ity broadening, at −110 °C in 2-to-1 THF-DME mixtures, the proton hyperfine spectra are well resolved with peak to peak widths of the order of 0.070 oe. Below −80 °C one obtains six triplet hyperfine coupling constants with mean magnitudes of 5.36, 3.36, 2.66, 0.70, 0.26, and 0.15 oe, each with more or less normal 1:2:1 intensity distributions. By virtue of the fact that these splittings are so grouped as being either quite large or quite small, a multiplet composed of the smaller splittings is separated from the remainder of the hyperfine spectrum. This group is not precisely symmetrical with respect to its center, and this asymmetry increases as the temperature is lowered. Between −70 and −50 °C this group resolves to a triplet of triplets, with a shifted center line. At −70 °C in DME the coupling constants were observed to be 5.40, 3.40, 0.71, and 0.16 oe with 1:2:1 intensity distribution, and a fifth triplet which has a separation of 2.97 oe and 1:4:1 intensities. The first four coupling constants appear to decrease slightly as the temperature approaches −50 °C, then increase slightly again at higher temperatures. The total variation is only about 5% over the entire temperature range. These couplings are ascribed therefore to the ring protons. When the temperature is further raised, near −20 °C the entire spectrum appears to be superimposed on a second hyperfine spectrum characterized by broader lines and a splitting interval of about 0.74 oe. The smallest splitting of the fine line spectrum is difficult to resolve much above room temperature and near the boiling point of DME, only the broad spectrum is obtained. Characteristic spectra are shown in Fig. 1 at various temperatures. The absorption maxima (derivative zeros) of many of the lines in the broad spectrum appear to coincide in field with the main lines of the narrow line spectrum. This suggests that the absorbing species have similar *g*-values and hyperfine couplings. In addition the 1:4:1 triplet structure noted above strongly suggests the existence of an interconversion process in which some of the lines are broadened by exchange.

Discussion

Assuming the anion to be non-planar, as the n.m.r. studies show the neutral compound to be, and to have a high barrier to inversion so that the ions exist as either one conformer or the other, then the inequivalence between the pairs of axial and equatorial protons should give rise to a triplet of triplets in the hyperfine spectrum. The couplings will be referred to as a_{CH_a} and a_{CH_b}, respectively. On the other hand a very low barrier would allow rapid interconversion between the conformers and an averaged 1:4:6:4:1 quintuplet would be observed with a coupling of $\frac{1}{2}(a_{CH_a} + a_{CH_b}) = \bar{a}$. With barriers of modest height and intermediate rates of conversion, the $M = \pm 1$ and part of the $M = 0$ line of he quintet would be broadened so that a 1:4:1 triplet would be obtained with, in this case, a splitting of $2\bar{a}$. Here $M = M_a + M_b$ and $M_a = m_{9a} + m_{10a}$, $M_b = m_{9b} + m_{10b}$ where m is the quantum number I_z. At fairly high rates of conversion, the widths of the lines are given (2*b*) by $T_2^{-1} = T_{2,0}^{-1} + j_{aa}(0)(M_a - M_b)^2$ where $T_{2,0}^{-1}$ is the natural line half width and $j_{aa}(0) = \gamma^2\tau \langle(\delta a)^2\rangle$ is the spectral density function, τ the correlation time and δa the fluctuation in the hyperfine coupling constant, $(a(t) - \bar{a})$, wherein $a(t)$ is the instantaneous value of the coupling constant. Of course the barrier to interconversion is fixed in this case and the rate ofinterconversion depends solely on temperature. The observed 1:4:1 triplet corresponds to an intermediate rate of conversion. The splitting is $2\bar{a} = a_{CH_a} + a_{CH_b} = 2.97$ oe. As the temperature is raised, the more rapid exchange between the conformers begins to narrow the broadened $M = \pm 1,0$ lines so as to give the quintuplet with hyperfine separations of $\bar{a} = 1.48$ oe. As this is approximately twice one of the ring coupling constants, an eleven line multiplet forms due to these particular protons, and the observed separation for the broad-line spectrum of about 0.74 oe is obtained. The smallest coupling constant is neglected. In particular, the multiplet structure goes from a 1:2:1:0:4:8:4:0:1:2:1 distribution at lower temperatures to 1:2:5:8:10:12:10:8:5:2:1 at higher temperatures. In the total broad-line hyperfine spectrum, the outermost few lines follow these ratios exactly. The two extreme lines of the spectrum are unaffected by the exchange process while the fourth line has a width determined by the frequency of exchange and hence is a function of temperature. A plot of the square root of the ratios of the peak-to-peak heights of the derivative spectra *vs.* $1/T$ gives an energy of activation of 4.6 kcal/mol. This value is rather larger than the 2.3 kcal/mol calculated from u.H.f.-s.c.f. computations made for the unsub-

stituted biphenyl anion (6), which suggests that the barrier to inversion in DHP anion arises from the energy requirements for distortion of the six-membered partly saturated ring, and is not determined by the size of the ring substituents as is the case in the n.m.r. studies (3). On the other hand this value may be compared to the difference in resonance energy between fluorene and biphenyl which is determined from thermochemical data to be 5 kcal/mol (7) and can be inter-

preted as he energy required to make the rings of diphenyl coplanar, as in fluorene, and overcome the repulsive energy of the protons in the ortho positions. In either case the barrier height determined here seems to be consistent with the other estimates of this quantity.

It is substantially lower than the estimates made from n.m.r. studies on the neutral compounds (*3a,c*), as expected, so that interconversion between the conformers of DHP itself must lie between about 5 kcal/mol and the upper limit of 9 kcal/mol cited earlier (*3a*).

Most of the coupling constants in the hyperfine spectrum can be assigned to specific positions in the DHP anion molecule by consideration of their temperature dependence, and by comparison to the spectrum of diphenyl anion which has the same π-electron system. Thus the low temperature splittings of 2.66 and 0.27 oe may be assigned to the axial and equatorial protons, respectively, of the methylene groups. At higher temperatures and exchange rates, their sum becomes the 2.97 oe splitting under the conditions of maximum broadening of the $M = \pm 1,0$ lines so as to give the anomalous 1:4:1 triplet. Eventually, at still higher temperatures and exchange rates, the normal quintuplet with the averaged 1.5 oe splitting is obtained. It is also clear that the outside group of lines of the low temperature spectrum is unsymmetrical because the exchange rate is still sufficiently high as to determine the line width for those hyperfine components which shift during conformer interconversion. This affects the lines on the inner side of the group, but not the outer and gives rise to the observed asymmetry as depicted in Fig. 1.

Since the diphenyl anion has coupling constants of $a_p = 5.26$, $a_o = 2.62$, and $a_m = 0.41$ oe, then by analogy, the large couplings for DHP anion can be assigned as $a_3 = a_6 = 5.26$, $a_1 = a_8 = 3.36$. Finally the two small splittings can be assigned by comparison to u.H.f.-s.c.f. results (8) or by use of a valence bond superposition method (9), and by analogy to other diphenyl compounds that have been deuterated or methylated in these positions (9, 10). Thus an assignment of $a_2 = a_7 = 0.70$ oe and $a_4 = a_5 = 0.15$ oe is consistent with all available data from other sources.

The methylene coupling ratio can be used with eq. 1 in the introduction to find that the spin density on the 11 and 12 positions is 0.065 and that the equatorial proton lies out the plane of the adjacent phenyl ring by 8°, while the axial proton lies 22° from the normal to the plane. If the bond lengths of 1.48, 1.39, and 1.54 Å are assumed for the interannular, ring, and bridge C—C bonds, respectively, and no distortion of the valency angles is presumed, then the dihedral angle between the two phenyl rings can be computed to be 21°. This value is at the low end of the range calculated (5) for unsubstituted diphenyl wherein the energy minimum is obtained considering both π-energies and ortho-hydrogen repulsions as a function of interplanar angle. This value also agrees well with measurements made from molecular models.

The author would like to thank Mr. Glen Smith for his technical assistance in carrying out the experiments, the National Research Council of Canada for financial assistance, and the University of Sydney, Australia, for the use of their spectrometer during sabbatical there.

A Paramagnetic Resonance Study of Unhindered Biphenyl Anion Radicals (III)

F. C. ADAM AND C. R. KEPFORD[1]

Department of Chemistry, University of Calgary, Calgary, Alberta

Received December 12, 1967[2]

The radical anions of biphenyl and some of its bridged derivatives have been studied by e.s.r. It is found that the proton hyperfine coupling constants change monotonically through the series of radical anions derived from biphenyl, 9,10-dihydrophenanthrene, fluorene, dibenzothiophene, and dibenzofuran. Deuterations have been carried out for the latter two compounds and the hyperfine coupling constants are assigned to specific positions in these anions. The data are displayed in the form of a correlation diagram from which assignments for other bridged biphenyl anions can be made.

Les anions radicalaires du biphényl et des dérivés pontés ont été étudiés par r.p.e. Il a été trouvé que les écarts hyperfins de protons changent graduellement dans la série des anions radicalaires dérivés du biphényl, 9,10-dihydrophénanthrène, fluorène, dibenzothiophène et du dibenzofuranne. Des deutérations ont été effectuées pour les deux derniers composés et les écarts hyperfins ont été assignés à des positions spécifiques pour ces anions.

Les résultats sont représentés sous forme de diagramme de corrélation au moyen duquel des valeurs de couplages d'autres anions hyperfins pontés peuvent être obtenues.

Introduction

In previous papers in this series (1, 2) the spectra of hindered diarylmethyl radicals were obtained and some insight was gained into the internal configuration of such molecules from a study of the proton hyperfine structure. The ideas behind this work have been extended to the biphenyl series of compounds. It has been suggested that biphenyl itself is not planar, and that steric interactions between the ortho protons prevent the two rings from assuming a perfectly coplanar arrangement. The results of gas phase electron diffraction studies suggest the rings are oriented at an angle of 42° to each other (3) while X-ray studies on the crystal suggest the rings are coplanar, but are connected by a rather long bond (for an aromatic) of 1.50 Å (4). The barrier to internal rotation cannot be too high, because optically active derivatives of biphenyl racemize very readily, unless bulky hindering groups are substituted at the positions ortho to the interannular bond (5). The long wavelength absorption of biphenyl in the ultraviolet region occurs near that of benzene, and apart from the difference in vibrational structure and intensity, the spectra are rather similar. These considerations all indicate that the π-electron interaction between the two rings is small, and, as a result, the dihedral angle between the rings may well be established by relatively weak repulsive interactions between the ortho protons.

Structural information about the radical anion of biphenyl is completely lacking, though simple valence considerations would suggest the interannular bond has somewhat more π-character than in the case of biphenyl, and will, as a consequence, tend more toward the planar configuration, steric forces notwithstanding. To determine whether the higher bond order of the central bond is sufficient to overcome residual steric forces is the purpose of the present research. The aim is simple; it is to study a series of biphenyl-type radicals which are bridged in the 2,2′ (ortho) positions and thereby forced to assume a planar configuration. The hyperfine spectra can then be compared. Changes in the electron spin distribution can be followed by changes in the coupling coefficients (a_i) of the hyperfine spectrum through the McConnell relationship,

$$a_i = Q\rho_i$$

wherein a_i is the ring proton hyperfine coupling constant, ρ_i is the spin density at the adjacent carbon, and Q is a proportionality constant with a value of about -22.5 oe.

Experimental

The chemicals which have been used appear in Table 1, along with the abbreviations used, and the proton hyperfine coupling constants obtained from the e.s.r. spectra

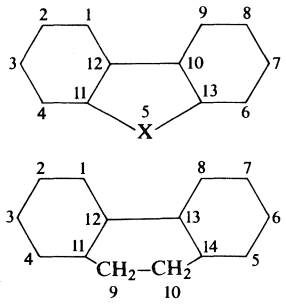
of their anions. Most of the parent compounds in Table 1 were obtained from Eastman Chemicals but the 9,10-dihydrophenanthrene came from the Aldrich Chemical Company and diphenylacetylene from The British Drughouses Limited. All were research grade chemicals except fluorene and dibenzofuran. The latter two were technical grade and were purified by repeated recrystallizations from 95% ethanol, with final melting points of 116 and 87 °C, respectively. The numbering scheme used for biphenyl is the usual ortho, meta, para nomenclature while the bridged compounds are indexed according to the following diagrams; in the first instance X = CH_2, S, O for fluorene (Fl), dibenzothiophene (DBT), and dibenzofuran (DBF), respectively, while the second diagram is appropriate to 9,10-dihydrophenanthrene.



Thus the para positions of biphenyl correspond to the 3,7 positions of the furan and thiophene compounds, or to the 3,6 positions of the phenanthrene derivative, and so on.

The deuterium labelled compounds in Table 1 were obtained from the corresponding bromides by standard magnesium Grignard procedures. The 2,8-dibromo derivative of dibenzothiophene was obtained by direct bromination of the parent compound in glacial acetic acid, following the method of Neymoyer and Amstutz (6). The product melted at 225–226 °C (lit. 226–228 °C). The 3,7-dibromo derivative was prepared through direct bromination of the sulfone of dibenzothiophene which was obtained from hydrogen peroxide oxidation of dibenzothiophene in glacial acetic acid (7). The resulting 3,7-dibromobenzothiophene sulfone (m.p. 310 °C) was reduced using lithium aluminum hydride in ether to give 3,7-dibromodibenzothiophene (m.p. 180 °C). The $3d_1$-dibenzofuran was obtained through the following sequence; dibenzofuran was nitrated (8) to give 3-nitrodibenzofuran (m.p. 180 °C), which was then reduced (m.p. 94 °C), diazotized, and treated with Cu_2Br_2 to give 3-bromodibenzofuran (m.p. 110 °C). The bromide was converted to the Grignard and treated with D_2O to give the desired product.

All compounds were reduced using standard high vacuum techniques, with potassium as reductant and dimethoxyethane (DME) as solvent. The spectra were taken on a modified Strand Labs X-band spectrometer. The spectra were obtained at reduced temperature (generally at $\sim -40°$) in a conventional Dewar train using cold nitrogen gas as a refrigerant, and all couplings reported were obtained by comparison against biphenyl anion in DME at room temperature. The results as quoted should therefore be internally consistent although there remains an error of about ± 0.02 oe in the coupling constants determined from erstwhile identical samples. The temperature variation of the ring proton coupling constants is also of this magnitude. For reasons to become apparent later, we also attempted to reduce diphenyl ether and diphenyl sulfide. These compounds decomposed, however, and we could not obtain the desired spectra.

Results

The results of an analysis of the hyperfine structure of the various spectra are as listed in Table 1. The assignments were made on the basis of the spectra of the deuterated derivatives, along with the assumption that the perturbations arising from the substitutions do not change the order of the hyperfine coupling constants. It is necessary to make one exception to this in order to explain the spectra of the deuterated dibenzothiophene (DBT^-) and dibenzofuran (DBF^-) compounds. As with biphenyl anion, the largest coupling constant in DBT^- is due to the 3,7 protons but in DBF^- the largest splitting is due to the 1,9 protons. Thus the relative magnitudes of the spin

TABLE 1. Bridged biphenyl derivatives investigated and the assigned proton hyperfine constants of their anions

Parent compound	Coupling constants (oe)				
	$a_1(o)$	$a_2(m)$	$a_3(p)$*	$a_4(m)$	a_{CH_2}
Dibenzofuran (DBF)	4.90	0.93	4.74	1.95

*d indicates deuterium coupling constants.

densities at the ortho and para positions have become inverted, or "crossed over" between these two compounds. In this respect these conclusions differ slightly from those due to Gerdil and Lucken (9) who assigned the coupling constants of DBT^- and DBF^- by comparison of the spectra of their methyl derivatives. In this particular case there was some ambiguity in the results, but the present deuteration experiments show unequivocally that the largest splitting in DBF^- is in fact due to the 1,9 ring protons (*i.e.* the ortho positions of biphenyl).

The deuterated biphenyl compounds allow the assignments given in Table 1 to be made. They agree with those of Lapp *et al.* (10) who used a different set of derivatives to obtain their assignments.

Some of the coupling constants in the remaining compounds are also known with certainty. Two of the triplets of the 9,10-dihydrophenanthrene anion may be ascribed to methylene protons by virtue of their temperature dependence (11). This ion is not planar and interconverts between two equivalent conformers with resulting modulation of the methylene coupling constants but not those due to ring protons. The spectrum for Fl^- obtained here corresponds to that reported for the mononegative radical anion (12) and not to the fluorenyl dianion species which has an entirely different e.p.r. spectrum (13) or to the ketyl which may be produced in electrolytic systems (14). The coupling constants for Fl^- can be seen from Table 1 to be very similar to those of DBT^-; it is known from the spectrum of the bridge methylated fluorene anion that the methylene coupling constant is about 4 oe (12*b*). The spectrum obtained from diphenyl acetylene clearly corresponds to the anion monomer (not the dimer) and agrees with the results of other workers (15) who have investigated this species.

Discussion

With the exception of diphenylacetylene, the compounds of Table 1 have similar π-electron systems and their hyperfine coupling constants under normal circumstances would be expected to show corresponding similarities. However, when one compares the anions of Bp, DHP, Fl, DBT, and DBF, some of the coupling constants show considerable variation, especially those assigned to the 1 and 4 positions. These changes cannot be simply accounted for by resonance or inductive parameters of the bridging group since one of the most sensitive sites is ortho while the other is meta to the substitution. Other factors which might contribute to the observed variance are that the first two members of the series are not planar, while the remainder are; there are also geometrical factors which remove the symmetry between the ortho protons and between the meta protons of the biphenyl anion. These occur with the loss of inversion symmetry. Analogous asymmetry has been observed, for example, with the stilbene anion (16) and with the anion of acetaldehyde (17) where markedly different coupling constants are observed for the ortho positions and to a lesser extent, the meta positions. The asymmetry is attributed to coulombic interaction between the off-axis group and the different positions in the perturbed phenyl group. Clearly this effect will increase through the series of compounds considered here, since the electronegativity of the bridging group increases monotonically through the series. This does not necessarily imply an increased spin density in the bridging element, however, as both carbazole and fluorenyl dianions (13) have small spin densities at this position. Furthermore, a large spin density at the heteroatoms in DBF^- and DBT^- would result in different *g*-values for these two compounds (18) but experimentally the centers of their spectra are found at the same field. In any case, it appears as if the electronic distribution in the rings is eventually controlled by competition between the effects of the interannular bond and those of the bridging substituent. In this respect it resembles the situation found in the substituted benzene anion radicals. The extreme sensitivity of the spin distribution to chemical substitution in the latter systems has been qualitatively explained by Carrington (19) as resulting from the manner in which the inductive effect of the substituent removes the orbital degeneracy of the benzene anion. In the case of Bp^- the degeneracy has already been lifted by the presence of the other ring, but the possibility must be considered that further substitutions in the ring, such as those represented by the bridging groups studied here, might produce perturbations every bit as large as the effect produced by the neighboring ring. Such might account for the extreme sensitivity of the wave functions which can be inferred from the variation in hyperfine coupling constants. An analogous situation is

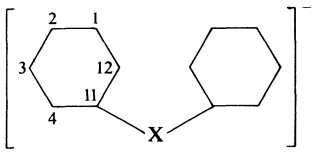
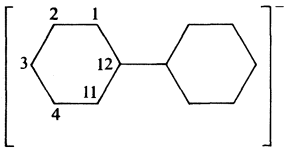
found with disubstituted benzene anions, where a wide variety of compounds have been correlated with a very simple "valence bond superposition" method formalized by Karplus and co-workers (20). Briefly, these authors suggest that the wave function for any disubstituted benzene anion can be represented by the linear superposition of the wave functions of two monosubstituted benzene anions which contain the two groups appropriate for the superposition. For dissimilar substitutions, the resulting electron distribution depends upon the fractional contribution of each fragment to the superposition. A description of the *p*-methyl benzonitrile anion would be given by the superposition of the toluene and benzonitrile anionic functions with suitable weighting factors. These ideas can be extended to the bridged biphenyl anions in the following way: any compound in the series can be looked upon as the linear superposition of



(A)

and



(B)

Unfortunately, the electronic structure of neither of these compounds is known, at least not in a proven planar configuration. As was noted above, attempts to produce anions of type A resulted in decomposition of the compound, rather than the formation of the mononegative ion. In the cases at hand, the spin densities of the composite molecules at the *i*th position would be given by

$$\rho_i = x\rho_i^{B} + (1 - x)\rho_i^{A}$$

where x is the fractional contribution of the planar biphenyl anion fragment B, and ρ_i^{B} and ρ_i^{A} are the spin densities at the appropriate position in the B and A fragments, respectively. While no experimental data is available for either the A or B species, it can be stated with certainty that in the limit where $x = 1$ (*i.e.* planar Bp^-), molecular symmetry requires that $\rho_1^{B} = \rho_{11}^{B}$ and $\rho_2^{B} = \rho_4^{B}$. For species A, in the other extreme, where $x = 0$, it must be assumed that $\rho_{12}^{A} = \rho_4^{A}$ and $\rho_1^{A} = \rho_3^{A}$. As mentioned earlier, this will be true only if there are no strong coulomb interactions between the two rings, although coulomb interactions with the bridging group itself do not matter. For A, the second identity is the more valid when such non-axial fields obtain. Accordingly, the most reasonable procedure to follow in correlating the data of Table 1 is to note that

$$\rho_1 = x\rho_1^{B} + (1 - x)\rho_1^{A}$$

and

$$\rho_3 = x\rho_3^{B} + (1 - x)\rho_3^{A}$$

The difference, $\rho_3 - \rho_1 = x(\rho_3^{B} - \rho_1^{B})$, using the above assumption. Alternatively, the difference in the coupling constants is proportional to the contribution of the biphenyl fragment to any composite molecule between the planar extremes represented by A and B, or $(a_3 - a_1) = xk$ wherein k is a constant. Accordingly the spin densities corresponding to the data of Table 1 have been plotted against $a_3 - a_1$ for the ring protons of each compound. The results appear in Fig. 1 taking $Q = -22.5$ oe. The "cross-over" of a_1 and a_3 between DBT^- and DBF^- is indicated. As may be seen, the points for ρ_1, ρ_2, ρ_3, and ρ_4, respectively, correlate linearly. The ordinates where $a_3 = a_1$ in Fig. 1 represent A, the hypothetical ϕ_2X^- species. It has a spin distribution such that $\rho_1^{A} = \rho_3^{A} = 0.215$, as defined by the cross-over, and at the same abscissa, $\rho_2^{A} = -0.041$ and $\rho_4 = 0.081$. By assumption $\rho_4^{A} = \rho_{12}^{A}$ at this point while from the normalization condition, $\rho_{11}^{A} = -0.047$, if use is made of the fact that the spin density on the heteroatom is zero, or at most, small. This gives the four spin densities needed for A.

The extrapolated tie lines in the correlation diagram must also satisfy the spin density distribution in the planar species, B. The lines representing ρ_1 and ρ_{12} must meet when $x = 1$, as must those representing ρ_2 and ρ_4. Accordingly the latter tie lines have been extended back to define this point. The same abscissa defines ρ_1 and hence ρ_{11} for B and a straight line is drawn between this point and ρ_{11} of A. The last spin density for B, ρ_{12}, is found from normalization, and the last tie line drawn in. The spin densities of the hypothetical B are $\rho_1^{B} = \rho_{11}^{B} = 0.120$,

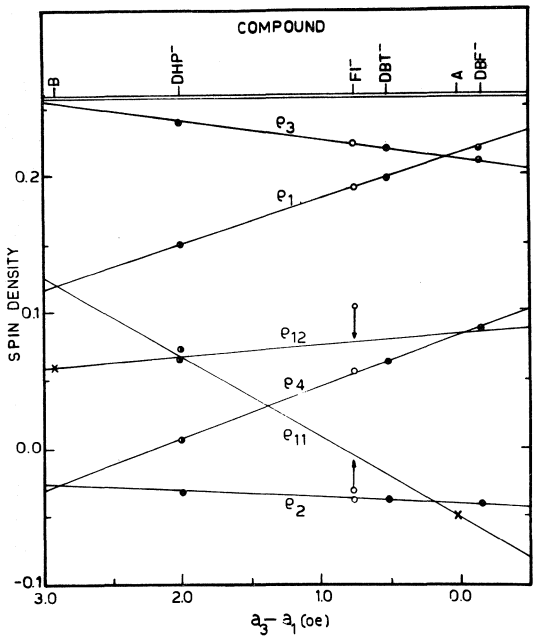


FIG. 1. Correlation diagram for the bridged triphenyl radical anions. The ordinates are spin densities of the compounds computed from Table 1, $Q = -22.5$ oe. The abscissa for each of the indicated compounds is determined by the difference in the coupling constants for positions 3 and 1. A and B are hypothetical compounds mentioned in the text, and X indicates spin densities computed using the normalization condition.

$\rho_2^B = \rho_4^B = -0.026$, $\rho_{12}^B = 0.058$ and $\rho_3 = 0.254$.

The internal consistency of this scheme can be checked in two cases. Both DHP^- and Fl^- have methylene proton splitting which may be considered to arise from spin density ρ_{11} on the ring position adjacent to the bridge. For DHP^-, an estimate of this spin density may be found if $a_{CH_2} = Q\rho_i$ and Q is taken to be $Q = 3.2 \pm 43.6 \cos^2\theta$ for these protons (see ref. 21 as presented in ref. 11). For the larger methylene splitting ($a = 2.66$ oe) and using a dihedral angle of 22° (11), one obtains the result that $\rho_{11} = 0.065$ which is so indicated in Fig. 1. The methylene protons in Fl^- are slightly different in that these protons are adjacent to two sites of unpaired electron density. The situation is analogous to that found in the cyclohexadienyl radical which exhibits coupling constants of 47.71 oe for the methylene protons, and 8.99 oe splittings for the protons on the adjacent sp^2 carbon atoms (22). Using the same proportionality, a spin density of ± 0.032 is obtained for ρ_{11} in Fl^-. This fits the diagrammed data in Fig. 1 if the sign is taken to be negative. It also implies (23) that the phase of the l.c.a.o.-m.o. coefficients at these positions in the two rings must be the same. This means that the singly occupied m.o. is symmetrical to that reflection plane of the molecule which contains the methylene protons. This agrees with Hückel m.o. expectations. The estimates of spin density from the methylene protons can be compared to the line drawn for ρ_{11} in Fig. 1.

An estimate of the cumulative errors in the analysis may now be obtained by determination of the spin densities for ρ_{12} in these two compounds.

From the normalization condition these are determined to be the relevant points indicated in Fig. 1. The value for DHP^- is slightly high, for Fl^- even more so. The worst fit is obtained for ρ_{11} of Fl^- where the expected value is too small. In a sense the correlation shown in Fig. 1 is not the best possible and other choices of Q for the ring and methylene protons could have been chosen to reduce the existing discrepancies. Alternatively, the tie lines could have been chosen so as to best fit the data presented, in which case an estimate of the inter-ring coulomb interactions involving positions 4 and 12, and the spin density in the bridging element of A could have been determined. It rather depends how much reliance one wishes to place on such linear correlations, and upon the particular molecular parameters chosen. Considered in this light, the correlation diagram of Fig. 1 can be considered to be a plot of the experimental data and may in point of fact not be as dependent on any conceptual model as has been indicated in the above development (24). As such, the diagram should be extremely useful in assigning the coupling constants of any radical which has the bridged biphenyl skeleton. Apparently therefore, the coupling constants at the positions 2, 3, and 12 are relatively insensitive to substitution while those at positions 1, 4, and 11 depend markedly on the particular substituent in the bridge. Both of the latter constants change sign through the series and accordingly may have very small values in some derivatives.

There are other features of interest brought out by these data. One of these is that the inter-annular interactions in biphenyl are not decisive, while the relatively small perturbations in the

bridging group produce large changes in the electron distribution in the molecule. This possibility was indicated in the Introduction and appears borne out by the experiments. If the extracyclic perturbations were indeed small by comparison, then according to the present interpretation, the plots for the molecules would be bunched to the left of Fig. 1, rather than evenly distributed along the horizontal axis. The insensitivity of proton coupling constants to the angle between the two rings is demonstrated by the fact that DHP^-, which is non-planar and has phenyl rings oriented at an angle of some 20° to each other, correlates with the data for the remaining planar species very well. Further evidence of the relative unimportance of planarity in these systems may be obtained by comparing the spin distribution of the "planar" species B of Fig. 1 with the values obtained experimentally for the presumably non-planar Bp^-, and those for the diphenylacetylene anion (DPA^-), the data for which are found in Table 1. This latter compound probably retains its linear configuration in the anionic form, as its spectrum is not at all similar to that of the stilbene anion (16). As a result there is little steric interaction between the ring protons, and it is unlikely the rings will have any preferred orientation relative to each other because of the cylindrical symmetry of the intervening "triple" bond. In any case the spin densities have been computed, and scaled up so that the net density in each ring is 1/2. One obtains $\rho_1 = 0.133$, $\rho_2 = -0.035$, $\rho_3 = 0.236$. This may be compared to the values of 0.12, −0.03, and 0.25 for the hypothetical planar B, and the experimental results of 0.116, −0.018, and 0.233 for the non-planar Bp^-. These are relatively small differences compared to the changes found for the remaining compounds. Calculations have been made on the biphenyl anion systems which show the spin density distribution only begins to change significantly when the interplanar angles exceed 35–40° (25). This further suggests that the resonance stabilization of the planar form is not marked enough to study the steric repulsive forces in these compounds using the present e.p.r. technique. The case of Bp^- is distinct in comparison to, say, the benzophenone anion, where ring substitutions do not materially affect the spin distribution in the rings, while changing the attitude of these rings produces relatively large effects (1, 25).

The success of the correlation diagram depends upon the correct choice of signs for the coupling constants. In particular, the meta coupling constants of Bp^- are found to be negative. The choice of opposite sign does not correlate at all and would not fit the superposition theory even in the limit of small perturbation. The McLachlan theory predicts negative spin densities at the meta position in accord with this (26) as do more refined open-shell calculations (27). On the other hand valence bond calculations such as those carried out by Schug *et al.* (28) for the naphthalene negative ion have also been carried out for Bp^- using a basis set of four structures. The results suggest that positive spin densities should be found at every carbon atom. The l.c.a o.-s.c.f. treatment proposed by Adam and Laidlaw (29) also predicts positive spin densities throughout the molecule in planar Bp^-. These latter calculations were extended to the case of DBT^-, and while pointwise agreement with the observed spin densities was still poor, the following trends were predicted: ρ_1 is predicted to increase markedly comparing DBT^- to Bp^-, ρ_2 becomes negative, ρ_3 decreases only slightly, while ρ_4 increases. These duplicate the trends found in Fig. 1. Similar trends were found by Gerdil and Lucken (30) who used McLachlan's method, and as far as DBT^- and DBF^- are concerned, were substantiated both as to direction and approximate magnitude using the u.h.f. method followed by spin annhilation (31). While these latter results do not predict the observed cross-over between DBT^- and DBF^-, they do suggest approximate equality of a_1 and a_3 in the latter compound. Furthermore, since these calculations contain coulomb repulsion effects explicitly, agreement with the correlation diagram of Fig. 1 may be taken to mean that the valence bond superposition model can be used to describe in a simple way the direction and magnitude of such effects in these molecules.

The diagram also suggests some interesting problems, the determination of the signs of the coupling constants for the meta protons, and the methylene protons in Fl^- being cases in point. Even lacking immediate experimental corroboration, Fig. 1 can be useful in assigning the proton coupling constants of other compounds with the biphenyl skeleton.

The authors would like to express their thanks to Mr. M. Williams of the Computing Centre, and to Dr. W. G.

Laidlaw for the programming assistance given. Thanks are also due to the National Research Council of Canada for financial assistance.

The Photolysis and Radiolysis of Simple Mercaptans in Dilute Glassy Matrices

J. SKELTON[1] AND F. C. ADAM
Department of Chemistry, University of Calgary, Calgary, Alberta

Received March 4, 1971

The e.p.r. spectrum of thiyl radicals is obtained when dilute solutions of aliphatic mercaptans are photolyzed in a xenon matrix at 77 °K. No proton hyperfine structure is observed at low concentrations of thiol but it appears at higher concentrations due to the reaction of hot hydrogen atoms with solute mercaptan molecules. When small amounts of the thiols are dissolved in glassy hydrocarbon matrices such as 3-methylpentane, there is produced after photolysis hyperfine structure characteristic of the solvent as well as the thiyl resonance. The e.s.r. absorption due to the solvent species disappears when the matrix is warmed a few degrees above 77 °K but thiyl radicals are stable up to the melting point of the glass. The corresponding γ-irradiated glasses do not give thiyl absorption, but two other species are produced along with solvent radicals. No thiyl radicals are observed following radiolysis, or upon photobleaching the new species. The spatial distribution of the neutral radicals in the glasses is discussed in view of these results.

Le spectre de r.p.e. de radicaux thiyl est obtenu lors de la photolyse de solutions diluées de mercaptans aliphatiques dans une matrice de xénon à 77 °K. On n'observe pas la structure hyperfine du proton en utilisant de faibles concentrations de thiol, mais elle apparaît lorsqu'on utilise des concentrations plus élevées à cause de la réaction des atomes d'hydrogène chauds avec les molécules de mercaptan en solution. Si on dissout de petites quantités de thiol dans des matrices d'hydrocarbure vitreuses, tel le méthylpentane-3, il se produit après photolyse, une structure hyperfine qui est caractéristique du solvant aussi bien que de la résonance du thiyl. L'absorption r.p.e. due à l'espèce solvant disparaît quand la matrice est chauffée à quelques degrés au-dessus de 77 °K, mais les radicaux thiyl demeurent stables jusqu'au point de fusion du verre. Les verres irradiés aux rayons-γ ne donnent pas d'absorption thiyl, mais deux autres espèces sont produites en même temps que les radicaux de solvant. On n'observe pas de radicaux thiyl après radiolyse, ou pendant la photodécoloration des nouvelles espèces. On discute de la distribution spatiale des radicaux neutres dans les verres pour arriver à ces résultats.

Canadian Journal of Chemistry, 49, 3536 (1971)

Introduction

Studies carried out in the vitreous (1, 2) or crystalline state (3) have yielded a great deal of information concerning the processes which occur during photolysis or during ionizing radiolysis of organic materials. This is partly due to the fact that reactive intermediates are held immobilized in the medium and thus restrained from further reaction, and as long as the matrix remains rigid the labile species may be studied at leisure by their u.v. and visible absorption spectra (4) in transparent media, by their e.p.r. spectrum in the case of paramagnetic species (5), or by their conductivity in the case of charged particles (6). These reactive intermediates may also be sensitive to changes in chemical environment such as occur in different solvents (7), or when small amounts of certain additives are present (8). Postradiative treatment such as photolytic bleaching of the intermediates (9), or changing the physical nature of the matrix by warming the samples (10) may also affect the different species in a variety of ways, serving to characterize, or perhaps to identify, the particular molecules under observation.

In the process of studying the γ-radiolytic decomposition of mercaptan solutions we have had occasion to study the photolytic decomposition of simple thiols in dilute solid solutions of various matrices at 77 °K. The effect of radiation or of photolytic absorption on the pure mercaptans has been extensively studied in the gaseous state (11, 12), in the solid polycrystalline state (13, 14), and in single crystals such as cysteine (15, 16). The metastable intermediates of chemical oxidation in dilute aqueous solutions have also been studied using fast flow techniques (17, 18), flash photolysis (19), or pulse radiolysis methods (20), but until recently not much work had been done on the radiolysis and photolysis of thiols in dilute rigid solutions using inert or chemically indifferent organic matrices. We wish to report on some of the work done in this direction

and to discuss the relationship between the intermediates of photolysis and those resulting from γ-irradiation of the same dilute solutions.

Photolytic decomposition of thiols in the gas phase involves the rupture of the S—H bond (21), with the production of a thiyl radical and a hydrogen atom which may have kinetic energy in excess of thermal. The maximum value of this excess energy is the difference between the energy of the excitation photon and the S—H bond energy of 88 kcal. In this case the low pressure mercury resonance line at 2537 Å was used for photolysis and the excess energy may be as large as 24 kcal. This excess energy may be lost by subsequent lattice collisions, until the atoms are "thermalized". As formed, however, the hydrogen atoms are "hot" and may be able to follow reaction paths requiring an energy of activation but which would not be observed with atoms which had been thermalized at 77 °K. In the present situation the most important nonthermal process is that of hydrogen atom abstraction, in which a free radical is produced along with molecular hydrogen.

The experiments to be described concern the photolytic absorption of thiols and the production of hot hydrogen atoms and their subsequent thermalization in a completely inert matrix of solid xenon. The procedure was to study the reactions of thermalized hydrogen atoms in very dilute thiol–xenon matrices, and then to raise the concentration of thiol in the xenon matrix upwards until the point was found where the products due to hot hydrogen atom attack on nearby solute molecules could be detected. These results give a rough indication of the range that hot hydrogen atoms have in a rigid matrix before becoming effectively thermalized and hence incapable of abstracting hydrogen from the CH bonds of an organic molecule. Corresponding experiments were then carried out using a rigid hydrocarbon matrix in which the solvent molecules can undergo reactions with hot hydrogen atoms quite independently of solute concentration. The various metastable species which were produced in these systems were characterized by their color and by their e.p.r. spectra and then compared to the intermediates obtained when similar glasses were subjected to γ-radiolysis.

Experimental

Matheson, Coleman and Bell were the suppliers of the solvent, 3-methylpentane (3MP), and ethanethiol, while 2,2-dimethylethanethiol (*t*-butyl mercaptan (*t*-BuSH)) was obtained from K and K Laboratories. 3MP was purified by standard techniques (1) and stored over sodium–potassium alloy under vacuum. Ethanethiol (EtSH) was distilled and stored in a dark bottle. Xenon gas was used as obtained from Air Reduction Corporation. The required amount of ethanethiol was introduced from a pipette into a clean cell which was then attached to a mercury-free high vacuum line, frozen, and evacuated to a pressure of 10^{-5} Torr. Solvent was then distilled in, and freeze–pump–thaw cycling followed until the residual pressure at 77 °K was less than 10^{-5} Torr. The cell was sealed off from the vacuum line, the sample was shaken until a homogeneous solution resulted and then refrozen preparatory to irradiation or photolysis. Xenon solutions were made up by freezing the appropriate amount of xenon on top of the degassed thiol. The resulting mixture was warmed in a petroleum ether – liquid nitrogen slurry at a temperature between −110 and −115 °C until the xenon liquified. With a melting point of −140 °C, EtSH is also a liquid at this temperature. The resulting mixture was well shaken then refrozen for photolysis.

Irradiations were carried out in a Gammacell 220 unit from Atomic Energy of Canada Ltd. Hanovia 87A45 low pressure mercury lamps were used for the photolyses.

Hydrogen yields were measured using the method of Johnson and Allen (22) except that palladium thimble rather than a combustion apparatus was used for disposal of the hydrogen gas. Electron spin resonance spectra were taken on a modified X-band Strand-Laboratory spectrometer using a 12 in. Harvey–Wells magnet system.

Results

A. Photolysis

Photolysis of the xenon–ethanethiol mixtures at 2537 Å gives rise to a yellow coloration which remains until the matrix is melted. Similar results are found with 3MP–EtSH mixtures, both dilute and concentrated, and with photolyzed pure solid EtSH. The e.p.r. spectrum of a 0.13 *M* EtSH–Xe solution at 77 °K consisted of a single unsymmetrical line near $g = 2.0$. However, the same illumination of a 0.270 *M* solution shows that this is only the high field line of three e.p.r. peaks which correspond to anisotropic g values of 2.063, 2.027, and 1.999 as shown in Fig. 1(*a*). Photolysis of higher concentrations of EtSH in xenon (>0.4 *M*) gives some proton hyperfine structure in addition to the three line spectrum, as is seen in Fig. 1(*b*). The proton hyperfine structure is characteristic of an odd-line spectrum, if it is assumed to arise from an aliphatic hydrocarbon radical with a g value near that of the free electron, and a hyperfine splitting of ~23 oe, as suggested by the larger high field lines.

The unsymmetrical three line spectrum and yellow color are ascribed to the EtS· radical, in agreement with the u.v. absorption work of

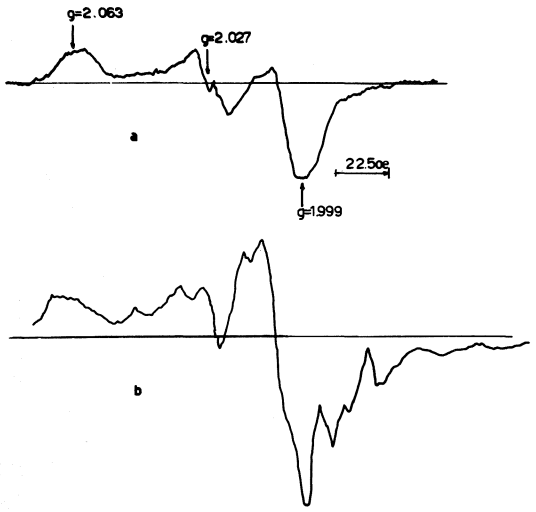

FIG. 1. First derivative e.s.r. spectra of photolyzed ethanethiol in xenon at 77 °K: (*a*) concentration 0.27 *M*; (*b*) 0.41 *M*. Corresponding positions along the horizontal axes are at the same field value.

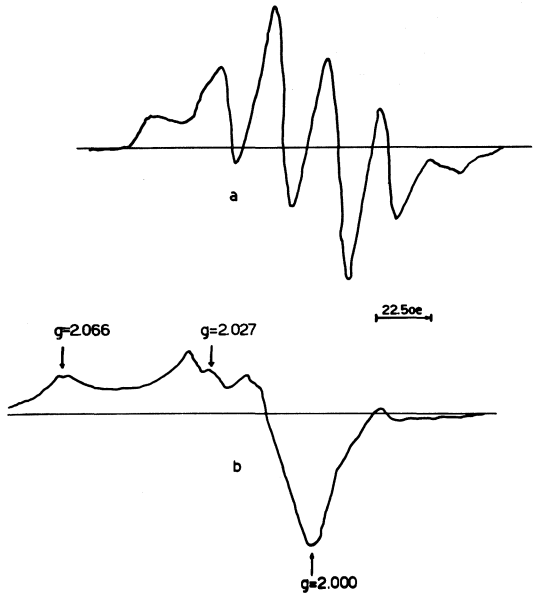

FIG. 2. First derivative e.s.r. spectra of photolyzed 0.1 *M* ethanethiol in 3 methylpentane: (*a*) temperature 77 °K, photolysis time 3 h; (*b*) temperature 91 °K, photolysis time 2 h.

Rosengren (23) and the e.p.r. work of Henriksen (24) and Kurita (25). By way of comparison, Kurita obtained principle **g**-tensor values of 2.0552, 2.0246, and 2.0032 from a single crystal study of an analogous organic thiyl radical.

As with the pure xenon matrix, illumination of the pure 3MP glass with 2537 Å radiation at 77 °K gave neither e.p.r. signal nor coloration. However, the photolysis of a 0.03 *M* solid solution of EtSH in 3MP gave an intense even-line e.p.r. spectrum with at least six hyperfine components. This is entirely different from the unsymmetrical spectrum described above and is attributed to the 3-methylpentyl radical (3MP·) because of its similarity to the hyperfine spectrum observed in glasses of this solvent after γ-radiolysis (26) and after photolysis of rigid 3MP solutions containing HI (27).

Photolysis of slightly higher concentrations (0.07 *M*) yields, in addition to the proton hyperfine structure, the low field absorption of EtS· corresponding to the *g* value of 2.06. It is significant that on warming these solid solutions to about 81 °K, the six line hyperfine structure disappears, leaving the same unsymmetrical three line as observed in the xenon matrix at lower EtSH concentrations. The corresponding spectra are shown in Fig. 2 (*a*) and (*b*). These e.p.r. signals disappear when the glass is heated to the melting point near 90 °K.

Photolysis of 0.09 *M* *t*-butyl mercaptan in a 3MP glass lends added assurance that the proton spectrum indeed arises from the 3MP solvent molecules, and not from fragmented solute molecules such as might arise through loss of HS·, for instance. This is because *t*-BuSH gives the same six line proton hyperfine spectrum as does EtSH, with the same *g* value, and on warming to ~81°K, the spectrum also fades so as to expose an analogous unsymmetrical three line spectrum due to the *t*-butyl thiyl radical. It has anisotropic *g* values of 2.060, 2.030, and 2.003, is yellow, and is also stable up to the temperature of fusion of the glass.

Similar results are obtained with solutions up to about 1 *M* in EtSH, but the intensity of the e.p.r. signals does not increase proportionately at higher concentrations. These photolyzed glasses were observed to be intense yellow at the front surface, but practically colorless deeper in the solutions. In view of this it is likely the thiyl radicals and the other products of photolysis strongly absorb the 2537 Å radiation of the source. Rosengren's (23) results for the absorption spectra of these solid solutions appear to bear out this conclusion, and as such, could explain the fact that the product yields do not increase linearly

with time of illumination, contrary to what is observed in the liquid and vapor phase photolyses for corresponding yields of product.

B. Radiolysis

Rigid hydrocarbon glasses, both with and without added mercaptan, have also been γ-irradiated. In agreement with other workers (2), the labile e.p.r. singlet and blue coloration of the "solvated electron" are observed in pure radiolysed 3MP at 77 °K. This species saturates easily at high r.f. powers and decays in a matter of minutes at any temperature above that of liquid nitrogen. The even-line proton hyperfine spectrum of 3MP· is also observed and this too will disappear slowly if the matrix is warmed a few degrees above the boiling point of nitrogen. The glasses appear to be still solid under these circumstances, and in view of the stability of the thiyl radicals in the corresponding photolyzed system it would appear that the much larger 3MP· radicals must be disappearing by some process other than those involving molecular diffusion of the radicals.

When increasing amounts of EtSH are added to the 3MP matrix, the color of the irradiated glass changes from the original blue, through green, to the orange coloration found at higher concentrations of EtSH. The e.p.r. spectrum still consists of a single line near $g = 2$ but is considerably different from the solvated electron signal in that it is much more stable at temperatures above 77 °K and can in fact be observed at temperatures beyond which the 3MP· spectrum has faded. It is considerably broader and may be observed at high microwave powers. Glasses which have been thermally annealed to remove the 3MP· and solvent trapped electrons reveal a slightly unsymmetrical singlet e.p.r. absorption with ΔH_{pp} of 26 oe and $g = 2.011$. The glass is yellowish green. An i.r. bleach with $\lambda \sim 700$ mμ gives a yellow glass and a reduced e.p.r. signal which has structure which may be attributed to a radical with $g_1 = 2.002$, $g_2 = 2.012$, and $g_3 = 2.025$. The width between extreme peaks is ~38 oe. Exposure of the glass to 420 mμ light does not regenerate the green coloration, but prolonged exposure (> 1 h) will bleach the yellow coloration. The u.v. and visible absorption spectra of the glasses (28) show the presence of transitions at 420 mμ and at 700–900 mμ. The latter is readily removed by bleaching but not the former. Only the 420 mμ absorption is obtained for EtSH in 2-methyltetrahydrofuran glasses which accounts for its yellow coloration. A broad e.p.r. spectrum has also been detected for this system and has been attributed to the radical anion $EtSH^-$ (29).

Some idea of the ability of EtSH to act as an electron scavenger in 3MP glasses may be determined by irradiation of solutions containing small amounts of other known electron scavengers. For instance, addition of CO_2 to 3MP produces an anion which is characterized by a narrow e.p.r. line near $g = 2.0$ (30). This line is not bleached by i.r. or visible light. On the other hand irradiation of the ternary mixture of 3MP with equimolar (0.02 *M*) EtSH and CO_2 at 77 °K produces a clear yellow glass which clearly exhibits the proton hyperfine structure of 3MP· in the e.p.r. spectrum, but no narrow unbleachable CO_2^- line. It appears as if it is the EtSH rather than the CO_2 which has scavenged the available electrons to produce the broad $EtSH^-$ absorption which lies under the 3MP· spectrum. The yellow coloration of the glass substantiates this conclusion. The unbleachable CO_2^- line will reappear if the concentration of EtSH is substantially reduced below that of CO_2. These effects are to be seen in Fig. 3.

The unsymmetrical spectrum of EtS· in 3MP was not observed at any time before, during, or after photobleaching, nor during the warming up of the γ-irradiated EtSH/3MP mixture to 85 °K. Nor did photobleaching at 77 °K produce any additional signal which could be attributed to the formation of additional 3MP· radical, in either pure 3MP or the thiol glasses.

Irradiation of 0.1 *M* EtSH for extended times (~10^{20} eV/g) does not materially affect the above described situation.

Products were analyzed by v.p.c. using ampoules in which the irradiated glass had been melted and brought to room temperature. Samples were withdrawn by syringe through a rubber septum at the top of the ampoule. While some fragmentation of solvent molecules is found in both the photolyzed and radiolyzed systems, the greatest changes occur with photolysis due to the formation of thioethers and ethyl disulfide. Somewhat less disulfide and no thioethers were detected in the γ-radiolyzed system. Ultraviolet absorption of the liquid solutions bear out these conclusions insofar as the photolyzed samples absorb more strongly in the disulfide region near 250 mμ than do the γ-radiolyzed samples. H_2S was detected in neither system using g.l.c.

