyronitrile (AIBN), the rate of disappearance of NBS is zero order in NBS, half order in AIBN and first order in olefin. This result is consistent with a succinimidyl radical chain and termination via two succinimidyl radicals. It is also consistent with a bromine atom chain and termination via two bromine atoms. The former pathway, proposed by Bloomfield in 1944 (9), was widely accepted for some time (7), but more recent work (10–13) has proved the latter process, first suggested by Goldfinger and his co-workers (14), to be the operative one.

The Goldfinger mechanism considers the elementary steps 2–5, where RH is an alkene. For low concentrations of X_2, the ratio of addi-

tion (a) to substitution (s) is given by eq. 6 so

[6] $$r_{a/s} = k_{3a} \cdot k_{4a}[Br_2] / k_{3s} \cdot k_{5a}$$

that addition would be favored by higher, and substitution by lower concentrations of Br_2. The function of NBS is two-fold: to maintain the required low concentration of Br_2 by reaction 7 (10); and, by serving as a scavenger for HBr, to maintain a non-polar medium.

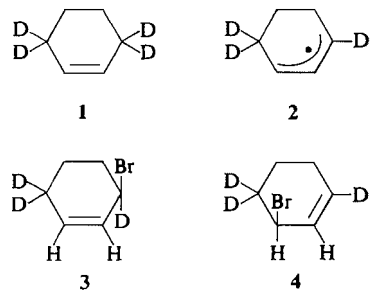
[7] $$HBr + NBS \rightarrow Succinimide + Br_2$$

Two significant features of allylic bromination by NBS are that both NBS (15) and succinimide are virtually insoluble in CCl_4, the solvent of choice for the reaction, and that the rate of the reaction depends greatly upon the purity of the reagent and its surface area. High purity and/or the employment of large crystals lead to a reduction in the rate (8, 16). These facts have led Horner and Winkelmann to suggest (16) that the reaction takes place at the surface of the NBS, but an alternate explanation (8*a*) for the rate-diminishing effect of purification of the reagent is that this removes trace impurities which catalyze the adventitious formation of molecular bromine, and the surface mechanism is usually discounted (see *e.g.*, ref. 12*a*, footnote 28).

If the surface mechanism were unimportant, it could be expected that slow addition of a *solution* of NBS to an alkene might be equivalent to the usual heterogeneous reaction conditions. However, although addition to the double bond of cyclohexene is not detected under the heterogeneous conditions, when the reaction is performed in refluxing CH_2Cl_2 with slow addition of the NBS and catalysis by light and peroxides the conversion to dibromocyclohexane cannot be reduced to less than 25% (17).

Further, if there were no constraint upon the intermediates in the reaction, the mesomeric structure of an allyl radical should cause the product of kinetic control to be a mixture of two allyl bromides. In the case of a symmetrical substrate like cyclohexene-3,3,6,6-d_4 (**1**), the allyl radical will have structure **2**, and the products of kinetic control would be **3** and **4**, formed in equal amounts. It has been suggested, however, that an equimolar mixture of **3** and **4** is seen in the product of *thermodynamic* control, the product of kinetic control being mainly **3** (18). This result is not compatible with a "free" radical mechanism but might be compatible with a "trapped" radical if the surface mechanism were operative.

On the basis of the above results and considerations it appeared that Horner and Winkelmann's surface mechanism needed further examination. The approach selected involved repetition of the cyclohexene-3,3,6,6-d_4 experiment with NBA. It was assumed that NBA does effect allylic bromination and that the ratio of **3** to **4** in the product of kinetic control would differ from that given by NBS, either because NBA bromination affords a free radical, or because the surfaces of NBA and NBS are not the same. The choice of NBA for this study was also dictated by the fact that it, like NBS, is only slightly soluble in refluxing CCl_4 and was reported to effect allylic bromination in this medium (19–21).



Results and Discussion

Reaction of NBA with Cyclohexene

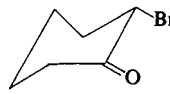
In refluxing carbon tetrachloride, NBA is a solid and is only slightly soluble. Acetamide, the expected product of allylic bromination, is soluble in refluxing CCl_4; therefore, dissolution of the insoluble solid provides a convenient visual assay of the progress of an NBA reaction under these conditions. When cyclohexene was allowed to react with NBA in refluxing CCl_4, with catalysis by light and peroxide, the NBA disappeared within 5 min. The g.l.c. analysis of the reaction mixture at this point revealed only *trans*-1,2-dibromocyclohexane (**5**) and, surprisingly, no 3-bromocyclohexene. Continued refluxing caused darkening of the solution, and in the g.l.c. two new peaks appeared. The relative amounts of the new compounds gradually increased and, after 1 h, on the basis of the areas under the three peaks, one of the new compounds represented about 55% of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mixture and the other about 5%. The new compounds were isolated by preparative g.l.c. and identified as *trans*-cyclohexene bromohydrin (**6**; major product) and 2-bromocyclohexanone (**7**; minor product). Repetition of the experiment, with addition of benzonitrile as an internal standard for the g.l.c. analyses, revealed that **6** and 7 were not formed at the expense of **5** and confirmed that 3-bromocyclohexene was not present at any time. (It was established that 3-bromocyclohexene is stable to the reaction conditions and to the g.l.c. procedure employed.)

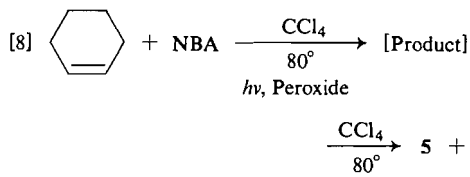
5

6

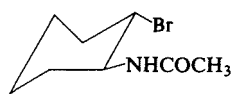


7

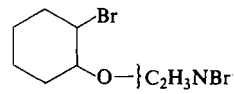
It seemed likely that **6**, especially, had been formed by thermal decomposition of a primary product of higher molecular weight or polarity whose retention time was too great to permit its detection under the g.l.c. conditions utilized. If **5** and **7** also were formed from this primary product, the course of the reaction could then be described tentatively as shown in eq. 8. For



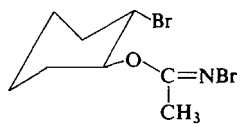
the isolation of this primary product, the reaction of cyclohexene with one molar equivalent of NBA was terminated by rapid cooling as soon as the NBA had disappeared. Acetamide precipitated and was removed by filtration; evaporation of the filtrate under reduced pressure at 30° yielded a colorless oil. Treatment of this oil afforded, besides a small amount (*ca.* 1%) of *trans*-2-acetamidocyclohexyl bromide (**8**), massive crystals melting at 28.0–28.5°. Microanalysis indicated a formula $C_8H_{13}Br_2NO$, *i.e.*, an *adduct* of cyclohexene plus NBA plus Br minus H. In view of the nature of the products **5**–**7** a part structure **9** could be assigned, and the gross structure **10**, 2-bromocyclohexyl-*N*-bromoacetimidate, became clear upon examination of the i.r. and n.m.r. spectra (6). The i.r. spectrum showed strong absorption at 6.2 and 7.85 μ assigned, respectively, to the C=N and C—O—C groupings (22); the n.m.r. spectrum showed 1-proton multiplets at τ 4.96 and 5.87, a methyl peak at 7.62, and a cyclohexane envelope (8 protons) centered at 8.34. The stereochemistry of the addition to the double bond was determined to be *trans* by preparation and n.m.r. analysis of the adduct **11** of cyclohexene-3,3,6,6-d_4. This adduct showed an AB quartet (τ_A 4.96; τ_B 5.87) for the tertiary protons with a coupling constant of 9 Hz; the chemical shift assignments shown in **11** are based on comparison with those of cyclohexene-3,3,6,6-d_4 bromohydrin (18) (τ_{CHBr} 6.13; τ_{CHOH} 6.4) and its derived acetate (τ_{CHBr} 5.95; τ_{CHOAc} 5.2). The geometry of the C=NBr grouping of **10** was not investigated.



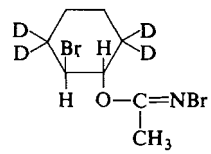
8



9



10



11

Because of its low m.p. no attempt was made to optimize the recovery of crystalline **10**. However, since the i.r. spectrum of the mother liquor obtained following removal of the first crop of **10** was superimposable upon that of **10**, it was concluded that **10** represented at least 90% of the non-volatile product of the primary reaction of equimolar amounts of cyclohexene and NBA. Since **10** contains two bromine atoms it seemed that at least 2 mol equiv of NBA per mol of alkene were necessary for the reaction. To check the stoichiometry, 0.5:1, 1:1, 2:1, 3:1, and 4:1 molar ratios of cyclohexene to NBA were allowed to react in refluxing CCl_4 with catalysis by light and peroxide. Each reaction mixture was rapidly cooled when the initial reaction was complete and the precipitated acetamide was collected and weighed; in each case this amounted to 90–95% of the theoretical based on eq. 9. Each filtrate was concentrated under reduced pressure and the distillate titrated with a standardized solution of Br_2 in CCl_4; except for the product from a

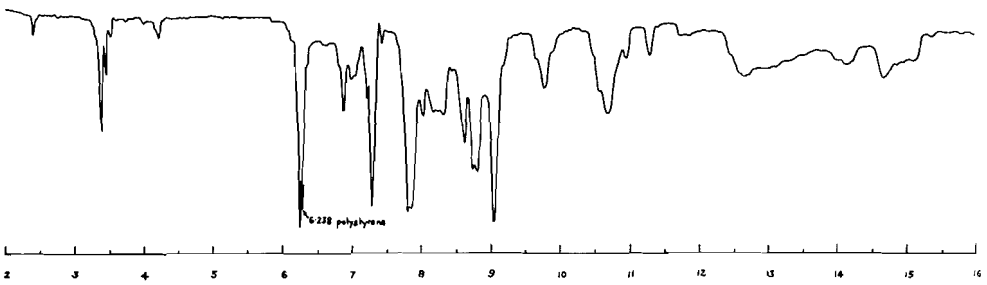


FIG. 1. The i.r. spectrum (KBr) of **12**.

0.5:1 molar ratio of reactants, which contained no cyclohexene, all distillates contained cyclohexene in amounts corresponding to 80–100% of that expected on the basis of eq. 9. The nonvolatile residue was then weighed and its i.r. spectrum recorded; in each case these i.r. spectra were virtually identical with the spectrum of pure **10**. It can be concluded that the reaction of cyclohexene with NBA is not an allylic bromination but an addition, closely obedient to the stoichiometry shown in eq. 9, in which **10**, a new class of compound, is produced.

[9] Cyclohexene + 2 NBA → **10** + Acetamide

Reaction of NBA with Tetramethylethylene

Since Wohl's initial experiment was performed with tetramethylethylene it was of interest to examine the reaction of this substrate with NBS employing the conditions and stoichiometry established for cyclohexene. A crystalline compound, m.p. 40–41°, was obtained. This compound analyzed as $C_8H_{15}Br_2NO$; its n.m.r. spectrum showed three methyl singlets, at τ 7.72, 7.99, and 8.17, in the ratio 1:2:2 and its i.r. spectrum, reproduced in Fig. 1, showed prominent peaks at 6.2 and 7.85 μ. All of these data are compatible with structure **12**, the 2-bromo-*N*-bromoacetimidate adduct of tetramethylethylene.

It was conceivable that the experimental conditions employed here, *viz.*, refluxing in CCl_4 in the presence of light and peroxide, had led to a reaction different from that envisaged by Wohl (1). To check this point, NBA was allowed to react with tetramethylethylene *in ether*. There was no reaction at 0° in the dark but, in 4.5 h at room temperature and in the diffuse light of the laboratory, a 75% conversion to **12** was achieved (*cf.* paragraph 2 of the Historical Introduction).

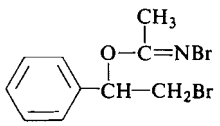
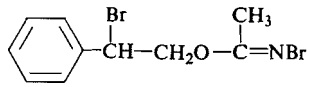
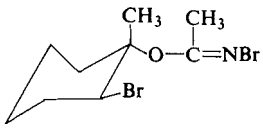
the sequence of these two additions it was necessary to determine the regioselectivity (23) of addition to unsymmetrical olefins. The styrene adduct is assigned structure **13** rather than **14** on the basis of the chemical shifts of its tertiary (triplet) and secondary (doublet) protons, comparison of these chemical shifts with those of the authentic styrene derivatives shown in Table 1, and the assumption that *N*-bromoacetimidate resembles acetate in its effect upon the chemical shift of a geminal proton. The 1-methylcyclohexene adduct was assigned structure **15** rather than **16** on the basis of the chemical shift data shown in Table 2. This structure and the formulation of the adduct as a product of *trans*-addition are supported by the chemical properties of the compound, described below.



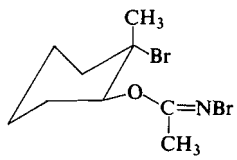
13



14



15



16

Mechanism of Formation of the Adducts

Adducts **13** and **15** contain bromine on the less-substituted carbon atom. Whether the addition of the two fragments is ionic (electrophilic) or radical, it follows that the C—Br bond is formed first. An ionic process for the addition seems more reasonable for the following reasons:

(*1*) Only the *trans*-adduct is obtained with cyclohexene. A radical addition reaction would have proceeded in a non-stereospecific manner. Thus, ionic chlorination of cyclohexene affords 1,2-dichlorocyclohexane which is at least 99% *trans* (24, 25) but, under radical conditions (25), the *cis* adduct is also observed, together with the products of vinylic, allylic, and homoallylic substitution. Similarly, ionic addition of bromine azide to cyclohexene and to 2-cholestene leads to the *trans*-adducts only; under radical conditions, the product from 2-cholestene is a 58:42 mixture of *trans* and *cis* adducts (26).

TABLE 2. Proton chemical shifts of some 1-methylcyclohexene derivatives

N,N-Dichlorourethane (DCU) adds to olefins by a free radical chain mechanism (27–29) to give 1:1 adducts **17**. With cyclohexene (27, 29) and cyclopentene (29) both *cis*- and *trans*-adducts are obtained together with the products of vinylic, allylic and homoallylic chlorination. Acyclic olefins react to give erythro–threo mixtures (27).

(*2*) Under ionic conditions, addition of IN_3 (26), ClN_3, and BrN_3 (30) to unsymmetrical olefins proceeds with attachment of halogen to the less substituted carbon atom, as in the present reaction. Under radical conditions the opposite regioselectivity is observed, *i.e.*, the *azido* group is attached to the less-substituted carbon atom. Similarly, in the radical addition of DCU, it is the nitrogen atom which becomes attached to the less-substituted carbon atom; *e.g.*, the styrene product is **18** (27).

(*3*) In the radical addition of DCU, as indi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

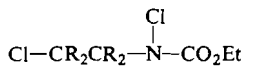
cated in **17** and **18**, a *nitrogen*–carbon bond is formed; in contrast, the addition reaction of NBA proceeds with formation of an *oxygen*–carbon bond.

(*4*) In a competition experiment involving reaction of NBA with a mixture of styrene and cyclohexene, only the cyclohexene adduct was formed. There is a variety of competition data which indicate that these two substrates display opposite selectivities in ionic and radical addition reactions (31). In a radical addition, styrene is several hundred times more reactive; and in an ionic addition, cyclohexene is five to ten times more reactive.

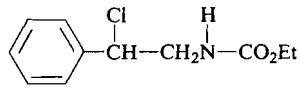
Although the final, adduct-forming stage of the NBA reaction with olefins thus appears to be ionic, the initial stage of the reaction is probably a free-radical chain process involving only the NBA. The over-all reaction is catalyzed by light and by peroxide. It is known (32) that u.v. irradiation of a refluxing solution of NBA in chloroform leads to rapid formation of a low equilibrium concentration of bromine. In the present work slow distillation of a refluxing suspension of NBA in carbon tetrachloride, illuminated by a 200 W bulb, led to the formation of bromine and acetamide in amounts compatible with the stoichiometry shown in eq. 10. Methyl isocyanate is indicated as a possible product of the decomposition, but attempts to detect this compound were not successful.

[10] $2NBA \rightarrow CH_3CONH_2 + Br_2 + [CH_3NCO]$

The elementary steps shown in eqs. 11–16 can be considered for the homolytic decomposition of NBA. The initiation step, eq. 11, must be followed by a rapid exchange, eq. 12 or eq. 13, which generates the *N*-bromoacetamidyl radical **19**. In each of these reactions there is a hydrogen abstraction *from NBA*; we believe that the availability of this hydrogen in NBA, and the absence of a reactive hydrogen in NBS,



17



18

is a major source of the difference in behavior of the two brominating agents. Reaction **13** would be followed rapidly by 14 (10) and then 15, the latter being necessary to account for the failure to observe allylic bromide or dibromoolefin as primary products. The sequences 13–15 and 11, 12, 16 each lead to a compound $C_2H_3NOBr_2$ (**20**). Consideration of bond strengths (33) indicates that 16 would be strongly endothermic and 13–15 would be slightly exothermic.

It will be noted that addition of **20** to an olefin would afford a compound having the molecular formula of a 2-bromo-*N*-bromoacetimidate. Two structures can be considered for **20**, *viz.*, *N*,*N*-dibromoacetamide (**21**) and *N*,*O*-dibromoacetimide (**22**). A compound, assigned structure **21**, was prepared by Hofmann in 1882 (34) but no other reference to this substance could be found in the literature. Repetition of Hofmann's synthesis gave a yellow crystalline compound having the reported m.p. (100°) which analyzed correctly for $C_2H_3NOBr_2$. This compound is stable at room temperature in the solid state and as a solution in CH_2Cl_2 or $CHCl_3$. The n.m.r. spectrum in the latter solvent shows *one* singlet, at τ 7.50; in the same solvent the methyl protons of NBA appear as two singlets of unequal intensity at τ 7.8 and 8.0 (because of hindered rotation about the amide bond (35)). Acetamide shows a methyl singlet at τ 8.0. Thus the dibromo compound appears to exist in solution as a single species. Its constitution is clearly seen to be **21** (NDBA) rather than **22**

[11] $CH_3CONHBr \rightarrow CH_3CONH\cdot + Br\cdot$

21 22 23

when the solution i.r. spectrum is compared to those of NBA and acetamide. Carbonyl stretching bands are observed for acetamide, NBA and NDBA at 5.95, 5.94, and 5.92 μ, respectively; and NDBA shows a strong band at 8.2 μ (N—Br?) approximately twice the intensity of a band at the same position in NBA.

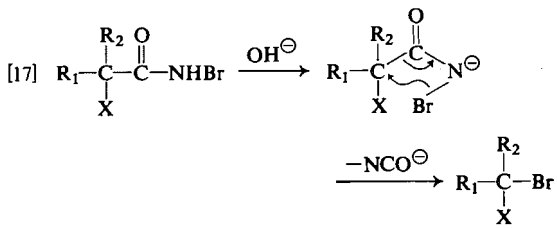
In methylene chloride or carbon tetrachloride solutions, at 0 or 25°, **21** reacted rapidly with cyclohexene to give a greater than 9/1 mixture of **10** and the isomeric compound **23**, the latter being isolated as the hydrolysis product **8**. The addition proceeded smoothly, and the ratio of the two adducts was not significantly different, both in the dark and in the light of the laboratory. It is evident, therefore, that the reaction of this olefin with NBA can be discussed in terms of a radical reaction of NBA with itself to produce NDBA, followed by an ionic addition of the latter to the double bond. An as yet unexplained feature of the addition reaction is the formation of a C—O bond (to form **10**) in preference to a C—N bond (to form **23**). This point is under investigation and will be reported later along with the detailed discussion of the spectral and chemical properties of NDBA (36).

Reactions of 2-Bromo-*N*-bromoacetimidates

Rearrangement to Dibromides

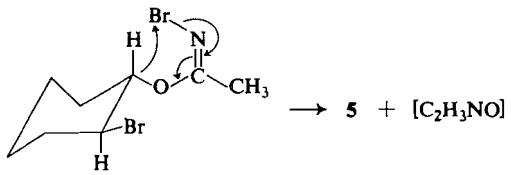
One of the differences that had been noted previously in the reactions of NBA and NBS with olefins (2, 17*b*, 20, 37, 38) was the much greater tendency of NBA to give dibromo addition compounds. The observations recorded in eq. 8 indicate that these may form during the thermal decomposition of 2-bromo-*N*-bromoacetimidates. Thus, when heated at 100° in the absence of a solvent, **10** underwent violent decomposition to give *trans*-dibromocyclohexane (30%) and other (tarry) products. Following injection of a solution of pure **10** into a gas chromatograph at 130°, only *trans*-dibromocyclohexane was detected. Refluxing of a 10% solution of **10** in carbon tetrachloride caused complete decomposition in 1 h. Even at room temperature, in the absence of a solvent, crystalline **10** decomposed completely in 18 h; g.l.c. analysis of the product of this decomposition revealed the ratio of cyclohexene bromohydrin to cyclohexene dibromide to be 3:1. If the crude product of the NBA–cyclohexene reaction was similarly left to decompose at room temperature an identical ratio of **6** to **5** was observed. These observations demonstrate that the dibromide is indeed a product of the decomposition of **10**; and the latter result indicates further that *all* of the dibromide is produced during this decomposition.

In dimethylformamide, at 100°, **10** decomposed to give (by g.l.c.) a 35:25:40 mixture of **5**:**6**:**7**. The proportions of these three compounds were unchanged, and no bromochlorocyclohexane was formed, when this experiment was repeated in the presence of a molar equivalent of lithium chloride. This result is consistent with the description of the conversion of **10** to **5** as an intramolecular rearrangement. The presence of **5** and the absence of *dibromocyclopentane* in the products of decomposition of **10** in refluxing cyclopentene (b.p. 44°) support the conclusion that **5** is the result of an intramolecular rearrangement. There appears to be a formal analogy between the nature of this rearrangement and base-catalyzed rearrangements of *N*-bromoamides, in which retention of configuration is also observed (39–43), see eq. 17. Following this



[17]

analogy, the conversion of **10** to **5** may be postulated to proceed by eq. 18. Methyl isocyanate



[18]

was considered to be a possibility for the species C_2H_3NO, by rearrangement of an acyl nitrene, but all attempts to isolate or trap the isocyanate were unsuccessful. It is relevant to note that recent investigations of the Curtius and Lossen rearrangements (44, 45) demonstrate that an isocyanate is formed from an acyl *azide*

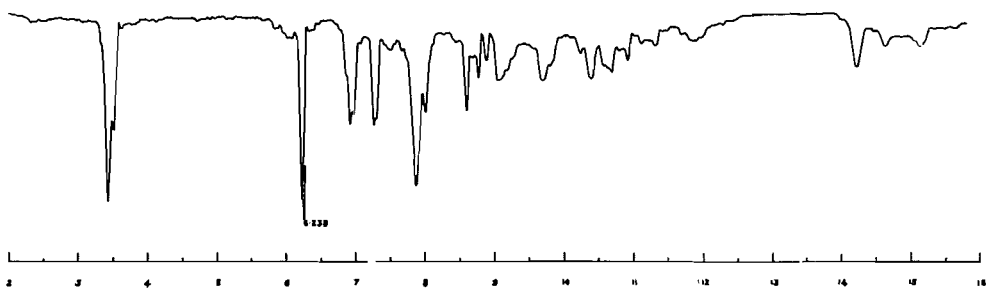

FIG. 2. The i.r. spectrum (KBr) of **15**.

in a concerted manner, intramolecular rearrangement of an acyl nitrene being much slower than intermolecular insertion, addition and abstraction reactions.

The rearrangement of a 2-bromo-*N*-bromoacetimidate to a dibromide just described is a general reaction of the adducts. After 60 h in ether at −20°, the styrene adduct had undergone 34% conversion to styrene dibromide. In chloroform at 30° this adduct decomposed completely within 1 h to give a mixture containing 30–40% of styrene dibromide. The 1-methylcyclohexene adduct was even less stable. The i.r. spectrum of **15** immediately after isolation is shown in Fig. 2; after 15 min in CCl_4 the peaks at 6.2 and 7.85 μ had disappeared completely. When this decomposition was followed by n.m.r., the disappearance of the tertiary proton absorption of **15** (τ 5.1) coincided with the appearance of peaks of equal intensity at τ 5.4 and 5.9, corresponding to 1-methylcyclohexene dibromide and 1-methylcyclohexene bromohydrin, respectively. In the reaction of NBA with stilbene, the adduct could not be detected; only stilbene dibromide (38%) was identified among the products of this reaction.

Reaction with HCl

In the investigations of Buckles *et al.* of the reaction of olefins with NBA (20, 37, 38), it was assumed that dibromides were primary products. This assumption caused some difficulty in the establishment of a stoichiometry. The reaction was clearly seen to be radical in nature, and acetamide was a product, but there was no obvious source of hydrogen to account for the formation of this compound or for the fate of the acetamidyl radical. In an attempt to optimize the recovery of the acetamidyl fragment, the product of the styrene reaction (0.1 mol of NBA to 0.05 mol of styrene) was treated with anhydrous hydrogen chloride (20); a precipitate was obtained and identified as bisacetamide hydrochloride on the basis of a "m.p. around 131°" (pure acetamide hydrochloride was also found to have "m.p. around 131°"). On the assumption that the precipitate had this structure, a 95–97% recovery of acetamide was claimed.

If this observation were correct, it would follow from the stoichiometry of the initial reaction (eq. 9) that half of the bisacetamide hydrochloride was derived from the adduct **13**. It is not immediately obvious how hydrogen chloride could react with **13** to give acetamide or bisacetamide hydrochloride, and it seemed desirable to examine the reaction of hydrogen chloride with a pure 2-bromo-*N*-bromoacetimidate. Because of its relative stability, the cyclohexene adduct was selected for this work. Titration of an ether solution of **10** at 0° with ethereal hydrogen chloride afforded in 91% yield a crystalline compound, m.p. 157.5–158.5°. This compound has the molecular formula $C_8H_{15}NOBrCl$. Its i.r. spectrum shows strong absorption at 6.0 μ (C=N), a broad peak at 3.5 μ (CH, NH_2^+), and no peak at 3.0 μ (NH). Structure **24** is assigned to this compound. The observation of an orange color during the reaction of **10** with hydrogen chloride is attributed to the formation of BrCl according to eq. 19.

Reaction with Triethylamine

It is known that *N*-bromo compounds react with triethylamine as shown in eq. 20 (8*a*, 16, 17*b*, 46). In agreement with eq. 20, the cyclohexene adduct **10** reacts with triethylamine to give triethylamine hydrobromide, 2-bromocyclohexanone (20%), and, in 75–80% yield, a compound assigned structure **25** on the basis of its i.r. spectrum which was identical with that of the acetimidic acid obtained upon neutralization

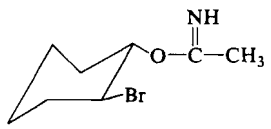
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[19] 
24

[20]

of **24** ($\lambda_{max}(CHCl_3)$ 3.0, 6.04 μ):

Further evidence that the reaction of the cyclohexene adduct with triethylamine occurs mainly at the nitrogen atom is found in the n.m.r. spectrum of the 3,3,6,6-tetradeuterio analog of **25**. Although the methyl peak of this compound shifts from τ 7.62 in the adduct **11** to τ 7.97, the position of the AB quartet for the *trans* tertiary protons is unchanged.



25

Formation of 2-bromocyclohexanone in this reaction is considered to be the result of the elimination shown in eq. 21.

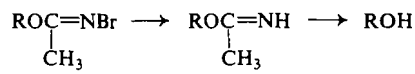
[21] 
+ CH_3CN + $Et_3N{\cdot}HBr$

Formation from 10 of Cyclohexene Bromohydrin and 2-Bromocyclohexanone

If the acetimidic acid **25** is allowed to stand at room temperature, a slow conversion to cyclohexene bromohydrin is observed (*cf.* ref. 47). This observation provides an important clue to the mode of formation of the bromohydrin from the 2-bromo-*N*-bromoacetimidate. It was already noted in the initial experiments that continued refluxing of the mixture obtained from the reaction of cyclohexene with NBA leads to a steady increase in the ratio of cyclohexene bromohydrin to cyclohexene dibromide and that the bromohydrin is not formed at the expense of the dibromide. It has also been noted that refluxing of a 10% solution of pure **10** in carbon tetrachloride causes complete decomposition in one hour. The g.l.c. analysis of the latter mixture revealed a 44:36:20 mixture of **5**, **6**, and **7**. When the solvent was removed and the residue allowed to stand overnight at room temperature, this ratio changed to 22:65:13. Since **25** was not detected by the g.l.c. procedure employed to determine the proportions of the volatile products **5**, **6**, and **7** these results can be interpreted in terms of the sequence shown in eq. 22. The i.r. spectra shown in Fig. 3

[22] 
support this interpretation. The initial product of decomposition of **10** (lower spectrum) shows a strong absorption at 6.0 μ, assigned to the C=N group of **25**, and a weaker absorption at 5.8 μ, assigned to the carbonyl group of **7**. The upper spectrum is that of the product obtained after the solvent was removed and the residue allowed to stand at room temperature overnight.

If the formation of the bromohydrin from the 2-bromo *N*-bromoacetimidate is to be explained in terms of the sequence,



it is necessary to provide a hydrogen source for the reaction **10** → **25**. Two possible hydrogen sources can be suggested. The first is HBr (*cf.* eq. 19[2]) formed, together with 2-bromocyclohexanone, by the route suggested below.

[2]During the decomposition of **10** in dimethylformamide, already described, a bromine color developed and then faded, possibly because of reaction or distillation from the medium, or both.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

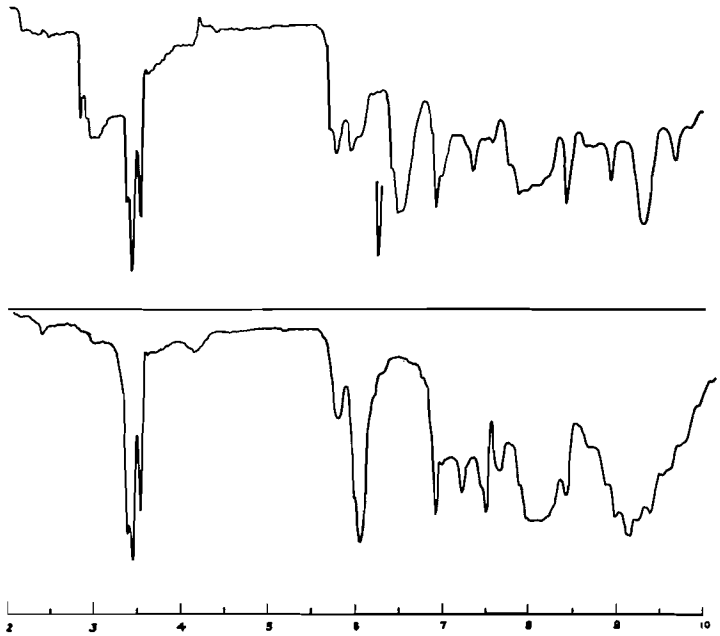


FIG. 3. The i.r. spectrum of the product resulting from thermal decomposition of **10**. The lower spectrum is that obtained when **10** was refluxed in CCl_4 for 1 h. The upper spectrum is that of the product obtained after the solvent was removed and the residue allowed to stand overnight at room temperature.

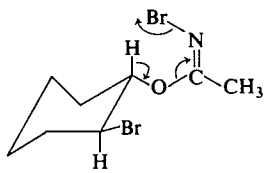

$\longrightarrow$ 7 + HBr + CH_3CN

This cannot be the sole hydrogen source for this transformation because, in the materials balance, equal amounts of bromohydrin and 2-bromocyclohexanone or derived products would be expected. In fact, the amount of bromohydrin always exceeds that of bromoketone. A second hydrogen source for the reaction **10** $\rightarrow$ **25** is the adduct **10** itself. It has been demonstrated recently (48) that heating of a solution of benzophenone *N*-bromoimine in cyclohexane affords cyclohexyl bromide. Although the mechanism of this bromination was not studied, the reaction does not provide precedent for a process, eq. 23. In the present case,

[23] $R_2C{=}NBr + R'H \rightarrow R_2C{=}NH + R'Br$

reaction of **10** with itself according to eq. 23 would be expected to afford, in addition to **25**, polybrominated adducts and/or the high boiling residues encountered in the decomposition of **10**.

Rearrangement to Aminoacetates

The i.r. spectrum displayed in the upper curve of Fig. 3 shows carbonyl absorption at 5.7 *and* at 5.8 μ. The 5.8 μ peak is attributed to 2-bromocyclohexanone; the 5.7 μ peak is consistent with an ester carbonyl absorption. Since the precursor of this material, with the spectrum shown in the lower curve of Fig. 3, appears to have no peak at 5.7 μ, it can be speculated that the decomposition of **25** leads not only to the bromohydrin but also to acetate-containing material. Attempts to obtain this compound in pure form were not successful, but the apparently analogous product of decomposition of the 1-methylcyclohexene adduct could be isolated in crystalline form, m.p. 208–210°. This compound has the formula $C_9H_8BrN_2O$; its n.m.r. and i.r. spectra, reproduced in Fig. 4, are compatible with structure **26**, 2-acetoxy-2-methylcyclohexylammonium bromide. Cyclization of the imidic acid **27** would afford the oxazoline hydrobromide **28**; hydrolysis of **28** could proceed to give the salt **26** or the acetamido alcohol **29**. A search for **29** was not made.

The scheme shown in eq. 24, if correct, provides chemical support for the structure and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

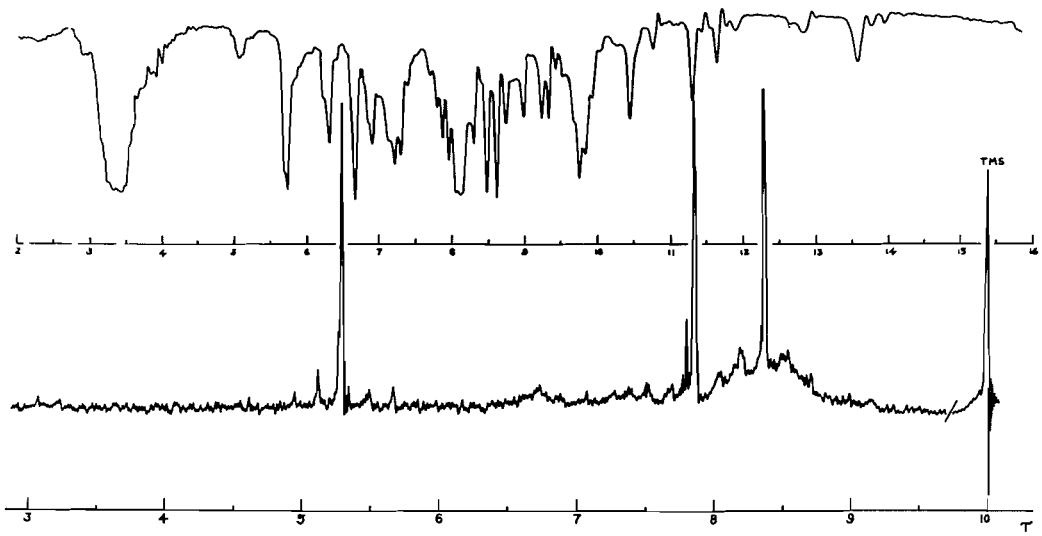

FIG. 4. The i.r. (KBr) and n.m.r. (D_2O) spectra of **26**.

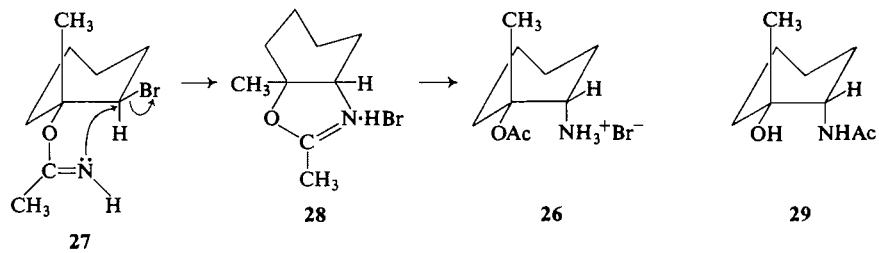
[24]



stereochemistry of the 1-methylcyclohexene adduct **15**. Formation of the oxazoline would require a *trans* relationship of the electronegative substituents; and attack on the C—Br bond with inversion of configuration would not be expected in the case of the tertiary bromide **16**.

Experimental

Melting points were determined on a Fisher–Johns m.p. apparatus, and are uncorrected. Boiling points are also uncorrected. The i.r. spectra were recorded on a Beckman IR 5A instrument unless otherwise indicated. The n.m.r. spectra were obtained on a Varian A60 spectrometer, tetramethylsilane (TMS) being employed as the internal standard, unless otherwise specified. The g.l.c. determinations were performed on a Beckman GC-2 chromatograph; a Fisher Prep. Partitioner was employed for preparative work. The column packing was 15% butanediol succinate on Embacel and separations were conducted at 130°. Microanalyses are by Dr. C. Daesslé, Montreal, Spang Microanalytical Laboratory, Ann Arbor, and J. Booker, Queen's University.

All solvents were Fisher Certified Reagent Grade and were used without further purification except for drying, where indicated, by conventional means.

N-Bromosuccinimide

BDH Reagent Grade material was employed.

N-Bromoacetamide

Commercial NBA was dissolved in boiling benzene, no attempt being made to remove the color of bromine in the solution. Perfectly formed colorless needles, m.p. 108°, were obtained when the solution was allowed to cool undisturbed at room temperature. The precipitated solid was collected, washed to whiteness with 30–60° petroleum ether and allowed to dry in the air. This material could be stored for long periods in the cold without apparent deterioration.

Olefins and Ketones

All substrate olefins and ketones except tetramethylethylene and 1-methylcyclohexene, were commercial products of "Reagent" or equivalent grade and were used unpurified if g.l.c. analysis indicated no significant (<1%) contamination. If color could be detected or g.l.c. analysis indicated significant impurity the material was distilled before use.

Tetramethylethylene

This material, b.p. 70–71° was synthesized by reduction of pinacolone, followed by acid-catalyzed dehydration of the resultant alcohol (49). Integration of the methyl peak at τ 8.36 against all extraneous peaks indicated greater than 90% purity.

1-Methylcyclohexene

This olefin, b.p. 108–110°, n_D^{25}, 1.4475, lit. (50) n_D^{25}, 1.4478, was prepared by acid-catalyzed dehydration of 1-methylcyclohexanol. Integration of the n.m.r. spectrum showed that the downfield multiplet centered at τ 4.66 was in the ratio 1:11 with the remaining upfield signals.

2-Bromocyclohexanone

Cyclohexanone was brominated with NBS (51) to yield 2-bromocyclohexanone, b.p. 82–84°/6 mm, lit. (52) 74°/3 mm.

3-Bromocyclohexene

This compound was prepared by treatment of cyclohexene with NBS (16) and had b.p. 60–62°/14 mm, lit. (8*a*) 55–57°/11 mm.

1,2-Dibromocyclohexane

A solution of molecular bromine in chloroform was added dropwise to a magnetically stirred solution of an equimolar amount of cyclohexene in chloroform maintained at 0–5°. Evaporation of the solvent and distillation gave a product b.p. 92–94°/10 mm, lit. (20) 93–96°/10 mm.

1,2-Dibromocyclopentane

The compound had b.p. 67–68°/11 mm, lit. (53) 75°/17 mm.

α,β-Dibromostyrene

This compound, m.p. 72–73°, lit. (38) 73–74°, and *trans-α,α′-dibromostilbene*, m.p. 225–228°, lit. (38) 235–237° were synthesized in the same manner as was 1,2-dibromocyclohexane.

Cyclohexene Bromohydrin

This compound, b.p. 85–87°/10 mm, lit. (54) 86.6–88.4°/10 mm, was prepared by ring opening of cyclohexene oxide with gaseous hydrogen bromide (55).

1-Methylcyclohexene Bromohydrin

This compound, b.p. 98–101°/10 mm, lit. (50*b*) 96.8°/8.5 mm, and *styrene bromohydrin* b.p. 134–136°/10 mm, lit. (56) 120–123°/5 mm, were synthesized by the method of Guss and Rosenthal (56) by reaction of the respective olefins with NBS and water.

The purity of all reference compounds, except α,α′-dibromostilbene and the styrene derivatives, was established by g.l.c. examination. The identity of the styrene derivatives was confirmed by determination of their n.m.r. spectra described later.

*2-Bromocyclohexyl-N-bromoacetimidate (**10**)*

A solution of cyclohexene (41.0 g, 0.5 mol) in carbon tetrachloride (100 ml) was added rapidly to a refluxing suspension of NBA (69.0 g, 0.5 mol) in carbon tetrachloride (400 ml) in a 1 l three-necked flask.[3] Refluxing was maintained by the heat from a 100 W Photoflood No. 2 lamp with reflector mounted close to the reaction flask. The reaction soon became vigorous and, after approximately 5 min, the solid NBA had disappeared and yellow droplets of acetamide could be discerned adhering to the sides of the vessel. The otherwise colorless reaction mixture was immediately cooled in an ice-bath until crystallization of the acetamide[4] was complete and this solid was then collected (15.4 g, 104% based on eq. 9). The mother liquor was distilled under reduced pressure below 40 °C to a residue of 81.1 g; the distillate was then found to contain 16.1 g (80%, based on eq. 9) of cyclohexene by titration of an aliquot with a standardized solution of bromine in carbon tetrachloride.

The residue, diluted with 30–60° *petroleum* ether (10 ml) and stored overnight at −20°, afforded 0.7 g (1%) of *trans*-2-acetamidocyclohexyl bromide, m.p. 110–111°, lit. (57) 109–110°. The i.r. spectrum of this product shows amide absorption at 6.05 and 6.38 μ, and the n.m.r. spectrum shows a peak at τ 7.93 consistent with the presence of an acetamidyl methyl group.

The filtrate was concentrated, *ethyl* ether (10 ml) was added and this solution was kept overnight at −20°. The massive camphor-like crystals then obtained weighed 26.4 g (36%) and melted at 28.0–28.5°.

Anal. Calcd. for $C_8H_{13}NOBr_2$: C, 32.12; H, 4.38; N, 4.72; Br, 53.46. Found: C, 32.34; H, 4.25; N, 4.69; Br. 53.57.

No attempt was made to optimize the recovery of crystalline **10**; however, it was noted that the i.r. spectrum of the residue following removal of **10** was superimposable upon that of the crystalline material.

*Reaction of NBA with Tetramethylethylene. Preparation of **12***

(i) In Carbon Tetrachloride

Tetramethylethylene (4.6 g, 0.055 mol) was added rapidly to a refluxing suspension of NBA (7.8 g, 0.059 mol) in carbon tetrachloride (25 ml), heat being supplied by a 100 W Photoflood No. 2 lamp mounted beneath the flask. When the crystalline NBA had disappeared and yellow droplets of acetamide could be seen, the reaction flask was immediately cooled in an ice–bath and the precipitated acetamide (1.3 g, 78%) was collected. The filtrate was evaporated to yield 5.7 g (66%) of a faintly yellow oil which was diluted with a small amount of ether and stored at −20°. The product crystallized overnight to a solid mass from which well-formed needles (4.7 g, m.p. 40–41°) were obtained; these crystals were washed with a small quantitiy of ice-cold anhydrous ether and analyzed.

Anal. Calcd. for $C_8H_{15}NOBr_2$: C, 31.90; H, 4.98. Found: C, 31.70; H, 4.97.

(ii) In Ether[5]

To a suspension of NBA (1.68 g, 0.013 mol) in anhydrous ether (10 ml), magnetically stirred and cooled in an ice-bath, was added dropwise a solution of tetramethylethylene (1.0 g, 0.012 mol) in anhydrous ether (5 ml). No apparent reaction had taken place by the end of the addition. A crystal of the solid residing at the bottom of the reaction flask was, therefore, extracted and its m.p. determined (107–108°); a mixture m.p. of this material with an authentic sample of NBA was 107–108°.

[3]Care should be taken to use a reaction flask of capacity at least twice the volume of solvent in order to obviate the possibility of overflow of its contents when the highly exothermic reaction begins.

[4]In all cases acetamide was identified by determination of its m.p. and a mixture m.p. with an authentic sample.

[5]Wohl (1) mixed 10 g of tetramethylethylene in 36 ml of ether with 16 g of NBA "under good cooling" and allowed the reaction to go to completion overnight. No other details, including the method of work-up, were mentioned.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

No further change was apparent after the reaction mixture had been stored overnight at 0° in the dark.

After approximately 4½ h stirring at room temperature in the diffuse light of the laboratory, the needles of NBA could not be detected and a voluminous precipitate was dispersed throughout the reaction medium. Filtration yielded acetamide (0.43 g, 78%, m.p. 76–78°; mixture m.p. with acetamide 76–78°). Evaporation of the filtrate yielded 1.5 g (75%) of a colorless oil, whose i.r. spectrum was almost identical with that of the crystalline adduct **12** prepared in (*i*), and which could be crystallized to give material melting at 39–40° by seeding with the former product.

Reaction of NBA with Styrene. Preparation of ***13***

A solution of styrene (1.0 g, 0.01 mol) in carbon tetrachloride (10 ml) was added rapidly to a refluxing suspension of NBS (2.76 g, 0.02 mol) in carbon tetrachloride (50 ml), with irradiation by a 100 W Photoflood No. 2 lamp. As soon as the NBA had disappeared, the mixture was rapidly cooled in an ice-bath, the precipitated acetamide was collected (0.4 g, 68%) and the filtrate was concentrated under reduced pressure at room temperature. The i.r. spectrum of the residue (2.7 g, 80%) showed the characteristic adduct absorptions at 6.2 and 7.8 μ and, as well, some slight absorption at 5.8 and 5.95 μ. The product was dissolved in ether (20 ml) and stored at −20° for 60 h. Fine needles (0.8 g, m.p. 72–73°) separated out and were identified as α,β-dibromostyrene by a mixture m.p. with an authentic sample (72–74°) and by superimposition of the i.r. spectra of the two samples.

The adduct has not yet been crystallized; that this may be due to its instability is evident upon examination of the n.m.r. spectrum of the newly formed product of the NBA–styrene reaction as a function of time. Immediately after isolation this spectrum showed, in addition to unreacted styrene, a triplet (1H) centered at τ 4.15, a doublet (2H) centered at 6.57, and a sharp peak (3H) at 7.85. Within 1 h at room temperature, the peaks at τ 4.15, 6.57, and 7.85 disappeared completely; (in the i.r. spectrum the characteristic peaks at 6.2 and 7.8 μ also disappeared). A doublet, centered at τ 6.18, was now present and was attributed to the β-protons of α,β-dibromostyrene. In the n.m.r. spectrum of the latter compound the α- and β-protons are found, respectively, at τ 4.95 and 6.18; however, in the n.m.r. spectrum of the concentrated NBA–styrene product the signal at 4.95 is obscured by signals due to residual styrene. This proton was readily seen when the product of decomposition was exhaustively evaporated to remove the residual styrene.

Reaction of NBA with 1-Methylcyclohexene. Preparation of ***15***

1-Methylcyclohexene (0.96 g, 0.01 mol) was added rapidly to a refluxing suspension of NBA (1.38 g, 0.01 mol) in carbon tetrachloride (25 ml) with irradiation from a 100 W Photoflood No. 2 lamp. Work-up in the usual manner yielded 1.4 g (81%) of a colorless oil whose i.r. spectrum, shown in Fig. 2, has the characteristic peaks at 6.22 and 7.86 μ. Dilution with ether and storage at −20° failed to crystallize the adduct.

The n.m.r. spectrum of the colorless oil, immediately after isolation, showed, in addition to the two methyl peaks and the ring protons, a 1-proton quartet centered at τ 5.1. After 15 min this quartet had disappeared and a triplet centered at τ 5.4, and a multiplet centered at 5.9 were present. The proton geminal to bromine in 1,2-dibromo-1-methylcyclohexane appears as a triplet centered at τ 5.4. 1-Methylcyclohexene bromohydrin shows complex absorption centered at τ 5.9.

Variable quantities of a chloroform and carbon tetrachloride - insoluble white solid, m.p. 208–210°, were isolated following decomposition of the adduct **15** in these solvents. This solid, a crystalline compound soluble in water, was isolated by filtration, washing with ether, and air-drying. Its i.r. and n.m.r. spectra, shown in Fig. 4, are compatible with structure **26**.

Anal. Calcd. for $C_9H_8BrN_2O$: C, 42.8; H, 7.14. Found: C, 42.89, 43.15; H, 7.53, 7.62.

Reaction of NBA with trans-Stilbene

trans-Stilbene (4.5 g, 0.025 mol) was dissolved in carbon tetrachloride (300 ml) and to the magnetically-stirred solution was added NBA (6.9 g, 0.050 mol). The reaction flask was immersed in a cold water bath which was also magnetically stirred. The temperature of the water bath was slowly raised by irradiation with a 100 W Photoflood No. 2 lamp mounted close to it. No apparent reaction took place until the bath temperature reached 60°, at which point the rate of solution of NBA seemed to increase dramatically; before all of the NBA had dissolved, the reaction mixture became noticeably yellow. The irradiation was immediately halted and the reaction mixture was quickly cooled in an ice-bath. The carbon tetrachloride - insoluble material was collected and triturated with cold water. After drying, the water-insoluble residue weighed 3.2 g and had an i.r. spectrum, m.p., and mixture m.p. identical with those of an authentic sample of α,α′-dibromostilbene.

The i.r. spectrum of the carbon tetrachloride filtrate showed no trace of a bromoacetimidate. Removal of the solvent yielded 4.2 g of an intractable brownish semi-solid residue.

Thermal Decomposition of 2-Bromocyclohexyl-N-bromoacetimidate

(i) In Carbon Tetrachloride and Cyclopentene

The crystalline adduct **10** (1 g) was dissolved in carbon tetrachloride (10 ml) and the solution quickly brought to reflux on a steam bath. One milliliter aliquots of the refluxing solution were withdrawn at 15–20 min intervals and subjected to i.r. and g.l.c. analysis. The g.l.c. analysis indicated formation of three compounds. These compounds were isolated by preparative g.l.c. and shown to be (in order of increasing retention time) cyclohexene dibromide, cyclohexene bromohydrin, and 2-bromocyclohexanone. The identifications were made in each case by i.r. and g.l.c. analysis.

When cyclopentene was employed as the solvent, g.l.c. analysis readily revealed cyclohexene dibromide, but no trace of cyclopentene dibromide could be detected.

(ii) In Dimethylformamide

The crystalline adduct **10** (1 g) was dissolved in DMF (5 ml), and the solution was heated on the steam bath for 1 h. The product was then diluted with water, extracted with ether, and the ether extract dried over anhydrous sodium sulfate and evaporated. The composition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the residue was established, as in (*i*) by i.r. and g.l.c. analyses.

This experiment was repeated in the presence of added lithium chloride (0.1 g, a molar equivalent) in order to test the effect of added chloride ions on the nature of the decomposition in DMF. There was no effect.

(iii) In a Closed System

The crystalline adduct **10** (0.6 g, 0.002 mol) was sealed in a pyrex tube and rapidly heated on the steam bath. The melt soon darkened and an eruption of vapor followed closely. When the reaction tube was cooled, a clear light brown oil was noted over a dark brown semi-solid residue. The tube was opened and the oil washed out with carbon tetrachloride. Evaporation of the solvent and distillation of the residue afforded 1,2-dibromocyclohexane (0.14 g, 30%) identified by comparison of its g.l.c. retention time and its i.r. spectrum with those of an authentic sample. The intractable semi-solid residue weighed 0.43 g.

*Preparation of 2-Bromocyclohexylacetimidium Chloride (**24**)*

Crystalline **10** (0.60 g, 0.002 mol) was dissolved in 10 ml of anhydrous ether. The solution was cooled to 0°, stirred, and treated dropwise with 45 ml of 0.07 *N* ethereal hydrogen chloride. In the course of the addition the reaction mixture acquired a decidedly orange tint and a white crystalline solid separated out. The mixture was stirred for 2 h in the ice-bath after the addition was complete and the solid was then collected. It weighed 0.34 g and melted at 154–155°. Concentration of the orange-colored filtrate caused loss of the orange color and precipitation of a further 0.15 g of the white solid, m.p. 152–155°. The total yield of the crystalline solid corresponded to 91% conversion of the bromoimidate to its derived salt on the basis of the hydrogen chloride utilized. Recrystallization from methanol–ether gave fine needles, m.p. 157.5–158.5° (sealed tube).

Anal. Calcd. for $C_8H_{15}NOBrCl$: C, 37.42; H, 5.85. Found: C, 37.26; H, 5.63.

*Neutralization of **24**. Preparation of 2-Bromocyclohexylacetimidic Acid (**25**)*

An ether suspension of the salt **24** was shaken with 1% aqueous bicarbonate. The ether layer was then separated, dried, freed of solvent, and the i.r. spectrum of the residue determined. Strong absorption at 6.0 μ was still present but the C–H region of the spectrum was now cleanly resolved and a sharp peak was observed at 3.0 μ. When an ether solution of this product (**25**) was shaken with D_2O, dried over anhydrous sodium sulfate, and the solvent removed, the i.r. spectrum of the residue showed no absorption at 3.0 μ. Instead a sharp peak was present at 4.1 μ indicating an N–H to N–D transformation. There was no change in the remainder of the spectrum.[6]

*Reaction of **10** with Triethylamine*

To an ice-cooled stirred solution of **10** (6.0 g, 0.02 mol) in anhydrous ether (20 ml), was added dropwise a solution of triethylamine (2.0 g, 0.02 mol) in anhydrous ether (20 ml). After the addition was complete, the product was stored in the refrigerator for 2 h and the precipitated solid was then collected (3.2 g) and identified as triethylamine hydrobromide on the basis of its i.r. spectrum and a mixture m.p. The filtrate was washed with cold water, dried over anhydrous sodium sulfate, and evaporated to yield 4.2 g of a light brown oil. The i.r. spectrum of this oil was found to contain all of the peaks of **25**, as well as absorption at 5.8 μ attributed to the carbonyl stretching band of 2-bromocyclohexanone. The presence of the latter compound was confirmed by g.l.c. comparison with an authentic sample of the bromoketone using a column of 1% SE 30 on Embacel in addition to the butanediol succinate column.

The n.m.r. spectrum of the product of triethylamine treatment of the adduct **11** from cyclohexene-3,3,6,6-d_4 is almost identical with that of the precursor adduct except for an upfield shift of the methyl peak to τ 7.97. The hydrogen atoms corresponding to H_A and H_B of the original adduct remain as a typical AB quartet with $J = 9$ Hz.

Decomposition of NBA

The NBA (6 g, 0.043 mol) was dissolved in refluxing carbon tetrachloride (500 ml) and the solution irradiated with an ordinary 200 W bulb.[7] Bromine was slowly codistilled with carbon tetrachloride as it formed, and collected in an ice-cooled receiver. After approximately 5 h, the residual solution was only faintly yellow. At this point crystals of a colorless solid were present in the water-cooled condenser; these were washed out with anhydrous ether and collected (0.2 g, m.p. 76–77°). The residual solution was then concentrated under reduced pressure below 40° and the residue triturated with ether to give a further 0.5 g of crystals, m.p. 76–78°. The volume of the bromine-containing distillate was then accurately measured, a sample retained for titration, and the remainder evaporated to dryness and the residue triturated with ether to yield a third crop of colorless crystals (0.2 g, m.p. 76–78°). The crystals were identified as acetamide by a mixture m.p. determination with an authentic sample (total yield, 0.9 g, 35% based on NBA; 70% based on eq. 10).

Titration of the bromine-containing aliquot with a standardized solution of cyclohexene in carbon tetrachloride indicated that the distillate contained 0.018 mol of Br_2, corresponding to 84% of that expected from the stoichiometry shown in eq. 10.

Methyl isocyanate and diacetylhydrazine (anticipated from coupling of two acetamidyl radicals) were, however, not detected.

Preparation of N,N-Dibromoacetamide (NDBA)

An ice-cooled solution of potassium hydroxide (112 g, 2.0 mol) in 1 l of water was added dropwise to a well-stirred mixture of acetamide (59 g, 1 mol) and bromine

[6]We thank Dr. H F. Shurvell for suggesting this procedure.

[7]The use of stronger illumination, such as the 100 W Photoflood No. 2 lamp used in bromoacetimidate preparations, led to more complex products; *bis*-acetamide hydrobromide m.p. 131°, lit. (32) 131° was isolated from such a decomposition. Buckles *et al.* (32) have reported deposition of impure *bis*-acetamide hydrobromide from a u.v. irradiated solution of NBA in chloroform.