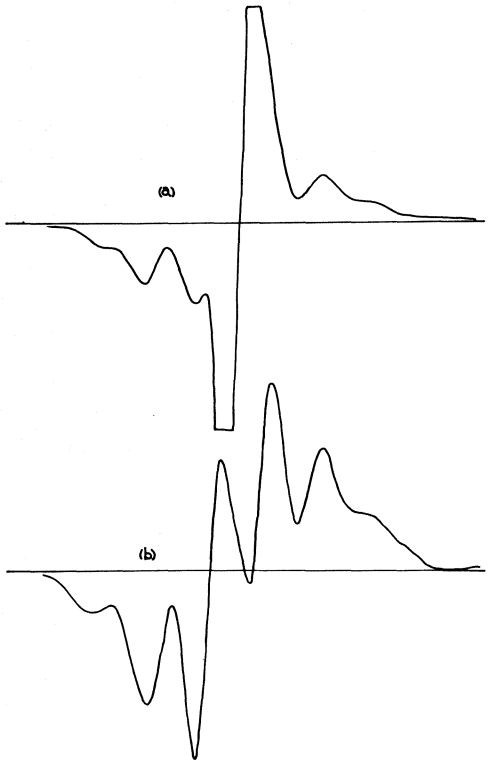

FIG. 3. First derivative e.s.r. spectra of γ-irradiated 3 methylpentane glass at 77 °K (dose 2×10^{19} eV g^{-1}): (*a*) 0.01 *M* in CO_2 (gain × 1); (*b*) 0.01 *M* in CO_2 and 0.01 *M* in ethanethiol (gain × 2).

Hydrogen gas appears to be the major product in both photolysis and radiolysis. The exposure times are such that roughly the same amount of decomposition occurs by each process. Compared to pure 3MP, the actual yields are only slightly reduced (by ~5%) for dilute solutions of EtSH in 3MP (0.01 – 0.05 *M*). The amount of hydrogen gradually increases as the concentration of EtSH is increased beyond these concentrations. A more complete report will be given on these analyses at a later date.

Discussion

A. Photolysis

The photolysis of EtSH in dilute xenon solutions produces the thiyl radical EtS· as a majority product in spite of the fact that the C—S and not the S—H bond is the weakest in the molecule (11, 29). This finding is in agreement with sulfhydryl photolysis experiments carried out in the vapor phase (11). The absence of ethyl or sulfhydryl radicals in the e.p.r. spectrum of dilute thiol solutions in xenon further indicates that the primary photolytic process must be similar in both the vapor and the glassy state. This may be true for 2537 Å mercury excitation alone, since it has been shown in the vapor phase with the use of higher photon energies, that C—S bond rupture becomes the more probable decomposition route (19).

The processes occurring in photolysis are thus best described by the reactions

[1] $$EtSH \xrightarrow{2537\ Å} EtS\cdot + H\cdot^{*}$$

[2] $$H\cdot^{*} + M \rightarrow H\cdot + M + \text{lattice energy}$$

[3] $$H\cdot^{*} + CH_3CH_2S\cdot \rightarrow CH_3CH{=}S + H_2$$

[4] $$H\cdot^{*} + CH_3CH_2SH \rightarrow \cdot CH_2CH_2SH + H_2$$
$$\rightarrow CH_3\dot{C}HSH + H_2$$

[5] $$H\cdot + CH_3CH_2SH \rightarrow CH_3CH_2S\cdot + H_2$$

Here H·* is a hydrogen atom with excess kinetic energy and M is a matrix molecule. Reaction 3 represents one of the various possible cage abstractions while reaction 4 represents the hot atom reactions occurring outside of the solvent cage. The observed hyperfine structure in Fig. 1(*b*) is what might be expected from radicals of the form given in reaction 4.

The activation energy for reaction 5 is believed to be quite small since this reaction has been shown (12) to compete favorably in the vapor phase with the olefin addition reactions which are already known to require only small energies of activation (32). On the other hand, abstractions as in reaction 4 require activation energies of about 8 kcal (2, 33). Since the photolytically produced hydrogen atoms may have energies well in excess of this, in hydrocarbon matrices one has in addition to the thermalization reaction 2

[6] $$H\cdot^{*} + C_6H_{14} \rightarrow C_6H_{13}\cdot + H_2$$

The radical so produced should therefore be close to the original site of absorption, and the resulting geminal pair may combine by the reaction

[7] $$CH_3CH_2S\cdot + \cdot C_6H_{13} \rightarrow CH_3CH_2SC_6H_{13}$$

Only slight relaxation of the matrix is required for this process, and this may explain why all 3MP· radicals produced by photolysis vanish when the matrix is warmed to 81 °K. The abstraction process 6 cannot prevail to the complete

exclusion of reaction 2 so that isolated pairs of thiyl radicals are still found resulting from reactions 2 and 5. These are the species which produce the thiyl e.p.r. signal and yellow coloration which remain up to the melting point of the glass near 95 °K, whereupon

[8] $2CH_3CH_2S\cdot \rightarrow CH_3CH_2SSCH_2CH_3$

The major products obtained by g.l.c. and hydrogen analysis support this simple scheme.

B. Radiolysis

The results of the γ-radiolysis experiments are not as clear cut as those for the photolysis, but since many of the products expected or purported to be formed (13, 14, 34) in γ-radiolysis are the same as those found in the photolysis experiment, one can proceed with a certain amount of confidence using the knowledge of the properties of those radicals which are common to both systems and which have been prepared in similar molecular environments. The effects of γ-irradiation on glasses such as 3MP have recently been reviewed (2). The reactions which best explain the experimental observations are as follows

[9] $C_6H_{14} \rightsquigarrow C_6H_{14}^*$

[10] $C_6H_{14} \rightsquigarrow C_6H_{14}^+ + e_m^-$

[11] $e_m^- + M \overset{h\nu}{\rightleftharpoons} M^-$

or

[12] $C_6H_{14}^+ + M \rightleftharpoons C_6H_{14} + M^+$

Following this will be neutralization as, for instance,

[13] $C_6H_{14}^+ + e_m^- \rightarrow C_6H_{14}^*$

In these equations, e_m^- is the mobile electron, M is some molecule in the matrix, and $C_6H_{14}^*$ is a solvent molecule in one of its excited electronic states. Following this, the excited molecule can be considered to decompose by two main routes

[14] $C_6H_{14}^* \rightarrow$ diamagnetic fragmentation products

or

[15] $\rightarrow C_6H_{13}\cdot + H\cdot^*$ or other paramagnetic products

Hot atoms produced in reaction 15 can undergo subsequent transformations such as abstraction by reaction 6, thermalization as in reaction 2 or in the presence of EtSH, any of the reactions 3, 4, and 5. In the pure 3MP glass, however, γ-irradiation gives rise to only the solvent trapped electron and 3MP· as detected by e.p.r. or visible absorption spectroscopy. Photobleaching and thermal treatment produce no additional 3MP· which implies that diamagnetic products are the sole result of the neutralization process, reaction 13, and that most probably this paramagnetic species arises only during the actual irradiation, and results from the superexcited states depicted in reaction 9. It is unlikely that small amounts of added solutes would have any effect on this direct process. On the other hand, a compound such as EtSH would be expected to act as a trap for some of the ensuing secondary products. The photolysis experiments demonstrate the ability of EtSH to act as a trap for mobile radical carriers such as hydrogen atoms. It has also been shown above that it acts as a fairly good scavenger for mobile electrons. Because its ionization potential (9.28 eV) (35) is lower than that of the solvent (10.02 eV), it might also be expected to scavenge positive charge from ionized 3MP molecules. As a result EtSH intercepts the normal matrix neutralization reaction 13 and the ensuing reaction 14 which may give rise to some of the fragmented, unsaturated, and isomerized solvent molecules which are found in the products. Such would produce $EtSH^-$ and $EtSH^+$ in the first instance; these ions are analogous to those found by Truby in the γ-radiolysis of aliphatic disulfides (36). The present experiments show that post radiative photolysis or thermal annealing of EtSH/3MP glasses produce no new radical species such as 3MP·, H·*, EtS·, H·, Et· in anything but a transitory way, and that if formed at all, then their decomposition is such as to give rise to only diamagnetic and uncolored products. Finally it should be noted that the odd-line hyperfine structure due to solute molecules is not observed in any but the xenon matrices which suggests that the range of hot hydrogen atoms is very restricted in hydrocarbon solvents.

C. Comparison of Photolyzed and Irradiated Glasses

Both photolysis and γ-radiolysis of EtSH–3MP glasses produce 3MP· radicals during the primary excitation process, but not during subsequent photochemical or thermal treatment. On the other hand EtS· radicals are produced only by photolysis and are not found in the γ-irradiated system regardless of the post-radiative treatment. In

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

both systems the hyperfine structure due to 3MP· fades when the temperature is raised a few degrees above 77 °K. In the γ-irradiated systems signal due to charged species remains, while in the photolyzed samples signals due to EtS· are observed until the matrix is melted. Compared to the thiyl radical, the instability of the hydrocarbon species appears to arise either from differences in the spatial distribution of these radicals in the matrix, or by some spin diffusion property characteristic to 3MP·. Molecular diffusion may be ruled out on the basis of size and the fact that EtS· is quite stable in the same matrix. The resonant hydrogen transfer reaction

[16] $C_6H_{13}\cdot + C_6H_{14} \rightarrow C_6H_{14} + C_6H_{13}\cdot$

would be specific to 3MP· in a 3MP matrix, and would allow migration of only this particular species away from the actual site of formation. Such a process would also be favored in a less-than-completely-rigid lattice and might therefore be expected to have the temperature dependence displayed by the fading 3MP· signal. The decrease observed would then result from radical–radical annihilation reactions such as reaction 7 or reaction 17

[17] $2C_6H_{13}\cdot \rightarrow$ diamagnetic products

However, in systems containing modest amounts of EtSH, the "repair" reaction

[18] $C_6H_{13}\cdot + C_2H_5SH \rightarrow C_6H_{14} + C_2H_5S\cdot$

is much more favorable than radical–radical recombinations and the fading of the 3MP· signal should therefore be accompanied by a gain in the EtS· signal. Such a gain was observed in neither of the systems studied. This suggests that no mobile radical carrier, including 3MP· and thermal hydrogen atoms, is produced subsequent to the original excitation process in γ-irradiated systems.

The alternative to the spin diffusion process has already been suggested; reaction 1 or reaction 14 produce hot hydrogen atoms that may proceed by the abstraction reaction 6 to produce a geminal pair of radicals that are restrained from reacting only by virtue of the rigidity of the matrix. However, in photolysis the intrinsically lower energies involved allow for some of the hydrogen atoms to be thermalized and give rise to a diffuse population of thiyl radicals at spacings determined by the initial concentration of EtSH. These radicals cannot react except by molecular diffusion and as a result may be detected until the matrix becomes fluid at higher temperatures. Since no such residual signal for 3MP· occurs in the γ-irradiated glasses, it must be presumed that no "isolated" 3MP· radicals are produced in the original excitation through the simultaneous production of thermal hydrogen atoms. Each act that results in the production of a 3MP· radical must also result in the production of a second, geminal partner that reacts by reaction 17 when relaxation of the matrix occurs.

The scheme outlined above for radical formation requires that decay of the 3MP· radicals should be a first order or a composite first order reaction. It has been reported that the decay is second order at 77 °K (2). We have been unable to check this result since we do not have adequate enough temperature control between 77 and 81 °K to ascertain whether the decay process is also second order in this critical temperature range.

The authors would like to express gratitude to the National Research Council of Canada, the Defence Research Board of Canada, and the United States Institute of Health, without whose financial aid this work could not have been finished. Thanks for time and help are also due to Mr. Glen Smith, Mr. David Oseen, and members of Technical Services at the University of Calgary.

The Analytical Reduction of Porphyrins to Pyrroles[1]

R. A. CHAPMAN,[2] M. W. ROOMI,[3] T. C. MORTON,[4] D. T. KRAJCARSKI, AND S. F. MACDONALD
Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada

Received June 21, 1971

When porphyrins or related pigments are reduced by HI–AcOH, their meso-substituents (R = H or alkyl) appear as α-CH_2R groups in the resulting pyrroles. The identification of the pyrroles, as by g.l.p.c., defines and orders the meso-substituents flanking each pair of peripheral substituents in the porphyrin. If one meso-substituent differs from the others, all the substituents about the two adjacent pyrrole nuclei are then ordered.

The pyrroles can be reductively alkylated *in situ*, and symmetry then reduces their number when the aldehyde used (R.CHO) corresponds to a bridge and its meso-substituent. This may simplify the pyrrole mixtures, identify meso-substituents, or make pyrroles distinguishable by g.l.p.c.

The critical pyrrole – propionic acids are separable as methyl esters by g.l.p.c. Desoxophylloerythrin and pyrophaeophorbides (the latter first reduced with potassium borohydride) are reduced to cyclopenteno-pyrroles which reveal the isocyclic rings and the 5-substituents. The r.r.t.'s of relevant pyrroles are reported.

La réduction des porphyrines et des pigments du même genre par HI–AcOH fait que les substituants méso (R = H ou alkyle) apparaissent sous forme de groupements CH_2R en α des pyrroles résultants. L'identification des pyrroles par c.p.l.g., par exemple, définit et classe les substituants méso qui se trouvent à côté de chaque paire de substituants périphériques dans la porphyrine. Si un des substituants méso diffère des autres, tous les substituants autour des deux noyaux pyrroles adjacents sont alors classés.

L'alkylation réductive *in situ* des pyrroles peut réduire par symétrie le nombre de pyrroles lorsque l'aldéhyde utilisé (R.CHO) correspond au pont et au substituant méso de la porphyrine initiale. Ceci peut simplifier le mélange des pyrroles, identifier les substituant méso et différentier les pyrroles par c.p.l.g.

Les acides critiques pyrrole – propioniques sont séparables de leurs esters méthyliques par c.p.l.g. La désoxophylloérythrine et les pyrophaephorbides (ces dernières d'abord réduites par le borohydrure de potassium) sont réduites en cyclopenténo-pyrroles, ce qui révèle les noyaux isocycliques et les substituants en 5. Les données t.r.r. des pyrroles correspondants sont rapportées.

Canadian Journal of Chemistry, **49**, 3544 (1971)

The pairs of peripheral substituents on porphyrins and related pigments are now usually determined by identifying the maleinimides or the pyrrole-2,5-dicarboxylic acids resulting when the pigments are oxidized with chromic acid or with permanganate, respectively. The maleinimides have been separated and identified by g.l.p.c., by g.l.p.c. and mass spectra, t.l.c., or by t.l.c. and mass spectra (1–3, 60), the pyrrole-2,5-dicarboxylic acids by paper chromatography (4). Chromic acid is usually preferred because it gives much higher yields and these can be significant when two identical pairs of peripheral substituents are present. However, permanganate has advantages: while permanganate degrades isocyclic rings to carboxyl, chromic acid destroys the pyrrole ring bearing either of these groups. The reference pyrrole-2,5-dicarboxylic acids are also more generally available synthetically than are the corresponding maleinimides.

To the same end, the pigments had been reduced by HI–AcOH at 100° to mixtures of homologous pyrroles, meso-substituents being absent or ignored (Scheme 1, $R^1 = R^2 = H$). This method was abandoned for the yields were divided among homologues, complex mixtures of labile pyrroles had to be separated by fractionating the picrates, and some pyrroles do not form picrates. Although some of the purely alkyl pyrroles were recently separated by g.l.p.c., the chromic acid method was more suitable for more complex pigments (1). The chief disadvantage of the HI–AcOH reduction had been avoided by reducing the pigments and *C*-methylating the pyrroles in one step with KOMe—MeOH at 220° (*5a*, *b*). One tetra-alkyl pyrrole then replaced four homologues (Scheme 1), but propionic acid side-chains were partially replaced by methyl (6).[5]

[5]This suggests a reversed Michael addition followed by methylation. The analogous thermal fission of 2,4-dimethyl-5-carbethoxy-3-(2,2-dicarboxyethyl)-pyrrole dihydrazide to 2,4-dimethyl-5-carbethoxy-pyrrole (7) is interesting because perhaps facilitated by the formation of a pyrazolidone.

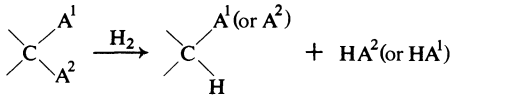
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Although chromic acid oxidation is unique in revealing the reduced pyrrole ring in chlorins and phaeophorbides as a succinimide (1, 8), the HI–AcOH reduction had potential advantages. It was unnecessary to reduce α-hydroxyethyl side-chains to prevent further degradations. The reagent was an excellent solvent, used in indefinite excess, and easily removed. The total yields were also competitive and the products more volatile. Three considerations (9) then made the reductive method more attractive: reference pyrroles were now more easily available, the pyrrole mixtures could be simplified by reductive methylation *in situ*, avoiding KOMe—MeOH at 220°, and it was possible that meso-substituents in the pigments might be retained on the pyrroles. The implications of these are developed in Scheme 1, where the rôle of alkylation is rationalized and extended. It should be noted that vinyl or α-hydroxyethyl groups are converted to ethyl, and that ring carbethoxy or acetyl groups are split off by HI–AcOH.

Scheme 1 assumes that all and only the indicated C—C fissions will take place. The only experimental evidence here lay in the pyrroles obtained by reducing porphyrins lacking meso-substituents, particularly hemin, and in the reduction of meso-methyl-dipyrrylmethanes to α-free and α-ethyl-pyrroles (10). Not all the expected pyrroles were obtained from coproporphyrin (5*b*), but the methods of isolation were presumably inadequate.

The assumption in Scheme 1 differs only in emphasis from what was apparently Küster's interpretation of the reduction of hemin: that it was reduced to monopyrroles because α,α-dipyrrylmethane bridges, but only these, would undergo reductive fission (11). Although this led him to the correct structure for the porphin nucleus in 1912, the central 16-membered ring was unacceptable at that time (12*a*), and only synthetic evidence for the structure (symmetry) of the nucleus was acceptable much later (5*f*).

In the meantime Küster's idea was apparently regarded as an *ad hoc* assumption supporting an impossible structure. However, analogous reductions had previously been correctly interpreted in the same way by Boehm (13): the reductive fission of linear methylene-bis-phloroglucin derivatives in male fern by zinc and alkali. More generally, the reduction of porphinogens, the intermediates in the HI–AcOH reduction of porphyrins, is analogous to many reductive fissions of C—O, C—N, and C—C bonds:



where A^1 = or ≠ A^2, and both are such that A^- and are usually regarded as stabilized; in porphinogens, here represents a bridge.

Küster's assumption was confirmed (although its reasonableness was denied) when a 1,2-di-(α-pyrryl)-ethane, unlike dipyrrylmethanes, proved stable to HI–AcOH (14). It was then concluded that the α-pyrryl residues in hemin could hardly be linked through two carbon atoms, but the result was not used to eliminate the two rival porphyrin structures (5*f*) and a third which arose later (5*g*). All three would require that the porphyrins reduce to derivatives of two pyrroles and a 1,2-dipyrrylethane. The confusion is further illustrated by an apparent attempt to find a hydrocarbon, representing the γ-substituent or the γ-bridge, among the reduction products of phylloporphyrin (15). However, in a return to Küster's interpretation and its implications, the absence of α-ethyl derivatives among the pyrroles was somewhat tentatively cited as evidence for the absence of meso methyl groups in hemin (16). Ironically, α-ethyl pyrroles from hemin had been reported (5*b*); although the methods then current were probably inadequate to decide their existence, hindsight had rejected them as unlikely (17).

The presence of meso-substituents in a pigment has been inferred from a missing methine C*H* signal in the n.m.r. spectrum, or by degrading the pigment to a porphyrin with a "phyllo-type" visible spectrum. The substituent was then identified and located by identifying the porphyrin with a synthetic one. Similarly, although the pairs of peripheral substituents in a pigment could be determined analytically, their further ordering depended ultimately upon the identification of an analytical with a synthetic porphyrin. In both cases the possible structures might be limited by empirical rules governing spectra etc. or by biogenetic ideas. However, the former could be misleading if based on an unforeseeably in appropriate model, *cf.* (18, 19), and the relevance of the latter may be in question, *cf.* petroporphyrins (20).

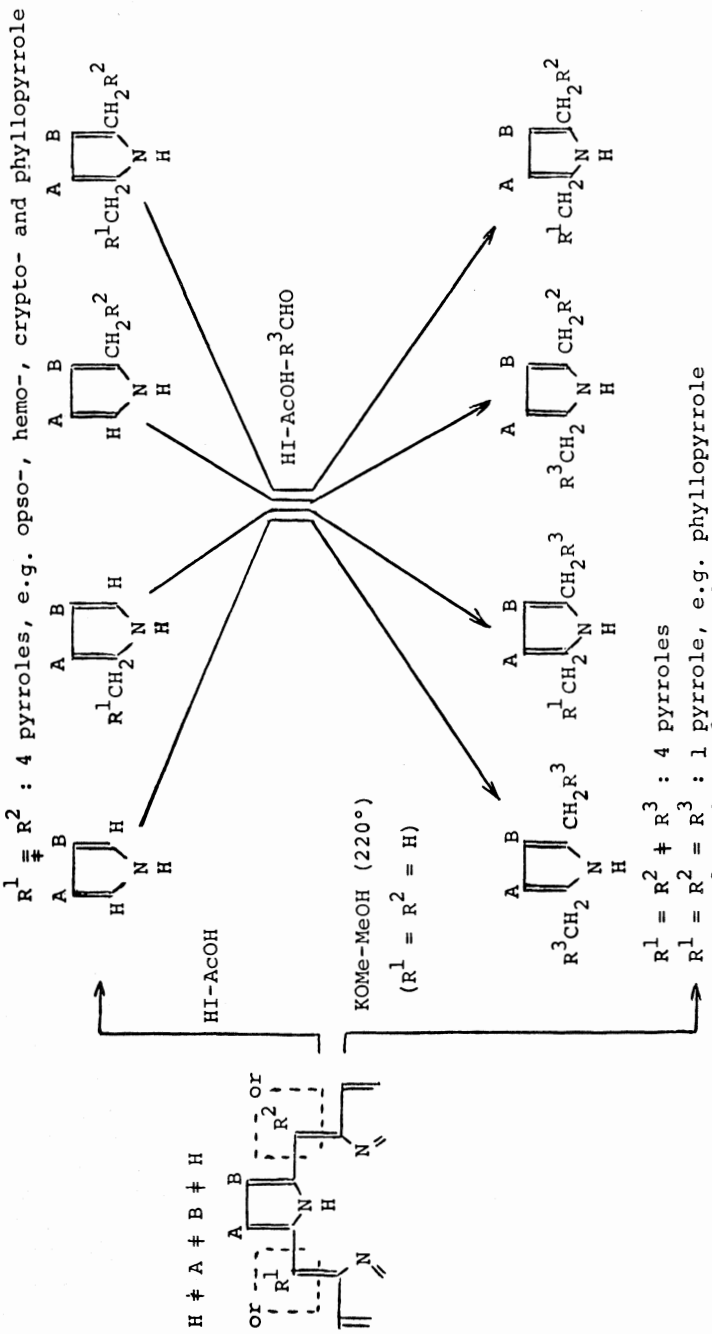
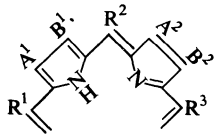


SCHEME 1. Pyrroles expected from one pyrrole nucleus in a porphyrin.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

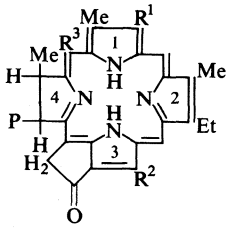
Scheme 1 implies that the identification of the pyrroles obtained by reduction will identify and locate the meso and peripheral substituents about a pyrrole nucleus in a pigment and, if any meso-substituent (R^2) is different from the others, all the substituents about the two adjacent pyrrole nuclei:



On the other hand, methylation will be fully effective in simplifying the pyrrole mixtures only in the absence of meso-substituents in the pigment. Some further implications of Scheme 1 are inescapable; these will be illustrated by the examples in Tables 1 and 2.

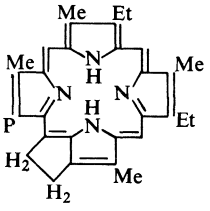
Tables 1 and 2 show the products expected from the pyrrole nuclei of typically substituted porphyrins. The products are those required by Scheme 1 but some represent special cases wherein a peripheral position is unsubstituted (A or B = H, becoming CH_2R^3 after alkylation), or one of the meso-substituents (X) is sufficiently large that the pyrroles bearing it do not appear with the others on g.l.p.c. The products from the reduced ring 4 of phorbins and chlorins should be unreduced pyrroles (15), the same as those from ring 4 of the corresponding porphyrins. Examples (*i*), (*j*), and (*k*) in Table 2 with large meso-substituents (X) will then represent the simplest model for ring 4 of pyrophaeophorbides and desoxophylloerythrin. The relative retention times (r.r.t.) in the tables were determined with reference pyrroles (see below), and the logarithmic scale suggests the separabilities, *e.g.* the pyrroles **2** and **3**, like **21** and **23**, could be distinguished by their r.r.t.'s but ran together under one peak.

Ignoring the r.r.t.'s in these examples, the following information could be obtained merely by counting the pyrroles and by noting whether or not the highest pyrrole homologue obtained by reduction was unchanged by alkylation, *i.e.* was a tetra-alkylpyrrole. A large meso-substituent would be recognized, but only as such, when reduction gave two pyrroles as in examples (*i*), (*j*), and (*k*). All other meso-substituents would be identified by the aldehyde used when the number of pyrroles was reduced from four to one as in

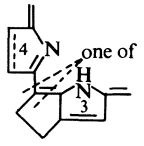


Pyrophaeophorbides

R^1 = $CH{:}CH_2$; R^2 = Me; R^3 = H:
Pyrophaeophorbide-*a*
R^1 = $CH(OH)CH_3$; R^2 = Et; R^3 = H:
Chlorobium phaeophorbide 650 fraction 4
R^1 = $CH(OH)CH_3$: R^2 = Et; R^3 = Me:
Chlorobium phaeophorbide 660 fraction 5



Desoxo-phylloerythrin



Assumed fissions

(*a*), (*b*), (*c*), (*d*), and (*g*), from three to one (see below), from four to two as in (*e*), (*f*), and (*h*), or from two to one as in (*i*) and (*j*). In the absence of a large meso-substituent (more than two pyrroles on reduction), no pyrrole common to the three chromatograms would show that one or both of the peripheral positions was unsubstituted as in (*c*), (*d*), and (*f*). The peripheral substituents would not be further defined unless the meso-substituents were identical. If they were, reduction would give three pyrroles if A = B (*cf.* Scheme 1; no examples in Tables 1 and 2); A and B would then be an alkyl group if there was a pyrrole common to the three chromatograms, H if not, and the aldehyde defining the meso-substituents here would convert the three pyrroles to one. If the meso-substituents were identical and A = H, B = alkyl as in (*c*) and (*d*), B would usually be identifiable. In (*d*), the general case, one aldehyde would identify the meso-substituents as usual by converting four pyrroles to one in which the 2- and 5-substituents were identical, and another aldehyde would identify B by converting four pyrroles to three in which the 3- and 4-substituents were B. In (*c*), the degenerate case wherein B (Me) is the next higher homologue of the meso-substituent (H), B could not be identified because the aldehyde identifying the meso-

substituents would also make the 3- and 4-substituents on the pyrroles identical.

The practicability of the methods suggested here depends, although in varying degrees, on the extent to which all and only the expected pyrroles are formed and are distinguishable. The following was clear from the behavior of reference pyrroles (see below). All the pyrroles expected from naturally substituted porphyrins were sufficiently stable in HI–AcOH at 110°, although opsopyrrole–carboxylic acid, **28**, unlike phyllopyrrole–carboxylic acid, **32**, was reportedly destroyed at 130° (15). This is fortuitous, for the instability of some pyrroles expected from unnaturally substituted porphyrins would result in missing pyrroles or extra ones. There was also no evidence that the pyrroles were alkylated significantly in HI–AcOH through scavenging. It may be significant here that cryptopyrrole was unchanged in hot HI–HCOOH, although we had expected that it would be converted into the dipyrrylmethene and thence into the fully methylated phyllopyrrole, *cf.* dipyrrylmethenes from pyrroles and HBr–HCOOH (5*h*). The methylations and ethylations were also clean. On the other hand, it was clear from the r.r.t.'s of the reference pyrroles that overlapping peaks would limit the usefulness of counting methods, *e.g.* the situation in example (*c*) would be confused with that in (*d*) because the pyrroles **21** and **23** appear under one peak.

The assumption in Scheme 1 governing the reduction remained to be tested. Twelve typical porphyrins of known structure were reduced in HI–AcOH at 110° and the products were submitted to g.l.p.c. before and after alkylation, the latter being effected by adding paraformaldehyde or paraldehyde to the mixture and continuing the heating. Mass spectra were used only occasionally for they do not readily distinguish

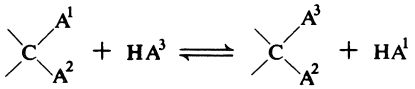
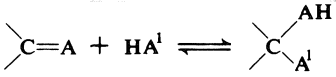
isomeric alkyl pyrroles with the same substituents (21). Chromatograms like those in Charts 1 and 2 were obtained only after several sources of extraneous peaks had been eliminated; this was our major effort. The peaks to the right of the ester peaks in Chart 2 correspond to incompletely removed alkyl pyrroles and become more obvious when shifted by alkylation. The numbers identifying the pyrroles correspond to those of the pyrroles in Tables 1 and 2.

The validity of the assumption (Scheme 1) may be judged by the extent to which the chromatograms represent the examples (Tables 1 and 2) or composites thereof. A subjective element exists here whenever the base lines depart from the horizontal, but the following general remarks apply equally to the chromatograms not reproduced here. There were no peaks in the chromatograms not attributable to pyrroles even when the yields were low, and although the g.l.p.c. detector is less specific than the diazonium salt or chlorine-benzidine used in the paper chromatography of pyrrole dicarboxylic acids or the t.l.c. of maleinimides. In particular, reduced pyrroles were not detected, *cf.* (12*b*). An unexpected pyrrole peak appeared among the esters from pyrophaeophorbides, and others appeared among the alkyl pyrroles if these pigments were first reduced with potassium borohydride (see below). Otherwise all the definite peaks were anticipated. This was surprising if only because any "scrambling" of the porphinogens in hot acid[6] would result in the loss of translocation of bridges.

[6]"Scrambling" refers to intermolecular redistribution reactions of porphinogens in hot acid leading to new porphinogens in which the pyrrole nuclei are randomized (22) and added formaldehyde may form the bridges (23). Analogous reactions have been observed in dipyrrylmethanes (24) and in their meso-alkyl derivatives (25); the latter may also lose their bridges with KOMe—MeOH at 220° (6, 26). It will be clear from the following expressions that the reductive C—C fissions and "scrambling" have the same structural requirements, and that the latter is analogous to many more familiar reactions:



a special case of which is



where A, A^1, A^2, A^3 are defined as above. Syntheses of unsymmetrical dipyrrylmethanes and dipyrrylmethenes may give symmetrical products in the same way.

The chromatograms also showed significant peaks corresponding to all the expected pyrroles. Although this was meaningless when a peak represented more than one pyrrole, some components appeared alone when other porphyrins were reduced, and some others could be identified unambiguously after the pyrroles were alkylated (see comments on the chromatograms below). In the absence of evidence to the contrary, it may reasonably be assumed that all the expected pyrroles will appear on the chromatograms, and some significance may be attributed to their absence. Incidentally, stoichiometry requires equal amounts of 2,5-dialkylpyrroles and 2,5-free pyrroles except from phaeophorbides, and the somewhat larger amounts of the former may reflect their greater stability.

Aside from the extra peaks mentioned above, the assumption underlying Scheme 1 appears to be justified, and the chromatograms can be inferred from the structures of the porphyrins. However, the structural information available from the chromatograms is limited by overlapping or ambiguous peaks and by other factors. When less than four differently substituted nuclei are found, qualitative data will not show when this is because two or more are identically substituted, and awkward possibilities then arise unless it can be assumed that large substituents are absent and all the products appear on the chromatograms. For this reason, and because the peripheral substituents would not all be ordered unless there were four different meso-substituents, the structures of more complex porphyrins will be more completely determined. The following discussion of the chromatograms will illustrate this and introduce some variations in the method.

The chromatograms of the alkyl pyrroles and pyrrole esters from hemin (Charts 1 and 2) and the r.r.t.'s of the reference pyrroles (Tables 1 and 2) define all the substituents about two pyrrole nuclei as those in examples (*a*) and (*g*). Ignoring the r.r.t.'s in each case, the patterns before and after methylation indicate unambiguously two different peripheral substituents, neither H, and no meso alkyl substituents. Only two differently substituted pyrrole nuclei are identified but the peripheral substituents on a third are also as in example (*a*) because the yields of the alkyl pyrroles were 64% of 2 mol before methylation and 70% after; the yield of the esters was 42%, 35% after methylation and 18% after

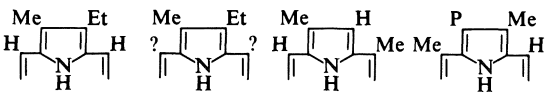
ethylation. Largely because only two differently substituted nuclei are identified, the chromatograms would not exclude a structure with three nuclei as in (*a*) and one as in (*g*), or a large substituent, but a meso methyl or ethyl group is excluded. The chromatograms of the alkyl pyrroles from hemin, etioporphyrin *1*, pyrophaeophorbide-*a*, and Chlorobium chlorophyll 650 fraction 4 were essentially the same, as were those of the pyrrole esters from hemin, coproporphyrin *3*, and deuteroporphyrin *9*.

The peaks in the chromatograms from 1,3,5,7-tetramethyl-2,6-diethyl-4,8-di-*n*-propyl-porphin are identified by their r.r.t.'s as the pyrroles from (*a*) and (*b*). The composite pattern alone is ambiguous but it illustrates the simplification of pyrrole mixtures and one method for the resolution of composite peaks by alkylation.

The chromatograms of the alkyl pyrroles from deuteroporphyrin *9* and the r.r.t.'s of the reference pyrroles identify a nucleus substituted as in (*c*). The unmethylated pyrroles were run at a lower temperature here to reveal 3-methylpyrrole. After ethylation, the chromatogram (not shown) was like that of the ethylated pyrroles from hemin. The pattern alone correctly shows the unsubstituded meso positions and peripheral hydrogen. However, as the pyrroles **2** and **3** run together as do **21** and **22** (see the chromatograms from hemin), the pattern is that of a nucleus without meso or peripheral substituents. The chromatograms of the alkyl pyrroles from deuteroporphyrin *9* and from methyl 1,4,5,8-tetramethylporphin-2,3,6,7-tetracarboxylate were essentially the same.

The chromatograms of the alkyl pyrroles from diacetyl-deuteroporphyrin *9* were like those from deuteroporphyrin *9*, the acetyl groups being lost. However, their presence was evident when diacetyl-deuteroporphyrin was first reduced with potassium borohydride to hematoporphyrin. When the latter was reduced with HI–AcOH, the chromatogram showed the peaks of **12**, **13**, **16** together with unidentified peaks with higher r.r.t.'s, but no peaks of **2**, **3**, or **5**.

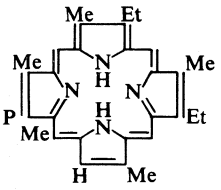
The r.r.t.'s of the alkyl pyrrole peaks from phyllochlorin except those marked **1**, **3**, **6**, and **14**, identify a nucleus substituted as in (*a*). Their yield was 49% of 2 mol as **9**, **13**, and **16**, aside from the contribution of **12**. This requires a second nucleus with peripheral substituents as in (*a*) wherein one meso-substituent might be a large alkyl group but not methyl. The remaining alkyl peaks and the ester peaks then each represent a single nucleus. The pyrrole **1** is identified unambiguously, the distinctive peak of 2-ethyl-3-methylpyrrole (r.r.t. 0.46) is absent, and alkyl groups moderately higher than ethyl would be evident after alkylation. The other set of alkyl pyrrole peaks is then either **1**, **3**, **6**, and **11** as indicated, or **1**, **2** with **3**, and **5**; these represent nuclei substituted as in (*f*) or (*c*), respectively. In principle, the two sets could be distinguished by propylation: were **5** present, it would appear among the products as the distinctive peak of 2,4,5-trimethyl-3-*n*-propylpyrrole; the data are in Table 3. The method is not yet practicable because a small peak coinciding with this one has not yet been eliminated from the propylation blank. Another way of distinguishing the two sets appears to have been found. When **11** and **12** are methylated to **18** and **16**, respectively, **11** disappears in 70 min, **12** in 25 min; **6** is equivalent to **11** here, to which it is even more rapidly methylated. The persistence of the **12**/**11** peak after methylation (1 h but not much longer) can then be attributed to **11** and **6**, and there is a nucleus substituted as in (*f*). A fourth nucleus is identified as in (*h*) by the chromatograms of the esters. As the latter represent only one nucleus, a favorable situation typical of many chlorophyll derivatives, their pattern alone would identify the meso-substituents. The following nuclei are then determined.



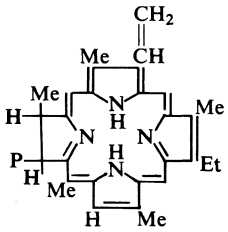
(*a*) (*f*) (*h*)

The meso-substituents on the second of these must be H, the only one allowed (see above) which has counterparts on the other three nuclei. The nuclei may be assembled in only four ways. One represents the skeleton of phyllochlorin, and the other three differ in the order of the peripheral substituents (Me and Et) on rings 1 and 2. The chromatograms from γ-phylloporphyrin *15* differed from these only in being cleaner, in having the shoulder of **31** better developed, and in the higher yields (alkyl pyrroles 70%, esters 39%).

Chromic acid oxidation will reveal the reduced ring 4 in phyllochlorin as a succinimide but it will not distinguish between 120 skeletons, *i.e.* 96



γ-Phylloporphyrin **15**



Phyllochlorin

phylloporphyrins, and 24 pyrroporphyrins which lack the meso methyl group. Not only is the meso methyl group easily identified and located by reduction, but its presence allows the structure of the porphyrin to be more completely determined, for the substituents on the two flanking nuclei can then be ordered.

From pyrophaeophorbides (see above), Scheme 1 requires the usual number of pyrroles from rings 1 and 2 but not from rings 3 and 4. One mode of fission between the latter would yield only four non-volatile derivatives of 1-(3-pyrryl)-3-(2-pyrryl)-propanone-1. The other fission would yield two pyrrole esters from ring 4, as in examples (*i*), (*j*), (*k*) (Table 2), and two ketocyclopenteno-pyrroles from ring 3. Presumably the higher r.r.t.'s of the last two would prevent their appearance with the alkyl pyrroles, and no serious attempt was made to detect them. Despite the threat of fissions about the carbonyl group, the chromatograms from the pyrophaeophorbides conform to this model except that an extra peak (r.r.t. 1.91 before alkylation) appears with the esters. As the same peak appeared whether the 5-position on ring 3 bore methyl or ethyl groups, it presumably represents ring 4. However, it has not yet been identified with any of several pyrrole – 2-propionic acids and pyrrole – 3-propionic acids made for the purpose. In the interpretation of the chromatograms, it can only be ignored in the hope that its ultimate identification will be revealing rather than confusing, *cf.* other extra peaks discussed below. It was most obvious among the peaks of the pyrrole esters from pyrophaeophorbide-*a*, least so among those from Chlorobium phaeophorbide 660 fraction 5.

We have studied only three pyrophaeophorbides, the Chlorobium phaeophorbides 660 fraction 5 and 650 fraction 4, and pyrophaeophorbide-*a*; no phaeophorbides bearing the 10-carbomethoxy group were examined. Chlorobium phaeophorbide 660 fraction 5 provides a model for the identification of the meso alkyl groups in the higher Chlorobium phaeophorbides 660, and for the confirmation of their location on the δ-positions. The structures of the lower members, fractions 5 and 6, had been determined, in part, by degrading them to δ-phylloporphyrins. This method was impracticable with the higher members because their degradations involved progressively lower yields, and some of these fractions occurred in relatively small amounts. The comparison of the results from the Chlorobium phaeophorbides 660 fraction 5 and 650 fraction 4, or from the latter and pyrophaeophorbide-*a*, were instructive because the two former differ only on the δ-position and the latter two differ significantly only on ring 3. The results from Chlorobium 650 fraction 4 and from pyrophaeophorbide-*a* suffice for these comparisons, but they are limited by the availability of the former, and by the yield of pyrroles from the latter: alkyl pyrroles 45% of 2 mol, esters 9% before methylation and 7% after.

As expected, the chromatograms from Chlorobium phaeophorbide 650 fraction 4 and from pyrophaeophorbide-*a* were the same. The 2-substituents on both were reduced to ethyl, and the pyrroles from ring 3 were not represented. The chromatograms of the alkyl pyrroles, the same as those of the alkyl pyrroles from hemin, identified one nucleus substituted as in example (*a*), but the yields were not high enough to reveal the second. It is typical of this method that no such difficulty would arise were rings 1 and 2 differently substituted as in all the higher Chlorobium phaeophorbides. Provided the anomalous peaks are ignored, the chromatograms of the esters and the r.r.t.'s of the reference pyrroles require a nucleus substituted as in (*i*), and the absence of a meso-substituent on the δ-position is revealed by the pattern alone.

The chromatograms of the alkyl pyrroles from Chlorobium phaeophorbide 660 fraction 5 (yield 75% of 2 mol) require a nucleus as in example (*a*) giving rise to the pyrroles **9**, **12**, **13**, **16**, and a second nucleus with the same peripheral substituents giving rise to **21** (as indicated) or **23**. All the cognates of **21**, *i.e.* **9**, **12**, and **17** from a nucleus as in (*e*), would be accommodated under the other peaks. All those of **23** would not, for 2,3-diethyl-4-methylpyrrole would be a distinct peak of r.r.t. 1.62. In the absence of this pyrrole, propylation confirmed **17** unambiguously (Chart 3 and the r.r.t.'s in Table 3), and thus the second

*The substituents on a pyrrole are defined by the position of its r.r.t. in the Table. In each temperature group the r.r.t.'s are relative to the R_f of the pyrrole whose r.r.t. (1.00) is in italics. A single note or reference appended to an r.r.t. refers to the preparation of the pyrrole in quantity. The first of two indicates the precursor from which the pyrrole was prepared *in situ* as described in the Experimental; the second gives the source of the precursor. (*a*) See Experimental, (*b*) from the corresponding 2-carbethoxypyrrole, (*c*) from the 3-carbethoxypyrrole, (*d*) from the 4-carbethoxypyrrole, (*e*) from the 5-carbethoxypyrrole, (*f*) from the 2,4-dicarbethoxypyrrole, (*g*) from 2,4-dimethyl-3-carbethoxypyrrole, (*h*) from the 2-carboxy-5-carbethoxypyrrole, (*i*) from 2-carbethoxy-3-methyl-4-bromo-5-carboxypyrrole, (*j*) from 2,3-dimethyl-5-carbethoxypyrrole, (*k*) from 2,5-dimethyl-3-carbethoxypyrrole, (*l*) from 2,5-diethyl-3-carbethoxypyrrole. P = CH_2CH_2COOH, P^{Me} = CH_2CH_2COOMe.

nucleus is as in (*e*). Mass spectra across the **17**/**16** peak gave no indication that it was even partially resolved. The anomalous peak is much reduced in the chromatograms of the esters here. These (yield 25%), with the r.r.t.'s of the reference pyrroles, identify a third nucleus as in (*j*); the pattern alone would indicate the meso-substituents. The pyrrole ester **33** was further identified under its g.l.p.c. peak by its mass spectrum, in which the mass peaks were those calculated and in the ratio found with the reference pyrrole: M = 195, $M - CH_3$, $M - CH_2COOMe$, $M - CH_2$-CH_2COOMe. As the **33** peak was undiminished when the HI–AcOH used had previously been heated with cryptopyrrole, it did not arise through scavenging (see under Reference Pyrroles below).

In connection with these chromatograms, it should be noted that propylation also confirmed **16** and **21** as tetraalkyl pyrroles by a method which, unlike methylation or ethylation, could not produce them from lower homologues. Further, if the analytical problem is only that of the meso alkyl group, the identification of **16** excludes its presence on the α-position. Finally, the δ-methyl group here is even more favorably situated than the γ-methyl group in phyllochlorin, for the derived pyrrole esters are better separated by g.l.p.c. Presumably there should be no difficulty in identifying and locating the meso alkyl groups in small amounts of the higher Chlorobium phaeophorbides 660.

Analytically, the isocyclic ring in chlorophylls has been identified only indirectly, and its presence prevents the identification of ring 3 by chromic acid oxidation. The indirect methods, except successive degradations, may be capriciously invalidated by other structural features. For example, the characteristic visible spectrum associated with the isocyclic ring in phylloerythrin is shared by cyclic lactones, but is not evident in phylloerythrin derivatives if the carbonyl group is reduced or if there is a δ-methyl substituent. *A priori*, the identification of the isocyclic ring and ring 3 as a cyclopentenopyrrole, after HI–AcOH reduction, appeared more promising with desoxo-phylloerythrin than with pyrophaeophorbides wherein the isocyclic ring might be labilized by the keto group. As other analytical methods take advantage of the keto group in one way or another, the reduction of desoxo-phylloerythrin was also interesting because its analogues among the petroporphyrins involve the same analytical problem.

The chromatograms of the alkyl pyrroles from desoxo-phylloerythrin showed the peak of **39** before (Chart 4 and the r.r.t.'s of the reference pyrroles in Table 3) and after methylation, as well as the usual alkyl pyrroles from rings 1 and 2. To make the pyrophaeophorbides amenable to this method, conveniently and on the same scale, their keto groups were first reduced with potassium borohydride to carbinole groups (27) which would be reduced to methylene by HI–AcOH, *cf.* the reduction of 9-hydroxy-desoxo-phyllo-

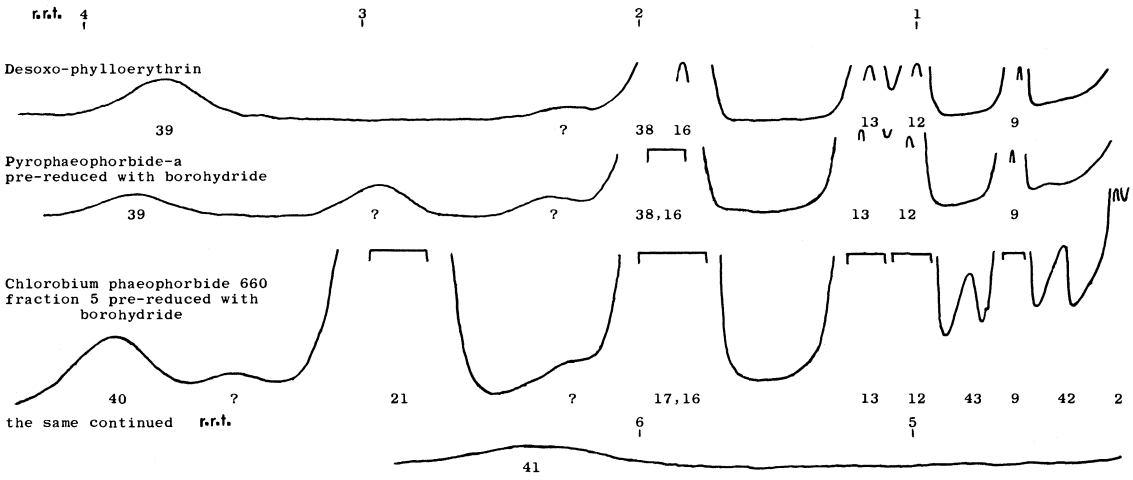

CHART 4. The g.l.p.c. of cyclopenteno-pyrroles and alkyl pyrroles from desoxo-phylloerythrin and from pre-reduced pyrophaeophorbides at 75°.

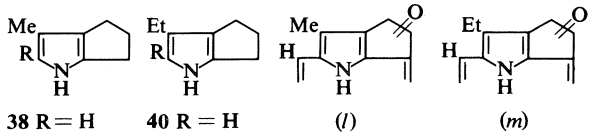
erythrin (*5i*). The chromatograms of the alkyl pyrroles from the modified pyrophaeophorbide-*a* then showed the peak of **39** before and after methylation. Those from the modified Chlorobium phaeophorbide 660 fraction 5 showed the peaks of **40** and **41** before methylation, and **41** after; this distinguishes **40** from **39**. Two of these pyrroles were also identified under their g.l.p.c. peaks by their mass spectra, in which the mass peaks were those calculated and in the ratios found with the reference pyrroles: **39** from desoxo-phylloerythrin (*M* = 135, *M*−*1*, *M*−*15*); **40** from the phaeophorbide 660 (*M* = 135, *M*−*1*, *M*−*15*, *M*−*29*). When the alkyl pyrroles from both the modified and unmodified Chlorobium phaeophorbide 660 fraction 5 were chromatographed at 135°, minimal amounts of **40** and **41** were also apparent in the latter, about 1/40 of the amounts in the former, and not enough to be detected in chromatograms run at 75°. In view of the contrasting results before and after borohydride reduction, but ignoring the possibility of other labile groups on the isocyclic rings, the nucleus (1) is determined in pyrophaeophorbide-*a* and (*m*) in Chlorobium phaeophorbide 660 fraction 5.

The remaining peaks (Chart 4), like the anomalous peak among the esters, differ from all others previously discussed. Although definitely located, they are not always present, and their absence may then have no significance. Those identified below arise through side-reactions not contemplated in Scheme 1, without firm precedents, and apparently dependent on structural factors remote from the groups involved. Further, they represent by-products and thus a second set of pyrroles from one nucleus.

The r.r.t.'s of three peaks in the chromatogram from Chlorobium phaeophorbide 660 fraction 5 (Chart 4 and Table 3) identify the pyrroles **43**,

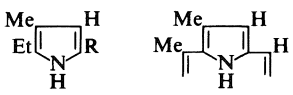


38 R = H
39 R = Me

40 R = H
41 R = Me

(*l*)

(*m*)



42 R = H
43 R = Me

(*n*)

42, and thus **2** rather than **3**. A second reduction showed the peak of **42** better developed but neither **43** nor **2**; a third confirmed these as **14** after methylation. If the pigment was not first reduced with potassium borohydride, these peaks were barely noticeable or absent. The three pyrroles require the nucleus (*n*), and this must result from the partial loss of a labile C_2 group (the α-hydroxy-ethyl group on ring 1) from a precursor of (*e*). If two carbons of the isocyclic ring were lost, pyrroles isomeric with the above would be formed from ring 3 but their r.r.t.'s would be different. The identification of (*n*) through a set of peaks here is more convincing than it would be through a single peak, *e.g.* of a maleinimide.

The behavior of pyrophaeophorbide-*a* suggests that vinyl groups may also be partially lost. About half the chromatograms from this pigment, whether or not it was prereduced with borohydride, showed very small but sometimes sharp peaks of **5** and **2** or **3**. These might arise from ring 1 if the vinyl group were lost, or from ring 3 if two carbons of the isocyclic ring were lost; the latter is unlikely, particularly in view of the behavior of Chlorobium phaeophorbide 660 fraction 5.

Presumably vinyl groups and α-hydroxy-ethyl groups would behave similarly here in the strong acid and, in contrast to acetyl groups (*cf.* diacetyldeuteroporphyrin *9*), they are both largely reduced to ethyl if not completely so (*cf.* hemin). More evidence is required, but it seems that these side-chains will be identified but not distinguished by their partial loss, provided that other structural factors are favorable. If this be so, the nuclei in Chlorobium phaeophorbide 660 fraction 5 identified as (*e*) and (*n*) are derived from (*o*); the other nuclei present were defined as (*a*), (*m*), and (*j*). The assembly of these yields the skeleton of the pigment except for the order of the substituents on ring 2. It also identifies a modified ethyl group on ring 1 and a carbonyl group in the isocyclic ring (see Fig. 1).

Aside from the question of the meso-substituent in Chlorobium chlorophyll 660 fraction 5, purely analytical methods had not ordered the substituents on rings 1, 2, or 4, and the evidence for the isocyclic ring was more indirect than usual. However, although the reductive method would have shown to its best advantage here, it would not have solved the essential analytical problem: the unspecified order of the substituents on ring

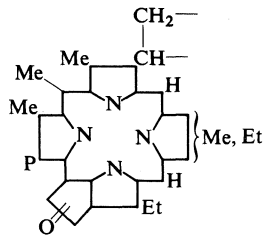

FIG. 1. The skeleton of Chlorobium phaeophorbide 660 fraction 5 derived by reductive degradations.

2 would have necessitated the degradation of the pigment to a phylloporphyrin or, the meso-substitution being known, a pyrroporphyrin for comparison with synthetic material.

These reductions suggest an alternative to a second component, in addition to porphobilinogen, in some studies of the biosynthesis of porphyrins. The abundance of the parent ions in the mass spectra of the pyrroles from a pigment would show which, if either, of the nuclei adjacent to a bridge was derived from the porphobilinogen contributing that bridge. This would require that the pigment was formed from a mixture of natural and doubly labelled porphobilinogen (*e.g.* from δ-aminolevulinic acid-5-^{13}C), and that the pyrroles were sufficiently distinguished by their β-substituents.

The Reference Pyrroles and Their Relative Retention Times

Table 3 gives the r.r.t.'s of most of the pyrroles expected from the chlorophylls, of some isomers from which these pyrroles should be distinguished, and of all the *C*-methyl, *C*-ethyl, and *C*-methyl-ethyl pyrroles. The pyrrole – propionic acids were chromatographed as their methyl esters; a few of the free acids were run for comparison but they had longer retention times and their peaks showed tailing. The pyrrole esters from uroporphyrin, and higher alkyl pyrroles such as the 2,3- and 3,5-dimethyl-4-*n*-octadecylpyrroles can be chromatographed at 180–210° but are not reported here.

We had made few alkyl pyrroles on a preparative scale, and these had usually been stored as their more stable carbethoxy derivatives. Consequently, with few exceptions, the alkyl pyrroles were prepared from carbethoxy derivatives (1 mg) by decarboxylating the latter in HI–AcOH at 110°. If the product was to be alkylated, an aldehyde was added and the mixture was heated again

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

before being worked-up for chromatography. The same procedure was used to reduce the porphyrins and chromatograph their pyrroles. It should be noted that β-alkyl pyrroles may be obtained from their tricarboxylic acid-diesters in HI–AcOH at the dilution used here. We had first decarboxylated the latter to dicarboxylic esters in the belief that tricarboxylic acids would not be decarboxylated (see Table 3).

The general reliability of decarboxylations in HI–AcOH is implicit in much of Fischer's work, *cf.* (*5b*), and the alkylations were restricted to types which had offered no difficulty (28). However, the usual controls on the identities of the products were impracticable here and it was assumed that the chromatograms would reveal any anomalous products. In some cases the identities of the pyrroles were confirmed chromatographically by comparison with bulk products, or with the same pyrroles from different precursors; all the important pyrroles were also obtained by reducing porphyrins.

The only apparent failures obviously arose from the instability of the pyrroles in HI–AcOH. Pyrrole itself is decomposed in HI–AcOH, and its 2,5-dialkyl derivatives are not sufficiently stable in the acid at temperatures above 90°; in neither case do the decomposition products appear on the chromatograms. In other cases only the side-chains are degraded. As *t*-butyl groups are easily split off from aromatic nuclei (29, 30), it was not surprising that HI–AcOH converted 2,4-dimethyl-3-*t*-butyl-5-carbethoxypyrrole into 2,4-dimethylpyrrole. Neither *i*-propyl nor *sec*-butyl groups were lost from analogous pyrroles, but the *sec*-butyl group was degraded to ethyl etc. though to a negligible extent. As noted above, none of these unstable pyrroles would be expected from natural porphyrins.

In about 75% of the decarboxylations only one pyrrole appeared on the chromatogram and its r.r.t. was consistent with those of its homologues. In the remaining decarboxylations, which usually involved 3- or 4-carbethoxypyrroles, there were in addition one or two unidentified peaks which usually represented <5% of the product. However, a second peak representing 20% of the product accompanied that of 2-ethyl-5-methylpyrrole.

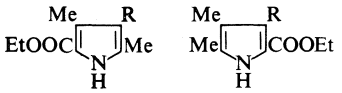
When precautions were taken (see Experimental), neither methylation nor ethylation introduced further complications but extra peaks were often noted after propylations, and these also appeared in the blank.

The purification of the ether used eliminated some extra peaks. Others arose during the esterification of the pyrrole – propionic acids with diazomethane. Some of the latter were eliminated when the diazomethane was prepared from *N*-nitroso-*p*-toluenesulfonylmethylamide rather than from *N*-nitroso-methylurea, *cf.* (31), but two further peaks of r.r.t. 2.0 and 2.2 were only eliminated when the ethereal diazomethane was purified by washing it with concentrated aqueous ammonia; ammonia does not interfere with the esterification, *cf.* (32). Other extra peaks were finally traced to the *C*-methylation of the pyrrole – propionic acids (but not their esters) by ethereal diazomethane when catalyzed by traces of water or, more effectively, the solution from which the acids had been extracted. This was most obvious when the peak of methyl phyllopyrrole-carboxylate accompanied the expected peak of methyl cryptopyrrole-carboxylate. This *C*-methylation was prevented by drying the ether solution of the acids with $MgSO_4$, an excess of which lowered the yield. The esterifications were also slower in the absence of water. A possible source of extra peaks was eliminated when it was found that diazomethane would not bring about the base catalyzed trans-esterification of the pyrrole methyl esters in the presence of ethanol or ethyl acetate.

Although we had anticipated the alkylation of pyrroles in HI–AcOH through scavenging, it was demonstrated in only one case. When crystalline opsopyrrole-carboxylic acid was esterified by diazomethane in dry ether, the chromatogram showed only the one expected peak of **28**. If it was esterified in wet ether, a small peak of the *C*-methyl derivative **30** was also evident. If it was first heated in HI–AcOH, a third and smaller peak corresponding to **33** appeared in heavily loaded chromatograms; this peak did not appear if the HI–AcOH used had first been heated with cryptopyrrole. Evidently this alkylation is both insignificant and easily eliminated.

Some of the carbethoxypyrroles were obtained in roundabout ways merely because the materials were at hand. Aside from this, the more important ones were obtained as follows, *cf.* (33).

The Knorr synthesis gave **44** (R = COOEt, $COCH_3$, or CH_2CH_2COOEt (34)), thence successively **44** (R = COOEt → COOH → H →



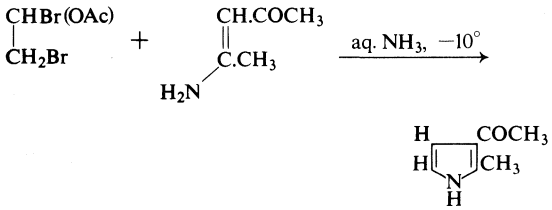
44 **45**

alkyl), but **44**, (R = $COCH_3$ → Et). If higher acylacetates or diethyl β-ketoadipate were used in the ring synthesis, the methyl groups were replaced by others.

The pyrroles **45** (R = H or Et) were obtained via the Hantzsch synthesis, thence **45** (R = H → alkyl) (33). If a higher acylacetate was used in the ring synthesis, the α-methyl group was replaced by another.

The α-methyl groups in **44** and **45** were converted successively to COOH, halogen or H (35), and alkyl; alternatively to CH_2Br then CH_2R (36). Pyrroles with higher α-alkyl groups were thus obtained without the use of higher acylacetates in the ring synthesis.

The only unconventional pyrrole ring synthesis used represents a further extension of the Hantzsch synthesis wherein acetylacetone (as its imine) replaces the acylacetate



A list of Hantzsch syntheses given earlier (33) did not include that of 2-methyl-3-cyanopyrrole from diacetonitrile (37) or that of 2-(α-pyridyl)-3-carbethoxypyrrole from α-pyridoylacetic ester (38). A third such synthesis (39) had given a low-melting 2,5-dimethyl-4-ethyl-3-carbethoxypyrrole, *cf.* (28), from questionable 3-chloropentanone-2 (40). We regret that our demonstration (33) that the 2,3-dimethyl-5-carbethoxypyrrole of Fischer and Fink (41) was contaminated with the 4-methyl derivative had been anticipated (42).

Experimental

The ether used was reagent grade anhydrous ether, washed twice with acidified aqueous ferrous sulfate, three times with water, then stirred 15 min with anhydrous $MgSO_4$; it was then distilled and the center 60% was stored < 10 days in the dark at 0°.

Diazomethane: distilled ethereal diazomethane, from *N*-nitroso-*p*-toluenesulfonylmethylamide using Carbitol (52), was stirred magnetically at 0° with 1/2 volume of concentrated aqueous ammonia for 20 min. The ether layer was stored at 0° in the dark over KOH (1 pellet/2 ml) for less than 1 week, but > 24 h if it was essential to avoid *C*-alkylation. Solutions < *ca.* 0.5 *M* gave lower yields of esters.

The paraformaldehyde gave no trouble but some lots of paraldehyde were rejected because they gave peaks in the blank; no specimens of propionaldehyde or parapropionaldehyde were consistently satisfactory in this respect. Hemin (Eastman) was converted into deuterohemin, thence into deuteroporphyrin, or into diacetyldeuterohemin and diacetyl-deuteroporphyrin (5). Etioporphyrin *I* (51), 1,3,5,7-tetramethyl-2,6-diethyl-4,8-di-*n*-propylporphin (51), desoxo-phylloerythrin (51), methyl 1,4,5,8-tetramethylporphin-2,3,6,7-tetracarboxylate (53), and coproporphyrin *3* (35) had been made previously. Pyrophaeophorbide-*a*, phylloporphyrin (54), and phyllochlorin (55) were from H. Fischer's collection, the Chlorobium phaeophorbides (56, 57) were from A. S. Holt's.

The Borohydride Reduction of Chlorobium Phaeophorbide 660 Fraction 5

The pigment (1 mg) was dissolved in 2 drops of pyridine. Methanol (50 ml) was added then potassium borohydride (100 mg) in methanol (1 ml) was dropped in. The solution was stirred for 1 h then shaken with ether and 4% HCl. The pigment in the acid layer was brought into fresh ether. This was washed with water, dried ($MgSO_4$), and evaporated.

The Reduction of Porphyrins or the Decarboxylation of Carbethoxypyrroles

As the chromatograph was not programmed, separate reductions were carried out to furnish the alkyl pyrroles and the pyrrole esters from the pigments. Here and in subsequent steps the specified heating times and temperatures must not be exceeded, and the pyrroles should be protected as far as possible from light; otherwise the yields suffer.

Acetic acid (Anachemia reagent, 1.0 ml) then hydriodic acid (AnalaR 66%, stored at 0° but not decolorized, 0.5 ml) were added to the pigment (1 mg, higher concentrations lower the yield) or the carbethoxypyrrole (1 mg) in a 1.5 ml flask fitted with a stirring bar and a reflux condenser. The flask was then placed in a pre-heated oil-bath and stirred magnetically. Carbethoxy derivatives of the sensitive 2,5-dialkylpyrroles were heated 45 min at 90°; pyrophaeophorbides, desoxo-phylloerythrin, and diacetyl-deuteroporphyrin were heated 3 h at 105–110°; all other compounds 1.5 h at 105–110°.

The Alkylation of the Products

If the products were to be alkylated, 3 mg of paraformaldehyde or 0.01 ml of paraldehyde (or other aldehyde) were added to the cooled mixture; if paraformaldehyde was added before the pigments were reduced, extra peaks appeared in the chromatograms. The mixture was then heated again at 105–110° for 30 min or, when β-free pyrroles present were difficult to alkylate, 1 h. However, if methylated pyrrole esters were to be chromatographed, the mixture was heated for 30 min at 50°; a higher temperature resulted in lower yields and sometimes in an extra peak (r.r.t. 2.25) in the chromatograms.

The Extraction of the Alkyl Pyrroles

This procedure was the same whether or not the pyrroles were alkylated and whether alkyl pyrroles or esters were to be chromatographed.

The solution was decolorized with the minimum amount of phosphonium iodide (a few mg) (9), starting the reaction by returning the flask to the oil-bath for a few seconds. The solution was then colorless, very pale orange, or green (hemins); the turbidity, if any, was very slight.

The flask was fitted with a reflux condenser modified to trap the distillate, cooled, and placed in a 20° oil-bath. The solvent was removed at 5–10 mm with magnetic stirring as the bath was raised to 65–70° over 30 min. Only a film or a very little oil should remain on the walls of the flask or the yield will be lowered. When the products had been propylated, some extra peaks were minimized when the residue at this stage was kept 1 h at 65° and 0.05 mm. The flask was cooled in ice, and NaOH (1 ml of 10%) was added. The alkyl pyrroles were then extracted with 3 × 1 ml of ether at p*H* > 10.

If the alkyl pyrroles were to be chromatographed, the ether extracts were placed in a chilled tube and centrifuged (5 min), transferred to a 10 ml conical flask, and swirled at intervals over 15 min with anhydrous $MgSO_4$ (40 mg). The ether was transferred to a pear-shaped flask and removed at room temperature under a partial vacuum; unless care is taken, the more volatile pyrroles may be lost here. The residue was dissolved in ether: 1.0 ml if the product was derived from a carbethoxypyrrole, 0.10 ml if from a pyrophaeophorbide or desoxophylloerythrin, 0.25 ml if from another porphyrin and the products had been ethylated, 0.5 ml in all other cases. In every case, 2 μl of the ether solution was applied to the column.

The Preparation of the Pyrrole Esters

If the pyrrole esters were to be chromatographed, the flask containing the alkaline aqueous layer was placed in an ice-bath and stirred magnetically. Phosphoric acid (*ca.* 1 ml of 1 vol 85%:4 vol of water) was added until the mixture just began to turn congo red to black, and the pyrrole acids were extracted with 3 × 1 ml ether at p*H* 4.0. The extract was centrifuged for 10 min then transferred to a 10 ml conical flask.

When it was not essential to minimize *C*-methylation, 1 ml of ethereal diazomethane was added to the extract which was then kept in the dark for 45 min. To minimize *C*-methylation, the extract was stirred for 15 min in the dark with 40 mg of anhydrous $MgSO_4$, transferred to another flask, and esterified as above. In either case, the evaporation of the ether solution followed that of the alkyl pyrroles. The residue was dissolved in ether: 0.10 ml if the esters were derived from a pyrophaeophorbide or desoxo-phylloerythrin, or if the pyrroles had been ethylated; otherwise 0.5 ml. In all cases 5 μl were applied to the column.

Chromatography

A Pye Argon Chromatograph was used with glass columns packed with 0.5 × 117 cm of Chromosorb G (acid washed and treated with DMCS) with 5% SE-30. Unlike other columns (45), these do not separate the 2- and 3-methylpyrroles. Low-temperature column: 50 ± 0.1°, flow rate 171 ml/min, *ca.* 10.5 p.s.i., R_t of the 2,4-dimethylpyrrole standard 6.8 min; 75°, 171 ml/min, *ca.* 12.1 p.s.i., R_t of the cryptopyrrole standard 8.0. High-temperature column: 100°, 158 ml/min, *ca.* 16 p.s.i., R_t of the phyllopyrrole standard 5.4; 135°, 80 ml/min, *ca.* 10.1 p.s.i., R_t of the phyllopyrrole standard for alkyl pyrroles 2.4, R_t of the methyl cryptopyrrole-carboxylate standard for pyrrole esters 11.0. The sample was injected quickly through the open top of the column and as close to the packing as possible while the gas flow was interrupted; sophisticated methods gave poorer results. The R_t's were measured from the start of the ether peak. Yields were calculated from the areas under the peaks, assuming that the response of the detector was molar; bulk samples of cryptopyrrole and of methyl cryptopyrrole-carboxylate were used in calibrating for alkyl pyrroles and pyrrole esters, respectively, immediately before every determination of a yield.

2-Methyl-3-acetylpyrrole

Crude dibromovinyl acetate (from 43 g of vinyl acetate and 27.5 ml of bromine (43)) and 50 g of acetylacetoneimine were stirred into 400 ml of 28% aqueous ammonia at −10°. Stirring was continued for 18 h while the temperature rose slowly to 20°. The mixture was heated to 90°, cooled, and evaporated (rotary, 25 mm, 50° bath). The residue was mixed with 100 ml of water and made acid to congo red with hydrochloric acid then extracted with ether (4 × 200 ml). The extract was evaporated, the residue distilled (to 135°, 0.01 mm), and the distillate was crystallized from 100 ml of water (Darco) giving 6.1 g of colorless prisms, m.p. 95.5–96.5°. For analysis it was recrystallized from pentane (thimble) as colorless prismatic rods, m.p. 94.5–95.5° (lit. (58) 94–95°).

Anal. Calcd. for C_7H_9ON: C, 68.27; H, 7.37; N, 11.37. Found: C, 68.43; H, 7.48; N, 11.40.

To confirm its structure, it was methylated in HI–AcOH–paraformaldehyde to 2,4,5-trimethyl-3-acetylpyrrole (9), identified by m.p. and mixed m.p.

2-Methyl-3-ethylpyrrole

2-Methyl-3-acetylpyrrole (0.03 mol) was reduced with $LiAlH_4$ by the method given for 3-carbethoxy-pyrroles (33). The product was distilled (65°, 15 mm) as a colorless oil (78%).

Anal. Calcd. for $C_7H_{11}N$: C, 77.01; H, 10.16; N, 12.83. Found: C, 77.18; H, 10.32; N, 12.98.

Ethyl α-Oximinopropionylacetate

The crude oil (59) crystallized at 0° overnight. It was dried on tile, sublimed (60°, 1 × 10^{-4}), crystallized from pentane (thimble), and resublimed. Yield 7 g, m.p. 60–63° (lit. (49) 62°).

Anal. Calcd. for $C_7H_{11}O_4N$: C, 48.55; H, 6.40; N, 8.09. Found: C, 48.21; H, 6.58; N, 8.27.

2-Carbethoxy-3-ethyl-4,5-cyclopentenopyrrole

This was obtained like the 3-methyl analogue (49) using 6 g of ethyl α-oximinopropionylacetate, 10 g of cyclopentanone, 40 ml of AcOH, and 12 g of zinc dust. After the supernatant was diluted with 400 ml of water, the crude product separated at 0°. It was dried on tile, sublimed (85°, 1 × 10^{-4} mm), and crystallized thrice from absolute ethanol as colorless plates (138 mg), m.p. 113–115°.

2-n-Propyl-4-methyl-5-carbethoxypyrrole

2-*n*-Propyl-4-methyl-3,5-dicarbethoxypyrrole was obtained by the Knorr synthesis from 11 g of crystalline ethyl α-oximinoacetoacetate, 11 g of ethyl *n*-butyrylacetate, AcOH, and zinc dust at 65°. It formed colorless needles (38%), m.p. 115–118°, from ethanol. This ester (2 g) was converted into the 3-carboxylic acid in 20 ml concentrated H_2SO_4 at 40° for 35 min (*cf.* 2,4-dimethyl-5-carbethoxypyrrole (5*e*)). The acid was decarboxylated in refluxing ethanolamine (15 ml) for 40 min and the mixture was poured into ice-water. The product was extracted into ether, the extract was washed with water and the ether was evaporated. The residue was sublimed as colorless needles (44%), m.p. 55–57°. It was analyzed after conversion to the 3-*n*-propyl derivative (see below).

2,4-Di-n-propyl-5-carbethoxypyrrole

2,4-Di-*n*-propyl-3,5-dicarbethoxypyrrole (5*c*) was converted to the 3-carboxylic acid in concentrated H_2SO_4 as usual. The acid was decarboxylated in refluxing ethanolamine, and the product was precipitated by water. After sublimation it melted at 47–50°; yield from the diester 58%. It was analyzed as the 4-methyl derivative (see below).

2,3-Dimethyl-5-ethyl-4-carbethoxypyrrole

The Knorr synthesis was carried out with 2,3-butanedione monoxime, ethyl propionylacetate, and zinc dust in AcOH at 65°. The product was precipitated by water and crystallized from ethanol as needles, m.p. 102–103.5° (lit. (33) 99–101°).

2-Ethyl-5-acetyl-3-carbethoxypyrrole

Acetyl chloride (1.2 ml) in 2 ml of CS_2 was slowly added to a stirred mixture of 2-ethyl-3-carbethoxypyrrole (1 g (33)), powdered anhydrous $AlCl_3$ (0.8 g), and CS_2 (20 ml) at 0°. The mixture was then stirred for 4 h at 20° then poured into ice-water. This was extracted with ether and the extract was washed with 5% aqueous NaOH and with water. The extract was evaporated and the residual product was sublimed (105°, 1×10^{-4} mm), m.p. 119–122°; yield 70%.

2,5-Diethyl-3-carbethoxypyrrole

The corresponding 5-acetylpyrrole (above) was hydrogenated in ethanol over Raney nickel (120°, 1700 p.s.i., 4 h). The product was distilled as an oil (140–150°, 15 mm). The structure was confirmed by reductive alkylation to 2,5-diethyl-4-methyl-3-carbethoxypyrrole, m.p. and mixed m.p. 101–103° (lit. (28) 101–103°).

2-Ethylpyrrole and 2-Ethyl-5-carbethoxypyrrole

2-Ethyl-3-carbethoxypyrrole (33) was heated with 10% aqueous NaOH at 170° for 20 h in a Teflon lined screw-capped metal vessel. The resulting 2-ethylpyrrole (5*a*) was an oil (79%), b.p. 12 mm 59–61°. Using phosgene, just as with 2-methylpyrrole (43), this was converted to 2-ethyl-5-carbethoxypyrrole (70%), b.p. 15 mm 130°, m.p. 50–51° (lit. (5*e*) 48°).

Anal. Calcd. for $C_9H_{13}O_2N$: C, 64.65, H, 7.84; N, 8.38. Found: C, 64.60; H, 7.77; N, 8.38.

2-Ethyl-3-acetyl-5-carbethoxypyrrole

A solution of 2-ethyl-5-carbethoxypyrrole (2 g) and anhydrous stannous chloride (2 g) in 10 ml of acetic anhydride was heated to the boiling point, filtered hot, cooled, and mixed with excess 5% aqueous NaOH. The precipitate was distilled (120°, 1×10^{-4} mm), yield 47%, m.p. 100–101°.

2,3-Diethyl-5-carbethoxypyrrole

The corresponding 3-acetylpyrrole (above) was hydrogenated in ethanol over Raney nickel (170°, 1800 p.s.i., 6 h) and the product was distilled (60°, 1×10^{-4} mm); yield 53%, m.p. 60–62°.

Anal. Calcd. for $C_{11}H_{17}O_2N$: C, 67.66; H, 8.78; N, 7.17. Found: C, 67.83; H, 8.94; N, 7.33.

2-Carboxy-3-n-propyl-4-methyl-5-carbethoxypyrrole

The corresponding 2-methyl pyrrole (28) in dry ether was treated with sulfuryl chloride (3.3 mol) and the solution was then refluxed 1 h. The ether was evaporated at 20°, more ether was added and then evaporated, and hot aqueous sodium acetate was added to the residue. The mixture was boiled 10 min, cooled, and extracted with ether. The product was extracted from the ether into aqueous Na_2CO_3, and precipitated from the latter with acid. It formed needles (35%) from ethanol, m.p. 208–210°.

Anal. Calcd. for $C_{12}H_{17}O_4N$: C, 60.24; H, 7.16; N, 5.85. Found: C, 59.97; H, 7.04; N, 5.72.

2-Carboxy-3-i-butyl-4-methyl-5-carbethoxypyrrole

The corresponding 2-methyl pyrrole (9) was treated with sulfuryl chloride like the 3-*n*-propyl pyrrole above. The product was sublimed (130°, 1×10^{-4} mm) and crystallized twice from aqueous ethanol; yield 12%, m.p. 198–199°.

Anal. Calcd. for $C_{13}H_{19}O_4N$: C, 61.64; H, 7.56; N, 5.53. Found: C, 61.82; H, 7.44; N, 5.42.

2,4-Dimethyl-3-t-butyl-5-carbethoxypyrrole

A solution of 0.5 g of isobutylene in 0.5 g of concentrated H_2SO_4 was added to a stirred solution of 2,4-dimethyl-5-carbethoxypyrrole in 5 ml of acetic acid at 75° over 1/2 h. After a further 2 h at 75°, the mixture was poured into ice-water which was then brought to p*H* 8 with aqueous NaOH. The precipitated product was sublimed. The cubic crystals in the sublimate were separated manually and recrystallized twice from aqueous methanol, m.p. 108–110°, yield 6%.

Anal. Calcd. for $C_{13}H_{21}O_2N$: C, 69.92; H, 9.48; N, 6.27. Found: C, 69.73; H, 9.31; N, 6.45.

2-Carbethoxy-3-n-propyl-4,5-dimethylpyrrole

Hydriodic acid (*d* 1.95, 10 ml) was slowly added to 10 ml of stirred and cooled acetic acid; hypophosphorous acid (50%, 2 ml) was then added. 2-Carbethoxy-4,5-dimethylpyrrole (0.004 mol (28)) was added to the mixture at room temperature followed by propionaldehyde (0.008 mol). The solution was stirred 2½ h at *ca.* 25° then poured into 200 ml of water. This was made alkaline with ammonia, extracted with ether, and the ether was evaporated to leave the crude product. This was an oil which solidified after distillation (1×10^{-4} mm). It was recrystallized from aqueous ethanol then from ethanol, m.p. 101–104° (lit. (5*e*) 102°), yield 40%.

Anal. Calcd. for $C_{12}H_{19}O_2N$: C, 68.86; H, 9.15; N, 6.69. Found: C, 68.79; H, 9.02; N, 6.54.

2-Carbethoxy-3-n-propyl-4-methyl-5-ethylpyrrole

The crude product, obtained as above but using 2-carbethoxy-4-methyl-5-ethylpyrrole (33), was an oil which largely solidified after distillation (75°, 1×10^{-4} mm). It was dried on tile then crystallized from ethanol as long colorless needles (19%), m.p. 73–74°.

Anal. Calcd. for $C_{13}H_{21}O_2N$: C, 69.91; H, 9.48; N, 6.27. Found: C, 69.77; H, 9.32; N, 6.42.

2-Carbethoxy-3-i-butyl-4-methyl-5-ethylpyrrole

The crude product, obtained as above but using 2-carbethoxy-4-methyl-5-ethylpyrrole and isobutyraldehyde, solidified at 0° after distillation (70°, 1×10^{-4} mm). It was recrystallized twice from methanol, m.p. 53–55° (12%).

Anal. Calcd. for $C_{14}H_{23}O_2N$: C, 70.85; H, 9.77; N, 5.90. Found: C, 70.83; H, 9.86; N, 6.06.

2-Carbethoxy-3-ethyl-4-methyl-5-n-propylpyrrole

The crude product, obtained as above but using 2-carbethoxy-4-methyl-5-*n*-propylpyrrole (33) and paraldehyde, was crystallized from aqueous ethanol, sublimed, recrystallized and resublimed, m.p. 58–59.5°.

Anal. Calcd. for $C_{13}H_{21}O_2N$: C, 69.92; H, 9.48; N, 6.27. Found: C, 69.75; H, 9.50; N, 6.45.

2-n-Propyl-3-(2-carbethoxy-ethyl)-4-methyl-5-carbethoxypyrrole

3-(2-Carbethoxy-ethyl)-4-methyl-5-carbethoxypyrrole (0.4 g (35)), 5 ml of hydriodic acid, 5 ml of acetic acid, 1 ml of hypophosphorous acid and 0.23 ml of propionaldehyde were reacted as above. The solution was poured into 60 ml of water which was then brought to p*H* 5 with ammonia. The precipitate (of the partially hydrolyzed product) was esterified in 5 ml of 5% ethanolic HCl. The solvent was evaporated and the residue was distilled then recrystallized from pentane (0.1 g), m.p. 61.5–63.5° (lit. (36) 63–64°).

Anal. Calcd. for $C_{16}H_{25}O_4N$: C, 65.08; H, 8.53; N, 4.74. Found: C, 65.19; H, 8.40; N, 4.90.

2-Methyl-3,4-diethyl-5-carbethoxypyrrole

Acetic anhydride (20 ml) was stirred into 5 ml of concentrated hydrochloric acid with cooling. 2-Methyl-4-ethyl-5-carbethoxypyrrole ((5*e*), 0.004 mol), paraldehyde (0.008 mol), and zinc amalgam (20 mesh, 10 g) were added at 25° and the mixture was stirred 1/2 h. The solution was decanted into 200 ml of water, this was made alkaline with ammonia and the crude product was filtered off. It was purified by sublimation, m.p. 76–77° (lit. (5*e*) 75°). Yield 20%.

Anal. Calcd. for $C_{12}H_{19}O_2N$: C, 68.86; H, 8.96; N, 6.67. Found: C, 68.83; H, 9.15; N, 6.87.

2-Ethyl-3-n-propyl-4-methyl-5-carbethoxypyrrole

The crude product, obtained as above but using 2-ethyl-4-methyl-5-carbethoxypyrrole (5*e*) and propionaldehyde, was sublimed (80°, 1×10^{-4} mm), m.p. 86–87° (50%).

Anal. Calcd. for $C_{13}H_{21}O_2N$: C, 69.92; H, 9.48; N, 6.27. Found: C, 70.14; H, 9.31; N, 6.48.

2-Ethyl-3-i-butyl-4-methyl-5-carbethoxypyrrole

The crude product, obtained as above but using 2-ethyl-4-methyl-5-carbethoxypyrrole and isobutyraldehyde, was sublimed (80°, 1×10^{-4} mm) and recrystallized from aqueous ethanol, m.p. 94–96° (44%).

Anal. Calcd. for $C_{14}H_{23}O_2N$: C, 70.85; H, 9.77; N, 5.90. Found: C, 70.95; H, 9.59; N, 6.07.

2,4-Di-n-propyl-3-methyl-5-carbethoxypyrrole

The crude product, obtained as above but using 2,4-di-*n*-propyl-5-carbethoxypyrrole (above) and paraformaldehyde, was extracted with ether then sublimed (65°, 1×10^{-4} mm), m.p. 78–80° (17%).

Anal. Calcd. for $C_{14}H_{23}O_2N$: C, 70.85; H, 9.77; N, 5.90. Found: C, 70.72; H, 9.74; N, 5.98.

2,3-Di-n-propyl-4-methyl-5-carbethoxypyrrole

The crude product, obtained as above but using 2-*n*-propyl-4-methyl-5-carbethoxypyrrole (above) and propionaldehyde, was distilled (80°, 1×10^{-4} mm). The partially solidified distillate was dried on tile then recrystallized twice from aqueous ethanol as colorless needles (20%), m.p. 84–87°.

Anal. Calcd. for $C_{14}H_{23}O_2N$: C, 70.85; H, 9.77; N, 5.90. Found: C, 70.68; H, 9.53; N, 6.05.

2-n-Propyl-3-i-butyl-4-methyl-5-carbethoxypyrrole

The crude product, obtained as above using 2-*n*-propyl-4-methyl-5-carbethoxypyrrole (0.65 g) and isobutyraldehyde (0.5 g), was repeatedly sublimed (65°, 1×10^{-4} mm) and recrystallized to remove starting material which was evident in the g.l.p.c.; yield, 30 mg, m.p. 78–79°.

Anal. Calcd. for $C_{15}H_{25}O_2N$: C, 71.67; H, 10.03; N, 5.57. Found: 71.49; H, 10.21; N, 5.68.

2,4-Dimethyl-3-sec-butyl-5-carbethoxypyrrole

The crude product, obtained as above but using 2,4-dimethyl-5-carbethoxypyrrole with 2-butanone and stirring at 30–35°, was sublimed then thrice recrystallized from ethanol as colorless plates (130 mg), m.p. 102–104°.

Anal. Calcd. for $C_{13}H_{21}O_2N$: C, 69.92; H, 9.48; N, 6.27. Found: C, 70.08; H, 9.31; N, 6.26.

2,3,4-Triethyl-5-carbethoxypyrrole

The crude product, obtained as above but using 2,4-diethyl-5-carbethoxypyrrole (5*e*) with paraldehyde, was this time extracted by ether. The ether was evaporated and the residue was distilled. The distillate partially solidified at 0°. It was dried on tile at 0°, recrystallized from aqueous methanol and again distilled (30%), m.p. 47–49°.

Anal. Calcd. for $C_{13}H_{21}O_2N$: C, 69.92; H, 9.48; N, 6.27. Found: C, 70.00; H, 9.42; N, 6.12.

Ferrocene Studies. VII. 1,2-Disubstituted Ferrocenes[1]

E. Bradley Moynahan and Frank D. Popp
Department of Chemistry, Clarkson College of Technology, Potsdam, New York 13676

Received June 28, 1971

Further examples of the utility of the 2-lithiation of *N,N*-dimethylaminomethylferrocene are presented.

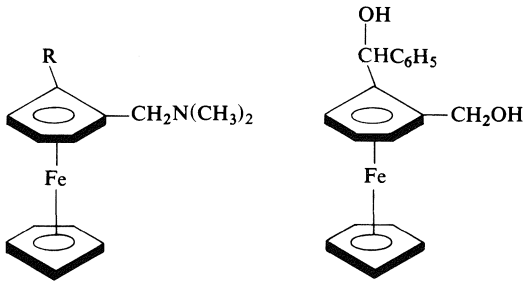
L'action du lithium sur la *N,N*-diméthylaminoéthylferrocène a été discutée (1). Cette réaction appliquée à d'autres exemples, constitue une voie d'accès importante aux ferrocènes disubstitués en −1,2.

Canadian Journal of Chemistry, **49**, 3565 (1971)

The lithiation of *N,N*-dimethylaminomethylferrocene has been discussed (1). We now report on further examples of this reaction as an important route to 1,2-disubstituted ferrocenes.

Earlier we reported (2) that the reaction of ferrocenyllithium with aromatic aldehydes gave aryl ferrocenyl ketones. The lithio derivative of *N,N*-dimethylaminomethylferrocene behaves in a similar manner with benzaldehyde to give the ketone **1** as a red oil which was characterized as its methiodide. Ketone **1** was previously obtained by another route (1) as a red oil characterized as its picrate. Reduction of the ketone **1** gave the alcohol **2**. Although treatment of the methiodide of **1** with potassium hydroxide yielded only decomposition products, a similar reaction of the methiodide of **2** gave rise to the diol **3**.

Reaction of ethylene oxide with the lithio derivative of *N,N*-dimethylaminomethylferrocene gave the alcohol **4** which was characterized as its hydrochloride.



3

1 R = $-\overset{\overset{O}{\|}}{C}-C_6H_5$

2 R = $-\overset{\overset{OH}{|}}{CH}-C_6H_5$

4 R = $-CH_2CH_2OH$

Experimental

2-Benzoyl-N,N-dimethylaminomethylferrocene (1)

To 20.0 g (84.2 mmol) of *N,N*-dimethylaminomethylferrocene in 100 ml of diethyl ether was added over a 10 min period at room temperature 42 ml of *n*-butyllithium in hexane solution (105 mmol). After stirring for 1 h, 26.8 ml of freshly distilled benzaldehyde was added dropwise. After further stirring at room temperature under nitrogen, 30 ml of water was added and the ether layer removed. The ether layer was washed with water, dried over magnesium sulfate, and concentrated *in vacuo* to give an oil. Chromatography of the oil on Grade II alumina gave 14.7 g of starting material eluted with benzene – Skelly solve B and 6.9 g of a red oil, **1**, eluted with chloroform–methanol; i.r. (neat): 1640, 1115, 1010 cm^{-1}. Addition of methyl iodide to an ether solution of the red oil gave a crystalline orange methiodide, m.p. 153° (with sintering from 100°); i.r. (KBr): 1630, 1110, 1005 cm^{-1}.

Anal. Calcd. for $C_{21}H_{24}FeINO$: C, 51.56; H, 4.95; N, 2.86. Found: C, 51.49; H, 4.90; N, 2.84.

2-(α-Phenylhydroxymethyl)-N,N-dimethylaminomethylferrocene (2)

2-Benzoyl-*N,N*-dimethylaminomethylferrocene (**1**) (1.5 g) in 20 ml of diethyl ether was added dropwise to 0.5 g of lithium aluminum hydride in 20 ml of diethyl ether. The mixture was then refluxed for 2 h and the excess lithium aluminum hydride was decomposed with water and base. The ether layer was extracted with 1:10 phosphoric acid which was then added dropwise to a stirred solution of saturated sodium carbonate. The resultant oil was extracted with ether, dried, and concentrated to give 1.22 g of yellow solid which was chromatographed on Grade II alumina using Skelly solve B – chloroform and recrystallized from Skelly solve B to give m.p. 108–109°; i.r.(KBr): 3060, 2975–2780, 1600, 1102, 1005 cm^{-1};

[1]For Part VI, see ref. 3.

n.m.r.: 2.32 (s, $2CH_3$), 3.57 (q, CH_2), 4.20 (m over s, 8FcH), 5.89 (s, CH), 6.37 (m, OH), 7.95 δ (m, 5 benzene H).

Anal. Calcd. for $C_{20}H_{23}FeNO$: C, 68.78; H, 6.64; N, 4.01; Fe, 15.99. Found: C, 68.74; H, 6.63; N, 3.97; Fe, 16.20.

2-(α-Phenylhydroxymethyl)-1-(hydroxymethyl)ferrocene (3)

The methiodide of **2** (0.322 g) was placed in 35 ml of 1 *N* potassium hydroxide solution, refluxed for 5 h, and filtered hot. After cooling, the solution was extracted with ether and the ether layer was washed with water, dried, and concentrated to give **3**, m.p. 117–118° from benzene–heptane; i.r. (KBr): 3325, 1115, 1005 cm^{-1}.

Anal. Calcd. for $C_{18}H_{18}FeO_2$: C, 67.10; H, 5.63. Found: C, 67.35; H, 5.81.

2-(β-Hydroxyethyl)-N,N-dimethylaminomethylferrocene (4)

N,N-Dimethylaminomethylferrocene (20.0 g, 82.4 mm) in 100 ml of diethyl ether was lithiated with 41.0 ml (103 mm) of *n*-butyllithium in hexane. After lithiation was complete, 14.4 g (0.33 mol) of ethylene oxide in 25 ml of diethyl ether was added dropwise with cooling. After the addition was complete the reaction mixture was allowed to warm to room temperature and stirred for 9 h. Water and 10% sodium thiosulfate solution were added and a large amount of polymeric material separated. The ether layer and ether washes of the reaction mixture were combined and extracted with 1:10 phosphoric acid. The acid extracts were added dropwise to 20% sodium carbonate solution and the resultant oil extracted with ether. The dried ether extract was concentrated to give an oil which was chromatographed on alumina to give 6.85 g of starting ferrocene and 5.86 g of *4* as a yellow oil; i.r. (neat): 3400, 3100, 1110, 1005 cm^{-1}. The yellow oil gave a hydrochloride, m.p. 165° (darkens from 145°); i.r. (KBr): 3300, 3100, 2650, 1110, 1005 cm^{-1}.

Anal. Calcd. for $C_{15}H_{22}ClFeNO$: C, 55.66; H, 6.85; N, 4.33. Found: C, 55.77; H, 6.92; N, 4.30.

Revisions of Structural Assignments for 1-Methyl-(3 and 5)-amino-4-nitropyrazoles and Related Compounds

Misbahul Ain Khan and Brian M. Lynch
Organic Chemistry Laboratory, St. Francis Xavier University, Antigonish, Nova Scotia

Received July 5, 1971

Amino proton chemical shifts recorded for the compounds described as 5-amino-1-methyl-4-nitropyrazole and the 3-amino isomer (3) are inconsistent with charge densities calculated from simple H.m.o. treatments.

Unequivocal synthesis of 5-amino-1-methyl-4-nitropyrazole from 5-amino-1-methylpyrazole proves that the assignments should be interchanged; the structures of compounds derived from these aminonitropyrazoles are revised accordingly.

Les déplacements chimiques des protons amino du composé décrit comme étant l'amino-5 méthyl-1 nitro-4 pyrazole ainsi que de l'isomère amino-3 (3), ne sont pas compatibles avec les densités de charge calculées par simple traitement H.m.o.

Une synthèse sans ambiguité possible de l'amino-5 méthyl-1 nitro-4 pyrazole à partir de l'amino-5 méthyl-1 pyrazole, prouve que les attributions doivent être interchangées; les structures des composés qui dérivent de ces aminonitropyrazoles ont été corrigées en conséquence.

Canadian Journal of Chemistry, **49**, 3566 (1971)

Introduction

In earlier papers (1, 2) we have pointed out that simple Huckel molecular-orbital (H.m.o.) π-electron densities at amino nitrogen are linearly related to the chemical shifts of amino protons for aromatic amines in hydrogen-bond-acceptor solvents. We suggested also that these computationally trivial calculations could be used to predict chemical shifts.

The present note reports an example of such prediction, resulting in the proposed interchange of the structures assigned to 5-amino-1-methyl-4-nitropyrazole (**1**) and to 3-amino-1-methyl-4-nitropyrazole (**2***a*) by Brown and co-workers (3).

and confirmation of the proposal by unambiguous synthesis of compound **1**.

Discussion and Results

Brown's group discovered that 4-methoxy-5-nitropyrimidine was converted into 3-amino-4-nitropyrazole (**2***b*) by hydrazine, and they obtained two products of respective m.p. 200 and 265–266° when the pyrimidine was treated with an excess of ethanolic methylhydrazine. The p.m.r. spectra of these products in dimethylsulfoxide-d_6 showed amino proton signals at δ 7.17 and 7.49, and they were assigned structures **1** and **2***a* respectively. However, simple resonance concepts suggest that the electron density at the 5-amino nitrogen in **1** should be significantly less than in **2***a*, in view of contributions from the form **3** (the charge displacement corresponding to **3** explains the extreme downfield position of the amino proton signal in *ortho*-nitroaniline (1)); no similar contribution is possible for structure **2***a*. Thus, qualitative considerations would indicate that **1** should have the lowfield amino proton signal at δ 7.49, and **2***a* the higher field signal at 7.17. This qualitative indication is confirmed by H.m.o. calculations on models of **1** and **2***a*, with results illustrated as **4** and **5**. The difference between the high and low field signals and the low and high charge densities indicates a response to electron density variations of *ca.* 7 p.p.m./electron, in agreement with previous work (1, 2). Further, the methyl proton signals of the compounds of m.p. 200 and 265–266° are at δ 3.65 and 3.57, and the pyrazole ring proton signals are at δ 8.42 and 7.82, respectively. If the compound of m.p. 265–266° is reassigned as **1**, and the compound of m.p. 200° as **2***a*, then the orders of the appropriate pairs of chemical shifts are in agreement with all previous charge-density/chemical shift correlations (4–7). The chemical shift patterns of the reassigned products are also consistent with the proton chemical shifts of the closely related isomeric amino-1-methyl-pyrazole-4-carbonitriles, whose structures are firmly established (8, 9). The shifts are compared in Table 1. Final confirmation of the validity of this interchange is afforded by nitration of 5-amino-1-methylpyrazole, which forms 5-amino-1-methyl-4-nitropyrazole, m.p. 266° (p.m.r. spectrum in dimethylsulfoxide-d_6: δ 3.60 (s, 3H (1-Me)); 7.60 (s, br, 2H (5-NH_2)); 7.87 (s, 1H (3-H)). Similar nitration of 5-amino-1-phenylpyrazole also afforded the 4-nitration product, 5-amino-4-nitro-1-phenylpyrazole, m.p. 154–156°, whose p.m.r. spectrum in hexadeuterodimethyl sulfoxide resembled that of **1**: δ 7.30 (s, br, 2H (5-NH_2)); 7.75 (s, 5H (1-Ph)); 8.20 (s, 1H (3-H)). The upfield shift of the amino signal as compared with **1** reflects ring-current shielding by the 1-phenyl substituent.

In view of the exchange of structural assignments for the amino-1-methyl-4-nitropyrazoles, assignments of structure for compounds derived from these species should be revised appropriately. For example, the compound described (3) as 4,5-diamino-1-methylpyrazole is actually 3,4-diamino-1-methylpyrazole, and the compound described as 1-methylpyrazolo(3,4-*b*)pyrazine (**6***a*) is the 2-methyl isomer **7**. This corrects a discrepancy between the coupling constants J_{56} for

TABLE 1. Proton chemical shifts for aminopyrazoles*

Literature structure	Correct structure	Proton shifts 1-Me	3-H	5-H	Amino
3-Amino-1-methyl-4-nitropyrazole (m.p. 265–266°)	5-Amino-1-methyl-4-nitropyrazole	3.57	7.82	—	7.49
	5-Amino-1-methylpyrazole-4-carbonitrile	3.57	7.57	—	6.57
5-Amino-1-methyl-4-nitropyrazole (m.p. 200°)	3-Amino-1-methyl-4-nitropyrazole	3.65	—	8.42	7.17
	3-Amino-1-methylpyrazole-4-carbonitrile	3.60	—	8.00	5.53

*In p.p.m from TMS, in dimethyl sulfoxide-d_6. Values for the aminonitro compounds from ref. 3.

1*H*-pyrazolo(3,4-*b*)pyrazine (**6***b*) and for the supposed **6***a* (the respective values are 3.0 and 1.8 Hz). With the revised assignment, the smaller coupling in the quinonoid ring of **7** is consistent with expectation from established bond order/coupling constant relationships (10, 11).

Finally, other structural revisions required include: 2,5,6- for 1,5,6-trimethylpyrazolo(3,4-*b*)pyrazine; 11- for 10-methyldibenzo(*f*,*h*)pyrazolo(3,4-*b*)quinoxaline; 3- for 5-diacetylamido-1-methyl-4-nitropyrazole; 3- for 5-acetamido-1-methyl-4-nitropyrazole; and 3- for 5-acetamido-4-amino-1-methylpyrazole.

Experimental

General

The p.m.r. measurements were made using a Varian A-60D spectrometer. Combustion analyses were carried out by Mrs. M. Petranovic of this laboratory using a Hewlett–Packard Model 185 CHN Analyzer. The H.m.o. calculations were made using a standard program (1), and with the following heteroatom parameters: pyrrole and nitro nitrogen, and oxygen, $h = +1$; pyridine and amino nitrogen, $h = +\frac{1}{2}$.

Reference Samples and Starting Materials

3-Amino-1-methylpyrazole-4-carbonitrile, m.p. 135–136°, was prepared using the method of Schmidt and co-workers (8); 5-amino-1-methylpyrazole-4-carbonitrile, m.p. 224–225°, was prepared following Cheng and Robins' method (9). 5-Amino-1-phenylpyrazole was a commercial sample (Aldrich Chemical Company) and was used without further purification.

5-Amino-1-methylpyrazole

5-Amino-1-methylpyrazole-4-carbonitrile (30 g) was dissolved cautiously in 85% w/w aqueous sulfuric acid (100 ml) and heated under reflux for 12 h. The mixture was cooled and added to crushed ice (500 g), basified with aqueous ammonia, and left overnight at 5°. The mixture was filtered and the filtrate extracted five times with 200 ml portions of chloroform. The chloroform extract was dried ($MgSO_4$) and the solvent was removed under reduced pressure, yielding 5-amino-1-methylpyrazole (19.9 g, 84%), m.p. 69° (lit. (12) m.p. 71–72°); p.m.r. spectrum in dimethylsulfoxide-d_6: δ 3.52 (s, 3H (1-Me)); 5.00 (s, br, 2H (5-NH_2)); 5.27 (d, $J = 2$ Hz, 1H (4-H)); 7.00 (d, $J = 2$ Hz, 1H (3-H)).

5-Amino-1-methyl-4-nitropyrazole

5-Amino-1-methylpyrazole (5.00 g) was dissolved in ice-cold 36 *N* sulfuric acid (10 ml) and 70% nitric acid (5 ml) and allowed to stand for 3 h. The reaction mixture was basified with aqueous ammonia and extracted with chloroform (200 ml) followed by ethyl acetate (5 × 100 ml). Evaporation of the ethyl acetate followed by crystallization from methanol yielded 5-amino-1-methyl-4-nitropyrazole (1.6 g, 23%), m.p. 266°.