(320 g, 2.0 mol), the temperature of the reaction mixture being maintained between 0 and 5° by cooling in an ice-salt bath. After the addition was complete the orange colored solid (obviously impregnated with bromine) was rapidly filtered and washed with ice-cold water. The wet bright orange solid was vacuum dried to yield 60.8 g (30%) of a bright yellow solid. This material could be recrystallized with care from hot water to give a 52% recovery of lustrous golden yellow plates, m.p. 100°, lit. (34) 100°.

Anal. Calcd. for $C_2H_3NOBr_2$: C, 11.06; H, 1.38. Found: C, 11.03; H, 1.55.

Reaction of NDBA with Cyclohexene

Cyclohexene (0.82 g, 0.01 mol) in methylene chloride (10 ml) was added dropwise to a magnetically-stirred solution of NDBA (2.17 g, 0.01 mol) in methylene chloride (20 ml), the reaction mixture being cooled in an ice-bath. At the end of the addition the solution was decidedly yellow. Evaporation of the solvent yielded 2.82 g of a yellow oil whose i.r. spectrum showed the absorptions at 6.2 and 7.85 μ characteristic of the bromoacetimidate adduct **10**, as well as a peak of much lower intensity at 5.9 μ. The oil was diluted with ether, and petroleum ether (30–60°) was added to the cloud point. Storage at 0° produced colorless needles, 50 mg, of **8**, m.p. 111–112° (yield 2.5%). The mother liquor was evaporated to dryness and the residue treated with ether (1 ml). After 1 day at −20° crystallization had occurred. The crystals were collected and identified as **10** by m.p. and i.r. determinations.

Competition Experiment of NDBA with Cyclohexene and Styrene

The above experiment was repeated except that a mixture of cyclohexene (0.01 mol) and styrene (1.04 g, 0.01 mol) was added to the NDBA solution. The n.m.r. spectrum of the resulting product showed the peaks of **10** and of styrene. Peaks corresponding to the adduct **13** and styrene dibromide were not observed.

On the Distinction between Reaction Fluxes and Phenomenological Rate Constants

R. K. BOYD
Chemistry Department, University of Guelph, Guelph, Ontario

Received October 19, 1970

The physical interpretation of the phenomenological rate constants of chemical kinetics is examined. For perfect gas systems, the traditional view of the rate constants for elementary reactions as one-way reaction fluxes is compared with a more recent interpretation (3) in terms of more complicated functions; it is concluded that, for real systems, the former view is a special case of the latter, while for systems in which the phenomenological rate equation is exact, the rate constants are shown to be one-way fluxes.

In any given system, the applicability of the special interpretation is a function of the detailed nature of the transport matrix, which is generally unknown; practical implications of these ideas are presented. For systems other than perfect gases, the problem is complicated by the absence of well-defined molecular states; however, it is suggested that the flux interpretation is the most reasonable.

L'interprétation physique des constantes de vitesse phénoménologiques en cinétique chimique est examinée. Pour des systèmes de gaz parfaits, le point de vue traditionnel, qui consiste à assimiler les constantes de vitesse des réactions élémentaires à des flux de réaction uni-directionnels, est comparé à une interprétation plus récente (3) en termes de fonctions plus complexes; il est conclu que, pour les systèmes réels, le premier point de vue est un cas particulier du dernier; cependant, dans le cas des systèmes, pour lesquels l'équation de vitesse phénoménologique est exacte, il est montré que les constantes de vitesse sont des flux uni-directionnels.

Pour un système donné, l'applicabilité de l'interprétation spéciale est fonction de la nature de la matrice de transport, laquelle est en général inconnue; l'implication pratique de ces idées est présentée. Pour des systèmes autres que de gaz parfaits, le problème est compliqué par l'absence d'états bien définis des molécules; toutefois, il est suggéré que l'interprétation en termes de flux est la plus raisonnable.

Canadian Journal of Chemistry, 49, 1401 (1971)

Introduction

For elementary chemical reactions in homogeneous systems, it is found experimentally that the observed reaction rate may be expressed as the difference of two terms, one of which contains only the concentrations of reactants, and the other only the concentrations of products. For example, consider an isomerization reaction in a perfect gas system

$$[1] \qquad X_1 + Y \rightleftharpoons X_2 + Y$$

X_1 and X_2 denote chemical isomers, which are undergoing interconversion through the agency of collisions with an inert collision partner Y, assumed present in large excess. The observed rate law is assumed to take the form,

$$[2] \qquad -d[X_1]/dt = k_f[X_1] - k_b[X_2]$$

where k_f and k_b are constants for a given value of [Y]. For present purposes, isomerizations involving low and high pressure limits are excluded, *i.e.* there are no "spontaneous" reactive transitions, which do not require a collision with Y.

The traditional interpretation of the rate constants is well expressed in the following quotation from Denbigh (1) "··· there is no specifically thermodynamic reason why the measured reaction rate must be expressible as a difference of two terms ··· the existence of the two terms must therefore be given an interpretation which is *kinetic*, and it has become customary to regard the observed reaction rate as being equal to the difference of the rates in the forward and backward directions ··· there is clearly an element of convention in identifying the two terms with the forward and backward rates."

More recently, this convention has been challenged by Widom (3), on the basis of an analysis due to Zwolinski and Eyring (2), later developed by Snider (4). As emphasized by Widom (3) as a result of this analysis, "the constants k_f and k_b are *not* the probabilities per unit time of an X_1 molecule making an $X_1 \rightarrow X_2$ transition, and an X_2 molecule making an $X_2 \rightarrow X_1$ transition; $k_f[X_1]$ and $k_b[X_2]$ are *not* the separate $X_1 \rightarrow X_2$ and $X_2 \rightarrow X_1$ fluxes." (The symbols used here are slightly different from those used by Widom (3).)

In the present work, the nature of this fundamental disagreement concerning the physical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

meaning of rate constants will be further explored; some basic notation is first defined. The microscopic description of the chemical rate is given by

$$[3] \qquad (\mathrm{d}/\mathrm{d}t)|\boldsymbol{a}\rangle = -\mathbf{K}|\boldsymbol{a}\rangle$$

where a_i is the fraction of the total reactant molecules in internal state i, *i.e.* $a_i = x_i/\sum_{i=1}^{n} x_i$, where x_i is the concentration of molecules in internal state i. The transport matrix $\mathbf{K}$ is defined by

$$[4] \quad \mathbf{K}_{ii} = \sum_{j=1}^{n} k_{ji};\ \mathbf{K}_{ij} = -k_{ij} \quad \text{for } i \neq j$$

where the concentration [Y] is again conveniently included in the k_{ij}.

By assigning states 1 to m to species X_1, and states $m + 1$ to n, to X_2, Snider proposed (4) that eqs. 2 and 3 are mutually consistent after an incubation time, and that the rate constants are given by

$$[5] \quad k_f = \lambda_2 K_{eq}/(1 + K_{eq});\ k_b = \lambda_2/(1 + K_{eq})$$

where λ_2 is the smallest non-zero eigenvalue of $\mathbf{K}$, and K_{eq} is the thermodynamic equilibrium constant $([X_2]/[X_1])_{eq}$. Since λ_2 is a function of *all* microscopic rate constants k_{ij}, it is not possible (3), in general, to identify k_f and k_b, and the corresponding terms in eq. 2, with one-way fluxes.

Exact Solutions

The present approach is based on the elegant lumping analysis technique introduced by Wei and Kuo (5). Reduction of eq. 3 to eq. 2 corresponds to linear transformation of the n-tuple composition vector $|\boldsymbol{a}\rangle$ into a two-fold vector $|\hat{\boldsymbol{a}}\rangle$, by means of a $(2 \times n)$ proper (5) lumping matrix $\mathbf{M}$, of rank 2

$$[6] \qquad \mathbf{M} \equiv \left(\begin{array}{ccc|ccc} 1 & 1 & 1 \cdots & 0 & 0 & \cdots 0 \\ 0 & 0 & 0 \cdots & 1 & 1 & \cdots 1 \end{array}\right)$$

where the vertical division in $\mathbf{M}$ occurs between the mth and $(m + 1)$th columns.

In common with other work on this problem (3), the theoretical constructs $(\hat{a}_1 R)$ and $(\hat{a}_2 R)$ are now assumed to correspond *exactly* to the experimentally determined quantities $[X_1]$ and $[X_2]$, respectively; $R = [X_1] + [X_2]$ is the total concentration.

The system described by eq. 3 is said to be exactly lumpable (5) by $\mathbf{M}$ if, and only if, there exists a matrix $\hat{\mathbf{K}}$ such that

$$[7] \qquad (\mathrm{d}/\mathrm{d}t)|\hat{a}\rangle = -\hat{\mathbf{K}}|\hat{a}\rangle$$

Equation 7 corresponds to eq. 2, with

$$[8] \qquad \hat{\mathbf{K}} \equiv \begin{pmatrix} k_f & -k_b \\ -k_f & k_b \end{pmatrix}$$

Thus, in view of the above assumption, exact lumpability by $\mathbf{M}$ (eq. 6) implies that the phenomenological rate eq. 2 is *exactly* consistent with the microscopic description, eq. 3. The necessary and sufficient condition for exact lumpability (5) is

$$[9] \qquad \mathbf{MK} = \hat{\mathbf{K}}\mathbf{M}$$

For the present case, where $\mathbf{M}$ is given by eq. 6, this condition is readily shown to require that

$$[10] \quad \sum_{i=m+1}^{n} k_{i1} = \sum_{i=m+1}^{n} k_{i2} = \cdots = \sum_{i=m+1}^{n} k_{im} = k_f$$

and $$\sum_{i=1}^{m} k_{i,m+1} = \cdots = \sum_{i=1}^{m} k_{i,n} = k_b$$

It is clear that the conditions for exact lumpability are not met, in general; however, elucidation of the physical meaning of these conditions is a simple extension of earlier work of Widom (6), and will be only briefly sketched in here. The term $k_f[X_1]$, from eq. 2, may be transformed as follows

$$\begin{aligned}[11] \quad k_f[X_1] &= k_f \cdot [R] \cdot \sum_{i=1}^{m} a_i \\ &= [R] \cdot \sum_{i=1}^{m} \left[a_i \left(\sum_{j=m+1}^{n} k_{ji} \right) \right] \\ &= [X_1] \cdot \sum_{i=1}^{m} \left[b_i \left(\sum_{j=m+1}^{n} k_{ji} \right) \right] \\ &= r_f[X_1] \end{aligned}$$

with a similar relationship for $k_b[X_2]$. The first step uses the above assumption relating $[X_1]$ and $[X_2]$ to $\hat{a}_1$ and $\hat{a}_2$, and the second requires conditions [10]; the one-way reaction fluxes r_f and r_b (1, 2), are defined by eq. 1, with

$$\begin{aligned}[12] \quad b_i &= x_i \Big/ \sum_{i=1}^{m} x_i = a_i([R]/[X_1]) \\ &\qquad \text{for } 1 \leqq i \leqq m \\ b_j &= x_j \Big/ \sum_{j=m+1}^{n} x_j = a_j([R]/[X_2]) \\ &\qquad \text{for } (m + 1) \leqq j \leqq n \end{aligned}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

Since the rate constants k_f and k_b are functions of temperature only, the equalities $k_f = r_f$ and $k_b = r_b$ can hold only if the b_i and b_j have their Boltzmann values (6); the corresponding fluxes will be denoted by R_f and R_b. Thus, the necessary and sufficient conditions [10], for eq. 2 to be an *exact* consequence of eq. 3, also ensure that the rate constants are given by the corresponding one-way fluxes, with the internal distribution functions Boltzmannized.

The sense in which the $\hat{\mathbf{K}}$ matrix, given by eqs. 5 and 8, may be said to be an exact solution, is now investigated. An entirely equivalent condition to eq. 9, for exact lumpability (5), is

$$[13] \qquad \mathbf{MX} = \hat{\mathbf{X}}(\mathbf{I}(2)|\mathbf{0})$$

where $\mathbf{X}$ is the eigenvector matrix of $\mathbf{K}$, defined as $(|\mathbf{x}_1\rangle, |\mathbf{x}_2\rangle, \cdots, |\mathbf{x}_n\rangle)$, and $\hat{\mathbf{X}}$ is the corresponding eigenvector matrix of $\hat{\mathbf{K}}$; $\mathbf{I}(2)$ is the 2×2 identity matrix, and $\mathbf{0}$ is a $2 \times (n-2)$ null matrix. Each of the non-vanishing vectors $\mathbf{M}|\mathbf{x}_i\rangle$ is an eigenvector of $\hat{\mathbf{K}}$, with the same eigenvalue $\lambda_i = \hat{\lambda}_i$ (5). If now $\hat{\mathbf{K}}$ is chosen to correspond to Snider's rate constants (4) given by eq. 5, and the nature of the corresponding exact lumping matrix $\mathbf{M}'$ is derived from eq. 13, it is easily shown that $\mathbf{M}'$ is an improper (5) lumping matrix. That is to say, although a vector $|\hat{a}'\rangle$ does exist, whose time-evolution is *exactly* described by eqs. 5 and 7, the quantities $\hat{a}_1'$ and $\hat{a}_2'$ bear no relation to the experimentally measured quantities $[X_1]$ and $[X_2]$.

The conclusions of the present section, while exact, are probably not applicable to any real system, since conditions [10] and [13] are unlikely to be fulfilled. Master equations like eq. 3 are unlikely to prove invalid for the present example, so that the range of validity of the rate eq. 2 must be questioned. Since this is a phenomenological equation found to be adequate to within experimental uncertainty, approximate solutions and their associated errors must be sought.

Approximate Solutions

The techniques of error estimation for approximately lumped systems, devised by Wei and Kuo (5), are here applied to the present problem; the conditions under which reaction system [3] is approximately lumpable by $\mathbf{M}$ (eq. 6) are required. By retaining this proper lumping matrix, the elements of the lumped distribution vector $|\hat{\boldsymbol{a}}\rangle$ correspond to $[X_1]$ and $[X_2]$; this section is concerned with the error associated with estimates of these observables.

For any given choice of the matrix $\hat{\mathbf{K}}$, the corresponding error matrix $\mathbf{E}$ is defined (5) as

$$[14] \qquad \mathbf{E} \equiv \mathbf{MK} - \hat{\mathbf{K}}\mathbf{M}$$

In addition, there are thermodynamic constraints upon the choice of the $\hat{\mathbf{K}}$ matrix (1, 7–9), since the rate and the reaction affinity must vanish together. For the case of reaction 1, this constraint is simply the rate-quotient law

$$[15] \qquad k_f/k_b = K_{eq}$$

There is an infinite set of possible $\hat{\mathbf{K}}$ matrices (eq. 8) fulfilling this condition, including that proposed by Snider (4), (eq. 5). The choice recommended by Wei and Kuo (5) involves specifying an error matrix such that

$$[16] \qquad \mathbf{EAM}^{\mathrm{T}} = \mathbf{0}(2)$$

where $\mathbf{A}$ is the diagonal matrix whose non-zero elements are the equilibrium fractions a_i^*, $\mathbf{M}^{\mathrm{T}}$ is the transpose of $\mathbf{M}$, and $\mathbf{0}(2)$ is the 2×2 null matrix. For the present example, combination of eqs. 8, 14, and 16 readily shows that the resulting rate constants are identifiable with R_f and R_b.

The concepts of one-way fluxes and Snider's rate coefficients have now both been introduced as acceptable approximate solutions for a system not exactly lumpable by the proper lumping matrix $\mathbf{M}$ (eq. 6). In order to investigate which of the two solutions is likely to be the more accurate, the error of lumping is defined (5) as

$$[17] \quad |\hat{\boldsymbol{a}}(t)\rangle - |\hat{\boldsymbol{a}}'(t)\rangle = (\mathbf{M}\, e^{-\mathbf{K}t}|\boldsymbol{a}(0)\rangle) - (e^{-\hat{\mathbf{K}}t}\mathbf{M}|\boldsymbol{a}(0)\rangle)$$

i.e. the difference between the true (observable) composition vector $|\hat{\boldsymbol{a}}(t)\rangle$, obtained by lumping the integrated form of the correct eq. 3, and the estimate $|\hat{\boldsymbol{a}}'(t)\rangle$, obtained from the lumped initial distribution $\mathbf{M}|\boldsymbol{a}(0)\rangle$, and eq. 7. Two exactly analogous expressions may be obtained for the errors in the approximate solutions in terms of Boltzmannized fluxes (eqs. 11 and 12), and Snider's rate coefficients (eq. 5); the former will be denoted by a superscript or subscript R, and the latter by S. Further, define a matrix $\mathbf{N}$ for each case by

$$\mathbf{N} \equiv \hat{\mathbf{X}}^{-1}\mathbf{MX}$$

Then, eq. 17 may be written (5) in the form

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.22.46.98 on 09/08/12
For personal use only.

[18] $$|\hat{a}(t)\rangle - |\hat{a}'(t)\rangle = \hat{\mathbf{X}}\mathbf{P}\mathbf{X}^{-1}|a(0)\rangle$$

where $\mathbf{P}_{ij} = 0$, for $i = 1$ or $j = 1$; $\mathbf{P}_{ij} = n_{ij}(e^{-\lambda_j t} - e^{-\hat{\lambda}_i t})$, for $i,j \neq 1$. The error vector is thus a vector function of time, which asymptotically approaches zero as $t \to \infty$, provided the chosen $\hat{\mathbf{K}}$ satisfies condition [15]. In order to discover which of $\hat{\mathbf{K}}_R$ and $\hat{\mathbf{K}}_S$ gives the error vector with the more rapid approach to zero, examine the elements P_{ij}. Since $\hat{\lambda}_2{}^S = \lambda_2$, by choice, $P_{22}{}^S = 0 \neq P_{22}{}^R$, *i.e.* $\mathbf{P}^S$ has one additional zero element. If $\mathbf{X}^{-1}|a(0)\rangle \equiv |d\rangle$, the error vectors for the two cases may be written

[19] $$|\hat{a}(t)\rangle - |\hat{a}_R(t)\rangle = \hat{X}_2{}^R(1) \sum_{j=2}^{n} d_j n_{2j}{}^R(e^{-\lambda_j t} - e^{-\hat{\lambda}_2{}^R t}) \hat{X}_2{}^R(2) \sum_{j=2}^{n} d_j n_{2j}{}^R(e^{-\lambda_j t} - e^{-\hat{\lambda}_2{}^R t})$$

[20] $$|\hat{a}(t)\rangle - |\hat{a}_S(t)\rangle = \hat{X}_2{}^S(1) \sum_{j=3}^{n} d_j n_{2j}{}^S(e^{-\lambda_j t} - e^{-\lambda_2 t}) \hat{X}_2{}^S(2) \sum_{j=3}^{n} d_j n_{2j}{}^S(e^{-\lambda_j t} - e^{-\lambda_2 t})$$

For all $\hat{\mathbf{K}}$ matrices corresponding to eq. 8, which conserve mass, it is readily shown that $\hat{X}_2(1) = -\hat{X}_2(2)$, so that the sum of the elements of the error vector is zero, as required.

Equations 19 and 20 permit evaluation of the errors in the case that the detailed nature of $\mathbf{K}$ is known; however, it is the present purpose to determine whether any general conclusions, concerning the physical interpretation of observed rate constants, may be drawn in the case that $n_{ij}{}^R$, $n_{ij}{}^S$, λ_i, and $\hat{\lambda}_2{}^R = (R_f + R_b)$, are unknown. The summation over j, in eq. 20 has one term less than that in eq. 19, since $P_{22}{}^S = 0$; this suggests that the $\hat{\mathbf{K}}$ matrix proposed by Snider (4) should, in general, yield a satisfactory approximation to the true $|\hat{a}(t)\rangle$, after a shorter time than the Boltzmannized fluxes. (Such prediction of the experimental observables would seem to be the only possible criterion.) However, the incubation times, after which the error vectors corresponding to the two approximate solutions, become less than some appropriate measure of experimental uncertainty, are seen to be complex functions of $\mathbf{K}$. Thus, the above conclusion may not be regarded as a completely general result, but rather as a strong indication.

Through additional general considerations, the relationship between the two interpretations of phenomenological rate constants, in terms of one-way fluxes (1) and composite functions (3), would appear to be a reflection of the relationship between "equilibrium" and "steady state" theories of chemical kinetics; that is, the former is a special case of the latter. (The steady-state implied by Snider's analysis (4) is not the usual steady-state of conventional chemical kinetics, in that the quantity which is essentially time-independent (4) is $(a_i - a_i^*/a_j - a_j^*)$, for all i,j.) For, if the two incubation times are *both* much shorter than the characteristic time for reaction, it seems reasonable to suppose that the two interpretations should be equivalent. This suggestion may be formalized as follows: for times after which both error vectors [19] and [20] are acceptably small

[21] $$R_f[X_1] - R_b[X_2] \equiv k_f[X_1] - k_b[X_2] = -d[X_1]/dt$$

where eq. 21 has been written as an identity, to express the fact that at a given temperature rate constants measured in a reaction mixture of some arbitrary composition may be used directly to compute rates in *all* reaction mixtures. Identity [21] is valid if, and only if

[22] $$k_f \equiv R_f \quad \text{and} \quad k_b \equiv R_b$$

where k_f and k_b are here taken to represent the quantities defined in eq. 5. This analysis is applicable only to systems in which the microscopic rate constants governing internal relaxation are much larger than those describing "chemical" transitions, so that the appropriate incubation time is a small fraction of the reaction time. For cases where this condition is not met, the relevant fluxes are r_f and r_b, corresponding to time-dependent internal distribution functions for X_1 and X_2. An equation analogous to [21] is still valid, but since r_f and r_b are now functions of $[X_1]$ and $[X_2]$, the one-to-one correspondence of eq. 22 does not apply. Since, in general, the less stringent steady-state condition will be reached before the internal modes are approximately Boltzmannized, Snider's approximate solution (2, 4) is expected to have a wider range of validity than that in terms of one-way fluxes; this conclusion supports that drawn from eqs. 19 and 20.

Practical Application

As a practical illustration of these problems, the reaction system

[23] $$Br_2 + Y \rightleftharpoons 2Br + Y$$

will be considered. This system has non-linear recombination terms in the rate equation, and the above analysis cannot be applied directly; however, for present purposes, the broad conclusions concerning the physical interpretation of empirical rate constants will be assumed valid for this case also. Significant discrepancies have been found, both in absolute magnitude and temperature dependence, in rate coefficients measured by different experimental techniques (10) for this system. These discrepancies are readily explicable qualitatively on the assumption that the rate coefficients for dissociation, derived for initial rates immediately behind shock-waves, were measured before the necessary incubation times (2–4) were over. A simplified model (10) of the coupling of vibrational relaxation to dissociation, was able to account quantitatively for the observed discrepancies; this model involves several approximations, such as the assumption of a unique, time-dependent vibrational temperature T_v, for Br_2. Apart from such approximations, necessitated by the lack of more detailed information, a fundamental assumption of this model, relevant to the present work, is the identification of the experimental recombination rate constants, obtained from flash photolysis experiments at high temperatures (10), with the normalized recombinative flux R_r. As shown above, this requires that the internal modes were essentially fully relaxed in these recombination experiments. Using this assumption, the corresponding dissociative flux R_d could be evaluated, and the non-equilibrium flux r_d was approximated by

[24] $$r_d/R_d = [Q_v(T)/Q_v(T_v)] \exp [(-D/R)(1/T_v - 1/T)]$$

where Q_v and D are the vibrational partition function and dissociation energy, respectively, for Br_2. The right side of eq. 24 is simply the ratio of the fractional populations of states very close to the dissociation limit (assumed to be the only states involved in "chemical" transitions) for $T_v \neq T$ and $T_v = T$.

This evaluation of the observed behavior, during the incubation times, was possible only through the *assumption* that the observed recombination rate constants (10) correspond to R_r values; this implies that the incubation times for this system are true relaxation times, during which internal modes of Br_2 become essentially Boltzmannized. Direct experimental information on the latter assumption is not available, since the volume concentrations of states involved in the "chemical" transitions are not measurable by current techniques; the only justification for this procedure, in the present example, lies in its empirical success (10).

However, the present considerations have shown that there is no fundamental conflict between this model and the established theories of kinetics, as has been suggested (11). The rate quotient law [15] arises, as a special case, from general conditions for the mutual consistency of the thermodynamic and kinetic descriptions of reversible reactions at equilibrium (1, 7–9). As such, it is, indeed, an essential feature (11); however, the rate coefficients, observed immediately behind shock waves in Br_2, involved measurements of concentration, and its rate of change, at a single time (10). There is *no* experimental evidence that these coefficients are rate *constants*, which may be used at all times, including the equilibrium limit, to derive [15]; indeed, for the Br_2 example, the noted discrepancies (10) suggest that this may not be the case, and that the measurements were made during the incubation times. Equation 15 is known to be inapplicable to such quantities (2–4, 6, 12).

Discussion

The physical interpretation of phenomenological rate constants, as contained implicitly in microscopic theories of reaction rates (3, 4, 6, 12) has been shown above to depend on whether or not *exact* correspondence, with the microscopic master equation, is demanded. For real systems, with only approximate correspondence to within experimental uncertainty, no completely general and clearcut conclusions have been reached; however, the quantities defined by Snider (4) (eq. 5) do appear, indeed, to offer the most likely interpretation, but to be equivalent to one-way fluxes in special cases. For the exact case, it has been shown unambiguously that the rate constants are one-way fluxes.

The entire foregoing discussion, in terms of single-particle quantum states, is restricted to ideal gases. For reaction 1, proceeding in solution, the form of the rate equation, found to be generally satisfactory, is (ref. 1, pp. 447–450),

$$[25] \quad -\mathrm{d}[\mathrm{X}_1]\mathrm{d}t = k_\mathrm{f}' \cdot \beta \cdot a(\mathrm{X}_1) - k_\mathrm{b}' \cdot \beta \cdot a(\mathrm{X}_2)$$

where k_f' and k_b' are functions of temperature only, $a(\mathrm{X}_1)$ and $a(\mathrm{X}_2)$ are the activities of the reacting chemical species, and β depends on the concentrations of all species in the solution. The same problem arises here, *i.e.* can the two terms on the right side of eq. 25 be identified with one-way fluxes, assuming the latter can be defined. Strictly, any rigorous physical model would deal only with system states; however, the fact that distinct chemical species may be meaningfully inferred to exist in solution, indicates that "chemical" classifications must be somehow imposable upon the "physical" model of the reaction mixture. An account of this difficult problem has been given by Golden (13); unfortunately, "··· the formal theory which has been derived, is, without further embellishments, completely incapable of rendering unique theoretical expressions identifiable as the rate constants of chemical change" (ref. 13, p. 153). As emphasized by Golden (13), this particular conclusion has no bearing on the description of the observables, *i.e.* chemical composition and its rate of change, but is concerned only with the conventional identification of measured rate constants with theoretical constructs (1, 2).

On a less rigorous level, the only existing theory which has been usefully applied to reactions in solution is transition state theory; now, β (eq. 25) is identified as the reciprocal of the activity coefficient of the activated state. As applied to ideal gas reactions, this theory is explicitly an "equilibrium" theory, and the calculated rate constants are, indeed, normalized one-way fluxes; this latter feature is most clearly seen in the exposition given by Denbigh (ref. 1, pp. 450–459). The situation is not so clear for the "thermodynamic" formulation of the theory, applicable to solution reactions, but it seems that the same identification is the most reasonable that can be made; this is entirely consistent with the fact that relaxation of internal modes of molecules appears to be extremely fast in the liquid phase (14), even though a rigorous definition of such modes (13) involves conceptual difficulties.

The author's interest in these problems was originally stimulated by a period spent in the research group of Professor George Burns; the continued encouragement of Professor Burns is gratefully acknowledged. Professor B. Widom very kindly took time to offer valuable criticisms of an early version of the paper. The work was supported by financial assistance from the National Research Council of Canada.

Molecular Theory of Energy Conversion and of Initiation of Chemical Reactions in Solids[1]

CHARLES E. MELTON
Department of Chemistry, University of Georgia, Athens, Georgia 30601

Received October 8, 1970

A theory has been developed to describe the initiation of chemical reactions in solids. Two basic assumptions are made to formulate the model. First, the initiation of chemical reactions in solids ultimately results from the vibrational excitation of the individual molecules in the solid, and second, the lattice vibrations in a solid can be treated as pseudocollisions between the individual molecules in the lattice. In effect, the solid is treated as an ordered dense gas. These assumptions permit us to describe chemical reactions in a solid within the framework of collision theory. The resultant rate constant, k, depends on molecular and lattice parameters and on the temperature. It is of the form $k = P_{t\rightarrow f}v/\sqrt{2}Nb$, where N is the number of nearest neighbor molecules, b is the lattice spacing, v is the mean velocity of the individual molecules, and $P_{t\rightarrow f}$ is the probability of translational–vibrational energy conversion.

Conclusions based on the present model are in accord with qualitative results from a hard sphere model. For example, energy conversion (translational to vibrational) is many orders of magnitude greater in the region of a defect. Consequently, the probability for initiation of chemical reactions is orders of magnitude greater in the region of a defect.

Une théorie a été développée pour décrire l'initiation des réactions chimiques dans les solides. Le modèle utilisé est basé sur deux hypothèses. Premièrement, l'initiation des réactions chimiques dans les solides résulte tout compte fait de l'excitation vibrationnelle des molécules individuelles dans le solide et, deuxièmement, les vibrations de réseau dans un solide peuvent être traitées comme des pseudocollisions entre molécules individuelles dans le réseau. En effet, le solide est traité comme un gaz dense ordonné. Ces hypothèses nous permettent de décrire les réactions chimiques dans un solide en termes de la théorie des collisions. La constante de vitesse résultante, k, dépend des paramètres moléculaires, de ceux du réseau et de la température. Elle est de la forme $k = P_{t\rightarrow f}v/\sqrt{2}Nb$, où N est le nombre de molécules voisines les plus proches, b est l'espacement du réseau, v est la vitesse moyenne de la molécule individuelle et $P_{t\rightarrow f}$ est la probabilité de conversion de l'énergie translationnelle en énergie vibrationnelle.

Les conclusions, basées sur le modèle présenté, sont en accord avec des résultats qualitatives d'un modèle de sphères rigides. Par exemple, la conversion de l'énergie (translationnelle en vibrationnelle) est plus grande de plusieurs ordres de grandeur dans la région d'un défaut. Par conséquence, la probabilité de l'initiation de réactions chimiques est plus grande de quelques ordres de grandeur dans la région d'un défaut.

Canadian Journal of Chemistry, **49**, 1407 (1971)

Introduction

The primary purpose of this work was to develop a theory of initiation of chemical reactions in solids. Theories of reactions (1–5) in solids have generally been based on the macroscopic properties of the material. Thus, properties such as pressure, temperature, and energies suggested by a sense of preception were related within the framework of fluid flow to give the so called hydrodynamic theories. Within this framework, matter is a continuous substance and energy behaves like an incompressible weightless fluid. Consequently, the analysis of chemical processes provided by macroscopic theories can give only limited insight into the actual physical process. The chemist is not satisfied to look at the process from a macroscopic point of view. For him the properties and reactions of substances are determined by the configuration of the atoms which make up the individual molecules. Thus, the macroscopic theories are not aesthetically good despite their success in describing many aspects of the problem.

To attack the problem from a microscopic or molecular point of view, one simply tries to conceive of the elementary steps of the overall process. Each step is then described by an appropriate mathematical model. Formulation of the elementary steps is somewhat arbitrary. In the present approach, we define six elementary steps which occur in temporal sequence to give the overall reaction. The six steps are: (*1*) excitation

[1]Supported by the U.S. Atomic Energy Commission under contract No. At-(40-1) 3729 with the University of Georgia.

of molecules in the solid; (*2*) propagation of energy from the region of primary excitation to the region of initiation of chemical reactions (conduction through the lattice); (*3*) energy transition from the lattice to the internal degrees of freedom of the individual molecules (electronic, vibrational, and rotational); (*4*) decomposition of the individual molecules into primary products (ions, free radicals, excited species, etc.); (*5*) reaction of primary products with neighbors to form intermediate products (nonequilibrium conditions); (*6*) reactions of intermediate products to form final reaction products (equilibrium conditions).

Steps 1–6 are actually a step by step description of the reaction path of each species from initiation to its ultimate fate. Actually, this sequence is a description of the rate of attaining chemical equilibrium which is normally called chemical kinetics. The model is fully described qualitatively by steps 1–6. Our task is to develop a rigorous mathematical model which will qualitatively describe each step.

Much previous work has been carried out on steps 1 and 2. In general, however, these studies were within the framework of a hard sphere model. Nevertheless, it is instructive to briefly review the previous work because the hard sphere model gives considerable insight into the problem of energy transfer through the lattice.

In a previous report (6), we studied the problem of initiation of chemical reactions from the point of view of the hard sphere lattice of one molecule per unit cell and considered the effect of an impurity added to the molecular crystal. Relationships governing the transmission T' and reflection R' of energy for this type of lattice are known (7). They are

$$[1] \quad T' = \left[1 + \left(1 - \frac{M_1}{M_2}\right)^2 \frac{\omega^2}{\omega_L{}^2 - \omega^3}\right]^{-1}$$

$$[2] \quad R' = \left(1 - \frac{M_1}{M_2}\right)^2 \omega^2 \times \left[\omega_L{}^2 - \omega^2 \left(1 - \left(1 - \frac{M_1}{M_2}\right)^2\right)\right]^{-1}$$

where $\omega = 2\pi$ and ω_L is the maximum lattice frequency, M_1 and M_2 are the masses of the hard spheres. We note that the transmission coefficient is unity for the interior of a pure crystal because $M_1 = M_2$ in eq. 1. On the other hand, energy tends to concentrate near an impurity in an impure crystal. Thus, chemical reactions according to the hard sphere model occur in the region of an impurity. Similar conclusions are apparent from the work of Montroll and Potts (8) on the effect of defects in solids.

Propagation of energy through a two dimensional lattice has been investigated by Payton, Rich, and Visscher (9). These investigators approached the problem by numerical integration of the Newton's equations of motion. The lattice consisted of a ten by fifty array at fixed boundaries. An initial impulse of energy of about 7 kT was given to all atoms at the boundary. Results in Fig. 1 show the propagation of energy through the lattice. The energy in the lattice is proportional to the height of the grid. In Fig. 1, we see the effects of an impurity on the transmission of energy through the lattice. In Fig. 1*a*, the energy shows a dip in the region of the light impurity. The replacement of an atom in the lattice by a light impurity causes a local variation in mass, force constant, and consequently vibrational modes. In a simple cubic lattice, the introduction of an impurity changes six force constants considering only nearest neighbor interactions. Thus, in the region of the light impurity, localized modes are generated. The frequency of these local modes is higher than that of the host atoms which means the light impurity does not couple with the normal modes to increase its energy. This fact explains the dip in energy in the region of the light impurity in Fig. 1*a*. A heavy impurity, on the other hand, has a lower local mode. This means that the particle remains in phase with the energy pulse for a longer period and consequently more energy is transferred to the particle. This phenomenon is illustrated by the results of Fig. 1*b*. Note the spike in the energy pulse at the heavy

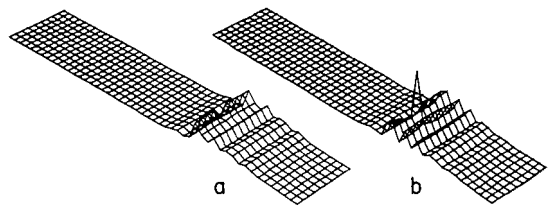

FIG. 1. Illustrations of the dip occurring in the energy wave as it passes over a light impurity (*a*) and the spike resulting from encounter with a heavy impurity (*b*).

impurity. Both light and heavy impurities in a 2D lattice cause energy to concentrate in the region of the impurity in accord with the conclusions drawn from the simple 1D model.

Theoretical Model

Thus far we have discussed an ideal system, namely, the hard sphere model. This model can never be used to describe the actual physical phenomena of chemical reactions in a solid although the model does provide considerable insight into the process of energy transfer. Let us restrict the molecules in the solid to two dimensions as shown in Fig. 2. We assume that line 5 is composed of impurities and further assume that collisions in the solid can be treated by the same techniques as those used for the gas phase. To make any real progress in the development of a theory of reactions in solids, the hard sphere restriction suggested in Fig. 2 must be removed. Specifically, the process must be described in terms of the properties of the individual molecules. This means we must formulate a mechanism for the transfer of energy from translation into internal energy (most likely vibrational). We now make the assumption that the initiation of chemical reactions in solids results from the excitation of vibrational modes of an individual molecule by some mechanism. This mechanism includes absorption of photons, conversion of kinetic energy to vibrational energy by collision, etc. In this treatment we consider vibrational excitation by collision with other molecules in the lattice. A collision, it should be emphasized, is simply an interaction between collisional partners. The basic assumption of vibrational excitation permits us to attack the problem of chemical reactions with the machinery of collision theory. In this approach the colliding partners suffer an inelastic collision which results in the vibrational excitation of one or more modes of the individual molecules. We now define a quantity which we call the molecular activation energy E_m. This quantity is the minimum vibrational excitation required to produce a chemical reaction. Thus, we have the requirement for chemical reaction

$$[3] \qquad E_m = \sum_{j=1}^{3N-6} n_j h\nu_j = \text{constant}$$

$$\{n_j\} = 0, 1, 2, \cdots$$

where N is the number of atoms in the molecule and $h\nu_j$ is the energy of the jth oscillator in the molecule, and $\{n_j\}$ is any set which will give the constant E_m. A bimolecular reaction in the gas phase can be described by the relationship

$$[4] \qquad A + B \xrightarrow{k'} C + D$$

where A, B, C, and D are any species: atoms, molecules, ions, electrons, etc, and k' is the rate constant. The rate constant can be expressed in terms of reaction cross section as

$$[5] \qquad k_\sigma = 2\left(\frac{2kT}{\pi\mu}\right)^{\frac{1}{2}}\sigma_R = \bar{v}\sigma_R$$

where v is the mean velocity. The reaction cross section is given by

$$[6] \qquad \sigma_R = \sigma_t P_{i\to f}$$

where σ_t is the total cross section and $P_{i\to f}$ is the probability that one of the collisional partners will undergo a transition from the initial state i to a final state f which corresponds to E_m of eq. 3. We have now reduced the problem of chemistry in solids to that of calculating $P_{i\to f}$. The other variables can be easily obtained from other considerations. If one deals with the gas phase, one must use a three dimensional theory. However, one can apply the approach to the solid state by simply assuming that lattice vibrations actually represent collisions of particles restricted to move along a straight line connecting their centers of mass. Thus, one can treat the problem as that of a one dimensional collision process.

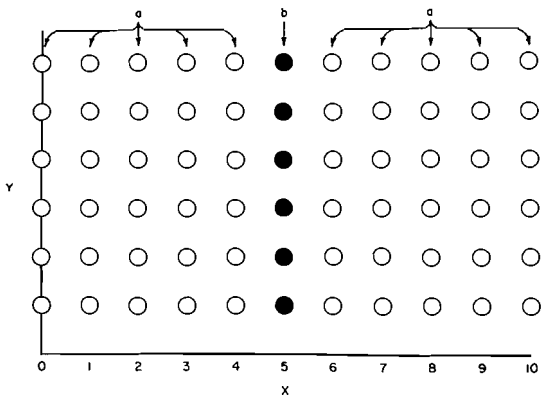

FIG. 2. Two dimensional gas with a line of impurities (*b*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

There have been a number of treatments of inelastic collisions in which an exchange of translational and rotational energy occurs. Most of these calculations are based on the original work of Zener (10) and of Landau and Teller (11). We now look briefly at the general method.

In an ideal treatment one would obtain a total wave function for the molecules. This would be done by expanding the complete set of eigenfunctions for the stationary states of the system to give

$$[7] \qquad \Psi = \sum_n c_n \psi_n$$

We then substitute the expansion into the Schrödinger equation. A set of coupled differential equations in the coefficients c_n is obtained from the property of orthogonality of the states. A solution to this set of equations with appropriate boundary conditions gives the transition probability. Unfortunately, a solution to the complete set of coupled differential equations is an arduous task. Thus, various simplifying approximations must be introduced to obtain a solution to the equations.

The simplest treatment is the first order perturbation approximation. In this approximation the wave function is taken as a linear combination of terms corresponding to the initial and final states

$$[8] \qquad \psi = c_i \Psi_i + c_f \Psi_f$$

The coefficient of the initial state c_i is set equal to unity throughout the collision. This is equivalent to assuming a small transition probability.

First order perturbation theory can be extended by removing the restrictions on c_i and c_f. Such a treatment is called the two state approximation. In this treatment, the wave function is given by [8], without setting $c_i = 1$.

If one cares to increase the complexity and presumably the accuracy, the Nth order perturbation approximation is used. In this approximation all energetically possible states between the initial and final state are retained as well as the initial and final states. Transition probabilities are assumed to be small thus restricting c_i to unity.

The most accurate and most complex method is the N state approximation in which all N states of [8] are used. In addition, virtual transitions among the N states are included. A solution is obtained by a variational type approach. The value of $P_{i\to f}$ is considered "best" when the addition of more states produce no significant change in $P_{i\to f}$.

A serious problem in calculating $P_{i\to f}$ is that of obtaining a suitable interaction potential. The assumption is sometimes made that the interaction can be approximated by a product which is a function of the intermolecular distance r and the normal vibrational coordinates, $s_i (i = 1, 2, 3, \cdots, n)$. Thus,

$$[9] \qquad V = V_0 V_{(r)} V_i(i) \cdots V_m(s_m)$$

Sometimes an exponential of the form

$$[10] \qquad V = V_0 \, e^{-r/a}$$

is used, where r is the intermolecular distance measured in atomic units and a is a length measured in atomic units and is of the order of the gas kinetic radius of the molecules.

The problem of evaluating $P_{i\to f}$ has been treated fairly successfully with a simple one dimensional model for the collision (10–13). Schwartz, Slawsky, and Herzfeld (12) obtained the relationship for an initial velocity of v_0 and a final velocity of v_f

$$[11] \quad P_{i\to f}(v_0) = \frac{16\pi^2 V_0^2}{v_0 v_f h^2} \times [V(i_1 \to f_1) \cdots V(i_n \to f_n) R]^2$$

where R is defined as

$$[12] \qquad R = \int_{-\infty}^{\infty} F_0 F_f V_r \, dr$$

and F_0, F_f are solutions of the Schrödinger equation for the motion of a free particle in the potential field V_r. The term $V(i_i \to f_i) \cdots$ is defined as

$$V(i_n \to f_n) \equiv \int_{-\infty}^{\infty} \psi_i V_n \psi_f \, ds_n$$

where s_n is the nth vibrational coordinate.

Results calculated by this approach (12) are given in Table 1. These data have implications for solids. Consider a hypothetical solid consisting of O_2 with a line of CO impurities. Let us give the solid translational energy. We see $P_{i\to f}$ for O_2 is 8.5×10^{-8} and $P_{i\to f}$ for pure CO is 7×10^{-10}. In sharp contrast $P_{i\to f}$ for O_2 colliding with CO is about two orders of magnitude greater 2×10^{-6}. Thus energy is converted more readily where unlike partners collided.

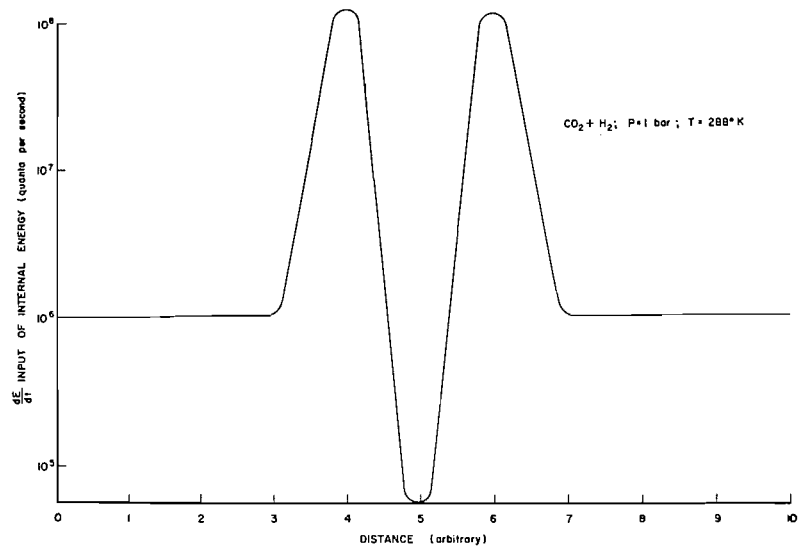

FIG. 3. Energy conversion as a function of distance in a solid of the type shown in Fig. 2 where $a = CO_2$ and $b = H_2$.

TABLE 1. Probability of collision induced vibrational excitation in pure gases and in mixtures*

Gases (a, b)	T (K°)	$P_{0\to1}$ Pure gas (a)	Pure gas (b)	Mixture (a, b)
O_2, N_2	288	8.5×10^{-8}	0	3×10^{-7}
O_2, CO	288	8.5×10^{-8}	7×10^{-10}	2×10^{-6}
CO_2, N_2	288	4×10^{-4}	0	7.5×10^{-4}
CO_2, H_2	288	4×10^{-4}	0	4.5×10^{-2}
N_2, Ar	600	7×10^{-9}	0	3×10^{-8}

*Reference 12.

Results for a system of CO_2 and H_2 $a = CO_2$ and $b = H_2$ (Fig. 2) are shown in Fig. 3 for a pressure of 1 bar and a temperature of 288°. This figure shows that the energy input to lines *4* and *6* (Fig. 2) is over two orders of magnitude greater than that to other areas of the system. Consequently, any chemical reaction would be expected to occur in this area, because of the higher effective temperature.

In summary, an impurity or unlike molecules in a system increases the transfer of translational to internal energy in the region near the impurity. If the treatment were extended to a three dimensional system the results would be qualitatively the same. In the three dimensional treatment, the relative motion of the molecules has an angular dependence. Several investigations (13–16) have developed relationships for the three dimensional gaseous system. The results of Tanczos (15) will be given here because they can be applied to complicated molecules. The probability that a pair of molecules in vibrational states i_a and i_b will, after collision, be in higher energy states f_a and f_b is given for nonresonant conditions by

$$[13]\quad P(a,b) = P_0(a)P_0(b)P_c V^2(a)V^2(b)8\left(\frac{\pi}{3}\right)^{1/2}\left[\frac{8\pi^3\mu\Delta E}{(a^*)^2h^2}\right]^2 X^{1/2}\exp\left[-\left(3X - \frac{\Delta E}{2kT} + \frac{\phi_0}{kT}\right)\right]$$

where

$$X = \frac{\mu(v^*_0)^2}{2kT} = \left[\frac{2\pi^4\mu(\Delta E)^2}{(a^*)^2h^2kT}\right]^{1/2}$$

and

$$\Delta E = h\nu_a(i_a - f_a) + h\nu_b(i_b - f_b)$$

The factors $P_0(a)$ and $P_0(b)$ are geometrical steric factors for the molecules a and b. The preexponential factor P_c relates probabilities as calculated for an elastic collision cross section and is given approximately by

$$[14]\quad P_c = 1.364(1 + C/T)^{-1}(r_c/r_0)^2$$

where C is the Sutherland constant, r_c the distance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

between molecular centers at the point of closest approach, and r_0 is the distance for zero potential value. Combining all of these relationships one obtains for the transition probability under resonance conditions ($\Delta E = 0$) the relationship

$$[15] \quad P(a, b) = P_0(a)P_0(b)V^2(a)V^2(b)\frac{64\pi^2\mu kT}{\alpha^2 h^2} \times \exp[-(\phi_0/kT)]$$

Let us now apply the results to chemical reactions in solids. Consider the region of an impurity where $P_{i\to f}$ has a relatively large value. To form an activated complex, one molecule must receive an energy of E_m.

If the reaction occurs by bimolecular decomposition, the rate constant is given by eq. 5. We have already evaluated $P_{i\to f}$, *e.g.*, eq. 11, now all that remains is an evaluation of σ_t and v. We evaluate σ_t in the solid by means of the concept of the mean free path λ. We know that

$$[16] \quad \lambda = \int_0^\infty P(x)\,dq = \frac{1}{\sqrt{2}\sigma_t N}$$

where (P_x) is the probability that the particle goes a distance x without collision. In a solid the mean free path is the lattice spacing, b; thus σ_t is given by

$$[17] \quad \sigma_t = \frac{1}{\sqrt{2}bN}$$

where N is the number of nearest neighbor molecules substituting for and in eq. 5 one obtains the chemical rate constant, k

$$[18] \quad k = \frac{P_{i\to f}\bar{v}}{\sqrt{2}bN}$$

In summary, we have shown that the rate constant for chemical reactions in solids can be expressed in rather simple terms (eq. 18). Other techniques can be used to calculate the mean velocity of molecules in a solid and thereby increase the precision of the calculation. It should be mentioned that the same type of relationship could be used to describe reactions in the liquid state. Because of mathematical difficulties in calculating $P_{i\to f}$, results from the present model are considered of qualitative rather than quantitative significance.

The basic problem under study is that of energy transfer in a crystal from lattice vibrations, vibration of the molecule as a whole about its lattice position, to internal vibrations, vibrations of the atoms comprising the molecule within the molecule. Sometimes the higher lattice vibrational frequencies overlap the lowest internal mode, but usually there is little overlap. One can develop a model based on coupling between these vibrational modes. However, such a model requires, in general, high order perturbation theory (to tenth order) to explain the energy transfer. We investigated and rejected the "perturbation model" in favor of the present "collision model" mainly on the basis of the less complex mathematical treatment of the present model.

Infrared Studies of Water in Crystalline Hydrates: Sodium Nitroprusside Dihydrate, $Na_2[Fe(CN)_5NO].2H_2O$ [1]

MICHAELA HOLZBECHER AND OSVALD KNOP
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

AND

MICHAEL FALK

Received October 14, 1970

Infrared spectra of polycrystalline $Na_2[Fe(CN)_5NO].2H_2O$ at different degrees of deuteration were studied as a function of temperature. The single peaks observed for the bending fundamentals of isotopically dilute H_2O and D_2O show that all the water molecules are equivalent, as required by Manoharan and Hamilton's structure determination; the doublets observed for the three fundamentals of isotopically dilute HDO show that the water molecules are asymmetric. Doublet separation decreases gradually with increasing temperature, indicating decreasing asymmetry. The water molecule appears to orient itself so as to maximize the strength of one OH···NC bond, while the other OH group interacts only very weakly with another CN group. The hitherto unknown extent to which the nitroprusside ion deviates from the ideal C_{4v} symmetry has been estimated from the $^{13}C^{14}N$ stretching spectrum. The $^{15}N^{16}O$ and $^{14}N^{18}O$ stretching spectrum was used to confirm that only one type of NO group is present in the crystal, and hence that all nitroprusside ions are equivalents.

Les spectres infrarouge du $Na_2[Fe(CN)_5NO].2H_2O$ polycristallin à des degrés différents de deutération ont été étudiés en fonction de la température. Les pics uniques observés pour les fondamentales de déformation angulaire de H_2O et D_2O isotopiquement dilués montrent que toutes les molécules d'eau sont équivalentes, comme il était requis par les déterminations de structure de Manoharan et Hamilton. Les doublets observés pour les trois fondamentales du HDO isotopiquement dilué montrent que les molécules d'eau sont asymétriques. La séparation du doublet décroît graduellement avec l'accroissement de température, montrant la diminution de l'asymétrie. La molécule d'eau semble s'orienter afin de maximiser la force d'un lien OH···NC, tandis que les autres groupements OH intéragissent seulement très faiblement avec un autre groupe CN. Jusqu'ici, la déviation de l'ion nitroprussique de la symétrie idéale C_{4v} a été estimée du spectre de valence du $^{13}C^{14}N$. Le spectre de valence de $^{15}N^{16}O$ et $^{14}N^{18}O$ a été utilisé pour confirmer qu'il y a seulement un type de groupement NO dans le cristal, et ainsi que tous les ions nitroprussique sont équivalents.

Canadian Journal of Chemistry, **49**, 1413 (1971)

The water molecule in the crystal structure of sodium nitroprusside dihydrate, $Na_2[Fe(CN)_5NO].2H_2O$,[2] has been quoted as an example of structural water not forming a definite pair of hydrogen bonds (1, 2). The evidence from a crystal-structure determination by photographic X-ray diffraction methods (1) is incomplete, as only the oxygen atoms, O_w, of the water molecule have been located. The shortest O_w–O_w distance is 3.63 ± 0.04 Å (O_wD–O_wC in Table 1 and Figs. 1 and 2) and thus outside the accepted range for O—H···O bonding. As for the possibility of the water molecule participating in two O_w—H···N bonds, the two distances singled out in ref. 1 as the shortest O_w–N distances in the SND structure, 3.27 ± 0.05 and 3.36 ± 0.05 Å,[3] involve oxygen and nitrogen atoms all of which are part of the same coordination octahedron about sodium. This has been considered to disqualify these two interatomic vectors as coincident with hydrogen bonds (2). However, there are other O_w–N distances between 3 and 4 Å in the structure, some of them just as short as the two used in Manoharan and Hamilton's argument (1) (Table 1); all of these must be examined in turn for the possibility of hydrogen-bond engagement with the water molecule.

The O_w atoms have been placed in the general equipoint 8(*h*) of the tetramolecular unit cell of

symmetry D_{2h}^{12}-*Pnnm* (Table 2). This makes the eight water molecules in the unit cell equivalent, but their hydrogen atoms must belong to two nonequivalent sets, $8H_1 + 8H_2$. Like in gypsum (4, 5), the distances O_w–H_1 and O_w–H_2 are in principle different, but as the positions of the hydrogen atoms have not been determined, the extent of asymmetry of the water molecule is not known. The water molecules in SND differ from those in gypsum in that they do not participate

in strong hydrogen bonding, as is apparent from the observed O_w–N distances. It was therefore of interest to see whether the two weakly bonded OH groups of the water molecule have fundamental frequencies that are sufficiently different to be distinguishable in the infrared (i.r.) spectrum of isotopically dilute HDO.

The subject of main interest to us has been the fundamentals of the water molecule. None of the many i.r. and Raman spectroscopic studies of SND that have been reported (6–17)[4] was primarily concerned with this aspect of the SND structure. The vibrational frequencies of the nitroprusside *ion*, $[Fe(CN)_5NO]^{2-}$, have been recently reviewed in detail in refs. 13 and 16 which appeared while the present work was in progress. We have restricted our attention to structural deductions from those vibrational bands of the anion that arise from minor isotopic species (^{13}C, ^{15}N, ^{18}O).

Experimental

The identity of the brownish-red crystals of SND (May and Baker, Ltd.; reagent-grade, recrystallized from distilled water) was verified by the i.r. spectrum.

The material was partially deuterated by crystallization from hot solutions in H_2O–D_2O mixtures. The higher deuterations were carried out by dissolving the sample in D_2O of 99.7% isotopic purity and evaporating the excess D_2O under reduced pressure into a cold trap. Three successive deuteration steps yielded samples of H:D ratio of about 1:20. The approximate H:D ratio was calculated from the areas of the HOH, DOD, and HOD bands (4).

Samples were studied as mulls in Nujol and as pressed pellets in KBr and NaCl matrices, as in earlier work (4). The spectra were recorded on a Perkin–Elmer Model 521 spectrophotometer [*cf.* ref. 4]. Survey spectra (*e.g.* those in Figs. 3 and 4) were recorded at a scanning speed of about 100 cm^{-1}/min. The more important spectral features (*e.g.* those in Figs. 5–10) were recorded with expanded abscissa scale at a scanning speed of about 10 cm^{-1}/min. Frequencies of the sharp peaks were read to the nearest 0.1 cm^{-1} and are believed to be accurate to ± 1.0 cm^{-1}. All frequencies quoted in the following are the averages of several runs.

Results

Spectrum of Undeuterated SND

Spectra of Nujol mulls and of KBr and NaCl pellets were essentially the same. Figure 3 shows typical survey spectra in a form useful for identification and catalogue purposes. In[5] Table 3 our frequencies for the major bands in the spectrum at room temperature are compared with values reported by other workers (6–8, 10, 13, 15, 16). Our values agree particularly well (within 1 cm^{-1} for most bands) with those of refs. 13, 15, and 16.