Anal. Calcd. for $C_4H_6N_4O_2$: C, 33.81; H, 4.26; N, 39.42. Found: C, 33.80; H, 4.17; N, 39.30.

5-Amino-4-nitro-1-phenylpyrazole

5-Amino-1-phenylpyrazole (1.00 g) was dissolved in acetic anhydride (10 ml) and the solution was cooled to 0°. To the cold, stirred solution was added 90% nitric acid (2 ml); the temperature was maintained between −5 and 0° by addition of dry ice. After addition of the acid was complete, the reaction mixture was stirred for a further 5 min, and was added with stirring to crushed ice (100 g). The precipitate was collected and crystallized from ethanol, yielding 5-amino-4-nitro-1-phenylpyrazole (1.20 g, 92%), m.p. 154–156°.

Anal. Calcd. for $C_9H_8N_4O_2$: C, 52.94; H, 3.95; N, 27.44. Found: C, 53.10; H, 3.79; N, 26.90.

Isomerization of 1-*exo*-4,5,6,7,8,8-Heptachloro-2,3-*endo*-epoxy-3*a*,4,7,7*a*-tetrahydro-4,7-methanoindane with Base

W. P. COCHRANE AND M. A. FORBES[1]

Analytical Services Section, Plant Products Division, Canada Department of Agriculture, Ottawa, Canada

Received June 8, 1971

Treatment of the title compound, **2**, with excess sodium methoxide produced an unsaturated secondary alcohol, **3**. Structure elucidation was achieved by MnO_2 oxidation followed by $CrCl_2$ reductive dechlorination to give as the major product 2-oxa-4,5,6,7,8,8-hexachloro-3*a*,4,7,7*a*-tetrahydro-4,7-methanoindane.

Le composé, **2**, donné dans le titre, traité avec un excès de méthylate de sodium a conduit à un alcool secondaire insaturé **3**. La recherche de la structure a été menée à bien par une oxydation avec MnO_2 suivie d'une déchloration réductive par $CrCl_2$ pour donner comme produit principal l'oxa-2 hexachloro-4,5,6,7,8,8-tétrahydro-3*a*,4,7,7*a* méthano-4,7 indane.

Canadian Journal of Chemistry, **49**, 3569 (1971)

In connection with previous work on polychlorinated cyclodiene pesticides it was observed that the action of base on the biological metabolite of heptachlor,[2] namely heptachlor epoxide **1**, resulted in preferential epoxide isomerization, yielding an α,β-unsaturated alcohol (1). Molecules containing the required configuration *i.e.*, a *trans* coplanar arrangement of one of the carbon–oxygen bonds of the epoxide ring and a hydrogen on an adjacent carbon, apparently undergo transformation readily (2). In heptachlor epoxide the *cis*-arrangement of the epoxy ring to the C-1 chlorine atom resulted in initial abstraction of the C-1 proton (1). As an extension to this work it was of interest to study the isomeric compound **2** in which the epoxy group is *trans* to the C-1 chlorine atom (3).

Accordingly, a solution of *trans*-epoxide **2** in methanol was treated under reflux with an excess of sodium methoxide. Reaction occurred readily to yield, after water–hexane partition, an oil which was purified by distillation, b.p. 130–132°/0.1 mm. The molecular formula $C_{10}H_5Cl_7O$ was established by elemental analysis and mass spectrometry. The i.r. spectrum indicated a bonded hydroxyl, 3380 cm^{-1} together with a double bond at 1595 cm^{-1}. Previously, an isomeric hydroxyl-containing product had been formed from the *cis*-epoxide **1**. The n.m.r. spectrum substantiated the presence of only one olefinic proton and one hydroxyl proton whose signals appeared at τ 3.95 and 7.21 respectively. Consideration of the foregoing data and the

lack of characteristic ions in the mass spectrum due to retro-Diels–Alder fragmentation (4) suggested the reaction product to be the α,β-unsaturated alcohol, 2-*endo*-hydroxy-1-*exo*-4,5,6,7,8,8-heptachloro-4,7-methanoisoindene (**3**).

Oxidation of **3** with active MnO_2 gave a keto compound **4** which exhibited both i.r. carbonyl, 1745 cm^{-1}, and double bond absorptions, 1638 and 1595 cm^{-1}. Multiplets at τ 3.54 and 6.0, equivalent to 1 and 2 protons respectively, were observed in the n.m.r. spectrum which together with the i.r. and mass spectra are consistent with structure **4**. Treatment of **4** with aqueous $CrCl_2$ solution resulted in reductive dechlorination of the C-1 chloro atom and the addition of two protons to the unhindered double bond as observed from the mass spectral fragmentation pattern. This together with n.m.r. analysis, which displayed only two signals at τ 6.5 and 7.0 corresponding to 2 and 4 protons respectively, indicated the compound contained a saturated pentacyclic ring ketone group. Comparison of the i.r. spectrum, which lacked the 1638 cm^{-1} peak observed in **4**, with the two previously reported keto compounds[3] which have the carbonyls situated at C-1 or -2 in the cyclopentane ring, proved the $CrCl_2$ product to have structure **5**. The replacement of halogen by hydrogen in allylic halides, α-haloketones and *vic*-dihalides by Cr^{2+} reagents has been reported (5, 6). Reduction of multiple bonds by Cr^{2+} reagents has also been observed to occur in acidic solution but, so far, only when the olefin forms part of an enedione or an α,β-unsaturated ketone attached to an aromatic ring.

The *endo*-configuration of the C-2 hydroxyl group in **3** was confirmed by the failure of the octachloro derivative **6**, formed by reaction of **3** with PCl_3, to reconvert to **3** on treatment with aqueous alcoholic Ag_2CO_3 (1, 8). The latter reaction, monitored by g.l.c., produced only one peak which, on silylation, gave a single derivative with a different retention time to that for the silyl ether of **3**. Presumably the octachloro intermediate **6** is formed with inversion at C-2. Such a process occurs during the chlorination of *endo*-hydroxyl groups in similar polychlorinated cyclodiene compounds (9, 10).

The possible mechanism for the formation of **3** is given in Scheme 1. It is thought to be similar to that for heptachlor epoxide but, in this instance, involves initial nucleophilic attack on the *trans*-proton situated on the C-3*a* ring-junction position. The *cis* and *trans*-epoxides each gave their respective isomeric products with *t*-BuOK/t-BuOH as when NaOMe/MeOH or NaOEt/EtOH were used as the basic media, indicating the general nature of this base catalyzed isomerisation. Lack of evidence for attack at position C-2 or -3 is explained by the large steric

effect of the *exo*-chloro atom at C-1, inhibiting methoxide ion approach, since it has been observed that heptachlor is resistant to both peracid epoxidation and chlorine addition. Recently polychlorinated cyclodiene compounds possessing ring-junction double bonds have been prepared by the action of KOH on decachlorodicyclopentadiene (11).

Experimental

Melting points were determined on a Fisher–Johns hotstage and are uncorrected; i.r. spectra were recorded on a Beckman IR-7 spectrophotometer; n.m.r. spectra were measured in $CDCl_3$ using a Varian T-60 spectrometer with tetramethylsilane as internal standard; mass spectra were determined on a Bendix time-of-flight spectrometer, Model 12101, with the continuous ionization modification, operating at 40 eV, ambient temperature and 10^{-6} Torr, and are reported based on the ^{35}Cl fragmentation pattern. Microanalyses were determined by G. Morris, Research Branch, Canada Department of Agriculture, Ottawa.

*2-endo-Hydroxy-1-exo-4,5,6,7,8,8-heptachloro-3a,4,7,7a-tetrahydro-4,7-methanoisoindene (**3**)*

The *trans*-epoxide **2** (2.5 g) and sodium methoxide (5 g) were dissolved in methanol (50 ml), and the resulting solution was heated under reflux for 2 h and then cooled. Distilled water (300 ml) was added and the aqueous mixture extracted with chloroform (total 150 ml) which provided a brown oil (2.25 g) on evaporation. Distillation under vacuum yielded the product **3** as a colorless oil 1.97 g (80% yield), b.p. 130–132°/0.1 mm; i.r. bands (liquid film) at 3380 (broad hydroxyl) and 1595 cm^{-1} (ClC=CCl double bond); n.m.r.: τ 3.95 (dd, 1H, H-3, $J_{3,7a}$ = 1.5, $J_{2,3}$ = 7 Hz), 5.0 (m, 1H, H-2), 6.25 (dd, 1H, H-1, $J_{1,3}$ = 7, $J_{1,7a}$ = 9 Hz), 6.65 (dd, 1H, H-7*a*, $J_{7a,3}$ = 1.5, $J_{7a,1}$ = 9 Hz), 7.2 (s (broad), 1H, OH); 386 (M^+), 351 (M-Cl), 314 (M-2HCl), 287, 280, 251, 217, 181, 115.

Anal. Calcd. $C_{10}H_5Cl_7O$: C, 30.8; H, 1.3; Cl, 63.9. Found: C, 30.73; H, 0.98; Cl, 63.84.

*1-exo-4,5,6,7,8,8-Heptachloro-2-oxa-3a,4,7,7a-tetrahydro-4,7-methanoisoindene (**4**)*

Compound **3** (1.1 g) dissolved in acetone (50 ml) was stirred for 2 h at room temperature with activated MnO_2 (11 g; prepared according to Attenburrow *et al.*) (12). Filtration and evaporation of the solvent yielded a yellow semi-solid which was crystallized from ether–hexane to give prismatic crystals, m.p. 144–145 °C, 0.93 g (85% yield); n.m.r.: τ 3.5 (d, 1H, H-3, $J_{3,7a}$ = 1.5 Hz), 5.98 (s, 2H); 384 (M^+), 349 (M-Cl), 321 (M-Cl—CO), 314 (M-2Cl), 285, 279 (M-3Cl), 251 (M-Cl—CO—2Cl) 214, 181.

Anal. Calcd. for $C_{10}H_3Cl_7O$: C, 31.00; H, 0.78: Cl, 64.23. Found: C, 31.03; H, 0.48; Cl, 64.41.

*1-exo-2-exo-4,5,6,7,8,8-Octachloro-3a,4,7,7a-tetrahydro-4,7-methanoisoindene (**6**)*

Compound **3** (1.7 g), thionyl chloride (2 ml), and pyridine (5 drops) in benzene (50 ml) were refluxed for 3 h. Evaporation resulted in a dark brown viscous oil (1.77 g) which was partitioned between hexane–water. The organic phase was washed, treated with decolorizing charcoal (4 g), filtered, evaporated, and the residue crystallized from hexane to give needles, 1.2 g (68% yield), m.p. 159–160°. The i.r. ν_{max} (Nujol) 1595 cm^{-1} (ClC=CCl); n.m.r.: τ 3.69 (dd, 1H, H-3, $J_{3,7a}$ = 2, $J_{2,3}$ = 4 Hz), 5.12 (m, 1H, H-2), 5.75 (dd, 1H, H-7*a*, $J_{7a,3}$ = 2, $J_{7a,1}$ = 8 Hz), 6.18 (dd, 1H, H-1, $J_{1,7a}$ = 8, $J_{1,2}$ = 4 Hz); 404 (M^+), 369 (M-Cl), 333 (M-Cl—HCl) 298 (M-2Cl—HCl) 285, 263 (M-2Cl—HCl), 251, 228, 217.

Anal. Calcd. for $C_{10}H_4Cl_8$: C, 29.4; H, 1.0; Cl, 69.66. Found: C, 28.9; H, 0.81; Cl, 70.05.

2-oxa-4,5,6,7,8,8-Hexachloro-3a,4,7,7a-tetrahydro-4,7-methanoindane

Compound **4** (100 mg) was dissolved in acetone (5 ml), aqueous $CrCl_2$ solution (3 ml of 1 *N*) added, and the mixture placed in a water bath maintained at 55–60°. The g.l.c. analysis showed the reaction was complete after 15 min and resulted in two products. The mixture was extracted with hexane (50 ml) and evaporated to small volume. Crystallization afforded the major product as long needles, 75 mg (82% yield) m.p. 192–193° (lit. (9) m.p. about 180°). Identification was based on comparison of the i.r. spectrum with that of a previously reported sample (9); n.m.r.: τ 6.5 (m, 2H, HC—CH), 7.0 (m, 4H, $2CH_2$); 352 (M^+), 317 (M-Cl) 289 (M-Cl—CO) 270 (C_5Cl_6), 253, 235 ($C_5Cl_5^+$), 217, 183.

We wish to thank E. C. Martelock for technical assistance and P. Elliott, Food Research Institute, Canada Department of Agriculture, Ottawa, for mass spectroscopic data.

Introduction

3,5-Dibromotyrosine (**1***a*), 3,5-diiodotyrosine (**1***b*), and certain related compounds such as thyroxine have been found in corals (1), sponges (2), seaweeds (3), thyroid glands (4), and human blood serum (5). We were interested in synthesizing related compounds of general formula **2**, which are also internal salts, but are of a hitherto unknown type. This new type of structure is vinylogously related to the normal zwitterionic tautomer of the α-amino carboxylic acids (**3**).[3] Thus the system was of interest from the points of view of both structural novelty and the relationship to naturally occurring materials.

This note reports the preparation and spectral properties of 2-ammonio-3′,5′-dibromo-4′-oxidoacetophenone (**4***a*) and 2-pyridinio-3′,5′-dibromo-4′-oxidoacetophenone (**4***b*).

Preparation

The internal salt **4***b* was prepared in good yield by heating 2-bromo-3′,5′-dibromo-4′-hydroxyacetophenone (**5***c*) with excess pyridine in methanol. Lower concentrations of pyridine or less severe heating conditions gave rise quantitatively to the pyridinium salt **4***e*.

Reaction of 2-bromo-3′,5′-dibromo-4′-hydroxyacetophenone (**5***c*) with ammonia likewise yielded its ammonium salt, **4***d*, under mild conditions, and the internal salt, **4***a*, under rigorous conditions. The conditions were somewhat critical since overheating led to complex mixtures of self-condensation products.

Structure

The structures of the ammonia and pyridine reaction products were deduced mainly by tabulation of their spectral data together with the spectral data of 2-bromo-3′,5′-dibromo-4′-hydroxyacetophenone (**5***c*) and its potassium salt. Table 1 shows that the i.r., u.v., and p.m.r. spectra fall into two distinctly different, self-consistent categories having general formulae **4** and **5**. In the i.r. spectra the carbonyl band of **4** absorbs at 1642–1675 cm^{-1}, whereas that of **5** absorbs at

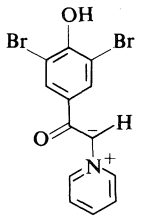
*$CDCl_3$ solvent. Unstable in DMSO.
†Acetic acid solvent.

1686–1695 cm^{-1}. The u.v. spectra reveal that **4** has two bands at 253–261 (ε 6200–9800) and 339–355 nm (ε 18 000 – 27 000), and **5** has a single band at 281–286 nm (ε 9900 – 14 000). In the p.m.r. spectra the aromatic protons fall at 2.05–2.16 τ for **4** and 1.77–1.86 τ for **5**, a shift of about 0.3 p.p.m.

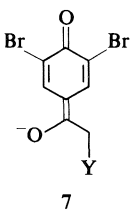
It is of interest that the zwitterionic structure **4***a* is the preferred tautomer in DMSO and the solid state, rather than the uncharged form **5***d*, which behavior is also usually the case with the α-amino carboxylic acids. Further evidence for the predominance of zwitterionic tautomer **4***a* is given by pK_a measurements. One can predict that the pK_a (proton gained) for the neutral compound (**5***d*) should be *ca.* 7.5 by analogy to glycine methyl ester (pK_a = 7.59). The observed[4] pK_a was 3.81, nearly four units different from that predicted, indicating tautomer **5***d* to be incorrect.

Concerning the products arising from pyridine, **6** was initially considered as a possible structure for the compound now known to be **4***b*, since this structure places the compound into the known class of pyridinium benzoylmethylids (8). However the structure was rejected since the p.m.r. spectrum in DMSO shows two aliphatic protons rather than one. Nevertheless the presence of the ylid **6** in trace amounts in solutions of **4***b* is inferred by the observation that the aliphatic protons of **4***b* exchange rapidly in acetic acid solutions. The p.m.r spectrum in acetic acid-d_4 shows that exchange is virtually complete within 10 min at 37 °C.

A further point of interest concerning the compounds of general formula **4** was the question of whether resonance structure **7** contributes much to the resonance hybrid. The i.r. data indicate that the resonance contribution is small, since the carbonyl bond at 1642–1669 cm^{-1} is less than 5% lower than that of **5** which falls at 1686–1695 cm^{-1}. This conclusion is also supported by the observation of only a single sharp aromatic absorption in the p.m.r. spectrum at 37 °C indicating that free rotation of the aryl group around an essentially single bond is occurring.



6



7

Experimental

Melting points were determined on a Meltemp apparatus and are uncorrected. Microanalyses were carried out by Dr. C. Daesslé, Organic Microanalyses, Montreal, Quebec. The reported i.r. data give only the principle sharply defined peaks. The n.m.r. spectra are reported in τ units relative to internal tetramethylsilane.

2,3′,5′-Tribromo-4′-hydroxyacetophenone was prepared by the method of Priestley and Moness (9). The product was recrystallized from methanol/water mixture three times to give a constant m.p. of 128°, ν_{max} (Nujol): 3333, 1686, 1580, 1555, 1307, 1252, 861, 776, 732, 721 cm^{-1}.

Pyridinium Salt of 2,3′,5′-Tribromo-4′-hydroxyacetophenone (4e)

2,3′,5′-Tribromo-4′-hydroxyacetophenone (**5***c*) (3.7 g) was dissolved in a minimum of methanol and pyridine (0.9 ml) was added. The mixture was boiled for 5 min. On cooling, 2.9 g (65%) of the white solid **4***e* precipitated. Removal of solvent gave a further 1.6 g (35%) of product. The two crops were combined and recrystallized from

[4]We thank Dr. M. J. O'Hare of this department for kindly determining this pK_a for us, using the method of Albert and Serjeant (7).

methanol; m.p. 230° (dec.); ν_{max} (Nujol): 3205–3012, 2381–2273, 1669, 1580, 1321, 1295, 1250, 1219, 1200, 1144, 689 cm^{-1}.

Anal. Calcd. for $C_{13}H_{10}O_2NBr_3$: C, 34.51; H, 2.21; N, 3.10. Found: C, 34.40; H, 2.41; N, 3.31.

2-Pyridinio-3′,5′-dibromo-4′-hydroxyacetophenone Chloride (5b)

2,3′,5′-Tribromo-4′-hydroxyacetophenone (**7***c*) (3.7 g) was dissolved in the minimum volume of methanol, pyridine (1.8 ml) was added, and the solution refluxed for 10 min. On removal of most of the solvent, a yellow precipitate of 2-pyridinio-3′,5′-dibromo-4′-oxidoacetophenone (**4***b*) was formed in almost quantitative yield. This was filtered off and ground with an excess of dilute hydrochloric acid. The white solid produced was crystallized from water to give **5***b* in 95% yield; m.p. 245° (dec.); ν_{max} (Nujol): 3571, 1689, 1248, 756, 688 cm^{-1}; τ (acetic acid): 0.95–1.42 (3H multiplet, pyridinium), 1.60–1.98 (2H multiplet, pyridinium), 1.78 (2H singlet aromatic), and 3.57 (2H singlet, CH_2).

Anal. Calcd. for $C_{13}H_{10}Br_2ClNO_2$: C, 38.35; H, 2.46; N, 3.44; Cl, 8.82; Br, 39.30. Found: C, 38.59; H, 3.04; N, 3.21; Cl, 8.82; Br, 39.21. (The H analysis was high; however, the H analysis of this compound's conjugate base (**4***b*) was acceptable.)

2-Pyridinio-3′,5′-dibromo-4′-oxidoacetophenone (4b)

2-Pyridinio-3′,5′-dibromo-4′-hydroxyacetophenone chloride (**5***b*) was dissolved in water and aqueous solution of an equivalent amount of sodium bicarbonate was added. The yellow precipitate was washed with water and methanol. The yield of **4***b* was quantitative; m.p. 225° (dec.); ν_{max} (Nujol): 1678, 758, 714, 685 cm^{-1}; τ (DMSO): 0.98–2.16 (5H multiplet, pyridinium), 2.04 (2H singlet, aromatic), and 3.80 (2H singlet, CH_2).

Anal. Calcd. for $C_{13}H_9Br_2NO_2$: C, 42.05; H, 2.43; N, 3.77; Br, 43.10. Found: C, 42.17; H, 2.61; N, 3.51; Br, 43.12.

2-Ammonio-3′,5′-dibromo-4′-oxidoacetophenone (4a)

2,3′,5′-Tribromo-4′-hydroxyacetophenone (2 g) was dissolved in diglyme (10 ml) and concentrated ammonia solution (90 ml) was added. This solution was evaporated to one third its volume in an open beaker on a hot plate over a 20 min period. It was then allowed to stand at room temperature for 18 h. The grayish-yellow precipitate which was crude 2-ammonio-3′,5′-dibromo-4′-oxidoacetophenone (**4***a*) (1.4 g, 87%) was filtered off and washed with water and ether. It was then boiled for 15 min with vigorous stirring in concentrated hydrochloric acid (80 ml). The undissolved solid was removed using a sintered-glass filter. The filtrate was neutralized by adding solid sodium bicarbonate, which caused **4***a* to precipitate (1.2 g). Further purification was effected by filtering off the solid, redissolving it in hydrochloric acid, filtering the solution and reprecipitating with sodium bicarbonate. The m.p. 230° (dec.); ν_{max} (Nujol): 2300–2650, 1661, 1250, 869, 786, 750, 719 cm^{-1}; τ ($CHCl_3$-*d*): 1.84 (2H singlet, aromatic), 5.36 (2H singlet, CH_2), and 6.46 (3H singlet NH_3^+).

Anal. Calcd. for $C_8H_7Br_2NO_2$: C, 31.20; H, 2.26; Br, 51.60; N, 4.54. Found: C, 31.35; H, 2.68; Br, 51.71; N, 4.70. (The H analysis was high; however, the H analysis of its hydrochloride salt **5***a* was acceptable).

2-Ammonio-3′,5′-dibromo-4′-hydroxyacetophenone Chloride (5a)

Compound **5***a* may be prepared by dissolving 2-ammonio-3′,5′-dibromo-4′-oxidoacetophenone (**4***a*) in the minimum amount of boiling dilute hydrochloric acid and allowing the product to crystallize. The m.p. 220° (dec.); ν_{max} (Nujol): 2620, 1690, 1253, 1142, 869, 736 cm^{-1}; τ (DMSO): 1.46 (1H broad, OH), 1.76 (2H singlet, aromatic), 5.42 (2H broad, CH_2), and 6.22 (3H broad, NH_3^+).

Anal. Calcd. for $C_8H_8Br_2ClNO_2$: C, 27.80; H, 2.32; Br, 46.40; Cl, 10.03; N, 4.06. Found: C, 28.00; H, 2.38; Br, 46.64; Cl, 10.05; N, 4.04.

Potassium Salt of 2,3′,5′-Tribromo-4′-hydroxyacetophenone (4c)

2,3′,5′-Tribromo-4′-hydroxyacetophenone (**5***c*) (1 g) was dissolved in the minimum of methanol (*ca.* 10 ml) and potassium hydroxide pellets (3 g) were added. A precipitate formed after 2 min. After 2 h the potassium hydroxide had dissolved and the remaining precipitate of **4***c* was filtered off and recrystallized from methanol, m.p. 265° (dec.); ν_{max} (Nujol): 1642, 1567, 1250, 1124, 962, 895, 809, 806, 747, 714, 665 cm^{-1}; τ (DMSO): 2.20 (2H singlet, aromatic) and 5.57 (2H singlet, CH_2).

Addition of acid to a solution of **4***c* reconverts it to **5***c*.

Ammonium Salt of 2,3′,5′-Tribromo-4′-hydroxyacetophenone (4d)

2,3′,5′-Tribromo-4′-hydroxyacetophenone (**5***c*) (3.7 g) was dissolved in benzene (40 ml) that had been dried over sodium sulfate, and excess ammonia gas (dried over potassium hydroxide pellets) was passed through this solution for 10 min. Immediately a greenish-yellow precipitate formed. After 1 h the precipitate was filtered off, washed with benzene and ether, and dried in a vacuum desiccator; yield 3.0 g (77%). The product was purified by vacuum sublimation, m.p. 120° (dec.); ν_{max} (Nujol) 3155–3030, 1650, 1563, 1334, 1274, 1198, 1176, 725 cm^{-1}; τ (DMSO): 2.14 (2H singlet, aromatic), 5.56 (2H singlet, CH_2), and 6.65 (singlet band of H_2O impurity in solvent probably hides NH_4^+).

Addition of acid to a solution of **4***d* reconverts it to **5***c*.

Free Energy Barrier to Rotation of the Amino Group in 2-Aminoacetophenone

R. WASYLISHEN[1] AND T. SCHAEFER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received July 5, 1971

The free energy of activation for hindered rotation of the amino group about the *N*-aryl bond in 2-aminoacetophenone is found to be 10.6 ± 0.5 kcal/mol in toluene solution at 233 ± 10 °K. Separate amino p.m.r. peaks are observed at low temperatures and these are strongly broadened by incompletely relaxed spin–spin coupling to the quadrupolar ^{14}N nucleus, making a more accurate determination of activation parameters impractical. Some INDO molecular orbital calculations are performed in an attempt to rationalize the barrier magnitude.

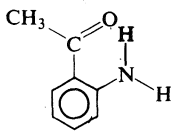
L'énergie libre d'activation pour la rotation empêchée du groupe amine autour de la liaison *N*-aryle dans l'amino-2 acétophénone est de 10.6 ± 0.5 kcal/mol dans une solution de toluène à 233 ± 10 °K. Des pics séparés, relatifs à la r.m.p. de l'amine, sont observés à basses températures; ceux-ci s'élargissent beaucoup par suite d'une relaxation incomplète du couplage spin–spin au noyau quadrupolaire de ^{14}N. De ce fait, une détermination précise des paramètres d'activation n'est pas pratique. Dans le but de rationaliser la grandeur de la barrière, des calculs INDO d'orbitales moléculaires ont été effectués.

Canadian Journal of Chemistry, 49, 3575 (1971)

The barrier to rotation about the amino nitrogen – ring carbon bond in *N*-alkyl derivatives of 2,6-dinitro- and 2,4,6-trinitroanilines is evidently determined mainly by hydrogen bonding of the N—H proton to the nitro group, repulsion between the *N*-alkyl group and the other, adjacent, nitro group being less important (1–3). The barriers are found by following the temperature dependence of the n.m.r. spectra of the ring protons, which are non-equivalent at low temperatures. A barrier was not detected by n.m.r. methods in *N*-unsubstituted and *N*,*N*-dimethyl derivatives (1).

If hydrogen bonding is the determining factor, a barrier should be detectable in *N*-unsubstituted aniline derivatives and observation of non-equivalent amino protons is then a direct indication of hindered rotation about the *N*-aryl bond.

When a 15 mol % solution of 2-aminoacetophenone (**1**) in toluene-d_8 is cooled to −70 °C, two broad amino p.m.r. peaks are observed. Their separation is 336 ± 10 Hz at 100 MHz and 200 ± 10 Hz at 60 MHz. The coalescence temperature is −37 ± 10 °C at 100 MHz; −43 ± 10 °C at 60 MHz. It follows (4) that the free energy of activation, $\Delta G^{\ddagger}$ for the hindered rotation at the coalescence temperatures is 10.58 ± 0.48 kcal/mol at 100 MHz and 10.54 ± 0.50 kcal/mol at 60 MHz.



1

The broadness of the amino proton peaks (~30 Hz) arises from incompletely relaxed scalar coupling to the quadrupolar ^{14}N nucleus and therefore a proper line-shape analysis will only be possible on the ^{15}N labelled compounds; unless, of course, decoupling facilities for nitrogen are available.

At room temperature, where rotation of the amino group is rapid on the time scale defined by the low-temperature peak separation, characteristic spin–spin coupling (5) of 0.3 Hz over five bonds between the amino protons and ring protons is observed, showing that any intermolecular amino proton exchange is unimportant in these experiments.

The well-known aromatic solvent induced shifts (6) are temperature dependent and must be allowed for in accurate rate studies by proton resonance measurements (7). Calibration of the shifts of the amino proton peaks as a function of temperature at temperatures substantially below coalescence demonstrated that any difference in the temperature coefficients of the solvent effects on the chemical shifts of the two peaks caused an error whose magnitude was much less than that quoted above for $\Delta G^{\ddagger}$.

By measuring the two-bond proton–deuterium coupling in the H–N–D group of monodeutero-2-

Cl-aniline-^{15}N, we have shown that the coupling of the protons in the amino group is 1 ± 1 Hz in magnitude (8). This parameter is therefore also unimportant in the experiments described above.

Molecular orbital calculations in the INDO approximation (9) predict that the conformation in which the amino group defines a plane perpendicular to the benzene ring is 15.0 kcal/mol less stable than a conformation in which a planar amino group has one N—H bond approaching the carbonyl group. In this hydrogen-bonded conformation the molecule is taken as completely planar, apart from the methyl hydrogens. Two C—H bonds of the methyl group are assumed to be staggered relative to the ortho C—H bond of the benzene ring. A planar amino group is a reasonable approximation in the hydrogen-bonded situation because the spin–spin coupling between the amino protons and the ring protons six bonds removed from them is apparently less than 0.1 Hz in magnitude (see ref. 5 for the arguments which allow for this conclusion).

Standard bond lengths and angles (9) were assumed in the INDO computations. Considering the many other approximations involved, *e.g.* the carbonyl group is kept coplanar with the benzene ring, the amino group is assumed planar in both conformations, the solvent may play a role and so on; the predicted barrier is reasonably close to the experimental one. A proper calculation would no doubt minimize the energy of the molecule as a function of bond lengths and angles at successive stages in the rotation of the amino group but the expense incurred would hardly be justifiable at this time.

We are pursuing the syntheses of appropriate ^{15}N-aniline derivatives with a view to finding accurate entropies of activation for the rotation of the amino group and to studying the changes in electron distribution in the N—H bond brought about by hydrogen-bonding, as detected by coupling constant variations.

Experimental

The solution of 15 mol % 2-aminoacetophenone in toluene-d_8 was carefully degassed by the freeze–pump–thaw technique. Tetramethylsilane served as internal reference. The p.m.r. spectra at 60 MHz were recorded on an A56-60 spectrometer, a methanol sample serving as a temperature calibrator. The spectra at 100 MHz were taken in the frequency sweep mode on an HA100-D spectrometer. Sample temperatures were known to at least 1 °K at 100 MHz but in view of the data given previously their accuracy is not crucial in this experiment.

Rate-dependent spectra approximating as closely as possible to observed line-widths and shifts were computed for a two-site exchange process by a program written by one of us (R.W.). Assurance was thereby obtained that the coalescence temperatures quoted above were known to at least the stated accuracy, the latter being rather a pessimistic estimate.

The INDO computations (10) were performed on an IBM 360/65 computer as were the line-shape simulations.

We are grateful for financial support from the National Research Council of Canada.

Magnetic Field Effect on Electrochemiluminescence of Carbazole

K. S. V. SANTHANAM

Chemical Physics Group, Tata Institute of Fundamental Research, Bombay 5, India

Received May 4, 1971

Effect of magnetic field on electrochemiluminescence of carbazole has been studied in *N,N* dimethylformamide. The emission intensity increases with increasing applied field with a tendency to decrease at high magnetic fields. An explanation involving perturbation of triplet–triplet annihilation rate is proposed.

L'effet d'un champ magnétique sur l'électro-chimioluminescence du carbazole a été étudié dans la *N,N*-diméthylformamide. L'intensité de l'émission augmente si l'intensité du champ appliqué augmente avec cependant une tendance à la diminution à des champs magnétiques élevés. Une explication impliquant la vitesse d'annihilation triplet–triplet est proposée.

For personal use only.

The generation of electrochemiluminescence of carbazole during the reduction of carbazole in *N,N* dimethylformamide (DMF) at −2.7 V *vs.* saturated calomel electrode has been reported (1, 2). The emission spectrum during this reduction has a maximum at 450 nm with shoulders at 420 and 470 nm. The electrochemiluminescence spectrum thus differs considerably from the photoexcited carbazole which has a maximum at 346 nm in fluid solutions and around 440 nm in rigid medium (corresponding to phosphorescence). The nature of the excited state could not be conclusively arrived at in the earlier studies. However, the close resemblance of the phosphorescent emission with electrochemiluminescent emission suggested the possible involvement of triplet carbazole in the emission process. Although our attempts to obtain unambiguous evidence of the triplet state by studying the half field transition in electron spin resonance have not yielded fruitful results, nevertheless during these studies the application of magnetic field changed the electrochemiluminescent intensity significantly. In this note the results of the effect of magnetic field on electrochemiluminescent intensity and the probable reasons for the change in the intensity are discussed.

Experiments were conducted by holding the potential of the mercury pool cathode at −2.7 V in DMF containing $(C_4H_9)_4NI$ as the supporting electrolyte in the conventional cell (2). The cell was rigidly mounted between the pole pieces of Varian Magnet (V 4500) of 9 in. diameter with a Fieldial power supply. The light output was monitored by a photomultiplier tube 1P 28 with an S_5 spectral response which was placed about 50 cm away from the magnet to avoid any field effects leading to stray emission. The field near the location of the photomultiplier tube was tested with a Gaussmeter and found to be negligible. The output from the photomultiplier was amplified through a pre-amplifier and fed to a HP *X–Y* recorder (Model 135 AM). In some experiments the preamplifier output was connected to a voltage to frequency (HP 2212 A) converter whose frequency was measured by a counter.

The change in the emission intensity after subtracting the dark current values is shown in Fig. 1. The intensity change is negligible up to 500 G and showed a significant increase at higher fields. The intensity showed a tendency to decrease at fields greater than 3000 G. It should be pointed out that the intensity fluctuations were similar both in the presence and the absence of the field.

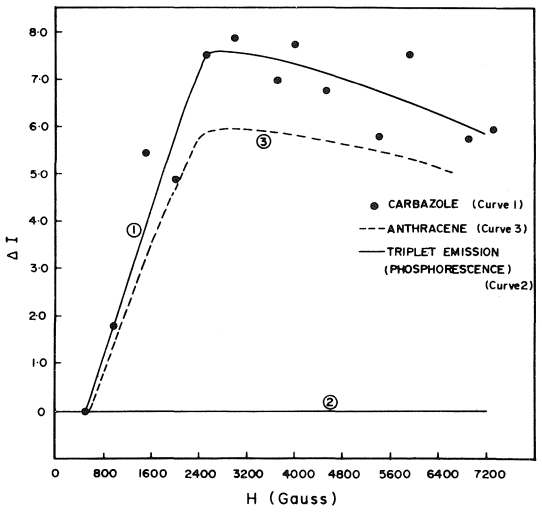

FIG. 1. Variation of emission intensity with field.

The zero field intensity was measured every time before the magnetic field was turned on and the zero field values were highly reproducible. The zero field values were restored generally within 10 s of the removal of the magnetic field.

In Fig. 1 is also shown the emission intensity behavior in the magnetic field of a system where triplet–triplet annihilation is involved (anthracene) in one of the rate determining steps of electrochemiluminescence. The curve *3* in the figure was obtained by carrying out the electrochemiluminescence of anthracene in the presence of *p*-phenylenediamine. The excited state is formed by reaction of anthracene anion with *p*-phenylene diamine cation through triplet–triplet annihilation. The absence of perturbation in the emission intensity in the magnetic field of triplet emission (3) (phosphorescence) is also shown by curve *2* in the figure.

The emission intensity enhancement in the magnetic field could arise if there is increased production of the radical in the field. The reduction of carbazole (A) to form the carbazole radical anion (A^-) is diffusion controlled and hence the reduction current is not altered in the magnetic field, suggesting the absence of increased formation of A^-. This is in agreement with the observations of Faulkner and Bard (4). The other possibility would involve mixing up of paramagnetic energy states (triplets) with singlet states resulting in population changes of the singlet emitting state. The singlet level of carbazole and its derivatives are placed about 1 eV above the triplet (5) and the zero field splitting value is of the order of 0.10 cm^{-1} (6). Hence mixing up of states in small magnetic fields seems to be remote.

It is established experimentally that the emission arising from triplet–triplet annihilation is influenced by a magnetic field. This process is understood theoretically in the case of solid state luminescence by Merrifield and co-workers (7, 8). The fact that the same magnetic field dependence is observed in the electrochemiluminescence of carbazole in solution indicates that triplet–triplet annihilation occurs after the electrochemical process. Thus the mechanism appears to be

$$A + e \rightarrow A^-$$

$$A^- + X \rightarrow {}^3F + X^-$$

$$^3F + {}^3F \rightarrow {}^*F + F$$

and accounts for the emission at 450 nm.

The author wishes to thank Dr. B. Venkataraman for helpful discussions and Mr. V. R. Bhagat, Mr. Pachauri, and Mrs. Shah for technical assistance.

Crystal Structure of *cis*-Dithiocyanatobis(1,10-phenanthroline)mercury(II), a Six-coordinate Mercury Complex

A. L. Beauchamp, B. Saperas, and R. Rivest
Département de Chimie, Université de Montréal, Montréal, Québec

Received June 24, 1971

cis-Dithiocyanatobis(1,10-phenanthroline)mercury(II) is a six-coordinate monomeric molecule with a distorted octahedral geometry.

Le *cis*-dithiocyanatobis(1,10-phenanthroline)mercure(II) est une molécule monomère où le mercure hexacoordonné possède un environnement octaédrique déformé.

Canadian Journal of Chemistry, **49**, 3579 (1971)

In the crystals of $HgCl_2$, $Hg(CN)_2$, $K_2HgCl_4.H_2O$, HgO and many other compounds (1), the mercury atom occupies the center of an approximate octahedron of donor atoms. However, the metal does not interact to the same extent with all of its six neighbors. In $HgCl_2$, for instance, mercury forms only two short Hg—Cl bonds of 2.25 Å and the crystal is best described in terms of discrete Cl—Hg—Cl molecules. The environment of mercury is completed through weaker interaction with two more pairs of chlorine atoms on neighboring molecules, at 3.34 and 3.63 Å, respectively. According to the classification proposed by Grdenic (1), the mercury atoms in such a compound would have an *effective* coordination number of six, but a *characteristic* coordination number of two.

Several neutral ligands have been reported to form $[HgL_6]^{2+}$ or $[Hg(L—L)_3]^{2+}$ monomeric complex ions in which mercury would achieve a characteristic coordination number of six (2). However, detailed information on the geometry and bond lengths in such species appears to be missing at the present time (1). On the basis of the infrared spectrum, the adduct $Hg(SCN)_2.2Phen$ (where Phen = 1,10-phenanthroline) was recently described as potentially six-coordinate (3). Preliminary results on the crystal structure of the latter compound definitely confirm this assumption.

The crystal belongs to the space group $P\bar{1}$ with two $Hg(SCN)_2Phen_2$ molecules per unit cell: $a = 13.25$ Å, $b = 11.08$ Å, $c = 8.44$ Å, $\alpha = 105° 12'$, $\beta = 83° 15'$, $\gamma = 90° 55'$, $D_m = 1.95$ g cm^{-3} and $D_c = 1.99$ g cm^{-3}. The intensity data were collected with a Picker FACS-1 automatic diffractometer using Ni-filtered CuKα radiation. A total of 1763 independent observed reflexions within a halfsphere of $2\theta \leqslant 120°$ were used to solve the structure by means of the heavy atom method. At the present time, all atoms, except hydrogens, have been located and the refinement has been carried out with individual isotropic thermal parameters to a conventional R factor of 0.116.

The crystal consists of discrete monomeric molecules. Two thiocyanato groups *cis* to each other and four nitrogen atoms from phenanthroline molecules acting as bidentate ligands achieve an approximately octahedral environment about mercury. Optical isomerism is expected for *cis*-$MX_2(L—L)_2$ octahedral complexes and the crystal actually is a racemic mixture, the enantiomorphs being related by the inversion center of the unit cell.

The fixed spacing of the nitrogen atoms within the rigid phenanthroline ligand involves certain constraints on the geometry of the complex. Thus, the nitrogen–metal–nitrogen angles in the chelate rings and the corresponding metal–nitrogen bond lengths become fully correlated. In *cis*-$Hg(SCN)_2Phen_2$, the small N—Hg—N angles (66 and 69°) appear reasonable in regard to the Hg—N bonds ranging from 2.37 to 2.53 Å, where the large mercury atom is involved. A still smaller value of 63° has been obtained for the N—Tl—N angle in $[Tl(CH_3)_2Phen]ClO_4$, where the Tl—N distances are 2.57 Å (4). The values

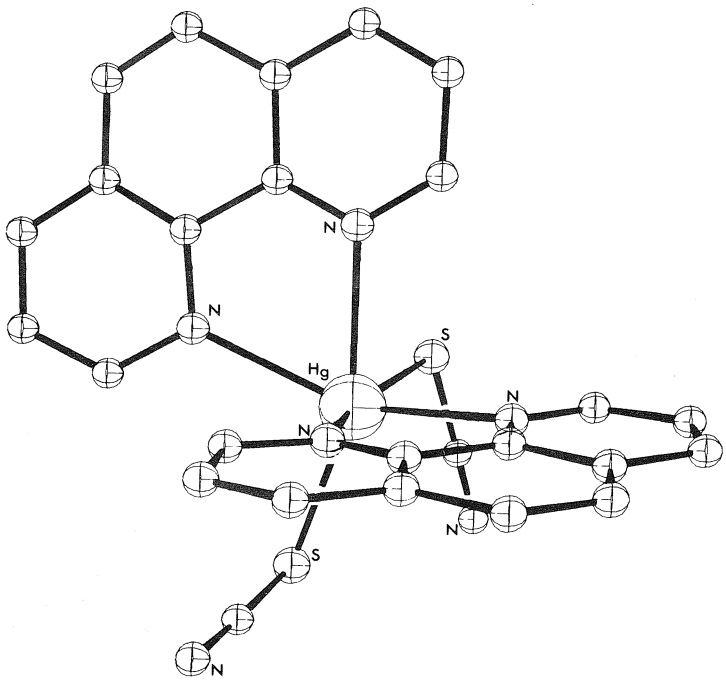

FIG. 1. Projection of the molecule. Unlabeled circles are carbon atoms.

stated above for the Hg—N bond lengths are similar to those reported for the mercurous complex salt $[Hg_2Phen](NO_3)_2$ (2.30 and 2.48 Å) (5). The Hg—N distances reported for the adducts $HgCl_2$.2Pyridine (2.60 Å) (1) and $HgCl_2$.Collidine (2.18 Å (6)) differ considerably from each other in spite of the close similarity of the ligands. Consequently, the lack of sufficient structural data on mercuric complexes with pyridine-type ligands precludes any significant conclusion at this time as to the specific effects of the rigid phenanthroline ligands in mercury compounds.

Coordination of the thiocyanato group through the sulfur atom is quite common for mercury (1). The available data on the mercury-thiocyanato compounds indicate a trend of decreasing Hg—S bond lengths with decreasing characteristic coordination number. Thus, in this six-coordinate complex, Hg—S distances of 2.58 and 2.62 Å are observed. In a series of compounds containing the tetrahedral four-coordinate $[Hg(SCN)_4]^{2-}$ unit, the Hg—S bonds average 2.52 Å (2), while the linear two-coordinate molecules ClHgSCN, BrHgSCN (7), and $Hg(SCN)_2$ (8) show still shorter bonds of 2.31, 2.32, and 2.38 Å, respectively.

Exchange Averaging of Methylol Groups Attached to Phosphorus

S. E. ELLZEY, JR., W. J. CONNICK, JR., AND GORDON J. BOUDREAUX
Southern Regional Research Laboratory,[1] *New Orleans, Louisiana 70179*

Received June 21, 1971

Variable temperature ^1H n.m.r. spectra of pyridine solutions of tetrakis(hydroxymethyl)phosphonium chloride indicate that chemical exchange of methylol groups of the salt with those of the small amount of tris(hydroxymethyl)phosphine formed is the cause of their magnetic equivalence at elevated temperatures. Triethylamine transforms the salt into the phosphine and at least two other phosphorus species which may result from reaction of formaldehyde at oxygen of the phosphine.

Des spectres r.m.n. ^1H à différentes températures de solutions de chlorure de tetrakis (hydroxyméthyl) phosphonium dans la pyridine indiquent que l'échange chimique des groupements méthylol du sel avec ceux provenant d'une petite quantité de tris (hydroxyméthyl) phosphine formée, est la cause de leur équivalence magnétique à température élevée. La triéthylamine transforme le sel en phosphine et en au moins deux autres produits contenant du phosphore, qu'on pourrait attribuer à la réaction de la formaldéhyde avec l'oxygène de la phosphine.

Canadian Journal of Chemistry, **49**, 3581 (1971)

Reaction of aqueous or alcoholic alkali hydroxide (1) or anhydrous triethylamine (2) with tetrakis(hydroxymethyl)phosphonium chloride (**1**) yields tris(hydroxymethyl)phosphine (**3**) as the isolable product. In a recent report (3) employing ^1H and ^{31}P n.m.r. in a study of the reaction of **1** with sodium hydroxide, it was concluded that in addition to **3**, hemiformals of **3** [*e.g.*, $(HOCH_2)_2PCH_2OCH_2OH$] were also formed.

$$[1]\quad \underset{\mathbf{1}}{(HOCH_2)_4\overset{+}{P}\overset{-}{Cl}} + B \rightleftharpoons \underset{\mathbf{2}}{(HOCH_2)_3\overset{+}{P}CH_2\overset{-}{O}} + H\overset{+}{B} + \overset{-}{Cl} \rightleftharpoons \underset{\mathbf{3}}{(HOCH_2)_3P} + CH_2O$$

Evidence has now been obtained from variable temperature ^1H n.m.r. spectra of **1** in pyridine that the CH_2OH groups of **1** and **3** can become magnetically equivalent through chemical exchange. This exchange is an example of a rather rare reorganization involving C—P bonds at quadruply-connected phosphorus (4). In a solvent of higher base strength, such as triethylamine, in which the phosphonium salt is completely neutralized, attack of the liberated formaldehyde at phosphorus of the phosphine is somewhat slower than in pyridine and is apparently accompanied by attack at oxygen.

In Table 1 are summarized the results of a ^1H n.m.r. study of the phosphonium salt **1** dissolved in pyridine or triethylamine, either dry or in the presence of D_2O. In pyridine, as the temperature was raised from 33°, the doublets for **3** and **1**, in turn, collapsed to singlets before these merged into the composite singlet at δ 5.13 (Fig. 1) in the range 84–100°. The small amount of tris(hydroxymethyl)phosphine oxide (**4**) which is present was then readily seen. The coalescence was completely reversible with a change in temperature and after cooling the solution from 100° to 33°, K_{eq} was about 5×10^{-4}. In pyridine–D_2O, the signal for the phosphine **3** was already a singlet at 22°. The position of equilibrium (5), judging from the shifts of **1** (δ 4.92 at 0°), **3** (δ 4.28), and the composite signal in the aqueous medium, appears to be about the same as in neat pyridine.

These reversible effects are compatible with chemical exchange averaging of the CH_2OH groups of **1** and **3** according to eq. 1. Reversible neutralization of **1** leads to a small amount of **3**, probably through **2**. Since the overall equilibrium involves breaking and making of all P—C bonds, methylene doublets for **1** and **3** will not be observed when the overall rate is somewhat greater than J_{PCH} for a component. Coalescence of the separate signals to a *composite singlet* takes place when the rate exceeds the difference (in Hz) in chemical shift for **1** and **3**. The lower coalescence temperature of these signals (faster rate) in the more polar aqueous medium is consistent, moreover, with involvement of an ionic species, such

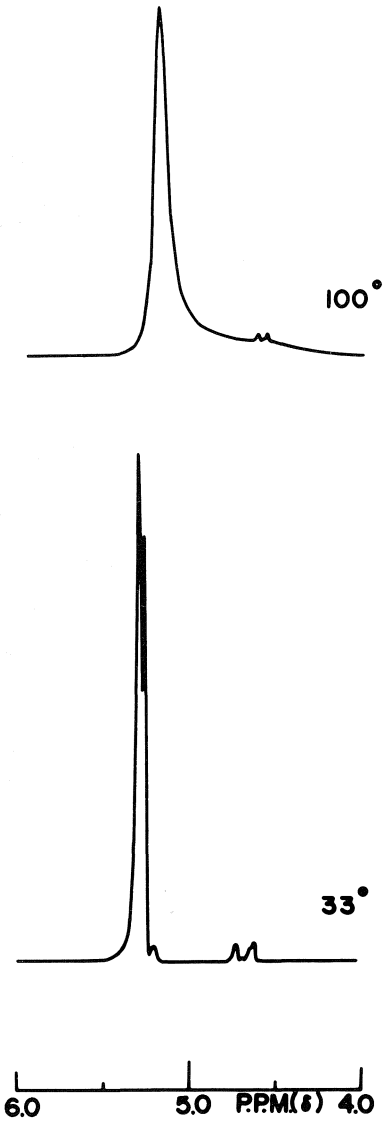

FIG. 1. The ^1H n.m.r. spectra of 20% solution of **1** in pyridine at 33 and 100°.

as **2**. The influence of formaldehyde on the rate was demonstrated by collapse to a singlet of the phosphine doublet upon addition of gaseous formaldehyde to a pyridine solution of the salt **1** at room temperature.

The complex spectrum of a triethylamine solution of **1** (amine hydrochloride filtered) is reversibly simplified at higher temperature (Fig. 2), but complete coalescence to a singlet is not achieved at 85°. Coalescence of the doublet in the triethylamine–D_2O solution is nearly complete at 33° and the position of this signal, as well as the lack of a signal for **1** at low temperature, indicates complete conversion of the salt. The numerous lines noted in the δ 4.1 region for the neat triethylamine solution are not seen in the D_2O solution. It is tentatively suggested that in dry triethylamine reversible attack of formaldehyde at phosphorus is rather slow on the n.m.r. time scale and the predominant reaction may be reversible formation of hemiformals (3), cyclic (6) or even linear formals, together with averaging of all existing PCH couplings into one doublet (P—C bonds preserved) at high temperature. As with pyridine–D_2O, addition of D_2O to triethylamine brings about faster attack of formaldehyde at phosphorus, resulting in loss of PCH coupling.

Results of an n.m.r. study of the neutralization of **1** with aqueous sodium hydroxide (7) will be reported later.

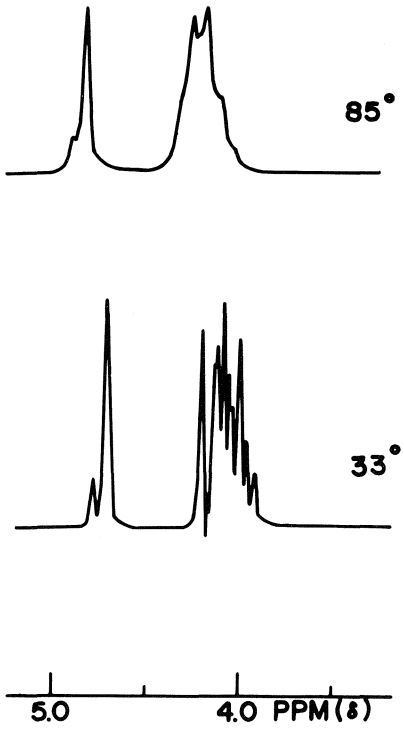

FIG. 2. The ^1H n.m.r. spectra of 20% solution of **1** in triethylamine at 33 and 85°.

Dimethylsulfoxidepentaammineruthenium(II) Hexafluorophosphate. A Spectroscopic Study

C. V. SENOFF, E. MASLOWSKY, JR., AND R. G. GOEL

Department of Chemistry, University of Guelph, Guelph, Ontario

Received May 6, 1971

The infrared spectra of $[Ru(NH_3)_5(CH_3)_2SO]X_2$, $[Ru(ND_3)_5(CH_3)_2SO]X_2$, $[Ru(NH_3)_5(CD_3)_2SO]X_2$, and $[Ru(ND_3)_5(CD_3)_2SO]X_2$ where $X = PF_6^-$ have been examined in detail between 4000–200 cm^{-1}. These data, together with the ^1H n.m.r. spectrum of $[Ru(NH_3)_5(CH_3)_2SO](PF_6)_2$ in D_2O, suggest that dimethyl sulfoxide is bonded to ruthenium *via* the sulfur atom in spite of the fact that the ν_{SO} frequency is not very different from that observed for uncoordinated dimethyl sulfoxide.

Les spectres infrarouges de $[Ru(NH_3)_5(CH_3)_2SO]X_2$, $[Ru(ND_3)_5(CH_3)_2SO]X_2$, $[Ru(NH_3)_5(CD_3)_2SO]X_2$ et $[Ru(ND_3)_5(CD_3)_2SO]X_2$ où $X = PF_6^-$, ont été examinés en détail entre 4000 et 200 cm^{-1}. Ces données, ainsi que le spectre r.m.n. de $[Ru(NH_3)_5(CH_3)_2SO](PF_6)_2$ dans D_2O, suggèrent que le diméthyle sulfoxyde est lié au ruthénium *via* un atome de soufre et ceci en dépit du fait que la fréquence ν_{SO} n'est pas très différente de celle observée dans le diméthyle sulfoxyde non-coordonné.

Canadian Journal of Chemistry, 49, 3585 (1971)

During the course of investigating the chemical reactions of $[Ru(NH_3)_5N_2](PF_6)_2$, it was found that this dinitrogen complex would react with dimethyl sulfoxide to form $[Ru(NH_3)_5DMSO](PF_6)_2$ where DMSO = $(CH_3)_2SO$ (1, 2). Further interest was generated by this compound by virtue of the fact that the ν_{SO} vibration in the infrared remained virtually unchanged from that observed for free dimethyl sulfoxide. At present, all known compounds containing coordinated DMSO have been reported to exhibit a shift in the ν_{SO} vibration to *higher* frequency when DMSO is bonded to the metal *via* the sulfur atom and to *lower* frequency when bonding occurs through the oxygen atom (3, and references cited therein). Consequently, it was decided to study this ruthenium(II) complex further in order to determine the nature of the DMSO–Ru bond. The initial approach has involved a detailed examination of the infrared and ^1H n.m.r. spectra of the complex. The results of this investigation are herein presented.

Results and Discussion

The infrared spectral data are presented in Table 1, together with the assignments for the observed absorption bands.[1]

(a) NH_3 Vibrations (4000–600 cm^{-1})

Band assignments for the various NH_3 modes occurring in this region were made by comparison with the spectra of other ammine complexes of ruthenium (4); this procedure was facilitated by the infrared spectra of the *N*-deuterated derivatives (Table 1). As expected, the NH_3 vibrations were not very different from those recorded for other pentaammineruthenium(II) complexes (2, 5, 6).

(b) $(CH_3)_2SO$ Vibrations (4000–600 cm^{-1})

The various CH_3, SO, and CS vibrational modes are expected to occur in this region. The CH_3 and CS modes were assigned by taking into account the previous assignments for DMSO and DMSO-d_6 (7, 8). Comparison with the spectra of the *C*- and *N*-deuterated derivatives provided a useful internal check for these band assignments.

Absorption bands which did not shift with *C*- and/or *N*-deuteration were assigned to PF_6^- vibrations.

The SO stretching vibration was of particular interest since its position has been found useful to ascertain the nature of the DMSO—metal bond, *i.e.*, to determine whether oxygen or sulfur is the donor atom (3 and references cited therein). The ν_{SO} vibration for $[Ru(NH_3)_5DMSO](PF_6)_2$ was observed at 1045 cm^{-1} as a strong, sharp band and between 1049–1059 cm^{-1} for the *C*- and or *N*-deuterated derivatives (Table 1). It is of interest to note that the position of this band is not very different from that reported for uncoordinated DMSO where ν_{SO} has been reported to occur at 1045 cm^{-1} in nitromethane (9) and in the vapor phase at 1102 cm^{-1} (7).

In spite of the fact that the ν_{SO} mode for DMSO and its complexes is not a pure S—O stretching vibration, it has been claimed that it is possible to determine the nature of the donor atom (O or S) from $\Delta\nu_{SO}$ *i.e.*, (ν_{SO} (ligand) $-$ ν_{SO} (complex)) (3). This generalization appears to be violated by the infrared spectrum of $[Ru(NH_3)_5DMSO](PF_6)_2$ since $\Delta\nu_{SO} \sim 0$ for this particular complex (Table 1).

Ruthenium(II) would be classified as a "soft" acid according to Pearson's concept of "hard and soft acids and bases" (10, 11). Consequently, it would be anticipated that sulfur would be the donor atom in $[Ru(NH_3)_5DMSO](PF_6)_2$ since "soft" acids have an affinity for "soft" donor atoms (oxygen is a "hard" donor atom). This "$\Delta\nu_{SO}$ rule" has received support from several single crystal X-ray diffraction studies. For example, the S—O bond length in *trans*-$PdCl_2(DMSO)_2$ (12, 13) and *cis*-$Pd(NO_2)_2(DMSO)_2$ (14), in both of which sulfur is the donor atom, is shorter than the S—O bond length reported for DMSO itself (15). Hence this particular bond length has been noted to reflect the increase in ν_{SO} observed in the infrared spectra of these complexes (13) (two ν_{SO} vibrations have been reported for *cis*-$Pd(NO_2)_2(DMSO)_2$ (14)). Also, the observed S—O bond length in those complexes where DMSO is bonded to the metal *via* the oxygen atom is significantly longer than that for free DMSO (12, 16). This observation parallels the shift in ν_{SO} to lower frequency when oxygen is the donor atom. If this trend is followed, one would expect little difference between the S—O bond length in free DMSO and that in the complex $[Ru(NH_3)_5DMSO](PF_6)_2$.

Thus, it would appear that in view of the infrared data for $[Ru(NH_3)_5DMSO](PF_6)_2$ presented here, ν_{SO} by itself is not a suitable criterion for determining the nature of the donor atom. Although the infrared data do not provide an unambiguous indication of the donor atom in this complex, ^1H n.m.r. (*vide infra*) add support to the suggestion that sulfur is the donor atom.

(c) Far Infrared Spectra (600–200 cm^{-1})

This region of the spectrum is of interest because it is here where the metal–ligand vibrations are expected to occur. Unfortunately, DMSO vibrations also occur in this region (17) but the spectra of the *C*- and *N*-deuterated derivatives in this region (Fig. 1) may be used to clarify some of the metal–ligand vibrations. No bands which could be readily assigned to metal–ligand vibrations were observed in the spectrum of $[Ru(NH_3)_5(CH_3)_2SO](PF_6)_2$. On the other hand, the spectrum of $[Ru(NH_3)_5(CD_3)_2SO](PF_6)_2$ in this region exhibited two new weak bands at 450 and 420 cm^{-1} as a result of the isotopic shifting of the δ_{CSO} vibrations (Table 1). These new bands have been assigned to metal–nitrogen stretching modes and are shifted to 420 and 402 cm^{-1} respectively in the spectrum of $[Ru(ND_3)_5(CH_3)_2SO](PF_6)_2$. No bands which could be assigned to ν_{RuN} were observed in the spectrum of the completely deuterated complex, $[Ru(ND_3)_5(CD_3)_2SO](PF_6)_2$. The strong band occurring at 279 cm^{-1} in the spectrum of $[Ru(NH_3)_5(CH_3)_2SO](PF_6)_2$ has been assigned to a Ru–N bending mode. This assignment must be considered tentative since the band absorbs near the lower end of the instrument used.

(d) ^1H n.m.r. Spectra

The ^1H spectra of several DMSO and related complexes have been recently investigated (3, 18, 19). From these studies it has been observed that the methyl proton resonance of DMSO shifts downfield by *ca.* 1 p.p.m. from free DMSO when S is the donor atom but scarcely shifts when O is the donor atom. The ^1H n.m.r. data for $[Ru(NH_3)_5DMSO](PF_6)_2$, DMSO, and $[(CH_3)_3SO]I$ in D_2O are presented in Table 2. The chemical shift for the NH_3 protons was not examined in detail. It has been suggested that S-coordination results in more deshielding of the CH_3 pro-

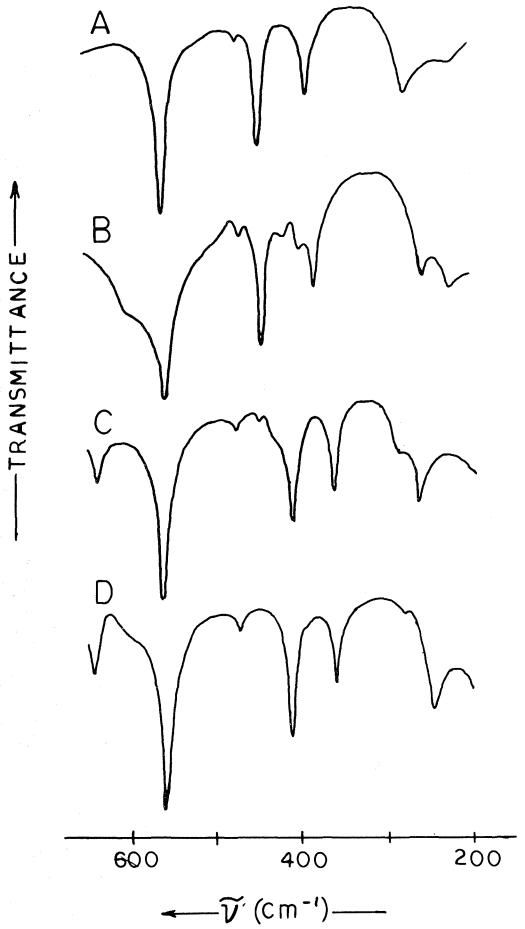

FIG. 1. Infrared spectra (600–200 cm^{-1}) of Nujol mulls of (*A*) $[Ru(NH_3)_5DMSO](PF_6)_2$, (*B*) $[Ru(ND_3)_5DMSO](PF_6)_2$, (*C*) $[Ru(NH_3)_5DMSO\text{-}d_6](PF_6)_2$, and (*D*) $[Ru(ND_3)_5DMSO\text{-}d_6](PF_6)_2$.

TABLE 2. ^{1}H n.m.r. spectra in D_2O

Compound	$\delta(CH_3)^a$	$\Delta[\delta(CH_3)]^b$
$(CH_3)_2SO$	2.70	—
$[Ru(NH_3)_5DMSO](PF_6)_2$	3.28	0.58
$[(CH_3)_3SO]^+I^-$	3.83	1.13

[a]Chemical shift quoted in p.p.m. downfield from DSS.
[b]$\Delta[\delta(CH_3)] = \delta(CH_3)_{complex} - \delta(CH_3)_{DMSO}$.

tons as compared to O-coordination because of the fewer number of bonds between the metal and the CH_3 protons in the former instance compared to the latter (18). Therefore, if it is assumed that this is a general phenomenon, then the n.m.r. data presented for $[Ru(NH_3)_5DMSO](PF_6)_2$ are consistent with the suggestion that sulfur is the donor atom. As expected, the CH_3 protons are less shielded for $[(CH_3)_3SO]I$ than $[Ru(NH_3)_5DMSO](PF_6)_2$ relative to free DMSO.

After completion of the spectroscopic investigation reported herein, preliminary results of a single crystal X-ray diffraction study became available and unambiguously show that sulfur is indeed the donor atom in $[Ru(NH_3)_5DMSO](PF_6)_2$. Complete details are presented in the following paper (20).

In conclusion, the spectroscopic data presented herein indicate that the "$\Delta\nu_{SO}$ rule" must be used with caution and must not be regarded as an infallible generalization.

Experimental

Dimethylsulfoxidepentaammineruthenium(II) hexafluorophosphate, $[Ru(NH_3)_5(CH_3)_2SO](PF_6)_2$

To an aqueous slurry of nitrogenpentaammineruthenium(II) hexafluorophosphate (5) (0.53 g in 3 ml of water) was added 1 ml of dimethyl sulfoxide and the resulting mixture was refluxed until a clear solution developed. The solution was filtered hot. From the cooled filtrate, pale yellow crystals of the complex were collected and washed with a small amount of ice-cold water, ethanol, and ether. Yield, 0.30 g (49%). The complex was recrystallized from the minimum amount of hot water as very pale yellow crystals. After washing as before, the complex was dried *in vacuo* at 78 °C in the presence of P_4O_{10}.

Anal. Calcd. for $C_2H_{21}F_{12}N_5OSRu$: C, 4.33; H, 3.82. Found: C, 4.86; H, 3.86.

Dimethylsulfoxidepentaammine-d_{15}-ruthenium(II) hexafluorophosphate, $[Ru(ND_3)_5(CH_3)_2SO](PF_6)_2$

Nitrogenpentaammineruthenium(II) hexafluorophosphate (5) was prepared using D_2O (99.8%) rather than H_2O as the solvent. The procedure used to prepare $[Ru(NH_3)_5(CH_3)_2SO](PF_6)_2$ was then followed except that D_2O was used in place of water. The crude product was dissolved in the minimum amount of D_2O and then refluxed for *ca.* 30 min. The solution was filtered hot, allowed to cool, and the yellow crystals which were deposited were collected and washed with ethanol and ether. This crop of crystals were then refluxed again with more D_2O, the resulting solution filtered hot, allowed to cool, and the product collected and washed as before. The ammine ligands were more than 90% deuterated as estimated from the intensity of the ν_{NH} bands in the infrared. No exchange of the methyl protons of DMSO were observed.

Dimethylsulfoxide-d_6-pentaammineruthenium(II) hexafluorophosphate, $[Ru(NH_3)_5(CD_3)_2SO](PF_6)_2$

The procedure used to prepare $[Ru(NH_3)_5DMSO](PF_6)_2$ was followed except that DMSO-d_6 was used in place of DMSO.

Dimethylsulfoxide-d_6-pentaammine-d_{15}-ruthenium(II) hexafluorophosphate, $[Ru(ND_3)_5(CD_3)_2SO](PF_6)_2$

The procedure used to prepare $[Ru(ND_3)_5DMSO]$-

$(PF_6)_2$ was followed except that DMSO-d_6 was used in place of DMSO.

Trimethylsulfoxonium iodide, $[(CH_3)_3SO]I$

A solution of DMSO (6.75 ml), methyl iodide (1.75 ml), and diethyl ether (10 ml) was refluxed for 3 days, after which a white solid was produced. This was filtered off, washed several times with ether, and air-dried.

Anal. Calcd. for C_3H_9IOS: C, 16.37; H, 4.12. Found: C, 16.33; H, 4.32.

Microanalyses were carried out by A. B. Gygli, Toronto, Ontario. Infrared spectra were recorded with a Beckman IR-12 infrared spectrophotometer as Nujol or halocarbon mulls between NaCl or CsI discs. Nuclear magnetic resonance spectra were recorded with a Varian A60 spectrometer in D_2O with DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) as internal standard.

The authors wish to acknowledge their appreciation for financial support from the National Research Council of Canada and the Department of University Affairs of the Province of Ontario.

The Crystal Structure of Dimethylsulfoxidepentammineruthenium(II) Hexafluorophosphate

FRANK C. MARCH AND GEORGE FERGUSON
Department of Chemistry, University of Guelph, Guelph, Ontario

Received May 6, 1971

The crystal structure of dimethylsulfoxidepentammineruthenium(II) hexafluorophosphate ($[Ru(NH_3)_5DMSO]^{2+}$ $2PF_6^-$) has been determined from three-dimensional X-ray data. The crystals are monoclinic, space group $P2_1/c$, with four formula units in a unit cell of dimensions $a = 8.805(2)$, $b = 17.335(5)$, $c = 12.373(2)$ Å, $\beta = 94.24(2)°$. The structure has been refined by full matrix least-squares methods to a final residual R of 0.054 for 1987 reflections greater than 3σ. The DMSO ligand coordinates through the sulfur atom and the S—O bond distance (1.527(7) Å) is considerably longer than that found for other sulfur–donor complexes of the ligand. The Ru—S bond distance is 2.188(3) Å.

La structure cristalline de l'hexafluorophosphate de diméthylsulphoxydepentammineruthénium (II) ($[Ru(NH_3)_5DMSO]^{2+}$ $2PF_6^-$) a été déterminée par diffraction de rayons-x à partir des données tridimensionnelles. Ce sel cristallise dans le système monoclinique, groupe d'espace $P2_1/c$, avec quatre unités formulaires dans une maille de dimensions: $a = 8.805(2)$, $b = 17.335(5)$, $c = 12.372(2)$ Å et $\beta = 94.24(2)°$. La structure a été affinée par moindres-carrés (matrice complète) jusqu'à un facteur d'accord $R = 0.054$ pour les 1987 réflexions considérées observées. Le ligand DMSO est coordonné à l'atome de soufre et la longueur de la liaison S—O (1.527(7) Å) est considérablement plus grande que celles rencontrées dans d'autres complexes de ce ligand ou le soufre est donneur. La distance Ru—S est de 2.188(3) Å.

Canadian Journal of Chemistry, 49, 3590 (1971)

Introduction

The results of an infrared and ^1H n.m.r. spectral investigation of some ruthenium complexes of dimethylsulfoxide (DMSO) are presented in a previous paper (1). It was inferred from this study that the DMSO ligand coordinates through the sulfur atom, however, the ν_{SO} vibration did not show a shift to higher frequency on complex formation as would be expected for a sulfur coordinated species. A single crystal X-ray diffraction investigation was undertaken to determine if sulfur was in fact the donor atom, and to find the effect of coordination on the length of the S—O bond.

Experimental

Crystal Data for Dimethylsulfoxidepentammineruthenium-(II) hexafluorophosphate[1]

$C_2H_{21}F_{12}N_5OP_2RuS$ f.w. = 554.3

Monoclinic $a = 8.805(2)$, $b = 17.335(5)$, $c = 12.373(2)$ Å, $\beta = 94.24(2)°$, $V = 1883.4$ Å^3, $\rho_o = 1.958 \pm 5$, $Z = 4$, $\rho_c = 1.955$, (20 °C; MoKα, $\lambda = 0.71069$ Å). Space group $P2_1/c$ (C_{2h}^5, No. 14) from systematic absences. Linear absorption coefficient for X-rays ($\lambda = 0.71069$ Å) $\mu = 10.0$ cm^{-1}.

[1]Numbers in parentheses are the estimated standard deviations in the least significant digits, which are generally derived from the inverse matrix in non-linear least-squares calculations.

Preliminary precession and Weisenberg photographs indicated monoclinic symmetry, while the systematically absent intensities for $h0l$ (l odd) and $0k0$ (k odd) gave space group $P2_1/c$ uniquely. The cell dimensions were obtained from least-squares refinement of the setting angles of 12 reflections. The crystal chosen for the data collection was a rectangular prism with approximate dimensions $0.5 \times 0.2 \times 0.2$ mm^3. Intensity data were collected to a maximum Bragg angle (θ) of 24° on a Hilger and Watts Y290 computer controlled 4-circle diffractometer. The $\theta/2\theta$ scan technique was used, with a symmetric scan of 0.8° and a scan rate of 1.667 deg/min. Stationary crystal/stationary counter background counts of 10 s duration were measured at each end of the integrated scan. Two standard reflections were monitored at approximately three hourly intervals throughout the data collection. The maximum variation in the intensity of the standard reflections was less than 3.4%.

Each intensity was corrected for background and the estimated standard deviation for each intensity ($\sigma(I)$) was given by $\sigma(I) = [\text{scan} + \text{background} + (p.\text{intensity})^2]^{1/2}$ where p is a factor introduced to avoid over weighting of the intense reflections (2). A value of 0.05 for p gave an adequate weighting of data. A total of 2757 independent reflections were accessible, of which 1987 were greater than three times their e.s.d.'s. The data were corrected for Lorentz and polarization factors, but not for absorption or extinction.

Structure Solution and Refinement

The x, y, and z coordinates of the Ru atom were obtained by inspection of a three dimensional Patterson distribution. One cycle of least-squares refinement on F (with $\sigma(F) = 0.5\ \sigma(F^2)/F$) in which the scale and positional and isotropic temperature parameters of the

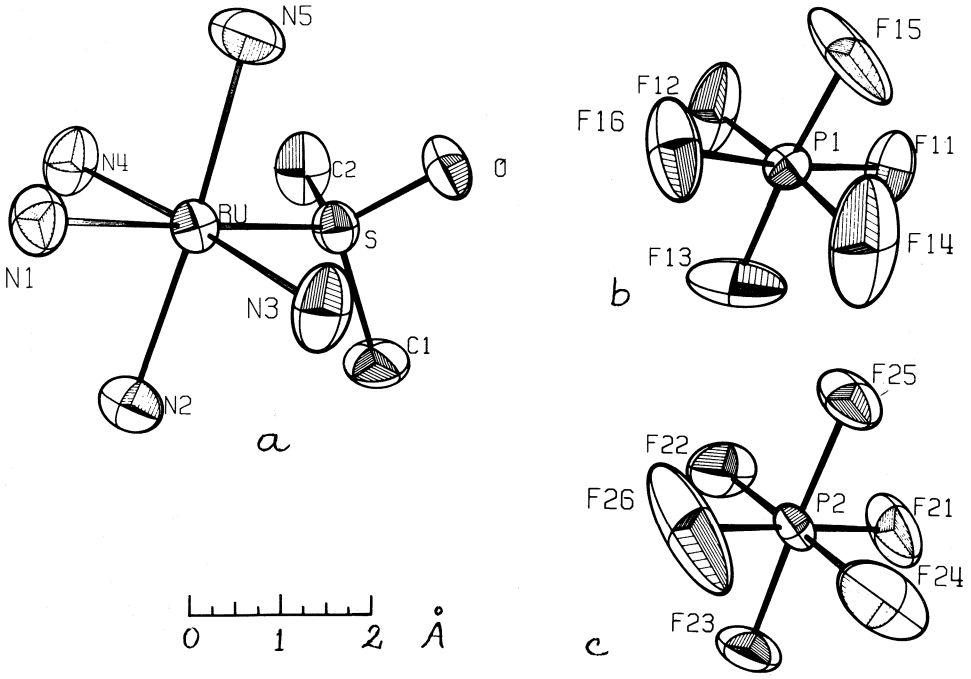

FIG. 1. View of the cation (*a*) and the anions, (*b*) and (*c*), drawn to the same linear scale. The ellipsoids in (*a*) are scaled to represent envelopes of 50% probability, while those in (*b*) and (*c*) represent envelopes of 20% probability.

ruthenium were varied yielded $R_1 = \Sigma| |F_o| - |F_c| |/ \Sigma|F_o|$ and $R_2 = [\Sigma\omega(F_o - F_c)^2/\Sigma\omega F_o^2]^{1/2}$ of 0.388 and 0.457, respectively. In all calculations of F_c the usual atomic scattering factors for C, N, O, F, S and Ru (3) were used. Corrections for anomalous dispersion for Ru were included at later stages of the refinement. Only 1987 reflections greater than 3σ were included in the least-squares calculations, and the function minimized was R_2 (above). Absolute weights (based on $\sigma(F_o)$) were used throughout the refinement. Successive difference maps of electron density distributions eventually gave all the non-hydrogen atoms. Four cycles of full matrix refinement of the model with isotropic atoms converged with $R_1 = 0.108$. At this stage all the fluorine atoms had high isotropic temperature factors (U_{iso} ranging from 0.09 to 0.22 Å^2); however, an F_o electron density map calculated using phases from all the non-fluorine atoms did not reveal any evidence of disorder of the fluorines about the phosphorus atoms. The model was refined for seven more cycles with first the ruthenium, sulfur, and phosphorus atoms allowed to vibrate anisotropically followed by all the non-fluorine atoms, and finally with all atoms allowed anisotropic vibration. The refinement converged with $R_1 = 0.054$ and $R_2 = 0.072$. On the last cycle the maximum shift in any of the positional parameters was less than 1 e.s.d., and that for the thermal parameters was less than 1.5 e.s.d.'s. The final atomic positional and thermal parameters are listed in Table 1.

A difference map calculated using the F_c values from the positional and thermal parameters given in Table 1 contained a number of small peaks (highest 1.2 e/Å^3). Many of the peaks appeared in positions corresponding to methyl and ammine hydrogen atoms, however, no attempt was made to include these in any calculations.

The final error in an observation of unit weight calculated over all "observed" data was 1.55, and ranged from 1.41 to 1.71 over 10 ranges of intensity, indicating that the relative weighting of the data was good. A table of final values of the structure amplitudes, $|F_o|$, $|F_c|$ and $\sigma(F_o)$ (the standard deviations from which the weights employed in the refinement were derived), is placed with the Depository of Unpublished Data.[2] The final values of the agreement factors for all data including those less than 3σ are: $R_1 = 0.073$ and $R_2 = 0.078$.

Discussion

The structure consists of discrete $[Ru(NH_3)_5DMSO]^{2+}$ cations and PF_6^- anions. The ranges of closest contacts between groups which are not bonded to common atoms are given in Table 2. Coordination about the Ru atom is octahedral, and the DMSO ligand is coordinated through the sulfur as inferred (1). Figure 1 shows a view of the cation and anions drawn to the same scale, showing the atomic numbering scheme. Figure 2 is a packing diagram of the structure with the unit

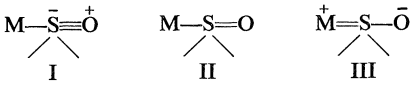
expected (4). The average P—F distance, uncorrected for thermal motion, is 1.53(4) Å, which is not significantly shorter than distances in previously determined structures, *e.g.* 1.55(2) Å (5), 1.58 Å (6). Correction for thermal motion increases the P—F bond lengths greatly (average corrected distance 1.66(5) Å). Since a high degree of rigid body motion is present, we doubt if such corrections are meaningful in this case. It seems probable that the true value lies between the two extremes, and close to previously determined values.

The structure found for the cation is consistent with the results of the infrared study carried out by Senoff, Maslowsky, and Goel (1). Two similar structures in which DMSO is complexed to a second row transition metal (palladium) have been reported. The Ru—S distance (2.188(3) Å) is considerably shorter than the Pd—S distance found for either *trans*-$PdCl_2(DMSO)_2$ (2.299(2) Å) (ref. 7) or *cis*-$Pd(NO_3)_2(DMSO)_2$ (2.231(3), 2.253(3) Å) (ref. 8), while the S—O distance (1.527(8) Å) is longer than that found for either of the Pd complexes (1.476(5) (ref. 7) 1.463(7) (ref. 8)).[3] The principal resonance structures for these complexes may be represented as



The present structure indicates that a relatively higher proportion of structure III is present for the Ru complex compared with either of the Pd complexes, with a consequently greater degree of metal → ligand π-interaction. This results in a lower S—O bond order, which is consistent with

[3]All bonded distances quoted in the body of the paper and referring to the present structure are corrected for thermal motion except for those of P—F and Ru—S.

the observed low value for the ν_{SO} bond stretching frequency compared with that found for other S-bonded DMSO complexes (1), including those of palladium discussed above. The greater extent of metal → ligand π-interaction for the present complex is presumably due to the absence of competing groups in the Ru coordination sphere for the available π-donor orbitals.

Two determinations of the crystal structure of free DMSO (9) have yielded S—O distances of 1.471 (determined at −60 °C) and 1.531 (determined at +5 °C). It has been suggested (7) that the latter value is more reliable for comparison with structures determined at room temperature. It is probably coincidental that the S—O distance is similar for the Ru complex and free DMSO as found in the second of the two determinations; however, this is consistent with the observation that the ν_{SO} frequency for the Ru complex is close to that found for free DMSO.

The S—C distance in the Ru complex (1.84(1) Å) is longer than that found for free DMSO (1.80–1.82 Å) (ref. 9) or for the Pd complexes (1.78(1) Å (ref. 7), 1.79(1) Å (ref. 8)). The Ru—N distances (2.169(5), 2.209(8) Å) are longer than normal for single Ru—N bond lengths (2.10–2.14 Å) (ref. 5). The nitrogen *trans* to the sulfur atom is significantly further from the ruthenium than the other four nitrogens. This reflects a "bond weakening" effect due to the sulfur bonded DMSO ligand, which has been found to have a considerable *trans* effect (10).

It is a pleasure to acknowledge the crystallographers and groups who have made their computer programs available to us. These include Dr. F. R. Ahmed and Mrs. M. E. Pippy at the National Research Council of Canada for the suite of IBM 360-50 programs, and the crystallography group at the University of Canterbury, New Zealand for data reduction routines and for modifications of Zalkin's Fourier program (FORDAP), the Busing–Levy full matrix least-squares (ORFLS) and function and error (ORFFE) programs. The diagrams were prepared with the assistance of Johnston's ORTEP.

We wish to thank Dr. E. Maslowsky, Jr. for supplying crystals of the ruthenium complex, Dr. C. V. Senoff for helpful discussions and the National Research Council of Canada for an operating grant (No. 576-34 to G.F.).

Photocyclization Reactions of Aryl Polyenes. IV.[1] The Syntheses of Isatogens and Isatogen-like Compounds

CLIFFORD C. LEZNOFF AND ROGER J. HAYWARD
Department of Chemistry, York University, Downsview, Ontario

Received June 22, 1971

Photochemical reactions of 1-*o*-nitrophenyl-4-phenyl-1,3-butadiene, 1,4-di-*o*-nitrophenyl-1,3-butadiene, 1-*o*-nitrophenyl-6-phenyl-1,3,5-hexatriene, and 1,6-di-*o*-nitrophenyl-1,3,5-hexatriene all gave the appropriate 2-substituted isatogen. The related *m*- and *p*-nitrophenyl polyenes were inert to the irradiation conditions. A six-membered ring isatogen-like compound, 2-phenyl-3-oxo-benzo[*d,e*]quinoline-*N*-oxide was prepared by irradiation of 1-[1′-(8′-nitronaphthyl)]-2-phenylacetylene. A seven-membered ring isatogen-like compound, 6-phenyl-7-oxo-dibenzo[*b,d*]azepine-*N*-oxide, was prepared by heating 1-[2-(2′-nitrobiphenyl)]-2-phenylacetylene.

Les réactions photochimiques de *o*-nitrophényle-1 phényle-4 butadiène-1,3, du di-*o*-nitrophényle-1,4 butadiène-1,3, de l'*o*-nitrophényle-1 phényle-6 hexatriène-1,3,5, et du di-*o*-nitrophényle-1,6 hexatriène-1,3,5 donnent toutes les isatogènes appropriées substituées en 2. Les *m*- et *p*-nitrophényle polyènes correspondants sont inertes, s'ils sont soumis à une irradiation. Un composé cyclique à six chaînons du type isatogène, l'oxyde-*N* de la phényle-2 oxo-3 benzo[*d,e*]quinoline a été préparé par irradiation du [(nitro-8′ naphtyle)-1′]-1 phényle-2 acétylène. Un composé cyclique à sept chaînons du type isatogène, l'oxyde-*N* de phényle-6 oxo-7 dibenzo[*b,d*]azépine a été préparé en chauffant le [(nitro-2′ biphényle)-2]-1 phényle-2 acétylène.

Canadian Journal of Chemistry, 49, 3596 (1971)

Introduction

The photocyclization and oxidation of substituted stilbenes have been shown to give substituted phenanthrenes (1), provided one of the substituents is not a nitro group (2). The photocyclization–oxidation reaction of 1,4-diaryl-1,3-butadienes, where the aryl groups are phenyl or substituted phenyl groups, gave mixtures of substituted 1-phenylnaphthalenes (3, 4). It was thought that the irradiation of 1-*m*- and 1-*p*-nitrophenyl-4-phenyl-1,3-butadienes (**1** and **2**) may give 1-*m*- and 1-*p*-nitrophenylnaphthalenes respectively, since photocyclization in this case can occur to a phenyl ring not substituted by a nitro group. In any case, irradiation of **1** and **2** gave no reaction. It has been shown that irradiation of 1,6-diphenyl-1,3,5-hexatriene gives chrysenes (3) but 1-*m*- and 1-*p*-nitrophenyl-6-phenyl-1,3,5-hexatrienes (**3** and **4**) are inert to photochemical reaction conditions (see Experimental).

The irradiation of 1-*o*-nitrostilbene gave 2-phenylisatogen (5), a reaction which can be more readily explained in the photochemistry of the nitro group (5, 6) than in the photocyclization–oxidation of the diaryl polyene.

Isatogens are an interesting group of compounds in that a number of them have shown marked anti-microbiological activity (7) and thus it was decided to examine the syntheses of isatogens in more detail. It was of interest to know whether the extended conjugated system of 1-*o*-nitrophenyl-4-phenyl-1,3-butadiene (**5***a*) and 1-*o*-nitrophenyl-6-phenyl-1,3,5-hexatriene (**5***b*) would influence the photochemical formation of 2-substituted isatogens (Scheme 1).

Results and Discussion

Thus, irradiation of 3.8×10^{-3} *M* solutions of **5***a* and 7.9×10^{-3} *M* iodine in dry benzene under nitrogen gave, after 3 days, a 12% yield of red crystals of 2-styrylisatogen (**6***a*). The structure of **6***a* was confirmed by comparison with a sample synthesized by another route (8).

Irradiation of 3.6×10^{-3} *M* solutions of **5***b* and 8.0×10^{-3} *M* iodine in dry benzene under nitrogen gave, after 3 days, a dark red product, 2-(4-phenylbuta-1,3-dien-1-yl)isatogen (**6***b*) in a 25% conversion from **5***b*. In addition, 60% of the starting material was recovered.

The photochemical reaction of *o,o*′-dinitrostilbene gave 2-(*o*-nitrophenyl)isatogen (5). The analogous photo-reactions of 1,4-di-*o*-nitrophenyl-1,3-butadiene (**5***c*) and 1,6-di-*o*-nitrophenyl-1,3,5-hexatriene (**5***d*) were attempted to determine the affect of the additional nitro group

[1]For Part III, see ref. 23.

a R = Ph
b R = Ph
c R = o-NO2Ph
d R = o-NO2Ph

SCHEME 1

on the photochemical formation of isatogens and to explore the possibility of formation of bis isatogens (Scheme 1).

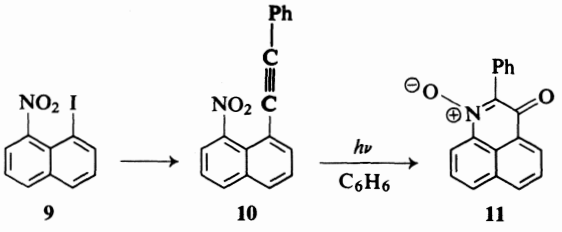
Thus, the photo reaction of a 3.4×10^{-3} *M* solution of **5***c* and 8.0×10^{-3} *M* iodine in dry benzene under nitrogen for 3 days gave a 30% yield of 2-(*o*-nitrostyryl)isatogen (**6***c*). Similarly irradiation of **5***d* gave a 9.1% conversion to 2-(4-*o*-nitrophenylbuta-1,3-dien-1-yl)isatogen (**6***d*) and a 30% recovery of starting material. On the other hand, 1,6-di-*m*- and 1,6-di-*p*-nitrophenyl-6-phenyl-1,3,5-hexatrienes (**7** and **8**) respectively were inert to the irradiation conditions.

Isatogens **6***c* and *d* were purified by preparative t.l.c. and irradiated. No further reactions occurred and no bis isatogens were formed.

The structures of isatogens **6***a–d* were determined primarily from spectroscopic data. The i.r. spectra were especially informative and showed —C=O— stretching vibrations at 1710 cm^{-1} and —$\overset{+}{N}$—$O^{\ominus}$—absorption peaks at 1170 cm^{-1} typical of the isatogen structure. The mass spectra of isatogens **6***a–d* showed parent ions and were consistent with the fragmentation pattern of the published mass spectra of known isatogens (9). All isatogens were dark red compounds and had correct elemental analyses. The n.m.r. spectra of **6***a* and *b* were uninformative and simply showed multiple absorption peaks between 6.5 and 7.5 p.p.m.

Isatogen-like compounds containing six- and seven-membered rings have not been prepared and it was thought that the photochemical reactions of suitable nitrostilbene derivatives could lead to the appropriate isatogen analog. Recently, however, Bond and Hooper (10) have shown that isatogens can be synthesized through tolan intermediates and it was decided to attempt the syntheses of isatogen-like compounds by this method.

The reaction of 1-iodo-8-nitronaphthalene (**9**) with cuprous phenylacetylide in pyridine for 72 h gave a mixture of 1-[1′-(8′-nitronaphthyl)]-2-phenylacetylene (**10**) and starting iodo **9**. The presence of **10** was shown by a sharp band in the i.r. spectrum of **10** at 2242 cm^{-1}, characteristic of the —C≡C— stretching frequency. The crude acetylene **10** was irradiated for 72 h in dry benzene under nitrogen to give, after purification by preparative t.l.c., a 15% yield of the dark red, 2-phenyl-3-oxo-benzo[*d,e*]quinoline-*N*-oxide (**11**), a six-membered ring isatogen analog (Scheme 2). The i.r. spectrum of **11** was characteristic of an isatogen-like compound and showed absorption peaks at 1710 and 1723 cm^{-1} (—C=O) and a weak absorption at 1173 cm^{-1} due to the $\overset{+}{N}$—$O^{\ominus}$ group. The n.m.r. spectrum of **11** showed an absorption peak at 8.96 p.p.m. due to the two ortho protons of the 2-phenyl substituent. The two ortho protons of the phenyl substituent of 2-phenylisatogens are known to be shifted downfield relative to the other protons attached to an aromatic ring (10).



9 10 11

SCHEME 2

The reaction of 2-iodo-2′-nitrobiphenyl (**12**) with cuprous phenylacetylide in pyridine under reflux for 72 h gave a mixture of *o*-(2′-nitrophenyl)tolan (**13**) and starting iodo **12**. The mixture was heated further for 72 h with excess cuprous acetylide to give a 2.6% yield of a dark-brown product, 6-phenyl-7-oxo-dibenzo[*b,d*]azepine-*N*-oxide (**14**), a seven-membered ring isatogen-like compound (Scheme 3). The i.r. spectrum of **14** showed typical carbonyl absorption at 1712, 1721, and 1728 cm^{-1} and a weak (—$\overset{+}{N}$—$O^{\ominus}$) absorption peak at 1187 cm^{-1}. The n.m.r. spectrum of **14** showed peaks at 8.38 p.p.m. due to the ortho protons of the 6-phenyl substituent.

The spectral data of all the compounds are consistent with the assigned structures.

The mechanism of formation of isatogens from the photoreaction of *o*-nitrostilbenes has been discussed by other workers (5, 6) but firm

12 **13** **14**

SCHEME 3

evidence regarding postulated intermediates is lacking. The formation of **11** and **14** by photochemical and thermal means respectively is significant in the fact that the steric requirements necessary for the formation of isatogens (five-membered ring) is *not* stringent and the formation of six and seven-membered ring isatogen-like compounds is readily achieved.

Experimental

All melting points were determined on a Kofler hot stage and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer 257 i.r. spectrometer using KBr discs. The u.v. spectra were measured using a Cary 14 u.v. spectrometer and benzene as a solvent. The n.m.r. spectra were measured on a Varian A60 spectrometer using tetramethylsilane as an internal standard ($\delta = 0$ p.p.m.) and deuterochloroform as solvent. Mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6 mass spectrometer. Silica gel was used for thin- and thick-layer chromatography. All photochemical reactions were carried out in a Rayonet photochemical reactor using RPR 3500 Å lamps. Microanalyses were performed by A. B. Gygli of Toronto.

Synthesis of 1-Nitrophenyl-4-phenyl-1,3-butadienes

A typical example is given for the preparation of 1-*o*-nitrophenyl-4-phenyl-1,3-butadiene (**5***a*). To a mixture of 3.43 g (0.026 mol) of cinnamaldehyde and 12.0 g (0.025 mol) of *o*-nitrobenzyltriphenylphosphonium chloride in 100 ml methanol, was added 130 ml of 0.2 *M* lithium methoxide. The mixture was allowed to crystallize overnight after which crystals of **5***a* were obtained in 30% yield; m.p. 96–97° (lit. 98–99° (11)).

1-m-Nitrophenyl-4-phenyl-1,3-butadiene (1)

The m.p. 145–146° (lit. 145–146° (12)); yield 46%.

1-p-Nitrophenyl-4-phenyl-1,3-butadiene (2)

The m.p. 180–181° (lit. 181.5–182° (13)); yield 36%.

Synthesis of 1,4-Di-o-nitrophenyl-1,3-butadiene (5c)

1,4-Di-*o*-nitrophenyl-1,3-butadiene (**5***c*) was prepared by reacting *o*-nitrobenzyltriphenylphosphonium chloride and *o*-nitrocinnamaldehyde by the Wittig procedure identical to that given above. Product **5***c* was obtained in 49% yield; m.p. 219–220° (lit. 210–220° (14)).

Preparation of 1-Nitrophenyl-6-phenyl-1,3,5-hexatrienes

A typical example is given for the preparation of 1-*o*-nitrophenyl-6-phenyl-1,3,5-hexatriene (**5***b*). To a mixture of 2.0 g (0.0126 mol) of 5-phenylpenta-2,4-dien-1-al (15) and 6.0 g (0.0126 mol) of *o*-nitrobenzyltriphenylphosphonium chloride in 30 ml methanol was added 50 ml of 0.4 *M* lithium methoxide. The mixture was allowed to crystallize overnight after which crystals of **5***b*, m.p. 104–105°, were obtained in 17% yield.

Anal. Calcd. for $C_{18}H_{15}NO_2$: C, 77.98; H, 5.42; N, 5.04. Found: C, 78.19; H, 5.21; N, 5.14.

1-m-Nitrophenyl-6-phenyl-1,3,5-hexatriene (3)

The m.p. 184–185° (lit. 184–185° (13)); yield 54%.

1-p-Nitrophenyl-6-phenyl-1,3,5-hexatriene (4)

The m.p. 194–195° (lit. 194–196° (16)); yield 63%.

Preparation of 1,6-Di-nitrophenyl-1,3,5-hexatrienes

A typical example is given for the preparation of 1,6-di-*o*-nitrophenyl-1,3,5-hexatriene (**5***d*). To a mixture of 2.25 g (0.015 mol) of *o*-nitrobenzaldehyde and 3.25 g (0.007 mol) of 2-butene-1,4-bis(tri-*n*-butylphosphonium chloride) (17) in 50 ml methanol was added 60 ml of 0.2 *M* lithium methoxide. The mixture was allowed to crystallize overnight after which crystals of **5***d*, m.p. 232–233°, were obtained in 64% yield.

Anal. Calcd. for $C_{18}H_{14}N_2O_4$: C, 67.08; H, 4.38; N, 8.69. Found: C, 67.01; H, 4.75; N, 8.37.

1,6-Di-m-nitrophenyl-1,3,5-hexatriene (7)

The m.p. 165–166°; yield 83%.

Anal. Calcd. for $C_{18}H_{14}N_2O_4$: C, 67.08; H, 4.35; N, 8.69. Found: C, 67.24; H, 4.22; N, 8.54.

*1,6-Di-p-nitrophenyl-1,3,5-hexatriene (**8**)*

The m.p. 218–219° (lit. 218–219° (17)); yield 62%.

Spectral Properties of the Substituted-nitrophenylpolyenes

The spectral data of these compounds are given in Table 1.

Synthesis of Mono-nitrobenzyltriphenylphosphonium Halides

The mono-nitrobenzyltriphenylphosphonium halides were prepared by a procedure identical to that given previously (4).

o-Nitrobenzyltriphenylphosphonium Chloride

The m.p. 233–234° (lit. 230° (18)).

m-Nitrobenzyltriphenylphosphonium Bromide

The m.p. 260–262° (lit. 261° (19)).

p-Nitrobenzyltriphenylphosphonium Bromide

The m.p. 279–279.5° (lit. 275–275.5° (13)).

Irradiation of Nitrophenyl Polyenes

The general techniques of irradiation on a preparative scale have been described previously (4). The photocyclization reaction products were isolated by preparative thick layer chromatography (t.l.c.) using hexane:benzene (1:2) as eluant. All the photocyclization products moved slower than the starting *o*-nitrophenyl polyenes on t.l.c. Since, in general, the results have already been mentioned, only details of identification are given (see Tables 2 and 3).

*Preparation of 1-Phenyl-2-[1′(8′-nitronaphthyl)]-acetylene (**10**)*

A mixture of 0.5 g (0.0167 mol) of 1-iodo-8-nitronaphthalene (20) and 0.275 g (0.0167 mol) of cuprous phenylacetylide (21) in 50 ml of dry pyridine was heated under reflux for 72 h in a nitrogen atmosphere. The pyridine was removed under reduced pressure and the residue was extracted with a benzene:water (1:1) mixture. The benzene layer was purified by preparative t.l.c. to give an inseparable mixture of what appeared to consist of the starting material 1-iodo-8-nitronaphthalene and the tolan (**10**). The i.r. spectrum of the mixture showed an absorption peak at 2242 cm^{-1}.

The Irradiation Product of 1-Phenyl-2-[1′(8′-nitronaphthyl)]-acetylene

The isatogen-like analog 2-phenyl-3-oxo-benzo[*d,e*]-quinoline-*N*-oxide was identified by its physical and spectral properties given in Tables 2 and 3 and by its n.m.r. spectrum which showed signals at 8.96 for H-2 (doublet) and 8.12–8.64 p.p.m. for H-9 (multiplet).

*Preparation of 6-Phenyl-7-oxo-dibenzo[b,d]azepine-N-oxide (**14**)*

A mixture of 1.0 g (0.0036 mol) of 2-iodo-2′-nitrobiphenyl (22) and 0.5 g (0.00306 mol) of cuprous phenylacetylide (20′) in 50 ml of dry pyridine was heated under reflux for 72 h in an atmosphere of nitrogen. Then the pyridine was removed under reduced pressure and the residue was extracted with benzene:water (1:1) mixture. The benzene layer was purified by preparative t.l.c. to give two products. The first consisted of a mixture of what appeared to be 2-iodo-2′-nitrobiphenyl (**12**) and *o*-(2′-nitrophenyl)tolan (**13**) (the i.r. spectrum of the mixture showed an absorption peak at 2226 cm^{-1}). The other product, a dark brown compound, was found to be 6-phenyl-7-oxo-dibenzo[*b,d*]azepine-*N*-oxide (**14**) identified by its physical and spectral properties (Tables 2 and 3) and by its n.m.r. spectrum which showed signals at 8.38 for H-2 (doublet) and 7.58–7.18 p.p.m. for H-11 (multiplet).

The authors are grateful for the support of this research by the National Research Council of Canada and to Professor R. L. Letsinger for some helpful discussions.

Cyclopentadienylidenecarbonyl: the Major Primary Thermolytic Fragment of Salicylaldehyde

O. A. MAMER

Division of Clinical Biochemistry, Department of Experimental Medicine, McGill University, Montreal, Quebec

Received July 5, 1971

The thermal fragmentation of salicylaldehyde was studied from two aspects. Firstly, the temperature dependence of the intensity of the thermolytic fragment molecular ions was observed at 11 eV in the effluent from a helium flow thermal reactor attached through a helium separator to the ion source of a mass spectrometer. Secondly, the products of the thermolysis on a semi-preparative scale under trapping conditions were determined by coupled gas chromatographic – mass spectrometric analysis.