Partially Deuterated SND

Figure 4 shows the spectra in the regions of H_2O, HDO, and D_2O fundamental vibrations at increasing deuterium content. Details of interest are shown in Figs. 5–8 as a function of temperature,[5] and more detailed comments may be found in Appendix 1.[5]

Of major importance structurally are the fundamentals of the *isotopically dilute* water molecules; such molecules are vibrationally "isolated" (4). The bending fundamentals of isolated H_2O and D_2O in SND were sharp *singlets* at 1616.5 and 1191.2 cm^{-1}, respectively, essentially independent of temperature (Fig.[5] 8 and Table 4). All three of the fundamentals of isolated HDO were *doublets*, the separation of which decreases gradually with increasing temperature (Fig.[5] 5 and Table 4).

At higher isotopic concentrations the bending fundamentals of HDO, H_2O, and D_2O showed additional components (best resolved at low temperature), indicating vibrational coupling. As has been reported by Khanna, Brown, and Jones (13), the HOH and DOD bending fundamentals of undeuterated and highly deuterated SND were found to be triplets, the separations of which decreased with temperature (Figs.[5] 6 and 7).

The stretching fundamentals of HDO, H_2O, and D_2O did not appreciably change their frequencies and half-widths at higher isotopic concentrations, indicating absence of vibrational coupling.

CN and NO Stretching Fundamentals

The small bands on the low-frequency side of the CN stretching fundamentals in the spectra of undeuterated SND (Fig.[5] 9) are due to the minor isotopic species $^{13}C^{14}N$ and $^{12}C^{15}N$ (13, 16). All the CN stretching bands shifted to higher

[4]Reference 17 seems to convey the impression that *anhydrous* sodium nitroprusside was studied. However, the "deep dark red color" of the samples and the partial i.r. and Raman spectra reported there leave little doubt that the substance studied was in fact the dihydrate.

[5]Table 3, Figs. 5–11, and Appendices 1 and 2 have been placed in Depository of Unpublished Data. Photocopies may be obtained free of charge upon request, from: Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada.

frequencies at decreasing temperatures, by 2–4 cm^{-1} per 100°.

The small bands on the low-frequency side of the NO stretching fundamental (Fig.[5] 10) arise from the minor isotopic species $^{15}N^{16}O$ and $^{14}N^{18}O$ (13). The center of the major NO stretching band, as well as the two minor isotopic bands, shifted to higher frequencies with decreasing temperature, by 3.5 cm^{-1} per 100°.

Discussion

Site Symmetry of the Water Molecules

The single peaks observed for the bending fundamentals of isotopically dilute H_2O and D_2O show that all water molecules in SND are crystallographically equivalent. The doublets observed for the three fundamentals of isotopically dilute HDO indicate that the water molecules are asymmetric (4, 5). These conclusions agree with the expectations from the orthorhombic space-group symmetry of SND and the concomitant site symmetry for the water molecule, C_1-*1* (1). The OH:OD frequency ratios are the same for the two components of the doublet, 3603.0/2653.5 = 1.3578 and 3568.0/2629.5 = 1.3569, which confirms that the doublet is due to the presence of two nonequivalent OH groups rather than to other possible effects such as proton tunnelling (4, 5).[6] The gradual decrease in the doublet separation with increasing temperature, which occurred for all three fundamentals of HDO in proportion, indicates that the water molecule becomes effectively more symmetric, probably as a result of increased motion with respect to the neighboring atoms. A similar interpretation accounts satisfactorily for the observed temperature dependence of the split HDO fundamentals in other hydrates (18).

Correlation Field Splitting

It is seen from the correlation diagram of the site symmetry C_1 with the factor-group symmetry D_{2h} (Fig.[5] 11) that correlation field splitting (*i.e.* coupling of like vibrations within the unit cell) should cause each internal vibration of a water molecule to give rise to eight coupled vibrations of the unit cell, of which three (B_{1u}, B_{2u}, B_{3u}) are i.r. active. In agreement with Khanna *et al.* (13) and Tosi (16) we have found three components of the bending fundamentals of H_2O in undeuterated SND (and of D_2O in highly deuterated SND). Correlation splitting was also observed for the HOD bending fundamental. As may be expected, the correlation components increase their separation at lower temperature.

On the other hand, correlation splitting was not observed for the stretching fundamentals of HDO, H_2O, or D_2O. Hence it must be smaller than the half-widths of the stretching bands, 8 and 21 cm^{-1} for the two D_2O stretching peaks at −170 °C, and 14 and 21 cm^{-1} for the two H_2O stretching peaks at −160 °C. The magnitude of correlation field splitting commonly observed for stretching vibrations of water in crystals is 50–

[6]Khanna, Brown, and Jones previously reported the doubling of HDO fundamentals but could not explain it (13). Bates and Khanna have since ascribed the doubling to "orientational splitting" (15). This view appears to coincide with our analysis.

100 cm^{-1} (19, 20). The unusually small splitting in SND is probably due to the water molecules not being interconnected by hydrogen bonds (*vide infra*).

Hydrogen Bonding

The environment of the water molecule according to ref. 1 is shown in Figs. 1 and 2 (*cf.* Table 2 for symmetry relationships and site symmetries of the atoms). The two sodium atoms Na*1* (*A*) and Na*2* (*D*) are the only two neighbors of O_wD within 3 Å (for interatomic distances, see Table 1). The nitrogen atoms of the eight CN groups surrounding the water molecule are at distances between 3.27 ± 0.05 and 3.63 ± 0.05 Å. The carbon atoms are somewhat farther away than the corresponding nitrogen atoms, although the differences may be slight and well within the limits of uncertainty of the interatomic distances (compare, for example, N*3E* and C*2E*, or N*4D* and C*3D*).

Hydrogen bonds corresponding to O–N distances greater than 3.2 Å will necessarily be very weak;[7] still, it is reasonable to assume that the OH groups of the water molecule will seek to maximize the H···NC interactions and tend to orient themselves toward the closest-lying N atoms. Which of the latter will be available for such interaction is determined by the cation–proton repulsion between the sodium ions and the water molecule; the repulsion may be expected to cause the O—H bonds to point away from the Na^+ ions. Five of the eight N atoms (*4A*, *3H*, *3G'*, *3G*, and *2D* of Figs. 1 and 2) are ruled out because of the smallness of their N—O_w—Na*1* or N—O_w—Na*2* angles, which are all under 50°. Of the remaining three N atoms, N*4B* is 3.27 ± 0.05 Å away from O_wD compared with 3.61 ± 0.04 Å for N*3E* and 3.63 ± 0.05 Å for N*4D*. Aligning one of the OH groups, O_w—H_1, of the water molecule approximately along O_wD–N*4B* not only leads to the shortest O_w–N distance in this situation, but is also consistent with each of the two lone pairs on O_w pointing in the direction of one of the sodium ions, Na*1A* or Na*2D*. The most reasonable orientation for the second OH group, O_w—H_2, is then in the general direction of N*4D*: the angle N*4B*—O_wD—N*3E* is only 75.9 ± 1.3°, while the angle N*4B*—O_wD—N*4D* is 115.0 ± 2.3°, which is much closer to the H—O—H angle of about 109° usually found in crystalline hydrates (21). The orientation N*4B*···H_1—O_wD—H_2···N*4D*, which thus appears the most probable, may be viewed as the result of the tendency of the water molecule to maximize the strength of the one hydrogen bond it can make (exemplified by O_wD—H_1···N*4B*—C*3B*) at the price of the other OH group remaining essentially non-hydrogen-bonded.

The i.r. spectrum supports this deduction. The high-frequency component of the stretching doublets of isotopically dilute HDO is at 3603.0 cm^{-1} for OH and at 2653.5 cm^{-1} for OD. These are the highest stretching frequencies so far reported for HDO in crystalline hydrates. They clearly correspond to the stretching of O_w—H_2. The frequency of the other component of the stretching doublet, 3569.0 cm^{-1} for OH and 2629.5 cm^{-1} for OD, is sufficiently lower, and the intensity sufficiently higher, for this component to be considered as arising from the more strongly interacting OH group, O_w—H_1, which is oriented toward N*4B* and corresponds to an O_w–N distance of 3.27 ± 0.05 Å.

Comparison with Related Compounds

High OH (or OD) stretching frequencies appear to be characteristic of hydrates of cyano complexes. They indicate that the hydrogen bonding between water and CN groups is generally weak. The OD stretching frequencies of isotopically dilute HDO extend, at −165°, up to about 2624 cm^{-1} in $K_4[Fe(CN)_6].2H_2O$, and up to about 2630 cm^{-1} in $K_4[Ru(CN)_6].3H_2O$ (22). Another example is the unassigned sharp doublet in the spectra of partially deuterated $K_4[Mo(CN)_8].2H_2O$ and $K_4[W(CN)_8].2H_2O$ at room temperature (23): The doublet, at 2614 and 2640 cm^{-1} in the Mo compound and at 2614 and 2641 cm^{-1} in the W compound, undoubtedly corresponds to HDO, in analogy to the doublets in the spectrum of partially deuterated SND. The H_2O···N separations in the Mo compound range upward from 3.16 Å (24).

The CN Stretching Fundamentals

If the nitroprusside ion had the point-group symmetry C_{4v}-*4mm*, the four CN groups num-

[7]This is true regardless of whether the hydrogen-bonding interaction is considered to be between O_w and N or, more vaguely, between O_w and the π system of the CN group.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

bered *2–5* in Fig.[8] 12 would be equivalent. In the crystal of SND the symmetry of the ion is lowered to C_s-*m*; the mirror plane passes through the atoms N_1C_1–Fe–N_6O and bisects the angles C_3—Fe—C_4 and C_2—Fe—C_5. Consequently the groups C_2N_2 and C_3N_3 are no longer equivalent by symmetry, and likewise C_4N_4 and C_5N_5. How closely the C_{4v} symmetry is simulated by *metric* similarity is difficult to determine because of the insufficient accuracy of the crystal-structure determination: Fe—C_2, 1.91 ± 0.06 Å; Fe—C_3, 1.93 ± 0.06 Å; Δ = 0.02 ± 0.09 Å; C_2—N_2, 1.15 ± 0.06 Å, C_3—N_3, 1.14 ± 0.06 Å; Δ = 0.01 ± 0.09 Å; similar uncertainties obtain in the bond angles.

The effective symmetry of the nitroprusside ion in SND can in principle, *i.e.* without reference to crystal structure determination, be deduced from the vibrational spectrum in the region of the CN

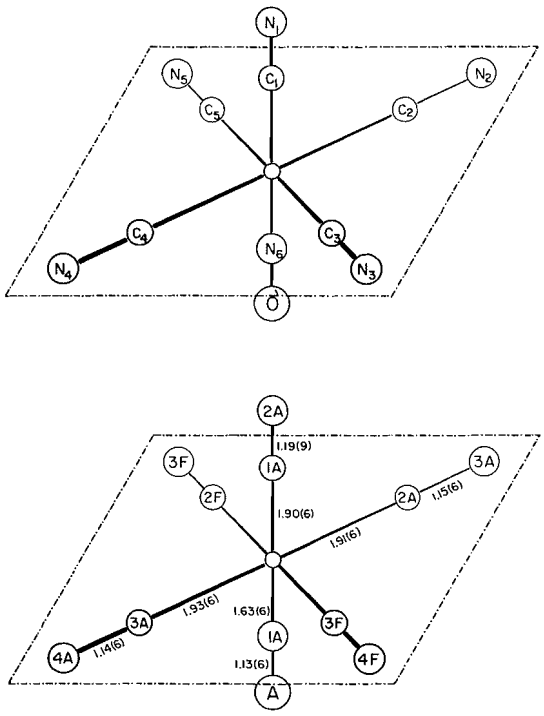

FIG. 12. Geometry of the $[Fe(CN)_5NO]^{2-}$ ion. The schematic coordination figure (*top*), which is drawn as if the symmetry of the ion were C_{4v}, can be correlated with Fig. 1 as indicated in the bottom drawing.

[8]This numbering refers only to Fig. 12; it is not to be confused with the notation for C and N atoms used in ref. 1 (*cf.* Table 2).

stretching fundamentals. However, that information is difficult to obtain from the $^{12}C^{14}N$ stretching spectrum, as discussed in Appendix[5] 2. On the other hand, a simple and unequivocal confirmation of the local symmetry of the nitroprusside ion, as well as an estimate of the extent to which the ion deviates from the ideal C_{4v} symmetry, can be derived from the minor isotopic bands due to ^{13}C and ^{15}N.

The natural abundance of these isotopes is sufficiently low for the $^{13}C^{14}N$ and $^{12}C^{15}N$ groups to have mostly $^{12}C^{14}N$ groups as neighbors. As a consequence the two factors that complicate the $^{12}C^{14}N$ stretching spectrum, the internal coupling of vibrations within the complex ion and the coupling of vibrations of neighboring ions in the unit cell cease to be important.[9] Every crystallographically distinct CN group will then yield one $^{13}C^{14}N$ and one $^{12}C^{15}N$ fundamental vibration, so that the number of observed $^{13}C^{14}N$ (or $^{12}C^{15}N$) fundamentals will be two under C_{4v}, C_4, or $C_{2v}[\sigma_d]$; three under $C_s[\sigma_d]$ or $C_{2v}[\sigma_v]$; four under $C_s[\sigma_v]$; and five under C_1 symmetry (*cf.* Table 5 and Fig. 12).[10]

The calculated frequencies and abundancies of the isotopic CN groups (Table 6) show that the species $^{13}C^{14}N$ will dominate the spectral region below the $^{12}C^{14}N$ stretching frequencies. Bands of $^{12}C^{15}N$ will be only one-third as intense, and those of $^{13}C^{15}N$ will be vanishingly small. Because the $^{13}C^{14}N$ and $^{12}C^{15}N$ stretching fundamentals occur in approximately the same spectral region, care must be taken to assign the observed bands correctly.

The observed spectrum in the CN stretching region (Fig.[5] 9) shows four features in the $^{13}C^{14}N$–$^{12}C^{15}N$ region, 2098–2130 cm^{-1}. The lowest-frequency peak, at 2098.2 cm^{-1} (2101.2 cm^{-1})[11] must be due to $^{13}C^{15}N$: if it were due to $^{12}C^{15}N$, a $^{13}C^{14}N$ peak three times more intense would be expected at a frequency 11–17 cm^{-1}

[9]Thus the assumption of correlation field splitting, *i.e.* vibrational coupling for $^{13}C^{14}N$ fundamentals, by Tosi (16) is incorrect.

[10]There are two ways in which the nitroprusside ion can assume C_s or C_{2v} symmetry. A mirror plane σ_d bisects a C—Fe—C angle involving *neighboring* equatorial C atoms (C_2—Fe—C_3 or C_3—Fe—C_4); a mirror plane σ_v bisects a C—Fe—C angle involving *alternating* equatorial C atoms (C_2—Fe—C_4 or C_3—Fe—C_5) and contains the remaining carbon atoms.

[11]Frequencies in parentheses refer to −160°.

TABLE 6. Relative natural abundances and vibrational frequencies of isotopic CN and NO groups

Species	Abundance (%)	Frequency shift (cm^{-1})* Calculated†		Observed
$^{12}C^{14}N$	98.6	0	0	0
$^{13}C^{14}N$	1.10	−45.6	−48.1	−46.3
$^{12}C^{15}N$	0.38	−33.8	−31.1	—
$^{13}C^{15}N$	0.004	−79.8	−79.4	—
$^{14}N^{16}O$	99.4	0	0	0
$^{15}N^{16}O$	0.38	−35.1	−41.1	−31.7
$^{14}N^{18}O$	0.20	−51.3	−39.3	−37.0
$^{14}N^{17}O$	0.04	−26.9	−20.8	—
$^{15}N^{18}O$	0.0008	−87.1	−81.6	—
$^{15}N^{17}O$	0.0002	−62.3	−62.5	—

*The shifts are relative to $^{12}C^{14}N$ stretching frequency of 2172.3 cm^{-1} and $^{14}N^{16}O$ stretching frequency of 1947.0 cm^{-1} (−150°).
†The first column refers to calculation by a harmonic diatomic-molecule approximation (CN or NO); the second column, to calculation by a harmonic linear triatomic-molecule approximation (FeCN or FeNO) neglecting the stretch–stretch interaction force constant.

lower. The corresponding $^{12}C^{15}N$ peak must occur at 2109–2115 (2112–2118) cm^{-1} with about one-third of its intensity. The band observed at 2109.4 (2114.4) cm^{-1} has an intensity comparable with that of the band at 2098.2 cm^{-1}, so it too must be largely due to $^{13}C^{14}N$. The weak shoulder at 2113.5 cm^{-1} (apparently too close to the 2114.4 cm^{-1} band to be resolved at −160 °C) must then arise from $^{12}C^{15}N$ stretching and corresponds to the $^{13}C^{15}N$ band at 2098.2 cm^{-1}. This leads to a $^{12}C^{15}N$–$^{13}C^{14}N$ frequency shift of 16.2 cm^{-1}, a reasonable value compared with a shift of 11.7 cm^{-1} calculated by a diatomic approximation and 17.0 cm^{-1} calculated by a simple triatomic approximation (Table 6).

The band at 2125.2 (2130.0) cm^{-1} lies 15.8 (15.6) cm^{-1} below the $^{13}C^{14}N$ band at 2109.4 (2114.4) cm^{-1}. This is the right value for a $^{12}C^{15}N$–$^{13}C^{14}N$ shift, but the 2125.2 cm^{-1} band is too intense to be due only to $^{12}C^{15}N$. A part of its intensity must therefore come from a $^{13}C^{14}N$ band. There are thus *three* $^{13}C^{14}N$ bands, at 2098.2, 2109.4, and 2125.2 cm^{-1} (2101.1, 2114.4, and 2130.0 cm^{-1} at −160°), with intensities in the approximate ratio 2:2:1. This is the expected intensity ratio if the two bands at lower frequency arise from the equatorial pairs C_3N_3, C_4N_4 and C_2N_2, C_5N_5; the high-frequency band is due to the axial C_1N_1 group. This agrees with the results of the analysis of the $^{12}C^{14}N$ vibrations, which also show that the axial C_1N_1 group has the highest stretching frequency (13, 14, 16).

The presence of three isotopically isolated $^{13}C^{14}N$ stretching bands proves unequivocally that there are three types of CN groups in the nitroprusside ion in SND. The symmetry of the ion must therefore be either $C_{2v}[\sigma_v]$ or $C_s[\sigma_d]$; it is the latter that is compatible with the reported space-group symmetry of SND. From the frequencies of the three bands, $\nu(CN)_{1,3} = 2098.2$ cm^{-1}, $\nu(CN)_{2,4} = 2109.4$ cm^{-1}, and $\nu(CN)_5 = 2125.2$ cm^{-1}, the distortion of the ion from the C_{4v} configuration can be approximately calculated. Badger's rule (25) provides an empirical relationship between the force constant for bond stretching, k_{CN}, and the C—N interatomic distance, r_{CN}

$$r_{CN} = 0.68 + (1.86 \times 10^5/k_{CN})^{1/3}$$

Using the harmonic diatomic approximation for the force constant,

$$k_{CN} = 4\pi^2\mu_{CN}c^2\nu_{CN}^2$$

where $c = 2.998 \times 10^{10}$ cm/s and $\mu_{CN} = 1.1189 \times 10^{-23}$ g, the reduced mass of the $^{13}C^{14}N$ group, the following bond lengths are obtained: $r_1 = 1.149$ Å, $r_{3,4} = 1.152$ Å, $r_{2,5} = 1.154$ Å. The absolute values of these distances have no claim to accuracy, but the relative values indicate that the three crystallographically nonequivalent CN groups have very similar bond lengths. The two pairs of equatorial CN groups differ by only about 0.002 Å, which makes the distortion of the ion, relative to interatomic distances though not necessarily to bond angles, from C_{4v} symmetry very small.

The NO Stretching Fundamental

Cotton *et al.* (7) reported the band at 1944 cm^{-1} as a doublet, 1943 and 1955 cm^{-1}. They attributed the splitting of this fundamental to the existence of "environmentally distinguishable ions in the crystal". This interpretation, which has not been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

discussed by later workers (8–17), cannot be reconciled with the crystal-structure determination, according to which the four nitroprusside ions in the unit cell are equivalent (*cf.* Table 2). In refs. 8–10 the stretching band in the i.r. spectrum has been reported as a singlet. In ref. 13 it has been reported as a peak with a shoulder. In ref. 16 considerable fine structure has been observed in the polarized spectra of single crystals. Our spectra show the band to be a doublet at low temperature (Fig.[5] 10), although it is rather hard to resolve as the separation is only about 3 cm^{-1}, and the band is extremely intense. Thus Cotton's original claim that the band is a doublet is confirmed, although the splitting is much smaller than that reported in ref. 7.

The splitting of the NO stretching band is almost certainly due to correlation field splitting and not to crystallographically nonequivalent NO groups. The NO stretching fundamental is A' under the C_s site-group symmetry and should yield two i.r. active components, B_{2u} and B_{3u}, under the D_{2h} factor-group symmetry of the crystal (13, 16).

An unequivocal proof that all NO groups, and hence all nitroprusside ions, in SND are equivalent is obtained from the number of $^{15}N^{16}O$ and $^{14}N^{18}O$ stretching fundamentals. Table 6 shows that these fundamentals can be expected to occur at 30 to 55 cm^{-1} below the corresponding $^{14}N^{16}O$ fundamental.[12] In our spectrum two bands occur at 1909.1 and 1903.7 cm^{-1} at 25° and at 1915.3 and 1910.0 cm^{-1} at −150°. The temperature shift is the same as that for the main band (1941.0 cm^{-1} at 25° and 1947.0 cm^{-1} at −150°) as expected for satellite bands. There is little doubt that the two small bands should be assigned to $^{15}N^{16}O$ and $^{14}N^{18}O$ stretching, as their intensities are consistent with the natural abundances of ^{15}N and ^{18}O.[13] The occurrence of only one $^{15}N^{16}O$ and only one $^{14}N^{18}O$ stretching fundamental confirms that all the NO groups in the crystal belong to one crystallographic type.

[12]The calculated shifts for the isotopic NO species differ by as much as 12 cm^{-1}, depending on the model assumed, and so are uncertain by a similar amount.

[13]These bands are clearly visible in the spectrum of ref. 8, but were not assigned. They were correctly assigned in refs. 13 and 15, but no structural deductions were drawn from them. In ref. 16 both bands were incorrectly assigned to $^{15}N^{16}O$.

Conclusions

The results of the present i.r. study of SND are consistent with the conclusions from Manoharan and Hamilton's crystal-structure determination. In particular:

(*1*) The equivalence of the water molecules and their site symmetry C_1 are confirmed.

(*2*) The symmetry of the water molecule deviates considerably from C_{2v}: the uncoupled stretching frequencies of isotopically dilute HDO are 3603 and 3569 cm^{-1} for OH, and 2654 and 2630 cm^{-1} for OD.

(*3*) It is very likely that both O_w—H bonds of the water molecule point toward CN groups (or their N atoms), each CN group belonging to a different nitroprusside ion. One of the two O_w—H···N distances is significantly greater than the other, which explains the dissimilarity of the uncoupled OH (and OD) stretching frequencies.

(*4*) The two N atoms which we believe are involved in the O_w—H···N bonds do not correspond to those thought to be so involved in ref. 1. While the shorter of the two distances appears to be 3.27 Å in both descriptions, the longer distance is taken to be 3.36 Å in ref. 1 but 3.63 Å in the present work. Thus the difference between an O_w—H···N interaction at 3.27 Å and what must be a *very* weak interaction at 3.63 Å corresponds to 34 (24) cm^{-1} in the uncoupled OH (OD) stretching frequency. The frequency of the fundamental corresponding to the longer bond is the highest so far reported; high stretching frequencies appear to be typical of water in hydrates of cyano complexes

(*5*) The equivalence of the nitroprusside ions is confirmed. The symmetry of the ion, $[Fe(CN)_5NO]^{2-}$, must be either $C_s[\sigma_d]$ or $C_{2v}[\sigma_v]$, consistent with the site symmetry $C_s[\sigma_d]$ required by the crystal structure. The deviation from the C_{4v} symmetry of the idealized ion has been estimated to be very small, at least so far as the CN bond lengths are concerned. Minor isotopic bands have been found useful for structural deductions.

Oxidation of Pentoses in Alkaline Solution[1]

W. B. GLEASON AND R. BARKER
Department of Biochemistry, The University of Iowa, Iowa City, Iowa 52240

Received August 6, 1970

The reaction of pentoses with oxygen in dilute aqueous potassium hydroxide at 25.00 ± 0.05° has been studied by determining the initial rate of oxygen uptake and the rate of disappearance of reducing sugar. Pentose reactivity decreased through the series: D-xylose (2.0), D-ribose (1.4), L-arabinose (1.2), D-lyxose (1.0). The products formed were identified by paper chromatography, isolation, and n.m.r. spectroscopy. In all cases less than one molar equivalent of tetronic acid is produced. The results are discussed with reference to recent studies on the behavior of sugars in alkaline solution. The reaction of pentoses with oxygen in 0.5 *M* sodium carbonate at 25.00 ± 0.05° was also studied. The order of pentose reactivity in this system was changed to D-ribose (5.7), D-lyxose (2.2), D-xylose (1.9), L-arabinose (1.0).

On a étudié la vitesse de réaction des pentoses avec l'oxygène à 25.00 ± 0.05 °C en présence d'hydroxyde de potassium en solution aqueuse diluée; les mesures ont été effectuées en déterminant le taux initial d'absorption d'oxygène et le taux de disparition du sucre réducteur. La réactivité des pentoses diminue dans l'ordre suivant: D-xylose (2.0) D-ribose (1.4), L-arabinose (1.2), et D-lyxose (1.0). On a identifié les produits formés, et isolés, par chromatographie sur papier et spectroscopie r.m.n. Dans tous les cas la quantité d'acide tétronique produite correspond à moins d'un équivalent. On discute les résultats en fonction d'études récentes sur le comportement des sucres en milieu alcalin. On a aussi étudié la réaction des pentoses avec l'oxygène, à 25.00 ± 0.05 °C, en présence de solutions 0.5 *M* de carbonate de sodium. L'ordre de la réactivité des pentoses dans ce système est maintenant D-ribose (5.7), D-lyxose (2.2), D-xylose (1.9), L-arabinose (1.0).

Canadian Journal of Chemistry, 49, 1425 (1971)

Introduction

Our original goal was to develop a preparative synthesis of the D- and L-forms of erythronic and threonic acids because of the potential of their phosphorylated derivatives as substrate analogs for enolase (1, 2). Oxidation of pentoses in alkaline solution appeared to be a good route since pentoses with the desired configuration at C-3 and -4 are readily available.

Nef and his students (3) described a degradation of L-arabinose and D-xylose in which an alkaline solution of the pentose was aerated yielding formic, glycollic, glyceric, and tetronic acids as major products. In an analogous degradation of D-glucose, Spengler and Pfannenstiehl (4) showed that the yield of arabinonic acid was much increased when pure oxygen was used rather than air. Isbell (5), in an attempt to increase the yield of tetronic acids from pentoses, studied the alkaline degradation with pure oxygen, but succeeded in increasing Nef's yields only slightly. Hardegger *et al.* (6) have also described the synthesis of tetronic acids in yields of about 40% by oxygenation of an alkaline pentose solution.

In alkali, sugars undergo isomerization, internal oxidation–reduction reactions, and rearrangements of the carbon skeleton. Perhaps the best known of these transformations is the isomerization of glucose to fructose and mannose first described by Lobry de Bruyn and Alberda von Ekenstein (7), which is commonly considered to proceed with the initial formation of an enediol (8). Another well-known sugar rearrangement, that of saccharinic acid formation, is generally considered to proceed by the Nef-Isbell (9) mechanism which also invokes initial formation of an enediol.

A plausible reaction scheme involving enediol intermediates that might account for the main products of oxygenation of a basic pentose solution is given in Scheme 1. Similar schemes have been proposed by Dubourg and Naffa (10) and by Bamford and coworkers (11) for the oxidation of hexoses. This mechanism requires that the molar amount of formic acid produced should equal that of tetronic acid, that the molar amount of glyceric acid should equal glycollic acid, and that with a great excess of oxygen the only products should be formic and tetronic acids.

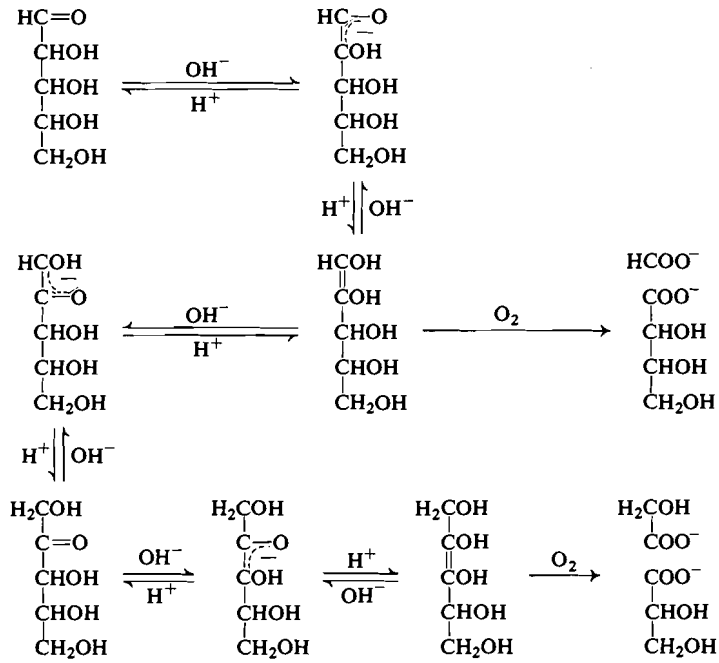

SCHEME 1

However, it was found that these compounds were never formed exclusively, even in very dilute sugar solutions with an oxygen pressure of 50 p.s.i. This finding casts doubt on a mechanism as simple as that of Scheme 1 and led us to study the initial rate of oxygen uptake and reducing sugar disappearance for the pentoses as well as the product distribution. Studies were also made of the behavior of D-ribose-2-*t* in alkali, the subject of the following paper.

Experimental

Pentoses were obtained from Pfansteihl Laboratories (Waukegan, Illinois) with the exception of D-lyxose which was prepared by Ruff degradation of calcium D-galactonate (12). The sugars were dried over phosphorus pentoxide under vacuum before use.

Rate of Initial Oxygen Uptake for the Pentoses

Oxygen uptake was measured by Warburg manometric technique (13) using the ferricyanide–hydrazine system for evaluation of flask constants. The Bunsen coefficient for oxygen in 0.833 *M* potassium hydroxide was obtained by interpolation of the data presented in the International Critical Tables. Temperature was maintained at 25.00 ± 0.05° and the shaking rate was 110 c.p.m. The sugar solution (0.5 ml) was placed in the Warburg flask side-arm and 2.5 ml of standard base in the main compartment. The concentrations of sugar solutions ranged from 6.6×10^{-5} to 5.68×10^{-1} *M*. For experiments in carbonate solution 0.6 *M* sodium carbonate was used in the main compartment of the Warburg flask and 1.2 *M* sugar solution in the side-arm.

Rate of Reducing Sugar Disappearance

Standard base (95.0 ml) was equilibrated with oxygen in a vessel which was connected to an oxygen reservoir. The system was alternately filled with oxygen and evacuated to remove air and then filled with oxygen to a final pressure of 1 atm. The vessel was shaken vigorously in a water bath at 25.00 ± 0.05°.

A calibrated syringe was used to inject 5.0 ml of a sugar solution through a side-arm fitted with a rubber septum. Concentrations of sugar solutions ranged from 1.32 to 2.24 *M* and were selected to give the same final concentrations as in the oxidation experiments. Samples of approximately 5 ml were removed with a syringe through the side-arm at various times.

An aliquot of the sample was placed in a 5 ml volumetric flask containing 0.1 ml of 0.05% bromocresol green and 2.0 ml of 1 *M* hydrochloric acid to stop the reaction and then back-titrated to green with 0.1 *M* potassium hydroxide and the final volume adjusted with water. The reducing sugar present in the sample was determined by the dinitrosalicylate method (14). First-order rate constants were calculated by a least squares fit of the data.

Determination of Formate by Nuclear Magnetic Resonance Spectroscopy

A 100 ml sample of reaction mixture was passed slowly over a small (1 × 10 cm) column of Rexyn 201 (OH^-) and then the column was washed with 200 ml of water. Acids were eluted with 90 ml of *M* potassium hydroxide. The eluate was passed through a column (3 × 60 cm) of Dowex 50 (H^+) to give a strongly acidic solution free of reducing sugars. To a sample of the acidic eluate containing approximately 2.0 mmol of acid was added 0.500 mmol of malonic acid. The mixture was brought to

p*H* 6.5 with pyridine and concentrated to dryness at reduced pressure. The sample was dissolved in 0.5 ml pyridine to obtain the n.m.r. spectrum. The absorption peaks were separated sufficiently at a sweep width of 100 Hz to allow their complete resolution with a DuPont curve analyzer.

Preparation of Erythro- and Threonolactones

A 0.05 *M* solution of the appropriate pentose in 0.15 *M* aqueous potassium hydroxide was shaken in a 2 l bottle under an atmosphere of oxygen on a Parr pressure reaction apparatus at room temperature. After 40 h the reaction mixture was passed over a column containing 100 ml of Rexyn 101 (H^+) to remove cations and then over a column containing 200 ml of Rexyn 201 (OH^-) to remove the acidic products. The eluate from this column contains the unreacted and transformed neutral sugars. The Rexyn 201 column was eluted with *M* potassium hydroxide and the alkaline eluate containing the acid products was passed over a column of Rexyn 101 (H^+) to remove potassium. The acidic eluate from this column was concentrated several times from water to remove formic acid and then to a sirup and heated at 80° for 2 h to promote the formation of lactones. The acidic sirup was dissolved in water and passed over a column containing 50 ml of Rexyn 203 (HCO_3^-) to remove acids and the neutral eluate containing lactones was concentrated to dryness. Crystalline D-erythronolactone was obtained from D-ribose in 40% overall yield and crystalline D-threonolactone was obtained from D-xylose in 38% overall yield by this procedure.

Results and Discussion

The experimental rates of oxygen uptake for the pentoses in 0.833 *M* KOH at 25.00 ± 0.05° are given in Table 1. To demonstrate that these data reflect the rate of oxygen uptake for the pentoses, it must be shown that diffusion of oxygen into the solution is not rate-limiting. This was accomplished by varying the concentration of sugar. If the amount of oxygen taken up per h per mol of sugar is the same at various levels of sugar concentration, then oxygen diffusion into solution is not rate-limiting. The experimental results indicate that the measured rate of oxygen uptake (expressed as mol O_2/mol/h) is constant over the range of concentrations studied and oxygen diffusion is not rate limiting in the experiments reported here. Within experimental error, three of the pentoses showed strictly first-order oxygen uptake. D-Lyxose, the only sugar not obtained from a commercial source, did not. With this sugar an initial fast reaction was observed equivalent to the oxidation of 0.2% of the D-lyxose present. The fast reaction was followed by a slower, constant rate of oxygen uptake. The initial fast reaction is probably due to the presence of a small amount of impurity in the sample. The first preparation was quite brown and was decolorized with charcoal repeatedly and recrystallized from ethanol. The final preparation has an absorption (6.0 mg/ml) of 0.05 at 287 nm and showed a smaller rapid initial oxygen uptake. On this basis the rate of oxygen uptake for D-lyxose was computed from the period of slower oxygen uptake.

Pseudo-first order rate constants for the disappearance of reducing sugar at 25.00 ± 0.05° in 0.833 *M* potassium hydroxide are given in Table 1. It can be seen that the relative rate of disappearance of the pentoses agrees well with their relative rates of oxygen uptake; however, the relative reactivities of the pentoses was at first surprising because it differed significantly from the relative rates of enolization reported by Isbell and co-workers (15) who studied the uptake of

tritium by sugars in 0.5 *M* aqueous sodium carbonate. MacLaurin and Green (16) also found recently that the relative reactivities of glucose (1.0), fructose (3.0), and mannose (0.3) in interconversion reactions conducted in 1 *N* sodium hydroxide at 22° differed from rates of enolization reported by Isbell who found relative rates to be, glucose (1.0), fructose (10.7), and mannose (0.5) in 0.5 *M* sodium carbonate solution. Isbell *et al.* (15) found that ketoses, such as fructose, take up tritium faster than aldoses, and they suggested that this may be due to the reversible formation from the ketoses of glyceraldehyde and its enediol, to the presence of three replaceable hydrogens α to the carbonyl group, and to the possibility of a β-elimination reaction leading to an unsaturated sugar that can rearrange with hydrogen incorporation. Since a pentose could be converted to a ketose the figures given for tritium uptake of the pentoses may not reflect the primary rate of enolization alone. It is probable, however, that the tritium uptake in the early stages of the reaction is related to enolization rates. In this study 0.833 *M* potassium hydroxide and oxygen was used, whereas Isbell and co-workers used 0.5 *M* aqueous sodium carbonate under anaerobic conditions and it is possible that this difference alters the relative reactivities of the sugars.

That relative reactivities depend upon the conditions of the oxidation was shown by a study of the rates of oxygen uptake by the pentoses, glucose, and fructose in the carbonate system. The results are shown in Fig. 1 and Table 2. The rates given in Table 2 are maximum oxidation rates; those observed after the induction period apparent in Fig. 1. The agreement between the relative rates obtained by oxidation and by tritium uptake (Isbell *et al.* (15)) is quite good; however, the values for absolute rates are consistently higher for oxygen uptake than for tritium incorporation. It is possible that this difference is due to a dis-

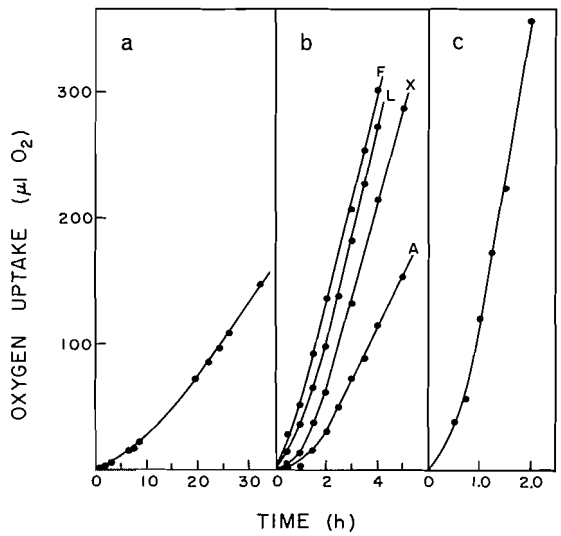

FIG. 1. The uptake of oxygen by 0.2 *M* sugars in 0.5 *M* sodium carbonate at 25°. a, D-glucose; b, F = D-fructose, L = D-lyxose, X = D-xylose, A = L-arabinose; c, D-ribose.

crimination against tritium incorporation from the solvent resulting in an under-estimation of the enolization rate by the method of Isbell *et al.* The agreement between the data presented here and that obtained by Isbell *et al.* (15) is good enough for us to conclude that both are measuring the same event and it seems reasonable to conclude, in agreement with others (10, 11), that an enolate anion is the species attacked by oxygen. A striking feature present in our data is the induction period which occurred for all of the sugars examined. Isbell *et al.* (15) did observe an increase with time in the rate of tritium uptake for D-glucose and certain other sugars and in most cases they obtained rates from observations made before the rate increase was significant, however, the induction period shown in Fig. 1 for the pentoses would have ended. We cannot explain this induction period, but it must be accounted for

in any mechanistic hypothesis. Bamford *et al.* (11) have reported that oxygen uptake by glucose in aqueous sodium hydroxide begins immediately and is first order. Our experiments on oxygen uptake by the pentoses in aqueous potassium hydroxide also lack an induction period; however, it is possible that a very short induction period is present in the reactions occurring in strong alkali. Tentative evidence that this may be the case is provided by our observation that in 0.2 *M* potassium hydroxide under anaerobic conditions D-ribose and D-xylose develop a strong absorbance at 305 nm that shows an induction period of approximately 5 min.

The occurrence of an induction period in the oxidation of sugars in 0.5 *M* sodium carbonate solution (p*H* 11) implies that the species derived from the sugar which is attacked by oxygen is formed in a multi-step process from the starting sugar. It is unlikely that mutarotation is a step of significance in limiting the rate of oxidation under these conditions although it may be that the species from which the oxidizable intermediate is derived is produced by mutarotation. It is more probable that an intermediate formed by ionization of a hydroxyl group (perhaps that at C-2) rearranges to an enolate anion which is susceptible to oxidation and that this rearrangement is responsible for the induction period. Differences in rate then would be due to differences in the ease with which the oxidizable species is formed. The differences in rate do not correspond to the differences in rate of mutarotation (17) or to the relative amounts of various tautomers present in solution (18).

Alternatively, the induction period could be due to the oxidation being a radical reaction that is initiated by the carbohydrate and becomes autocatalytic. Bamford *et al.* (11) were unsuccessful in accelerating the reaction by using free radical initiators; however, evidence for a free radical mechanism by initiation techniques may be difficult to obtain because of reaction of the initiator with oxygen.

The relative rates of oxidation of the pentoses in 0.833 *M* potassium hydroxide differ from those in 0.5 *M* sodium carbonate. If the hydroxide ion concentration is the only important difference between the two systems, then the two systems should yield the same relative reactivities with a series of sugars. The oxidation reaction is not first-order with respect to hydroxide ion. The carbonate system (p*H* 11.0) is equivalent to a hydroxide concentration of 0.001 *M*, but the rates of oxidation of the pentoses are only a factor of 3.5 to 17 lower than in 0.883 *M* potassium hydroxide. Similarly, when 0.02 *M* D-xylose is oxidized in 0.05 *M* potassium hydroxide at 25°, a rate of 0.06 mol of oxygen $mol^{-1}\ h^{-1}$ is observed compared to a rate of 0.08 mol of oxygen $mol^{-1}\ h^{-1}$ in 0.883 *M* potassium hydroxide. Although the carbonate ion may act as a base in catalyzing the reaction, the results with D-xylose in potassium hydroxide clearly demonstrate that the reaction is not first-order with respect to hydroxide ion. This finding does not explain the differences in relative rates since if the same rate-limiting step is involved in each case, the effect of configuration on that step should be a constant regardless of the order with respect to hydroxide ion. Nor can the differences be explained on the basis that different pK_a values of the pentoses determine the amount of ionic forms present that are capable of rearrangement, since the pK_a values of lyxose and ribose are identical and are not very different from that of xylose (19). Using the published pK_a values of the pentoses (19) and the assumptions that the rates measured in 0.833 *M* potassium hydroxide are maximum values, relative rates for the carbonate system can be calculated. They are L-arabinose, 1.0; D-lyxose, 2.2; D-ribose, 2.5; D-xylose, 2.9. Both D-ribose and D-xylose differ significantly from the observed values. Thus, the change in relative rates cannot be related to any obvious parameter and may reflect a specific effect of the carbonate ion or a change in mechanism with change in hydroxide ion concentration.

The carbonate system, although of great theoretical interest, does not lend itself to studies on degradations because of the slowness of reaction and an examination of reaction products was conducted only for the potassium hydroxide system.

In Fig. 2*a* is shown the n.m.r. spectrum of a complete xylose oxidation mixture after 8 h with added acetate as an internal standard. The acetate peak E is well separated from the complex part of the spectrum D which is due to the α- and β-pyranose forms of D-xylose, plus the acidic products. The peak C is due to HOD; the singlet A is due to formate. In Fig. 2*b* is shown the simplification that occurs when xylose is removed from such a mixture. In this spectrum C is due to the complex mixture of acidic products. Although apparently better resolution of the still complex

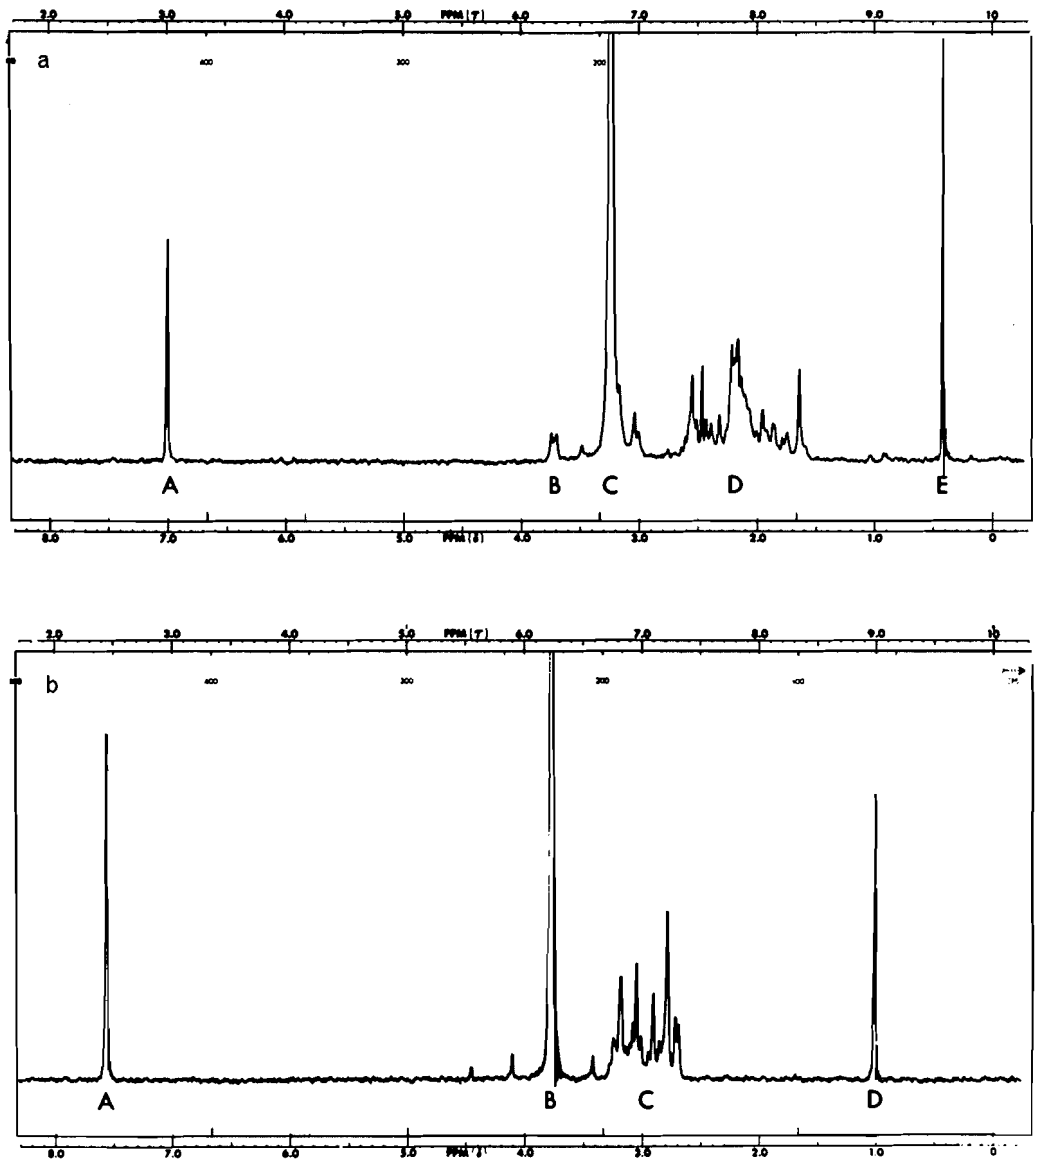

FIG. 2. The 60 MHz p.m.r. spectra of D-xylose oxidation reaction mixtures at 50% reaction. *a*, Total mixture with added acetate, A, formate; B, anomeric protons; C, HOD; D, non-exchangeable protons of xylose and acidic products. *b*, Acidic products only, A, formate; B, HOD; C, non-exchangeable protons of acidic products; D, acetate.

mixture of acidic products can be obtained by adding sulfuric acid, the tetronic acids lactonize making interpretation difficult. When pyridine is used as the solvent, the resolution at 100 Hz sweep width is good enough for product quantitation. In Fig. 3*a* is shown a standard mixture in pyridine of the acidic products from a xylose oxidation reaction with malonic acid added as an internal standard for quantification. The identification of peaks was made by running authentic samples individually. The doublet A is due to the C-2 proton of threonic acid split by the protons at C-3. Peak B is due to the methylene protons of glycollic acid. Peak C is a composite of the signals of the methylene protons of glyceric acid and threonic acid. In both acids the methylene proton peaks are doublets because there is a proton on the penultimate carbon. Quantitation can be achieved

by careful integration with a planimeter and by calculating the proportions of the various acids relative to the total acids from the peaks that characterize them. The proportion of glyceric acid was calculated from peak C by subtracting out 2 × the area of peak A. When erythronic acid is in the reaction mixture, the same procedure is used.

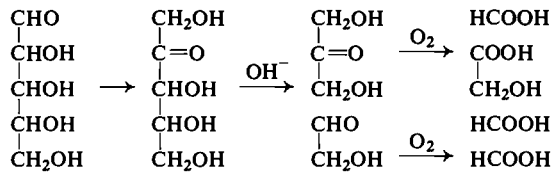
Mixtures of known amounts of acids were used to test the experimental procedure. Results from such experiments are given in Table 3. When the only products present are the acids of the synthetic reaction mixture, the results are highly reproducible; however, by paper chromatography in *n*-butanol : formic acid : water (*n*5:10:15) it was shown that there are other reaction products present, probably in small amounts. Thus, in the analysis of the reaction mixture, the amounts given are upper limits.

The n.m.r. analysis of pentose oxidation mixtures given in Table 4 indicates that with ribose, arabinose and lyxose there must be a source of formic acid other than the cleavage of a five carbon 1,2-enediol, since the molar proportions of formic acid and tetronic acid exceed the ratio of one predicted if the cleavage of that intermediate is the source of formic acid. Erythronic and threonic acids are stable under the conditions of the reaction. For example, when erythronic acid (5.05 mmol) was exposed to oxidizing conditions in 100 ml of 0.833 *M* KOH, no breakdown could be detected during 17 h. Thus, the formation of formic acid in a molar amount significantly greater than tetronic acid is not due to the breakdown of the latter.

TABLE 3. Quantitation of a synthetic reaction mixture by n.m.r.

	Actual (mmol)	Found (mmol)
Formate	1.15	1.15
Erythronate	0.69	0.68
Glycollate	0.36	0.38
Glycerate	0.31	0.31
Formate	1.41	1.42
Threonate	0.25	0.23
Glycollate	0.91	0.87
Glycerate	1.22	1.29

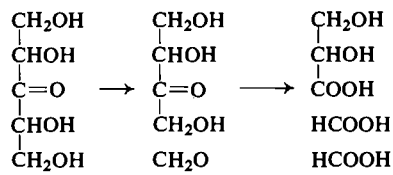
Excess formate might arise from oxidation of the products of a reverse aldol reaction as in Scheme 2.



SCHEME 2

In this sequence glycollic acid is produced in excess of the molar amount of glyceric acid. This route cannot be ruled out in the case of arabinose, but for xylose, ribose, and lyxose apparently it is not a reaction of importance since for these sugars the ratio of glycollate to glycerate is close to unity.

If a 3-pentulose is formed, the reaction in Scheme 3 could result. If Schemes 2 and 3 both occurred to a similar extent, the molar amounts of glyceric and glycollic acid could be reasonably close.



SCHEME 3

Similar conclusions concerning an alternative to the simple enolization mechanism were drawn by Dubourg and Naffa (10) from their studies on the oxidation of glucose in alkaline solution. There is, however, a dilemma regarding the nature and source of the compound which undergoes fragmentation. In the original reverse aldol mechanism of Schmidt (20) the initial formation of an enediol was postulated which should be oxygenated if enediols are the susceptible species. Isbell (21) has suggested that the reverse aldol may occur via a ketose; however, this requires that

the ketose be formed by other than an enolization mechanism.

Although the consensus seems to be that the Lobry de Bruyn – Alberda von Ekenstein reaction occurs by an enolization mechanism, there have been suggestions that a hydride transfer may operate under certain circumstances. Thus, Gutsche *et al.* (22) have drawn attention to the fact that glyceraldehyde in pyridine isomerizes to dihydroxyacetone but no aldolization occurs. Since an enolate anion is supposed to be involved in the aldol condensation, the failure of aldolization to occur in this reaction is puzzling. Thus, it was suggested that either pyridine interferes in some way with the aldolization step or that a route exists for interconversions which does not involve the formation of an enolate ion, namely a hydride transfer. Precedent was taken from the Cannizzaro reaction, the benzylic acid rearrangement and the base-catalyzed rearrangement of α-dicarbonyls.

Another observation that may be relevant is the report of Fodor and Saccheto (23) that in slightly alkaline D_2O, glucose-3-phosphate was converted to a 3-deoxyketose with no incorporation of deuterium. This behavior was interpreted in favor of a hydride shift mechanism.

It seems that a simple enolization scheme cannot account satisfactorily for the product distribution observed, nor for the inability to obtain exclusive cleavage of a 1,2-enediol even in very dilute alkali. These findings led us to investigate this reaction further by studying the oxidation of D-ribose labeled with tritium at C-2 (24).

Evidence for a Hydride Shift in the Alkaline Rearrangements of D-Ribose[1]

W. B. GLEASON AND R. BARKER
Department of Biochemistry, The University of Iowa, Iowa City, Iowa 52240

Received August 6, 1970

The synthesis of D-ribose-2-t from D-arabinose is described and its conversions in aqueous alkali in the presence and absence of oxygen reported. In both situations a significant amount of label is transferred from C-2 to -1 and a relatively small proportion is released to the solvent. It is concluded that hydride transfer is occurring and that enolization, which requires the loss of hydrogen from C-2, is not an obligatory first step in base-catalyzed rearrangements of D-ribose.

On décrit une synthèse du D-ribose-2-*t* à partir du D-arabinose et on rapporte ce qui lui survient en milieu alcalin en présence et en l'absence d'oxygène. Dans chaque cas une quantité significative de tritium est transférée du C-2 au -1 et une faible proportion se retrouve dans le solvant. On en conclut qu'un transfert d'hydrure se produit et qu'une enolisation, qui implique une pente d'hydrogène du C-2, n'est pas nécessairement la première étape lors du réarrangement du D-ribose au milieu alcalin.

Canadian Journal of Chemistry, **49**, 1433 (1971)

Introduction

In the preceding paper (1) circumstantial evidence was presented that the pentoses in aqueous potassium hydroxide, in the presence of oxygen, cannot react only by a simple enolization mechanism initiated by abstraction of the hydrogen at C-2. To further test this conclusion, we have studied the behavior of D-ribose-2-*t* in aqueous potassium hydroxide under both aerobic and anaerobic conditions.

Experimental

The n.m.r. spectra were obtained on a Varian A-60 spectrometer and i.r. spectra were obtained on a Perkin–Elmer Model 521. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tennessee. Evaporations were carried out at water-aspirator pressure. Melting points are corrected.

A Beckman LS-100 scintillation counter equipped with automatic external standardization was used for radioactivity determination. Aqueous samples were added in a volume of 0.100 to 10.0 ml of scintillation fluid containing 5 g PPO and 100 g napthalene with dioxane added to make 1 l. Water insoluble samples were added directly to the scintillation fluid and then 0.100 ml H_2O added to this mixture.

Gas chromatographic analyses were performed using a Varian Aerograph Hy-Fi, Model 600 D, with a flame ionization detector (hydrogen flow rate of 30 ml/min). The column was 1/8 in. × 6 ft copper tubing packed with 10% Hi-eff-3-CP (Applied Sciences Laboratories, Inc.) with helium carrier gas at 30 ml/min. Silyl derivatives were prepared by dissolving 10 mg of material in 0.5 ml pyridine and adding 0.2 ml hexamethyl disilazane and 0.1 ml trimethylchlorosilane (Applied Sciences Laboratories). The derivative mixture (2 μl) was injected after 10 min. Acetylated derivatives were prepared by warming a 10 mg sample in 0.5 ml pyridine and acetic anhydride (1:1) for 30 min. Peak areas were determined by planimetry.

The t.l.c. was carried out on plates prepared with Silica gel G (Merck) using isopropyl ether as solvent. Spots were visualized by spraying with 10% sulfuric acid and heating at 110° for 5 min.