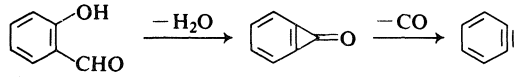
The title compound is the major primary thermal fragment in this study and was trapped with methanol as carboxymethylcyclopentadiene.

On a étudié la fragmentation thermique de la salicylaldéhyde sous deux aspects. On a observé premièrement la dépendance de la température sur l'intensité des fragments thermolytiques d'ions moléculaires obtenus à 11 eV dans un réacteur thermique à courant d'hélium, fixé dans un séparateur à hélium à la source d'ions d'un spectromètre de masse. On a déterminé deuxièmement les produits de la thermolyse sur une échelle semi-préparative par une analyse combinée c.p.g.–s.m.

Le composé mentionné dans le titre de l'article est le fragment thermique primaire principal obtenu dans cette étude et fut recueilli avec le méthanol sous forme de carboxyméthylcyclopentadiène.

Canadian Journal of Chemistry, 49, 3602 (1971)

In the course of a preliminary investigation into the relationships between the electron impact fragmentation of some ortho-substituted phenols it became of interest to study the thermolysis (1)[1] of salicylaldehyde (**1**). It was thought that the presence of an odd electron, even mass number peak *m/e* 76, 19% (2) in the spectrum of **1** might suggest a facile thermolytic preparative method for benzyne (Scheme 1) in much the same way as the thermolysis of phthalic anhydride is known to yield benzyne (3).

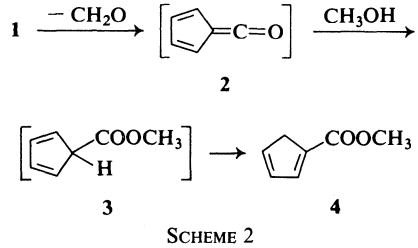


1

SCHEME 1

Surprisingly, the primary major thermolytic fragment of **1** was eventually shown to be the title compound **2** by trapping it with methanol (Scheme 2) as **4**, the methyl ester of cyclopentadienecarboxylic acid, by a modification of a method recently reported for the same compound (4). Rearrangement of **3** to the more highly conjugated **4** has been previously reported (5).

The thermolytic behavior of **1** was studied with two furnaces. Furnace A, Fig. 1, is a low pressure



SCHEME 2

quartz flow reactor capable of reaching a temperature in excess of 1100° with a helium carrier. Furnace effluent is split in a ratio which determines in part the furnace pressure, one part going to the pumps, the second through the Becker–Ryhage helium separator (6) to the ion source of the LKB 9000 coupled gas chromatograph–mass spectrometer (g.c.–m.s.) used for the study.

By employing low ionizing energy (11 eV typically) we could sort out the molecular ions of thermolytic fragments and observe their behavior while varying the furnace temperature. Figure 2 shows the temperature dependence of the significant mass numbers in the thermolysate of **1**.

As *m/e* 122 decomposes, a thermal fragment with *m/e* 92 is produced which also decomposes with increasing temperature, probably into fragments of *m/e* 64 and 28. At very high temperatures as the yield of 92 begins to greatly diminish, 64

[1]As opposed to "pyrolysis".

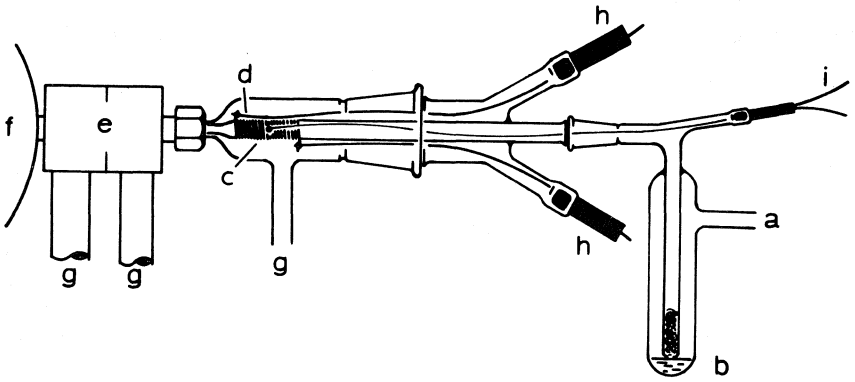


FIG. 1. Furnace A. Quartz reactor for flash thermolysis in a low pressure helium flow; (*a*) helium inlet (0.01–0.1 Torr); (*b*) sample; (*c*) Chromel–Alumel thermocouple junction; (*d*) nichrome windings on quartz furnace; (*e*) Becker–Ryhage separator; (*f*) ion source; (*g*) to pumping system; (*h*) furnace electrical leads soft-soldered through Kovar seals; (*i*) thermocouple leads in a single 1.6 mm diameter Inconel sheath soft-soldered through Kovar seal. Furnace effluent is stripped of most of the helium carrier by the separator allowing thermolysate molecular ion detection at greater concentrations in the ion source. A glass wool plug between the sample and furnace is needed to reduce the introduction of aerosols or dusts into the furnace.

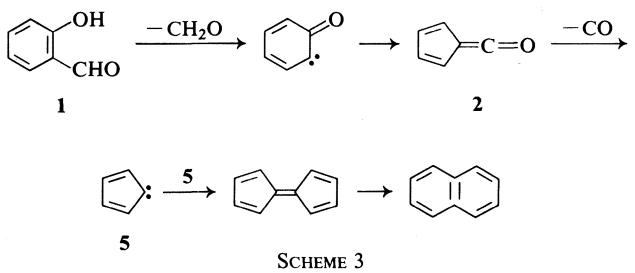

SCHEME 3

appears to fall off due to a dimerization reaction yielding 128. No significant increase at *m/e* 76 could be detected to support the occurrence of benzyne in this thermolysis.

Scheme 3 is proposed to account for the ion intensity *vs.* temperature data of Fig. 2 in the pyrolysis of **1**. A similar scheme has been proposed for the thermolysis of *o*-phenylene carbonate (4) involving **2** as an intermediate based on product analysis. A competing process in this last work is the elimination of two molecules of CO to yield cyclopentadienone which was detected as the dimer.

Furnace B, Fig. 3, was used to thermolyze **1** in such a way as to enable the trapping of reactive intermediates by bubbling them at a high rate in the argon carrier through the trapping methanol. The furnace pressure in B is necessarily higher than in furnace A because a hydrostatic head of approximately 1 to 2 mm of methanol must be overcome for bubbling to occur.

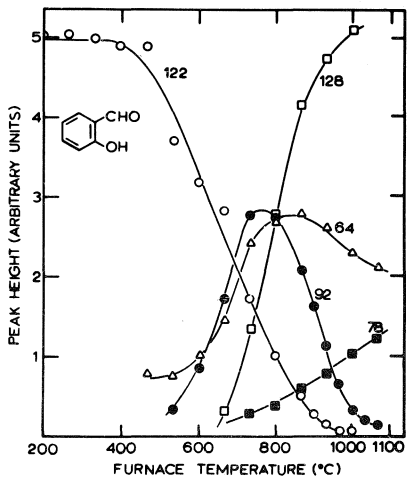

FIG. 2. Thermolysis of salicylaldehyde. Variation of significant *m/e* values with temperature of furnace A.

Thermal fragment assignments are: ○, *m/e* 122, **1**; ●, *m/e* 92, **2**; △, *m/e* 64, **5**; □, *m/e* 128, naphthalene; ■, *m/e* 78, benzene.

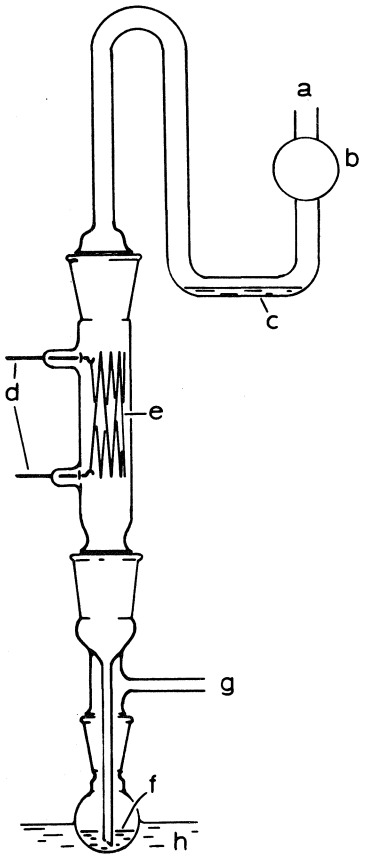

FIG. 3. Furnace B. Semi-preparative thermolysis reactor arranged for trapping experiments; (*a*) argon supply (1 atm); (*b*) flow moderating needle value; (*c*) sample; (*d*) furnace electrical leads; (*e*) nichrome filaments; (*f*) trapping reagent; (*g*) to pumping system; (*h*) cooling bath (acetone – Dry Ice).

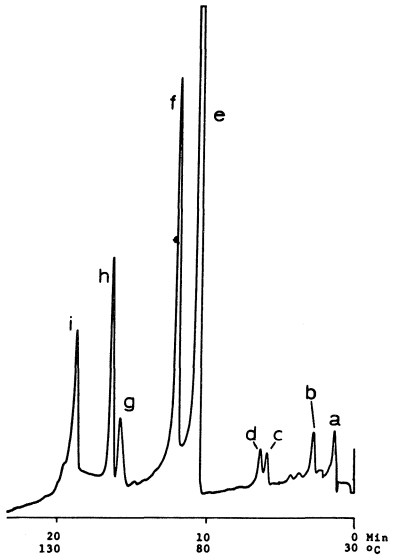

FIG. 4. Gas chromatogram of thermolysate–methanol solution prepared with furnace B; (*a*) benzene; (*b*) toluene; (*c*) phenylacetylene; (*d*) styrene; (*e*) carboxymethylcyclopentadiene; (*f*) salicylaldehyde; (*g*) unknown; (*h*) naphthalene; (*i*) salicylaldehyde dimethylacetal. The height of peak *e* (**4**) is approximately 5.5 times the recorder limits. Apparent baseline drift is due to slow decomposition of salicylaldehyde dimethylacetal on the column.

By keeping the trapping methanol at $-78°$, the methanolysis of the ketene moiety appears complete while the Diels–Alder dimerization reaction through the cyclopentadiene ring is inhibited to the extent that the sample may be stored for several days at this temperature relatively unchanged (5).

Figure 4 is the gas chromatogram obtained on analysis of the trap contents immediately after the conclusion of the thermolysis. Each eluting peak in the g.c. record was scanned at high speed with the mass spectrometer. Each spectrum and retention time was compared with those for authentic samples when available to make the identifications indicated in Fig. 4. The mass spectrum of carboxymethylcyclopentadiene (**4**) is reproduced in Fig. 5. The isotopic distribution pattern in the molecular ion requires the formula $C_7H_8O_2$ and the spectrum is consistent with the structural assignment indicated. It is also consistent with what might be considered that part of the spectrum reported (7) for dimeric **4** arising from a retro-Diels–Alder monomerization in the ion source.

When ethanol is used as the trapping agent the corresponding ethyl ester is obtained in similar yields and has a mass spectrum consistent with this assignment (molecular ion 138, $C_8H_{10}O_2$ by isotopic distribution).

DeJongh and Brent (4*b*) propose that **2** dimerizes under thermolytic conditions to yield a tricyclic diketene intermediate which in turn suffers loss of C_2O and CO and re-arrangement to indene. No trace of indene could be detected in our thermolysate possibly because rapid quenching and methanolysis may compete more successfully for **2** than dimerization.

The other significant thermolytic product de-

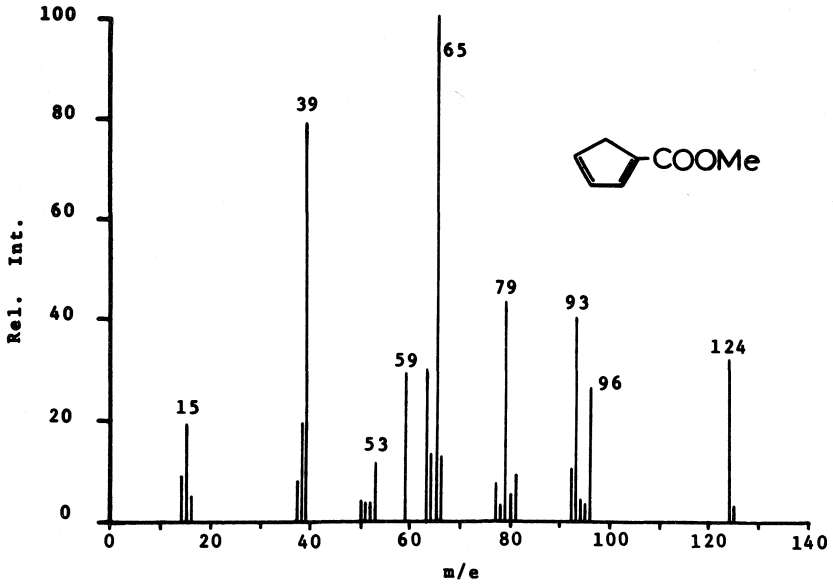

FIG. 5. Mass spectrum of **4** "on the fly" in the thermolysate gas chromatogram (Fig. 4, peak *e*). Presumed molecular ion *m/e* 124, formula $C_7H_8O_2$ by isotopic distribution.

tected was naphthalene which supports that part of the pathway of Scheme 3 earlier proposed in the *o*-phenylene carbonate pyrolysis (4*b*).

The relatively minor amounts of benzene, toluene, phenylacetylene, and styrene probably arise from the recombination of small fragments like acetylene and ethylene (8) or radical hydrocarbons formed by direct contact of heavier fragments or **1** at the incandescent nichrome wire.

Salicylaldehyde dimethylacetal is probably formed by the condensation of surviving thermally excited **1** with methanol in the trap. The mass spectrum of this peak is identical with the authentic compound (9).

Our data strongly suggest that Scheme 3 is the main thermolytic pathway of **1** and that under proper conditions cyclopentadienylidenecarbonyl can be generated from **1** in useful concentrations as a highly reactive intermediate for synthetic or trapping purposes.

Experimental

The thermolyses were conducted on salicylaldehyde as received from the supplier (British Drug Houses). Gas chromatographic retention times and mass spectra of commercially available compounds were used to establish the identity of most of the thermolytic products. An LKB 9000 combined g.c.–m.s. was used for the study in two modes as explained below.

Thermolytic Experiments

Furnace A (Fig. 1)

Before an experiment, the system was equilibrated by allowing a few milligrams of **1** to evaporate slowly from the sample holder into the helium flow over a period of about 30 min with the furnace set at about 250° and the helium flow rate adjusted to that required for the experiment. Several heating and cooling cycles of the furnace were made immediately prior to a run to ensure against ion source pressure increases due to volatilization of any condensed material from the cooler parts of the furnace.

After each furnace temperature increment, a 2 min thermal re-equilibration period was observed. Increasing the length of this period had no apparent effect on the data. Following re-equilibration, a slow scan (20 s) of the mass range *m/e* 10–250 was made with the detector output heavily filtered to reduce amplifier noise at the top of the mass peaks. Peak heights were then measured from the u.v. oscillograph tracing corresponding to each furnace temperature. Figure 2 summarizes this data. The operating conditions were: ionizing energy, 11 eV at 60×10^{-6} A; accelerating potential, 3.5 kV; source temperature, 290°; separator temperature 280°; electron multiplier output filter cutoff at 20 Hz; source slit, 0.15 mm; detector slit 0.5 mm; furnace pressure, 30 μ.

Furnace B (Fig. 3)

Thermolysis with furnace B was carried out with methanol (0.5 ml) in the trap at −78°, the nichrome filaments at approximately 800°, and an argon carrier flow rate moderated with the needle valve to maintain a rapid and violent bubbling in the trap (40 ml min^{-1} argon measured at room temperature and pressure at the pump outlet). Contact time was calculated to be 50 ms. Cooling the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

furnace with a draught of ambient air was necessary to prevent softening and collapse of the Pyrex walls. Thermolysis was allowed to proceed for approximately 15 min and then the furnace was cooled and the system brought to room pressure by closing off the pumping system and increasing the argon flow.

The trap containing the methanol solution of the thermolysate (pale yellow) was disconnected and kept at Dry Ice temperature. Aliquots of the mixture were withdrawn by syringe and analyzed with the m.s. in the g.c. coupled mode: injector 300°; column, 2 m × 6 mm glass containing 3% SE 30 Ultraphase on Chromosorb W, High Performance (Pierce Chemical), temperature programmed from 30–200° at 5° min^{-1}; helium flow rate, 30 ml min^{-1}; separator, 280°; ion source, 290°, ionizing energy 70 eV scan mode (20 eV g.c. detection mode) at 60 × 10^{-6} A; scan range *m/e* 10–250 in 3 s. The gas chromatogram with peaks identified is shown in Fig. 4.

Integration of the peak areas in Fig. 4 indicates that **4** amounts to 78% of the volatile components of the thermolysate (excluding methanol).

Storage of the thermolysate solution at room temperature caused a reduction of the size of the peak for **4** to near extinction in a day or two and a simultaneous increase in a broad peak having a mass spectrum similar to that reported (7) for the dimer of **4**.

The LKB 9000 g.c.–m.s. used in this study was granted by the Medical Research Council of Canada (#ME 3720) to the Faculty of Medicine of McGill University. The author also wishes to acknowledge the general assistance in this work of Miss S. S. Tjoa. The author is especially indebted to Dr. F. P. Lossing for his suggestions and interest in the progress of this work. A useful discussion with Dr. I. P. Fisher on the design and coupling of furnace A through the Becker–Ryhage separator is gratefully recognized.

Isolation and Structure of a Dilignol Rhamnoside From the Leaves of *Thuja plicata* Trees

GARY D. MANNERS[1]

Faculty of Forestry, University of British Columbia, Vancouver, British Columbia

AND

ERIC P. SWAN[2]

Department of the Environment, Western Forest Products Laboratory, and Faculty of Forestry, University of British Columbia, Vancouver, British Columbia

Received June 24, 1971

The isolation of a series of dilignol glycosides from the leaves of western red cedar trees is described. The structure of the first member of this series was determined by chemical degradation reactions and n.m.r. and mass spectra of its derivatives. It is 1-(3′-methoxy-4′-hydroxyphenyl)-2-*O*-1′′-[2′′-hydroxy-4′′-(propane-3′′′-*O*-α-L-rhamnopyranoside)phenyl]-propane-1,3-diol (**1**). The novel features of this compound are discussed, together with its possible roles in the leaves.

On décrit l'isolement d'une série de glycosides de dilignol à partir des feuilles du cèdre rouge de l'ouest. La structure du premier membre de cette série fut déterminée par des réactions de dégradation chimique, par résonance magnétique nucléaire et par spectrométrie de masse de ses dérivés. Il s'agit du 1-(3′-méthoxy-4′-hydrophényl)-2-*O*-1′′-[2′′-hydroxy-4′′-(propane-3′′′-*O*-α-L-rhamnopyranoside)phényl]-propane-1,3 diol (**1**). On discute des caractéristiques de ce composé, de même que des fonctions possibles qu'il peut occuper dans les feuilles.

Canadian Journal of Chemistry, **49**, 3607 (1971)

Studies of western red cedar (*Thuja plicata* Donn) extractives from these laboratories have dealt mainly with heartwood. We now describe some phenolic compounds in leaves. The only previous work on these compounds from this species was on the biflavonoids (1). However, two glycosides of guaiacylglycerol were identified in leaves of another softwood (*Pinus sylvestris* L.) (2). These compounds are the only ones germane to this paper, other studies on softwood leaf tissues having been concerned with carbohydrate content.

Compound **1** was obtained as an amorphous solid from a sequence of column chromatographic separations of the ethyl acetate fraction from leaf extract. Attempts to crystallize the compound from organic solvents were unsuccessful. On the basis of the following results, compound **1** was identified as 1-(3′-methoxy-4′-hydroxyphenyl)-2-*O*-1′′-[2′′-hydroxy-4′′-(propane-3′′′-*O*-α-L-rhamnoside)phenyl]-propane-1,3 diol.

The color reaction of **1** with diazotized sulfanilic acid (bright orange) and its positive reaction with Gierer's reagent (6) were characteristic of an α-hydroxyguaiacyl derivative. Schroeder's reaction (7), for the detection of dihydroxy groups, was negative. Since alkaline nitrobenzene oxidation of **1** gave vanillin and protocatechualdehyde, the test with Schroeder's reagent showed that one of the hydroxyl groups on the pyrocatechol nucleus must be etherified. Hydrolysis of the compound showed several phenolic products and L-rhamnose.

Ethanolysis gave the Hibbert's ketones 1-guaiacyl-2-ethoxypropan-1-one and 1-guaiacylpropan-2-one, and an uncharacterized pyrocatechol derivative indicated by color reactions. Another ethanolysis of the fully methylated derivative of compound **1** yielded dihydroconiferyl alcohol and 1-verartryl-2-ethoxypropan-1-one. The free aromatic hydroxyl group of dihydroconiferyl alcohol established the unusual 4′′-*n*-propan-3′′′-ol side chain and the 2-4′′ alkyl–aryl ether linkage in **1**. The free aliphatic hydroxyl group established the point of attachment of the L-rhamnose in the molecule.

Proof that the arrangement of pyrocatechol and L-rhamnose groups were as shown and not interchanged, or that the substitution was as

1 R = H
2 R = Ac
3 R = CH_3

a β-aryl ether rather than γ- etc. was obtained from the following experiment. Periodate oxidation of diazomethane methylated (aromatic hydroxyls C-4′ and -2′) compound **1** showed an uptake of exactly 2 mol per mol of starting compound. This 2 mol consumption of periodate was solely from the L-rhamnose moiety and showed the absence of any other vicinal diol in compound **1**. Lack of a bathochromic shift of the u.v. maximum of the oxidized product in base was evidence that the glycosidic bond did not occur through an aromatic hydroxyl.

The low melting point of the acetate derivative **2** (m.p. 48–50°) suggested that the parent **1** was a mixture of *erythro-* and *threo*-isomers. Since t.l.c. (silica and cellulose) in several solvent systems had indicated purity for both **1** and **2**, n.m.r. was necessary to confirm that **1** was indeed a mixture of isomers.

Mass spectral determination of the molecular weight of **2** gave 804, with a calculated empirical formula (from M + 1/M ratio) of $C_{39}H_{48}O_{18}$, supported by carbon and hydrogen analyses. The u.v. $\Delta\varepsilon$ value (8.04×10^3) of **1** showed the existence of two phenolic hydroxyl groups. The i.r. data substantiated the existence of aromatic nuclei, a large number of hydroxyl groups, and the absence of carbonyl. The n.m.r. spectral analyses, including double resonance experiments, were primarily done on **2** and confirmed the above structure. All the expected features of spectrum of **2** were present: six aromatic protons equally divided amongst two rings, an α-L-rhamnopyranoside moiety, an *n*-propyl side chain, a glycerol side chain, one methoxyl, two phenolic acetates, and five aliphatic acetates; with no other unexpected features present and the correct proton integral for the above. The glycerol side chain was responsible for the mixture of *erythro-* and *threo*-isomers mentioned above. The chemical shift data and nature of the n.m.r. spectrum of **2** is in agreement with similar data recorded for 1-(3,4-dimethoxyphenyl)-2-(2′-methoxyphenoxy)-propane-1,3 diol acetate reported by Ludwig *et al.* (8), and by Hemmer and Liaaen–Jensen for methyl-α-L-rhamnopyranoside triacetate (4).

Similarly, the mass spectrum of **2** shows the parent ion at *m/e* = 804 and other features expected from its fragmentation. The rhamnose triacetate moiety corresponded to the published data on the mass spectrum of methyl α-L-rhamnopyranoside triacetate (4). Several other features of the acetylated guaiacylglycerol part of **2** can be illustrated through probable formulae related to major ions *m/e* 323, 201, 221, 179, and 153, and of the acetylated *n*-propylcatechol part of **2** to *m/e* 331, 169, and 123.

Several characteristics of compound **1** are novel and require comment. First, this compound constitutes the first isolation and characterization of a free dilignol (9) glycoside. Second, the compound exists as an unusual rhamnoside rather than more commonly observed glucosides. Third, the rhamnoside is connected to the compound through a previously unreported aliphatic hydroxyl position rather than the expected aromatic hydroxyl position. Fourth, the existence of a saturated propyl side chain is unreported among other dilignols which were isolated using hydrolytic conditions, and is biosynthetically unusual. Finally, the existence of a pyrocatechol group is unreported among dilignols previously isolated and characterized.

The structure of **1** suggests the possibility of its hydrolysis and polymerization into a lignin molecule. The occurrence of pyrocatechol groupings in bark lignins (10) substantiates this, but translocation much beyond local environs of aromatic (particularly dimeric) lignin precursors is unlikely. Thus, either **1** is destined to incorporation into leaf lignin, or it may be representative of extractives which exist as free dilignols with secondary physiological functions, for example, protection mechanisms in the leaves. Since injury or disease reactions may occur in leaves, then the rhamnosidic linkage of the dilignol rhamnoside may be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

cleaved to make the aglycone available for participation in detoxification or sealing-off activities.

The unusual structure of **1** suggests its participation in the less intensively studied bark or leaf lignin. A study of western red cedar bark using n.m.r. (11) has shown a lower methoxyl content and more aliphatic character than wood lignin. Thus **1** may act as precursor to lignin different in character than that observed in the wood. Such lignin may contain aryl–aryl bonded lignin polymers, which originate from coupling ortho to the *n*-propyl side chain of dilignol activated by the free pyrocatechol hydroxyl grouping. Further research on leaf lignin structure is planned.

The separation of several other related compounds isolated with **1** was accomplished. Their n.m.r. and mass spectra showed that they were also dilignol rhamnosides, but they were incompletely characterized so that structures for them are not reported here. All other compounds isolated were similar to **1**, but hydrolysis experiments gave D-glucose and L-arabinose as well as L-rhamnose. Work on their structures is continuing and will be reported later.

Experimental

Melting points (uncorrected) were taken on a Fisher–Johns apparatus. The i.r. spectra were obtained from KBr disks on a Perkin–Elmer 521; u.v. were obtained of ethanol solutions on a Beckman DK-2; n.m.r. spectra were obtained in deuterated solvents (tetramethylsilane $\tau = 10$ internal standard) on a Varian HA-100; mass spectra were obtained from Morgan-Schaeffer Corp., Montreal. Elemental analyses were obtained from Galbraith Laboratories Inc., Knoxville, Tennesee.

Paper chromatography and t.l.c. on cellulose were run with the solvents: 2% aqueous acetic acid (AA); *n*-butanol, chloroform, acetic acid, water (BCAW, 4:1:1:1); lower layer chloroform, acetic acid, water (CAW, 4:6:3). Detecting reagent was diazotized sulfanilic acid (DSA). The t.l.c. on silica used the solvents: chloroform, methanol (CM, 4:1) and benzene, ethanol (BE, 9:1). Detecting reagent was mixed nitric – sulfuric acids. Column chromatography was on Sephadex LH-20 (Pharmacia) and deactivated silicic acid (Fisher). The pressure pump was a Milton-Roy 196-47 and the eluant u.v. monitor was a Gilson UV 280 IF.

Isolation of Compounds

Yields of 1.47 g (0.76%, o.d. basis) of ethyl ether solubles and 23.8 g (3.86%) of ethyl acetate solubles were obtained from 1.5 kg (58.6% moisture) of fresh comminuted western red cedar leaves. The methanol-soluble chloroform-insoluble leaf extracts were partitioned first between ether–water and then the water fraction between ethyl acetate – water to obtain the above fractions, all others were discarded. The crude ethyl acetate extract contained at least five phenolic compounds giving the distinctive yellow–orange color with DSA characteristic of α-hydroxy guaiacyl groups. These compounds were separated from other material by two-stage column chromatography on LH-20 (gradient elution), and the major compound **1** was separated from its relatives by a similar procedure on silica gel. Approximate yields: **1**, 0.15 g; other relatives (orange–yellow with DSA), 0.35 g (o.d. basis) from the leaves.

Compound 1

The R_f values on cellulose were 0.76, 0.63, and 0.50 for AA, BCAW, and CAW, and on silica were 0.14 and 0.29 for BE and CM. A white amorphous powder, **1** had λ_{max} 279 shifting to 289.5 nm in base with $\Delta\varepsilon_{max}$ 8.04×10^3, indicating two phenolic hydroxyl groups. The i.r. bands: 3400 (s, strong), 2928 (s), 1770 (w, weak), 1605 (s), 1505 (s), 1449 (m, medium), 1429 (m), 1370 (m), 1270 (s), 1230 (m), 1207 (m), 1123 (s), 1089 (s), 1042 (s), 978 (2), 909 (w), 877 (w), 805 (w), 781 (w) cm^{-1}.

The n.m.r. (deutero-dimethyl sulfoxide τ numbers) 6H multiplet at 2.9–3.61, two singlets (1.30, 2.5, phenolic OH) 12–14H multiplet at 6.1–6.8 (aliphatic OH), singlet at 5.07 (1H, benzyl proton), 1H (methine) at 6.00 (determined by nuclear magnetic double resonance (n.m.d.r.)) and 2H multiplet at 8.18 (methylene); total integral 30–35H.

Compound **1** reacted to give a positive Gierer (6) test for benzyl hydroxyl group and a negative Schroeder (7) test for *o*-dihydroxyphenyl group. Alkaline nitrobenzene oxidation showed (t.l.c) vanillin and protocatechualdehyde as the products.

Catalytic hydrogenolysis (1 atm, room temperature) of **1** (10 mg in 10 ml ethanol) was run with $PdCl_2$–$BaSO_4$ (10 mg), a catalyst (3) highly reactive in the reduction of benzyl hydroxyl groups. The product, which was also not crystalline, gave a negative Gierer test.

Hydrolysis of **1** was very difficult. Enzymatic hydrolysis gave a very low yield of probable aglycone (low R_f in CM). More vigorous hydrolyses (2% aqueous oxalic acid or 6% methanolic hydrogen chloride at 100° for 2 h) were unsuccessful because of the formation of several phenolic compounds, none of which was the aglycone (high R_f in CM). This was probably due to the side reactions of the benzyl alcohol group. L-Rhamnose was determined by paper chromatography in the hydrolysates.

Methylation

Aromatic hydroxyl methylation of **1** used diazomethane in methyl alcohol – ether. Silica t.l.c. (CM) of the product showed two compounds (R_f 0.45, 0.55); the R_f 0.55 was the desired compound. The R_f 0.45 compound was considered to be a singly methylated derivative, because remethylation of it (separated by column chromatography) gave the higher R_f compound, aromatically methylated **1**. The n.m.r. of this product showed 9H at $\tau = 6.21$ (3 methoxyl). This product (20 mg) in ethanol (2 ml) was reacted with 0.01 *N* sodium periodate, according to the procedure of Dyer (5). Aliquots of the reaction mixture were titrated with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

excess sodium arsenite (0.005 *M*) after 1 and 2 h. Consumption of periodate showed 2 mol consumed per mol of compound used after 1 h and no further after 2 h. The remainder of the reaction mixture was reacted with excess sodium arsenite, the p*H* was adjusted to 4.0 and the reaction product was taken into ethyl acetate by extraction (3 × 10 ml) in a separatory funnel. The combined ethyl acetate solutions were dried, filtered and the solvent was then removed *in vacuo*. The product (7 mg) was taken up in ethanol (100 ml) and its u.v. spectrum had λ_{max} 283 nm, unshifted in 0.01 *N* sodium methoxide. This showed that no new phenolic hydroxyl group was formed after the periodate cleaved the L-rhamnose.

Compound **1** (125 mg) was dissolved in dimethylformamide (5 ml) – methyl iodide (1 ml) and silver oxide (100 mg) was added. The reaction mixture (under nitrogen) was stirred overnight at room temperature, and then filtered and the volatile reactants removed *in vacuo*. The residue was added under nitrogen to a solution of sodium hydride (100 mg) in dimethylsulfoxide (10 ml) and, after a few minutes, methyl iodide (1 ml) was added. The reaction proceeded as before and was worked-up in the same way. The product was purified by preparative t.l.c. with BE solvent (R_f 0.10). The purified product was taken up in chloroform (1 ml) and added to petroleum ether (6 ml) – ether (2 ml) and set aside at about 5° to crystallize. The product **3** (light yellow crystals) had m.p. 54–58°, yield 22 mg.

Anal. Calcd. for $C_{32}H_{48}O_{11}$: C, 63.14; H, 7.95. Found: C, 63.17; H, 7.94.

Ethanolyses

Compound **1** (10 mg) was dissolved in 3% ethanolic hydrogen chloride (1 ml) under nitrogen in a sealed tube and heated at about 100° for 2 h. After cooling, the product was neutralized with sodium bicarbonate and shown to contain 1-guaiacyl-2-ethoxypropane-1-one (cellulose t.l.c. with butyl alcohol saturated with ammonia solvent).

The fully methylated derivative **3** (16 mg) was also subjected to ethanolysis using the same amounts and conditions as above. The product was neutralized with sodium bicarbonate, and shown to contain (t.l.c. and comparative i.r. spectra) dihydroconiferyl alcohol and 1-verartryl-2-ethoxypropan-1-one.

Acetylation to Compound 2

Compound **1** (25 mg) was treated at about 70° with pyridine (2 ml) and acetic anhydride (2 ml). After one h the volatile reactants were removed *in vacuo* and the residue was triturated with petroleum ether (65–110°) to give **2** (0.44 mg) as off-white microcrystals, m.p. 48–50°.

Anal. Calcd. for $C_{39}H_{48}O_{18}$: C, 58.20; H, 6.01. Found: C, 57.98; H, 5.85.

The n.m.r. (deutero-chloroform, τ numbers); 6H multiplet at 3.04–3.30, 3H singlet at 6.22 (methoxyl), two 3H singlets at 7.73 and 7.77 (aromatic acetates), 15H multiplet at 7.9–8.4 (aliphatic acetates); total integral 47–49. Rhamnose moiety: the anomeric H of an α-L-rhamnopyranoside is a singlet at 5.36 (4). A high field 3H doublet at 8.83 originated from C-6 coupling with the C_5-H (J = 6.5 Hz). The C_2–C_4 protons were at: H-2, 4.79 ($J_{2,3}$ = *ca.* 1 Hz); H-3, 4.77 ($J_{2,3}$ = 1.5, $J_{3,4}$ = *ca.* 10 Hz); H-4, 5.0 ($J_{4,5}$ = 4.5 Hz). The C-5 proton at 6.21 was not shifted through acetylation, as shown by n.m.d.r.

A 1H double doublet at 4.00 was assigned to the benzyl proton of a glycerol grouping. These doublets at 3.97 ($J_{1,2}$ = 7.0 Hz) and 4.05 ($J_{1,2}$ = 4.0 Hz) were attributed to a diastereomeric pair of β-guaiacylglycerol isomers. Since the C_2-H was associated with an ether-bonded carbon, it should have appeared in the region 4.5–6.0 (8). Using n.m.d.r. techniques, the 4.5–6.0 region was scanned while monitoring the low field doublet. The C_2-H resonance was located at 5.38, hidden beneath the anomeric proton resonance. The n.m.d.r. of the C_2-H caused the C_1-H doublets to collapse to two singlets at 3.97, 4.05. This irradiation of the C_2-H also clarified the multiplets in the region 5.6–6.1, indicating the C_3-(2H) resonance associated with the multiplet in this range.

The triplet (2H) at 7.37 (J = 3.7 Hz) and the multiplet (2H) at 8.18 were characteristic of the C-1‴ and C-2‴ protons of the *n*-propyl chain. When the resonance at 8.18 (under the aliphatic acetate envelope) was irradiated, the triplet at 7.37 collapsed to a singlet, thereby establishing it as the $C_{1'''}$-H resonance, and the 8.18 resonance as the $C_{2'''}$-H resonance. Irradiation of the C-2‴ resonance simplified the multiplet at 6.30–7.75 to an AB quartet 6.5 (τ_A = 6.35, τ_B = 6.65, $J_{(gem)}$ = 10.0 Hz). This resonance was from $C_{3'''}$-(2H). The chemical shift of the AB quartet suggested that they were methylene H associated with an ether bond which would occur at 5.5–6.0, rather than an ester bond. The AB nature of the spin–spin coupling of the geminal H of the methylene group indicated non-equivalence and suggested restricted rotation at the $C_{2'''}$—$C_{3'''}$ bond due to the bulky L-rhamnose moiety. Mass spectrum: *m/e* at 804 (1), 762 (7), 702 (8), 660 (2), 600 (3), 556 (2), 440 (8), 331 (8), 323 (20), 287 (10), 273 (38), 221 (24), 213 (12), 179 (19), 169 (45), 153 (80), 123 (24), 111 (49), 109 (32), 91 (33), 43 (100), figures in parentheses are percent heights of the base *m/e* of 43. Six acetate decomposition transitions were seen, two were accompanied by metastable ions:

$$804 \xrightarrow{m^* = 722.2} 762 + CH_2{=}C{=}O$$

and

$$762 \xrightarrow{m^* = 621} 702 + CH_3{-}COOH.$$

The others were:

$$702 \longrightarrow 642 + CH_3{-}COOH$$

$$642 \longrightarrow 600 + CH_2{=}C{=}O$$

$$702 \longrightarrow 660 + CH_2{=}C{=}O$$

and

$$660 \longrightarrow 600 + CH_3{-}COOH$$

The rhamnoside triacetate moiety was shown in the occurrence of an *m/e* = 273 and the ions 273, 213, 153, 111, and 109 are part of the fragmentation pathway (4).

Other Components

Several other compounds, with the same DSA color reaction as **1**, were isolated. Two in particular, **4** (R_f 0.73, 0.95 in BCAW, CAW) and **5** (R_f 0.73, 0.84),

were characterized sufficiently (n.m.r., mass spectra) to show they were closely related (dilignol rhamnosides) to **1**. Thus **4** had the same R_f as hydrogenated **1**, and mild hydrolysis of **4** gave **5**. Work on them is continuing. Other compounds gave D-glucose and L-arabinose on hydrolysis, but all had the same DSA color reaction.

We thank Dr. J. F. Manville for his generous help in interpreting the n.m.r. and n.m.d.r. spectra.

The Trifluoroacetic Acid Solvent System. Part III. The Acid, $HB(OOCCF_3)_4$, and the Solvent Autoprotolysis Constant

M. G. HARRISS AND J. B. MILNE[1]

Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received June 25, 1971

The limiting equivalent conductivities, Λ^0, of the acids, $HB(OOCCF_3)_4$ and $HSbF_5(OOCCF_3)$, and the salt, $CsB(OOCCF_3)_4$, have been measured and found to be 22.34, 18.77, and 48.56 ohm^{-1} cm^2 $equiv^{-1}$, respectively. Calculation of the solvent autoprotolysis constant gives the value: 4×10^{-14} mol^2 l^{-2}. The salt, $CsB(OOCCF_3)_4$ is readily prepared but the parent acid, $B(OOCCF_3)_3$ could not be isolated.

Les conductivités equivalentes limites, Λ^0, des acides $HB(OOCCF_3)_4$ et $HSbF_5(OOCCF_3)$, et du sel, $CsB(OOCCF_3)_4$, ont été mesurés et determinées comme étant 22.34, 18.77 et 48.56 ohm^{-1} cm^2 $equiv^{-1}$ respectivement. Le calcul de la constante autoprotolytique du solvant a donné la valeur: 4×10^{-14} mol^2 l^{-2}. Le sel $CsB(OOCCF_3)_4$ est facilement preparé mais l'acide correspondant $B(OOCCF_3)_3$ ne peut pas être isolé.

Canadian Journal of Chemistry, 49, 3612 (1971)

Introduction

Trifluoroacetic acid is a moderately strong acid in water (1) but as a bulk solvent it is weakly acidic and does not protonate even water (2, 3). As a base trifluoroacetic acid is very weak, being a non-electrolyte in 100% sulfuric acid (4). Several studies of acids in pure trifluoroacetic acid have been made (5–7) but the hygroscopic nature of the solvent and the low concentrations of solute that must be studied to avoid complication from higher ion aggregates ($< 10^{-4}$ M) make such studies difficult (7). Any water present in the solvent will react with an acid solute, HA, to give $H_3O^+A^-$ which will produce spurious results. Even the most carefully dried trifluoroacetic acid contains $\sim 10^{-3}$ M water (3). To avoid interference from water, trifluoroacetic acid anhydride may be added in small amounts ($\sim 0.5\%$) without seriously affecting the dielectic constant and viscosity of the solvent. However, the anhydride is found to react with many of the common strong acids (7). Two acids which may be studied in the presence of anhydride are $HSbF_5(OOCCF_3)$ (7) and $HB(OOCCF_3)_4$. The electrical conductivity of these acids and the cesium salt of the latter acid, $CsB(OOCCF_3)_4$ as well as the determination of the solvent autoprotolysis constant are the subject of this paper.

Experimental Section

The experimental methods and the extrapolation procedure for the conductivity measurements have been described in Part I (3). More recently, the first fractions (~500 ml) of doubly distilled trifluoroacetic acid (b.p. 71–72 °C) were used to rinse out the conductivity cell before collecting the fraction for conductivity studies. This procedure was followed without disconnecting the cell from the distillation apparatus by using a siphon arrangement. In this way pure acid with a conductivity one fifth of that previously reported (3) was obtained ($K_{sp} = 0.0064$ μmho cm^{-1}).

Solutions of $HB(OOCCF_3)_4$ for additions to the conductivity cell were made up in trifluoroacetic acid from stoichiometric quantities of boric acid (Analar) and trifluoroacetic acid anhydride. Several days were required for the boric acid to dissolve. The anhydride was prepared from trifluoroacetic acid and phosphorus pentoxide (3). A solution of $CsB(OOCCF_3)_4$ for conductivity studies was made up by dissolving a 1:1:3 mole ratio of $B(OH)_3$/$CsOOCCF_3$/$(CF_3CO)_2O$ in trifluoroacetic acid. A small excess of anhydride was present (~0.5%) in these solutions to maintain anhydrous conditions. All insoluble material dissolved within hours at room temperature. The procedures followed are essentially those used for the alkali metal trifluoroacetates (3).

The cesium salt, $CsB(OOCCF_3)_4$, was isolated from the solution as prepared for conductivity studies by removal of trifluoroacetic acid under vacuum to the point of crystallization. The crystals were then filtered out, washed with anhydride, and dried.

Anal. Calcd. for $CsB(OOCCF_3)_4$: B, 1.81; Cs, 22.27; ratio of acidic (CF_3CO_2) groups to B, 3. Found: B, 1.81; Cs, 22.26; ratio of acidic (CF_3CO_2) groups to B, 2.99.

The compound $B_2O(OOCCF_3)_4$ was isolated in several procedures while attempting to prepare $B(OOCCF_3)_3$. In one instance the analysis approached that of $B(OOCCF_3)_3$ but this compound was never obtained pure.

(*a*) Boric acid was mixed with trifluoroacetic acid anhydride slightly in excess of that required for the formation of $B(OOCCF_3)_3$. The insoluble material dissolved after several weeks at room temperature. The solution was then evaporated to the point of crystallization, filtered, washed with anhydride and dried.

Anal. Calcd. for $B_2O(OOCCF_3)_4$: B, 4.4; (CF_3CO_2), 92.3. Found: B, 4.3; (CF_3CO_2), 90.5.

(*b*) For the reaction of BCl_3 and $HOOCCF_3$ in *n*-pentane the procedure of Gerrard *et al.* (8) was followed. In one experiment the reactants were mixed at −60 °C, the mixture was allowed to warm up to 20 °C overnight and then all volatile material was removed at water aspirator pressure. The product analyzed as for $B_2O(OOCCF_3)_4$: % (CF_3CO_2), observed, 91.8; theoretical, 92.3. When the acid was added dropwise to the *n*-pentane solution at 20 °C the product analyzed as a mixture of 56 mol% $B(OOCCF_3)_3$ and the remainder $B_2O(OOCCF_3)_4$.

Anal. Calcd. for mixture: B, 3.68; (CF_3CO_2), 94.9. Found: B, 3.63; (CF_3CO_2), 94.7.

(*c*) The reaction of 100 mmol of BCl_3 with 300 mmol of $(CF_3CO)_2O$ in 20 ml *n*-pentane gave after filtration and drying, $B_2O(OOCCF_3)_4$.

Anal. Calcd. for $B_2O(OOCCF_3)_4$: B, 4.42; (CF_3CO_2), 92.3. Found: B, 4.40; (CF_3CO_2), 92.1.

A computer program was written to calculate the conductimetric titration curve from Λ^0 and K_a for the acid, base, and salt. From the known association constants, the composition of the mixture, assuming reaction 5 to be complete, and the activity coefficients calculated from the extended Debye–Hückel expression used for the Fuoss extrapolations (3), the concentrations of all ionic species present were calculated by an iterative procedure. The distance of closest approach, "*a*", used in the expression for the activity coefficient was a weighted average of the "*a*" values for the electrolytes present, according to the concentrations of the electrolyte ions present. From the concentrations of the ions present and the equivalent conductivities as calculated from the simple Debye–Hückel–Onsager relation for the respective ionic strengths, the specific conductance for each experimental point was calculated.

Results and Discussion

Conductivity Studies

Antimony pentafluoride is known to act as an acid in acidic solvents such as HF (9) and HSO_3F (10). Fluorine-19 nuclear magnetic resonance studies show that it behaves similarly in $HOOCCF_3$ (7).

[1] $$HOOCCF_3 + SbF_5 \rightarrow HSbF_5OOCCF_3$$

The reaction of boric acid with sulfur trioxide in sulfuric acid gives a strong acid in 100% H_2SO_4 (11) and the analogous reaction in trifluoroacetic acid would be

[2] $$B(OH)_3 + 3(CF_3CO)_2O \rightarrow HB(OOCCF_3)_4 + 2HOOCCF_3$$

The results of conductivity studies on $HSbF_5(OOCCF_3)$ and $HB(OOCCF_3)_4$ are given in Table 1. The runs give good Fuoss plots and the equivalent conductivities, Λ^0, association constants, K_a, and standard % errors on Λ^0 are given in Table 2. As discussed below, attempts to isolate

TABLE 1. Specific conductances (K_{sp}) at 25 °C

$= 0.0064 \times 10^{-6}$	0.06054	1.296
ohm^{-1} cm^{-1}	0.08517	1.633
	0.1081	1.907
	0.1282	2.130
	0.1496	2.351
	0.1710	2.556

$B(OOCCF_3)_3$ from solutions of $HB(OOCCF_3)_4$ yielded $B_2O(OOCCF_3)_4$. This behavior is like that of boric acid in water which is present as $B(OH)_4^-$ at low concentrations but forms condensed ions at higher concentrations. The complex acid, $HB(HSO_4)_4$, behaves similarly in H_2SO_4 (11). In order to further establish that $HB(OOCCF_3)_4$ was the electrolyte present at low concentrations and not the acid produced from $B_2O(OOCCF_3)_4$, a Fuoss extrapolation was carried out assuming that $B_2O(OOCCF_3)_4$ was present and that it behaved as a monobasic acid according to

[3] $$B_2O(OOCCF_3)_4 + 2HOOCCF_3 \rightarrow H_2OOCCF_3^+B_2O(OOCCF_3)_5^-$$
$$H_2OOCCF_3^+B_2O(OOCCF_3)_5^- \rightleftarrows H_2OOCCF_3^+ + B_2O(OOCCF_3)_5^-$$

If the acid were dibasic the second dissociation would be expected to be small and unlikely to be important in a low dielectric constant solvent. The extrapolation yielded $\Lambda^0 = 42.9$ ohm^{-1} cm^2 equiv^{-1} and $K_a = 1.5 \times 10^6$ mol l^{-1}. The value of Λ^0 is more than double that for $HSbF_5(OOCCF_3)$. It is doubtful in view of the relative sizes of the two anions, that $B_2O(OOCCF_3)_5^-$ should be more mobile than $SbF_5(OOCCF_3)^-$

and the presence of $HB_2O(OOCCF_3)_5$ is unlikely for this reason.

It is interesting that the association constant for $HSbF_5(OOCCF_3)$ is ~15 times smaller than that for $HB(OOCCF_3)_4$. Considering the similar size of the two anions, one would expect comparable K_a. For this reason it would appear that $B(OOCCF_3)_3$ produces a weaker acid than SbF_5 and the formation of the ion pair according to

[4] $B(OOCCF_3)_3 + 2HOOCCF_3 \rightleftarrows H_2OOCCF_3^+ B(OOCCF_3)_4^-$

is not as extensive as for SbF_5.

The results of a conductivity experiment with $CsB(OOCCF_3)_4$ are given in Table 1, and the Λ^0 and K_a values in Table 2. The results of the conductimetric titration of $HB(OOCCF_3)_4$ with $CsOOCCF_3$ are given in Table 3 and plotted in Fig. 1. A break in the titration curve is barely perceptible at the Cs/B mole ratio near unity. The plot is certainly not characteristic of the usual conductimetric titration but it may be accurately reproduced by calculation, assuming the neutralization

[5] $HB(OOCCF_3)_4 + CsOOCCF_3 \rightarrow CsB(OOCCF_3)_4 + HOOCCF_3$

Using the K_a and Λ^0 for $HB(OOCCF_3)_4$, $CsB(OOCCF_3)_4$, and $CsOOCCF_3$ and assuming that reaction 5 goes to completion, the conductimetric titration curve may be calculated. The curve fits the experimental points very well as shown in Fig. 1 and shows that reaction 5 is complete.

Solvent Autoprotolysis

From the limiting equivalent conductivities of $HB(OOCCF_3)_4$, $CsB(OOCCF_3)_4$, and $CsOOCCF_3$, Λ^0 for the hypothetical 100% dissociated trifluoroacetic acid may be calculated from

$$\Lambda^0_{H^+OOCCF_3^-} = \Lambda^0_{HB(OOCCF_3)_4} + \Lambda^0_{CsOOCCF_3} - \Lambda^0_{CsB(OOCCF_3)_4}$$

Using the Λ^0 in Table 2, $\Lambda^0_{H^+OOCCF_3^-}$ is calculated to be 26.19 ± 4.13 ohm^{-1} cm^2 equiv^{-1}.