Acidic products were separated by paper chromatography on Whatman 3MM paper to which a wick of Whatman 1 (10 × 57 cm) had been sewn. The freshly prepared solvent, *n*-butanol : formic acid : water (75:10:15), gave an adequate separation provided that samples of 100 mg or less were used. Standards of glyceric (R_f = 0.46), glycollic (R_f = 0.61), and erythronic or threonic (R_f = 0.31) acids were applied 3 cm from each edge and were used to locate the main reaction components. Acidic compounds could be located as yellow spots on a blue background with the indicator bromocresol green (0.05%) in slightly alkaline ethanol if the chromatograms were allowed to dry for several days to free them of formic acid. Alternate cycles of steaming and drying at 100° in an oven was used also to remove formic acid more rapidly.

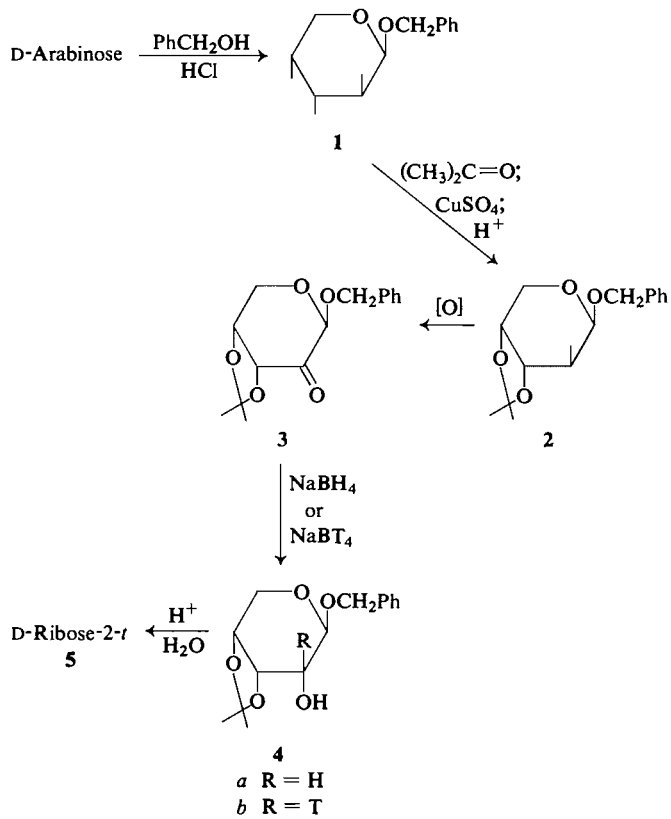
For quantitation of the reaction products, strips were cut from the chromatogram and eluted with water. The eluted acids were titrated to p*H* 7.0 with 0.050 *M* potassium hydroxide. In cases where lactonization had occurred (indicated by a rapidly fading end-point) an excess of alkali was added and the sample was back titrated with 0.050 *M* hydrochloric acid to determine the total amount of acid and lactone.

Benzyl 3,4-O-Isopropylidene-β-D-ribopyranoside (4)

(A) By Dimethyl Sulfoxide – Acetic Anhydride Oxidation

The reaction sequence used to synthesize this compound is shown in Scheme 1. D-Arabinose was converted

[1]Supported in part by a Public Health Service Grant (HD 02618) from the Institute of Child Health and Human Development and an NSF Predoctoral Fellowship to W.B.G.



SCHEME 1

to benzyl β-D-arabinopyranoside (**1**) by the method of McCormick (2). Benzyl 3,4-*O*-isopropylidene-β-D-arabinopyranoside (**2**) was prepared from (**1**) by the method of Ballou (3).

Benzyl 3,4-*O*-isopropylidene-β-D-arabinopyranoside (**2**), 3.0 g, was oxidized in a mixture of 30 ml dimethylsulfoxide and 20 ml acetic anhydride (4). The progress of the reaction was monitored by t.l.c.; the starting material had $R_f = 0.15$. After 8 h reaction two new spots of about equal intensity appeared with $R_f = 0.37$ and 0.46. After 24 h only the two product spots were present. At this time the reaction mixture was quite yellow. Dimethylsulfoxide and acetic anhydride were removed by evaporation at 55°. The residue, a thin sirup, was reduced at 0° in 150 ml ethanol–water (3:1) using 3 g sodium borohydride. After 2 h acetic acid was added to destroy the excess borohydride and the reaction mixture was passed over 70 ml Rexyn 101 (H^+) and the eluate evaporated to dryness. Finally, boric acid was removed as its volatile methyl ester by three evaporations from 100 ml portions of methanol.

The t.l.c. of the mixture indicated that material of $R_f = 0.46$ was still present, but that the material of $R_f = 0.37$ had disappeared and a new spot with R_f approximately equal to that of the starting material had appeared. The mixture was dissolved in 15 ml ether and petroleum ether added to turbidity. After several hours at 4°, a cotton-like precipitate was removed by filtration and the filtrate was evaporated to dryness. The residue was dissolved in a minimum amount of absolute ethanol and petroleum ether was added to produce turbidity. The product, **4***a*, 1.25 g (41% from **2**), could be recrystallized from ether – petroleum ether and melted at 94–96°; $[\alpha]_D^{25} -105 \pm 5°$ (*c* 3.1, EtOH). Follmann and Hogenkamp report m.p. 92–94° (5). The n.m.r. data: τ 2.65 (singlet, 5 protons, phenyl ring hydrogens); 5.06 (doublet, 1 proton H-1, $J_{1,2}$ 3.5 Hz); 5.20, 5.36, and 5.55 (multiplet, 3 protons, H-2, -3, and -4); 6.20 (multiplet, 4 protons, H_2-5 and benzyl methylene hydrogens); 2.47 and 2.63 (singlets, 6 protons, acetal methyl hydrogens).

Anal. Calcd. for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19. Found: C, 64.27; H, 7.29.

The cotton-like precipitate which was removed from the product by filtration as described above proved to be a methylthiomethyl ether, presumably benzyl 3,4-*O*-isopropylidene-2-*O*-methylthiomethyl-β-D-arabinopyranoside. It could be isolated in yields of approximately 40% and crystallized readily from ether – petroleum ether. It melted at 43.8–45°; $[\alpha]_D^{25} -175 \pm 8°$ (*c* 1.2, EtOH). The n.m.r. data: τ 2.67 (singlet, 5 protons, phenyl ring hydrogens); 5.06 (doublet, 1 proton, H-1, $J_{1,2}$ 3.3 Hz); 5.23, 5.31, and 5.39 (multiplet, 3 protons, H-2, -3, and -4); 5.76 (singlet, 2 protons, methylthiomethyl methylene hydrogens); 6.06 (multiplet, 4 protons, H_2-5 and benzyl

methylene hydrogens); 2.47 and 2.67 (singlets, 6 protons, acetal methyl hydrogens).

Anal. Calcd. for $C_{17}H_{24}O_5S$: C, 59.97; H, 7.11; S, 9.42. Found: C, 59.90; H, 6.98; S, 9.28.

This compound proved to be the material of $R_f = 0.46$ observed in thin layer chromatograms of the reaction mixture.

(B) Alternate Oxidation Procedures

Because the dimethyl sulfoxide – acetic anhydride oxidation gave such a large amount of side-product, other oxidation methods were investigated.

(1) Pfitzner–Moffat Oxidation (6)

Benzyl 3,4-*O*-isopropylidene-β-D-arabinopyranoside (837 mg) was added to a mixture of 1.85 g dicyclohexylcarbodiimide (DCC), 5 ml dimethylsulfoxide, 10 ml benzene, 0.24 ml pyridine, and 0.12 ml trifluoroacetic acid. After 24 h, benzene was removed by evaporation and 20 ml water added to the reaction mixture. After 2 h the DCC had been converted to insoluble dicyclohexylurea, which was removed by filtration. The filtrate was evaporated to a sirup and extracted three times with 10 ml portions of chloroform. The chloroform extract was dried to a sirup. This sirup was applied to a 60 × 1.5 cm column of silica gel (60–200 mesh, W. R. Grace and Co.) and eluted with isopropyl ether, 3 ml fractions were collected at a flow rate of 0.2 ml per min. The first peak, found in fractions 1–14, contained at least three components as judged by t.l.c. Fractions 14–30 contained only the product, **3**: overall yield 38–42%.

(2) Catalytic Ruthenium Dioxide – Sodium Metaperiodate Oxidation (7)

Benzyl 3,4-*O*-isopropylidene-β-D-arabinopyranoside (1.0 g) was dissolved in 20 ml carbon tetrachloride containing 20 mg of ruthenium dioxide (Englehard Industry). Sodium metaperiodate (5%) was added by a burette to a rapidly stirred solution. The p*H* was maintained between 6.0 and 7.0 by the addition of dilute sodium bicarbonate. After 3 h and the addition of 23 ml of periodate, the end of the reaction was signalled by a permanent yellow ruthenium tetroxide color which was not darkened by conversion to the dioxide. The excess oxidant was destroyed by adding *n*-propanol. The organic layer was removed, filtered, and evaporated to a colorless sirup (0.78 g) which gave one spot on t.l c ($R_f = 0.37$ in isopropyl ether) and a carbonyl absorption (5.8 μ) in the i.r.

Benzyl 3,4-O-isopropylidene-β-D-ribopyranoside-2-t (4)

Benzyl 3,4-*O*-isopropylidene-β-D-*erythro*-pentopyranos-2-uloside (150 mg) was dissolved in a mixture of 7.5 ml ethanol (distilled from 2,4-dinitrophenol) and 5 ml distilled water. Sodium borohydride-*t* (3 mg, New England Nuclear, 200 mc/mmol), dissolved in 5 ml H_2O, was added drop by drop. The solution was allowed to stand overnight at 4° and then 25 mg of unlabeled borohydride was added. The t.l.c. indicated complete reduction. The reaction mixture was partitioned between ether and water; the ether extracts were evaporated at reduced pressure, and the residue was taken-up in a small volume of ether and 1.5 g of unlabeled benzyl 3,4-*O*-isopropylidene-β-D-ribopyranoside was added. The addition of petroleum ether gave 1.40 g of chromatographically pure product which had a specific activity of 0.232 mc/mmol, a radiochemical yield of 77%.

D-*Ribose-2-t*

Benzyl 3,4-*O*-isopropylidene-β-D-ribopyranoside-2-*t* (250 mg) was hydrolyzed with 10 ml of 1 *N* HCl at 100° for 3 h. The reaction mixture was passed through Rexyn 203 (OH^-) and 6 g unlabeled D-ribose was added to the eluate as carrier. After removal of the solvent the product was recrystallized three times from ethanol to a constant specific activity of 4.14 μCi/mmol; 4.0 g of material equivalent to a radiochemical yield of 54% was obtained.

To show that label was present only at C-2 the following experiments were performed. D-Ribose-2-*t* was reduced with borohydride to ribitol which then was oxidized with periodic acid – bicarbonate as described by Reeves (8) and the dimedon derivative of formaldehyde isolated. The dimedon derivative from a ribose sample containing 215 000 c.p.m. had 78 c.p.m.; indicating that less than 0.04% of the radioactivity was at C-1. The phenylosazone of ribose was then prepared and found to be free of radioactivity, indicating that there was no tritium bound to C-1, -3, -4, or -5 and that the counts observed in the dimedon derivative could have been due to contamination with formic acid or to migration of label under the alkaline conditions of the borohydride reduction.

Treatment of Ribose-2-t with Alkali

Into a 10 ml vial equipped with a rubber septum 1 ml of sugar solution was injected. An outlet needle was inserted in the septum and the vial was flushed with nitrogen (or oxygen) for 10 min and then degassed potassium hydroxide (5 ml) was injected. Vials were incubated in a constant temperature water bath and aliquots of approximately 0.5 ml were removed at various times and assayed for tritium as described below.

For larger scale experiments the reaction vessel consisted of a flask having a side-arm equipped with a rubber septum and an outlet to a gas reservoir. The reaction vessel was immersed in a constant temperature bath and attached to a shaker mechanism. The reaction vessel was filled with an alkaline solution and flushed repeatedly with oxygen or nitrogen with shaking. The reaction was initiated by injecting the sugar solution with a calibrated syringe. Aliquots were removed at intervals by syringe through the septum.

Assay of Tritium Release to Solvent

Samples were placed in a standard taper test-tube and shell-frozen in liquid nitrogen. The sample tube was attached to one side of a standard taper U-tube equipped with a stop-cock and another standard taper test tube was attached to the other arm. The system was evacuated to 0.1 mm Hg while the sample side was immersed in liquid nitrogen. After the system had been evacuated, the stop-cock was closed and the receiver tube was placed in liquid-nitrogen. In 15 min enough water had sublimed so that 0.100 ml could be obtained and assayed for tritium by scintillation counting.

Isolation of Products from the Alkaline Treatment of D-Ribose-2-t

The oxidation mixture was passed through a column containing 100 ml Dowex 50 (H^+) to remove potassium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ions. The acidic solution was then passed over 25 ml Rexyn 203 (free base form) to remove acids; and the acids were recovered by elution with potassium hydroxide. The salts so obtained were converted back to the acids by treatment with Dowex 50 (H^+). The acidic fraction was resolved by preparative paper chromatography. The neutral sugar fraction was concentrated and applied to a column of Rexyn 101 (Ba^+) for fractionation (21).

Reduction of D-*Arabinose-t*

Unlabeled D-arabinose (53.5 mg) was added to a sample of 1.96 mg arabinose-*t* isolated from a reaction mixture; the mixture was dissolved in 7 ml of water and the solution was stirred at 0°. The p*H* was monitored and kept below 9 with dilute acetic acid while 50 mg of sodium borohydride dissolved in 5 ml water was added dropwise. The reaction was kept for 24 h at 4°. Excess borohydride was destroyed with acetic acid and the reaction mixture was passed over a small column of Dowex 50 (H^+). The eluate was evaporated to dryness, with five additional evaporations from 10 ml of methanol. The yield was 50.5 mg. The product gave a quantitative yield of pentabenzoate m.p. 151.0–151.7, undepressed on admixture with the authentic material.

Results and Discussion

This study was undertaken to determine the role of enolization in the oxidative degradation of sugars, specifically the pentoses. Two hypotheses have been advanced for the analogous degradation in the hexose series. Bamford and Collins (9), supported by subsequent experiments of Dubourg and Naffa (10), proposed that in the oxidation of glucose an enediolate anion intermediate is attacked by oxygen to produce a peroxide which cyclizes and decomposes to give formic and arabinonic acids. This mechanism requires that the starting material lose the proton at C-2.

Samuelson and Thede (11) have recently reported that after 26 h in 4.5 *N* sodium hydroxide, at 1 atm oxygen pressure, glucose was converted to a mixture of at least 13 monoprotic carboxylic acids, as well as small amounts of mannose, fructose, and arabinose. These workers suggested the intermediate formation of osones, because D-glucosone gives approximately the same mixture of products as D-glucose does. This mechanism also requires loss of the proton from C-2 of the starting material.

Because the reaction of the pentoses with oxygen at neutral p*H* values is negligible compared to the base-catalyzed reaction, it is apparent that some reaction of the sugar with base must occur prior to the actual oxidation. Thus, it is also of interest to study the reaction of the labeled sugar with alkali in the absence of oxygen. Many other base-catalyzed sugar reactions such as the Lobry de Bruyn – Alberda van Ekenstein rearrangement and the formation of saccharinic acids occur by mechanisms that have been much debated but which usually are thought to involve enolization as the first step (12). Although D-ribose-2-*t* might appear to be an ideal substrate to test the proposal that alkaline rearrangements of sugars involve an initial enolization resulting in the loss of the C-2 hydrogen, it is not. Reactions involving breaking the carbon–tritium bond in the rate-determining step can be expected to differ in rate from those involving the carbon–hydrogen bond by a factor of 10, or more. In addition, ribose is an unusual sugar, it reacts many times faster than other sugars in reactions involving ring opening. Nevertheless, one would expect that the loss of tritium to solvent would occur if enolization is a principal event and that other reactions involving the hydrogen at C-2 would be reflected by qualitatively, if not quantitatively, similar reactions of tritium.

The release of tritium to water in the absence of oxygen in 0.88 *M* potassium hydroxide solution is shown in Fig. 1. The conditions were chosen to be pseudo-first order in D-ribose-2-*t*, that is with a large relative excess of alkali so that the formation of acidic products would not decrease the effective hydroxide ion concentration. The first 50% of the reaction follows first-order kinetics, but it is clear that a portion of the tritium (40%) is incorporated into a position from which base-catalyzed exchange with solvent is very slow. The initial rate of tritium release to solvent is strongly temperature dependent and increases five-fold between 30 and 40°.

Although no extensive study was made, we find that tritium release is not first-order with respect to base concentration.

To investigate the effect of oxygen on tritium release from D-ribose-2-*t*, experiments were carried out at 25° in the presence and absence of oxygen. The results obtained are given in Table 1. The presence of oxygen depresses the rate of tritium release to the solvent by a factor of two. The release of tritium in volatile acids was estimated by distillation of an acidified sample of the reaction mixture; the acid was shown to be formic acid by DuClaux distillation (13) and by n.m.r. spectroscopic examination of the neutralized distillate.

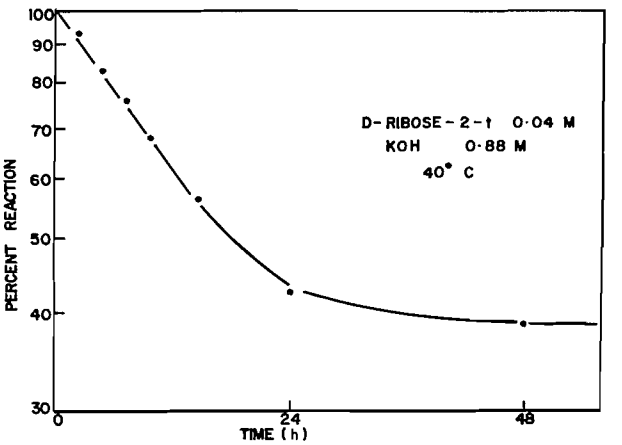

FIG. 1. The release of tritium to solvent from D-ribose-2-*t* in 0.88 *M* aqueous potassium hydroxide at 40°.

TABLE 1. Products from ribose-2-*t* (0.05 *M*) in 100 ml of 0.833 *M* KOH for 12 h at 25.00 ± 0.05 °C

Gas	Acid produced (mmol)	Percent of total counts released to		
		Solvent	Formic acid	Other acids
O_2	6.03	2.1	17.5	—
	5.92	2.0	17.2	—
N_2	1.73	4.15	0.0	1.87
	1.67	4.14	0.0	1.91

TABLE 2. Specific activity of acids from the aerobic degradation of D-ribose-2-*t* in c.p.m. per mmol

	Experiment 1	Experiment 2
Erythronic acid	5.1×10^4	1.2×10^5
Glyceric acid	3.1×10^4	3.8×10^4
Glycollic acid	2.0×10^5	2.6×10^5

The acids formed in the aerobic degradation of D-ribose-2-*t* were separated by paper chromatography, titrated and counted; their specific activities are listed in Table 2. The data for erythronic acid do not agree well and the counts in that fraction may be due partly to contamination with small amounts of starting material. There is no doubt, however, that tritium is present in significant amounts in glyceric and glycolic acids.

Acids produced under anaerobic conditions when 22% of the reducing sugar had been transformed were isolated, after removal of cations, by adsorption on a weakly basic anion exchange resin and elution with alkali. The whole fraction contained 1.5×10^4 c.p.m., 1.9% of the original activity; equivalent to 50% of the tritium released to solvent. The acids were regenerated by removal of solvent, converted to silyl derivatives, and examined by g.l.c. Two main peaks and at least eight minor peaks were present. The major peaks are probably the saccharinic acids, 3-deoxy-D-*erythro*-, and 3-deoxy-D-*threo*-pentonic acids. Attempts to isolate and separate these acids by fractional crystallization of their quinine salts (14) were unsuccessful.

The reaction of D-ribose-2-*t* was further examined by isolating the pentoses (neutral sugar fraction) after 12 h reaction and determining the proportion of label present at C-1 (or C-5) by reduction to the penitol with sodium borohydride, oxidation with periodate, and isolation of the dimedon derivative. The results of these experiments are shown in Table 3. Ribose was not purified after reisolation and the label present in the dimedon fraction, which is significantly greater than in the dimedon fraction from the starting material, could be due to the presence of small amounts of other pentoses or pentuloses. The increase in specific activity of the neutral sugars allows an approximate calculation to be made of the isotope effect. Under the conditions used in the aerobic degradation experiments 50% of the protium sugar had reacted in the 12 h reaction period. During the same time 19% of the tritium sugar had reacted; an apparent isotope effect (k_H/k_T) of 3.3. A similar calculation gives an isotope effect of 4.1 in the anaerobic reaction in which approximately 22% of the reducing sugar had been converted. By themselves, isotope effects cannot be used to demonstrate the operation of a specific mechanism, however, the isotope effects observed in

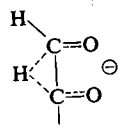
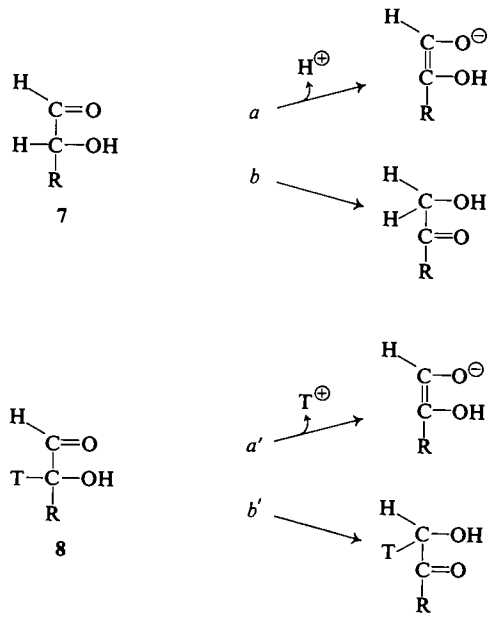
this study are of the order expected for a hydride shift (15) but are smaller than expected for a simple enolization reaction (16, 17). The principal reaction occurring in the absence of oxygen is in a large part attributable to enolization since tritium is lost to the solvent. The small isotope effect is not incompatible with an enolization reaction even though a much larger effect is observed with acetone (16). The magnitude of the isotope effect depends on the symmetry of the transition state (15), changes in bending frequencies (18), the linearity of the transition state (19), and the occurrence of prerate-determining equilibria (20). All of these factors could be important in producing the small isotope effect observed here; however, the data do not permit a more detailed analysis of the mechanism.

The principal reaction in the presence of oxygen involves the transfer of hydrogen from C-2 to -1; it cannot be accomplished by an enolization reaction since tritium lost to solvent cannot return. In this case, the small isotope effect is probably attributable to the occurrence of a cyclic transition state, **6** (14, 18).



6

The possibility that tritium ribose and protium ribose react by different pathways must be considered. In Scheme 2 a hypothetical reaction sequence is shown in which two pathways are available to ribose; pathway *a* for enolization and pathway *b* for hydride shift. If we assume that protium ribose **7** reacts 100 times faster through pathway *a* than through pathway *b* and that the enolization isotope effect is 20 (pathway *a'*) while that for the hydride shift is 2 (pathway *b'*), then, of the tritium ribose **8** that

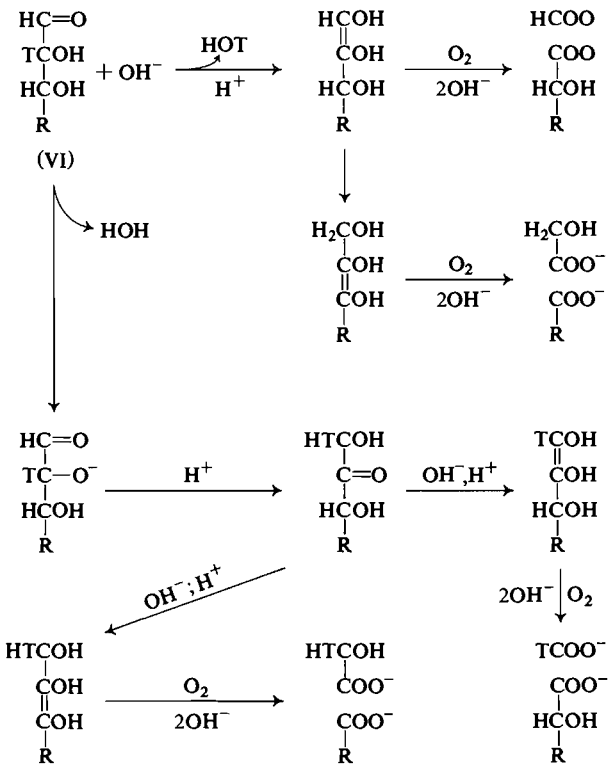


SCHEME 2

had reacted at any given time, 10 parts would have traversed pathway *a'* and one part pathway *b'*. Thus, the observation of an overall isotope effect less than 5 allows us to conclude that a substantial portion of the protium ribose is reacting by the same pathways as the tritium ribose, and that under both aerobic and anaerobic conditions a hydride shift to C-1 is important.

The evidence for a hydride shift in the aerobic degradation of D-ribose-2-*t* is very convincing, 17% of the label is present in formic acid and a small amount in the dimedon derivative from the recovered neutral sugars. In the anaerobic system, however, the evidence is weaker, although there is a significant increase in the tritium content of the dimedon derivative (*i.e.*, at C-1), and this is hard to explain by other than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



SCHEME 3

a hydride shift mechanism. To further demonstrate that a hydride shift does occur in this system, D-arabinose was isolated from the neutral sugar fraction of the anaerobic degradation when the reaction had proceeded to 22% completion (as judged by reducing sugar content). D-Arabinose was isolated by chromatography on the barium form of Rexyn 101 as described by Jones and Wall (21). Two fractions were obtained, the first fraction containing arabinose had 4% of the radioactivity of the neutral sugar fraction; the second fraction had 96% of the radioactivity. Unlabeled D-arabinose was added to the material of the first peak and the whole reduced to D-arabinitol with sodium borohydride. After recrystallization a sample was subjected to periodate oxidation and the dimedon derivative of the formaldehyde so released was prepared. A second sample of the D-arabinitol was converted to the pentabenzoate and recrystallized to constant specific activity. The results of this experiment are presented in Table 4. It is clear that D-arabinose is formed from D-ribose in the anaerobic reaction and that it contains a significant amount of radioactivity.

TABLE 4. Radioactivity present in D-arabinose derived from ribose-2-*t* treated with 0.833 *M* KOH, 12 h at 25.00 ± 0.05 °C; oxygen excluded

	Specific activity (c.p.m./mmol)
Starting material (ribose-2-*t*)	6.36×10^6
Arabinitol pentabenzoate	$2.13 \pm 0.02 \times 10^4$
Formaldehyde dimedon of periodate oxidized arabitol	$7.53 \pm 0.07 \times 10^3$
Arabinose-*t* from reaction mixture (= 28.3 × specific activity penta-benzoate)	6.03×10^5

At least 70% of the activity in the D-arabinose is present in hydrogen attached to C-1. The overall isotope effect for the conversion of D-arabinose can be estimated to be approximately 10 from the specific activities of the starting material and product. The conversion by hydride shift involves two equivalent steps, that is, conversion of D-ribose to an intermediate and conversion of the intermediate back to the epimer D-arabinose. Both steps should show approximately the same isotope effect and the overall isotope effect is the multiple of those for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

individual steps. Thus, in the conversion of D-ribose to D-arabinose each step has an isotope effect of approximately 3.0 consistent with the observed effect for the transfer of tritium from C-2 to -1.

The results of this investigation indicate that an intermediate enediol is not a necessary intermediate in the alkaline conversion of one aldose to another. This may explain the many contradictory findings in the literature concerning the incorporation of solvent deuterium during the treatment of carbohydrates with alkali. Thus, one reviewer (22) concluded that a pathway for the Lobry de Bruyn – Alberda von Ekenstein which does not permit the exchange of carbon bound hydrogen with the solvent was invalid, while another author (23) concluded that the reaction can proceed by two mechanisms (enolization and hydride transfer) the operation of which depends on the nature of the catalyst, temperature, and structure of reactant. Scheme 3 is based on these mechanisms; in it the reactions of a tritiated molecule are shown. The protium isomer would follow the same pathways in different proportion. This scheme accounts only for the major products of the aerobic conversion of D-ribose in alkali. The overproduction of formic acid (1, 9) and the formation of saccharinic acids are not shown since our data do not permit us to comment on the validity of proposals that have been made to explain their formation (9, 11).

Isbell *et al.* (17) have shown that sugars take up tritium from solvent in alkaline medium and have interpreted their data in terms of the rate of primary enolization of the sugars with incorporation at C-2 of the aldoses. Our data would suggest that this incorporation may be a secondary event, depending upon the prior formation of a ketose anion.

It is possible that our findings are peculiar to the D-ribose-2-*t*, potassium hydroxide system, but it appears that this is the first direct demonstration of the operation of a mechanism other than enolization for carbohydrate interconversions. Experiments are in progress in this laboratory to investigate the interconversion mechanism for glucose, fructose, and mannose in order to test the generality of the findings for ribose-2-*t*.

Sulfonyl Chloride Kinetics. Part II. Solvolysis of a Series of Benzenesulfonyl Chlorides: An Unexpected Heat Capacity Variation[1]

R. E. ROBERTSON AND B. ROSSALL[2]

Department of Chemistry, The University of Calgary, Calgary, Alberta

Received July 8, 1970

First order rate constants for the solvolysis of a series of 4-X-benzenesulfonyl chlorides (where X = MeO, Me, Br, and NO_2) were measured by the conductance method in H_2O over the approximate temperature range of 0 to 25°. Pseudothermodynamic parameters, $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ were derived and the high accuracy of the rate constants enabled an estimation of $d\Delta C_p^{\ddagger}/dT$.

A trigonal bipyramidal transition state is favored for the nucleophilic attack which is probably by an S_N2 type mechanism. A novel explanation for the effect of 4-methoxy on $\Delta C_p^{\ddagger}$ involves a temperature dependent water–solute interaction, which has general applicability to the behavior of 4-methoxy substituents.

On a mesuré, par la méthode de la conductivité, dans l'eau et à des températures entre 0 et 25 °C, les constantes de vitesse du premier ordre pour la solvolyse d'une série de chlorures de benzenesulfonyles substitués en position 4. On en a dérivé les paramètres pseudothermodynamiques $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, et $\Delta C_p^{\ddagger}$ et grâce à la grande précision des mesures, on a pu estimer la valeur de $d\Delta C_p^{\ddagger}/dT$.

On favorise un état de transition trigonal et bipyramidal pour l'attaque nucléophile qui est probablement un mécanisme S_N2. Une nouvelle explication pour l'effet du groupement méthoxy en position 4 sur $\Delta C_p^{\ddagger}$ implique une intéraction entre l'eau et le soluté qui serait dépendante de la température; cette explication serait d'application générale chaque fois que des substituants méthoxyle en position 4 seraient impliqués.

Canadian Journal of Chemistry, 49, 1441 (1971)

The practical importance of knowing relative reaction rates is readily apparent: corresponding energy relationships between structure and reactivity are more obscure, and generally so difficult to define that the search is frequently abandoned where it should begin. Indeed, practical arguments can be advanced to support the position that free energy differences are the proper end (1, 2).[3] This attitude may have gained credence from repeated failure of many to find sufficient analytical and predictive value in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ differences to warrant a serious consideration. As a consequence, these pseudo-thermodynamic parameters frequently have been treated as a by-product of questionable value, or as an empirical tool for approximate interpolation and extrapolation of rate data. Because of the wide-spread belief that no useful information can be gained from such derived parameters, in planning a kinetic study, there is no imperative to meet the more stringent experimental requirements needed to ensure rate data of the required accuracy (3). Hence these less accurate rates (which may be adequate for free energy comparisons) lead inevitably to unreliable values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ and thus on each successive occasion apparently supply factual support to confirm the negative approach. Granted this attitude, our appreciation of structure–reactivity relationships must remain in its present primitive state.

We do not accept this philosophy of despair and would prefer to draw encouragement from those studies of the temperature dependence of the rate where progress has been recorded. In this paper we demonstrate that useful information can be gained from such studies of the hydrolysis of a series of para-substituted benzenesulfonyl chlorides in water.

Nucleophilic displacement from a tetrahedral sulfur has been treated generally as analogous to the corresponding displacement from carbon and the same terminology based on similar mechanistic distinctions has tended to be used (4–13). To the degree that the activation processes are similar, such a comparison is valid but in this and in the following paper we attempt to identify and evaluate the source of differences. Thus differences have been recognized in the

Br		80–81	81–82	9
NO_2		78–79	79	9

higher selectivity ratio (12, 14) and the enhanced kinetic solvent isotope effect (15). Scott has reported evidence of different steric requirements for the solvolysis of a series of alkyl sulfonyl chlorides (16, 17). Some kinetic requirement other than that of solvent reorganization was needed to account for the large change in $\Delta S^{\ddagger}$ noted above in the hydrolysis of methanesulfonyl chloride and of benzenesulfonyl chloride (18). The latter study also led us to expect that there would be no change in $\Delta C_p^{\ddagger}$ through a series of para-substituted benzenesulfonyl chlorides. The degree to which these expectations are supported by experimental facts and the reasons for departure supply strong support for the value of derived parameters in detecting significant kinetic factors provided, as always, sufficiently accurate rate data are available.

Experimental

The hydrolysis of a sulfonyl chloride molecule produces four ions, two of which are protons, hence the system is particularly suited to rate determination by a conductimetric method. The details of the system, the methods of computation, of temperature control, and of rate measurement have been described elsewhere (19).

The 4-substituted benzenesulfonyl chlorides were commercial samples. 4-Nitrobenzenesulfonyl chloride contained a considerable amount of impurity and was subjected to a preliminary vacuum distillation (b.p. 144° at 2 mm Hg) (20). Further purification of all samples was achieved by recrystallization from petroleum ether to constant m.p. (see Table 1).

Recrystallized samples of 4-methyl and 4-bromobenzenesulfonyl chloride were further purified by zone refinement. Kinetic measurements on all samples gave excellent first order rate constants. This was considered to be the most reliable test of purity for the purpose of this study. Water was purified by preliminary distillation and then passed through an ion exchange column (Rexyn R 208-1-300 H–OH). Analar HCl ($<0.0001\ M$) was added as a backing electrolyte to adjust the solution conductance to the optimum range for accurate rate determination. Rate measurements were made using our Auto-Ram system (19). Since substituted benzenesulfonyl chlorides are only sparingly soluble in water, supersaturation had to be avoided to obtain consistent rate data. This was accomplished by the following dilution technique which has much wider application than in the present study. Kieselguhr (dried at 500° for 24 h) in large excess was intimately mixed with a small amount of the sulfonyl chloride and a suitable amount of this mixture added to a flask containing backing electrolyte at bath temperature and shaken. This solution was pressure filtered through a glass-sinter into Queen-type cells. Each cell had been 9/10 filled with backing electrolyte solution and brought to bath temperature. The resultant dilution of the reacting solution was sufficient to avoid any supersaturation. This process requires about 200 s to fill four cells. This time, together with that for the reestablishment of temperature equilibrium, sets an upper limit to the rates which can be determined by this method. Rates with $t_{1/2} \simeq 200$ s were the fastest which could be determined, corresponding to an upper temperature limit of about 25°. Rate studies[4] were carried out at 2 or 3° intervals from this upper temperature limit down to 0°.

Results

The temperature dependence of the rate constants was expressed by an equation of the general form

$$[1] \quad \log_{10} k = A_1 + A_2/T + A_3 \log_{10} T + A_4 T \ldots$$

TABLE 2. Empirical constants for the rate–temperature relation for the hydrolysis of 4-X-benzenesulfonyl chlorides in H_2O

*Calculated from a four constant fit to eq. 1 assuming $d^2\Delta C_p^{\ddagger}/dT^2 = 0$.

using a modified form of the Clarke–Glew transformation (21). Corresponding constants for the benzenesulfonyl chloride series are given in Table 2. These permit calculation of rates, the values of which are in excellent agreement with experimental values. Pseudothermodynamic parameters $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ were derived from the constants A_1, A_2, A_3 making the *usual* assumptions with respect to the applicability of the transition state theory and also assuming that $d\Delta C_p^{\ddagger}/dT = 0$. The values so derived are given in Table 3.

The assumption that $d\Delta C_p^{\ddagger}/dT = 0$ has been made frequently in our work not from any strong experimental or theoretical reasons but rather because the rate data did not normally justify including such a term in the analysis. The kinetic rate data in this study are sufficiently accurate to warrant an examination of the coefficient $d\Delta C_p^{\ddagger}/dT$, assuming now that the derivative of the latter term with respect to temperature is zero. The kinetic rate–temperature data were therefore fitted to a four constant equation of the same form as eq. 1 with the added term in T. These constants are not given since the three-constant equation is adequate for interpolation. Nor are the values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ given since in the middle of the temperature range these values are identical with those in Table 3. The heat capacity of activation, $\Delta C_p^{\ddagger}$ and its temperature derivative are in Table 4.

It is recognized that the values of $d\Delta C_p^{\ddagger}/dT$ are small and not significantly different from the calculated uncertainty.

Discussion

While no detailed study of the structure of the RSO_2Cl molecule has been reported,[5] available evidence suggests that this class of molecules has a distorted tetrahedral shape (22). From X-ray analysis of the related structure 1-parabromobenzenesulfonyloxymethyl-bicyclo-2,2,2-octane, we learn that the O^2—S—O^3 bond angle is

[5]Such a study will be undertaken shortly by Professor K. Ann Kerr of The University of Calgary, Calgary, Alberta.

118.9 ± 5°, while O^1—S—O^3 is 103.9°, the remaining angles having intermediate values. The S—O bond lengths are shorter than those in SO_4^{2-} (1.49 Å) giving an estimated π-bond order of 0.7 (23). The corresponding O—S—O bond angle in SO_2Cl_2 is 119.8 ± 5° and Cl—S—O, 106.5 ± 5° with an S—O bond length of 1.43 ± 0.02 Å (24). Similar conclusions can be drawn from data for SO_2F_2 (25). From the above evidence we conclude that the stereochemistry of the RSO_2Cl molecules may be considered as a distorted tetrahedron but with shortened S—O bonds due to pπ–dπ interaction (26). The question of importance here is how this initial state structure will alter in the preliminary activation and how the resulting activated molecule will influence the approach of the displacing nucleophile.

It is assumed that only those molecules will react with a nucleophile which achieve some *critical* charge level. This activated state will be equivalent to the so-called intimate-ion-pair postulated by Winstein and co-workers (27)[6] and adopted by many writers. It might equally be considered equivalent to the activated molecule postulated by Arrhenius (29).

For the present purpose the equilibrium can be shown formally as

$$RX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [R^{\delta+} \cdots X^{\delta-}] \xrightarrow[+H_2O]{k_3} \text{Products}$$

$$k_{obs} = \frac{k_2}{k_1} \cdot k_3$$

in which $k_2/k_1 = K_e$.

Evaluation of K_e is difficult (28, 30, 31). Clearly, K_e will depend on the nature of the solute and on the solvent but such elementary questions as the following must be answered.

(*1*) Is the formation of the intimate-ion-pair accompanied by solvent reorganization?

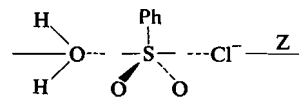
(*2*) Is the same degree of charge separation required where the nucleophile is OH^-, F^-, or acetate$^-$ as when the agent is water?

(*3*) Is the activated intermediate, in fact, a series of states depending on the requirements of the particular reaction?

No clear answers have been provided either by those who proposed or by those who have adopted this working hypothesis (27, 28, 30–32). In the absence of such elementary information it remains a convenient working hypothesis.

Whatever the nature of the intimate-ion-pair, the lack of strong sensitivity to the ionizing power of the solvent points to a lower degree of charge separation at the intimate-ion-pair than, for example, the activated alkyl halides. The higher kinetic solvent isotope effect (k.s.i.e.) might be given a similar interpretation (15) as would the higher k_{OH^-}/k_{H_2O} ratio (12). However we do not know how to make a quantitative estimate of these differences since for both the halides and the sulfonyl chlorides the rate of activation can be regarded as the product of an initial activation equilibrium followed by the product forming step, or in the case of some reactants, a kinetically significant step preceding a kinetically insignificant product forming step(s).

It can be recognized that the distorted tetrahedral form of the sulfonyl chloride with π-bonding of oxygen pπ-electrons into empty dπ-orbitals on sulfur and leaves available an empty d_{z^2} orbital for the approaching nucleophile. Thus in the activation process corresponding to k_3 it is attractive to postulate a trigonal bipyramidal structure for the transition state with displacement of Cl^- from RSO_2Cl and the nucleophile approaching along the *z*-axis.



The steric requirements apparent in Scott's kinetic studies of alkyl sulfonyl chlorides (16) and the substituent effects on the rate and entropy of activation (see below) differ from the analogous S_N2 displacement from the sp^3 carbon. The enhanced k.s.i.e. values compared to corresponding values for displacement from carbon (15) are consistent with this hypothesis. A similar model was proposed by Bunton and Frei (33) for the hydrolysis of aryl sulfonates and by Christensen (34, 35) for the hydrolysis of aryl sulfonic anhydrides. This transition state configuration was favored by Kice and Kasperek (36) over several alternatives for the hydrolysis of diaryl sulfones and for aryl sulfinyl sulfones in the absence of compelling evidence in favor of a tetrahedral configuration. In the latter cases,

[6]For a review and assessment of this analysis see ref. 28.

in order to account for the much larger k.s.i.e. (2.3–2.7) compared to 1.2 for the hydrolysis of halides and 1.4–1.8 for hydrolysis of the sulfonyl chlorides (37) it was necessary to introduce an *ad hoc* Grottius chain extension (38) in order to accommodate the stereochemical implication of the bipyramidal transition state. On this evidence the above hypothesis is not unreasonable and the k.s.i.e. for the hydrolysis of the sulfonyl chlorides in water is at least consistent with such a proposal.

The fact that Jenkins and Hambly (9) found a linear correlation between log $k_3/(H_2O)^2$ and the first power of the dielectric constant might be taken as evidence supporting the requirement for two ligands in the transition state, implying an octahedral configuration. Such an hypothesis would require a much more extensive change in the O—S—O bond angle in contrast to the almost negligible change required in the above model and hence is not considered as a reasonable alternative. The evidence that the enhanced k.s.i.e. which characterizes the hydrolysis of the sulfonyl chlorides compared to the alkyl halides or to the diaryl sulfones derives from enhanced nucleophilic interaction rather than extended solvation requirements will be given in the accompanying paper (37).

para-Substitution and Relative Rates

The effect of para-substitution on the S—Cl bond in the initial state appears to be small judging by the negligible changes in the Raman spectra (375 cm^{-1} for *p*-Me, -H, -Cl, -Br) (39).

At the level of relative rates, no surprises were anticipated in view of previous work by Hedlund (5), Tommila and Hirsjärvi (6), Vizgert and Savchuk (7, 8), Jenkins and Hambly (9, 10), and most recently by Rogne (12), but such duplication was incidental to the purpose of this investigation. Corresponding data have been collected for convenience in Table 5. The changes in the relative effect of substituents on the rate with changes in solvent are illustrated in Fig. 1. This can be taken as evidence of the opposing electronic requirements of the two stages of the activation process ($k_{obs} = K_e k_3$), Under good ionizing conditions and with an uncharged nucleophile the effect of the substituents on the concentration of the activated intermediate (K_e) is dominant (ρ is negative). Under poorer ionizing conditions (mixed aqueous/organic solvents) or with a charged nucleophile in water (12) then those factors influencing the approach of the nucleophile take precedence and the corresponding Hammett constant changes sign (ρ is positive) (Fig. 1). To this point our work confirms but does not add any new insight. Only when the derived parameters are examined is new information provided.

Enthalpy and Entropy of Activation

While it is recognized that ionogenic reactions occurring in solution produce solvation changes which are reflected in the derived terms, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ it is unlikely that such an explanation can account for the major differences in $\Delta S^{\ddagger}$ found in the hydrolysis of sulfonyl chlorides (18). This generalization is possible because of a lack of correlation between $\Delta S^{\ddagger}$ and $\Delta C_p^{\ddagger}$ (Fig. 2), the former quantity changing while the latter term, with two exceptions, remains relatively constant. Such constancy in $\Delta C_p^{\ddagger}$ was taken as an indication that solvent reorganization attending the activation process tended to be uniform through the series and prompted a search for some alternative source of change in $\Delta S^{\ddagger}$.

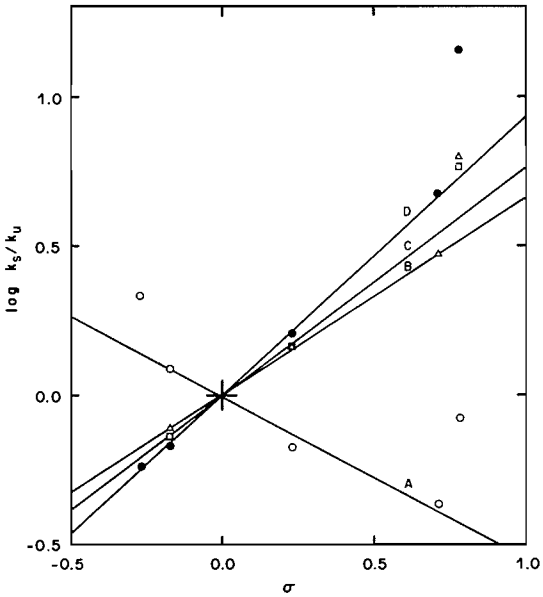

FIG. 1. Hammett plots for solvolysis of substituted benzenesulfonyl chlorides. See Table 5 for letter identification.

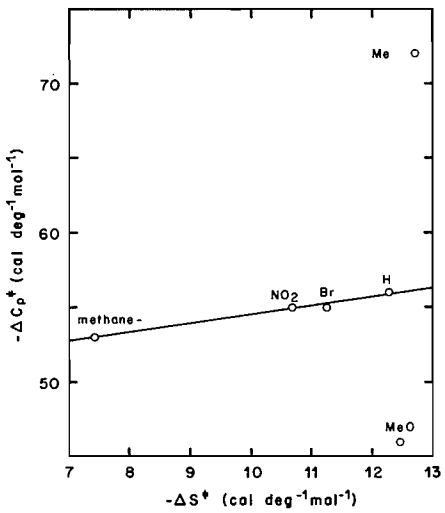

FIG. 2. $-\Delta C_p^{\ddagger}$ plotted against $-\Delta S^{\ddagger}$ for the solvolysis of sulfonyl chlorides in H_2O at 15°.

If an initial activated equilibrium precedes nucleophilic attack, then the expected effect of the para-substituent on that equilibrium will be just the opposite to that required for the approach of the nucleophile. The change in the sign of the Hammett plot with a change in solvent suggests

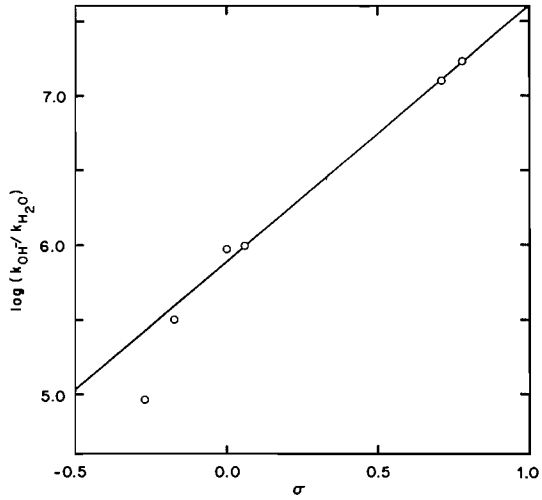

FIG. 3. Log (k_{OH^-}/k_{H_2O}) plotted against Hammett σ (rate data at 15°, this work and ref. 12).

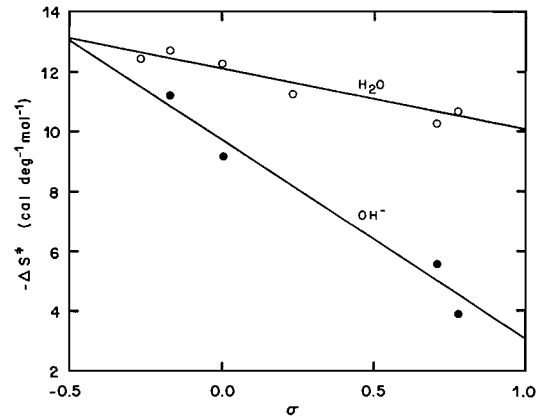

FIG. 4. $-\Delta S^{\ddagger}$ plotted against Hammett σ (H_2O reaction at 15°, this work and ref. 5, OH^- reaction ref. 12).

that in solvolysis these effects are just about balanced. Granted K_e for the reaction with OH^- and with H_2O are about the same throughout the series, then this constant will disappear in the ratio k_{OH^-}/k_{H_2O} (31). A plot of the latter *vs.* σ gives a linear correlation with a positive slope, Fig. 3, an indication that the nucleophilic displacement step (k_3) is dependent on the positive charge on the sulfur atom. Further $\Delta S^{\ddagger}$ values for solvolysis in water and for displacement with OH^- *vs.* σ give linear correlations reflecting a similar relationship between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ (Fig. 4). It is apparent that the same or a related

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

factor which enhances the probability of reaction enhances enthalpy requirement. Such compensation has been noted frequently (40–43), but it is of particular interest here because solvation effects can be eliminated as a cause, in favor of short range interactions. It may be significant in this connection that the authors found that the degree of bond-making at the transition state (as reflected by the kinetic solvent isotope effect) is the same for the methanesulfonyl chloride and benzenesulfonyl chloride (18), is greater for the 4-nitro member of the series, and less for the 4-methoxy and 4-methyl members (37). We assume that these differences in k.s.i.e. are indications of corresponding differences in the electron sharing required to achieve a critical charge on the chloride ion but note that there is no obvious correlation between such indicated differences in bond-making and the trend in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. Hence we suggest that the correlation of changes in these latter terms (Fig. 5) is a consequence of the difference in the electron supply to sulfur. The changes in $\Delta H^{\ddagger}$ reflect differences in the energy requirement for rehybridization; the changes in $\Delta S^{\ddagger}$ reflecting the probability of approach of the nucleophile. Other components in $\Delta S^{\ddagger}$ and $\Delta H^{\ddagger}$ are assumed to be about the same throughout the series.

Heat Capacity of Activation

For an S_N2 hydrolysis occurring in water, the temperature dependence of the enthalpy of activation ($\Delta C_p^{\ddagger}$) has been interpreted as reflecting the temperature dependence of the structural stability of the solvent shell about the reactant, or more particularly about the displaced group

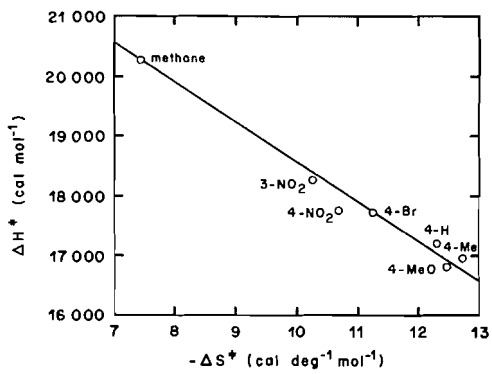

FIG. 5. $\Delta H^{\ddagger}$ plotted against $-\Delta S^{\ddagger}$ for sulfonyl chloride solvolysis in H_2O at 15° (3-NO_2 from ref. 5).

(44). Where displacement of a halide was from carbon, the charge development at the activated intimate-ion-pair was such that the degree of bond-making was minimal.[7]

Where displacement occurs from a tetrahedral sulfur, k.s.i.e. values are higher but as argued in our previous paper (18), it was anticipated that solvent reorganization would be about the same no matter what the substituent on the benzenesulfonyl chloride and that solvent reorganization would still be the major contributor to $\Delta C_p^{\ddagger}$. The results (Table 3) supported our expectations in part only. A plot of $\Delta C_p^{\ddagger}$ *vs.* $\Delta S^{\ddagger}$ (Fig. 2) showed little or no dependence of $\Delta C_p^{\ddagger}$ on $\Delta S^{\ddagger}$ for three para-substituents H, Br, NO_2, and methanesulfonyl chloride. The value of $\Delta C_p^{\ddagger}$ for two substituents, *p*-Me and *p*-MeO lie off this plot ($\Delta C_p^{\ddagger} = -72$ and -46 cal deg^{-1} mol^{-1} compared to the "normal" value of -55 cal deg^{-1} mol^{-1}). Both of these values are outside the expected error and were carefully checked to ensure that the deviation was not due to some experimental error.

In previous discussions of the significance of $\Delta C_p^{\ddagger}$ for ionogenic reactions occurring in water (44, 46) we have normally considered the contributions to $\Delta C_p^{\ddagger}$ arising from the effect of temperature on that solvent structure which was necessarily reorganized in the activation process. In exceptional cases the effect of competing reactions on $\Delta C_p^{\ddagger}$ was recognized (45–48). The latter explanation is unlikely in the two exceptions noted above. Less negative values of $\Delta C_p^{\ddagger}$ have been attributed to a modification of the initial state in the direction of less structure (49, 50). This might accommodate the value of $\Delta C_p^{\ddagger}$ for the *p*-methoxy substituent but not for the *p*-methyl group. A more likely explanation for the latter case is that in the formation of the transition state, sufficient electron demand occurs such that hyperconjugative interaction with the phenyl group raises the level of charge on the methyl group to the point where added solvent reorganization occurs about this group as well as at the seat of reaction. Preliminary results obtained in mixed solvents where water structure has been decreased tend to support this interpretation (51). If the above hypothesis is correct, then deuterium substitution on the *p*-methyl

[7]For MeBr and *t*-butyl Cl, $k_{H_2O}/k_{D_2O} = 1.2$–1.3 (45).

group should show a significant isotope effect, but this experiment was not done. The argument used previously to account for the reduction in $\Delta C_p^{\ddagger}$ ($= -63$ cal deg^{-1} mol^{-1}) for the solvolysis of $MeOCH_2(CH_3)_2CCl$ (50) was based on the reasonable assumption that the methoxy group would modify the initial state solvation shell thus reducing the extent of reorganization required in the activation process compared to that for *t*-butyl chloride ($\Delta C_p^{\ddagger} = -83$ cal deg^{-1} mol^{-1}). Clearly such an explanation is inadmissable here since there is no reason to assume that solvent reorganization occurs about the benzene group in the activation process (*cf.* $\Delta C_p^{\ddagger}$ for methanesulfonyl chloride and benzenesulfonyl chloride, Table 3). However, the unexpected value of $\Delta C_p^{\ddagger}$ obtained for the *p*-methoxybenzenesulfonyl chloride points to an important solvation effect, influencing substituent effects on rates and equilibria.

The more positive value of $\Delta C_p^{\ddagger}$ found in the case of the *p*-methoxy compound is related to: (*1*) the interaction of the *p*-methoxy group with the benzene ring is opposed by the interaction of this group with water; (*2*) the interaction of water with the methoxy group is opposed by water–water interaction, and the latter is associated with the tendency of water to form three-dimensional structures. This latter tendency is known to decrease as temperature increases (52–54).

Because of the presence of the methyl group, some degree of steric hindrance to hydrogen bonding toward structured water would be expected, but less so toward "freed"[8] water. Following the same reasoning, this steric hindrance to solvation will not exist in the case of an hydroxyl substituent (55).

It would seem reasonable that the more extensive hydrogen bonded co-ordination of structured water would be more sensitive to temperature than the hydrogen-bonding of "freed" water molecules to the methoxyl-oxygen. The number of "freed" water molecules will increase as the temperature increases (55). Hence as the temperature increases, interaction of the latter with water will increase and there will be a corresponding decrease in the electronic effect of the phenyl group on the sulfonyl-sulfur, with a consequent increase in the positive charge on sulfur. To predict the consequence of such a temperature dependent solvent effect it is necessary to examine the relationship between changes in the nominal charge on sulfur and the corresponding values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$.

In Fig. 5, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are shown to be linearly dependent for the hydrolysis of sulfonyl chlorides. Here it is sufficient to note that in this series, electron withdrawal leads to higher values of $\Delta H^{\ddagger}$ and less negative values of $\Delta S^{\ddagger}$. We shall return to this fact presently. First let us examine how $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ will change as the effect of the *p*-methoxy group on $S^{\delta+}$ is modified through enhanced interaction with water as temperature increases. Clearly, as water interaction with the methoxy group increases, electron release to the phenyl group will *decrease* and the positive charge on $S^{\delta+}$ will *increase*. It follows, from Fig. 5, that there will be a corresponding *increase* in $\Delta H^{\ddagger}$, resulting in a positive ($d\Delta H^{\ddagger}/dT$) contribution to the apparent $\Delta C_p^{\ddagger}$. This positive contribution will be unrelated to the negative component arising from the need to reorganize water about the chloride quasi-ion in the activation process. Such an explanation must appear contrived unless supporting evidence can be found in other systems. In principle such a temperature dependent solvent effect would be expected to be quite general provided certain requirements are met. Firstly, the substituent group must be capable of relatively strong interaction with the solvent but not sufficiently strong to cause a breakdown of water–water interaction. Thus the effect is observed with MeO— but not with Br—, NO_2—, Me—, or H—. We would not expect the effect with OH— since the latter can fit into the water lattice in the initial state (52, 55). It is equally clear that changes in the effect of the substituent as a consequence of enhanced solvent interaction must be readily transmissible to the "seat of reaction", otherwise changes in electronic requirements will be unobserved between initial and transition states.

These simple corollaries to our interpretation of the exceptional $\Delta C_p^{\ddagger}$ value for the hydrolysis of *p*-methoxybenzenesulfonyl chloride find ready support from the changes in ΔC_p^{0} for the ionization of carboxylic acids and from our

[8]We have used the vague word "freed" intentionally since at this stage it would be speculative to suggest that only non-hydrogen bonded water molecules can interact, or some variant on this theme. The general principle seems implicit in the facts and that is all that is required here.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

kinetic solvent isotope effects (discussed in the following paper). The ΔC_p^0 values for the ionization of substituted benzoic acids and acetic acids tend to lie in the range -31 to -40 cal deg^{-1} mol^{-1}, but the value for anisic acid is reported to be -50 cal deg^{-1} mol^{-1} while the value for vanillic acid is even more negative.[9]

The change in sign for the incremental contribution of $d\Delta H^0/dT$ to ΔC_p^0 follows directly from the electronic requirements of the ionization process and serves as a secondary check on the basic correctness of the postulate. Enhanced solvent interaction with the methoxy group will increase the relative strength of the acid, decreasing ΔG^0 and ΔH^0.

A consideration of these ΔC_p^0 values suggests that this temperature dependent solvation need not be specific to the methoxy-group in the latter system but rather varies according to the electronic nature of the substituent. Further, it will be obvious that the competition between the substituent and water–water interaction will also be present with respect to interaction with the π electrons of the benzene group, an interaction of possible importance in discussing solvation effects in the benzyl system (58).

The consequence of the temperature effect on the above temperature dependent competition is clearly illustrated by a consideration of the change in ΔC_p^0 for ΔH_1^0 and ΔH_2^0 as illustrated in the case of *o*-phthalic acid (59, 60). Thus the ΔC_p^0 value for the second ionization constant for a dibasic acid is normally much more negative than for the first ionization constant, *e.g.* *o*-phthalic (1) $\Delta C_p^0 = -22$ cal deg^{-1} mol^{-1}, while *o*-phthalic (2) $\Delta C_p^0 = -70$ cal deg^{-1} mol^{-1}. For this and similar cases the above hypothesis provides a reasonable explanation of observed ΔC_p^0 values.

We do not propose to discuss the application of the above concept to the ionization of weak acids at this time, preferring to cite the data as support for the basic idea. Inherent in this idea is the corrollary that as the temperature rises the carboxylic group can compete more successively with water in establishing a solvation sphere, hence from this effect the acid gets stronger with increasing temperature. It would appear that at still higher temperatures, this differential interaction of water with the carboxylic group which comes into play below 40° decreases as the temperature exceeds this value. This may account for the typical shape of the log K_a *vs.* T plots. This idea is related to, but somewhat different from, the explanation used to account for the large negative $\Delta C_p^{\neq}$ values which characterize ionogenic reactions in water (44).

One further observation is implicit in the above rationalization. In all of the examples cited the basis for the effect springs from the unique structure of water and the effect of temperature on that structure. It follows that if that structure is destroyed by a co-solvent then we should anticipate that the above effects would tend to disappear. This does not imply that the ΔC_p^0 for ionization in such systems or $\Delta C_p^{\neq}$ for the reaction kinetics in mixed solvents would disappear, but the available evidence suggests that this term will be much reduced (19, 44, 46) and the greatest reduction will be observed for those kinetic and equilibria situations where the most negative values were observed in water.

[9]Chaturvedi *et al.* report a value of -130 cal deg^{-1} mol^{-1} (56) but Larson and Hepler have questioned this value (57). Even were a truer value closer to one-half the quoted value, it would still support the argument.

Sulfonyl Chloride Kinetics. Part III. Nucleophilic Interaction on the Transition State for 4-X-Benzenesulfonyl Chloride Solvolyses[1]

B. ROSSALL[2] AND R. E. ROBERTSON

Department of Chemistry, The University of Calgary, Calgary, Alberta

Received July 8, 1970

The kinetic solvent isotope effect (k.s.i.e.) = k_{H_2O}/k_{D_2O}, was measured for 4-X-benzenesulfonyl chlorides (where X = MeO, Me, H, Br, and NO_2) and shown to vary systematically, giving linear correlations with Hammett σ values and with k_{OH^-}/k_{H_2O} ratios. These results contrast with the lack of sensitivity in k.s.i.e. to structural changes for displacement from a saturated carbon atom. This behavior is attributed to a greater degree of bond making required to achieve a critical charge on the chloride of the sulfonyl chloride at the transition state.

On a mesuré l'effet isotopique cinétique du solvant (e.i.c.s.) = k_{H_2O}/k_{D_2O}, pour des chlorures de benzenesulfonyles substitués en position 4 et on a démontré qu'il varie d'une façon systématique donnant une corrélation linéaire entre les valeurs σ de Hammet et les rapports k_{OH^-}/k_{H_2O}. Ces résultats sont en opposition avec ceux obtenus pour des réactions de substitutions sur des carbones saturés alors que e.i.c.s. est peu sensible aux changements structuraux. Ce comportement serait dû à ce que l'état de transition ressemble au produit final et nécessite un haut degré de formation de lieu pour atteindre une charge critique sur le chlorure du chlorure de sulfonyle.

Canadian Journal of Chemistry, 49, 1451 (1971)

Introduction

Robertson and Laughton (1) showed that the kinetic solvent isotope effect ((k.s.i.e.) = k_{H_2O}/k_{D_2O}) for benzenesulfonyl chloride and methane sulfonyl chloride were similar (1.58 at 10 and 20°, respectively) and larger than the values which characterize the hydrolysis of alkyl halides (1.2 to 1.3 over widely differing temperature ranges) (2, 3). These results are interesting since it seemed unlikely that a phenyl and a methyl group could have identical electronic effects. Especially so, since Rogne (4) measured k.s.i.e. for dimethylsulfamoyl chloride at 25° = 1.33. Hence our studies were extended to discover whether k.s.i.e. were dependent on changes in the para-substituent of the benzene ring. In our initial investigation (5) we noted the claim by Vizgert (6) that the solvolytic rate constant for mesitylenesulfonyl chloride was not increased by base addition. This is in contrast to a "normal" acceleration of 10^5–10^7 (7, 8). We expected this compound to have a k.s.i.e. distinct from that arising from nucleophilic interaction. Unfortunately, this substrate proved quite insoluble in water and the rate ratio was unavailable. However, since rate constants and pseudothermodynamic parameters of activation, $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p{}^{\ddagger}$ have been determined in H_2O (9), the rate studies were repeated in pure D_2O, over a similar temperature range. In view of the k.s.i.e. values previously reported (10–12), the results of this study must be regarded as surprising.

Experimental

Substituted benzenesulfonyl chlorides were commercial samples purified as previously described (9). The purification of D_2O and D analysis have been previously reported (5).

First order rate constants were measured using the Auto-RAM system (13). In all reactions excellent pseudo-first order kinetics were observed. Sulfonyl chlorides were only sparingly soluble in heavy water and supersaturation was carefully avoided by the use of Kieselguhr as a filter aid in a dilution technique (9).

Results

First order rate constants were computed from the conductance–time data. Rate constants, for 15°, are presented in Table 1, along with the corresponding data obtained in H_2O. These rate constants are recalculated smoothed curve values, obtained as described below.

The kinetic modification of the Clarke and

H	6.986[b]	11.04	1.580
Br	4.576	7.447	1.627
NO_2	5.143	9.373	1.822

*The k.s.i.e. = k_{H_2O}/k_{D_2O}; *a* from ref. 9, *b* from ref. 5. For 2-nitrobenzenesulfonyl chloride, at 14.862°, $k_{D_2O} = 1.18 \times 10^{-4}\ s^{-1}$ and at 19.142°, $k_{H_2O} = 3.45 \times 10^{-4}$ and $k_{D_2O} = 1.93 \times 10^{-4}\ s^{-1}$.

Glew equation (14) was used to calculate pseudothermodynamic parameters from the rate constant – temperature data.[3]

The temperature dependence of the rate constants was expressed by an equation of the form

$$[1] \quad \log_{10}k = A_1 + A_2/T + A_3 \log_{10} T + A_4 T \ldots .$$

Empirical constants, A_1, A_2, A_3, for a three-parameter fit to eq. 1 are given in Table 2, and permit recalculation of rate constants, see Table 1, which are within the limits of experimental error.

Pseudothermodynamic parameters, $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p{}^{\ddagger}$ for solvolysis of 4-X-benzenesulfonyl chlorides in D_2O were calculated from the empirical constants, A_1, A_2, and A_3 assuming the transition state theory, well behaved differentiability of $\log_{10}k$ with respect to temperature and $d\Delta C_p{}^{\ddagger}/dT = 0$. These derived parameters are presented in Table 3.

The high degree of accuracy in the rate constants was sufficient for an evaluation of $d\Delta C_p{}^{\ddagger}/dT$, using a four parameter fit to eq. 1.

TABLE 2. Empirical constants for the three-parameter temperature–rate eq. 1 for hydrolysis of 4-X-benzenesulfonyl chlorides in D_2O

X	A_1	$-A_2$	$-A_3$	$n_{T_1}{}^{T_2}$*

Br	92.34299	7598.220	28.1806	$20_4{}^{22}$
NO_2	93.41010	7673.163	28.4881	$30_5{}^{30}$

*$n_{T_1}{}^{T_2}$ represents the number of individual rate determinations; T_1, T_2 define the lower and upper limits of the experimental temperature range.
†Reference 5.

[3]Experimental rate constants have been filed with the Depository of Unpublished Data, National Science Library, Ottawa 2, Canada.

The values obtained for $d\Delta C_p{}^{\mp}/dT$ were not significant and the corresponding values for $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p{}^{\ddagger}$ were similar to those derived for the three parameter analysis and given in Table 3 (9).

Discussion

The effect of para-substitution on k.s.i.e. values for hydrolysis of aromatic substrates has attracted little interest (12, 15). In the sulfonate and halide series, the effects of structural changes on k.s.i.e. were small (16, 17), in contrast to the systematic changes evident in Table 1. These differences are illustrated in Fig. 1, where log(k.s.i.e.) was plotted against Hammett σ values (18) for 4-X-benzenesulfonyl chlorides and methyl 4-X-benzenesulfonates. In the former series significant bond-making was assumed from the larger values of k.s.i.e. (1.405 to 1.822 at 15°), in contrast with the methyl benzenesulfonates where it is probable that bond-making requirements are smaller. The k.s.i.e. of the latter appears to be independent of the para-substituent. From Fig. 1, we conclude that the bond-making requirement of the transition state for sulfonyl chloride solvolyses is a function of the electronic property of the para-substituent, slope $\rho = +0.11$, small but significant. In such a comparison it must be borne in mind that we are comparing displacement from a distorted tetravalent sulfur atom with displacement from a

*From ref. 5.

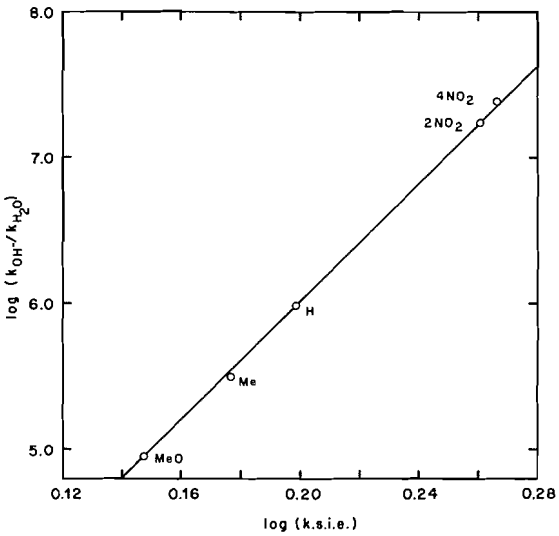

FIG. 2. Log (k_{OH^-}/k_{H_2O}) plotted against log (k_{H_2O}/k_{D_2O}), all rate constants at 15°.

tetravalent carbon atom. The electron supply to the SO_2Cl group required to raise the chloride to some critical charge level (δ^-) (16) would be expected to be greater than the sulfonate case where $ArSO_3^-$ is the leaving group.

If an intimate ion-pair mechanism is valid for the hydrolysis of the benzene sulfonyl chlorides it is reasonable to assume that K_e[4] (19) will be about the same in H_2O and D_2O. This is likely to be true for each substituent. The common assumption in such a correlation is that K_e is also about the same throughout the series or varies linearly with σ.[4] Then by consideration of log(k.s.i.e.), K_e will be eliminated, if indeed it exists. The correlation evident in Fig. 2, where $\log k_{OH^-}/k_{H_2O}$[5] was plotted against log(k.s.i.e.), reflects the charge characteristics of the product forming step. The large slope, +20.2, results from the acceleration of the base reaction relative to that of attack by a nucleophilic water molecule and is consistent with an S_N2 type of mechanism. We do not consider this plot as evidence of an ion-pair intermediate.

Since the pseudothermodynamic parameters of activation for the solvolysis in H_2O and D_2O are available we have inherently determined the temperature dependence of k.s.i.e. (17). By definition, $\delta_I\Delta G^{\ddagger}$, $\delta_I\Delta H^{\ddagger}$, $\delta_I\Delta S^{\ddagger}$, and $\delta_I\Delta C_p^{\ddagger}$ are considered as $\Delta X_{D_2O}^{\ddagger} - \Delta X_{H_2O}^{\ddagger}$, these data are presented in Table 4.

In the alkyl halide and sulfonate ester examples, the temperature dependence of k.s.i.e. was simply linear Arrhenius behavior, *i.e.* $\delta_I\Delta C_p^{\ddagger} = 0$ and $\delta_I\Delta H^{\ddagger}$ and $\delta_I\Delta S^{\ddagger}$ were constant over the experimental temperature range. A plot of log(k.s.i.e.) against reciprocal temperature for the sulfonyl chlorides was linear in each case and gave derived thermodynamic parameters identical to those in Table 4. The temperature dependence of the kinetic solvent isotope effects for all available examples was conveniently summarized by plotting $\delta_I\Delta H^{\ddagger}$ against $T \cdot \delta_I\Delta S^{\ddagger}$, see Fig. 3. Temperature was included in the entropy term to accommodate all the available data with common units. In the halide series, the larger values of $\delta_I\Delta H^{\ddagger}$ and $T \cdot \delta_I S^{\ddagger}$, which we relate to structural changes in the activation process, compensate each other to produce small values of $\delta_I\Delta G^{\ddagger}$, slope = +1.06 (20). Hence the small and relatively constant k.s.i.e. values observed for alkyl halides (1–3, 16, 17) are in fact the sum of two larger terms, $\delta_I\Delta H^{\ddagger}$ and $\delta_I\Delta S^{\ddagger}$, which have opposite sign and cancel each other

[4]Where $K_e = k_2/k_1$ and $k_{obs} = K_e \cdot k_3$ for the following mechanism

$$RX \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [R^+X^-] \xrightarrow{k_3} \text{Products}$$

then, $\alpha = k_2/k_3$.

[5]The k_{OH^-} values are those determined by Rogne (8).

to give small values for $\delta_I \Delta G^{\ddagger}$, which are equivalent to the k.s.i.e. term.

From Fig. 3, the sulfonyl chlorides behave quite differently from the halides, where the slope = +2.33 and the compensation effect is less important. The significance of the intercept at $T \cdot \delta_I \Delta S^{\ddagger} = 0$ is not obvious but corresponds to $\delta_I \Delta H^{\ddagger} = \delta_I \Delta G^{\ddagger} = 160$ cal mol^{-1}, that is k.s.i.e. = 1.2. We consider this common intercept to represent the minimum zero-point energy difference associated with the disruption of water structure about the displaced halide ion. Rogne has reported a k.s.i.e. (25°) = 1.33 for dimethylsulfamoyl chloride (4), and which according to Hall (21), hydrolyses by the S_N1 mechanism. We predict this compound would lie close to the intercept in Fig. 3.

In conclusion we consider that Fig. 3 is a useful summary of kinetic solvent isotope effects and illustrates a different nucleophilic process for attack of water molecules on sulfur from attack on carbon.

Carbon Disulfide. II. Reaction with Active Methylene Compounds. The Structures of the Desaurins[1,2]

PETER YATES,[3] DONALD R. MOORE, AND THOMAS R. LYNCH
The Departments of Chemistry, Harvard University, Cambridge, Massachusetts 02138, and the University of Toronto, Toronto 5, Ontario

Received October 1, 1970

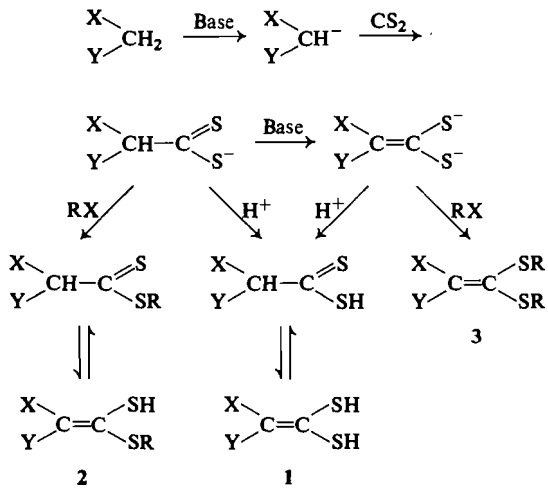
The desaurins, high-melting, neutral compounds formed by the reaction of active methylene compounds with base and carbon disulfide, have been shown to be derivatives of 2,4-bismethylene-1,3-dithietane.

On a montré que les désaurines, des composés neutres, à points de fusion élevés provenant de la réaction du sulfure de carbone avec de la base et des composés contenant des méthylènes actifs, sont des dérivés du bisméthylène-2,4-dithiétane-1,3.

Canadian Journal of Chemistry, 49, 1456 (1971)

Introduction

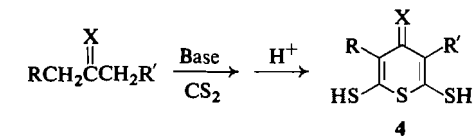
The reactions of active methylene compounds with carbon disulfide in the presence of bases have been observed to give both acidic and neutral products. The former have been shown to be dithio acids of type **1**; these acids have often been isolated as their more stable alkyl derivatives **2** and **3** (Scheme 1) (3–9). If an activating group is



SCHEME 1

flanked on both sides by methylene groups, acidic products of type **4** (and/or tautomers) can also be formed (eq. 1) (6*b*, 10).

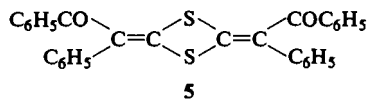
The first report of the formation of a neutral compound by the reaction of an active methylene



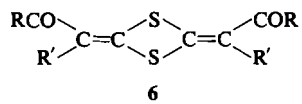
[1]

4

compound with carbon disulfide in the presence of a base is that of Norton and Oppenheim (11), who obtained a yellow product from the reaction of ethyl acetoacetate with carbon disulfide and zinc or lead oxide. Subsequently, Meyer and Wege (12) obtained a related compound by the reaction of deoxybenzoin with four equivalents of potassium hydroxide in carbon disulfide. The product was a high-melting, golden-yellow crystalline solid, that was identical with a compound formed on treatment of the sodio derivative of deoxybenzoin with thiophosgene (13). Meyer (14) showed that this compound has the molecular formula $C_{30}H_{20}O_2S_2$ and suggested that it has structure **5**.[4] He dubbed this class of compounds desaurins on account of their color [*des*oxybenzoin + *aur*um (L., gold)].



5



6

Analogs of **5** were subsequently prepared by treatment of compounds of type $ArCOCH_2Ar'$ and $ArCOCH_2CH_3$ with carbon disulfide and base (15, 16). Desaurins were also obtained by

pyrolysis of the dibenzoyl derivatives or heavy metal salts of dithio acids of type **1** (16); pyrolysis of the acids themselves gave the desaurins, but in very poor yields. Recently, Gompper and Töpfl (*7a*) have obtained desaurins directly from compounds of type **1** by treatment with acylating agents or with oxidizing agents (bromine, iodine, or ammonium persulfate). However, the latter agents give rise to products containing three sulfur atoms in some cases (*7a*, 17). These reactions are related to the earlier observations by Wenzel (18) of the formation of desaurins and three-sulfur compounds on treatment of active methylene compounds with bromine in carbon disulfide.

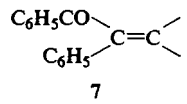
The structural type **6** originally proposed by Meyer (14) for the desaurins has found general acceptance by most other workers [*cf.*, however, Wenzel (18*b*)]. However, the assignment of **6** rested almost solely on the elemental composition and molecular weights of the compounds. The only degradative studies, those of Wachter (19) on the desaurin from deoxybenzoin, were performed under vigorous conditions and provided little structural information. The present work was undertaken to establish the structures of the desaurins and to investigate further the chemistry of this interesting group of compounds.

Reactions and Structures of the Desaurins

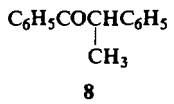
The desaurin from deoxybenzoin was prepared by the procedure of Meyer and Wege (12), and the molecular formula, $C_{30}H_{20}O_2S_2$, previously assigned to it was confirmed by elemental analysis and mass spectrometry (1). Its i.r. and u.v. spectra [λ_{max}(KBr) 6.17μ; λ_{max}($CHCl_3$) 266 (ε 22 900) and 419 mμ (ε 38 100)] showed the presence of one or more highly conjugated carbonyl groups.[5] It was found to be highly resistant to acid hydrolysis; after treatment with a boiling solution of concentrated hydrochloric acid in dioxane for 50 h, 96% of the desaurin was recovered.

Oxidation with chromic acid in acetic acid gave >3 molar equivalents of benzoic acid, demonstrating that no ring closure on the phenyl rings occurs in the formation of the desaurin. Oxidation of the desaurin with potassium permanganate in boiling acetone or ozonolysis in dichloromethane at 0° gave benzil and benzoic acid. The formation of these products is in accord with the presence of the structural feature **7** in **5** (21).

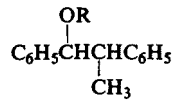
Reaction of the desaurin with zinc in boiling acetic acid for 50 h gave 2-phenylpropiophenone (**8**), *erythro*-1,2-diphenyl-1-propyl acetate (**9**) (22), and *trans*-1,2-diphenylpropene (**10**) (23). The formation of these products is again in accord with the presence of one or more groupings of type **7** in the desaurin molecule. Moreover, the desaurin was found to be stable to the action of zinc and acetic acid at room temperature, which makes it most unlikely that thione groups or disulfide linkages are present.



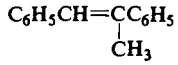
7



8



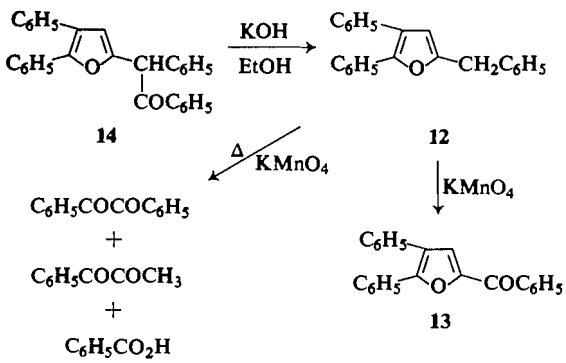
9 R = $COCH_3$
11 R = H



10

Treatment of the desaurin with Raney nickel in boiling dioxane also gave **8** together with *erythro*-1,2-diphenyl-1-propanol (**11**) (23). The same products were obtained when old sponge nickel catalyst was used; however, when fresh sponge nickel catalyst was used, a different product was obtained. This was a colorless crystalline compound, $C_{30}H_{22}O_2$, with a strong band at 5.91 μ in its i.r. spectrum and medium or weak bands at 6.25, 6.33, and 6.45 μ; its u.v. spectrum showed maxima at 249 (ε 31 600) and 291 mμ (ε 17 400), and its p.m.r. spectrum showed signals at δ 6.05 (s, 1H), 6.26 (s, 1H), 7.1–7.5 (m, 18H), 7.9–8.1 (m, 2H). It formed an orange 2,4-dinitrophenylhydrazone. These data suggested the presence of a benzoyl group attached to an sp^3 carbon atom, and a furan ring (24). The desulfurization product was cleaved by ethanolic potassium hydroxide to give benzoic acid and an oily product, $C_{23}H_{18}O$. This did not show a strong band in the carbonyl-stretching region of its i.r. spectrum, but retained a medium band at 6.45 μ, attributable to a furan ring. The cleavage product was oxidized by potassium permanganate to a ketone, $C_{23}H_{16}O_2$, that was characterized as its 2,4-dinitrophenylhydrazone. The spectra of the ketone [6.08 μ; 263 (ε 18 600) and 344 mμ (ε 19 100)] indicated that it was highly conjugated, a feature that was confirmed by the position of the long wavelength maximum in the u.v. spectrum of its 2,4-dinitrophenylhydrazone [418 mμ (ε 26 900)]. More vigorous oxidation with potassium permanganate

[5]The i.r. and u.v. spectra of the desaurins are discussed in detail in Paper III of this series (20).



SCHEME 2

gave benzoic acid, benzil, and 1-phenyl-1,2-propanedione. These data establish the structure of the cleavage product as **12**; the ketone formed on mild oxidation is formulable as **13** (see Scheme 2). The desulfurization product itself can then be formulated as **14**, its cleavage to **12** finding close analogy in the cleavage of 2,2-diphenylacetophenone by ethanolic potassium hydroxide to diphenylmethane and benzoic acid (25). The products formed on vigorous oxidation of **12** can be interpreted as arising via hydroxylation of **13** (Scheme 3).

The formation of **14** from the desaurin can be rationalized in terms of structure **5** by a route of the type shown in Scheme 4. The formation of a new carbon–carbon bond during desulfurization reactions with nickel has been observed in other cases (26), and the proximity of the carbon atoms involved in **5** could undoubtedly represent a favorable factor for the occurrence of such a reaction in the present case.

The chemical reactions of the desaurin from deoxybenzoin discussed thus far can all be interpreted in terms of structure **5**; the only alternative structure that could possibly provide a basis for their interpretation and might be in accord with the spectroscopic data is **15**. This differs from **5** in possessing one rather than two carbonyl groups, and means were therefore sought to establish the number of carbonyl groups present in the desaurin. This could not be done by the preparation of simple derivatives, because of the very low solubility of the desaurin in organic solvents. Advantage was therefore taken of its solubility in concentrated sulfuric acid to subject it to a Schmidt reaction in this medium by the addition of sodium azide. Two isomeric yellow products, $C_{30}H_{21}O_2S_2N$, were obtained, whose i.r. spectra were very similar. These spectra showed weak bands at 2.96–2.97 μ, and bands in the carbonyl-stretching region at 6.02–6.03 and 6.14 μ, and are in good accord with the assignment to the products of structures of type **16** or **17**. The u.v. spectra of the products confirmed the retention of the desaurin nucleus in these products (20). The very close similarity of their spectra suggested that they are *cis*- and *trans*-stereoisomers of either **16** or **17**, rather than structural

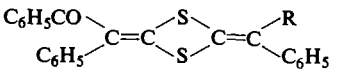
15



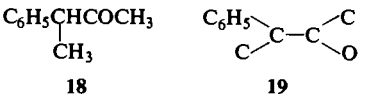
16 R = $CONHC_6H_5$
17 R = $NHCOC_6H_5$

isomers. Structure **16** can be assigned on the basis of the mass spectrum of one of the isomers, which shows, in addition to the molecular ion peak at *m/e* 491 (42%), a peak at *m/e* 399 (47%) corresponding to the ion $(M\text{-}C_6H_5NH)^+$. The formation of these amides that possess a second carbonyl group that gives rise to a carbonyl-stretching band in a similar position to that of the desaurin itself can readily be interpreted in terms of structure **5**, but not of structure **15**.

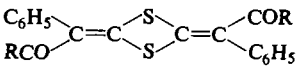
Because of the importance of establishing the presence of two ketonic carbonyl groups in the desaurins, and the possible ambiguity associated with the use of the Schmidt reaction for this purpose, *i.e.*, the possibility of cleavage or additional rearrangement reactions in the strongly acid medium, it was considered desirable to search for a more soluble desaurin, which would undergo derivative formation under mild reaction conditions. Apitzsch (10*a*) has previously reported the formation of an acidic product of type **4** from the reaction of phenylacetone with carbon disulfide and base; we have found that when the reaction is carried out under the conditions used for the preparation of the desaurin from deoxybenzoin, a lemon yellow neutral compound, $C_{20}H_{16}O_2S_2$, is formed whose spectra showed it to be a desaurin (20); it was considerably more soluble in organic solvents than the desaurin from deoxybenzoin.

Reduction with zinc and sodium hydroxide gave 1.44 molar equivalents of 3-phenyl-2-butanone (**18**), establishing the presence of *two* C_{10} moieties with structure **19**.

Treatment with 2,4-dinitrophenylhydrazine in ethanolic sulfuric acid gave a mono-2,4-dinitrophenylhydrazone that retained a carbonyl-stretching band in its i.r. spectrum, while treatment with this reagent in aqueous dioxane containing hydrochloric acid gave a bis-2,4-dinitrophenylhydrazone that showed no carbonyl-stretching band in its i.r. spectrum. Further, this desaurin could be converted to a dioxime, $C_{20}H_{18}N_2O_2S_2$, from which the desaurin could be regenerated by acid-catalyzed hydrolysis in the presence of formaldehyde, demonstrating that no skeletal change had occurred in its conversion to the derivative. These data show that the desaurin contains *two* carbonyl groups.



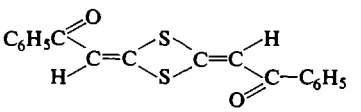
18 19



20 R = CH_3
21 R = OH

Treatment of the desaurin with sodium hypochlorite converted it to a yellow acidic product, $C_{18}H_{12}O_4S_2$, whose spectra demonstrated that it retained the desaurin nucleus (20). This transformation must involve the conversion of two *C*-acetyl groups to two carboxylic acid groups by haloform reactions; the occurrence of such reactions was confirmed by the isolation of iodoform when the desaurin was treated in basic solution with iodine and potassium iodide. Structure **20**, analogous to **5**, rather than a structure analogous to **15**, can thus be assigned unambiguously to the desaurin; this is in conformance with its p.m.r. spectrum, which shows signals at δ 2.10 (s, 6H) and 7.38 (m, 10H). The structure of the haloform reaction product is then **21**.

The chemical evidence discussed above (27) established that the structures of the desaurins investigated are of type **6**, as originally suggested by Meyer (14*a*). It did not, however, provide information concerning their configuration. This has been obtained in the case of the desaurin from acetophenone by a subsequent X-ray crystallographic study in collaboration with Nyburg and Mellor (28, 29). The desaurin was prepared by the method of Kelber and Schwarz (16) and obtained by slow crystallization from toluene or nitrobenzene as small plates, m.p. 270–272.5° (dec.). A complete three-dimensional X-ray analysis was performed and established the structure, configuration, and conformation of the desaurin as shown in **22**.[6]



22

[6]The two α,β-unsaturated carbonyl systems and the two sulfur atoms are essentially coplanar, while the two phenyl rings make an angle of 11° with this plane (29).

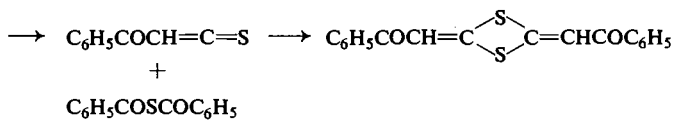
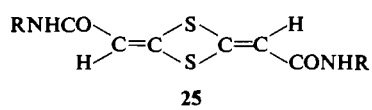
[4] 



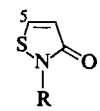
Mechanism of Desaurin Formation

The desaurins are formally dimers of thioketenes, **24**. In the preparation of desaurins by the action of carbon disulfide and bases on active methylene compounds, thioketenes (**24**) could be formed by the elimination of sulfide ion from the dianions **23** (eq. 2). However, formation of the desaurins by dimerization of the thioketenes **24** is unlikely, since the latter would be expected to undergo attack by the nucleophiles present more rapidly than dimerization. The probable pathway, then, would involve attack by **23** on **24** with elimination of sulfide ion (eq. 3). An alternative type of route, without thioketene formation, could involve direct dimerization of **23** followed by elimination of two sulfide ions; however, the dimerization of such dianions is counted improbable on electrostatic grounds (the intervention of the monoanions is also improbable under the highly basic conditions).

Very recently a novel method for the synthesis of the desaurins of type **25** has been reported by Chan, Crow, and Gosney (30), involving treatment of the corresponding *N*-alkyl-3-isothiazolones **26** with bases. These authors also rejected a mechanism for these reactions involving thioketene dimerization for a similar reason to that referred to above. They favored a pathway involving reaction of **26** with its C-5 anion, but did not consider explicitly the possibility of attack of this anion on the thioketene.



25



26

The formation of desaurins via thermal cleavage of diacyl derivatives of type **27** (16) [or the related alkyl derivatives (7*a*)] may well proceed via thioketene dimerization (*e.g.*, eq. 4); a related pathway could also account for the formation of desaurins by treatment of compounds of type **1** with phthalyl chloride (7*a*).

The dimerization of thioketenes has been implicated in related reactions (26*b*, 31) and Dickore and Wegler (31*b*) have trapped the thioketene intermediate with nitrile oxides (Scheme 5). However, Raasch (32) has observed that bis(trifluoromethyl)thioketene dimerizes only very slowly at room temperature in the absence of Lewis bases.

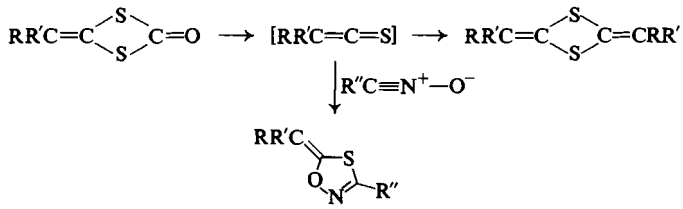

SCHEME 5

Experimental

Melting points were taken on a Fisher–Johns micro hot stage and are uncorrected, unless otherwise indicated. Solutions in organic solvents were dried over anhydrous sodium sulfate.

The Desaurin from Deoxybenzoin (5)

The desaurin was prepared essentially according to the procedure of Meyer and Wege (12). Deoxybenzoin (49.0 g, 0.250 mol) and powdered potassium hydroxide (56.0 g, 1.00 mol) were heated in boiling carbon disulfide (600 ml) under reflux for 8 h. The excess carbon disulfide was removed under reduced pressure, and the solid cake remaining was triturated with water. The suspension was filtered, and the solid was washed with successive small portions of water, alcohol, and ether and air dried to give **5** (23.7 g, 40%) as a bright yellow powder. An additional 2.0 g of the desaurin could be recovered by evaporation of the combined washings to one-half volume.

The desaurin could be purified most conveniently by extraction with chloroform in a Soxhlet apparatus. It crystallized from the hot chloroform as small golden needles, m.p. 300–302° (dec.). An analytical sample was prepared by recrystallization from nitrobenzene, and was dried under reduced pressure at 100° for 10 h; m.p. 300.5–302.5° (dec.).[5]

Anal. Calcd. for $C_{30}H_{20}O_2S_2$: C, 75.60; H, 4.23; S, 13.46. Found: C, 75.81; H, 4.38; S, 13.20.

The desaurin was insoluble in the usual organic solvents at room temperature; at elevated temperatures small amounts could be dissolved in chloroform, dioxane, xylene, and nitrobenzene. It was readily soluble in cold concentrated sulfuric acid to give a deep purple solution, from which it was precipitated unchanged (mixed m.p.) upon addition of water.

Attempted Acid-catalyzed Hydrolysis of 5

The desaurin **5** (1.14 g, 2.39 mmol) was added to concentrated hydrochloric acid (25 ml) and dioxane (50 ml), and the mixture was boiled under reflux for 100 h and filtered. The yellow crystalline solid (1.10 g) was identified as **5** by a mixed m.p.; recovery 96%. The acidic filtrate was extracted with dichloromethane, and the extract was dried, filtered, and evaporated. There was no residue.

Oxidation of 5 with Chromic Acid

The desaurin **5** (1.00 g, 2.10 mmol) was suspended in glacial acetic acid (75 ml), and chromic anhydride (5.00 g, 50 mmol) was added in portions. The mixture was stirred for 15 h at room temperature, then diluted with water (200 ml), and extracted with ether. The ethereal solution was extracted with aqueous 10% sodium hydroxide, washed with water, dried, and filtered. Removal of the solvent gave a gummy solid (0.05 g), whose i.r. spectrum showed it to be largely benzoic acid.

The basic extracts were combined, acidified to p*H* 1, and extracted with four portions of dichloromethane. The combined extracts were dried, filtered, and evaporated by gentle warming on the steam bath to give a white crystalline solid (0.76 g), m.p. 119–120.5°, undepressed on admixture with benzoic acid. The i.r. spectrum of the product was identical with that of benzoic acid. The total yield of benzoic acid was 0.81 g (79%, based on the formation of 4 mol from 1 mol of **5**).

Attempted oxidation of the desaurin with chromic anhydride in concentrated sulfuric acid, or with the chromic anhydride – pyridine complex led only to intractable red tars from which no pure organic compounds could be isolated.

Ozonolysis of 5

A suspension of **5** (1.00 g, 2.09 mmol) in dichloromethane (50 ml) was cooled to 0° in an ice bath. The mixture was maintained at this temperature throughout the ozonization. Ozonized oxygen from a Welsbach Ozonizer was passed through the mixture for 3 h. Additional dichloromethane was added as necessary to maintain the volume of the solution. The ozonide was decomposed by the addition of water (20 ml), removal of the dichloromethane under reduced pressure at room temperature, and heating of the mixture on the steam bath for 0.5 h.

Unconsumed desaurin (0.27 g, 0.564 mmol) was removed by filtration, and the filtrate was extracted with four portions of ether. The aqueous layer was acidified to p*H* 1 with 10% hydrochloric acid and warmed on the steam bath to 80°. Excess dilute aqueous barium chloride was added dropwise, the solution was allowed to cool, and the precipitate of barium sulfate (0.11 g) was collected.

The combined ethereal extracts were partitioned into acid and neutral fractions by extraction with four portions of aqueous 10% sodium hydroxide, combination and acidification of the basic extracts to p*H* 1, and extraction with four portions of dichloromethane. Both organic solutions were dried and stripped of solvent under reduced pressure.

A portion (0.20 g) of the acid fraction (0.25 g) was sublimed at a bath temperature of 55–60° and 2 mm pressure for 5 h. The white crystalline sublimate (0.16 g) was recrystallized from water to give colorless needles (0.12 g), m.p. and mixed m.p. with benzoic acid, 120.5–121.5°. The i.r. spectrum of the product was superimposable on that of benzoic acid.

A portion (0.23 g) of the neutral fraction (0.28 g) was dissolved in cyclohexane and chromatographed on silica gel (15 g). The major fraction, eluted with benzene, was a

For personal use only.

yellow solid (0.19 g), m.p. 88–92°, whose i.r. spectrum indicated it to be nearly pure benzil. A portion of this material was crystallized from ethanol to give yellow needles, m.p. and mixed m.p. with benzil, 93.5–95°; another portion was converted to the 2,4-dinitrophenylhydrazone by the method of Shriner *et al.* (33), and this was crystallized from ethanol – ethyl acetate; m.p. and mixed m.p. 188–190°.

The yield of benzil was 35%, based on a theoretical yield of 2 mol equiv from unrecovered **5**; that of benzoic acid was 20%, based on a theoretical yield of 4 mol equiv from unrecovered **5**.

Oxidation of 5 with Potassium Permanganate

The desaurin **5** (0.772 g, 1.62 mmol) was mixed with potassium permanganate (5.00 g, 31.6 mmol) in acetone (150 ml), and the mixture was boiled under reflux for 4 h, cooled, and filtered. The brown precipitate was treated with acidified aqueous sodium bisulfite, and the mixture was warmed gently. The desaurin **5** (0.2989 g, 0.627 mmol) was recovered as a yellow, insoluble precipitate.

The filtrate was poured into water, and the solution was extracted five times with ether. The combined ethereal extracts were extracted five times with aqueous 10% potassium hydroxide and once with water. The ethereal solution was dried and filtered, and the solvent was removed under reduced pressure to give a yellow crystalline product, m.p. 92.5–94.5° (0.128 g). This was shown to be benzil by a mixed m.p. determination and comparison of its i.r. spectrum with that of an authentic sample. The yield, based on the formation of 2 mol equiv from the unrecovered desaurin, was 39%.

The combined basic extracts were acidified to p*H* 1 with 10% hydrochloric acid, and the solution was extracted five times with dichloromethane. The extracts were combined, dried, filtered, and evaporated by gentle warming on the steam bath to give a colorless, crystalline mass (0.221 g). This material was sublimed at 50–60° (4–5 mm) for 5 h. The sublimate (0.208 g) had m.p. 119–120.5°. Recrystallization from water gave colorless needles, m.p. and mixed m.p. with benzoic acid, 120.5–121.5°. The i.r. spectrum was identical with that of benzoic acid. The yield, based on the formation of 4 mol equiv from the unrecovered desaurin, was 35%.

Reduction of 5 with Zinc and Acetic Acid

The desaurin **5** (5.00 g, 10.5 mmol) was suspended in glacial acetic acid (150 ml) and a large excess of powdered zinc (*ca.* 30 g) was added. The mixture was boiled under reflux for 50 h, during which time an odor resembling that of carbon oxysulfide was noticed at the top of the condenser. The mixture was cooled and filtered, and the excess zinc was thoroughly washed with acetic acid. The combined filtrate and washings were diluted with water (600 ml), acidified to p*H* 1 with 10% hydrochloric acid, and extracted with three portions of dichloromethane. The extracts were combined, washed three times with aqueous 10% sodium carbonate and once with water, dried, filtered, and evaporated to give a pale yellow-orange, neutral oil (3.94 g). The combined basic washings were acidified to p*H* 1 with 10% hydrochloric acid and extracted with three portions of dichloromethane. The combined extracts were dried, filtered, and evaporated to give a trace of acidic, gummy solid, m.p. 109–116°.

The neutral fraction was dissolved in benzene and chromatographed on alumina (Merck; 100 g) packed in petroleum ether. Early fractions (70% petroleum ether – 30% benzene eluent) crystallized upon evaporation to give a colorless solid (0.14 g), m.p. 57–65°, which after two crystallizations from ethanol gave colorless crystals, m.p. 81–82°, which did not depress the m.p. of authentic *trans*-1,2-diphenyl-1-propene (**10**) (*vide infra*). The two samples had identical i.r. spectra, and each decolorized neutral potassium permanganate in acetone.

Middle fractions (50% petroleum ether – 50% benzene eluent; 0.77 g) gave a product with an i.r. spectrum showing all the bands of methyldeoxybenzoin (**8**). The product was converted to its 2,4-dinitrophenylhydrazone by the method of Vogel (34). After two crystallizations from ethanol – ethyl acetate this had m.p. 153–155°, undepressed on admixture with authentic methyldeoxybenzoin 2,4-dinitrophenylhydrazone (*vide infra*).

Later fractions (benzene eluent; 0.80 g) gave a product that was crystallized twice from ethanol to give transparent squares, m.p. 108–109.5°, identified as *erythro*-1,2-diphenyl-1-propyl acetate (**9**) by a mixed m.p. and i.r. spectral comparison with an authentic sample (*vide infra*).

Stripping of the column with ethanol gave a mixture (0.82 g) whose i.r. spectrum showed bands attributable to **8** and **9** and an unidentified alcohol.

Attempted reduction of the desaurin with the same amounts of reagents at room temperature was unsuccessful.

Methyldeoxybenzoin (8)

Methyldeoxybenzoin was prepared by the method of Meyer and Oelkers (35). A recrystallized sample had m.p. 48–49°; $\lambda_{max}(CHCl_3)$ 5.94(s) and 7.28 μ(m).

The 2,4-dinitrophenylhydrazone was prepared by the procedure of Shriner *et al.* (33). Two recrystallizations from ethanol afforded orange prisms, m.p. 153–155° [lit. (36) m.p. 151.5–152.5°].

erythro-1,2-Diphenyl-1-propanol (11) and erythro-1,2-Diphenyl-1-propyl Acetate (9)

A mixture of methyldeoxybenzoin (2.40 g, 11.4 mmol), ethanol (50 ml), and sodium borohydride (0.75 g, 19.8 mmol) was boiled under reflux for 2 h, poured into water (150 ml), and extracted with three portions of dichloromethane. The combined extracts were dried, filtered, and evaporated. An i.r. spectrum of the crude product (2.14 g) revealed complete reduction, as evidenced by the disappearance of all carbonyl absorption.

The crude alcohol was purified by chromatography on alumina (Merck) with ether as eluent. The purified product was crystallized from petroleum ether to give **11** as fine, colorless needles, m.p. 47.5–49° [lit. (37) m.p. 48°]; $\lambda_{max}(CHCl_3)$ 2.82(m), 7.24 μ(m).

The acetate **9** was prepared by acetylation of **11** with pyridine – acetic anhydride in the normal fashion, and was crystallized three times from ethanol; m.p. 107–109° [lit. (22) m.p. 109–110°]; $\lambda_{max}(CHCl_3)$ 5.78(s), 7.30 μ(m).

trans-1,2-Diphenyl-1-propene (10)

erythro-1,2-Diphenyl-1-propanol (0.65 g, 3.06 mmol) was heated with potassium hydrogen sulfate (2.40 g, 17.6 mmol) at 200° for 0.5 h. The mixture was cooled, water was added, and the solution was extracted with three

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

portions of dichloromethane. The combined extracts were dried, filtered, and evaporated to give the crude alkene (0.53 g). Two recrystallizations from ethanol gave colorless plates, m.p. 80–81.5° [lit. (23) m.p. 81–82°]; $\lambda_{max}(CHCl_3)$ 6.10(w), 7.28 μ(m).

Reduction of **5** *with Nickel. Formation of* **14**

(A) Sponge nickel catalyst (Davison; 50.0 g) from a freshly opened bottle was washed 11 times by decantation with dioxane. Dioxane (200 ml) and **5** (5.00 g, 10.5 mmol) were added and the mixture, protected from atmospheric moisture with a calcium chloride drying tube, was boiled under reflux for 50 h. The catalyst was removed by filtration through a sintered glass disc and washed with several portions of boiling absolute ethanol. The combined filtrate and washings were evaporated under reduced pressure at room temperature. The residue was taken up in a small volume of hot ethanol and the solution was allowed to stand for 12 h. Filtration yielded 1.5 g (35%) of **14** as pale yellow needles, m.p. 126–127.5°. Four recrystallizations from ethanol afforded an analytical sample as fine, colorless needles, m.p. 129–130°; $\lambda_{max}(CHCl_3)$ 5.91(s), 6.25(m), 6.33(w), 6.45 μ(w); $\lambda_{max}(C_2H_5OH)$ 249 (ε 31 600), 291 mμ (ε 17 400); $\delta(CDCl_3)$ 6.05(s, 1H), 6.26(s, 1H), 7.1–7.5(m, 18H), 7.9–8.1(m, 2H).

Anal. Calcd. for $C_{30}H_{22}O_2$: C, 86.93; H, 5.35. Found: C, 86.94; H, 5.53.

The 2,4-dinitrophenylhydrazone was prepared by the method of Shriner *et al.* (33). Four recrystallizations from ethanol – ethyl acetate gave orange cubes, m.p. 160–162° (dec.).

Anal. Calcd. for $C_{36}H_{26}O_5N_4$: C, 72.71; H, 4.41; N, 9.42. Found: C, 72.65; H, 4.48; N, 9.20.

(B) Reduction of **5** with old Davison sponge nickel catalyst or W-6 Raney nickel (38), by the same procedure as in section A led to a mixture of products, from which no **14** could be isolated.

In a typical reduction desaurin **5** (5.00 g, 10.5 mmol) gave a crude mixture (4.14 g) whose i.r. spectrum showed no absorption at 6.45 μ. A mixture (5.00 g) from two reductions was chromatographed on alumina (Woelm, activity grade 3). From the early fractions (70% petroleum ether – 30% benzene eluent) there was obtained a product (1.78 g) whose i.r. spectrum was very similar to that of methyldeoxybenzoin (**8**). A portion of this material was converted to its 2,4-dinitrophenylhydrazone by the procedure of Shriner *et al.* (33), and this was chromatographed on alumina (Merck). The major fraction gave, after three crystallizations from ethanol – ethyl acetate, orange plates, m.p. 149.5–151°, undepressed on admixture with authentic methyldeoxybenzoin 2,4-dinitrophenylhydrazone.

Later fractions (80% benzene – 20% ether eluent) (0.75 g) from the original chromatogram were combined and rechromatographed on alumina (Merck). Benzene eluted a material which solidified, and whose i.r. spectrum was identical with that of *erythro*-1,2-diphenyl-1-propanol (**11**). Recrystallization from petroleum ether gave fine, colorless needles, m.p. 47–49°.

Base-catalyzed Hydrolysis of **14**. *Formation of* **12**

A solution of **14** (0.554 g, 1.34 mmol) in 95% ethanol (25 ml) containing potassium hydroxide (1.50 g, 26.7 mmol) was heated under reflux on the steam bath for 3 h. Water (25 ml) was added, and the solution was cooled and extracted with four portions of dichloromethane. The combined extracts were dried and stripped of solvent under reduced pressure to give a pale yellow oil (0.306 g).

The basic aqueous solution was acidified to p*H* 1 with 10% hydrochloric acid and extracted as above. The acidic product (0.133 g) was obtained as a white crystalline solid, m.p. 119–120.5°, undepressed upon admixture with benzoic acid. The i.r. spectrum of this product was identical with that of benzoic acid.

The neutral oily fraction was purified by chromatography on non-basic alumina (Woelm, activity grade 1) with elution with petroleum ether (b.p. 30–60°). Evaporation of the solvent at 10° under reduced pressure and for 12 h at 0.5 mm gave **12** as a colorless oil; $\lambda_{max}(CHCl_3)$ 6.24(m), 6.34(w), 6.45 μ(m); $\lambda_{max}(C_2H_5OH)$ 225 (ε 23 400), 297 mμ (ε 13 800).

Anal. Calcd. for $C_{23}H_{18}O$: C, 89.00; H, 5.85. Found: C, 88.88; H, 6.28.

Oxidation of **12** *with Neutral Potassium Permanganate. Formation of* **13**

A solution of **12** (2.13 g, 6.86 mmol) in anhydrous acetone (50 ml) was stirred with anhydrous magnesium sulfate (2.0 g). A solution of potassium permanganate (0.80 g, 5.06 mmol) in anhydrous acetone (30 ml) was added, and the mixture was stirred at room temperature for 2.5 h. The precipitate of manganese dioxide was filtered off and washed with acetone. The combined filtrate and washings were diluted with water (70 ml), and saturated aqueous sodium bisulfite was added until the pink color was discharged. The resulting solution was acidified with concentrated hydrochloric acid to p*H* 1 and extracted with three portions of ether. The combined ethereal extracts were washed with water and with aqueous 10% sodium bicarbonate, dried, filtered, and evaporated under reduced pressure to give the neutral fraction (1.08 g) as a pale yellow oil. This fraction was dissolved in benzene and chromatographed on alumina (Merck; 50 g). Elution with petroleum ether (b.p. 30–60°) and benzene led to recovery of 0.85 g of colorless oil, which was identified as **12** by its i.r. spectrum. The column was then eluted with dichloromethane to give **13** as a yellow viscous oil (0.18 g); $\lambda_{max}(CHCl_3)$ 6.08(vs), 6.25(m), 6.34(m), 6.62 μ(m); $\lambda_{max}(C_2H_5OH)$ 263 (ε 18 600), 344 mμ (ε 19 100).

Compound **13** was characterized as its 2,4-dinitrophenylhydrazone (33), which was purified by twice eluting it from alumina (Merck) with benzene, followed by three recrystallizations from ethanol – ethyl acetate to give deep orange microcrystals, m.p. 185–186° (dec.); $\lambda_{max}(CHCl_3)$ 290(sh, ε 17 800), 331 (ε 17 400), 418 mμ (ε 26 900).

Anal. Calcd. for $C_{29}H_{20}O_5N_4$: C, 69.04; H, 4.11; N, 11.11. Found: C, 69.02; H, 4.31; N, 10.71.

Oxidation of **14** *with Basic Potassium Permanganate*

A solution of **14** (0.593 g, 1.91 mmol) in acetone (100 ml) was treated with potassium permanganate (1.00 g, 7.97 mmol) and water (10 ml), and the mixture was boiled under reflux for 2.5 h. It was then cooled, acidified with 10% hydrochloric acid to p*H* 1, and treated with aqueous 10% sodium bisulfite (10 ml). After dissolution of the manganese dioxide was complete, the solution was extracted with four portions of dichloromethane. The ex-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

tracts were combined, washed with four portions of aqueous 10% potassium hydroxide and one of water, dried, filtered, and evaporated to give the neutral fraction (0.172 g).

The combined basic extracts and washings were acidified to p*H* 1 with 10% hydrochloric acid, and extracted with four portions of dichloromethane. The organic extracts were combined, filtered through anhydrous sodium sulfate, and evaporated under reduced pressure to give the acid fraction (0.333 g) as colorless crystals, m.p. 115–118°, undepressed upon admixture with benzoic acid. The i.r. spectrum of the acid fraction was identical with that of benzoic acid.

The neutral fraction was dissolved in benzene and chromatographed on Florisil. Two distinct yellow bands were developed and eluted with benzene. The first, when freed of solvent, furnished yellow needles (0.082 g), m.p. 91.5–93°, undepressed upon admixture with benzil; its i.r. spectrum was identical with that of benzil. The second gave a yellow oil (0.027 g), whose i.r. spectrum indicated it to be largely 1-phenyl-1,2-propanedione. It was converted *in toto* to its bis-2,4-dinitrophenylhydrazone (0.032 g) (33); this was recrystallized once to give orange micro-crystals, m.p. 153.5–155°, undepressed on admixture with 1-phenyl-1,2-propanedione bis-2,4-dinitrophenylhydrazone [lit. (39) m.p. 155–156°].

Reaction of **5** *with Hydrazoic Acid. Formation of* **16**

The desaurin **5** (0.48 g, 1.00 mmol) was dissolved in concentrated sulfuric acid (50 ml) and sodium azide (0.20 g, 2.3 mmol) was added in small portions. The mixture was allowed to stand for 12 h, and then an additional quantity of sodium azide (0.10 g, 1.2 mmol) was added. After standing for 24 h the color of the solution had changed from an initial intense red–violet to a deep red.

The solution was poured onto ice, the mixture was filtered, and the precipitate was air-dried. This yellow solid was thoroughly triturated with hot ethanol, and the mixture was allowed to cool and then filtered.

The resulting solid (0.22 g) was dissolved in chloroform and chromatographed on alumina (Merck; 50 g). A bright yellow band moved rapidly with chloroform as eluent and gave a fraction, which, after removal of solvent, was obtained as a yellow powder (0.80 g). This was purified by three recrystallizations from chloroform–cyclohexane to give fluffy yellow needles, m.p. 258–259°; *m/e* 491 (42), 399 (47), 161 (32), 105 (100).[5]

Anal. Calcd. for $C_{30}H_{21}O_2NS_2$: C, 73.29; H, 4.31; N, 2.85. Found: C, 73.56; H, 4.28; N, 2.70.