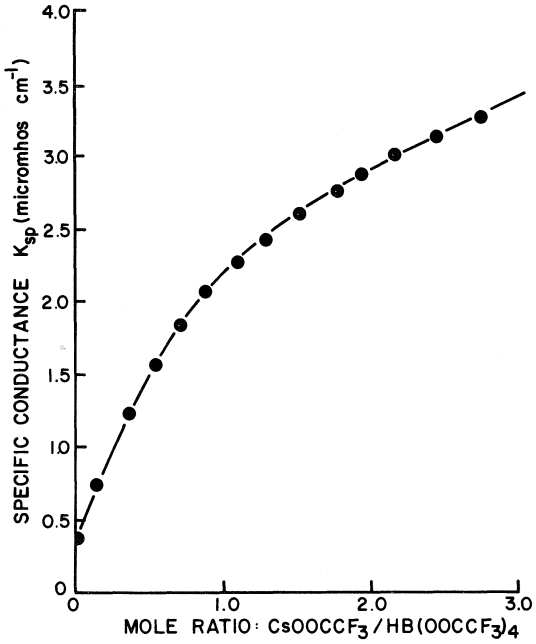

FIG. 1. Conductimetric titration of $CsOOCCF_3$ against $HB(OOCCF_3)_4$. The dots represent experimental points and the line, the calculated curve.

This is small compared to the mobilities of the alkali metal trifluoroacetates (3) and the comparison with Λ^0 for $CsB(OOCCF_3)_4$ shows that proton transfer conduction is unimportant in trifluoroacetic acid. In the simple model for ionic mobility, the low Λ^0 for small highly charged ions is accounted for by the increased effective size of the ion as a result of solvation. As the size of the ion increases solvation becomes less important and a point is eventually reached where the effect of unsolvated ion size becomes predominant and the larger ion is less mobile. In water the effect of solvation on the mobility of unipositive cations is of lesser importance than the unsolvated ion size effect at Rb^+ which is the most mobile. Trifluoroacetic acid is a more weakly solvating solvent than water and solvation is of lesser importance than the size of the unsolvated ion even for Na^+ (3). The proton is, however, strongly solvated as shown by its low mobility. The proton has a greater mobility than the sodium cation in acetic acid (12). This may indicate some contribution from a proton transfer mechanism in this solvent although many other explanations are possible.

The lowest K_{sp} we have been able to obtain for the solvent is 0.0064 μmho cm^{-1}. The concentration of autoprotolysis ions may be calculated from

$$c = 1000\, K_{sp}/\Lambda^0_{H^+OTFA^-}$$

and the autoprotolysis constant is then, $K_{ap} = c^2$. In view of the large uncertainty in $\Lambda^0_{H^+OOCCF_3^-}$, a more precise calculation employing activity coefficients and $\Lambda_{H^+OOCCF_3^-}$ adjusted for ionic strength effects is unwarranted. The solvent autoprotolysis constant is calculated to be 4×10^{-14} $(\pm 1 \times 10^{-14})$ $mol^2\, l^{-2}$.

$CsB(OOCCF_3)_4$ and $B_2O(OOCCF_3)_4$

Evaporation of an equimolar solution of $HB(OOCCF_3)_4$ and $CsOOCCF_3$ gives a crystalline solid, $CsB(OOCCF_3)_4$, the salt of the neutralization reaction. The corresponding compounds with acetic acid are known (13).

Gerrard *et al.* have reported the preparation of $B(OOCCF_3)_3$ from BCl_3 and $HOOCCF_3$ in *n*-pentane (8). They point out that the compound is unstable at its melting point (88 °C) decomposing to $B_2O(OOCCF_3)_4$. Kibbel has shown (14) that for the carboxylic acids he studied only the oxygen bridged compound was formed and not the tricarboxylate. Muetterties was unable to prepare $B(OOCCF_3)_3$ pure in his work (15). We have been unable to isolate $B(OOCCF_3)_3$ using several methods of synthesis. In all cases but one, the product was $B_2O(OOCCF_3)_4$ which appeared as colorless volatile crystals. Reaction temperature and the use of high vacuum for drying had no effect on the product obtained. In only one case the product was shown to contain some $B(OOCCF_3)_3$ (56%) in the presence of $B_2O(OOCCF_3)_4$.

Association of the Butyl Alcohols and *n*-Decanol

G. E. RAJALA AND J. CROSSLEY
Chemistry Department, Lakehead University, Thunder Bay, Ontario

Received June 22, 1971

The dielectric constants at 0.1 MHz of *n*-, iso-, sec-, and *t*-butanol and *n*-decanol each at nine concentrations in the range 0.2–1.0 mole fraction in cyclohexane, *p*-dioxane, mesitylene, and *p*-xylene have been measured at 25 °C. Apparent dipole moments and Kirkwood correlation factors have been evaluated. Cyclohexane is regarded as an inert solvent in which alcohol self association alone is considered responsible for the anomalous electric polarization. The other three solvents have a disassociating effect which increases *p*-xylene $\leqslant$ mesitylene $<$ *p*-dioxane. At the lowest concentrations the alcohols have larger apparent dipole moments in these solvents than in cyclohexane. The opposite tends to be the case for the more concentrated alcohol solutions. The results suggest that alcohol association is initially dominated by the formation of small, weakly polar multimers, and eventually larger highly polar multimers predominate.

Les constantes diélectriques à 0.1 MHz du *n*-, iso-, sec-, et *t*-butanol et du *n*-décanol, chacun avec neuf concentrations dans le domaine de 0.2–1.0 mole dans le cyclohexane, *p*-dioxane, mésitylène et le *p*-xylène, ont été mesurées à 25 °C. Les moments dipolaires apparents et les facteurs de corrélation de Kirkwood ont été évalués. On considère le cyclohexane comme un solvant inerte dans lequel seule une association intermoléculaire de l'alcool est considérée comme responsable de la polarisation électrique anormale. Les trois autres solvants ont un effet de dissociation qui croît *p*-xylène $\leqslant$ mésitylène $<$ *p*-dioxane. Aux concentrations les plus basses, les alcools ont des moments dipolaires apparents plus grands dans ces solvants que dans le cyclohexane. L'inverse a tendance à se produire pour des solutions alcooliques plus concentrées. Les résultats suggèrent que l'association de l'alcool est d'abord le fait de la formation de petites multimères légèrement polaires et éventuellement une plus grande quantité de multimères hautement polaires prédomine.

Introduction

Static dielectric constant, electric dipole moment, Kirkwood correlation factor, and dielectric relaxation measurements have provided useful means of examining molecular association in liquids (1–3). Hydrogen bonding in aliphatic alcohols, as the pure liquids and in dilute solution, in particular has received considerable attention. The majority of workers have been concerned with the temperature dependence of the above parameters and equilibrium constants for molecular association have been obtained (4). Relatively little work has been reported on the concentration dependence of these terms for alcohols in non-polar solvents. The powerful spectroscopic techniques have generally been limited to alcohols in dilute solution (1, 5, 6).

The nature and extent of alcohol self association are considerably influenced by the steric environment of the hydroxyl group and by changes in temperature. The former determines the geometry and size of the associated multimers, and association is favored by low temperatures. Dannhauser, in particular, has utilized these effects to study the structure of liquid alcohols (4). In solution the basicity of the solvent plays an important role in determining the extent of alcohol self association, which must compete with solute–solvent interactions (7). The electric polarization measurements appear to provide a useful method of studying molecular association in alcohols (8, 9).

In this paper we report the results of static dielectric constant measurements for several alcohol – non-polar solvent mixtures, in which the alcohol molecular size, the steric environment of the hydroxyl group, and the basicity of the solvent are variables. Cyclohexane is used as an inert reference solvent in which the self association of alcohol molecules is regarded as the only important interaction.

Experimental

Method of Measurement

The dielectric constants were measured at 0.1 MHz and 25 °C with a Wissenschaftlich-Technische Werkstatten Multi-Dekameter. No significant dielectric loss was detectable for any of the systems examined. The water jacketed WTW cells type MFLI and MFL 2/s were used for dielectric constant ranges 2–7 and 7–21, respectively. The instrument and cells were recalibrated for each set of measurements *i.e.* one solute–solvent

system. Refractive index measurements at 25 °C were made for each solution at the sodium D-line.

Purification of Materials

The alcohols, solvents, and calibration liquids were all dried and fractionally distilled prior to their use.

Experimental Results

The dielectric constants ε_0 are listed in Table 1, where the concentrations in mole fraction units, which have been rounded off for convenience, differ from the actual values in the third decimal place. The evaluation of dipole moments from dielectric constant and refractive index measurements on dilute solutions often involves the approximation $\varepsilon_\infty = xn_D^2$ (x may be 1.0, 1.05, 1.1) since ε_∞, the high frequency dielectric constant, is not measured. Dielectric dispersion measurements and ε_∞ values have been reported for *n*-butanol and *n*-decanol as the pure liquids (10) and in dilute solution (7) in the solvents

employed in this study. The dielectric absorptions of the remaining butanols in *p*-xylene solution have also been reported (11). The ratio $\varepsilon_\infty / n_D^2$ is not constant for these systems, and for many solutions n_D^2 is less than the dielectric constant of the solvent. In order to attain consistency, ε_∞ values were interpolated, assuming linearity, from the pure liquid and dilute solution values. Apparent dipole moments μ were then calculated from the equation

$$\mu^2 = g\mu_0^2 = \frac{9kT(\varepsilon_0 - \varepsilon_\infty)(2\varepsilon_0 + \varepsilon_\infty)}{4\pi N\varepsilon_0(\varepsilon_\infty + 2)^2}$$

where kT is the thermal energy and N is the number of solute molecules per ml. The values are given in Table 1. Kirkwood correlation factors g were estimated with the dipole moment of the molecule in vacuum μ_0 taken to be 1.68 D.

The accuracy of the ε_0 measurements is estimated to be $\pm 0.5\%$ although the absolute error may be larger, since the values are dependent upon the dielectric constants used for the calibration liquids. The results are self consistent and plots of ε_0, μ, and g against alcohol concentration yield relatively smooth curves. Figures 1–3 are representative and compare very favorably with those obtained previously for similar systems (8, 9).

Discussion

The concentration dependence of the dielectric constant for the four butanols and *n*-decanol in cyclohexane at 25 °C is shown in Fig. 1. Similar plots are obtained for these alcohols in *p*-xylene, mesitylene, and *p*-dioxane solution and in no case is a linear relationship observed. However, the Kirkwood correlation factor g is probably a more useful parameter for examining the data for these systems in terms of molecular structure.[1] Positive and negative deviations of g from unity correspond to predominantly parallel and antiparallel alignment of near neighbor dipoles, respectively.

Figure 2 shows plots of g against alcohol mole fraction for the five alcohols in cyclohexane and mesitylene. In the absence of association g should be unity at all concentrations. The strong self association of alcohols is evident especially for the pure liquids, for which g increases *t*-butanol < *n*-decanol < sec-butanol < iso-butanol ~ *n*-butanol in accord with previous results (12). At infinite dilution all the curves must meet at $g = 1$, thus in view of the small g values for the dilute solutions ($f_2 < 0.2$) especially in cyclohexane the initial association must predominantly involve the formation of multimers having smaller dipole moments than the free monomer. These multimers could be closed or open dimers and trimers. Evidence has been presented for all these species (4, 5, 8, 13). At low temperatures the g values for some alcohols are found to be very close to zero (14) and in these cases small closed multimers must exist. It is apparent that above 0.2 mole fraction g increases with increased alcohol concentration. The majority of workers seem to favor association into linear chains as the mechanism responsible for the large g values (4, 9) although there is evidence to support the existence of highly polar cyclic multimers (6, 15). The large alkyl group in *n*-decanol and chain branching close to the hydroxyl group in sec- and *t*-butanol present steric factors which are probably responsible for a lower concentration of large multimers, and thus smaller g values, than for the relatively unhindered *n*- and iso-butanols. In alcohols such as 3-methyl-3-heptanol the hydroxyl group is so effectively screened that association is limited to small weakly polar multimers (17), and the g values for the pure liquids are less than unity (4).

Plots of g against alcohol concentration for

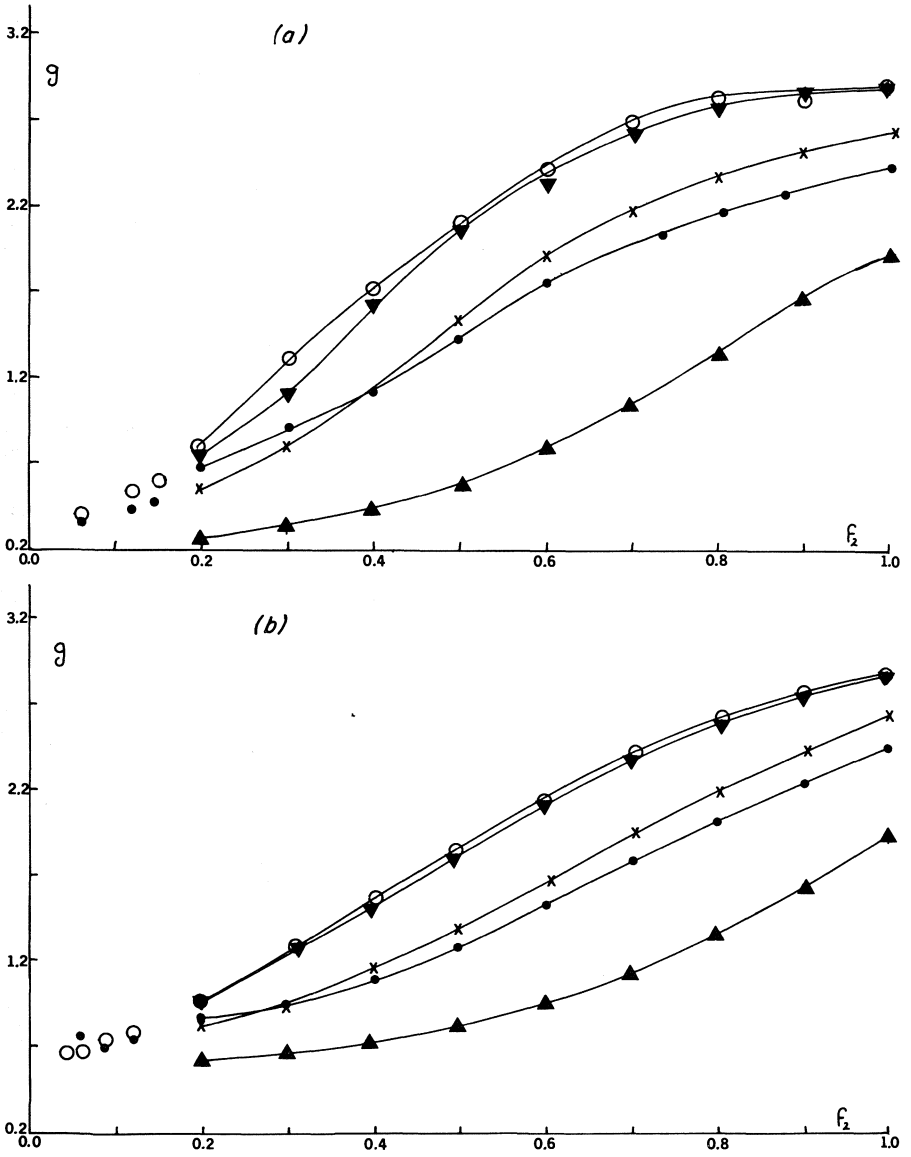

FIG. 2. Correlation factor against alcohol mole fraction in (*a*) cyclohexane and (*b*) mesitylene solution at 25 °C. The symbols have the same meaning as in Fig. 1. The points below 0.2 mole fraction for *n*-butanol and *n*-decanol are taken from ref. 7.

iso-butanol, *t*-butanol, and *n*-decanol in the four solvents are shown in Fig. 3. The two remaining butanols give curves which are similar to those for iso-butanol. For *n*-butanol, iso-butanol, sec-butanol, and *n*-decanol at 0.2 mole fraction g decreases with decreased solvent basicity *i.e.* *p*-dioxane > mesitylene ~ *p*-xylene > cyclohexane, whereas the reverse is true at 0.8 mole fraction. However, the correlation factor for *t*-butanol decreases *p*-dioxane > mesitylene ~ *p*-xylene > cyclohexane over almost the whole concentration range.

In cyclohexane solute–solvent interactions are restricted to weak van der Waals and dipole interactions (16), and the concentration dependence of g arises almost entirely from alcohol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

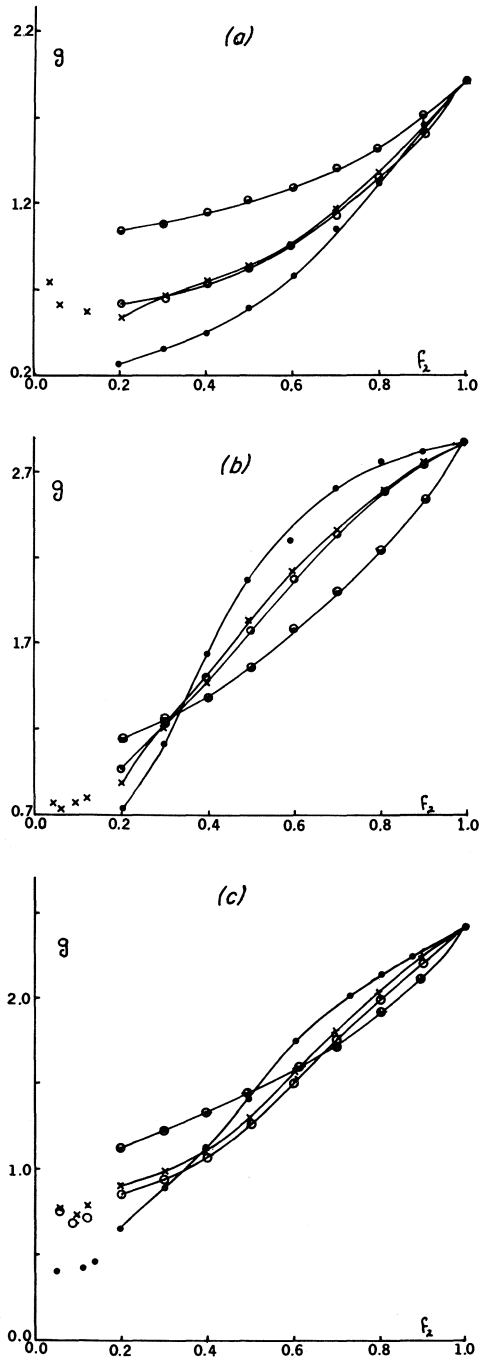

FIG. 3. Correlation factor against alcohol mole fraction in cyclohexane ●, *p*-xylene ×, mesitylene ○, and *p*-dioxane ◒ at 25 °C for (*a*) *t*-butanol, (*b*) iso-butanol, and (*c*) *n*-decanol. The points below 0.2 mole fraction for the *p*-xylene solution are taken from refs. 7 and 11.

self-association. Interactions between the hydrogen atoms of hydroxyl groups and the π-electrons of aromatic molecules or the oxygen lone pair electrons of dioxane are not negligible (11, 18). Thus, for alcohols in *p*-xylene, mesitylene, and *p*-dioxane, solute–solvent interactions will compete with solute–solute interactions. At a given concentration the proportion of self associated alcohol molecules will be less in these electron donor solvents than in the relatively inert cyclohexane. The disassociating effect produced by these solvents may be compared to that produced in the pure liquids by increased temperature (4). The extent of the disassociation should increase with the increased electron donor ability of the solvent, and a decrease in *g* with increased solvent basicity would indicate that alcohol self association involves large highly polar multimers. Conversely, for systems in which association predominantly involves small weakly polar multimers *g* should increase with increased solvent basicity. The application of this theory to the systems under discussion indicates that highly polar multimers become the most important species above about 0.3–0.5 mole fraction for *n*-butanol, iso-butanol, sec-butanol, and *n*-decanol. This alcohol concentration decreases *n*-decanol ~ sec-butanol > iso-butanol > *n*-butanol and *p*-dioxane > mesitylene ~ *p*-xylene *i.e.* with decreased degree of self association and decreased solvent basicity. Small weakly polar multimers appear to be the dominant associated species for *t*-butanol, which has the most hindered hydroxyl group, almost over the whole range of concentration. Dioxane has the largest disassociating effect which increases *n*-butanol < iso-butanol < sec-butanol < *n*-decanol < *t*-butanol.

Studies on Microcapsules. XII. Preparation and Characterization of Carboxylated Polyphthalamide Microcapsules

YOSHIMICHI SHIGERI, MICHIKO TOMIZAWA, KIKUKO TAKAHASHI, MASUMI KOISHI, AND TAMOTSU KONDO[1]

Faculty of Pharmaceutical Sciences, Science University of Tokyo, Funagawara-machi, Shinjuku, Tokyo, Japan

Received July 6, 1971

Carboxylated polyphthalamide microcapsules were prepared by utilizing the interfacial polycondensation reaction between basic amino acids in water and *p*-phthaloyl dichloride in organic solvent. The yield of the microcapsules was found to be dependent on the concentration of emulsifier in the organic solvent and temperature. The microcapsules moved towards the anode in an electric field irrespective of the p*H* of the medium owing to the presence of carboxylic groups in the membranes. Cation binding experiments indicated an increasing order, $Al^{3+} > Mg^{2+} > Cs^{+} > K^{+}, NH_4^{+}, Na^{+} > Li^{+}$, for the binding of these cations to the microcapsules.

On a préparé des microcapsules de polyphthalamide carboxylé en utilisant une réaction de polycondensation interfaciale entre des acides aminés basiques dans l'eau et le dichlorure de *p*-phtaloyle dans un solvant organique. Le rendement des microcapsules dépend de la concentration d'émulsifiant dans le solvant organique et de la température. Les microcapsules se déplacent vers l'anode dans un champ électrique, indépendamment du p*H* du milieu, à cause de la présence des groupements carboxyliques dans les membranes. Les expériences d'attachement de cation indiquent un ordre croissant, $Al^{3+} > Mg^{2+} > Cs^{+} > K^{+}, NH_4^{+}, Na^{+} > Li^{+}$, pour l'attachement de ces cations aux microcapsules.

Canadian Journal of Chemistry, **49**, 3623 (1971)

Introduction

In earlier papers (1, 2) of this series, the preparation and characterization of sulfonated polyphthalamide microcapsules have been reported. The principle of preparing sulfonated microcapsules had previously been described by Chang *et al.* (3). Those microcapsules were easily dispersible in water to form a quite stable dispersion owing to the presence of strongly acidic sulfonic groups in their membranes.

On the other hand, microcapsules with weakly acidic carboxylic groups in their membranes are very interesting because this kind of microcapsule may serve as a model for biological cells (3, 4) in view of the fact that many biological cells are known to have electrokinetic properties characteristic of the surface with carboxylic groups (5–7).

This paper describes the preparation and characterization of carboxylated polyphthalamide microcapsules. These microcapsules could be prepared by utilizing the interfacial polycondensation reaction between basic amino acids and *p*-phthaloyl dichloride.

[1]To whom all inquiries should be addressed.

Experimental

Materials

Basic amino acids used in this work were L-arginine, L-citrulline, L-cystine, L-histidine, and L-lysine. These amino acids were of highest purity available purchased from Ajinomoto Co. Ltd., Tokyo. Inorganic salts used for binding experiments were chlorides of aluminum, magnesium, lithium, sodium, potassium, cesium, and ammonium. All of these salts had a purity of more than 99.5%. Other chemicals employed were of reagent grade.

Preparation of Microcapsules

Carboxylated polyphthalamide microcapsules were prepared in the same way as that described in the previous paper (1) except that basic amino acids were used as diamine.

The carboxylated polyphthalamide microcapsules thus prepared are as follows: poly-L-arginine phthalamide (PAPA), poly-L-citrulline phthalamide (PCitPA), poly-L-cystine phthalamide (PCysPA), poly-L-histidine phthalamide (PHPA), and poly-L-lysine phthalamide (PLPA) microcapsules.

Partition of Amino Acids between Aqueous and Organic Phases

In the interfacial polycondensation reaction, the transfer of water soluble reactant to organic phase is a prerequisite for the reaction to occur since it has been demonstrated that polymers are formed on the organic side of interface (8). Therefore, the partition of the amino acids between the aqueous and the organic phases was determined under the conditions similar to those used in the preparation of the microcapsules.

TABLE 1. Relative partition coefficients of amino acids

Temperature (°C)	Concentration of Span 85 (%, v/v)	Relative partition coefficient		
		L-Arginine	L-Histidine	L-Citrulline
3	15	1.00	1.00	1.00
3	10	0.46	0.61	0.48
30	15	0.64	0.35	0.43

To 3 ml of a 0.4 *M* solution of amino acid in aqueous 0.45 *M* Na_2CO_3 solution in a 100 ml round bottom flask immersed in a constant temperature bath controlled at 3 and 30 °C was added 30 ml of the mixed solvent containing 10 or 15% (v/v) Span 85. The mixture was then mechanically agitated with the Chemistirrer at 620 r.p.m. for 5 min. In each case an emulsion was formed, which was centrifuged to completely separate it into two liquid layers. The amount of amino acid transferred into the aqueous phase was determined colorimetrically by making use of the color reaction with ninhydrin. The partition coefficient of an amino acid was defined as the ratio of the amount of the amino acid in the organic phase to that in the aqueous phase.

Electrophoretic Mobility

Electrophoretic mobility measurements on the carboxylated polyphthalamide microcapsules were conducted in a quartz flat microelectrophoretic cell at room temperature. For each measurement 40 microcapsules were timed in each direction to eliminate the polarization effect of the electrodes.

The dispersion media were the following buffer solutions (p*H* 3.9–9.9) of constant ionic strength (2×10^{-3}): CH_3COOH–CH_3COONa (p*H* 3.9 and 5.3), NaH_2PO_4–Na_2HPO_4 (p*H* 6.8 and 7.9), and $NaHCO_3$–Na_2CO_3(p*H* 9.9). The ionic strength of the media was adjusted by the addition of NaCl.

The microcapsule dispersion was dialyzed against distilled water before use in the same way as described in the previous paper (2). The samples for electrophoresis measurement were prepared by pipeting a few drops of the dialyzed microcapsule dispersion into a large volume of the above-mentioned dispersion media.

In view of the size of the microcapsules (*ca.* 3 μ in diameter) and the ionic strength of the dispersion media (2×10^{-3}), mobilities were converted into zeta-potentials, ζ, by means of the simple Smoluchowski equation,

$$\zeta = 4\pi\eta u/D \quad [1]$$

where u is the mobility in cm/s/V/cm, η and D are the viscosity and dielectric constant of dispersion medium.

Cation Binding

The binding of various cations to the carboxylated polyphthalamide microcapsules was measured by the method reported in the earlier paper (2). In all binding experiments of cations, the H form PLPA microcapsules, which were obtained by treating the dialyzed Na form microcapsules with hydrochloric acid, followed by dialysis against distilled water, were used. To a known volume of the redialyzed H form microcapsule dispersion in a beaker was added an equal volume of salt solution, and the mixture was allowed to react for 1 h with continuous shaking. At the end of this period, the mixture was centrifuged to remove the microcapsules. The supernatant liquid was then analyzed chelatometrically (Al^{3+} and Mg^{2+}) or potentiometrically (monovalent cations). The amount bound of Al^{3+} or Mg^{2+} was given by the difference between the cation concentrations before and after mixing with the microcapsule dispersion. The hydrogen ion concentrations liberated from the microcapsules in the supernatant liquid directly gave the amount bound of the monovalent ions.

Results and Discussion

Formation of Microcapsules

The formation of the carboxylated polyphthalamide microcapsules was affected by the concentration of Span 85 in the organic solvent and temperature. That is, the yield of microcapsules was high when they were prepared under the conditions of high Span 85 concentration and low temperature. These conditions were found to be favorable to the transfer of amino acids into the organic phase. Table 1 shows this situation, in which typical examples of relative partition coefficient of amino acid are given.

A rise in temperature or a fall in the Span 85 concentration caused a decrease in the partition coefficient. This may be due to the increased solubility of amino acid in the aqueous phase at high temperature or at low Span 85 concentration.

Electrophoresis of Microcapsules

The carboxylated polyphthalamide microcapsules moved towards the anode in an electric field irrespective of the p*H* of the medium, showing the disappearance of isoelectric point of amino acid through the reaction with *p*-phthaloyl dichloride.

In Fig. 1 are given the zeta-potentials of the microcapsules calculated from the mobility data by using eq. 1 as a function of the p*H* of the medium. The fact that the zeta-potentials become more negative as the p*H* of the medium increases will indicate the increase in the dissociation of carboxylic groups on the microcapsule surface with increasing p*H*. Figure 1 also seems to show that the carboxylic groups of all microcapsules dissociate in the same way independently of the kind of amino acid used in view of the experi-

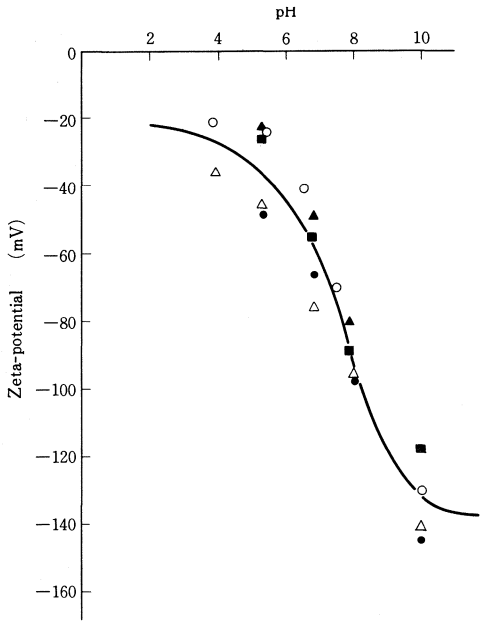

FIG. 1. Zeta-potential against p*H* for: -○-, PAPA; -△-, PCitPA; -■-, PCysPA; -●-, PHPA; -▲-, PLPA microcapsules.

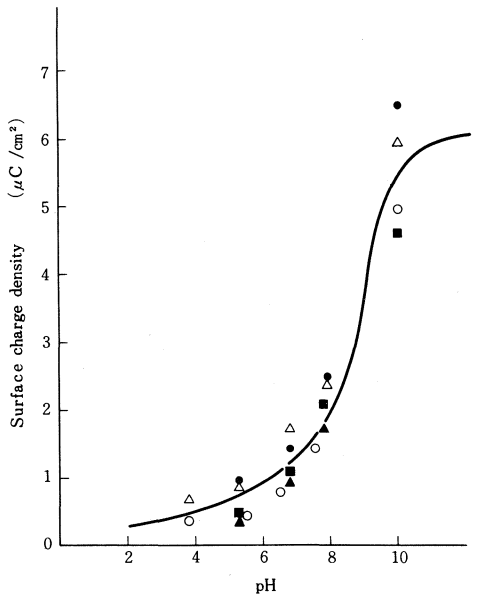

FIG. 2. Electrophoretic surface charge density against p*H* for: -○-, PAPA; -△-, PCitPA; -■-, PCysPA; -●-, PHPA; -▲-, PLPA microcapsules.

mental errors involved in the electrophoretic measurements.

The surface charge densities in the electrokinetic plane of shear, σ, were calculated from the zeta-potentials using the Gouy–Chapman relationship for a flat double layer in the form

$$[2] \quad \sigma = (1 + \sqrt{1-\alpha})\sqrt{\frac{Dn_0kT}{2}}\sinh\frac{ze\zeta}{2kT}$$

where n_0 is the number of ions per unit volume in bulk, D the dielectric constant of the medium, T the absolute temperature, k the Boltzmann constant, z the valency of the counter ion, e the electronic charge, ζ the zeta-potential of microcapsules, and α the fraction of the total space within the microcapsule surface which is not available to the counter ion (9). The factor α was introduced in eq. 2 to account for the fact that the microcapsule membranes are semipermeable (10, 11) and was arbitrarily assumed to be 0.5 (7). The calculated surface charge densities are plotted in Fig. 2 against the p*H* of the medium.

It will be of much interest to note here that the surface charge densities of the microcapsules are comparable to those of red blood cells from various animal species (6, 7). This may demonstrate the feasibility of using the carboxylated polyphthalamide microcapsules as a model for biological cells.

Cation Binding of Microcapsules

The binding isotherms for Al^{3+} and Mg^{2+} and for Li^+, Na^+, K^+, Cs^+, and NH_4^+ at 20 °C are illustrated in Figs. 3 and 4, respectively.

In these figures the amount bound of cations is expressed in terms of the number of carboxylic groups occupied by the cations in unit volume of the microcapsules (2). This quantity does not necessarily give the true amount adsorbed of the cations to the microcapsules because the binding is likely to be accompanied by the occlusion of the cations by the polymer chains of microcapsule membranes. However, the ion-exchanging ability of the carboxylated polyphthalamide microcapsules will be assured by the liberation of hydrogen ions from the microcapsules on the addition of the cations.

A remarkable effect of valency can be seen on the amount of the cations to the microcapsules. Namely, the higher the valency, the larger the amount bound to the microcapsules. This is reasonable since the cations are bound to the microcapsules by the electrostatic field of the carboxylic groups in the microcapsule membranes.

The difference in the amount bound among the monovalent cations used in this work is not

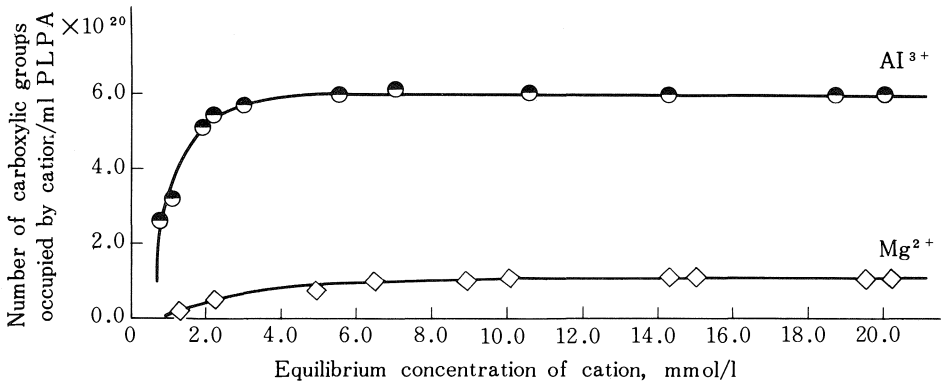

FIG. 3. Cation binding isotherms for PLPA microcapsules at 20 °C.

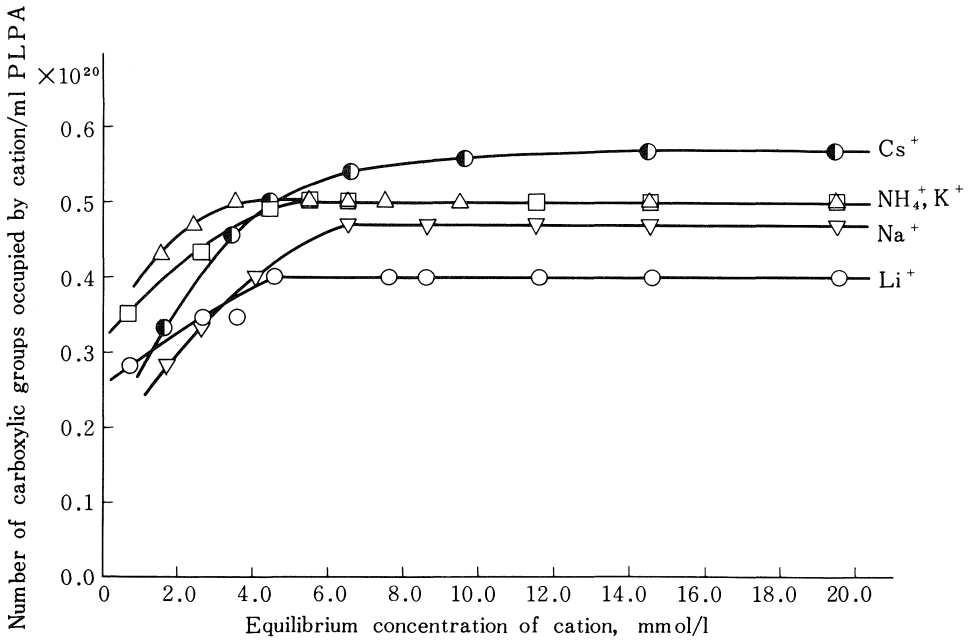

FIG. 4. Cation binding isotherms for PLPA microcapsules at 20 °C.

great enough to draw the conclusion about the exact order of these cations in the binding to the microcapsules. However, it will be safe to say that Cs^+ can be bound more strongly than Li^+.

The authors wish to express their sincere thanks to the Eisai Co., Ltd., Tokyo, for its financial aid to this work.

Proton Magnetic Resonance Spectrum of 2-Chloroaniline-^{15}N. Long-range Coupling Constants to Amino Protons from all Ring Protons

R. WASYLISHEN[1] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received June 10, 1971

The p.m.r. spectra of 2-chloroaniline and 2-chloroaniline-^{15}N in benzene and toluene solutions are analyzed at 60 and 100 MHz under conditions where the amino protons are exchanging intermolecularly and also where they are not exchanging. The spectrum of 2-chloroaniline-H^{15}ND in the absence of amino proton exchange is observed between −48 and 80 °C. In all situations fast rotation about the C—N bond evidently occurs. Long-range couplings of the amino protons to all ring protons are observed and their signs are determined. The nonplanarity of the amino group is discussed in terms of the long-range couplings, of the one-bond ^{15}N–H couplings, and of the two-bond H–H couplings in the amino group. The signs and magnitudes of the coupling constants between the ring protons and ^{15}N are also determined.

Les spectres de r.m.p. des 2-chloroaniline et 2-chloroaniline ^{15}N dans des solutions de benzène et toluène sont analysés à 60 et 100 MHz dans des conditions telles que l'échange intermoléculaire des protons de l'azote ait lieu, ainsi qu'en absence d'échange. Le spectre de la 2-chloroaniline-H^{15}ND en l'absence d'échange est observé entre −48 et 80 °C. Dans tous les cas, la rotation rapide autour de la liaison C—N est mise en évidence. Les couplages à longue distance entre les protons de l'azote et tous les protons du cycle sont déterminés avec leurs signes. La non-planéarité du groupement amine est discutée en termes de couplages à longue distance, de couplage ^{15}N–N et de couplages H–H à travers deux liaisons dans le groupement amine. Le signe et la valeur des constantes de couplages entre les protons du cycle et le noyau ^{15}N sont aussi déterminés.

Introduction

Spin–spin coupling between protons on side-chains like methyl or aldehyde functions and protons or fluorine nuclei on the benzene ring have been extensively investigated and discussed in terms of σ and π electron coupling mechanisms (1–5). Less is known about the coupling between phenolic or amino protons with ring protons in phenol or aniline derivatives (6–10). Apparently problems of intermolecular exchange of these protons make observation of their coupling patterns difficult. When phenolic protons are held in the plane of the molecule for periods of seconds or more by intramolecular hydrogen bonds, coupling over five bonds with ring protons via the familiar zig–zag path is observed (6–8). Similar couplings are known for amino protons (9, 10).

Whenever the bond holding the proton in the side-chain lies apparently in the plane of the aromatic ring no coupling occurs over six bonds to the para proton. This rule holds for H—C=O, H—CCl_2, H—O, and H—N—R sidechain functions and is taken to mean that a σ electron mechanism does not operate over six bonds and that the π electron mechanism comes into play only when the X—H bond of the side-chain moves out of plane and thereby undergoes hyperconjugative interaction with the π electron system of the ring. In contrast, the coupling over five bonds is dominated by σ electron contributions.

In this paper a full analysis of the p.m.r. spectrum of 2-chloroaniline and of 2-chloroaniline-^{15}N is presented with a view to finding the signs and magnitudes of the long-range couplings of the amino protons to all ring protons. Our methods of stopping amino proton exchange unfortunately do not as yet allow a similar study of aniline-^{15}N itself, although the exchange rate has now been decreased to within a factor of 5 of the value necessary for such a study.

Experimental

(1) Spectra at 60 MHz

A 10 mol % solution of 2-chloroaniline (Aldrich) in benzene-d_6, to which internal tetramethylsilane was added as an internal reference and locking material, was degassed by the freeze–pump–thaw technique (degassing was carried out for all samples). The p.m.r. spectra were taken in the frequency sweep mode on a

[1]Holder of NRCC Bursary, 1970–1971.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

DA60I spectrometer on a scale of 1 Hz/cm and at a sweep rate of 0.02 Hz/s. Each of 43 peaks in the ring proton region was calibrated at least five times by reading frequencies of the sweep and manual oscillators. Coupling between the amino protons and the ring protons meta to the amino group was clearly resolved. Coupling between the amino protons and the ortho and para ring protons (H-4 and -6) appeared as a marked broadening of the peaks due to these ring protons. Decoupling of the amino protons caused a marked increase of the H-4 and -6 peak heights, and some of these were measured repeatedly in the presence and absence of the decoupling field.

(2) Spectra at 100 MHz

A technique of stopping intermolecular proton exchange in benzene solutions of 2-chloroaniline was found. It was applied to solutions of 2-chloroaniline-^{14}N and 2-chloroaniline-^{15}N (96.47 atom % ^{15}N from Merck, Sharp and Dohme of Canada). A typical experiment was performed as follows. A 10 mol % solution in benzene-d_6 was left overnight in a small vial containing several NaOH pellets. The solution was then transferred to a thin-walled n.m.r. tube (ordinary thick-walled tubes cause swirling and loss of resolution in this case) containing some basic alumina and was then degassed. Such samples gave peaks whose line-widths at half-height were often less than 0.1 Hz. All clearly resolvable peaks, numbering between 60 and 85 in the different solutions, were calibrated at frequency intervals of less than 2.2 Hz at a sweep rate of 0.01 Hz/cm on an HA100D spectrometer.

Solutions of the ^{15}N compound in benzene were also studied in the presence of exchange so that comparison with nonexchanging solutions allowed a clear distinction between long-range couplings involving amino protons and ^{15}N.

A nonexchanging 20 mol % solution of the ^{15}N compound in toluene-d_8 was studied at -60 °C but the amino protons are magnetically and probably chemically (see below) equivalent even at this temperature.

(3) Deuteration Experiments

A 20 mol % nonexchanging solution in toluene-d_8 containing the ^{15}NHD group was prepared as follows. In a vial, 1.72×10^{-3} mol of D_2O were mixed with 1.32×10^{-3} mol of 2-chloroaniline-^{15}N. The mixture was shaken for 10 min and then several pellets of NaOH were added. The solution was transferred to another vial containing more pellets of NaOH, where it was left overnight. It was transferred to an n.m.r. tube containing basic alumina and was then degassed. The spectrum showed the presence of molecules containing $^{15}NH_2$ and ^{15}NHD groups in the ratio of about 8 to 3. The amino protons were not exchanging, either at -48 or at 80 °C.

(4) Double Resonance Experiments

Dozens of weak irradiation experiments (11) on all these solutions leave no doubt about the signs of the coupling constants given in Table 1. Some experiments necessitated the irradiation of a peak only 0.2 Hz displaced from another. The question then arises of how much the "unwanted" peak is being affected by the second radio-frequency field, *i.e.*, general double irradiation phenomena may occur (11). To insure the validity of the sign determinations a computer program in Fortran IV was written for the double resonance Hamiltonian of a first-order, three spin 1/2 system. Double resonance spectra were computed for various sensible choices of spectral parameters and of the intensities and frequencies of the second radio-frequency field. In this way one may show unequivocally that the weak irradiation experiments yield valid sign determinations.[2]

Results and Discussion

(1) Analyses of Spectra

(a) 10 mol % of 2-Chloroaniline in Benzene-d_6 at 60 MHz, $ABCDX_2$

Initial coupling parameters within the ring were taken from Smith *et al.* (12) and were used in a preliminary noniterative run using LAOCN3 (13). Several iterative runs in which up to 60 transitions were assigned in the ring proton region, while allowing all parameters to vary except the amino proton shift and the coupling between the amino protons and the ring protons in the ortho and para positions, gave the parameters in Table 1. The r.m.s. deviation of calculated from observed transitions was 0.012 Hz. The indicated difference between the amino proton couplings to the two meta protons is real.

The coupling between amino protons and ring protons in the ortho (H-6) and para (H-4) positions was inferred from the broad peaks for these two protons and from the narrow peaks obtained on decoupling of the amino protons. Four proximate peaks belonging to H-4 and -6 were studied in considerable detail as follows. Calculated spectra were plotted on a Calcomp plotter taking $^4J_o^{H,NH_2} = {}^6J_p^{H,NH_2} = 0.00$ Hz (decoupled spectra) with effective T_2 values chosen to reproduce the observed spectra (Lorentzian line-shapes). The two couplings were then increased in magnitude until the undecoupled observed spectra matched the calculated spectra as closely as possible. Considering the uncertainties (± 0.5 s) in the assumed T_2 values, the fact that the peaks need not have the same natural line-widths (14, 15) and the inherent uncertainties in intensity measurements, it was concluded that $^4J_p^{H,NH_2}$ and $^6J_o^{H,NH_2}$ remained uncertain to within 0.03 Hz. Their "best" magnitudes are given in Table 1.

[2]The doubting reader is assured that many cases were simulated and reproduced experimentally, including those in which the "offset" second r.f. field causes "shifting" instead of symmetrical "splittings" of peaks.

‖10 mol % solution in benzene-d_6, amino protons exchanging.
¶$^1J(^{15}N–H) = -82.3 \pm 0.2$ Hz, signs of other $^{15}N,H$ couplings being relative to this.

Their magnitudes agree with the precise values obtained later from resolved spectra.

(b) 2-Chloroaniline-^{15}N and ^{14}N at 100 MHz

As mentioned above, nonexchanging and exchanging solutions were prepared and their spectra examined. The spectral analyses using LAME (16) gave the parameters in Table 1. All observable ring proton transitions were assigned, the r.m.s. errors lying between 0.0094 and 0.0125 Hz. Allowing all parameters to vary gave all but one of the elements in the correlation matrix as less than 0.15. There was a correlation of 0.387 between $^5J_p^{HH}$ and $^5J_m^{H_3,NH_2}$. Numerous tickling experiments allowed the unambiguous sign determinations reported in Table 1.

Calculated spectra agreed very well with observed spectra. For reasons of space only parts of these are illustrated in Figs. 1 and 2. In Fig. 1 the observed and calculated spectra are shown for the H-4 and -6 protons of 2-chloroaniline-^{15}N in the presence of amino proton intermolecular exchange. Many of the observed peaks are less than 0.1 Hz wide at half-height and very clearly demonstrate the 0.17 Hz coupling between ^{15}N and H-4 over five bonds (doublets with smallest splittings). The calculated spectrum has a line-width, $\Delta\nu_{1/2} = 0.11$ Hz, a little too high compared to the observed spectrum but it nevertheless illustrates the reliability of the relevant parameters in Table 1.

In Fig. 2 are given the observed and calculated spectra for H-4 and -6 of 2-chloroaniline-^{14}N in the absence of amino proton exchange. There is now no observable coupling to nitrogen but the triplets arising from coupling to the amino protons are clearly present. The smallest such coupling occurs with H-4 and the observed spectrum indicates the non-Lorentzian nature of the triplet peaks but sweeping in the opposite direction again resolves the weaker member on the opposite side of the triplet. The amino proton coupling to H-3 and -5 is, of course, large (0.3 Hz) and is resolved to the base line in spectra not shown here. Weak irradiation of these peaks (see Experimental) unequivocally splits the expected components of the triplets in the H-4 and -6 regions and the irradiation intensities can now be kept small enough not to perturb peaks 0.3 Hz removed from the second radio-frequency field (the reverse experiments confirm the results). The $\Delta\nu_{1/2}$ in the calculated spectrum of Fig. 2 was 0.07 Hz.