A second yellow band that was eluted more slowly with chloroform gave a fraction which, after removal of solvent, yielded small yellow crystals (0.06 g). This product was purified by three recrystallizations from ethanol–water to give yellow micro-crystals, m.p. 210–211°.[5]

Anal. Calcd. for $C_{30}H_{21}O_2NS_2$: C, 73.29; H, 4.31; N, 2.85. Found: C, 73.02; H, 4.33; N, 2.92.

*The Desaurin from Phenyl-2-propanone (***20***)*

A mixture of finely powdered potassium hydroxide (56.0 g, 1.00 mol) and phenyl-2-propanone (33.5 g, 0.250 mol) in carbon disulfide (300 ml) was boiled under reflux for 15 h. The excess carbon disulfide was removed under reduced pressure at room temperature, and the residue was treated with water (500 ml). The basic mixture was extracted with four portions of dichloromethane, and the extracts were combined, dried, filtered, and evaporated. The neutral fraction was thus obtained as a dark red tar (22.40 g).

The basic solution was acidified with 20% sulfuric acid at 10°, and extracted three times with dichloromethane. The combined organic extracts were dried over sodium sulfate, filtered, and freed of solvent under reduced pressure to give the acidic fraction as a red-brown tar (12.5 g). A portion (3.0 g) of this acidic material was dissolved in benzene and chromatographed on silica gel (100 g). A light orange band (70% petroleum ether – 30% benzene eluent) was collected and evaporated to give a deep red tar; $\lambda_{max}(CHCl_3)$ 2.84–4.2(w), 6.24(m), 6.44(s), and 6.90 μ(s). The remainder of the acid fraction was dissolved in benzene (200 ml), and the solution was poured into petroleum ether (500 ml) with vigorous stirring to give a curdy light orange precipitate, which on filtration turned to a viscous deep red oil. The i.r. spectrum of the freshly filtered material was compared with that of a sample dried *in vacuo*. The spectra were similar with no extraneous bands unattributable to solvent and the spectrum of the dried sample was indistinguishable from that of the sample obtained by chromatography.

The neutral fraction was dissolved in benzene (50 ml), and chromatographed on alumina (Merck; 500 g). Early fractions (30% benzene – 70% petroleum ether eluent) on evaporation gave dark red oils whose i.r. spectra indicated the presence of large amounts of phenyl-2-propanone. Elution with benzene yielded red oils which solidified either spontaneously or upon trituration with ligroin (b.p. 66–75°). Increasingly polar solvents eluted tars which were not further investigated. The benzene-eluted solid was purified by five recrystallizations from benzene–cyclohexane to give **20** as lemon yellow needles (2.5 g), m.p. 233–233.5°; δ($CDCl_3$) 2.10 (s, 6H), 7.38 (m, 10H).[5]

Anal. Calcd. for $C_{20}H_{16}O_2S_2$ (mol. wt. 352): C, 68.15; H, 4.58; S, 18.20; 2 C—CH_3, 8.53. Found (355 (isothermal distillation)): C, 68.30; H, 4.50; S, 18.23; C—CH_3, 7.34.

The desaurin **20** was readily soluble in hot benzene, ethanol, dioxane, and sparingly soluble in ligroin (b.p. 66–75°). It was soluble in concentrated sulfuric acid to give an orange solution from which it was precipitated by the addition of water.

Reduction of **20** *with Zinc and Base*

The desaurin **20** (0.50 g, 1.42 mmol) was mixed with zinc dust (3.00 g, 45.9 mg-atoms), sodium hydroxide (5.00 g, 125 mmol), water (150 ml), and ethanol (25 ml), and the mixture was boiled under reflux for 5 days. Fresh zinc dust (1.00 g, 15.3 mg-atoms) and sodium hydroxide (1.00 g, 25 mmol) were added daily.

The reaction mixture was cooled and filtered, and the unchanged zinc was washed with several portions of ethanol. The combined filtrate and washings were diluted with water (100 ml) and extracted with three portions of dichloromethane. The extracts were combined, dried, filtered, and evaporated to give a pale yellow oil (0.30 g), whose i.r. spectrum was very similar to that of 3-phenyl-2-butanone. It was converted *in toto* to its 2,4-dinitrophenylhydrazone (33) to give a product (0.53 g), m.p. 166–169°. Two recrystallizations from ethanol – ethyl acetate afforded orange needles, m.p. 170.5–171.5°, undepressed by admixture with 3-phenyl-2-butanone 2,4-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dinitrophenylhydrazone (*vide infra*), with an i.r. spectrum identical with that of the authentic material.

The yield of crude ketone based on 2 mol from 1 mol of **20** was 72%; the overall yield of crude 2,4-dinitrophenylhydrazone based on 2 mol from 1 mol of **20** was 57%.

3-Phenyl-2-butanone

3-Phenyl-2-butanone was prepared by the method of Suter and Weston (40).

Its 2,4-dinitrophenylhydrazone (33) was recrystallized from ethanol – ethyl acetate to give fine orange needles, m.p. 173–174° [lit. (41) m.p. 171–172°].

*The Mono-2,4-dinitrophenylhydrazone of **20***

The mono-2,4-dinitrophenylhydrazone of **20** was prepared by the method of Shriner *et al.* (33). The crude product was purified by elution with benzene from alumina (Merck), and crystallized three times from benzene–ligroin (b.p. 66–75°) to give fluffy, deep red needles, m.p. 250–251°; λ_{max}(CHCl$_3$) 3.01(w), 6.05(m), 6.18(s), 6.27(s), 6.65(s), 6.72(s), 7.36(m), 7.48 μ(s); λ_{max}(CHCl$_3$) 356 (ε 23 400), 450 mμ (ε 22 900).

Anal. Calcd. for $C_{26}H_{20}O_5N_4S_2$: C, 58.63; H, 3.79; N, 10.52. Found: C, 58.75; H, 3.99; N, 10.41.

*The Bis-2,4-dinitrophenylhydrazone of **20***

The desaurin **20** (0.43 g, 1.28 mmol) was dissolved in dioxane and treated with 2,4-dinitrophenylhydrazine (0.60 g, 3.03 mmol), concentrated hydrochloric acid (1 ml), and water (5 ml). The mixture was warmed briefly on the steam bath to effect complete solution, then allowed to cool and stand at room temperature for 2 weeks. A deep purple–brown solid slowly separated from the solution and was collected from time to time by filtration. The combined, dried solid weighed 0.85 g (93%).

This product was extremely insoluble in all common solvents, including ethyl acetate, chloroform, nitromethane, dimethylformamide, pyridine, and quinoline. Purification was effected by extraction of the powder with boiling pyridine for 0.5 h, filtration of the undissolved solid, and drying at 100° (0.5 mm) for 12 h to give a deep purple-brown powder, m.p. 285–286°; λ_{max}(KBr) 6.19(s), 6.32(s), 6.63(s), 6.75 μ(s); λ_{max}(CHCl$_3$) 260 (ε 18 200), 341 (ε 30 000), 505 mμ (ε 21 900).

Anal. Calcd. for $C_{32}H_{24}O_8N_8S_2$: C, 53.92; H, 3.39; N, 15.72. Found: C, 53.92; H, 3.57; N, 15.54.

*The Dioxime of **20***

The dioxime was prepared in pyridine by the method of Shriner *et al.* (42). Five recrystallizations from ethanol–water afforded yellow needles, m.p. 209.5–210° (dec.); λ_{max}(KBr) 3.00(m), 6.17(m), 6.25(w), 6.44 μ(s); λ_{max} (C_2H_5OH) 250 (sh, ε 11 000), 267 (sh, ε 7800), 347 (ε 20 400), 368 mμ (ε 19 500).

Anal. Calcd. for $C_{20}H_{18}O_2N_2S_2$: C, 62.80; H, 4.74; N, 7.33; S, 16.77. Found: C, 62.78; H, 4.78; N, 7.00; S, 16.53.

The dioxime was hydrolyzed in ethanol in the presence of hydrochloric acid and a large excess of 37% aqueous formaldehyde. After being stirred at room temperature for 24 h, the solution was diluted with water, and the product was isolated by filtration. After four recrystallizations from aqueous ethanol, the product was obtained as fine, pale yellow needles, m.p. 232–232.5°, undepressed upon admixture with **20**, and having an identical i.r. spectrum with that of **20**.

*Reaction of **20** with Sodium Hypochlorite. Formation of **21***

A solution of **20** (0.50 g, 1.42 mmol) in dioxane and a solution of sodium hydroxide (0.70 g) in water (10 ml) were stirred together at room temperature for 1 min. Commercial sodium hypochlorite [Chlorox(5.25% NaOCl): fresh bottle; 10 ml], was added, and stirring was continued for 5 min. Water (100 ml) was added, and the solution was filtered and acidified with 30% hydrochloric acid. The curdy precipitate was filtered, washed thoroughly with water, and air-dried. Purification of the crude product (0.35 g) was effected by one recrystallization from ethyl acetate – cyclohexane, followed by four recrystallizations from 2-butanone-cyclohexane, to give **21** as pale yellow microcrystals, m.p. 298–299° (dec.).

Anal. Calcd. for $C_{18}H_{12}O_4S_2$: C, 60.66; H, 3.39. Found: C, 60.75; H, 3.47.

The sample dissolved in concentrated sulfuric acid to give a yellow brown solution, unchanged on standing.

Reaction of **20** with sodium hypoiodite under a variety of conditions led to mixtures of products in both the acidic and neutral fractions. From the neutral fractions low yields of iodoform, m.p. 117–119°, could be isolated by chromatography on Florisil.

*Preparation of the Desaurin from Acetophenone (**22**)*

The desaurin **22** was prepared by the pyrolysis of the mercury salt of benzoyldithioacetic acid (20) according to the method of Kelber and Schwarz (16). The yield of the crude product was 24%. It could also be obtained by pyrolysis of the dibenzoate of benzoyldithioacetic acid in acetophenone. The desaurin was purified by slow recrystallization from toluene or nitrobenzene. Several crystallizations from toluene gave **22** as small plates, m.p. 270–272.5° (dec.) (corrected); λ_{max}(Nujol) 6.18(s), 6.26(m), 6.34(m), 7.26(m), 7.59(m), 8.17(s), 9.80(m), 12.11(m), 12.98(s), 14.4 μ(s); λ_{max}(CHCl$_3$) 274 (ε 17 000), 377 (sh ε 45 700), 392 mμ (ε 49 000).

Anal. Calcd. for $C_{18}H_{12}O_2S_2$: C, 66.64; H, 3.73; S; 19.78. Found: C, 66.66; H, 3.78; S, 19.83.

Rapid crystallization from toluene followed by several recrystallizations gave **22** as small needles, m.p. 237–238° (corrected), with resolidification, followed by remelting with decomposition at *ca.* 265°; λ_{max}(Nujol) 6.18(s), 6.26(m), 6.34(m), 7.26(s), 7.49(m), 8.16(s), 9.80(m), 12.00(w), 12.96(m), 14.39 μ(m); λ_{max}(CHCl$_3$) 273 (ε 18 200), 379 (ε 45 700), and 391 mμ (ε 49 000).

Anal. Calcd. for $C_{18}H_{12}O_2S_2$: C, 66.64; H, 3.73; S, 19.78. Found: C, 66.71; H, 3.77; S, 19.44.

Carbon Disulfide. III. Reaction with Active Methylene Compounds. The Infrared and Ultraviolet Spectra of the Desaurins[1,2]

PETER YATES,[3] THOMAS R. LYNCH, AND DONALD R. MOORE

The Departments of Chemistry, University of Toronto, Toronto, Ontario, and Harvard University, Cambridge, Massachusetts 02138

Received October 1, 1970

The position of the carbonyl-stretching bands in the i.r. spectra of the desaurins, 2,4-bis(acylmethylene)- and 2,4-bis(carboxymethylene)-1,3-dithetane derivatives, establishes that there is a strong interaction between the sulfur atoms and the carbonyl groups. This is considered to involve mainly conjugative interaction rather than interaction through space, although the latter may account for the abnormally weak intensity of the carbonyl-stretching bands. These bands are split in the case of several desaurins and related compounds, and evidence has been obtained in one case that the splitting is due to Fermi resonance. The u.v. spectra of the desaurins and related compounds also indicate a strong conjugative interaction between the sulfur atoms and the carbonyl groups.

La position des bandes de vibration des carbonyles dans les spectres i.r. des désaurines, des dérivés des bis(acylméthylène)-2,4 et bis(carboxyméthylène)-2,4 diéthane-1,3, démontre qu'il existe une interaction forte entre les atomes de soufre et les groupes carbonyles. Ces résultats proviendraient principalement d'une interaction conjugative plutôt que d'une interaction à travers l'espace, quoique cette dernière hypothèse pourrait expliquer l'intensité anormalement faible des bandes de vibration des carbonyles. Dans le cas de plusieurs désaurines et composés analogues, les bandes sont divisées et des indications ont été obtenues dans un cas, que cette division est due à de la résonance de Fermi. Les spectres ultraviolets des désaurines et des composés voisins indiquent aussi qu'une interaction conjugative forte existe entre les atomes de soufre et les groupes carbonyles.

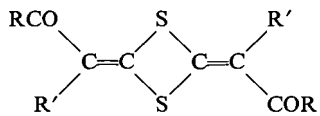
Canadian Journal of Chemistry, 49, 1467 (1971)

Preparation of Desaurins and Related Compounds

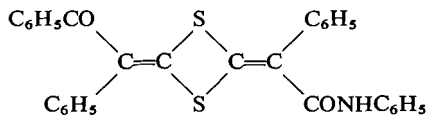
The desaurins, neutral compounds formed by the reaction of active methylene compounds **1** with base and carbon disulfide (eq. 1) have been shown to have structures of type **2**[4] (1, 3). We have described the preparation of the desaurins **3–7** previously (1). In studying the spectra of

[1] 
1 **2**

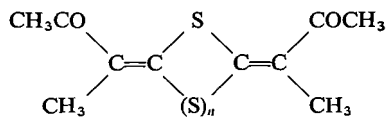
these desaurins, it was considered to be of importance to compare them with the spectra of a desaurin derived from a dialkyl ketone.



3 R = R′ = C_6H_5
4 R = CH_3; R′ = C_6H_5
5 R = OH; R′ = C_6H_5
6 R = C_6H_5; R′ = H
10 R = $(CH_3)_3C$; R′ = H



7



8 *n* = 1
9 *n* = 2

Previous to our investigation (3*b*), such a desaurin had not been prepared; however, during its course Kirby (4) reported the formation of the desaurin **8** by treatment of the trithiolane derivative **9** with triethyl phosphite. We pre-

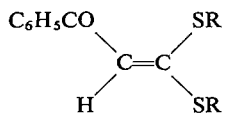
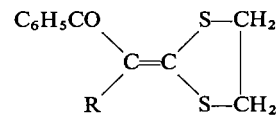
pared the desaurin **10** by a modification of the general method of Gompper and Töpfl (5), whereby the dianion of the dithio acid formed by reaction of pinacolone with carbon disulfide and base was treated with oxalyl chloride.

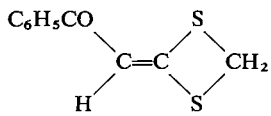
Four model compounds were also prepared for spectroscopic comparison with the desaurins. Compound **12** was first obtained by Kelber (6) by treatment of acetophenone with carbon disulfide and base to give benzoyldithioacetic acid (**11**), followed by methylation with methyl iodide and sodium; in the present work it was also prepared by methylation of **11** with methyl iodide and sodamide or with diazomethane. Its structure was confirmed by our spectroscopic observations and those of Gompper and Schaefer (7), and by an X-ray crystallographic study by Nyburg and Mellor (8).



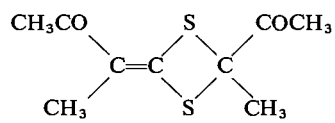
11 R = H
12 R = CH_3



13 R = H
14 R = C_6H_5



15



16

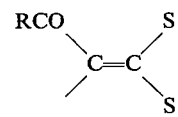
Compound **13** was prepared by the method of Kelber and Schwarz (9) by alkylation of **11** with 1,2-dibromoethane and base. These workers had established its structure by demonstrating that on reduction with zinc and sodium hydroxide it gave propiophenone and 1,2-ethanedithiol, thus establishing that both alkylations had occurred on sulfur.

Compound **14** was prepared by a similar alkylation with 1,2-dibromoethane of the salt of the β-keto dithio acid obtained from the action of carbon disulfide on the sodium derivative of deoxybenzoin. Its structure was established chemically by its reduction with zinc and sodium hydroxide to give *erythro*-1,2-diphenyl-1-propanol, isolated as its acetate (10), and 1,2-ethanedithiol, isolated as its dibenzoate (11). It has subsequently been confirmed by an X-ray crystallographic study by Schmidt and Tulinsky (12).

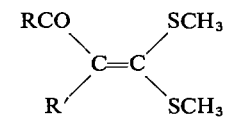
Compound **15** was prepared by alkylation of **11** with dibromomethane. Its structure is assigned on the basis of the close relationship of its i.r. and u.v. spectra (*vide infra*) to those of compounds **12** and **13**; its p.m.r. spectrum, with signals at δ 4.23 (s, 2H), 6.97 (s, 1H), 7.4–7.6 (m, 3H), and 7.8–8.0 (m, 2H), is in accord with this assignment. A related compound, **16**, has been obtained by Kirby (4) by the reaction of 3-diazo-2-butanone with carbon disulfide; its structure was established by an X-ray crystallographic study by Kapecki *et al.* (13).

Infrared Spectra of Desaurins and Related Compounds

Bands in the 2.8–3 and 5–6.5 μ regions of the i.r. spectra of the desaurins and of model compounds are listed in Tables 1 and 2, respectively. The spectra of the symmetrical desaurins **4**, **8**, and **10** with the group **17** show bands attributable to carbonyl-stretching vibrations at 6.05–6.07 μ. This position is at longer wavelength than that



17 R = alkyl



18 R = alkyl; R′ = H
19 R = R′ = alkyl

normally observed for simple α,β-unsaturated ketones, and indicates that the sulfur atoms interact with the carbonyl groups through the conjugated π-electron system and/or directly through space (*vide infra*).

Thuillier and Vialle (14) have examined the spectra of a number of compounds of type **18** and **19**. The former type of compound was found to have its carbonyl-stretching band at *ca.* 6.10 μ, while the latter type showed this band at *ca.* 5.90 μ. The striking effect of the introduction of an alkyl substituent in place of hydrogen at the vinylic carbon atom adjacent to the carbonyl group is most readily interpreted as being the result of a change in the nature of the preferred conformation (15). In these terms, a planar or near-planar *s-cis* conformation, **23**, is assigned to the compounds of type **18** (the *s-trans* conformation, **24**, would involve steric crowding of the R group and one of the sulfur

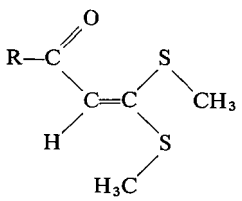
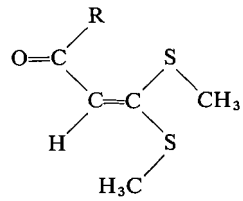
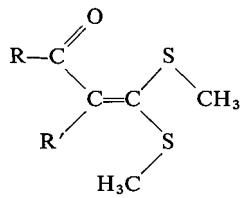
atoms). In compounds of type **19**, the analogous conformation, **25**, suffers from severe steric interaction between an S—CH_3 group and the R′ group, and probably also a further inter-



23



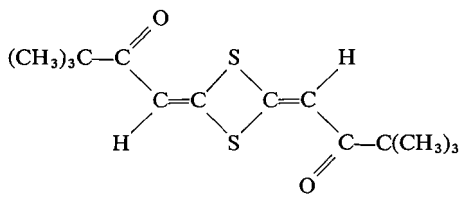
24



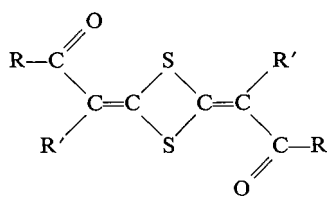
25

action between the R and R′ groups, due to a buttressing effect. As a result, compounds of type **19** are considered to take up a conformation in which there is a considerable departure from coplanarity, thus inhibiting the interaction of the carbonyl, ethylenic, and methylthio groups.

The desaurin **10** is expected to have the preferred conformation **26**, analogous to **23**, and this is reflected in the similarity of the position of its carbonyl-stretching band to that in the case of compounds of type **18**. The small shift to shorter wavelength may be due to the fact that in **23**, the two sulfur atoms interact through the conjugated system with a single carbonyl group, whereas in **26**, the two sulfur atoms inter-



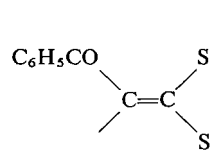
26



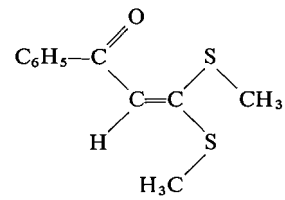
27

act with two carbonyl groups. The similarity of the carbonyl-stretching band positions for the desaurins **4**, **8**, and **10** suggests that **4** and **8** have preferred conformations of type **27**, analogous to **26**. In the case of **4**, this would require that the phenyl substituents (R′) be rotated considerably out of the plane of the conjugated carbonyl system.

The symmetrical desaurins **3** and **6** and the model compounds **12**–**15**, all having the grouping **28**, give rise to carbonyl-stretching bands at



28



29

longer wavelengths than those of the compounds with the grouping **17**. A double *s-cis* conformation has been established for **6** in the solid state (3) and the shift of its carbonyl-stretching band relative to the desaurin **10**, which has been assigned this conformation also, is attributable to the additional conjugation of the carbonyl groups with the aromatic rings. The magnitude of the shift (*ca.* 0.10 μ) is similar to that found in cognate cases (18). The spectrum in the 6.1–6.4 μ region of the model compound **13** resembles that of **6**; however in the spectra of **12**[5] and **15** two bands of approximately equal intensity appear between 6.13 and 6.21 μ in addition to lower intensity bands at 6.25 and 6.34 μ, attributable to the phenyl rings. Thus it appears that in these compounds the carbonyl bands are split.[6] The origin of the splitting will be discussed subsequently; it may be noted here that if the unsplit band positions are approximated by the average of the positions of the split bands, the range of carbonyl-stretching absorption for the compounds with the grouping **28** is 6.15–6.20 μ.

The positions of the carbonyl-stretching bands of the non-ketonic desaurins listed in Table 1 are readily related to those of the ketonic

[5]This compound has been shown to have the *s-cis* conformation **29** in the solid state with a close approach of the α,β-unsaturated carbonyl system and the sulfur atoms to coplanarity (8).

[6]Ill-defined shoulders on the low wavelength sides of the bands at 6.18 and 6.20 μ of **13** and **14**, respectively, suggest that there may be some splitting in these cases also.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

desaurins discussed already. The acid **5** has its carbonyl-stretching band at slightly shorter wavelength than the bands of **4**, **8**, and **10**, in conformity with the usual relationship between conjugated acids and conjugated ketones. Further, the amides **20–22** (16) have their carbonyl-stretching bands at slightly longer wavelength than the bands of **4**, **8**, and **10** in accord with the usual relationship between conjugated ketones and conjugated amides.

It has previously been reported (19) that the carbonyl-stretching bands of the desaurin **8** and the model compound **14** are abnormally weak; this conclusion was based on a qualitative examination of the spectra. Quantitative measurements have confirmed this in the case of **3**. The integrated intensity[7] of its 6.17 μ band measured in potassium bromide discs,[8] was 1.71, corresponding to 0.86 per carbonyl group, while the integrated intensity of the carbonyl-stretching band of benzophenone, measured in potassium bromide discs under the same conditions, was 1.20. However, similar measurements on the desaurin **6** gave a value of 2.86, or 1.43 per carbonyl group. The sum of the integrated intensities of the bands at 6.13 and 6.18 μ of **12** in solution in chloroform was determined to be 1.39. This value is low in comparison with values reported in chloroform solution for dialkyl ketones and benzophenone, *i.e.*, 1.9 and 2.4[9] (22), respectively.[10] In the case of planar chromophores, conjugation with an ethylenic double bond or aromatic ring brings about an increase in the carbonyl-stretching band intensity (20, 22). While the positions of the carbonyl-stretching bands of **3**, **6**, and **12** show a considerably higher degree of conjugation than that in benzophenone, their intensities per carbonyl group are similar to, or less than, that of the carbonyl-stretching band of benzophenone. This suggests that there is a significant reduction in intensity relative to simple conjugated ketones associated with the grouping **28** present in these compounds. The intensity relationships among **3**, **6**, and **12** may well reflect differences in the extent of coplanarity between the phenyl rings of the benzoyl groups and the α,β-unsaturated carbonyl system.[11]

The abnormally long wavelength of the carbonyl-stretching bands of the desaurins and related compounds and the reduced intensity of these bands raises the question whether these effects are due to an interaction through space between the sulfur and oxygen atoms in the *s-cis* conformations of these compounds. Recent X-ray crystallographic data have made it clear that for several of these compounds in the solid state the S—O distance is considerably shorter than the sum of the van der Waals' radii of sulfur and oxygen (3.05 Å),[12] *i.e.*, **6** (2.64 Å) (3, 8), **12** (2.72 Å) (8), **14** (2.70 Å) (12), and **16** (2.63 Å) (13).[13] However, 3-methylthio-2-cyclohexenone (**30**), which perforce has an *s-trans* relationship between the sulfur atom and the carbonyl group, gives rise to a carbonyl-stretching band in its neat or solution i.r. spectrum at 5.98–6.01 μ (26). This suggests that the effect of direct sulfur–oxygen interaction on the wavelength of the carbonyl-stretching vibrations in the desaurins and related compounds is relatively small, since compounds of type **18** absorb at 6.09–6.10 μ and the bathochromic shift of 0.10 μ is attributable in major part to increased conjugation resulting from the presence of the second sulfur atom.[14] Such an interaction may contribute significantly, however, to the reduction of band intensities, since the integrated intensity reported for **30** in solution is 2.70 (26), which is comparable or larger in magnitude than the values measured or estimated for the much

[7]Integrated absorption intensities are given in absorbance units (20): 1 absorbance unit = 1×10^4 mol^{-1} l cm^{-2}.

[8]Although integrated intensities are not normally measured in potassium bromide discs, this medium has been used with success for the analysis of mixtures (21*a*), and Lambert's and Beer's laws have been shown to hold (21).

[9]This was measured in the present work also and found to be 2.35.

[10]It has previously been found that absorptivities are greater in solution than in the solid state (23).

[11]The planes of these phenyl rings in **6** and **12** in the solid state have been shown to be inclined at 10 and 19°, respectively, to the planes of the α,β-unsaturated carbonyl systems (8). The angle is expected to be significantly larger in the case of **3** (*cf.* 12). It may be noted that benzophenone is itself nonplanar (24).

[12]This figure is based on a van der Waal's radius for sulfur of 1.65 Å (3*b*, 8), derived from the S—S contact distances in rhombic sulfur (25).

[13]For interpretations of these short S—O distances in terms of partial bonding between sulfur and oxygen, see refs. 3*b* and 8.

[14]Mollier *et al.* (27) have concluded that partial sulfur–oxygen bonding in the related case of 1,2-dithiol-3-ylidene ketones brings about a large shift of the carbonyl-stretching band to longer wavelength. However, Kapecki and Baldwin (28) have concluded from extended Hückel molecular orbital calculations that covalent bonding between sulfur and oxygen is negligibly weak in related cases.

TABLE 3. The u.v. spectra of the desaurins and related compounds

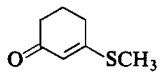
more highly conjugated ketones **3**, **6**, and **12** in solution. Further investigation is necessary to establish this, since the carbonyl-stretching band intensities are often weaker for *s-cis* than for *s-trans* α,β-unsaturated ketones in the absence of any special interactions of the oxygen atom (15*a*).



30

As has been noted earlier, several compounds with the grouping **28** have split carbonyl bands. A preliminary examination of the origin of the splitting was made in the case of compound **12**. In carbon tetrachloride solution the bands of equal intensity at 6.13 and 6.18 μ in chloroform solution were replaced by a sharp, intense band at 6.11 μ and a weak band at 6.18 μ. Such behavior could be due either to vibrational coupling or rotational isomerism (29). However, the latter origin is contra-indicated by the spectrum of **12** in a potassium bromide disc, which showed a sharp band at 6.20 μ with a medium intensity shoulder at 6.15 μ, and in a Nujol mull, which showed a broad band at 6.22 μ with a shoulder of medium intensity at 6.17 μ. Furthermore, the n.m.r. spectrum of **12** showed no temperature dependence in the range 27 to −60°. Thus the most probable sources of the bifurcation is vibrational coupling. Corroboration was sought by the preparation of **31**, *i.e.*, **12** with the vinylic hydrogen replaced by deuterium; n.m.r. spectroscopy indicated that there was *ca.* 70% incorporation of deuterium in the vinylic position.[15] In chloroform solution the i.r. spectrum of the labelled compound exhibited strong bands at 6.15 and 6.18 μ with a shoulder at 6.13 μ; in carbon tetrachloride the spectrum showed a strong, sharp band at 6.13 μ; in both spectra a band at 6.25 μ was also present. These observations are in accord with the attribution of the splitting of the carbonyl band of **12** to vibrational coupling, which is absent in the deuterated derivative **31**; the unperturbed carbonyl-stretching band positions are then 6.15 ($CHCl_3$) and 6.13 μ (CCl_4). This coupling could be with the fundamental stretching vibration of the ethylenic double bond or with an overtone or combination vibration (*i.e.*, Fermi resonance). If coupling to a fundamental vibration is involved, the estimates of the carbonyl-stretching band intensities made earlier may be too high, since they will also include the intensity of the other fundamental band; however, if Fermi resonance is involved, this error is unlikely to be significant because of the low intensity of overtone and combination bands. The data available do not permit a definitive choice between the two types of coupling, but the latter appears more probable. Jensen and Henriksen (17) have assigned a very intense band in the 6.5–7.0 μ region of the spectra of a series of compounds containing the function **32** to the ν_1 vibration of this grouping; they favored this assignment over one to a simple ethylenic stretching vibration because of the unusual intensity and long wavelength of the

[15]We thank Mr. A. Hepworth for the preparation of the labelled compound and obtaining the related spectra.

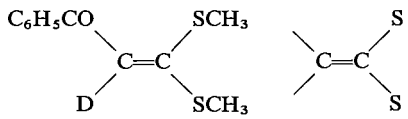
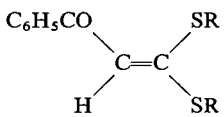
bands. In the spectra of all of the desaurins and related compounds that we have examined, a strong or very strong band appears in the 6.5–6.9 μ region, which is probably analogous to the bands in this region observed by Jensen and Henriksen. If this is the case, the splitting of the carbonyl-stretching bands cannot involve coupling with an ethylenic stretching vibration and must have their origin in Fermi resonance.[16] Again, further work is needed to establish this unequivocally, since strong bands due to aromatic C—C stretching and aliphatic C—H bending vibrations can also occur in the 6.5–6.9 μ region.



31 **32**

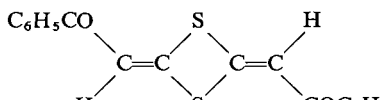
Ultraviolet Spectra of Desaurins and Related Compounds

The u.v. maxima of the desaurins and related compounds are listed in Table 3. The spectra of compounds **12**, **13**, and **15** with the grouping **33** have a high intensity, long wavelength maximum[17] at 344 mμ (ε 20 400 – 22 900) and another maximum at 257–263 mμ (ε 7940 –14 500).



33

R = CH_3 or $(CH_2)_n$



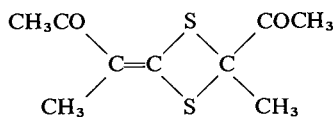
6

[16]Jensen and Henriksen (17) have also observed splitting of the carbonyl bands of certain of the compounds they have examined that have the ethylenic double bond of the grouping **32** conjugated with carbonyl groups. However, each of these has two such carbonyl groups, and the splitting may be due here to vibrational coupling between the carbonyl groups.

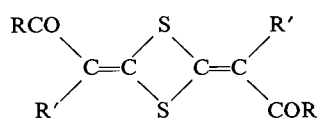
[17]These maxima are broad and unsymmetrical and may well represent the near superimposition of two peaks, as is suggested by the fact that some other compounds in Table 3 show either a high intensity shoulder on the long wavelength maximum or two close-lying long wavelength maxima of similar intensity; in the latter cases comparison is made with the average position of the maxima.

Introduction of a phenyl group in place of the vinylic hydrogen atom, as in **14**, causes a bathochromic and hypochromic shift of the long wavelength maximum to 350 mμ (ε 15 800), most probably due to extension of the chromophoric system with reduction in coplanarity (*vide supra*). The desaurin that is most closely related to compounds **12**, **13**, and **15** is **6**; its long wavelength maximum shows a bathochromic and hyperchromic shift with respect to the corresponding maxima of these compounds. The bathochromic shift is *ca.* 50 mμ and the hyperchromic shift >1500 per carbonyl group. The spectrum of the desaurin **3** in which the vinylic hydrogen atoms of **6** are replaced by phenyl groups bears a similar relationship to that of **14**, showing a bathochromic shift of the long wavelength maximum of 69 mμ and a hyperchromic shift of *ca.* 3000 per carbonyl group. These shifts are consistent with transmission of delocalization through the sulfur atoms in the desaurins (4, 16). The suggestion (16) that such effects may be due in part to the unusual short S–S distance in the desaurins and the resulting enhanced transannular S–S overlap must be viewed with some reserve on the basis of the present data. In compound **15** it may be anticipated that the S–S distance will be very short and similar to that in **6** rather than that in **12** or **13**.[18] Yet, although the long wavelength maximum of **15** shows a hyperchromic shift with respect to the maxima of **12** and **13**, it shows no bathochromic shift whatsoever and differs markedly from **6** in this regard.

As would be anticipated, the long wavelength maximum of **16** occurs at appreciably lower



16



8 R = R′ = CH_3
10 R = $C(CH_3)_3$; R′ = H
4 R = CH_3; R′ = Ph

wavelength than those of the phenyl ketones **12**, **13**, and **15** ($\Delta\lambda \sim -25$ mμ); its intensity is

[18]*Cf.* the S–S distance in **16** (2.71 Å) (13) with that in **6** (2.67 Å) (3, 8), **12** (2.94 Å) (8), and **14** (2.95 Å) (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

considerably lower also. The related desaurin **8** shows bathochromic and hyperchromic shifts analogous to those encountered in the phenyl ketone series ($\Delta\lambda \sim 50$ mμ; $\Delta\varepsilon \sim 5000$ per carbonyl group). The desaurin **10** that has no alkyl substituents on the ethylenic double bonds shows a shift of its longer wavelength maximum relative to that of **8** to lower wavelength ($\Delta\lambda \sim -15$ mμ), as expected. Conversely, substitution of phenyl for alkyl substituents on the ethylenic double bonds of **8** as in **4** leads to a bathochromic shift ($\Delta\lambda \sim 10$ mμ); the relatively small effect may be attributed to the deviation from coplanarity.

The non-ketonic desaurin spectra listed in Table 3 are readily related to those of the ketonic desaurins discussed above. The high intensity, long wavelength maximum of **5** occurs at shorter wavelength than that of the analogous ketone **4** ($\Delta\lambda \sim -30$ mμ; *cf.* benzoic acid *vs.* acetophenone: $\Delta\lambda \sim -15$ mμ). The amides **20–22** also give maxima at shorter wavelength than the maximum of the analogous ketone **10** ($\Delta\lambda \sim -35$ mμ; *cf.* benzamide *vs.* acetophenone: $\Delta\lambda \sim -20$ mμ). The spectra of the keto amides **7** are clearly also closely related to the spectrum of the diketone **3**.

Experimental

Melting points were taken on a Fisher–Johns micro hot stage and are uncorrected. Solutions in organic solvents were dried over anhydrous sodium sulfate.

The Desaurin from Pinacolone (10)

Pinacolone (20.0 g, 0.200 mol) was added dropwise to a cooled, stirred suspension of sodamide (8.00 g, 0.2005 mol) in anhydrous ether. When anion formation was complete, carbon disulfide (6.0 ml, 0.100 mol) was added slowly, and the yellow suspension formed was stirred for a further 5 min. Methanol (*ca.* 50 ml) was added to dissolve the suspension, and oxalyl chloride (10.0 ml, 0.120 mol) was added with great caution. The solution was stirred for a further 0.5 h, then transferred to a separatory funnel, and water and benzene were added. The organic layer was separated and washed several times with aqueous 10% sodium hydroxide, once with water, and dried. After removal of the solvent, hexane was added to the residue, and the precipitate (1.0 g) was filtered off. Crystallization of the solid from chloroform–hexane gave **10** (0.50 g, 4%), m.p. *ca.* 258°. Four further recrystallizations from chloroform–hexane gave an analytical sample, m.p. 259.5–260° (corrected).

Anal. Calcd. for $C_{14}H_{20}O_2S_2$: C, 59.11; H, 7.09; S, 22.55. Found: C, 59.00; H, 7.09; S, 22.62.

Benzoyldithioacetic Acid (11)

Acetophenone (120.6 g, 1.00 mol) was added dropwise to a stirred suspension of commercial sodamide (39.0 g, 1.00 mol) in benzene (250 ml) at room temperature under nitrogen. When the brisk evolution of ammonia was nearly complete, the sodium derivative of acetophenone separated suddenly to form a thick off-white paste. Additional benzene (100 ml) was added to facilitate stirring, which was continued while the system was swept with nitrogen until the evolution of ammonia appeared to be complete (negative test with moist litmus paper).

Carbon disulfide (100 g, 1.31 mol) was added under a current of nitrogen, and the deep orange suspension was stirred for 1 h. The slurry was poured onto ice (300 g), and the mixture was stirred thoroughly; the benzene layer was separated and washed with three portions of aqueous 10% sodium hydroxide. The combined basic extracts and original aqueous layer were cooled to 5° and neutralized with ice-cold 10% sulfuric acid while the temperature was maintained below 10°. At the neutral point a red-brown mass separated, accompanied by a vigorous evolution of hydrogen sulfide. Excess acid was added, and the mixture was filtered. The crude solid acid was washed with ice-cold water and air-dried at room temperature. The yield of crude benzoyldithioacetic acid was 90 g (46%).

Two recrystallizations of the crude acid from petroleum ether (b.p. 30–60°) gave golden leaflets, m.p. 62–64°, satisfactory for further reactions. Two further recrystallizations afforded a sample, m.p. 62.5–64° [lit. (30) m.p. 63–64°]; $\lambda_{max}(CHCl_3)$ 3.9–4.2 (w), 6.25 (m), 6.29 (ms), 6.45 μ (s); $\lambda_{max}(C_2H_5OH)$ 231 (ε 9300), 266 (ε 7800), 355 mμ (ε 14 800).

Methylation of 11. Preparation of 12

(A) Benzoyldithioacetic acid (**11**; 2.00 g, 10.2 mmol) was methylated by treatment with sodium and methyl iodide by the method of Kelber (6). Two recrystallizations of the product from ethyl acetate – ligroin (b.p. 66–75°) gave **12** as bright yellow needles (0.80 g, 35%), m.p. 93.5–94.0°, [lit. (6) m.p. 93–94°]; $\delta(CDCl_3)$ 2.52 (s, 3H), 2.54 (s, 3H), 6.73 (s, 1H), 7.42 (m, 3H), 7.86 (m, 2H); the n.m.r. spectrum was unchanged when recorded at −60°.

(B) A solution of **11** (1.00 g, 5.1 mmol) in ether (25 ml) was treated with 0.6 *N* ethereal diazomethane (20 ml). The mixture was allowed to stand at room temperature for 3 days. The ether was then removed on the steam bath, and the residue was chromatographed on alumina (Merck; 75 g). A small amount of yellow oil (0.035 g) was eluted with 50% petroleum ether in benzene. The major yellow band was eluted with dichloromethane to give **12** (0.85 g, 74%). After crystallization from ethyl acetate – ligroin this had m.p. 93.0–93.5°, undepressed on admixture with the product obtained by the procedure of Kelber (6).

Alkylation of 11 with 1,2-Dibromoethane. Preparation of 13

Benzoyldithioacetic acid (**11**; 10.00 g, 51.0 mmol) was alkylated with 1,2-dibromoethane by the method of Kelber and Schwarz (9) to give **13** (6.0 g, 53%). Two recrystallizations from ligroin (b.p. 66–75°) afforded bright yellow needles, m.p. 83–83.5° [lit. (9) m.p. *ca.* 80°].

Alkylation of 11 with Dibromomethane. Preparation of 15

Benzoyldithioacetic acid (**11**; 5.00 g, 25.5 mmol) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

dissolved in water (100 ml) containing potassium hydroxide (6.00 g, 107 mmol). Dibromomethane (8.00 g, 59.7 mmol) was added, and the mixture was stirred at room temperature for 12 h and then extracted with four portions of dichloromethane. The combined extracts were dried, filtered, and stripped of the bulk of the dichloromethane on the steam bath. The crude product was dissolved in benzene (25 ml), and the solution was boiled briefly to expel dichloromethane, cooled, and chromatographed on alumina (Merck; 150 g). The major fraction was eluted immediately with benzene to give **15** as stout yellow needles (2.0 g, 38%). Three recrystallizations from cyclohexane afforded fine, pale cream needles, m.p. 128–129°.

Anal. Calcd. for $C_{10}H_8OS_2$ (mol. wt 208): C, 57.66; H, 3.97; S, 30.79. Found (241 (Rast)): C, 57.50; H, 3.73; S, 30.54.

Preparation of ***14***

Deoxybenzoin (10.00 g, 50.9 mmol) was dissolved in benzene (300 ml), sodamide (2.0 g, 51.2 mmol) was added, and the mixture was boiled under reflux under nitrogen with stirring for 12 h. The sodium derivative of deoxybenzoin separated as a pale yellow suspension, and ammonia could no longer be detected in the effluent (moist litmus paper test). The stirred suspension was cooled and carbon disulfide (4.00 g, 51.3 mmol) was added. Stirring was continued for 5 days at room temperature; the suspension gradually assumed an orange–red color.

One-half of this reaction mixture was treated with 1,2-dibromoethane (4.80 g, 25.6 mmol), and the resulting mixture was boiled under reflux under nitrogen with stirring for 2 days. The mixture was filtered, and the solvent was removed from the filtrate under reduced pressure to give an orange solid (3.53 g). This was dissolved in benzene and chromatographed on alumina (Merck; 100 g). The column was thoroughly eluted with benzene, to give a yellow semi-solid product (1.70 g), whose i.r. spectrum indicated it to be largely deoxybenzoin. Elution of the column with chloroform gave **14** as a yellow–orange solid (1.40 g, 18%). This was recrystallized four times from aqueous ethanol to give small yellow needles, m.p. 157.5–158°.

Anal. Calcd. for $C_{17}H_{14}OS_2$: C, 68.42; H, 4.73; S, 21.49. Found: C, 68.42; H, 4.79; S, 21.69.

Reduction of ***14*** *with Zinc and Base*

A mixture of **14** (0.100 g, 0.335 mmol), sodium hydroxide (1.00 g, 25 mmol), zinc dust (1.00 g, 15.3 mg-atoms), ethanol (10 ml), and water (20 ml) was boiled under reflux. After 2 days additional sodium hydroxide (1.00 g, 25 mmol) and zinc dust (0.50 g, 7.6 mmol) were added. After 5 days the solution was cooled, filtered, and extracted with dichloromethane. The extract was dried, filtered, and stripped of solvent on the steam bath to give a pale yellow oil (0.058 g), whose i.r. spectrum showed it to be largely *erythro*-1,2-diphenyl-1-propanol. This was treated with pyridine (2.0 ml) and acetic anhydride (1.0 ml), and the mixture was heated for 4 h on the steam bath. The solution was poured into water, acidified to p*H* 1 with 10% hydrochloric acid, and extracted with dichloromethane. The extract was dried, filtered, and evaporated to give a crystalline mass (0.038 g), which was recrystallized from ethanol to give fine, colorless cubes, m.p. 107–108.5°, undepressed on admixture with *erythro*-1,2-diphenyl-1-propyl acetate (1, 10). The i.r. spectra of the two samples were identical.

The aqueous basic layer from the original extraction was diluted to 75 ml with water and evaporated nearly to dryness under reduced pressure. Water (50 ml) and benzoyl chloride (2.0 ml) were added. The mixture was shaken until no further warming was apparent and then filtered. The white precipitate (0.032 g) was recrystallized from ethanol–water to give colorless prisms, m.p. 92–92.5°, undepressed upon admixture with 1,2-ethanedithiol dibenzoate [lit. (11) m.p. 94.5–95°]. The i.r. spectra of the two samples were identical.

The yields of *erythro*-1,2-diphenyl-1-propyl acetate and 1,2-ethanedithiol dibenzoate were 45 and 31%, respectively.

Preparation of ***31***

A solution of acetophenone (2.50 g, 20.8 mmol) in dioxane (40 ml) containing deuterium oxide (18 ml, 1.00 mol) and a catalytic quantity of anhydrous potassium carbonate was boiled under reflux for 1 h. When cool, the solution was extracted with ether, and the dioxane was removed from the ethereal solution by washing with water. The acetophenone obtained after removal of the solvent showed 75% exchange of the α-hydrogen atoms by n.m.r. spectroscopy. The treatment was repeated using sodium-dried dioxane, and the product was distilled to give acetophenone-2-d_3 with 92% of the α-hydrogen atoms replaced by deuterium.

Acetophenone-2-d_3 (0.120 g, 1.00 mmol) was added to a suspension of sodamide (0.030 g, 1.00 mol) in anhydrous benzene. When anion formation was complete, carbon disulfide was added in excess, and after 15 min the excess carbon disulfide was boiled off. Sodamide (0.039 g, 1.00 mmol) was added, followed by methyl iodide (0.280 g, 2.00 mmol), and the reaction mixture was stirred overnight. Water was added, and the organic layer was separated, dried, and stripped of solvent. Addition of hexane to the residue caused it to crystallize, and filtration gave crude **31** (0.040 g, 18%). Recrystallization of the crude material from ethyl acetate – pentane gave **31**, m.p. 92.5–93.5° (corrected), undepressed on admixture with **12**. The ratio of the intensity of the vinylic proton signal at δ 6.73 to the intensities of the methyl proton signals at δ 2.52 and 2.54 in the n.m.r. spectrum of **31** showed *ca.* 70% incorporation of deuterium at the vinylic position.

Infrared Spectral Intensity Measurements

The spectra were recorded with a Perkin–Elmer 521 Grating Infrared Spectrophotometer [linear in frequency (ν)], whose horizontal scale was expanded by a factor of 4. Absorption bands, measured by the machine as percent transmittance, were replotted on the absorbance (A) scale, and integrations were performed by the method of cutting out and weighing. The solution spectra were obtained in chloroform solution with the use of two 0.5 mm cells, with Teflon spacers; the path length of the sample cell was determined to be 0.501 mm by the method of Sutherland and Willis (31). Potassium bromide pellets were made by adding a weighed sample of the compound to *ca.* 250 mg of anhydrous potassium bro-

mide (Harshaw) in a "Wig-L-Bug"; the mixture was then ground for 3 min, and all pellets were pressed for identical times and at identical pressures; a blank pellet was placed in the reference beam.

The integrated intensities, B (mol l^{-1} cm^{-2}), for the solution spectra were obtained by the use of the formula:

$$B = \frac{1}{cl}\int A \, dv,$$

where c is the concentration in mol l^{-1} and l is the path length in cm. For the pellet spectra, since c = mol/(area of pellet $\times$ l), the formula becomes:

$$B = \frac{\text{area of pellet}}{\text{mol}}\int A \, dv$$

Carbon Disulfide. IV. Reaction with Active Methylene Compounds. The Formation of 3,5-Bismethylene-1,2,4-trithiolanes[1]

PETER YATES AND THOMAS R. LYNCH
Department of Chemistry, Lash Miller Chemical Laboratories, University of Toronto, Toronto 5, Ontario

Received October 1, 1970

The three-sulfur compounds formed on oxidation of the β-keto dithio acids prepared by the reaction of active methylene compounds with base and carbon disulfide have been shown to be 3,5-bis(acylmethylene)-1,2,4-trithiolane derivatives. In several cases, two of the three possible geometrical isomers have been isolated and provisional stereochemical assignments have been made. The i.r. and u.v. spectra of the trithiolanes have been compared with those of corresponding 2,4-bis(acylmethylene)-1,3-dithietane derivatives (desaurins) and interpreted in terms of a strong conjugative interaction between the sulfur atoms and carbonyl groups.

Il a été démontré que les composés contenant des trois atomes du soufre et formés par oxydation des acides dithio β-cétoniques obtenus lors de la réaction du sulfure de carbone avec de la base et des composés contenant des méthylènes actifs sont des dérivés du bis(acylméthylène)-3,5 trithiolane-1,2,4. Dans plusieurs cas, deux des trois isomères géométriques possibles ont été isolés et des configurations stéréochimiques provisoires ont pu être attribuées. Les spectres infrarouge et ultraviolet des trithiolanes ont été comparés à ceux des dérivés bis(acylméthylène)-2,4 dithiétane-1,3(désaurines) correspondants et ont été interprétés en termes d'une interaction conjugative forte entre les atomes de soufre et les groupes carbonyles.

Canadian Journal of Chemistry, 49, 1477 (1971)

Introduction

In the course of our investigation of the desaurins (1), it was observed that during recrystallization of benzoyldithioacetic acid (**1**), the product obtained by treatment of acetophenone with base and carbon disulfide, an insoluble yellow material was obtained. This gave on further recrystallization yellow needles, m.p. 236–238° (dec.), with the formula $C_{18}H_{12}O_2S_3$.

Many years ago Wenzel (2, 3) had observed the formation of compounds containing three sulfur atoms when the sodium derivatives of active methylene compounds, such as diethyl malonate, were treated in carbon disulfide with bromine or iodine. These compounds were assigned structures of type **2** and were considered to arise via oxidation by the bromine of the salts of dithioacetic acids analogous to **1**.

Subsequently, Kelber (4) found that oxidation of the disodium salt of **1** with ammonium persulfate gave a three-sulfur compound, $C_{18}H_{12}O_2S_3$, m.p. 206–207°; he also obtained this compound by oxidation of **1** with iodine followed by recrystallization of the crude product from high boiling solvents, when hydrogen sulfide was eliminated. More recently, Gompper and Töpfl (5) have reinvestigated the oxidation by bromine, iodine, and ammonium persulfate of the disodium salts of dithio acids derived by reaction of active methylene compounds with carbon disulfide. In some cases they again obtained three-sulfur compounds, but in others two-sulfur compounds were isolated. The latter were shown to be desaurins (**3**)[2] (1); the former were assigned structures of type **4** on the basis of their chemical properties and the similarity of their spectra with those of the desaurins.

†C, Deuteriochloroform; S, 96% sulfuric acid.

Among the cases investigated by Gompper and Töpfl was that of the disodium salt of **1**; this on treatment with bromine gave in high yield a yellow crystalline compound, $C_{18}H_{12}O_2S_3$, m.p. 216–220° (dec.). We found that on repeated recrystallization from toluene the m.p. of the product formed in this reaction is raised to 236–238° (dec.) and that this m.p. is undepressed on admixture of the product with that obtained during our recrystallization of **1**; the spectra of the two products were also identical. It is thus clear that these products are the same and probable that our product was formed by air-oxidation during the recrystallization.

We embarked on a fuller study of these three-sulfur compounds for several reasons. First, to provide further evidence for the assignment of structure; although the spectral data excluded structures of type **2** for these compounds, they did not definitively establish structures of type **4**. Second, to examine the possibility of stereoisomerism among these compounds. Third, to examine in detail the relationship between their spectra and those of the desaurins.

Reactions and Structures of the Three-sulfur Compounds

The compound whose chemistry has been examined most extensively is that derived from pinacolone. This was prepared in 34% yield by the general method of Gompper and Töpfl (5) with the use of ammonium peroxydisulfate as oxidant. It was shown to have the molecular formula $C_{14}H_{20}O_2S_3$ by elemental analyses and mass spectrometry. Its n.m.r., i.r., and u.v. spectra are given in Tables 1–3; they are in accord with the assignment of a structure of type **8** and will be discussed subsequently.

Reduction of this substance with zinc and acetic acid gave three products. One was shown to be ethyl *t*-butyl ketone (**5**) by its i.r. and n.m.r. spectra and by the m.p. of its 2,4-dinitrophenylhydrazone.

One of the other products was a colorless, crystalline solid, $C_{14}H_{20}S_2$. Its i.r. spectrum showed a weak band at 6.15 μ, characteristic of ethylenic or aromatic bonds, and a doublet at 7.18 and 7.32 μ, assignable to *t*-butyl groups. Its n.m.r. spectrum exhibited two singlets at δ 1.40 (18H) and

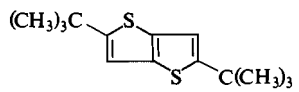
6.82 (2H). The high field signal could tentatively be assigned to two *t*-butyl groups in equivalent chemical environments; the position of the signal suggested that these groups might be attached to an aromatic ring system. The low field signal could then be due to two protons attached directly to this system in equivalent chemical environments. These spectral data, the origin of the compound, and the fact that its molecular formula requires the presence of a total of five double bonds and/or rings, suggested that it might be 2,5-di-*t*-butylthieno[3,2-*b*]thiophene (**6**).

$(CH_3)_3CCOCH_2CH_3$

5



6

$(CH_3)_3CCOCH_2CH_2SCH_2CH_2COC(CH_3)_3$

7

Strong confirmatory evidence for the presence of the ring system was provided by the u.v. spectrum which exhibited maxima at 269 (ε 17 400) and 280 mμ (ε 12 600), while the parent compound, thieno[3,2-*b*]thiophene, has u.v. maxima at 259 (ε 12 600), 268 (ε 10 000), and 278 mμ (ε 10 000) (7). The related thieno[2,3-*b*]thiophene and thieno[2,3-*c*]thiophene systems, however, give u.v. spectra (8, 9) that differ markedly from the spectrum of the product.

Conclusive evidence for the presence of the thieno[3,2-*b*]thiophene system was afforded by the observation (10) that *t*-butylation of the parent compound gave, *inter al.*, a compound whose i.r. and n.m.r. spectra and m.p. were identical with those of our product; a mixture m.p. point showed no depression.[3] Given this proof of the nature of the aromatic nucleus of the compound $C_{14}H_{20}S_2$, the only structures other than **6** that can be entertained are the corresponding 2,3- and 3,5-di-*t*-butyl derivatives. The former is most unlikely to give the simple n.m.r. spectrum observed for this compound, and both, unlike **6** (*vide infra*), could arise only by a complex series of rearrangements. Structure **6** is thus preferred for this product.

The third reduction product was an oil, which gave a yellow bis-2,4-dinitrophenylhydrazone, $C_{26}H_{34}N_8O_8S$. The formula of the oil was thus indicated to be $C_{14}H_{26}O_2S$, indicating that it is acyclic and has no double bonds other than those of the two carbonyl groups. Its i.r. spectrum showed a single carbonyl-stretching band at 5.84 μ. Its n.m.r. spectrum in carbon tetrachloride solution showed two singlets at δ 1.14 (18H) and 2.67 (8H); this simplicity was deceptive, however, since in benzene solution the lower-field signal appeared as a symmetrical multiplet at δ 2.62. On the basis of these data, structure **7** is assigned to this product; this was confirmed by the fact that on desulfurization with Raney nickel it gave **5**.

The formation of the three reduction products **5**, **6**, and **7** from the three-sulfur compound can readily be interpreted in terms of the assignment

[3]We thank Professor S. Gronowitz, University of Lund, for undertaking this synthesis and carrying out the mixture m.p. determination.

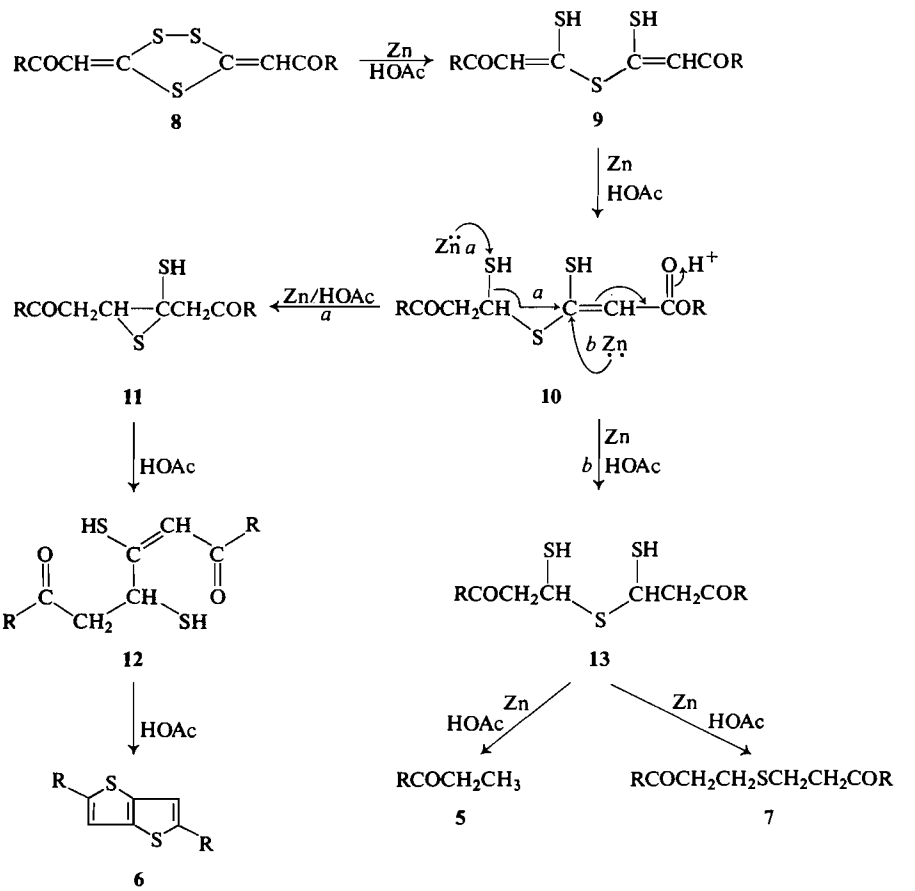
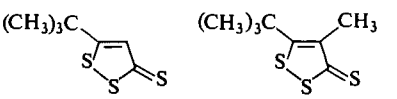


SCHEME 1

to it of a structure, **8**, of the type proposed by Gompper and Töpfl (Scheme 1). Reduction of the disulfide link would lead to **9**, which would give **10** on reduction of one of the α,β-unsaturated carbonyl systems (or of its thione tautomer). Reductive carbon–carbon bond formation as in path *a* could then lead to **11**,[4] which after ring cleavage to **12** followed by dehydration would give **6**. Alternatively, **10** could undergo reduction of its remaining α,β-unsaturated ketone system (or of its thione tautomer) to give **13**, which on further reduction would give **5** and **7**.

Reaction of the three-sulfur compound with phosphorus pentasulfide in boiling xylene gave a compound $C_7H_{10}S_3$, m.p. 69.0–69.5°. This product showed no bands in the 5–6.5 μ region of its i.r. spectrum. Its n.m.r. spectrum showed two singlets at δ 1.43 (9H) and 7.18 (1H). These data showed the product to be 5-*t*-butyl-1,2-dithiole-3-thione (**14**) (11). This structural assignment was corroborated by the similarity of the product's u.v. spectrum with that of **15** (12). The yield of **14**

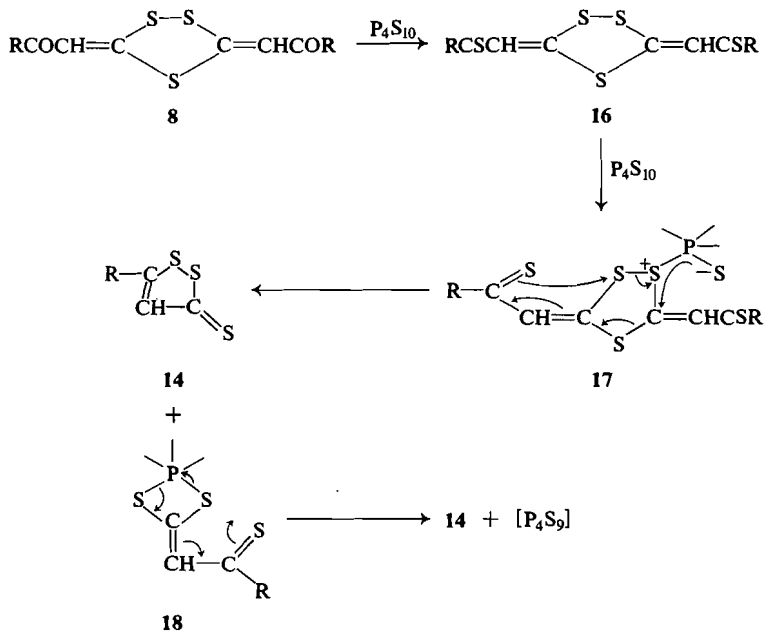


14 **15**

was 56%, based on the formation of 2 mol from 1 mol of the original three-sulfur compound. This reaction can again be readily interpreted in terms of the assignment of structure **8** to the latter compound (Scheme 2). Conversion of the diketone in the usual fashion to the corresponding dithione **16** could be followed by processes (**17** and **18**, arrows) that lead to two molecules of **14**.

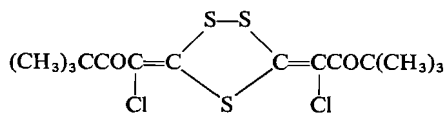
[4] *Cf.* the occurrence of C—C bond formation in the nickel reduction of the desaurin derived from deoxybenzoin (1).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

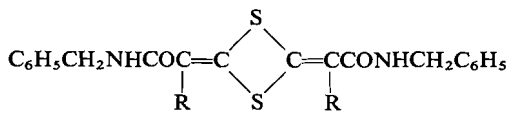


SCHEME 2

Reaction of **8** with phosphorus pentachloride gave a product, $C_{14}H_{18}Cl_2O_2S_3$. The u.v. spectrum of this product indicated that the original chromophore was intact (*vide infra*). Its n.m.r. spectrum showed only a singlet at δ 1.33. These data are clearly in accord with the assignment to this product of structure **19**, in which the vinyl hydrogen atoms are replaced by chlorine atoms. A related substitution reaction has been reported recently (13) in which treatment of the desaurin **20** with bromine gives **21**.

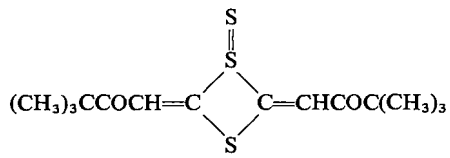


19

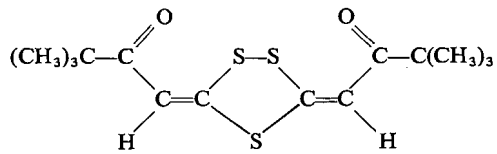


20 R = H
21 R = Br

Thus, these reactions of the three-sulfur compound from pinacolone can all be interpreted in terms of structure **8**. The only possible alternative appears to be the 2,4-bismethylene-1-thiono-1,3-dithietane, **22**. However, branched bonding at sulfur is unlikely in the present case. Such bonding appears to occur only in cases where the sulfur atom to which the branch is attached is also bonded to highly electronegative atoms (14). The assignment of structure **8** has subsequently been confirmed by an X-ray crystallographic study by Nyburg and Mellor (15), which has shown the compound to have the structure, configuration, and conformation shown in **23**.



22

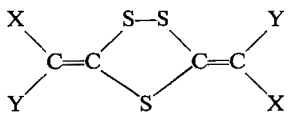


23

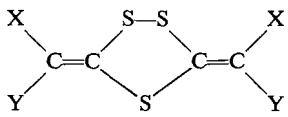
Compounds with the gross structure **4** can exist as three geometrical isomers: *trans* (**24***a*), *cis*$_2$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

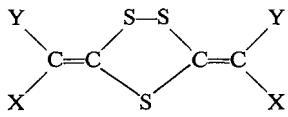
(**24***b*), and *cis*$_1$ (**24***c*).[5] As expected on the basis of the assignment of the *cis*$_2$ configuration **23** to the trithiolane from pinacolone, this compound shows a single vinyl proton signal in its n.m.r. spectrum (Table 1). The n.m.r. spectrum of the crude product and that of a sample recovered after solution of the pure product in 96% sulfuric acid and quenching on ice showed an additional, weak signal at δ 7.10, indicating the presence of a second geometrical isomer. Attempts to isolate this were unsuccessful, however.



24*a*



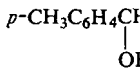
24*b*



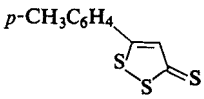
24*c*

More success was met in the case of the product from *p*-methylacetophenone. Two isomeric trithiolanes, $C_{20}H_{16}O_2S_3$, were obtained. The major product was insoluble in chloroform and had m.p. 251–252°, while the minor product was chloroform-soluble and had m.p. 213.5–214.5°. The i.r. and u.v. spectra of these products (Tables 2 and 3) were in accord with the assignment of structures analogous to that of the trithiolane from pinacolone. Furthermore, reduction of the higher-melting isomer with zinc and acetic acid followed by lithium aluminum hydride gave 1-*p*-tolyl-1-propanol (**25**), confirming the assigned carbon skeleton, and treatment with phosphorus pentasulfide gave a product, $C_{10}H_8S_3$, whose spectra (see Experimental) showed it to be **26**, the analog of **14**.

The n.m.r. spectrum ($CDCl_3$) of the lower-melting isomer (Table 1), showed in addition to

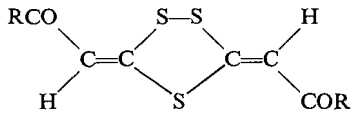


25

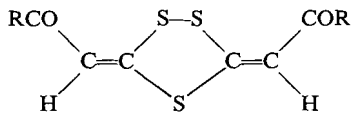


26

signals attributable to the *p*-tolyl protons, two singlets at δ 7.48 and 7.68 that can be assigned to the vinyl protons. This isomer must therefore be the *trans* compound **27***a*, since this is the only one of the three isomers of type **24***a–c* that has chemically non-equivalent vinyl protons. The two *p*-tolyl rings in **27***a* also are non-equivalent; however the difference between their environments must be too small to lead to differentiation of their proton signals. The n.m.r. spectrum of the higher-melting isomer could not be taken in conventional solvents because of its insolubility. Its spectrum in 96% sulfuric acid showed in addition to *p*-tolyl proton signals a singlet at δ 7.75 attributable to the vinylic protons. This is in accord with the assignment to it of either a *cis*$_2$ or *cis*$_1$ structure, each of which has chemically equivalent vinyl protons.[6] No firm basis for choice between their two structures is available, but the *cis*$_2$ structure **27***b* is provisionally assigned by analogy with **23**.



27*a* R = *p*-$CH_3C_6H_4$
28*a* R = C_6H_5



27*b* R = *p*-$CH_3C_6H_4$
28*b* R = C_6H_5

When the lower melting isomer was heated under nitrogen at 225° it was converted to the higher-melting isomer. The observation that thermal interconversion of one isomer to another can occur and that the higher-melting isomer is favored provides some evidence that this isomer has the *cis*$_2$ rather than the *cis*$_1$ structure. For it has been found that in this type of compound there is an attractive interaction between the oxy-

[5]In the general case the designations *cis*$_1$ and *cis*$_2$ are arbitrary. However for all the cases examined by us, X = RCO ≠ Y, and we define **24***b* as *cis*$_2$ (RCO groups *cis* to two-sulfur bridge) and **24***c* as *cis*$_1$ (RCO groups *cis* to one-sulfur bridge).

[6]The use of sulfuric acid as solvent leads to the possibility of isomerization in solution (*vide supra*); however, in this case there was no spectral evidence of such isomerization, and the higher-melting isomer was recovered unchanged on quenching the solution on ice.

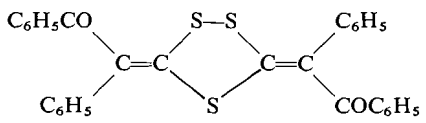
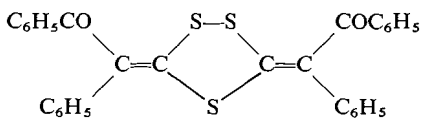
gen and sulfur atoms (1, 15),[7] and it may be anticipated that the cis_2 isomer will be more stable than the cis_1 isomer because the two oxygen atoms interact with a common sulfur atom in the latter case while in the former they interact with two different sulfur atoms.

The observation that two isomeric trithiolanes are formed from *p*-methylacetophenone led us to reexamine the case of acetophenone. As has been discussed previously, the major product, $C_{18}H_{12}O_2S_3$, has m.p. 236–238° (dec.). Work-up of the mother liquors from the crystallization of this compound led to the isolation of a more soluble, isomeric compound, m.p. 167.5–168.5°. The vinylic proton signals in the n.m.r. spectra of both isomers are embedded in the aromatic proton multiplets and do not serve to distinguish between the isomers in this case. A tentative assignment of stereostructures **28***a* and *b* to the lower- and higher-melting isomers is made on the basis of the m.p. and solubility relationships and analogy with **23**. The fact that the lower-melting isomer resolidified above its m.p. and melted again with decomposition at *ca.* 225° strongly indicates that thermal conversion of the lower- to the higher-melting isomers occurs in this case also.

A third instance of the formation of two stereoisomeric trithiolanes was observed in the case of deoxybenzoin. The major product, $C_{30}H_{20}O_2S_3$, m.p. 277–278° (dec.), was accompanied by a minor, isomeric, more soluble product, m.p. 219–220°. Since these products lack vinyl hydrogen atoms, the *trans* isomer cannot be recognized by n.m.r. spectroscopy. A tentative assignment of stereostructures **29***a* and *b* to the lower- and higher-melting isomers, respectively, is again made on the basis of the m.p. and solubility relationships and analogy with **23**.



29*a*



29*b*

From mesityl methyl ketone only a single trithiolane, $C_{24}H_{24}O_2S_3$, was obtained. Its n.m.r. spectrum (Table 1) showed a single low-field singlet attributable to superimposition of the signals due to both the vinylic and phenyl protons. Thus this is most probably a *cis* stereoisomer and it is provisionally assigned the stereostructure **30** by analogy.

We conclude this discussion of the reactions and structures of the 3,5-bismethylene-1,2,4-trithiolanes by noting that two reactions have been reported in which these compounds are converted to desaurins, *i.e.*, 2,4-bismethylene-1,3-dithietanes (**3**) (1). Wenzel (3) observed that saponification of the trithiolane **31** with sodium hydroxide in ethanol followed by acidification gave the desaurin **33**.[8] This transformation most probably involves the reductive cleavage of the disulfide linkage by the alcoholic base (*cf.* Scheme 1, **8** → **9**) to give **32** followed by closure to the desaurin with elimination of sulfide ion (Scheme 3).

More recently, Kirby (16) has converted the trithiolane **36** to the desaurin **37** by treatment with boiling triethyl phosphite. The trithiolane **36** was obtained by an analogous, novel method, *viz.*, reaction of triethyl phosphite with the tetrathiane **35** at room temperature (or by heating **35** in boiling toluene). The tetrathiane **35** (16, 17) was obtained by reaction of **34**, the adduct of biacetyl and trimethyl phosphite with carbon disulfide (Scheme 4).

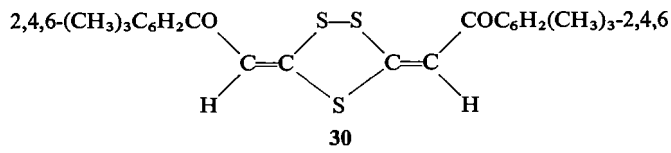
Spectra of the 3,5-Bismethylene-1,2,4-trithiolanes[9]

Aspects of the n.m.r. spectra of the trithiolanes have already been discussed in the discussion of stereochemistry. It remains here to comment that the expected relationship between the vinylic proton signals in the spectra of the alkyl ketone **23** and the aryl ketones **27***b* and **28***b* holds in that the former appears at δ 6.95, while the latter are shifted to lower field (δ 7.4–7.7). Further, the mesityl ketone **30** more closely resembles the alkyl ketone than the other aryl ketones in this respect, as anticipated to result from a considerable departure from coplanarity of the mesityl and α,β-unsaturated carbonyl systems (18). It is of interest to note that the vinylic proton signals of

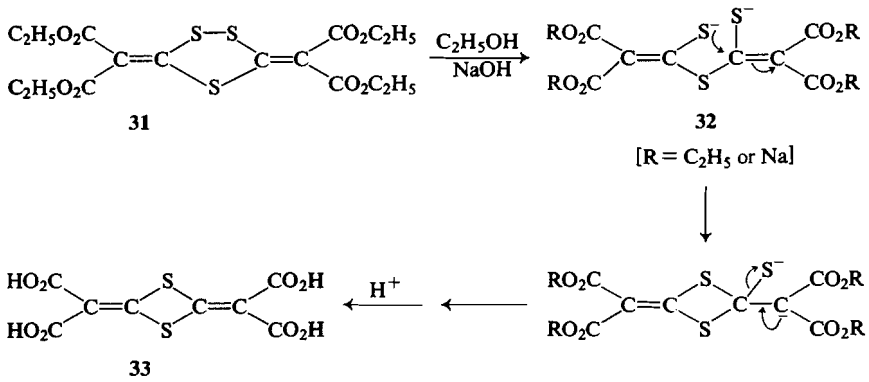
[7]Nyburg and Mellor (15) have found the shortest S—O distances (2.51 Å) in **23** to be markedly smaller than the sum of the van der Waals' radii of sulfur and oxygen (*cf.* ref. 1).

[8]The desaurin was originally considered to be a cyclobutane-1,2-dithione on the basis of the erroneous assignment of structure **2** to the trithiolane (3).

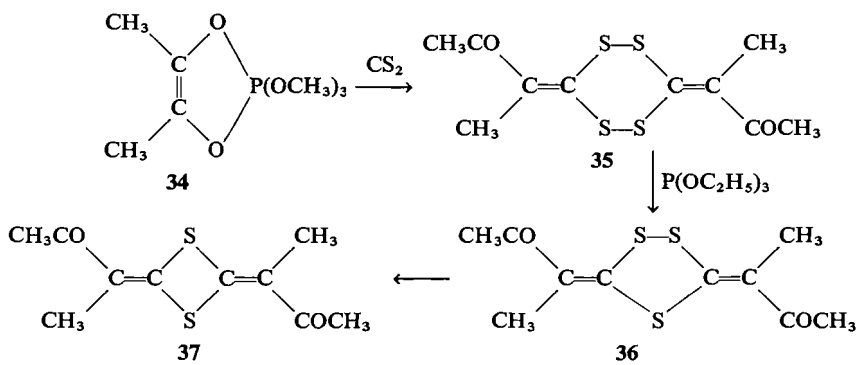
[9]For a discussion of the mass spectra of several 3,5-bismethylene-1,2,4-trithiolanes see ref. 6.



30

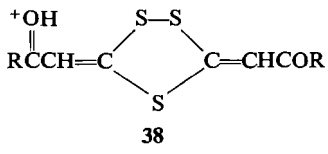


SCHEME 3

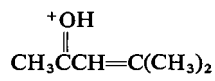


SCHEME 4

27*b* and **28***b* in sulfuric acid are only at slightly lower field than those of **27***a* and **28***a* in deuteriochloroform. Presumably, the species present in the sulfuric acid solutions are cations of type **38** (or the corresponding dications). Protonation of simple α,β-unsaturated ketones normally causes a shift of 0.6–1.0 p.p.m. to lower field of the α-vinylic proton signal (19, 20), *e.g.* protonated mesityl oxide (**39**) shows this signal at δ 6.96 (19) ($\Delta\delta$ = 1.0). The n.m.r. data in the present case indicate that the positive charge is more extensively delocalized, thus reducing the effect on the vinylic proton.



38



39

Bands in the 5–6 μ region of the i.r. spectra of the trithiolanes are listed in Table 2. These bands resemble those in this region in the spectra of the

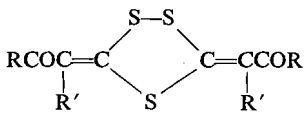
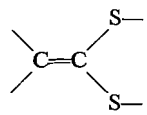
desaurins (1) in that the carbonyl-stretching bands are at unusually long wavelength and often appear to be unusually weak. The trithiolanes **23** and **36** of type **40** (R′ = H or alkyl) have their carbonyl-stretching band at 6.18–6.19 μ.[10] This represents a significant shift to longer wavelength relative to the corresponding desaurins. It is possible that this shift is related to the fact that the S—O distance in the trithiolane **23** has been found to be shorter than that in one of the desaurins (15). In more general terms, the geometry of the trithiolanes may be more favorable for delocalization of the unshared electrons on sulfur than that of the dithietanes. It is noteworthy that the carbonyl-stretching band of **19**, in which the vinylic hydrogen atoms of **23** are replaced by chlorine atoms, is shifted to 6.25 μ. In the case of cyclic enones substitution of chlorine for α-vinyl hydrogen usually causes a shift of the carbonyl-stretching band to lower wavelength (21). The present result can be interpreted as due to the existence of **19** in an *s-cis* conformation; the dipoles of the carbon–halogen bonds would then facilitate the stretching of the carbonyl bonds, in contrast to their effect in the *s-trans* cyclic enones.



40 R = alkyl
41 R = aryl



42

As in the case of the desaurins, the carbonyl-stretching bands of compounds of type **27** and **28** with an aryl group in conjugation with the carbonyl group (**41**) are moved to longer wavelength. Again they occur at longer wavelength than in the case of the corresponding desaurins. Their range cannot readily be defined because of overlap with aromatic stretching vibrations; the lower wavelength limit, however, is 6.21 μ. Compound **30**, the mesityl derivative falls at this lower limit as expected, due to departure from coplanarity of the aryl rings and the carbonyl groups (18). Another feature of the trithiolane spectra that resembles those of the desaurins is the occurrence of strong or very strong bands in the region 6.8–7.2 μ.[11] These are probably similar in origin to strong bands observed in the 6.5–7.0 μ region of the spectra of the desaurins and related two-sulfur compounds (1, 22). These have been assigned by Jensen and Henriksen (22) to the ν_1 vibration of the grouping **42**. As previously noted (1), this assignment must be considered as provisional because strong bands due to aromatic C—C stretching and aliphatic C—H bending vibrations can also occur in this region.

Examination of the i.r. spectra of the trithiolanes suggests that the carbonyl-stretching bands have unusually weak intensities relative to other bands in the spectra, as in the case of the desaurins (1). Measurement of the integrated absorption intensity for **27***a* in chloroform solution gave a value of 4.17, *i.e.*, 2.09 per carbonyl group, and for **27***b* in a potassium bromide disc a value of 2.24, *i.e.*, 1.12 per carbonyl group.[12] These values are comparable with those for benzophenone in chloroform and in a potassium bromide disc, *i.e.*, 2.35 and 1.20, respectively. The apparent abnormal weakness of the carbonyl-stretching bands observed on qualitative examination of the spectra is presumably due to the presence of unusually strong bands in other regions of the spectra and the fact that most of the spectra were recorded in the solid state.[13] In the case of planar chromophores, conjugation with an ethylenic double bond or aromatic ring brings about an increase in the carbonyl-stretching band intensity (23, 25). While the positions of the carbonyl-stretching bands of **27***a* and *b* show a considerably higher degree of conjugation than that in benzophenone, their integrated intensities per carbonyl group are slightly lower than the intensity of the carbonyl-stretching band of benzophenone. Thus, there does in fact appear to be a significant reduction in intensity relative to simple conjugated ketones when carbonyl groups are conjugated with the grouping **42**. As for the desaurins (1), this may be due to an interaction through space between the sulfur and oxygen atoms (15) in these compounds.

The u.v. maxima of the trithiolanes are listed in Table 3. The spectra of compounds **19**, **23**, and **36**

[10]The actual range may extend to slightly longer wavelength, since the shoulder at 6.26 μ in the spectrum of **23** suggests that the carbonyl-stretching band in this case may be split (*cf.* ref. 1).

[11]Although most of the spectra were recorded in Nujol mulls, it is clear that strong absorption due to the sample is superimposed on the Nujol absorption in this region.

[12]See ref. 1 for details of these integrated intensity measurements; the values are given in absorbance units (23), *i.e.*, 1×10^4 mol^{-1} l cm^{-2}.

[13]It has previously been found that absorptivities are less in the solid state than in solution (24).

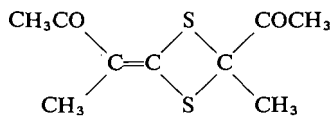
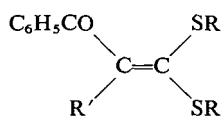
For personal use only.

of type **40** (R′ = H, CH_3, or Cl) have a high intensity long wavelength maximum at 339–352 mμ (ε 19 500 – 19 800) and another maximum at 232–241 mμ (ε 15 100 – 17 800). These may be compared with the spectra of analogous desaurins which have maxima at 350–370 mμ (ε 28 700 – 29 500) and *ca.* 242 mμ (ε 1440–2510) (1, 16), and of the related compound **43**, which has maxima at 317 (ε 8950) and 243 mμ (ε 5360) (16, 26). The relationship among these spectra is consistent with transmission of delocalization through one or more of the sulfur atoms in the trithiolanes, but to a lesser extent than in the desaurins (13, 16). This reduction most probably reflects reduced transmission through the disulfide linkage relative to that through the single sulfide linkage. The relationship among the spectra of **19**, **23**, and **36** is in accord with expectation in that substitution of alkyl groups or chlorine atoms for vinylic hydrogen atoms leads to a bathochromic shift of the long wavelength maximum.



43



44 R = CH_3 or $(CH_2)_n$

The stereoisomers of the trithiolanes **27**, **28**, and **29** of type **41** show maxima in their u.v. spectra at 378–395 mμ (ε 29 500 – 35 500) and 265–282 mμ (ε 21 400 – 27 500). The bathochromic and hyperchromic shifts of the long wavelength maxima relative to those of the trithiolanes of type **40** clearly reflect the additional conjugation of the carbonyl groups with the phenyl groups. Again, the spectra give evidence of transmission of delocalization through one or more of the sulfur atoms [*cf.* the spectra of the related compounds of type **44**: λ_{max} 344–350 mμ (ε 15 800 – 22 900) and 257–263 mμ (ε 7940 – 14 500) (1)], but indicate that this is less than in the case of the related desaurins [λ_{max} 392–419 mμ (ε 38 100 – 49 000) and 266–274 mμ (ε 17 000 – 22 900) (1)]. The relationship among the spectra of the stereoisomers of **27**, **28**, and **29** is analogous to that in the case of the related desaurins in that substitution of phenyl groups for vinylic hydrogen atoms leads to a bathochromic shift of the long wavelength maximum. The relationship between the spectra of each pair of stereoisomers indicates that the *cis* isomers have long wavelength maxima at somewhat longer wavelengths than the corresponding *trans* isomers; the relationship is clouded, however, by the fact that the long wavelength maxima can show shoulders at either shorter or longer wavelength.

The trithiolane **37** of type **41**, but with R = mesityl, has a u.v. spectrum that more closely resembles the spectra of the trithiolanes of type **40** than the spectra of the other trithiolanes of type **41**. This difference is readily attributable to the usual marked departure from coplanarity of the aryl ring and the carbonyl group in mesitoyl derivatives (18).

Experimental

Melting points were taken on a Fisher-Johns micro hot stage and are corrected. Solutions in organic solvents were dried over anhydrous sodium sulfate. The n.m.r., i.r., and u.v. spectroscopic data for the trithiolanes are listed in Tables 1–3 in the text.

Preparation of the Trithiolane ***23*** *(≡* ***8****) from Pinacolone*

Pinacolone (5.00 g, 50.0 mmol) was added dropwise to a stirred suspension of sodamide (1.95 g, 50.0 mmol) in anhydrous ether (40 ml) cooled in ice. When anion formation was complete, carbon disulfide (1.50 ml, 25.0 mmol) was added slowly. The bright yellow precipitate that formed was dissolved by the addition of methanol (5 ml). Ammonium peroxydisulfate (5.70 g, 25 mmol) in water was then added slowly, and, when the addition was complete, the solution was stirred for a further 0.5 h and filtered. The solid was dissolved in chloroform, the solution was filtered and dried, and the solvent was removed to give **8** (**23**) as a pale yellow solid (1.34 g, 34%), m.p. 202–204°. Five crystallizations from chloroform–hexane gave fine, very pale yellow needles, m.p. 211.5–212.5°.

Anal. Calcd. for $C_{14}H_{20}O_2S_3$: C, 53.12; H, 6.37; S, 30.39. Found: C, 53.23; H, 6.22; S, 30.24.

Reduction of ***8*** *with Zinc and Acetic Acid*

A mixture of **8** (6.80 g, 21.5 mmol), zinc dust (21.3 g, 325 mg-atoms), and glacial acetic acid was boiled under reflux with stirring for 5 h. After cooling, the reaction mixture was diluted with ether and filtered, and the filtrate was washed with water until free of acetic acid. The ethereal solution was dried, and the solvent was removed by careful distillation until only a few milliliters remained. The residual solvent and the volatile product were removed by distillation at 80° (10 mm) into a series of Dry Ice traps. Distillation of the material in the traps gave ethyl *t*-butyl ketone (**5**; 1.78 g, 36%), b.p. 120–125°, identified by its i.r. and n.m.r. spectra, and the formation of a 2,4-dinitrophenylhydrazone, m.p. 144.5–146° [lit. (27) m.p. 143.5–144.5°].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The non-volatile material (2.2 g) was chromatographed on silica gel. Elution with 2% benzene-pentane gave **6** as a white crystalline solid (0.10 g), m.p. 161.5–162°, after two sublimations at 100° (15 mm); $\lambda_{max}(CCl_4)$ 6.15 (w), 6.7 (w), 6.85 (m), 7.18 (w), 7.32 μ(w); $\lambda_{max}(C_2H_5OH)$ 269 (ε 17 400), 280 mμ (ε 12 600); δ (CCl_4) 1.40(s, 9H), 6.82(s, 1H); *m/e* = 252 (mol. ion; 33.5%), 237 (100%), 222 (16.3%), 207 (9%).

Anal. Calcd. for $C_{14}H_{20}S_2$: C, 66.61; H, 7.99; S, 25.41. Found: C, 66.47; H, 7.94; S, 25.24.

The third reduction product, **7**, was obtained as an oil (2.0 g) by elution of the column with 2–5% ether–benzene. Purification was effected by further chromatography followed by molecular distillation at 70° (0.2 mm); $\lambda_{max}(CCl_4)$ 5.84 (s), 6.76 (m), 7.18 (w), 7.31 μ(m); δ (CCl_4) 1.14 (s, 18H), 2.67 (s, 8H); δ (C_6H_6) 0.93 (s), 2.62 (m).

A bis-2,4-dinitrophenylhydrazone was prepared by the method of Shriner *et al.* (28) and purified by five crystallizations from ethanol – ethyl acetate; m.p. 196–197.5°.

Anal. Calcd. for $C_{26}H_{34}N_8O_8S$: C, 50.47; H, 5.54; N, 18.11; S, 5.18. Found: C, 50.62; H, 5.52; N, 17.86; S, 5.35.

*Desulfurization of **7** with Raney Nickel*

A mixture of **7** (0.19 g, 0.720 mmol) and W-2 Raney nickel (*ca.* 2 g) in ethanol (15 ml) was boiled under reflux for 3.25 h under a slow stream of nitrogen. Nitrogen was bubbled through the solution for a short time after it had cooled to remove any acetaldehyde present. The solution was filtered, and the filtrate was treated with an excess of 2,4-dinitrophenylhydrazine reagent (28). After standing overnight, the mixture was filtered to give the 2,4-dinitrophenylhydrazone of ethyl *t*-butyl ketone (0.082 g, 20%), m.p. 136–138°. One crystallization from 95% ethanol gave crystals, m.p. 142–143°, undepressed upon admixture with an authentic sample, m.p. 144.5–146°.

*Reaction of **8** with Phosphorus Pentasulfide. Formation of **14***

A mixture of **8** (0.54 g, 1.70 mmol) and phosphorus pentasulfide (1.00 g, 2.30 mmol) in *p*-xylene (40 ml) was boiled under reflux for 2 h. When cool, the dark solution was washed successively with aqueous 10% potassium hydroxide, aqueous 10% hydrochloric acid, and water and dried. The solvent was removed and the crude product was crystallized from hexane to give **14** as yellow needles (0.37 g, 56%), m.p. 69.0–69.5, after three crystallizations from methanol; $\lambda_{max}(CHCl_3)$ 6.84 (m), 7.31 μ(s); $\lambda_{max}(C_2H_5OH)$ 230 (ε 9600), 246 (ε 5900), 268 (ε 6900), 317 mμ (ε 4400), 408 mμ (11 000); δ ($CDCl_3$) 1.43 (s, 9H), 7.18 (s, 1H).

Anal. Calcd. for $C_7H_{10}S_3$: C, 44.17; H, 5.30; S, 50.54. Found: C, 44.21; H, 5.30; S, 50.46.

*Reaction of **8** with Phosphorus Pentachloride. Formation of **19***

Compound **8** (0.100 g, 0.316 mmol) was mixed with phosphorus pentachloride (0.150 g, 0.680 mmol) and the mixture was heated at 140–145° under nitrogen for 50 min. Water and chloroform were added to the dark yellow product after it had cooled, and the organic layer was washed several times with water and dried. Removal of the solvent and crystallization of the residue from acetone gave **19** as pale yellow needles (0.040 g, 35%), m.p. 222.5–223.5° after three further crystallizations from acetone.

Anal. Calcd. for $C_{14}H_{18}Cl_2O_2S_3$: C, 43.63; H, 4.71; Cl, 18.40; S, 24.96. Found: C, 43.78; H, 4.75; Cl, 18.50; S, 24.56.

*Preparation of the Trithiolanes **27a** and **b** from p-Methylacetophenone*

p-Methylacetophenone (6.70 g, 50.0 mmol) in anhydrous ether (10 ml) was converted to a mixture of **27*a*** and ***b*** by the method used for the preparation of **23**. The resulting yellow solid (3.87 g, 80%) was washed with water and methanol, air-dried, and heated briefly in chloroform. The insoluble material was filtered off, and the filtrate was retained. The chloroform-insoluble material was recrystallized five times from toluene to give **27*b***, m.p. 251–252°.

Anal. Calcd. for $C_{20}H_{16}O_2S_3$: C, 62.47; H, 4.19; S, 25.02. Found: C, 62.55; H, 4.49; S, 24.81.

Evaporation of the chloroform filtrates to dryness gave a yellow solid, which was crystallized from benzene to give yellow crystalline clumps, m.p. 210–212° (0.60 g, 13%). Four recrystallizations from benzene gave **27*a***, m.p. 213.5–214.5°.

Anal. Calcd. for $C_{20}H_{16}O_2S_3$: C, 62.47; H, 4.19; S, 25.02. Found: C, 62.73; H, 4.20; S, 24.90.

Compound **27*a*** (0.027 g) was heated at 225° for 3 min. After cooling, the reddish solid was crystallized twice from toluene to give yellow needles (0.018 g, 66%), m.p. 249–251°, undepressed on admixture with **27*b***.

*Reduction of **27b**. Formation of **25***

Compound **27*b*** (3.14 g, 8.10 mmol) and zinc dust (18.5 g) were suspended in glacial acetic acid (50 ml), and the mixture was boiled under reflux with stirring for 6 h. When the mixture had cooled, ether was added, and the acetic acid was removed by washing with water. Removal of the solvent gave a yellow oil (1.94 g) which was chromatographed on silica gel. Fractions eluted with ether–benzene mixtures were combined and evaporated. The product was treated with excess lithium aluminum hydride in anhydrous ether, and the oil obtained was chromatographed on silica gel. Elution with ether–benzene gave 1-*p*-tolyl-1-propanol (**25**) as an oil (0.52 g, 21%): $\lambda_{max}(CCl_4)$ 2.74 μ(m); δ (CCl_4) 0.82 (t, J = 7 Hz, 3H), 1.55 (m, 2H), 2.26 (s, 3H), 4.35 (t, 1H), 7.01 (s, 4H). The identity of this compound was confirmed by comparison of its spectra with those of an authentic sample prepared by reduction of *p*-methylpropiophenone with lithium aluminum hydride.

*Reaction of **27b** with Phosphorus Pentasulfide. Formation of **26***

A mixture of **27*b*** (1.00 g, 2.60 mmol) and phosphorus pentasulfide (2.00 g, 4.60 mmol) in xylene was boiled under reflux for 2 h. When cool, the xylene solution was washed successively with aqueous 10% potassium hydroxide, 10% hydrochloric acid, and water and dried. The solvent was removed to give a reddish residue which was chromatographed on neutral alumina (Woelm). Elution with benzene gave yellow–red oils, which crystallized spontaneously. These were combined and the product was recrystallized from benzene to give yellow crystals (0.757 g, 65%). Five further crystallizations gave **26**,

m.p. 119–120°; $\lambda_{max}(CHCl_3)$ 6.22 (m), 6.73 (s), 7.10 μ(w); $\lambda_{max}(C_2H_5OH)$ 230 (ε 12 600), 271 (ε 8300), 327 (ε 21 400), 433 mμ (ε 10 700); δ ($CDCl_3$) 2.40 (s, 3H), 7.42 (s, 1H), 7.23 and 7.55 (dd, J = 8.5 Hz, 4H).

Anal. Calcd. for $C_{10}H_8S_3$: C, 53.53; H, 3.59; S, 42.88. Found: C, 53.49; H, 3.56; S, 42.84.

Preparation of the Trithiolanes ***28a*** *and b from Acetophenone*

The method of Gompper and Töpfl (5) was followed, giving the crude product in 65% yield. The material was purified by recrystallization from toluene to give **28*b*** as fine yellow needles, m.p. 236–238° (dec.). The same material was also obtained by recrystallization of a yellow, insoluble, material obtained during the purification of benzoyldithioacetic acid. A mixed m.p. with the material obtained by Gompper and Töpfl's method showed no depression.

Anal. Calcd. for $C_{18}H_{12}O_2S_3$: C, 60.64; H, 3.39; S, 26.99. Found: C, 60.53; H, 3.44; S, 26.77.

The mother liquors from the first method of preparation were stripped of solvent, and the residue was crystallized several times from benzene–hexane to give **28*a***, m.p. 167.5–168.5°.

Anal. Calcd. for $C_{18}H_{12}O_2S_3$: C, 60.64; H, 3.39; S, 26.99. Found: C, 60.71; H, 3.52; S, 26.58.

Preparation of the Trithiolanes ***29a*** *and b from Deoxybenzoin*

Deoxybenzoin (2.00 g, 10.0 mmol) in anhydrous ether (10 ml) was converted to a mixture of **29*a*** and *b* by the method used for the preparation of **23**. The resulting yellow precipitate (0.49 g, 38%) was washed with water, air dried, and heated briefly in chloroform. The solution was filtered, and the filtrate was retained. The chloroform-insoluble material (0.40 g, 31%) was crystallized three times from toluene to give **29*b***, m.p. 277–278° (dec.).

Anal. Calcd. for $C_{30}H_{20}O_2S_3$: C, 70.83; H, 3.96; S, 18.91. Found: C, 70.85; H, 3.98; S, 18.60.

Evaporation of the chloroform filtrates gave **29*a***, m.p. *ca.* 213° (0.085 g, 7%). After several recrystallizations from benzene–hexane, this had m.p. 219–220°, with subsequent solidification and remelting at *ca.* 245° (dec.).

Anal. Calcd. for $C_{30}H_{20}O_2S_3$: C, 70.83; H, 3.96; S, 18.91. Found: C, 70.90; H, 4.29; S, 18.85.

Preparation of the Trithiolane ***30*** *from Mesityl Methyl Ketone*

Mesityl methyl ketone (2.0 g, 12.5 mmol) in anhydrous ether (15 ml) was converted to **30** by the method used for the preparation of **23**. Benzene was added to the reaction mixture, and the organic layer was washed several times with water and dried. The solvent was removed, and the crude product was crystallized from chloroform–hexane to give **30** as small plates (0.38 g, 29%), which after five further crystallizations from chloroform–hexane had m.p. 208.5–210°.

Anal. Calcd. for $C_{24}H_{24}O_2S_3$: C, 65.42; H, 5.49; S, 21.83. Found: C, 65.35; H, 5.52; S, 21.45.

Application of Proton Magnetic Resonance to Rotational Isomerism in Halotoluenes. VII. Barriers to Rotation and Conformational Preferences in α,α,α′,α′,2,4,5,6-Octachloro-*m*-xylene

J. PEELING,[1] B. W. GOODWIN,[2] T. SCHAEFER, AND C. WONG
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received December 14, 1970

At low temperatures α,α,α′,α′,2,4,5,6-octachloro-*m*-xylene exists as three conformers in solution and the proton resonance spectrum can be assigned by comparison to the spectrum of α,α,α′,α′,2,4,6-heptachloro-*m*-xylene. The temperature dependent spectra of the former in toluene-d_8 solution are fitted to computed spectra based on a set of coupled Bloch equations. The activation parameters for the rotation about the sp^2–sp^3 carbon–carbon bonds are $E_a = 14.93 \pm 0.13$ kcal/mol, $\log A = 12.45 \pm 0.09$, $\Delta H^* = 14.30 \pm 0.14$ kcal/mol, $\Delta S^* = -2.0 \pm 0.5$ e.u., $\Delta G^* = 14.9 \pm 0.05$ kcal/mol at 293 °K. The quoted errors are standard deviations.

Le bis(dichlorométhyl)-1,3 tétrachloro-2,4,5,6 benzène en solution existe, à basse température, sous trois conformations et son spectre r.m.n. qui varie avec la température peut être analysé par comparaison avec celui du bis(dichlorométhyl)-1,3 trichloro-2,4,6 benzène. Son spectre déterminé dans le toluène-d_8 peut être superposé à un spectre théorique calculé à l'aide d'une série d'équations de Bloch. Les paramètres d'activation pour la rotation autour de la liaison carbone–carbone sp^2–sp^3 sont $E_a = 14.93 \pm 0.13$ kcal/mol, $\log A = 12.45 \pm 0.09$, $\Delta H^* = 14.30 \pm 0.14$ kcal/mol, $\Delta S^* = -2.0 \pm 0.5$ u.e., $\Delta G^* = 14.9 \pm 0.05$ kcal/mol à 293 °K. Les erreurs mentionnées sont les déviations standards.

Canadian Journal of Chemistry, 49, 1489 (1971)

Introduction

In a series of experiments designed to determine the stable conformations of the side-chain and the barrier to rotation about the sp^2–sp^3 carbon–carbon bond in halotoluene derivatives, the temperature dependence of the ring p.m.r. spectra of α,α,2,4,6-pentachlorotoluene (PCT), α,α-dichloro-2,4,6-tribromotoluene (DCTBT), and of α,α,2,3,6-pentachlorotoluene (3PCT) was studied (1–4). The undetected presence of systematic errors in DNMR techniques (5) is always a danger and therefore the study of the rotation of the dichloromethyl group in α,α,α′,α′,2,4,5,6-octachloro-*m*-xylene (MOCX) was undertaken. In contrast to the above molecules, it is the protons of the side-chains which are temperature dependent, the exchange takes place between four sites instead of two; and because there exists no observable long-range coupling between the protons, a set of coupled Bloch equations can be used to describe the exchange process. In other words, any systematic errors in the analysis of PCT at 60 MHz are expected to be of rather different origin in the study of MOCX at 100 MHz, while the barrier to rotation should not be greatly different in the two cases.

This paper describes the results of a careful study of the barrier to rotation in MOCX.

Experimental

(1) Preparation of MOCX

Free radical chlorination of 2,4,5,6-tetrachloro-*m*-xylene, as described for PCT (1), was monitored by observing the proton chemical shifts of the side-chain protons and was terminated when the peaks arising from chloromethyl protons were no longer present. These peaks occur some p.p.m. to high field of those from the protons in the dichloromethyl groups.

(2) Preparation of α,α,α′,α′,2,4,6-Heptachloro-m-xylene (MHCX)

Ring chlorination of 3,5-dimethylaniline, in a manner similar to that used in the preparation of PCT from *m*-toluidine (1), followed by deamination and chlorination of the side-chains as for MOCX, yielded MHCX.[3]

(3) Spectral Measurements

A 6.1 mol % solution of MOCX in toluene-d_8 (C_7D_8) containing tetramethylsilane (TMS) as internal reference was carefully degassed. A similar solution containing about 5 mol % of MHCX was also prepared. Toluene-d_8 is a good solvent of these molecules between −50 and 110 °C and the temperature dependence of the proton chemical shifts can be accurately measured. Solvents like CCl_4, CH_2Cl_2, and acetone do not fulfill all of these conditions.

The p.m.r. spectra were recorded at a sweep rate of 0.02 Hz/s on a HA-100D spectrometer, taking care not

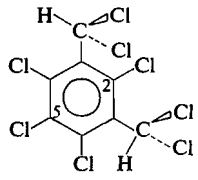
[3]We are grateful to Mr. K. Chum, summer student 1970, for this preparation.

to use excessive filtering of the d.c. signal.[4] Calibration of peak positions and of the sample temperature was done as previously described (3). Absolute temperatures are accurate to at least 1 °K and relative temperatures to 0.5 °K. Peak positions of MOCX were measured over a range of temperatures in the region of slow exchange. The magnetic field homogeneity was monitored by the width of a single sharp impurity peak (see Fig. 3).

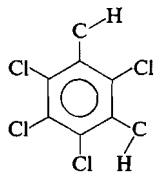
Results and Discussion

(1) Assignment of Peaks to Conformations in the Region of Slow Exchange

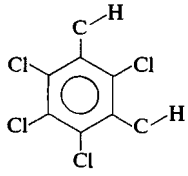
In view of the results for PCT (1, 2), it is clear that there exist three stable conformations of MOCX, **1** to **3**. The protons are isochronous in **1**



1



2



3

and in **3** but are anisochronous in **2**. In Fig. 1 the proton spectrum displays the expected four peaks but their assignment to the various conformers is not obvious because the peaks occur as pairs of apparently equal intensity within the pair.

On the basis of the zig–zag rule, coupling between the protons in **1** is possible but is unobservable because of the shift degeneracy. The zig–zag rule predicts zero coupling of the protons in **2** while shift degeneracy gives no observable coupling in **3**. Accordingly, the four peaks do not display any splitting.

Detailed electric field calculations, based on a dipole model as outlined by Buckingham (6), were carried out using scale diagrams and standard dipole moments for C—Cl bonds. The

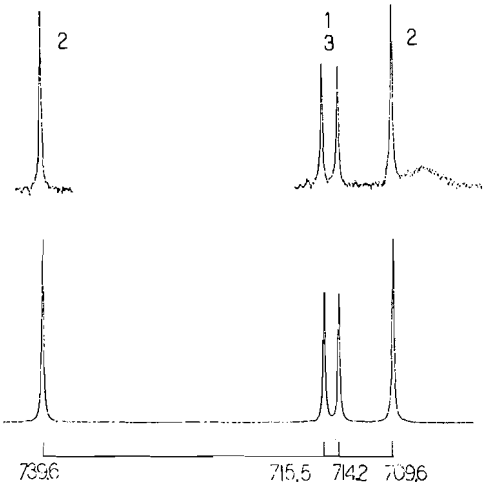


FIG. 1. The p.m.r. spectrum at 100 MHz of α,α,α′,α′-2,4,5,6-octachloro-*m*-xylene as a 6.1 mol % solution in toluene-d_8 at −41 °C. The chemical shift is given in Hz to low field of internal TMS. Note the broad resonance peak at high field due to incompletely deuterated toluene. The spectrum shown at the bottom of the figure was calculated using the computer program described in the text. The taller pair of peaks is assigned to the unsymmetrical conformation **2** with the methine proton at position 1 to lowest field. The smaller pair of peaks belongs to the symmetrical conformations **1** and **3**.

predicted shifts for the various conformers would assign **1** at highest field (739.7 Hz) and one proton of **2** at lowest field, clearly incompatible with the observed intensities in Fig. 1. It is unlikely that aromatic solvent shifts are responsible for the disagreement because the specific shifts induced by C_7D_8 on the methine protons are very small relative to those induced on the ring protons in PCT (1, 2). (At any rate, the calculated shifts do not qualitatively agree with a spectrum taken in CCl_4.) It is much more likely that the relative shifts of the protons in MOCX are dominated by intramolecular van der Waals (steric) interactions (see Appendix).

The assignment was therefore made on the basis of the spectrum of MHCX shown in Fig. 2. The ring proton peaks are broader than the methine peaks. The three conformations of MHCX can be represented by **4**, **5**, and **6**, where the presence of the chlorine atoms is understood. On the basis of the stereospecific five-bond coupling between ring and side-chain protons in PCT (1), the methine protons in **6** are coupled to the ring proton by 0.5 Hz (equal to the doublet splitting in PCT and in Fig. 2). Similarly, no

[4]A referee suggests that a sweep rate of 0.02 Hz/s is unusually slow and may well lead to signal distortion via saturation. In our opinion this sweep rate is more of an *upper* limit if other kinds of distortion are to be avoided. We emphasize that the signals showed no saturation effects.

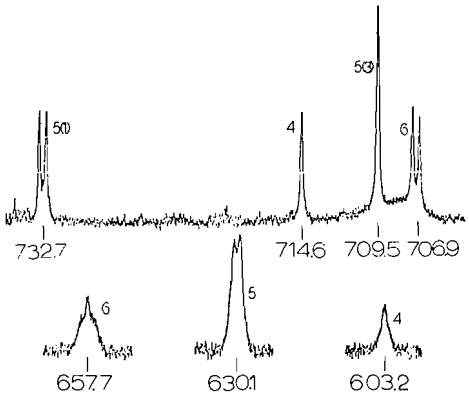

FIG. 2. The p.m.r. spectrum at 100 MHz and −41 °C of α,α,α′,α′,2,4,6-heptachloro-*m*-xylene as 7 mol % solution in toluene-d_8. The broad hump between 707 and 710 Hz to low field of internal TMS arises from incompletely deuterated toluene. The assignment is discussed in the text. The lower part of the figure gives the ring proton resonance peaks of the conformations **4** to **6** of the text. The splitting of the doublets at high and low field of the methine protons in the upper part of the figure is 0.5 Hz.

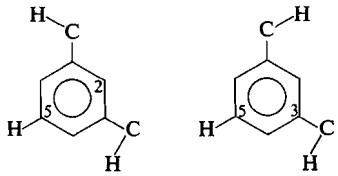
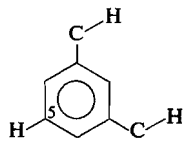


4 **5**



6

coupling will occur in **4** while in **5** the ring proton couples only to the methine proton in the dichloromethyl group at position 1 of the ring. Simple decoupling experiments and the relative peak intensities confirmed the assignments given in Fig. 2.

Assuming that the replacement of chlorine by hydrogen meta to the methine carbons has little effect on the methine proton shifts, it follows that in MOCX the most abundant conformer is **2** and the assignment of the peaks is given in Fig. 1. The unsymmetric **2** has been distinguished from the symmetric **1** and **3**. Which of the two smaller peaks belongs to **1** is irrelevant to the rate study because the populations of **1** and **3** are equal in C_7D_8 to within experimental error.

(2) Relative Populations of the Conformers in MOCX and MHCX

In MHCX the relative populations at −41 °C in C_7D_8 are **4**:**5**:**6** = 1:3.6:1.7 as determined by weighing of peaks. In MOCX the populations at −41 °C in C_7D_8 are **1**:**2**:**3** = 1:2.9:1, based on repeated measurements of peak areas by weighing. The larger population of the unsymmetrical conformer **2** in MOCX is likely an entropy effect (see below). The decrease in the stability of **4** relative to the other conformers of MHCX compared to the corresponding stability of **1** in MOCX is very likely a direct result of the absence of chlorine at position 5 in MHCX. Thus **5** and **6** become more stable in MHCX because steric crowding of the ortho C—Cl bonds by the dichloromethyl groups can be relieved by bending of the C—Cl bonds at positions 4 or 6 towards the C—H bond at position 5, whereas **4** and **1** have a very similar steric interaction of the two dichloromethyl groups with the C—Cl bond at position 2.

In the calculation of line-shapes for MOCX the relative populations of **1**, **2**, and **3** as a function of temperature are needed. But the peak area measurements in the limited temperature region of slow exchange are not accurate enough to determine enthalpy differences reliably. Therefore the following approach was adopted. At −41 °C, where no broadening from exchange was present, repeated peak area measurements yielded $\Delta G = G_2 - G_1 = G_2 - G_3 = -RT\ln K = RT\ln P_2/P_3 = 490 \pm 20$ cal/mol. Following Govil and Bernstein (7) it was assumed that the vibrational entropy differences between the conformers were negligible, particularly in view of the large barriers in the wells of which the torsional modes of the dichloromethyl groups are active (translational entropy differences are, of course, zero). The rotational entropy differences were then calculated from the product of the principal moments of inertia for each conformer, assuming tetrahedral angles in the side-chains and 120° bond angles in the benzene ring. This approximation is unimportant because the rotational entropy differences between the conformers turned out to be only about 0.02 e.u. and were therefore neglected.

From symmetry considerations it follows that $S_2 - S_1 = S_2 - S_3 = R\ln 2 = 1.38$ e.u. Hence

[1] Shift of **2** = $-11.340 \times 10^3/T + 788.54$ $r = 0.9997$

[2] Shift of **1** or **3** = $-15.603 \times 10^3/T + 782.78$ $r = 0.9999$

[3] Shift of **3** or **1** = $-13.823 \times 10^3/T + 773.82$ $r = 0.9998$

[4] Shift of **2** = $-17.804 \times 10^3/T + 786.34$ $r = -0.9999$

$H_2 - H_3 = -164$ cal/mol at -41 °C, so that the entropy effect on the relative stabilities is dominant. Then at 373 °K, near the highest temperature at which rate studies were carried out, one has $G_2 - G_1 = -680$ cal/mol. Therefore the population ratios change from $P_2/P_1 = 2.9$ at -40 °C to 2.5 at 373 °K. Calculated and experimental rate dependent spectra were fitted with these populations as well as under the assumption of temperature independent populations. As shown below, the activation parameters are insensitive to population changes of this extent.

(3) The Line-shape Theory and Computer Program

In terms of conformers **1** to **3** and with reference to Fig. 1, where the four resonance peaks display no spin–spin coupling, the McConnell formulation (8) of the Bloch equations under conditions of exchange was applied to this four-site problem. It can be seen that, in fact, only two independent preexchange lifetimes, τ, exist here by nature of the conformations and of the rate process, which is always a rotation by π radians from one in-plane C—H conformation to another (1). The other τ values are related to these via population ratios.

The final expression for the complex magnetization was written in terms of τ_1 and τ_2 which are, respectively, the mean preexchange lifetimes of conformers **1** and **3**, these conformers converting to **2** on rotation of either of the dichloromethyl groups. The expression carries four effective T_2 terms, one for each of the peaks, but only three population terms because the separate resonance peaks of **2** must have equal intensities.

A computer program in Fortran IV was written which took as input data the three populations, the four effective T_2 values, the two preexchange lifetimes, a scaling factor, and the frequencies of the exchange sites. The use of the program in line-shape fitting then follows the procedure described for the program ABXFIT(1) and a plotting procedure can be called for the line printer or the Calcomp plotter on an IBM 360/65 computer.

(4) Fitted Spectra and Activation Parameters

(a) Temperature Dependence of Peak Positions (Due to Solvent Effects) in the Absence of Exchange

As discussed previously (1), it is essential that this correction be made if severe errors in rate constants are to be avoided. In the region of slow exchange between -41 and -20 °C, the peak positions are best reproduced when plotted *vs.* T^{-1}. They are represented by eqs. 1–4, where the shift is measured in Hz at 100 MHz to low field of internal TMS and T is in °K.

As an example of the reliability of these equations in the region of fast exchange, the weighted mean of the four calculated nonexchanging peak positions at 94 °C is 743.04 Hz and can be compared with the exchange-averaged peak of width 0.76 Hz found at 743.11 Hz. Although the agreement is excellent it was found necessary to change the calculated shift of a few peaks by a few tenths of a Hz at some temperatures in order to obtain a sensible fit between calculated and observed spectra.

(b) Calculated Spectra

At low temperatures the linewidths of the four peaks were equal within experimental error. An impurity peak (to be seen in Fig. 3) was used to monitor the resolution of the spectrometer at each temperature. The T_2 values ranged from 1.59 to 1.72 s, depending on the temperature, and were used in the fitting procedure. Only those spectra showing substantial exchange broadening were fitted, those between -10 and 99 °C. It was further assumed that the barriers to rotation of the dichloromethyl group in **1** and **3** were equal. Their ground state free energies are the same (at least at -41 °C) and there appeared to be no reliable way in which a difference in barrier could be measured by the fitting method. The error introduced in this way is probably small (see below).

At 318 and 323 °K the spectra were so broad due to the low concentration of 6 mol %, that the line-shape could not be reliably measured in our opinion. Preexchange lifetimes were found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

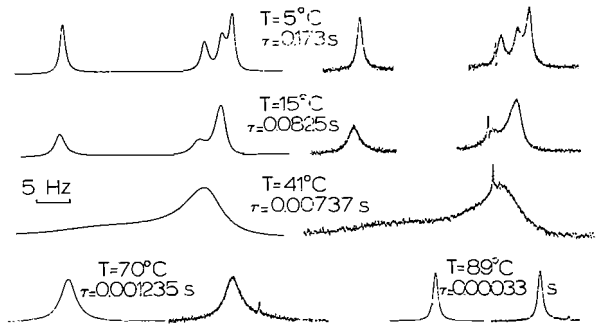

FIG. 3. A few representative observed and calculated proton resonance spectra of the methine protons of MOCX at various temperatures and preexchange lifetimes, τ. The small sharp peak observable in some spectra arises from an impurity.

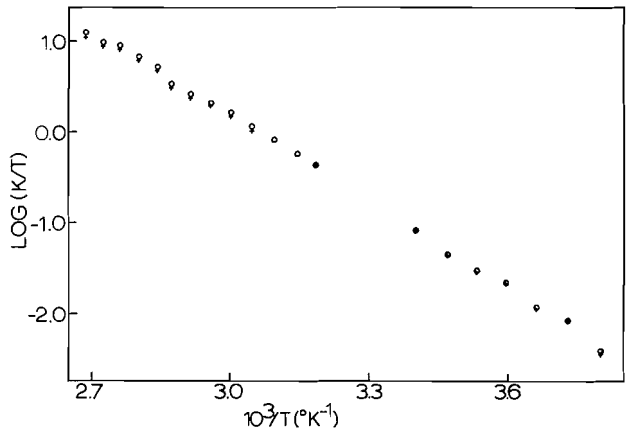

FIG. 4. A plot of log k/T *vs.* $1/T$ for the activated rotation of the dichloromethyl groups in MOCX dissolved in toluene-d_8. The open circles refer to the rate constants, k, obtained on the assumption of constant populations of the conformations. The crosses refer to the k values extracted when the populations of the conformations change with temperature in the manner described in the text. Both plots give a least squares fit with a correlation coefficient, $r = 0.999$.

at 20 temperatures and the rate constant, k, ranged from about 0.3 to 1400 s^{-1} between -10 and 99 °C.

Best fits were found on the assumption of no population change as well as with the populations calculated as described above. In Fig. 3 calculated and observed spectra are displayed at a few representative temperatures. In Fig. 4 a plot of log k/T *vs.* $1/T$ ($r = 0.9993$) indicates the differences obtained by using the two population assumptions above.

(c) The Activation Parameters

Plots of log k *vs.* $1/T$, log k/T *vs.* $1/T$, and $\Delta G^{\ddagger}$ *vs.* T were prepared based on the Arrhenius and transition state formulations of an activated process (5). Least squares analyses gave the parameter values shown in Table 1. It is customary to add the caveat that the least squares errors in Table 1 should be multiplied by a factor of from 2 to 4 to allow for systematic errors. In the present instance it is felt that the statistical errors may well lie near the true error. The temperature range is 110 °K and there are four peaks, presenting a number of coalescence temperatures. The temperature range falls into the region where it is most easily controlled in the probe and where temperature gradients near the receiver coil are relatively small.

Another way of estimating the uncertainty in the entropy of activation caused by errors in the rate constant k uses eq. 5 (9) where T_1 and T_2 are

$$[5]\quad \Delta(\Delta S^{\ddagger}) = (\pm R/T_2 - T_1)[(T_2\Delta k_2/k_2)^2 + (T_1\Delta k_1/k_1)^2]^{1/2}$$

TABLE 1. Activation parameters for the hindered rotation in α,α,α′,α′,2,4,5,6-octachloro-*m*-xylene

Parameter	Constant populations	Variable populations
E_A (kcal/mol)	15.08±0.12	14.93±0.13
log A	12.59±0.08	12.45±0.09 (r = 0.9994)
ΔH (kcal/mol)	14.46±0.12	14.32±0.13
$\Delta S^{\ddagger}$ (e.u.)	−1.6±0.4	−2.2±0.4
From log k/T vs. 1/T (r = 0.9993)		
$\Delta H^{\ddagger}$ (kcal/mol)	14.40±0.13	14.27±0.14
$\Delta S^{\ddagger}$ (e.u.)	−1.8±0.4	−2.4±0.4
From $\Delta G^{\ddagger}$ vs. T (r = 0.79)		
$\Delta G^{\ddagger}$ (kcal/mol at 293 °K)	14.9±0.05 at 293 °K	

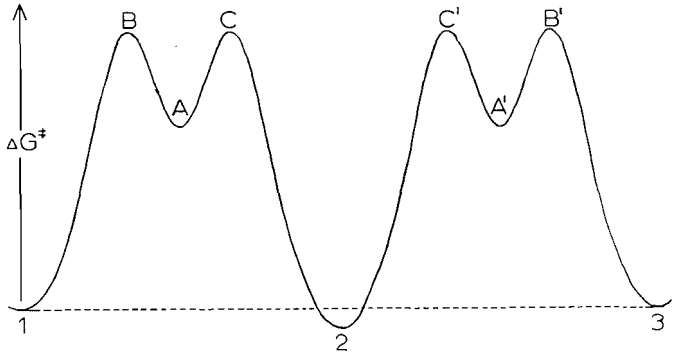

FIG. 5. A representation of the free energy profile for the interconversion of the conformers **1**, **2**, and **3** of α,α,α′,α′,-2,4,5,6-octachloro-*m*-xylene dissolved in toluene-d_8. Note that the unsymmetrical **2** has a lower free energy of about 0.5 kcal/mol than **1** and **3** at the temperatures under consideration. States B, B′, C, and C′ lie near 15 kcal/mol and A and A′ are about 10 kcal/mol above the ground state.

the end temperatures with corresponding rate constants k_1 and k_2 and errors Δk_1 and Δk_2. In this study we found $k_1 = 0.28_5 \pm 0.01$ s^{-1} at 263 °K and $k_2 = 1380 \pm 100$ s^{-1} at 372 °K. Then $\Delta(\Delta S^{\ddagger}) = 0.5$ e.u., in close agreement with the least squares errors given above.

(5) Discussion of Activation Parameters

Structures **1** and **3** are of equal stability and are less stable than **2** by about 0.5 kcal/mol in the temperature region under consideration. The free energy profile for the rotations can be depicted as in Fig. 5, where B, C, C′, and B′ represent transition states in which C—Cl bonds on the ring eclipse C—Cl bonds on the side-chain. The A and A′ represent intermediate conformers in which the C—H bonds of the side-chain are rotated by 90° out of the plane of the ring. As borne out by potential energy calculations (10), A and A′ are much too high in energy (A ≈ 0.7 B) to be appreciably populated at these temperatures.[5]

If B and C (and B′ and C′) are isoenergetic then the measured $\Delta G^{\ddagger}$ refers to the rate of rotation in **2** because the free energy barrier to rotation in **2** is then the higher by about 0.5 kcal/mol and is therefore rate controlling. The same conclusion holds if C (and C′) is lower or higher in free energy than B (and B′). It is not known which of the four transition states is of highest energy nor is it known that C and C′ (and B and B′) are isoenergetic. If, for example, B′ and C′ are both of lower energy than B and C, the measured $\Delta G^{\ddagger}$ refers to the rate of rotation from **2** to **1**. No difficulty in line-shape fitting was encountered, however, by assuming B and B′ (or C and C′) to be isoenergetic.

[5]The shape of the barrier justifies the use of a transmission coefficient near 1/2 (11).

In a similarly crowded molecule, α,α,α′,α′,2,3,5,6-octachloro-*p*-xylene (POCX), the entropy of activation lies near −7 e.u. (10), substantially more negative than in MOCX. The obvious difference between POCX and MOCX is that in POCX the ground states are symmetrical (each has a two-fold axis or a plane of symmetry). In MOCX the measured $\Delta S^{\ddagger}$ of near −2 e.u. evidently refers to the conversion of the unsymmetrical **2** to the symmetrical **1** and **3**. But **2** has greater entropy in the ground state than **1** or **3**, assuming the estimates in a previous section are correct. Then, if C (or C′) represents the transition state and if it partakes more of the ground state **2** than of **1** or **3** (C and C′ are obtained from **2** by a rotation of 60° about the sp^2–sp^3 carbon–carbon bond) the less negative $\Delta S^{\ddagger}$ of MOCX compared to POCX is perhaps understandable. If this line of argument is correct then $\Delta S^{\ddagger}$ for the conversion of **1** or **3** to **2** should be more negative than −2 e.u. There is no obvious method by which this prediction can be tested.

Appendix

Rationalization of Relative Proton Shifts in MOCX and MHCX

(a) Ring Proton Shifts in MHCX

The relative shifts cannot be explained on the basis of electric dipolar fields (6) because it is clear that the C—Cl dipoles in **4** would deshield the ring proton more than in **6**. Yet **4** lies to highest field in Fig. 2. However, a combination of solvent and steric effects can rationalize the relative shifts. It is well-known (12) that the aromatic solvent molecules avoid electron-rich regions of an aromatic solute molecule. Thus in **4** the C_7D_8 molecule can approach H-5 much more easily than in **5** or **6**, causing a preferred high-field shift in **4**. The aromatic solvent induced shifts are additive (12) and hence it is not surprising to note an increase of 27 Hz both from **6** to **5** and from **5** to **4**. In **6** the dichloromethyl groups have the C—Cl bonds near H-5 thus repelling the solvent molecules (12) while in **5** only one dichloromethyl group is so situated.

Again, the nonzero mean square electric fields originating in the C—Cl bonds of the dichloromethyl groups will deshield H-5 most in **6** and least in **4**, consistent with the observed order of the ring proton shifts.[6] Measurements of the ring proton shifts of MHCX in CCl_4 solution at low enough temperatures compatible with slow exchange are hampered by broadening effects due to precipitation of solute as well as freezing of the solution. Nevertheless, such measurements indicated that aromatic solvent shifts are the predominant cause of the observed relative shifts of the ring protons (in CCl_4 the ring proton shifts do not lie upfield from the methine proton shifts).

(b) Methine Proton Shifts in MHCX and MOCX

These shifts are relatively insensitive (2) to the aromatic solvent anisotropy probably because the proton is protected from a close approach of solvent molecules by the proximity of ring C—Cl bonds. The proton at position 3 of the unsymmetrical conformer occurs at 709.5(6) Hz to low field of internal TMS in both compounds. The proton at position 1 in this conformer occurs 7 Hz to lower field in MOCX than in MHCX. Both protons are strongly deshielded relative to those in the other sites. Steric crowding of the C—Cl bond at position 2 by the C—Cl bonds of the dichloromethyl group at position 3 forces a closer proximity of the coplanar C—H and C—Cl bonds (Cl and H overlap by 0.5 Å even in an uncrowded, coplanar situation), consistent with greater interference of the diamagnetic circulation of electrons in the C—H bond.[6] None of the other methine proton sites are characterized by such an interaction, indicated by Cl_2C—H···Cl···Cl_2-CH. In MHCX this interaction can be relieved somewhat by back-tilting of the dichloromethyl bearing the proton (chlorine at position 6 in MHCX can move away against the C—H bond at position 3), leading to less deshielding by 7 Hz.

If the single peaks at 714.3(6) Hz for MOCX and MHCX are assigned to **1** (**4**) then the upfield shift of 8.5 Hz of the proton in **6** of MHCX rela-

[6]A referee prefers to call these hydrogen-bonding shifts. Although the large shifts observed on the formation of hydrogen bonds arise to a large extent from fluctuating electric fields on the proton acceptor, we prefer to reserve the term for situations in which the hydrogen bond is mainly responsible for the stable conformation of a molecule. In our molecule, the coplanarity of the ring and the C—H bonds arises mainly from the steric interactions of the C—Cl bonds with each other (10).

tive to that of **3** at MOCX can be understood as a result of greater steric crowding of the dichloromethyl groups in **3** relative to **6**. In **6** crowding of the dichloromethyl groups by the C—Cl bonds at positions 4 and 6 can be relieved relative to **3** because these C—Cl bonds can bend towards the C—H bond at position 5 in MHCX, whereas there is a bulkier C—Cl bond at position 5 in MOCX. Consequently the C—H bonds of the dichloromethyl groups in **3** are forced closer to the C—Cl bond at position 2 leading to a deshielding of these protons relative to the ones in **6**.

Empirical σ Molecular Orbital Parameters and their Correlation with Rates of Substitution Reactions in Quadrate Cr(III) and Co(III) Complexes[1]

C. H. LANGFORD[2]

Department of Chemistry, Carleton University, Ottawa 1, Canada

Received December 1, 1970

Empirical measures of σ bonding involving metal 3d orbitals are derived from Perumareddi's (4) complete analysis of the quartet spectral bands of quadrate complexes in the families $Cr(NH_3)_5X^{n+}$ and $Cr(OH_2)_5X^{n+}$. These are shown to correlate with lability of X in the Cr(III) complexes and in $Co(NH_3)_5X^{n+}$ complexes in a sense indicating that relative reactivity is controlled by variation of ligand metal 3d σ interaction. The relationship between the two Cr(III) series implies that the non-labile ligands can labilize the leaving group in proportion to their σ donor capacities. This observation bears on some well-known difficulties in crystal field theories of reactivity. In evaluating the correlation of spectral parameters with reactivity, the role of solvation in reactivity of Cr(III) and Co(III) complexes is discussed with emphasis on the surprisingly small solvent effects that have been observed.

Les mesures empiriques des liaisons σ, impliquant les orbitales 3d d'un métal sont dérivées de l'analyse complète de Perumareddi des bandes spectrales quadruplet des complexes carrés de la famille $Cr(NH_3)_5X^{n+}$ et $Cr(OH_2)_5X^{n+}$. Ceux-ci montrent une corrélation avec la labilité de X dans les complexes Cr(III) et dans les complexes $Co(NH_3)_5X^{n+}$ dans un sens indiquant que la réactivité relative est contrôlée par les variations des intéractions σ du métal 3d ligande. La relation entre les deux séries Cr(III) implique que les ligandes non labiles peuvent rendre plus labile le groupe sortant, proportionnellement à leurs capacités de donneur σ. Cette observation porte sur des difficultés bien connues dans les théories de réactivité du champ cristallin. En évaluant la corrélation des paramètres spectraux avec la réactivité, le rôle de la solvatation sur la réactivité des complexes Cr(III) et Co(III) est discuté avec un accent sur le fait très surprenant, que les effets de solvant observés sont très petits.

Canadian Journal of Chemistry, 49, 1497 (1971)

Introduction

A calculation performed by Gray and Basch was reported (1) showing that the main features of the *trans* effect series, nucleophilicity series, and lability series, for ligands involved in substitution reactions at square planar Pt(II) may be correlated with the variation in values of ligand σ to metal 6p orbital overlap integrals. This result is strongly suggestive that the main feature governing the relationship between the ground state and transition state in a substitution reaction at the third transition series metal Pt is *sigma* bonding between the ligand and a metal p orbital. For halide ligands, lability in Pt(II) increases along the series $I^- < Br^- < Cl^-$. It has been remarked that the same lability order is observed in the substitution reactions of octahedral Rh(III) complexes. These complexes, like the octahedral complexes of the metals of the first transition series such as those of Cr(III) and Co(III), show little sensitivity to choice of entering ligand and must, therefore, react by a predominantly dissociative mechanism. It seems that metal p-ligand σ interaction also governs the bond that must be broken in a Rh(III) dissociative process.

In complexes of metals in the first transition series, the lability order is reversed, iodide is most labile and chloride is least labile. This reversal has been explained on the grounds that σ bonding in complexes of the first transition series is dominated by the interaction of ligand σ with metal d orbitals and that it is a bond of mainly σ-3d character which must be broken in reaching the substitution transition state (2, 3). This hypothesis helps to account for the absence of *large trans* effects in Cr(III) and Co(III) complexes since the four-fold symmetry of 3d orbitals does not uniquely relate a *trans* pair of ligands as metal p orbitals do (3). *Trans* effects are a feature of Rh(III) chemistry (3).

Intuitively, an m.o. (molecular orbital) theory for metal complex lability which can explicitly treat σ bonding is the most appealing. However, crystal field treatments have so far enjoyed greater, if limited, success as quantitative theories

because empirical spectroscopic parameters are easily derived for correlation with reactivity. The purpose of this report is to illustrate the use of an empirical spectroscopic parameter measuring ligand interaction with 3d metal orbitals of symmetry correct for σ bonding ($3d_{x^2-y^2}$, $3d_{z^2}$) derived from recent careful analysis of the spectra of numerous quadrate Cr(III) complexes of the type CrA_5X^{n+} where A is either NH_3 or H_2O and X is usually an anionic ligand.

Energy Levels of Quadrate d^3 Complexes

An octahedral d^3 complex such as $Cr(NH_3)_6^{3+}$ displays two easily assigned spin allowed absorption bands in the d–d region. The states accounting for these are shown on the left in Fig. 1. As the microsymmetry is reduced to C_{4v} in a complex like $Cr(NH_3)_5Cl^{2+}$, the ^4T octahedral states split as shown on the right of Fig. 1. The C_{4v} complexes should exhibit four d–d bands. The spectra have been extensively studied and analyzed, see ref. 4 and earlier work cited therein. Resolution of the $^4A_2$ and ^4E has been accomplished in only a few cases but the $^4B_2$ band is observed in most cases and remains essentially constant. Orbitally, this band corresponds to the transition $xy \rightarrow x^2 - y^2$ in strong field. (The unique ligand is placed on the z axis.) It is not only constant but also found at the position of the $^4T_{2g}$ band of the octahedral parent complex (*e.g.* $Cr(NH_3)_6^{3+}$). This means that the equatorial orbitals xy and $x^2 - y^2$ are not demonstrably affected by variation in the axial ligand. The strong field one electron orbitals

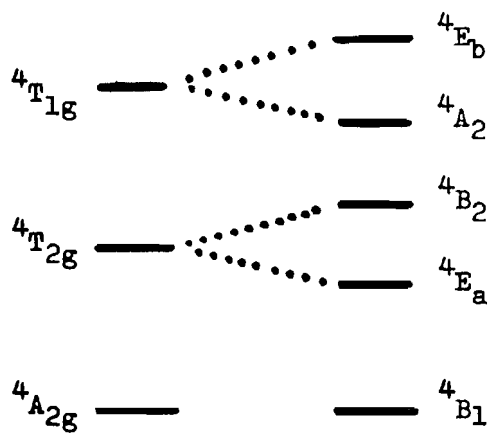

FIG. 1. Spectroscopic states of d^3 complexes in O_h and C_{4v} symmetry. O_h states are on the left and correlated with C_{4v} states (not to scale).

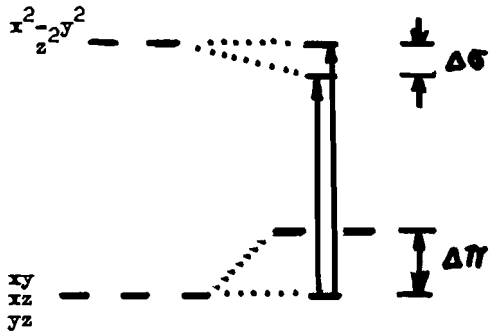

FIG. 2. Strong field d orbital energies in O_h and C_{4v} complexes of Cr(III). The specific ordering would be correct for $Cr(NH_3)_6^{3+}$ and $Cr(NH_3)_5Cl^{2+}$ (not to scale).

are shown in Fig. 2 with two transitions designated. The $^4B_2$ has been considered, the $^4A_2$ is the band of main interest here. The splitting of the orbitals $x^2 - y^2$ and z^2 is designated by Δσ since these are the σ *antibonding* orbitals in m.o. theory. Δσ is positive for z^2 lying above $x^2 - y^2$ and this implies stronger σ bonding by the unique ligand on the z axis. The energy of the $^4A_2$ band is $\Delta_0 + \Delta\sigma + f(B,C)$ where Δ_0 is the orbital splitting in the parent octahedral complex (or the difference between xy and $x^2 - y^2$ in the C_{4v} complex) and $f(B,C)$ is the appropriate combination of Racah's interelectronic repulsion parameters. As the unique ligand is varied (*e.g.* from Cl to Br to I), the quantities determining the shifts of the $^4A_2$ band should be only Δσ and $f(B,C)$.

If the evolution of the $^4A_2$ position in a series of complexes can be determined with suitable choice of B and C, relative σ bonding may be estimated. Recently Perumareddi and his colleagues have completed a comprehensive study of C_{4v} and D_{4h} Cr(III) complexes, which is reviewed in ref. 4. Although it was possible to achieve explicit resolution of the $^4A_2$ band in only a minority of examples, the constancy of the $^4B_2$ band and the small variation of B and C parameters permitted complete fitting and assignment of all bands within a crystal field framework of parameters that was highly "precise" (± 50 cm^{-1} (4)). Using Perumareddi's $^4A_2$ values for $Cr(NH_3)_5X$ and $Cr(OH_2)_5X$, the variation of Δσ with changing X is recorded in Table 1. There the parameter $\delta\Delta\sigma$ is defined, which is the difference between $^4T_{2g}$ of CrA_6 and $^4A_2$ of CrA_5X. This is the same as the

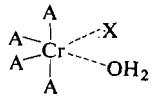
splitting of $x^2 - y^2$ and z^2 in CrA_5X according to Perumareddi (4).

Model of a Dissociative Substitution Transition State

To relate empirical sigma bonding parameters of complexes of the type CrA_5X to reactivity, we require a model for the transition state of the reaction. The reaction to be considered is

[1] $$CrA_5X + H_2O \rightarrow CrA_5OH_2 + X$$

and this reaction has been assigned a dissociative mechanism on the basis of several lines of evidence reviewed in ref. 3. The transition state must be supposed to have at most weak bonds to the leaving X and the entering H_2O. In compensation, it is expected to have stronger bonds to the remaining five A ligands. This transition state is crudely represented as



If σ bonding of ligand orbitals to metal 3d orbitals is crucial, this transition state model implies two consequences: (*i*) lability will increase nearly *proportionately* to *decreasing* $\Delta\sigma$, which measures reduction of the 3d-ligand σ interaction, and (*ii*) lability of a given leaving X will increase as the energy of the $x^2 - y^2$ orbital (determined by the A ligand and measured from the position of $^4T_{2g}$ of CrA_6 or $^4B_2$ of CrA_5X) increases. This is because strong σ donor properties of the A ligands can stabilize the transition state of reduced coordination by "capturing" the released metal 3d-σ orbital.

Results of Spectra–Rate Correlation

In Fig. 3, the values of $\delta\Delta\sigma$ are plotted against

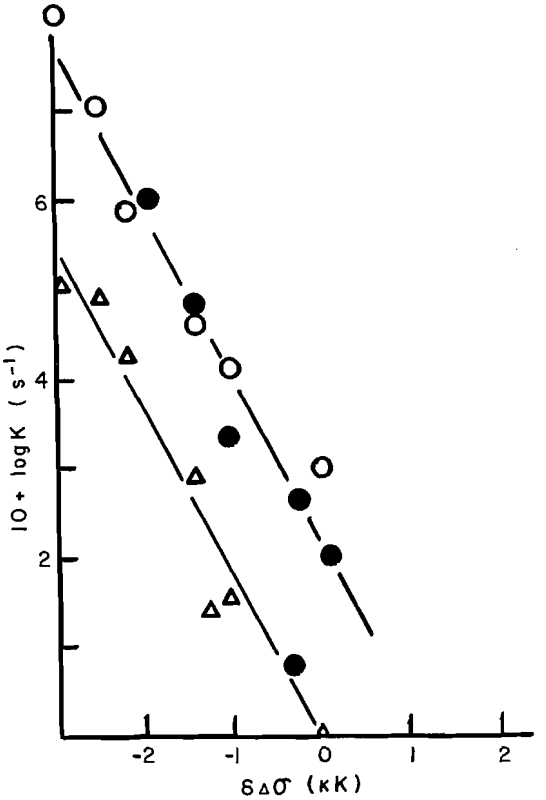


FIG. 3. Correlation of solvolysis rates with spectroscopic sigma bonding parameter defined in the text. (Rate data are from the compilations in refs. 5 and 6.) ○ = $Cr(NH_3)_5X$ with X = I^-, Br^-, Cl^-, F^-, NCS^-, NH_3 in decreasing order of rate. ● = $Cr(OH_2)_5X$ with X = I^-, Br^-, Cl^-, N_3^-, NCS^-, F^- in decreasing order of rate. △ = $Co(NH_3)_5X$ with X = I^-, Br^-, Cl^-, F^-, NCS^-, N_3^-, NH_3 in decreasing order of rate.

the log of the rates of acid hydrolysis for $Cr(NH_3)_5X$ and $Cr(OH_2)_5X$. Rate data are derived from compilations by Swadde and Guastalla (5) and Basolo and Pearson (ref. 6, chap. 3). The hydrolysis rates fit a linear correlation. The slope of the correlation is close to *unity* in consistent energy units (−0.88). The figure also shows points correlating the hydrolysis of complexes $Co(NH_3)_5X$ with $\delta\Delta\sigma$ values for $Cr(NH_3)_5X$. This correlation is successful and the slope (−0.92) is very nearly the same as the slope of the Cr(III) correlations. Such successful correlation of Co(III) rates with Cr(III) spectral parameters follows from the great similarity of Co(III) and Cr(III) spectra (7) and the substantial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

evidence of similar substitution reaction mechanisms in Co(III) and Cr(III) chemistry (3, ref. 6, chap. 3).

Discussion

The near unit slope of the correlation supports the transition state model in which a bond to the leaving ligand is nearly entirely broken. Moreover, it implies that metal 3d to ligand σ interaction dominated variations of that bond. The contrast between Pt(II), Rh(III), and Co(III), Cr(III) (including stereochemistry) appears to be satisfactorily explained by the shift of emphasis from σ bonding through metal *p* orbitals to σ bonding through metal *d* orbitals. It is worth noting that the correlation of near unit slope extends over six decades in rates and more than 3000 cm^{-1} in spectral shifts.

An important feature of Fig. 3 is that the $Cr(OH_2)_5X^{n+}$ and $Cr(NH_3)_5X^{n+}$ complexes correlate satisfactorily on the *same* line. The values of $\delta\Delta\sigma$ are differently defined for the two series. For the amines $\delta\Delta\sigma$ is a shift from the $x^2 - y^2$ level determined by four ammonia ligands (or from the $^4T_{1g}$ level of $Cr(NH_3)_6^{3+}$). The reference level for the aquo systems is determined by H_2O ligands. The single correlation for both systems implies that the increased lability of the ammine systems (relative to aquo systems) is *proportional* to the difference in the $x^2 - y^2$ energy in the two series of complexes. This is not entirely unexpected. The model octahedral substitution transition state has a vacancy in the bonding to the σ type d orbitals. Remaining ligands with stronger σ donor properties can *stabilize* the transition state more effectively. (This is an exact parallel to the concept used to explain the *trans* effect in Rh(III) and Pt(II).)

This last idea, that non-labile ligands can labilize the leaving group in proportion to their σ donor ability, has two consequences that suggest resolution of two major puzzles in octahedral substitution studies. First, we can understand the weakness of the simple crystal field treatments of lability of the complexes $M(OH_2)_n^{2+}$ ($M = V^{2+}$ to Cu^{2+}). Calculations of losses of crystal field stabilization energy have given a correct ordering of labilities in these systems but have quantitatively *over-estimated* the differences (8). This overestimate results from the assumption that 10 *Dq* for the transition states is the same as that for the ground state. Thus, the loss of crystal field stabilization energy has been over-estimated! Second, the surprising similarity of rates of solvent exchange for $Ni(solvent)_6^{2+}$ in solvents from NH_3 to CH_3SOCH_3 (3) can be understood. When the Ni(II) ion is transferred from one solvent to another, there is a change in the leaving group *and* a corresponding change in the other ligands. As weaker σ donors become leaving groups, the bond becomes easier to break, *but* the remaining groups are less effective in their role in stabilization of the transition state of reduced coordination number. Consequently, solvent exchange reactions are subject to a "levelling" effect. Relatively non-labile solvent molecules are labilized by the rest of the coordination sphere. Relatively labile solvent molecules are not labilized by the rest of the coordination sphere.

The Co(III) complexes do not correlate on the same line as the Cr(III) complexes. This, of course, is expected. Among other things, $\delta\Delta\sigma$ parameters derived from Cr(III) spectra were used. In fact, the main justification for treating Co(III) complexes in this way at all is that there are detailed parallels between quadrate Cr(III) and quadrate Co(III) spectra but there is no available analysis of the Co(III) case which compares in extent and precision to Perumareddi's analysis of Cr(III) spectra. (In fact, some reliable kinetic results are not included in the correlation because the relevant spectral data are not available from Perumareddi's precise studies.)

Finally, a difficult aspect of the correlation must be approached. Correlation of $\Delta G^{\ddagger}$ with $\Delta\sigma$ implicitly minimizes the importance of differences in *solvation* energy between the reaction ground state and transition state. It should, first, be observed that there is a significant tradition behind the argument that solvation effects are expected to loom large in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ but to cancel in $\Delta G^{\ddagger}$ (ref. 5, and earlier citations therein). But that is too easy an excuse for avoiding an issue that has not received the attention that it's due when significant experimental results are available. For example, a large body of evidence assigns the dissociative mechanism to solvolysis of *trans* $Coen_2Cl_2^{+}$. This should imply that a bound chloride becomes solvated on going from the ground state to the transition state. Now, the rate of solvolysis increases by only about a factor of *three* (ref. 6, p. 214) when the complex is transferred from *N,N*-dimethylformamide (DMF) to methanol. According to Parker's (11)

reliable extra-thermodynamic assessments of chloride ion activities, a free chloride ion should change activity by about 10^6 on transfer from DMF to CH_3OH. Parker's (9) methods of analysis would lead to the conclusion that the transition state for the solvolysis is "tight" (that is that chloride is still strongly bound to the metal in the transition state). This conclusion is contrary to a very large body of other evidence (1, 3, ref. 6, chap. 3) and the evidence of the present correlations. Reconciliation can be achieved if it is assumed that solvation of a bound ground state halide ligand is not profoundly dissimilar to solvation of the free halide ion. This is reasonable to the extent that metal halide bonding to "hard" metal centers may be considered "ionic".

Finally, solvation factors would tend to explain the largest deviations from the correlations in Fig. 3. For example, F^- ion, which fits very poorly in the case of $Cr(OH_2)_5F^{2+}$, is known to have a quite atypical $\Delta S^{\neq}$ (10).

I am indebted to Dr. V. S. Sastri for stimulating discussions and a key suggestion with respect to the role of non-labile ligands.

The Nickel(II)–γ-Picoline–Perchlorate Complex System

M. S. SUN AND D. G. BREWER

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received November 9, 1970

Three compounds have been isolated; *viz.*, $NiL_4(ClO_4)_2$, $NiL_4(H_2O)_2(ClO_4)_2$, and $NiL_6(H_2O)_2(ClO_4)_2$ (L = γ-picoline), and their spectral, magnetic, and other properties compared. Some tentative suggestions as to the possible structure of the last complex are offered; the first two compounds were reported previously (1).

On a isolé trois composés: $NiL_4(ClO_4)_2$, $NiL_4(H_2O)_2(ClO_4)_2$ et $NiL_6(H_2O)_2(ClO_4)_2$ (L = γ-picoline); on compare leurs propriétés spectrales, magnétiques et autres. Alors que des deux premiers complexes ont fait l'objet d'une communication antérieure (1), on fait maintenant des suggestions plausibles concernant la structure du dernier complexe.

Canadian Journal of Chemistry, 49, 1502 (1971)

Introduction

In the course of an investigation into the nuclear magnetic resonance (n.m.r.) isotropic shifts of some nickel(II) complexes with substituted pyridines, it was found necessary to become involved with the Ni(II)–γ-picoline–perchlorate system. Procedures in the literature (1) were used to obtain two compounds, *viz.*, $NiL_4(ClO_4)_2$ and $NiL_4(H_2O)_2(ClO_4)_2$, but under other conditions, a third compound was obtained, *viz.*, $NiL_6(H_2O)_2(ClO_4)_2$. The reversible conversion of the yellow $NiL_4(ClO_4)_2$ to the blue $NiL_4(H_2O)_2(ClO_4)_2$ when exposed to moisture, and the conversion of the blue $NiL_6(H_2O)_2(ClO_4)_2$ to the yellow $NiL_4(ClO_4)_2$ upon drying have led to a more detailed investigation of the spectral and physical properties of these compounds.

Experimental

$NiL_4(ClO_4)_2$ and $NiL_4(H_2O)_2(ClO_4)_2$ were prepared according to previously published procedures (1). Better crystals of the former compound were obtained from a solution of γ-picoline and nickel(II) perchlorate hexahydrate (molar ratio 4:1) in hot butanol.

$NiL_6(H_2O)_2(ClO_4)_2$ was precipitated as blue crystals upon the addition of an aqueous solution of $Ni(ClO_4)_2 \cdot 6H_2O$ to an aqueous solution of excess ligand. These crystals were filtered off and air dried for several hours.

*s = strong, m = medium, w = weak, v = very, sh = shoulder, br = broad. Infrared spectra were taken on a Beckman IR-12 spectrophotometer. Both KBr and Nujol mulls were used for the solid compounds in the 4000–200 cm^{-1} region. Solutions of the compounds in both chloroform and methylene chloride were also run using caesium bromide cells and polyethylene bags.

Anal. Calcd.: C, 50.70; H, 5.44; O, 18.76; N, 9.86; Cl, 8.32; Ni, 6.89. Found: C, 49.88; H, 5.44; O, 19.58; N, 9.92; Cl, 8.47; Ni, 6.67.

Analyses were performed by Dr. F. Pascher, Mikroanalytische Laboratorium, Bonn, West Germany.

Results and Discussion

It is apparent that γ-picoline, water, and perchlorate compete in solution for the nickel(II). It would also appear that some of these are not very strongly bound to the central metal, and ready conversion from one compound to another is observed.

In view of the previously assigned structures for Ni(II) complexes (1, 4) a square planar arrangement of four γ-picoline molecules is assumed for all three compounds. The two blue compounds could then have water and γ-picoline, respectively, occupying the octahedral positions. It is possible that the latter compound could be formulated as $NiL_4(H_2O)_2(ClO_4)_2.2L$, analogous to the compounds such as $Ni(pyr)_4(NCO)_2.2pyr$ reported by Norbury *et al.* (2). The perchlorate in all three solid compounds would be presumably ionic.

The infrared (i.r.) spectra of the three compounds (Table 2) tend to confirm these structural

‡Very weak absorption.

assignments. Free ligand peaks were observed in Nujol and $CHCl_3$ (or CH_2Cl_2) for $NiL_6(H_2O)_2(ClO_4)_2$, although they are not well-defined in KBr. Assignment of these peaks is based on that for the corresponding pyridine complexes (2, 5). The water peaks in both this compound and $NiL_4(H_2O)_2(ClO_4)_2$ are within the range of those for lattice water (ν_3:3465–3407 cm^{-1}) (6), indicating that the water is at most weakly bound to the metal. The thermal data in Table 1 also confirms this observation. Comparing the spectra in the perchlorate region with that of $Ni(ClO_4)_2.6H_2O$ (7, 8) in KBr and Nujol one can conclude that the perchlorate in all cases is ionic in solid state although there is some activation of the ν_1 mode and splitting of the ν_3 mode, presumably due to the effects of low site symmetry of the crystal lattice. However, in CH_2Cl_2 or $CHCl_3$ solutions, the spectra show that coordination of the perchlorate to the metal ion has taken place in all three compounds as the result of removal of this lattice effect in solution. The far infrared of the blue compounds show some unassigned peaks in the region 225–240 cm^{-1}, and could be an indication of a weaker Ni—N bond resulting from a constrained ligand conformation imposed by the waters at the octahedral positions. Similar peaks were observed in the compounds $Ni(\gamma\text{-pic})_4Cl_2$ and $Ni(\gamma\text{-pic})_4Br_2$ (3).

The electronic spectral data (Table 3) are consistent with a change from a square planar configuration in the yellow $NiL_4(ClO_4)_2$ to an octahedral geometry in the other two cases.

The conductance data (Table 1), taken in methylene chloride, indicate that 0.01 *M* solutions of all the complexes are very little ionized indicating coordination of the perchlorate in solution, consistent with the i.r. solution data. The solutions of these compounds, when saturated with water, increase these values only slightly; apparently the small amount of water thus added competes equally well with γ-picoline for the metal. The yellow compound dissolved in γ-picoline as solvent, shows a large increase in conductance consistent with increased concentrations of NiL_4^{2+}, $ClCO_4^-$, and NiL_6^{2+}. Upon heating and cooling, the solution turned yellow-green and the conductance increased even further, consistent with the greater stability of NiL_4^{2+} over NiL_6^{2+}.

The complex $NiL_6(H_2O)_2(ClO_4)_2$ has been turned over to Dr. H. Lynton of this department for an X-ray crystallographic determination of its structure.

The continued financial support of the National Research Council of Canada and the award of a U.N.B. demonstratorship to M. S. Sun are gratefully acknowledged. Thanks are also extended to Mr. M. Sears and Miss M. Tong for recording some of the spectra.

Studies of Substitution Reactions in Chromium(VI)–Fluorine Species

A. M. AKENA, D. S. BROWN, AND D. G. TUCK[1]

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received September 22, 1970

Nuclear magnetic resonance (n.m.r.) studies show that the exchange between fluorochromate(VI) and fluoride in dimethylsulfoxide is slow, in agreement with previous work on oxygen exchange between water and chromates(VI). No substitution was detected in the system CrO_3F^-/Cl^- in acetonitrile. Mixtures of chromyl fluoride and chromyl chloride show rapid fluorine exchange, both as the pure compounds, and in solution in trichlorofluoromethane. Possible mechanistic implications of these results are discussed.

Des études par r.m.n. permettent de démontrer que l'échange entre le fluorochromate(VI) et les ions fluorures dans le DMSO est une réaction lente; cette conclusion est en accord avec des travaux antérieurs sur l'échange d'oxygène entre l'eau et des chromates(VI). Dans l'acétonitrile, il n'est pas possible de détecter de substitutions dans le système CrO_3F^-/Cl^-. Toutefois des mélanges de fluorure de chromyle et de chlorure de chromyle s'échangent rapidement soit à l'état pur soit en solution dans le trichlorofluoromethane. On discute des implications mécanistiques possibles de ces résultats.

Canadian Journal of Chemistry 49, 1505 (1971)

Introduction

Much of the work on the inter-relationship of the various chromium(VI) species which may exist in aqueous solution has been based on the study of equilibria, but kinetic measurements can also provide significant information. The most recent studies in this field are those of Holyer and Baldwin (1), who investigated the rate of exchange of ^{18}O between chromium(VI) oxyanions and bulk water, as a function of p*H* and total chromium(VI) concentration. These authors, who also review the earlier literature, discuss their results in terms of the possible transition states for oxygen exchange.

During studies of the coordination chemistry of chromium(VI), we attempted to measure the equilibrium constant for substitution processes of the type

$$[1] \qquad CrO_3F^- + Cl^- \rightleftarrows CrO_3Cl^- + F^-$$

in non-aqueous solution, conditions chosen to eliminate competing hydrolytic processes such as

$$[2] \qquad CrO_3F^- + H_2O \rightleftarrows HCrO_4^- + HF$$

which must occur in aqueous solution. The rate of equilibration in [1] was found to be slow relative to the time limits imposed by the oxidative stability of the solvent. We subsequently investigated the exchange of ^{19}F between fluorochromate(VI) and fluoride in non-aqueous solution by n.m.r. methods. These latter results in particular bear upon the work of Holyer and Baldwin, and earlier workers, in that CrO_3F^- is isoelectronic with the $HCrO_4^-$ anion. Fluorine exchange in related systems, including chromyl fluoride plus chromyl chloride, was also studied, again in non-aqueous media.

The number of possible solvents for this work was rather restricted. For the n.m.r. studies of the CrO_3F^-/F^- and CrO_3F^-/Cl^- systems, the requirements for high solute concentration and reasonable resistance to chromium(VI) oxidation were met by dimethylsulfoxide, and the solubility was enhanced by using the tetraphenylarsonium or tetraalkylammonium salts throughout, and where necessary by working at temperatures above ambient. Ultraviolet spectroscopic studies of the CrO_3F^-/Cl^- system required a solvent which does not obscure the absorption bands of the halochromate anions, or (preferably) the fine structure of these bands (see below); acetonitrile proved satisfactory for this purpose. Nuclear magnetic resonance studies of chromyl fluoride either alone or mixed with chromyl chloride were carried out in trichlorofluoromethane, which has the necessary resistance to oxidation by these substances.

Experimental

Materials

(*1*) Solvents. Acetonitrile (Eastman, Spectroscopic grade) was distilled several times from phosphorus pentoxide before use. Dimethylsulfoxide (Fisher Scientific) was distilled three times from calcium hydride

[1]To whom correspondence should be addressed.

For personal use only.

(40 °C, 15 mm pressure), and stored over calcium hydride. Trichlorofluoromethane (Matheson Co., Inc., "Freon 11", 99.9% purity) was dried over Linde molecular sieve for several days before use.

(*2*) Halide salts. Tetraethylammonium chloride and fluoride (Eastman Kodak) were recrystallized in vacuo from absolute ethanol, and stored over phosphorus pentoxide. Analysis of the material showed a low fluorine figure (found (ionic) F 11.6; $(C_2H_5)_4NF$ requires F 12.7%); since the compound picks up solvent or moisture very rapidly, this result suggests the presence of solvent in the solid. Tetraphenylarsonium chloride was used as supplied.

(*3*) Tetraphenylarsonium fluorochromate(VI). An aqueous solution of tetraphenylarsonium nitrate, prepared by titration of the corresponding chloride with silver nitrate, was added to an aqueous solution of potassium dichromate in 2 *M* hydrofluoric acid. The yellow precipitate so formed was redissolved in 1:1 acetone:chloroform, and reprecipitated with petroleum ether. Analysis confirmed that this method, which is known to give the corresponding chlorochromate salt (2), yields tetraphenylarsonium fluorochromate.

Anal. Calcd. for $C_{24}H_{20}AsCrO_3F$: C, 57.4; H, 4.0; As, 14.9; Cr, 10.4; F, 3.5. Found: C, 57.2; H, 4.1; As, 14.9; Cr, 10.3; F, 3.5.

The infrared (i.r.) spectrum was in agreement in all relevant features with that of potassium fluorochromate(VI) (3).

Solutions of halochromate salts were found to undergo decomposition on exposure to light, and were therefore handled in the dark as far as possible.

(*4*) Chromyl chloride. The pure liquid (Alfa Inorganics Inc.) was distilled in a dry apparatus with phosphorus pentoxide traps immediately before use.

(*5*) Chromyl fluoride. Chromium trioxide was treated with sulfur tetrafluoride (4) in a glass apparatus, and the red product collected at −35° (5). The solid was then sublimed onto either $CFCl_3$ or chromyl chloride frozen at −78°; the resulting solutions were used for n.m.r. spectroscopy. All handling of such mixtures was carried out in a dry-box over phosphorus pentoxide.

Spectral Studies

^{19}F n.m.r. spectra were run on a Varian A56/60 Spectrometer, operating at an oscillator frequency of 56.4 MHz. Unless otherwise stated, the sample temperature was 35°. Chemical shifts for ^{19}F, defined as $\delta = -(\nu_{sample} - \nu_{ref})/\nu_{ref}$, were measured relative to $CFCl_3$ as either internal or external standard.

Visible/ultraviolet spectra were measured with Unicam SP 800 or Cary 14 spectrophotometers.

Results and Discussion

Fluorochromate(VI)–Chloride System

The electronic spectrum of tetraphenylarsonium fluorochromate(VI) in acetonitrile consists of a high intensity cation absorption, plus an anion band centered at 28 400 cm^{-1} ($\varepsilon = 794$). This latter showed symmetrical vibrational fine structure, with a frequency spacing of approximately 700 cm^{-1}. The spectrum of tetraphenylarsonium chlorochromate(VI) has the corresponding maximum at 27 500 cm^{-1} ($\varepsilon = 1.43 \times 10^3$), with a similar fine structure. The absorption spectrum of a millimolar solution of the fluorochromate salt in acetonitrile was unaffected by the addition to the solution of an equimolar quantity of tetraphenylarsonium chloride; no change could be detected over a time span of three days. The addition of a tenfold molar excess of the chloride salt ultimately produced a small change in the fluorochromate spectrum, but the rate of change was too slow to allow any significant rate measurements to be made, in view of the limitations imposed by the oxidation of the solvent.

The ^{19}F resonance of a 0.25 *M* solution of tetraphenylarsonium fluorochromate in dimethylsulfoxide (DMSO) is at $\delta = 161.4$ p.p.m. from (external) $CFCl_3$. The line width at half-height is 2.5 ± 0.5 Hz. The addition of equimolar quantities of either tetraphenylarsonium or tetraethylammonium chloride in DMSO had no effect; the ^{19}F resonance signal was unchanged in both frequency and intensity over 1 h. The only change in the ^{19}F resonance of mixed solutions stored in the dark for 12 h was a broadening of the peak.

Upper limits for the rate constant (k_f) for the forward reaction in [1] can be obtained from these results. We estimate that the minimum change which would have escaped detection in the u.v./visible spectroscopic measurements is 5%; this is almost certainly a generous overestimate. For a time interval of 3 days, this implies an upper limit for k_f in acetonitrile of 2×10^{-4} l mol^{-1} s^{-1}. Similarly, analysis of the n.m.r. results shows that the decrease in CrO_3F^- concentration over 1 h could not have exceeded 5%; the rate constant in DMSO is then less than 5×10^{-5} l mol^{-1} s^{-1}. We return to these conclusions below.

Fluorochromate(VI)–Fluoride System

A solution of tetraethylammonium fluoride in DMSO at 50° had the ^{19}F resonance at $\delta = 142.7$ p.p.m. Mixing equal volumes of 0.25 *M* solutions of this salt and tetraphenylarsonium fluorochromate(VI) produced no alteration in the resonance frequency of either fluoro species. Some difficulty was experienced in making measurements on the ^{19}F resonance of tetraethylammonium fluoride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in the mixed solutions, and for this reason all results refer to the more readily detectable ^{19}F resonance of the fluorochromate anion. No change in this resonance could be detected after 2 h, indicating the absence of significant ^{19}F exchange in the CrO_3F^-/F^- system in DMSO at this temperature. The average lifetime of each species can be calculated from standard formulae (6) as $> 10^{-3}$ s, corresponding to a gross upper limit for the rate constant for the fluorine exchange in

[3] $$CrO_3F^- + F^- \rightleftarrows CrO_3F^- + F^-$$

of 10^3 l mol^{-1} s^{-1}.

Holyer and Baldwin (1) have reported a value of 7×10^{-7} s^{-1} for the pseudo-first order rate constant k_1' ($= k_1/[H_2O]$) for the aqueous phase exchange

[4] $$CrO_4^{2-} + H_2O^* \rightleftarrows CrO_3O^{*2-} + H_2O$$

which is one of two possible paths for oxygen exchange between water and chromium(VI) species at high pH in aqueous solution. These authors note however that the process

[5] $$HCrO_4^- + \overset{*}{O}H^- \rightleftarrows HCrO_3\overset{*}{O}^- + OH^-$$

provides an alternative path for oxygen exchange; the rate constant deduced for the forward reaction in [5] is 70 l mol^{-1} s^{-1}.

There are of course significant differences in the nature of the species present in aqueous solution and in DMSO or acetonitrile. In particular, the lower dielectric constants of the organic solvents ($\varepsilon = 46.6$ for DMSO (7), $\varepsilon = 36.2$ for acetonitrile (8)) must bring about more extensive ion-pairing than in aqueous solution, so that coulombic repulsion between two anions forming the transition state must be lower than in water. Despite the problems raised by these differences, we believe that the slow exchange observed in CrO_3F^-/F^- and CrO_3F^-/Cl^- argues against the identification of [5] as a rate-controlling process in the aqueous system. A more important question, to which we return below, is the mode of formation of the transition state for ligand exchange in chromium(VI) species.

The water content of the DMSO used in the exchange experiments described above was shown by gas–liquid chromatography to be 0.03% by weight. When the water content was deliberately increased above this value, the ^{19}F resonance peak of the fluorochromate anion collapsed at a readily measureable rate. With a solution of tetraphenylarsonium fluorochromate in DMSO containing 10% H_2O, the peak height decreased by approximately 50% within the time necessary for mixing the solutions and running the spectrum (approximately 3 min). Some broadening of the resonance signal was also observed. In similar solutions left for longer periods (up to 24 h), the formation of chromium(III) species was observed spectroscopically for both fluorochromate(VI) and chlorochromate(VI) systems; with CrO_3Cl^- in DMSO/H_2O, broad absorptions at 24 700 and 16 250 cm^{-1} appeared, and with CrO_3F^-, a new absorption at 25 300 cm^{-1} was detected. These results are consistent with the presence of $[Cr(H_2O)_5Cl]^{2+}$ and $[Cr(H_2O)_5F]^{2+}$, respectively, following the work of Swaddle and King (9). The broadening observed in the ^{19}F n.m.r. spectrum is presumably due to the growth of paramagnetic species in the solution, and for this reason no attempt was made to follow the hydrolysis process [2] by n.m.r. methods.

Chromyl Fluoride/Chromyl Chloride System

The ^{19}F resonance of chromyl fluoride in trichlorofluoromethane solution is a sharp singlet at 30.4 ± 0.4 p.p.m. downfield from the $CFCl_3$ resonance, independent of temperature and concentration over the ranges studied, within experimental error (see Table 1). The addition of chromyl chloride causes this resonance to move downfield, but in all cases we observed a singlet, whose frequency was dependent on the CrO_2F_2:CrO_2Cl_2 molar ratio, and to a slight extent upon the temperature. In dilute solution in trichlorofluoromethane, the half-width of the signal was < 1 Hz; in solvent-free mixtures, some broadening was observed. Our results do not allow any deductions as to the origin of the small temperature dependence.

The ready exchange of ^{19}F, shown by the presence of a single resonance, can be ascribed to the rapid establishment of the equilibrium

[6] $$CrO_2F_2 + CrO_2Cl_2 \rightleftarrows 2CrO_2FCl$$

The existence of a chromyl fluorochloride has previously been reported by Flesch and Svec (10) on the basis of infrared and mass-spectrometric observations; a value of 2.0 was found for the equilibrium constant for [6] in a solvent-free mixture of the parent chromyl halides. We assume the ^{19}F spectrum observed in the presence of a

†Approximate value.

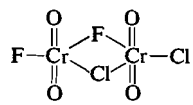
large excess of chromyl chloride (exp. 6 and 7 in Table 1) is essentially that of CrO_2FCl in $CFCl_3$ ($\delta = 38.9$ p.p.m.). If the resonance from an equimolar mixture in this (exp. 4) represents the time-averaged environment of the fluorine exchanging between CrO_2F_2 and CrO_2FCl, then one can calculate the relative concentration of all the species involved (11), from which we find the equilibrium constant for [6] is ~ 0.15. This value is of course for conditions which are different from those used by Flesch and Svec (10), but allowing for this, and for the differences inherent in the methods of measuring *K*, the agreement appears reasonable.

General Conclusions

The results reported show that chromium(VI) oxyfluoro-species undergo ligand exchange at rates which depend sharply on the nature of the compound. In seeking to explain such variations in terms of possible exchange mechanisms, we should first note that with few exceptions the normal coordination number of chromium(VI) is four. One group of higher coordination species is the peroxy complexes, which have been discussed elsewhere (12), and another exception is CrF_6, which decomposes above about −100°, but which probably has O_h symmetry (13). Chromium(VI) may have a coordination number greater than four in the 1:1 adduct of CrO_2F_2 and $K[HF_2]$ (14). No compound with a coordination number below four has been reported; even solid CrO_3 involves four-coordinate chromium(VI) (15). It is interesting that chromium(VI) does not show the easy 4 → 6-coordination expansion found in the corresponding oxidation states of molybdenum and tungsten.

On this evidence, substitution processes in chromium(VI) species must involve an S_N2 mechanism, but for CrO_4^{2-}/H_2O (or $HCrO_4^-/OH^-$), CrO_3F^-/Cl^- and CrO_3F^-/F^-, the formation of a five-coordinate transition state appears to be energetically unfavorable. A common factor in all these systems is the high molecular symmetry of the initial chromium(VI) species, and it seems probable that the highly symmetrical σ- and π-bonding system resists any rearrangement to a five-coordinate state. A useful analogy here is the energy barrier to rearrangement in $BF_3 \rightarrow BF_4^-$ (16).

For the CrO_2F_2/CrO_2Cl_2 system, exchange will be favored by two factors not applicable in the above discussion. These are; (*a*), the exchange involves neutral species, so that there will be no coulombic repulsion to be overcome in forming the transition state, and (*b*), the lower molecular symmetry could result in a weakening of those bonds which stabilize the initial structure. A number of possible transition states can be pictured; a model such as



clearly permits dissociation either to the starting materials, or to CrO_2FCl. The existence of $(CrO_2X_2)_2$ dimers in the gas phase has been deduced from mass-spectrometric experiments (10). It must be emphasized, however, in any

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

discussion of rapid halogen exchange between CrO_2F_2 and CrO_2Cl_2, that catalysis by residual traces of water cannot be excluded with absolute certainty.

This work was supported in part by Operating Grants from the National Research Council of Canada. Dr. E. J. Wells is thanked for a number of stimulating discussions.

Vibrational Spectral Studies of Hexaquozinc Nitrate and Hexaquozinc Nitrate-d_2

M. H. BROOKER[1] AND D. E. IRISH

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received July 9, 1970

Infrared and Raman spectra are reported for the hexaquozinc nitrate crystal. Replacement of water by deuterium oxide causes a remarkable intensity reversal of components in the ν_3 nitrate region and provides Raman spectra free from interference in the $2\nu_2$ and ν_4 regions. The nitrate spectrum is interpreted in terms of a site group approximation. The spectra are compared with those of concentrated aqueous solutions and partially dehydrated crystals to point up changes which result from a lowered site symmetry and those which result from ionic association.

Des spectres infrarouge et Raman sont présentés pour le cristal de nitrate de zinc hexahydraté. La substitution de l'oxyde du deutéreum à l'eau produit un renversement remarquable de l'intensité des composantes du ν_3 du nitrate et il crée des spectres Raman libres d'interférence dans les régions de la $2\nu_2$ et de ν_4. Le spectre du nitrate est interprété en termes d'une approximation des groupes de site. La comparaison des spectres avec ceux de solutions aqueuses concentrées et ceux des cristaux partiellement déshydratés a pour but de montrer les changements qui résultent d'une symétrie de site réduite et ceux qui résultent d'une association ionique.

Canadian Journal of Chemistry, 49, 1510 (1971)

Introduction

Vibrational studies of hydrated crystalline nitrate salts have received very little attention. Ferraro (1) and Addison and Gatehouse (2) have reported infrared spectra of some hydrated transition metal nitrates. Frequencies reported by these authors exhibit variations which are apparently dependent on the sampling technique used. Mathieu and Lounsbury (3) have reported Raman spectra for several hydrated metal nitrate crystals and have noted that the vibration spectra of the hydrated crystals resemble those of the aqueous solutions from which the crystal was precipitated. Infrared and Raman spectra have been recorded for room-temperature hexaquozinc nitrate crystals and interpreted in the light of the recently proposed crystal structure (4). Additional information has been obtained from substitution of water by heavy water. When D_2O is substituted for H_2O in the crystals, interesting intensity changes in the components of the ν_3 and ν_4 vibrations are observed. Partially dehydrated samples were also studied. Comparison of spectra for a system in which nitrate ion is influenced by an aquated cation with those for a system in which zinc and nitrate ion are in contact broadens the base for the interpretation of spectra of ionic solutions.