(c) 2-Chloroaniline-^{15}NHD, nonexchanging

The ring proton spectrum displayed a multiplicity of peaks arising from the mixture of NH_2, NHD, and ND_2 molecules and was not analyzed. The isotope shift of the N–H proton resonance was 0.0255 ± 0.0020 p.p.m. to high field at 31 °C. At −48 °C, where rapid spin–lattice relaxation of the deuterium nucleus occurs (17), the line-widths of the NHD and NH_2 protons were the same within experimental error. At 80 °C the proton resonance width of the NH_2 group was at least 80% of the NHD proton resonance. Assuming that quadrupolar relaxation of the deuterium nuclei is ineffective at this

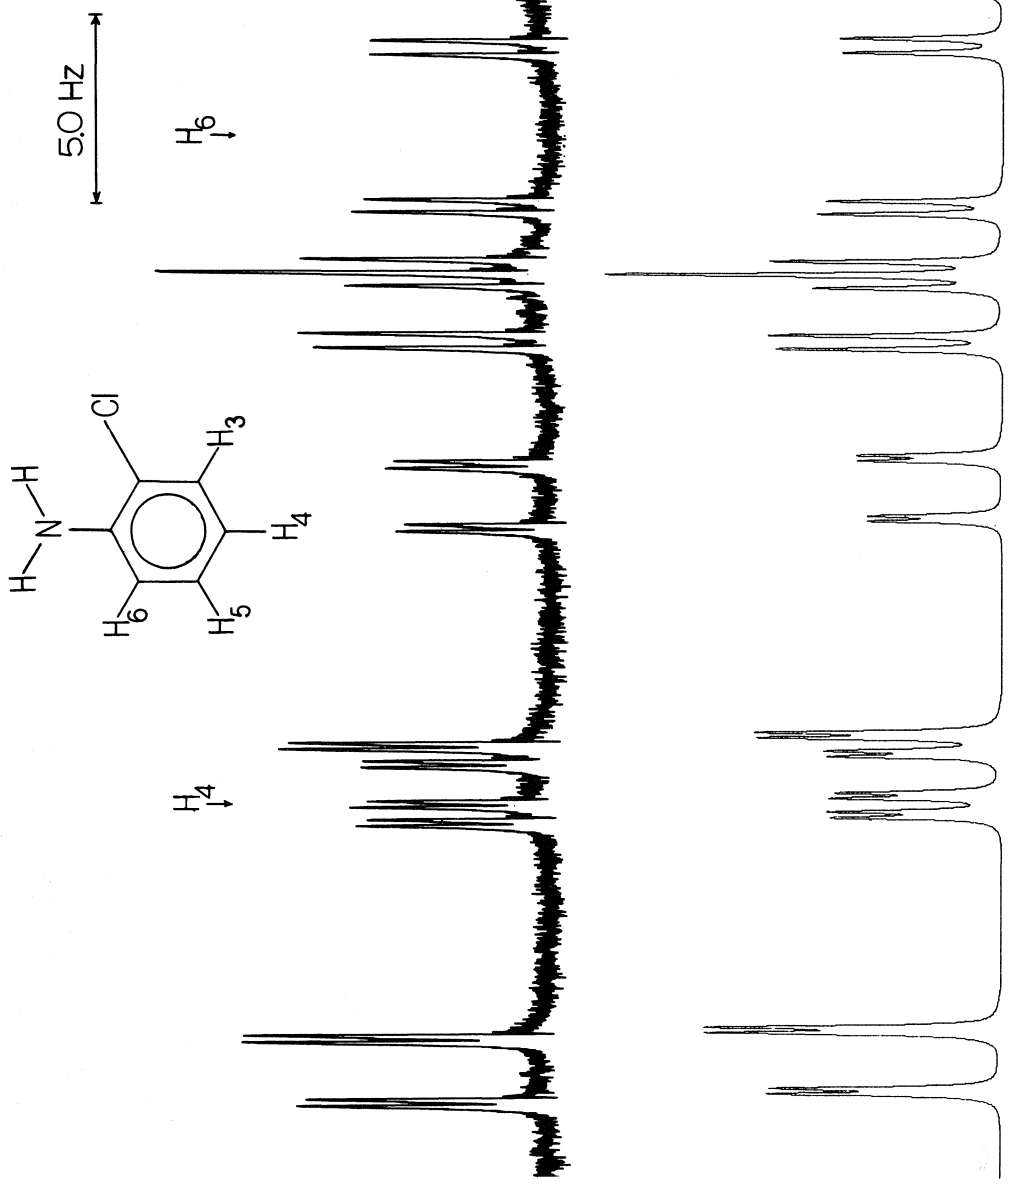

FIG. 1. The p.m.r. spectrum at 100 MHz of the H-4 and -6 protons in 2-chloroaniline-^{15}N as a 10 mol % solution in benzene-d_6. The shifts of H-4 and -6 are indicated by vertical arrows. The smallest doublet spacings in the H-4 region are about 0.17 Hz and arise from coupling to ^{15}N. The calculated spectrum uses the parameters in Table 1 with $\Delta\nu_{1/2} = 0.11$ Hz. In the observed spectrum fast intermolecular exchange of the amino protons is occurring.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

temperature (17), and knowing the ratio of the nuclear moments of ^1H and ^2H, it follows that $|^2J^{H,NH}|$ is probably less than 1 Hz.

(2) Nonplanarity of the Amino Group

(a) Long-range Proton-Proton Couplings

The relative magnitudes and signs of the coupling between the amino protons and the ring protons fall into the general pattern for side-chain protons described in the introduction if it is assumed that the amino protons lie out of the plane of the ring. The coupling to the para proton, H-4, over six bonds has not been previously observed in an aniline derivative. In 2,6-dibromoaniline such a coupling is not observed (10) suggesting a lower degree of nonplanarity of the amino group in this compound, likely caused by hydrogen bonding.

The barrier to rotation about the C—N bond is evidently quite low (10) in 2,6-disubstituted anilines and the equivalence of the amino proton shifts in 2-chloroaniline at −48 °C suggests a barrier to rotation in 2-chloroaniline of less than 10 kcal/mol when it is considered that shift difference of 1 p.p.m. (18) is expected between the two amino protons if no rotation is occurring. Alternative assumptions can now be made concerning the conformation of the amino group.

If the N—H bond *cis* to the chlorine lies in the plane of the ring, as it will if strong hydrogen bonding occurs, then the calibration procedures previously described (10) lead to an angle of 25° between the plane of the ring and the plane defined by the fragment H—N—C containing the N—H bond *trans* to the chlorine (rapid rotation about C—N on the time scale defined by the reciprocals of the chemical shifts and coupling constants is assumed, of course). If, on the other hand, the N—H bonds are symmetrically arranged then an average angle of 17.5° (as defined above) may be estimated.

If the coupling from the amino protons to the ortho and para ring protons is π electron dominated then (as in toluene (1)) the ortho coupling should be slightly larger in magnitude than the para coupling, as observed (see Fig. 2 and Table 1). The coupling between the amino protons and the meta ring protons, evidently slightly substituent dependent, behaves as expected on the basis of the couplings measured for other side-chain protons (1–5).

The estimated degree of nonplanarity is in broad agreement with the microwave data for aniline itself in the gas phase (19), but there is no doubt that the estimate is not very reliable.

(b) The Coupling Between Amino Protons and ^{15}N

A check on the semiquantitative conclusions above may be available from the value of −82.3 Hz for $^1J^{15N,H}$ in 2-chloroaniline-^{15}N. It has recently been established that this coupling in aniline, anilinium ion, and their 4-substituted derivatives, is a reliable measure of the hybridization at nitrogen (20). However, there are marked solvent effects on the coupling and calibrations of hybridization in one medium must be used with circumspection in another. Furthermore, although there is little doubt (20, 21) that the nitrogen in, say, pyrrole is trigonally hybridized (and the ^{15}N–H coupling also indicates as much), an equation (22) of the type (% s character of nitrogen orbital used for bonding to hydrogen) $= aJ^{15N,H} + b$, where a and b are constants, should be parameterized using very similar compounds if semiquantitative predictions are going to be made with reasonable validity.

Of the various possibilities, the following was finally judged to be most reliable. The ^{15}N–H coupling in aniline in DMSO is −82.6 Hz while in $CDCl_3$ it is −78.6 Hz (23), reasonably close to our unpublished value of −78.8 Hz in benzene-d_6 solution (the accuracy of all these values is probably 0.2 to 0.4 Hz). In anilinium ion in H_2SO_4 one has a value of −76.0 Hz (20) which compares with −74.8 Hz in ammonium ion dissolved in acidified water (24). The phenyl carbon therefore does not cause a large change in the coupling and sp^3 hybridization in the anilinium ion can be reasonably assumed. For the coupling in an sp^2 hybridized system we do not choose an indole or pyrrole derivative because of the unknown substituent effects (alteration of effective nuclear charge at nitrogen (25)), but choose to use the gas phase value of the HNH angle of 114° in aniline as a calibration point. From the equation, s character $= \cos\theta/(\cos\theta - 1)$, where θ is the HNH angle, the s character of the nitrogen orbital used in bonding to hydrogen is then 0.29. In benzene solution, where strong hydrogen bonding of the N–H bond to solvent molecules is not expected this result is probably reasonable.

For personal use only.

In going from DMSO solution to $CDCl_3$ solution, the coupling decreases in magnitude from 3 to 4 Hz (23) for aniline derivatives. If this correction is applied to the above value for anilinium ion, the aniline calibration point of 0.29 s character together with 0.25 s character for anilinium yields the relationship: s character $= -0.59\,J(^{15}N,H) - 17._5$.

For 2-chloroaniline-^{15}N, the coupling of -82.3 Hz then predicts an HNH angle of 116.7°. This value is hardly reliable to more than 1°, but is clearly compatible with the dihedral angle obtained from $^6J_p^{H,NH}$ above and with the idea of a nonplanarity of the amino group.[3] In addition to the errors in the coupling and the approximate nature of the correction for solvent effects, there is also the question of the direct effect of the ortho chlorine substituent on the coupling. The synthesis of a series of relevant derivatives of aniline-^{15}N is indicated.

(c) The Geminal Coupling Between the Amino Protons, $^2J^{H,NH}$

This coupling is likely less than 1 Hz in magnitude in 2-chloroaniline. In ammonium ion (27, 28) the coupling is -12.4 Hz, and is $+2.3$ Hz in formamide in aqueous solution (24). These values compare with a geminal proton coupling of -12.4 Hz in methane (29) and $+2.4$ Hz in ethylene (30). There is a striking similarity between the couplings and the probable s character of the nitrogen and carbon orbitals in these compounds.

In formamide (24) there exists a marked effect of the carbonyl group on $^1J(^{15}N,H)$. The coupling for the N—H bond lying *trans* to the C=O bond, *i.e.*, the one which will be most strongly polarized by the electric field from the C=O dipole, is 4.5 Hz larger in magnitude than the coupling for the N–H bond lying *cis* to the carbonyl group, which is -86.9 Hz. Nevertheless, if the mean value of these two couplings is decreased by 4 Hz to account for solvent effects the s character calculated from the equation above is 0.33, implying sp^2 hybridization at the nitrogen.[4]

If an HNH angle of 116 to 117° is assumed in 2-chloroaniline, the indicated proportionalities imply a value of -2.6 ± 2 Hz for $^2J^{H,H}$ in this compound, again compatible with the observed magnitude of 1 Hz or less. The uncertainty of 2 Hz in the estimated values derives from the total uncertainty of about 1 Hz in the couplings in the ammonium ion and formamide and from the uncertainty of about 1° in the HNH angle.

Although the amino group is in many respects different from a CH_2 fragment, a qualitative application of the theory of geminal proton coupling of Pople and Bothner-By (32) indicates a small positive shift of $^2J^{H,H}$ in aniline relative to ammonia, inasmuch as the H,H line is parallel to the plane of the ring.

In summary, the three rough estimates of the nonplanarity of the amino group in 2-chloroaniline are self consistent to within experimental error and suggest the measurement of the three coupling parameters in a series of aniline derivatives.

(3) Molecular Orbital Calculations in the CNDO/2 Approximation

(a) Dipole Moments and Relative Energies

Because CNDO/2 and INDO molecular orbital calculations (33, 34) yield reliable charge distributions and therefore dipole moments of relatively large molecules, *e.g.*, for fluorobenzene (33) and *p*-fluorobenzaldehyde,[5] CNDO/2 computations were done on 2-chloroaniline for various conformations of the amino group in an attempt to confirm or reject the tentative conclusions reached above. For aniline we calculate 1.56 D, the experimental value being 1.53 D (35). Although these calculations allow d orbital participation for the chlorine, the calculated dipole moment of chlorobenzene is 4.05 D,

[3]It is interesting to note that angles of 111.7 and 113.7° have been derived from solution i.r. data (26) for aniline and 2-chloroaniline, respectively.

[4]In the gas phase, the N—H bond *trans* to C=O is 0.01 Å shorter than the other and the HNH angle is 119°, the H_2N—C fragment forming a shallow pyramid (31).

[5]We calculate 1.87 D compared to the observed value at 1.98 D (35).

FIG. 2. The p.m.r. spectrum of the H-4 and -6 protons of a 10 mol % solution in benzene-d_6 of 2-chloroaniline when the amino protons are not exchanging. The small triplet splittings, less than 0.1 Hz in the H-4 region, arise from coupling to the equivalent amino protons. In the H-3 and -5 regions these couplings are large, about 0.3 Hz, and are resolved to the base line. The calculated spectrum uses the parameters in Table 1 with $\Delta\nu_{1/2} = 0.07$ Hz.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

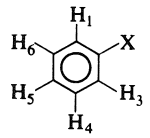
compared to the observed value in solution of 1.58 D (35). Therefore these computations were not pursued further.

(b) s-Bond Orders in the N—H Bonds

In view of the statements in section 2 concerning substituent effects on the ^{15}N–H coupling, the change in this coupling due to substituents should be reflected in change in the square of the s-bond order between ^{15}N and H (36–39). In aniline we calculate at N–H s-bond order of 0.4957 while in non-planar conformations of 2-chloroaniline the s-bond order increases by amounts sufficient to increase its square by as much as 8%. The observed increase in the magnitude of the ^{15}N–H coupling on substitution by chlorine is at most 6%, in rough agreement with the prediction (the reduced coupling is, of course, positive (40) because the gyromagnetic ratio of ^{15}N is negative).

(4) Coupling of ^{15}N to the Ring Protons

Immediately apparent from Table 1 is the substituent effect on $^4J(^{15}N,H)$. Allowing for the negative gyromagnetic ratio of ^{15}N, the effect has the same sign as that experienced by $^4J^{H,H}$ in **1** (41), where X is more electronegative



1

than hydrogen. In **1**, J^{H_1,H_3} is larger than, and J^{H_1,H_5} is smaller than, $^4J^{H,H}$ in benzene itself. In aniline-^{15}N one may then expect $^4J(^{15}N,H) \simeq -0.5$ Hz and, again by analogy to what is known for **1**, a smaller magnitude of $^5J(^{15}N,H)$ in 2-chloroaniline indicates a coupling of either sign in aniline-^{15}N.

We thank Dr. F. E. Hruska for a suggestion concerning the mono-deuteration of the amino group and are grateful to the National Research Council of Canada for financial support. We thank a referee for very useful criticisms.

The Effect of Some 3-Oxygen Functions on the Simmons–Smith Methylenation of 5,6-Unsaturated Steroids

J. F. Templeton and C. W. Wie
Faculty of Pharmacy, University of Manitoba, Winnipeg 19, Manitoba

Received July 2, 1971

The effect of 3α- and 3β-hydroxy, 3α- and 3β-acetoxy, 3-ethylene acetal, and 3α-methoxy derivatives of 5-cholestene on the addition of the Simmons–Smith reagent to the steroidal 5,6-double bond has been investigated. Reaction occurred only with *epi*-cholesterol to yield chiefly 3α-hydroxy-5,6α-cyclopropano-5α-cholestane. The 3α-ethyl ether, 3α-acetate, and a dialkoxymethane have been identified as byproducts. The p.m.r. and mass spectral data are given.

L'effet des dérivés hydroxy en 3α et 3β, acétoxy en 3α et 3β, éthylène acétal en 3, et méthoxy en 3α du cholestène-5 sur l'addition du réactif de Simmons–Smith sur une double liaison en 5,6 stéroidique a été étudié. La réaction se fait seulement avec l'*epi*-chlorestérol pour donner principalement l'hydroxy-3α cyclopropano-5,6α cholestane-5α. L'éthyl éther en 3α, l'acétate en 3α et un dialcoxyméthane ont été identifiés comme sous produits. Des données de r.m.p. et de spectrométrie de masse sont rapportées.

Canadian Journal of Chemistry, **49**, 3636 (1971)

Introduction

Since the introduction of the iodomethylzinc iodide reagent by Simmons and Smith (1–4), prepared from a zinc–copper couple and diiodomethane, it has been extensively used in organic synthesis to prepare methylene containing cyclopropane derivatives from olefins. Simmons *et al.* (4) have shown that the reagent is best represented as an equilibrium between the following species:

$$2\,ICH_2ZnI \rightleftarrows (ICH_2)_2Zn\cdot ZnI_2$$

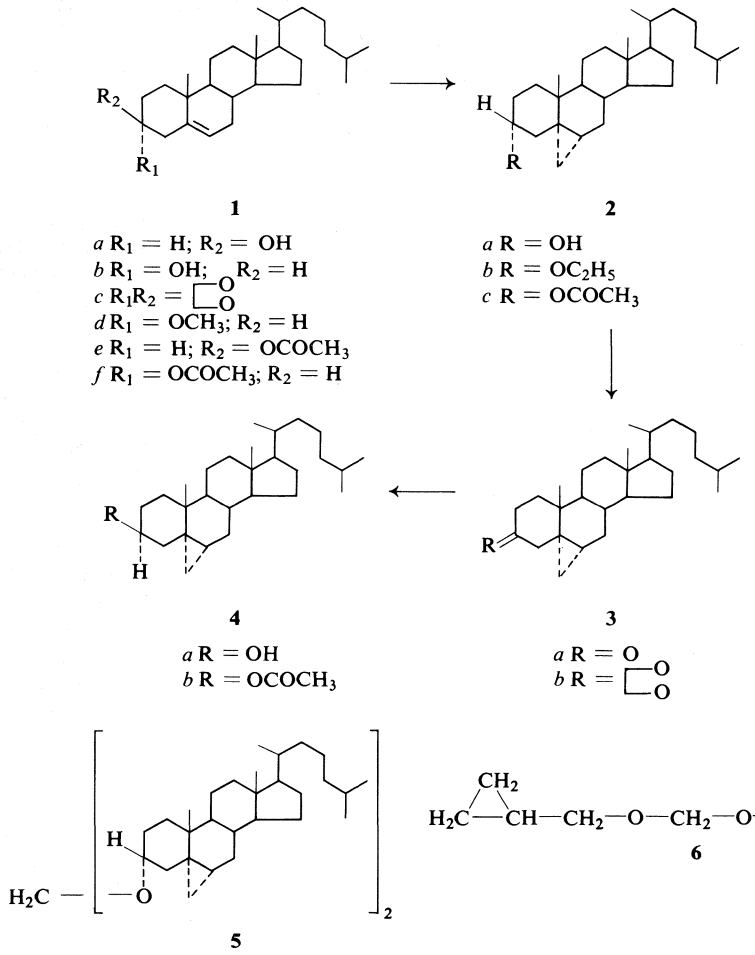
with possible solvent stabilization. It has been suggested (3–5) that the bis-compound is the reacting molecule in a one step addition of methylene to the olefin. An important extension of the synthetic application of this reaction followed from the discovery (6, 7) that the presence of neighboring electron-donating oxygen functions was capable of both accelerating the rate of reaction and maintaining steric control over the products in a *cis* sense (8). This effect is initiated by an interaction between the electron-donating group with the metal, prior to transfer of methylene, through formation of a zinc–oxygen bond (3) or by coordination (7).

The object of the present study has been to determine the effect of various 3-oxygen functions on the addition of the iodomethylzinc iodide reagent to the steroidal 5,6-double bond.

Results and Discussion

Addition of the iodomethylzinc iodide reagent to the steroidal 5,6-double bond would be expected to be accelerated and stereochemically controlled by an increased rate of addition to the α-face of the molecule by the presence of a 3-axial oxygen function capable of coordination or reaction with the metal. Alternatively, the rigid steroid structure would hold a 3-equatorial oxygen in such a position that any zinc oxygen interaction would leave the reagent spacially removed from the double bond, and sterically hindered by the 19-methyl group, from approaching the double bond from the β-face. An axial conformation which has been postulated (9) as the reacting conformation for homoallylic alcohols is not possible in the rigid steroid molecule containing a 3-equatorial oxygen.

When cholesterol (**1***a*) was treated with the Simmons–Smith reagent in refluxing ether, only starting material was recovered. However, when *epi*-cholesterol (**1***b*) was similarly treated, the product contained no starting material by t.l.c. and after chromatographic separation several products were obtained. The major product in 60% yield was a cyclopropane containing alcohol, the spectral properties of which are consistent with those of the expected 3α-hydroxy-5,6α-cyclopropano-5α-cholestane (**2***a*). The p.m.r. spectrum no longer showed the vinylic proton of *epi*-cholesterol but had typical high-field cyclopropane ring hydrogen resonance and a hydrogen having a band width at half height characteristic of a 3-equatorial hydrogen (10). The i.r. spectrum showed a weak absorption characteristic of cyclopropyl C—H stretching. By analogy



(11, 12) with other homoallylic steroidal alcohols, methylenation is concluded to have occurred *cis* to the hydroxyl group. Molecular rotation differences, which have been shown to be similar for corresponding epoxide and cyclopropane derivatives (13), are also consistent with the 5α,6α structure for **2***a*.

Chromic acid oxidation (14) of this alcohol **2***a* yielded a saturated ketone **3***a* which still contained the cyclopropane ring. Treatment of this ketone with perchloric acid in glacial acetic acid gave the known 6α-methyl-4-cholesten-3-one (15). Reduction of the ketone **3***a* with lithium tritertiary butoxyaluminum hydride (16) gave an epimeric alcohol **4***a* further characterized as its acetate **4***b*. Treatment of **4***a* with ethylene glycol and *p*-toluenesulfonic acid in refluxing benzene yielded the ethylene acetal **3***b*.

A dialkoxymethane **5** analogous to those reported (17) as a byproduct of the Simmons–Smith reaction with several low molecular weight allylic alcohols was also isolated. Bis(5,6α-cyclopropano-5α-cholestan-3α-oxy)methane (**5**) showed p.m.r. and i.r. spectra in agreement with the structure indicated. The mass spectrum of **5** has a weak signal corresponding to the molecular ion as does bis(cyclohexoxy)methane (18). This is in contrast to simple alicyclic dialkoxymethane derivatives which do not show a molecular ion peak (17–19). Signals corresponding to R^+, RO^+, and $ROCH_2^+$ ions are indicative of a structure of this type where cleavage of the ether bonds would be more favored than partial fragmentation of the hydrocarbon structure. The formation of this substance from a homoallylic alcohol suggests that there is a similar intermediate in the addition of the iodo-

methylzinc iodide to both allylic and homoallylic alcohols. The equivalent unsymmetrical formal intermediate suggested by Majerski and Schleyer (17) **6** for the allylic dialkoxymethane is unlikely because the 3-ethylene acetal **1***c* and 3α-methyl ether **1***d* derivatives of 5-cholestene (see below) fail to react under the same reaction conditions.

The presence of ethoxy derivatives has previously been noted (11) with the suggestion that they arise through formation of hydriodic acid which cleaves the ethyl ether solvent to form ethyl iodide, their formation being suppressed if the reaction mixture were first concentrated by distillation. From this reaction small quantities of 3α-ethoxy-5,6α-cyclopropano-5α-cholestane (**2***b*) have been isolated although the reaction was distilled during addition of the ethereal solution of the steroidal alcohol. Even when the zinc–copper couple was carefully washed with dry ether to remove acetic acid, it was possible to isolate 5,6α-cyclopropano-5α-cholestan-3β-yl acetate (**2***c*). This substance was also prepared by acetylation of the alcohol **2***a* and was identical in all respects with that product.

Joska *et al.* (20) state that reaction occurs between the Simmons–Smith reagent at 3-oxygen substituted 5,6-unsaturated B-norsteroids at 100°, with the 3α- and 3β-acetates giving much higher yields of methylene addition products than could be obtained from the corresponding alcohols. However, complete stereochemical control of addition was lost and principally addition from the α-face occurred irrespective of the stereochemistry at C-3. Stereochemical control in the 3β-derivatives is undoubtedly due to normal addition to the α-face, caused by hindrance from the C-10 methyl group and not because of complex formation. For the 3α-derivatives both steric hindrance and complex formation may operate.

Cholesteryl acetate (**1***e*), in contrast, was unreactive at 75° for 18 h. The p.m.r. spectrum of the crude reaction mixture did not indicate any high field resonance characteristic of the cyclopropyl protons shown by **4***b*. These findings are consistent with the decreased rate of reaction of tri-substituted six-membered olefins compared to the five-membered system as shown by the rate measurements of Rickborn and Chan (21). When cholesteryl acetate was treated under the conditions used by Joska *et al.* (20) cholesta-3,5-diene (22) was isolated. No cyclopropane derivatives were obtained. *epi*-Cholesteryl acetate (**1***f*) was recovered unchanged after refluxing overnight with the Simmons–Smith reagent.

Because of the relative difficulty of preparing 3α-hydroxy-5,6-unsaturated steroids (23), it was hoped to take advantage of the established ketalization of the steroidal 4-en-3-one system to place an oxygen atom in the 3-axial position of a steroidal 5-ene. Treatment of 5-cholesten-3-one ethylene acetal (**1***c*) with the Simmons–Smith reagent in refluxing ether gave no cyclopropane containing products as determined by p.m.r. spectroscopy and only a good yield of starting material was recovered. Six days refluxing in ether gave a crude product containing no high field resonance which corresponded to the signals of **3***b* as well as giving no corresponding acetal signals. Recently it has been suggested (9) that iodomethylzinc iodide addition to homoallylic alcohols, unlike allylic alcohols, is accelerated and sterically controlled when reaction of the alcohol and the iodomethylzinc iodide reagent occurs prior to methylenation. This mechanism rules out acceleration by an ethereal oxygen in this case. *epi*-Cholesteryl methyl ether (**1***d*) was also unreactive under refluxing ether conditions. However, in the similar case of 1-(*o*-methoxyphenyl)-propene, acceleration by an oxygen function did occur (2).

Of the 3-oxygen substituted 5-cholestene derivatives studied, only in the presence of the 3α-hydroxy function did reaction of the iodomethylzinc iodide reagent with the 5,6-double bond occur.

Experimental

Unless otherwise stated the following instruments and procedures have been used.

Melting points were carried out on a Thomas–Hoover capillary apparatus and are uncorrected. Optical rotations were measured in chloroform solution at 23° on a Bellingham and Stanley (Model A) Polarimeter (concentration range 0.4–1.5%). The i.r. spectra were determined on a Beckman Model 8 spectrophotometer using carbon tetrachloride as solvent. The u.v. spectra were recorded on a Beckman DU Model 2400 spectrophotometer using 1 cm silica cells. For p.m.r. spectra a Varian A60 instrument was used with deuterochloroform as solvent and tetramethylsilane as an internal standard. Mass spectra were determined on an A.E.I. MS12 instrument at 70 eV using a direct probe method by the Chemistry Department, University of Alberta, Edmonton. Elemental analyses were performed by Pascher and Pascher, Microanalytical Laboratory, Bonn, West Germany. Petroleum ether refers to the fraction boiling within the range of 60 to 80°. The t.l.c. was carried out on silica gel coated glass plates, developed with 10–25% v/v ethyl acetate in petroleum

For personal use only.

ether, visualized by spraying with 4% v/v concentrated sulfuric acid in ethanol followed by heating at approximately 100°. Silver nitrate treated plates were prepared by spraying the above plates with 0.1 *N* silver nitrate and drying at 100° for 30 min before use.

Simmons–Smith Reaction

Zinc–Copper Couple

A 1.85% w/w zinc–copper couple was freshly prepared essentially by the method of LeGoff (24) as follows: zinc dust (15 mmol) was added to a hot (bath temperature 130°) stirred solution of copper acetate monohydrate (0.28 mmol) in glacial acetic acid (2 ml). The reaction was quickly removed from the heat and excess acetic acid removed by pipette. The residue was washed with acetic acid (2 ml) followed by dry ether (3 × 20 ml) to remove all acetic acid.

Iodomethylzinc Iodide Reagent

To the freshly prepared couple in dry ether (20 ml) was added dry methylene iodide (10 mmol) m.p. 5–6°, in dry ether (10 ml). Refluxing usually occurred spontaneously and the reaction was refluxed for 30–60 min.

Reaction with the Unsaturated Steroid

The steroid (1 mmol) was dissolved in dry ether (10–25 ml), added to the reagent (10 mmol), and the mixture refluxed. In reactions carried out with a steroid containing a hydroxyl group the steroid was added dropwise over 20–30 min while ether was distilled at a rate slightly greater than the addition. Dry ether was added if required to maintain the volume.

Reaction Work-up

The reaction was poured into excess saturated aqueous sodium bicarbonate and the resulting slurry extracted with ether. The ether solution was washed with water, brine, dried over anhydrous sodium sulfate, filtered, and evaporated at reduced pressure to give the crude reaction product.

Simmons–Smith Reagent with epi-Cholesterol (1b)

epi-Cholesterol (10 mmol) was treated as described above and small aliquots removed and worked-up at intervals. The t.l.c. on $SiO_2/AgNO_3$ plates indicated no starting material after 6 h. Reactions run up to 18 h gave analogous results. Chromatography of the crude reaction product on alumina gave, on elution with petroleum ether, a fraction (806 mg) which on crystallization from ether gave bis(5,6α-cyclopropano-5α-cholestan-3α-oxy)-methane (**5**), recrystallization gave 287 mg; m.p. 221–222°; $[\alpha]_D$ −40°; i.r. ν_{max} 3060 (cyclopropyl C—H stretching), 1027 (C—O stretching) cm^{-1}; p.m.r. δ 4.61 (s, 2H, dialkoxymethylene), 3.90 (unresolved multiplet, 2H, width at half height, 7 Hz, 3-equatorial hydrogen), 1.04 (s, C-19 methyl), 0.60 (s, C-18 methyl), 0.42 (s, 2H, cyclopropyl hydrogen) p.p.m.; mass spectrum, strong signal at *m/e* 383 (R^+), moderately strong signals at 399 (RO^+) and 413 ($ROCH_2^+$), weak signal at 429 ($ROCH_2O^+$), no signals greater than 429 except near the very weak M^+ at 812.

Anal. Calcd. for $C_{57}H_{96}O_2$: C, 84.17; H, 11.90. Found: C, 84.12; H, 12.10.

The mother liquor on crystallization from methanol yielded 3α-ethoxy-5,6α-cyclopropano-5α-cholestane (**2b**) (66 mg); m.p. 117.5; $[\alpha]_D$ −43°; i.r. ν_{max} 3060 (cyclopropyl C—H stretching) cm^{-1}; p.m.r. δ 3.76 (1H, unresolved triplet, band width at half height 7.5 Hz, 3-equatorial proton); 3.60 (2H, quartet, $J = 7$ Hz, ethoxymethylene protons), 0.46 (broad singlet, 2H, cyclopropyl proton) p.p.m.; mass spectrum, strong signals at *m/e* 382 (M^+ − EtOH), moderately strong peaks at 227 (M^+ − EtOH-42-17β-sidechain), 329 (cleavage of C-1 to C-10 and C-4 to C-5), 428 (M^+).

Anal. Calcd. for $C_{30}H_{51}O$: C, 84.24; H, 12.01. Found: C, 84.05; H, 12.21.

Elution with 5% benzene petroleum ether gave 5,6α-cyclopropano-5α-cholestan-3α-yl acetate (**2c**) (420 mg), recrystallized from methanol, m.p. 131–132°; mixed m.p. was not depressed and the i.r. spectrum (KBr) was identical with the acetate of a **2a** (see below).

Elution with benzene gave 3α-hydroxy-5,6α-cyclopropano-5α-cholestane (**2a**) (2.4 g), recrystallized from acetone m.p. 120–121°; $[\alpha]_D$ −65°; i.r. ν_{max} 3600 (free O—H stretching), 3050 (cyclopropyl C—H stretching) cm^{-1}; p.m.r. δ 4.00 (unresolved multiplet, 1H, half band width, 8.5 Hz, 3-equatorial hydrogen), 1.05 (C-19 methyl), 0.61 (C-18 methyl), 0.49 (broad singlet, 2H, cyclopropyl) p.p.m.; mass spectrum, strong peaks at 382 ($M^+ - H_2O$) and 400 (M^+); moderately strong peaks at *m/e* 227 ($M^+ - H_2O - 42 - 17\beta$-sidechain).

Anal. Calcd. for $C_{28}H_{48}O$: C, 83.93; H, 12.07. Found: C, 84.27; H, 12.10.

In some experiments the alcohol **2a** could be crystallized from acetone directly from the crude reaction mixture in 50% yield.

Cholesterol (**1a**), cholesteryl acetate (**1e**), *epi*-cholesteryl acetate (**1f**), cholest-5-ene-3-one ethylene acetal (**1c**), and 3α-methoxy-5-cholestene (**1d**) were treated separately with the Simmons–Smith reagent as described for *epi*-cholesterol (**1b**), starting materials were recovered in high yields (identified by mixed m.p. and i.r.). Spectroscopic examination (i.r., p.m.r.) of the mother liquor gave no indication of cyclopropyl C—H absorption. The t.l.c. did not indicate any of the expected methylene addition products.

A similar result was obtained when cholesteryl acetate (**1e**) was treated as above with the reagent for 18 h at 75°.

Cholesteryl acetate (**1e**) (1.5 g) was subjected to Simmons–Smith reaction under conditions described by Joska *et al.* (20). The crude reaction product showed three major spots on t.l.c. Chromatography on alumina gave on elution with petroleum ether a fraction (586 mg) which on recrystallization from acetone yielded cholesta-3,5-diene, m.p. 78–79°; $[\alpha]_D^{24}$ −56°; i.r. ν_{max} 3020 (vinyl C—H stretching) cm^{-1}; u.v. λ_{max} (hexane): 244 (ε 11 040), 237 (ε 18 700), 229 (ε 15 880) nm; mass spectrum *m/e* 368 (M^+); [lit. (22) m.p. 79–80°; $[\alpha]_D$ ($CHCl_3$) −65°]. The remaining two spots corresponded to starting material and cholesterol. Elution with benzene–ether–methanol (15:4:1, v/v) gave cholesterol (**1a**) (315 mg) identified by mixed m.p. and i.r.

5,6α-Cyclopropano-5α-cholestan-3α-yl Acetate (2c)

3α-Hydroxy-5,6α-cyclopropano-5α-cholestane (**2a**) (142 mg) was acetylated in pyridine acetic anhydride (2:1) overnight at room temperature. Recrystallization from methanol afforded the acetate **2c** (125 mg); m.p. 133°; $[\alpha]_D$ −44°; i.r. (KBr) ν_{max} 3050 (cyclopropyl C—H stretching), 1730 (acetate carbonyl stretching), 1280–1180

(acetate C—O stretching) cm^{-1}, p.m.r. δ 5.04 (1H, triplet, J = 2.7 Hz, half band width, 7 Hz, 3-equatorial proton), 2.00 (s, acetate methyl protons), 1.06 (s, C-19 methyl), 0.62 (s, C-18 methyl), 0.40–0.46, (m, 2H, cyclopropyl protons) p.p.m.; mass spectrum, weak peaks at 442 (M^+) and 287 ($M^+ - 42 - 17\beta$-sidechain), strong peaks at 382 ($M^+ -$ HOAc), moderately strong peaks at *m/e* 227 ($M^+ -$ HOAc $- 42 - 17\beta$-sidechain).

Anal. Calcd. for $C_{30}H_{50}O_2$: C, 81.02; H, 11.79. Found: C, 81.13; H, 11.52.

5,6α-Cyclopropano-5α-cholestan-3-one (3a)

3α-Hydroxy-5,6α-cyclopropano-5α-cholestane (**2***a*) (2.35 g) was dissolved in acetone (250 ml) and oxidized with Jones reagent (14). The crude product showed one faster spot on t.l.c. Recrystallization from methanol afforded 2.2 g; m.p. 144°; $[\alpha]_D$ −10°; i.r. ν_{max} 3050 (cyclopropyl C—H stretching), 1715 (carbonyl stretching) cm^{-1}; p.m.r. δ 3.15, 3.17 (pair of doublets, J = 1 and 16 Hz, C-4 methylene hydrogen), 1.28 (C-19 methyl), 0.65 (C-18 methyl), 0.32, 0.18 (unresolved multiplet, 2H, cyclopropyl hydrogens) p.p.m.; mass spectrum, strong peak at *m/e* 398 (M^+), moderately strong signal at *m/e* 243 ($M^+ - 42 - 17\beta$-sidechain).

Anal. Calcd. for $C_{28}H_{46}O$: C, 84.35; H, 11.63. Found: C, 84.46; H, 11.94.

6α-Methyl-4-cholestan-3-one

5,6α-Cyclopropano-5α-cholestan-3-one (**3***a*) (260 mg) was treated with glacial acetic acid (26 ml) containing 60% w/v perchloric acid (3 ml) for 15 min at 100°. The reaction was poured into water and extracted with ether. The crude product (264 mg) was recrystallized from methanol (140 mg), m.p. 125–126°; $[\alpha]_D^{23}$ (dioxane) +61°; i.r. ν_{max} (KBr) 1675, 1630 (conjugated carbonyl stretching) cm^{-1}; u.v. λ_{max} (hexane) 231 nm (ε 15 100); [lit. (15) m.p. 127°; $[\alpha]_D$ +60°; λ_{max} (EtOH) 241 nm (ε 16 650)].

3β-Hydroxy-5,6α-cyclopropano-5α-cholestane (4a)

5,6α-Cyclopropano-5α-cholestan-3-one (**3***a*) (800 mg) and lithium tri-*t*-butoxyaluminum hydride (560 mg) in dry ether (80 ml) were stirred at room temperature for 20 h. The reaction was poured into saturated ammonium chloride and extracted with ether. The crude residue showed three spots on t.l.c. which after column chromatography on alumina were separated. Elution with 20–40% benzene – petroleum ether gave starting material (195 mg); mixed m.p. 144°; identical i.r. spectrum with **3***a*.

Elution with 50–100% benzene – petroleum ether gave 3α-hydroxy-5,6α-cyclopropano-5α-cholestane (**2***a*) (88 mg); mixed m.p. 120–121°; i.r. spectrum was identical to the previous compound.

Elution with 2–15% ethyl acetate – benzene gave 3β-hydroxy-5,6α-cyclopropano-5α-cholestane (**4***a*) (500 mg). Recrystallization from petroleum ether yielded needles (458 mg); m.p. 155–156°; $[\alpha]_D$ −52°; i.r. ν_{max} 3600 (free OH stretching), 3050 (cyclopropyl C—H stretching) cm^{-1}; p.m.r. δ 3.70 (m, 1H, half band width, 21 Hz, 3-axial proton), 1.16 (C-19 methyl), 0.60 (C-18 methyl), 0–0.47 (m, 3H, cyclopropyl protons) p.p.m.; mass spectrum, strong signals at *m/e* 329, moderately strong peaks at 400 (M^+), 245 ($M^+ - 42 - 17\beta$-sidechain) and 227 ($M^+ - H_2O - 42 - 17\beta$-sidechain).

Anal. Calcd. for $C_{28}H_{48}O$: C, 83.93; H, 12.07. Found: C, 83.85; H, 11.96.

5,6α-Cyclopropano-5α-cholestan-3β-yl Acetate

3β-Hydroxy-5,6α-cyclopropano-5α-cholestane (**4***a*) (250 mg) was acetylated in dry pyridine – acetic anhydride by the same method as compound **2***a*. Crude product showed a single spot on t.l.c. Recrystallizations from methanol yielded the acetate **4***b* (250 mg), m.p. 117–118°; $[\alpha]_D$ −53°; i.r. ν_{max} 3050 (cyclopropyl C—H stretching), 1730 (acetate carbonyl stretching), 1230 (acetate C—O stretching) cm^{-1}; p.m.r. δ 4.84 (1H, half band width 23 Hz, 3-axial proton), 2.00 (3H, s, acetate methyl protons), 1.12 (C-19 methyl), 0.62 (C-18 methyl), 0.36 (m, cyclopropyl protons) p.p.m.; mass spectrum, strong peak at *m/e* 382 ($M^+ -$ HOAc), moderately strong signals at 287 ($M^+ - 42 - 17\beta$-sidechain), 227 ($M^+ -$ HOAc $- 42 - 17\beta$-sidechain), and a weak parent peak at 442 (M^+).

Anal. Calcd. for $C_{30}H_{50}O_2$: C, 81.02; H, 11.79. Found: C, 81.09; H, 11.81.

5,6α-Cyclopropano-5α-cholestan-3-one Ethylene Acetal (3b)

The ketone (**3***a*) (300 mg) was added to a mixture of benzene (50 ml) and ethylene glycol (1 ml), and refluxed for 40 min with a Dean–Stark apparatus. *p*-Toluenesulfonic acid monohydrate (2 mg) was added, and refluxing continued for a further 3 h. The resulting mixture was washed with excess saturated sodium bicarbonate solution and water. The benzene solution was filtered through anhydrous sodium sulfate and evaporated. The crude reaction product (328 mg) showed a single spot on t.l.c. Recrystallization from methanol gave **3***b* (300 mg), m.p. 117–118°; $[\alpha]_D$ −50°; i.r. ν_{max} 3070 (cyclopropyl C—H stretching), 1090 (C—O stretching) cm^{-1} p.m.r. δ 3.76 (4H, s, ethylene acetal protons), 1.09 (C-19 methyl protons), 0.62 (C-18 methyl protons), 0.36–0.45 (m, cyclopropyl protons) p.p.m.; mass spectrum, strong peak at *m/e* 99, moderately strong signal at *m/e* 442 (M^+) and a weak signal at *m/e* 343 ($M^+ - 99$).

Anal. Calcd. for $C_{30}H_{50}O_2$: C, 81.45; H, 11.31. Found: C, 81.69; H, 11.21.

We wish to thank Dr. D. R. Dalton, Chemistry Department, Temple University, Philadelphia, Pennsylvania for helpful comments on the manuscript. We also thank Miss Marylin Calman and Mrs. Helga Block of the Faculty of Pharmacy for their technical assistance. Financial assistance from the Faculty of Graduate Studies, Research Board, University of Manitoba, is gratefully acknowledged.

Autoxidation of 2,3-Dialkylindoles

STEWART MCLEAN AND G. I. DMITRIENKO
Department of Chemistry, University of Toronto, Toronto, Ontario

Received June 28, 1971

Autoxidation of 2,3-dimethylindole leads to the formation of an oxidized dimer **6***a*, and 2-methyl-3-ethylindole gives rise to the corresponding product **6***c* under the same conditions. In contrast, 2-ethyl-3-methylindole resembles 2,3-diethylindole in behavior and forms 2-acetyl-3-methylindole via the 3-hydroperoxyindolenine, which is an isolable intermediate. Some of the side reactions which occur under autoxidative conditions have been studied, and an attempt has been made to give a satisfactory unified rationalization of our results and those obtained for related autoxidations by numerous other workers.

L'autoxydation du diméthyl-2,3 indole conduit à la formation d'un dimère oxydé **6***a* et celle du méthyl-2 éthyl-3 indole conduit, sous les mêmes conditions, au produit correspondant **6***c*. Au contraire, l'éthyl-2 méthyl-3 indole ressemble par son comportement au diéthyl-2,3 indole et conduit à l'acétyl-2 méthyl-3 indole via l'hydroperoxy-3 indolénine qui est un intermédiaire isolable. Certaines réactions secondaires qui se font sous les conditions de l'autoxydation ont également été étudiées. Ces résultats, ainsi que ceux d'autres auteurs concernant des réactions d'autoxydation analogues ont été rationalisés d'une façon satisfaisante.

Canadian Journal of Chemistry, 49, 3642 (1971)

The autoxidation of indoles and related oxidations by peroxy compounds have led to results of chemical interest and biochemical significance. The oxidation of 2,3-disubstituted indoles (**1**) has led to a variety of products, the nature of which has been shown to depend on the reaction conditions and the nature of the substituents (1–7). Isolable products from the autoxidation of compounds of general formula **1** have included 3-hydroperoxyindolenines (**2**), 3-hydroxyindolenines (**3**), compounds (**4**) in which the substituent at C-2 has been oxidized (corresponding products have been obtained from indoles carrying a heteroatom at C-2), and compounds (**5**) in which the heterocyclic ring has been opened oxidatively, as well as rearrangement, condensation, or cleavage products derived from these. It is widely accepted that a common reaction pathway starts with the conversion of the indole (**1**) to the 3-hydroperoxyindolenine (**2**), frequently isolable, which then leads on to the other products listed; there is, however, a considerable range of opinion about the details of the latter steps.

In 1954 Beer *et al.* (1*a*) showed that the simplest dialkylindole of this class, 2,3-dimethylindole (**1***a*), on autoxidation formed the hydroperoxide (**2***a*) and a second non-peroxidic product of higher molecular weight. Leete (2*a*) reported that the corresponding hydroperoxy derivative (**2***b*) could be obtained from 2,3-diethylindole (**1***b*) under specified autoxidation conditions, while 2-acetyl-3-ethylindole (**4***b*) was isolated under other conditions. Since **2***b* could be converted to **4***b* thermally it was implicated as an intermediate, and an intramolecular mechanism for this conversion, requiring a cyclic or quasi-cyclic intermediate, was proposed. He noted that, in contrast, the dimethyl analog **2***a* failed to undergo the corresponding reaction. This interpretation was criticized by Taylor (2*b*) who pointed out that the transformation represented a special case of a family of reactions in which a substituent at C-3 in an enamine tautomer (such as **2′**) was displaced by an external nucleophile. (In this proposal, although the enamine tautomer was a key intermediate, it was invoked only to effect allylic activation at C-3.) He showed, furthermore, that a small amount of the aldehyde **4***a* could, in fact, be isolated in the dimethyl case; it followed that the same pathway was, therefore, open in the dimethyl series as in the diethyl series, but the enamine tautomer was less readily formed in the former case since it lacked the stabilization of an alkyl substituent. An alternative mechanism proposed by Wasserman and Floyd (3) also required the enamine intermediate, but utilized its nucleophilic character to attack the hydroperoxy substituent intramolecularly.

Our interest in this area was aroused when we observed that a sample of 2,3-dimethylindole

(**1***a*) which had been stored in air for some time had become contaminated with a considerable amount of an impurity which, on isolation and purification, appeared to be the non-peroxidic autoxidation product originally described by Beer *et al.* (1*a*). From its analysis, mass spectrum, and other spectroscopic characteristics, which have now been described in detail elsewhere (1), we concluded that the product corresponded in composition to two molecules of **1***a* plus two oxygen atoms, that it was a bisindoline in which one methyl group of the original four had become a methylene bridge, the remaining three being tertiary in the product, and that two NH groups and one OH group were present, the second oxygen being, therefore, disubstituted and probably part of a bridge. These data strongly suggested that the product had structure **6***a* (without the stereochemical implications represented), but other structural possibilities could be envisaged and the stereochemistry was by no means established. Although the recent work of Dave and Warnhoff (1*d*) shows that our pessimism was unwarranted, we originally considered that it would be difficult, if not impossible, to establish unequivocally the structure and stereochemistry of this molecule on chemical and spectroscopic grounds since we expected it to be particularly susceptible to rearrangement. We turned, therefore, to X-ray analysis and, with the collaboration of our colleagues in crystallography, established the total structure **6***a* by direct methods which dispensed with the necessity of preparing a heavy atom derivative or perturbing the molecule in any way (1*c*).

One observation, which, as we noted in our preliminary communication (1*c*), caused us some concern, was that the n.m.r. signal for the bridge methylene protons was a singlet in a variety of solvents and at a range of temperatures when determined at 60 or 100 MHz; even the addition of tris(dipivalomethanato)europium did not cause the signal to split.[1] We can now report, however, that at 220 MHz the protons do appear as an AB pattern with a coupling constant of 13 Hz, but even here the internal chemical shift is only 6.5 Hz, and as a consequence the multiplet is near the practical limits of resolution.

It is abundantly clear that **6***a* results from a reaction sequence quite different from any followed by 2,3-diethylindole, and there is good evidence to suggest that the difference can be attributed to the presence of a 2-methyl substituent in the precursor **1***a*. In order to probe the generality of the proposal that the autoxidation of 2,3-dialkylindoles follows a distinctive pathway when the substituent at C-2 is a methyl rather than an ethyl or other alkyl group, we have studied the behavior of the isomers 2-methyl-3-ethylindole (**1***c*) and 2-ethyl-3-methylindole (**1***d*).

When a solution of **1***c* in benzene was stirred in air, **1***c* slowly underwent autoxidation to afford a single isolable product which we have identified as **6***c*, the analog of the dimeric product, **6***a*, obtained on autoxidation of 2,3-dimethylindole. The i.r. and u.v. spectra of **6***c*, $C_{22}H_{26}N_2O_2$, m.p. 157–160°, were very similar to those of **6***a*, and the n.m.r. spectra differed in the manner expected: seven aromatic protons of **6***c* appear as a complex pattern between τ 2.6 and 3.3 and one is more highly shielded, appearing as a doublet, $J \simeq 8$ Hz (with further fine splitting), at τ 3.63, the unsplit methyl signal is at τ 8.60, the methylene protons show an extremely close correspondence to those of **6***a*, appearing in the 100 MHz spectrum as a singlet at τ 7.62, and the protons of the ethyl groups appear as two three-proton triplets, each with $J \simeq 8$ Hz, at τ 8.90 and 9.09 and a complex pattern, corresponding to four protons in the region τ 7.8 to 8.5, recognizable as two overlapping methylene quartets which have been further split because of the diastereotopic relationship between each pair of protons.

In contrast, the 2-ethyl-3-methyl isomer **1***d* as a solution in benzene appeared to undergo autoxidation more rapidly than **1***c* under the same conditions and afforded in good yield a product identified as the hydroperoxy derivative **2***d*. The compound, $C_{11}H_{13}NO_2$, m.p. 109–111°, showed the spectroscopic characteristics appropriate for its structure and the expected close correspondence to the values reported for **2***b* (2*a*). In ethyl acetate containing acetic acid **2***d* was transformed into 2-acetyl-3-methylindole (**4***d*), a reaction completely analogous to that of 2,3-diethylindole (**2***a*). When the hydroperoxy compound **2***d* was first reduced to the hydroxyindolenine **3***d* and this compound was subjected to further autoxidation, we isolated 3-methyl-3-

hydroxyoxindole (**7***d*), a product obtained previously by Wasserman and Floyd (3) from the autoxidation of 2-isopropyl-3-methylindole. Our present result shows that **7***d* is formed from **3***d* rather than directly from the hydroperoxy compound **2***d*, and arises from a further, and essentially independent autoxidation reaction.

It is clear that the autoxidation of 2,3-dialkylindoles leads to a diverse array of products, the outcome of any specific oxidation being strongly dependent on variables related to structure and reaction conditions. Nevertheless, we believe that it is now possible to account for all of the observed products in a unified manner and in mechanistic terms which consistently assign nucleophilic character to enamines and electrophilic character to the carbon atom of imines (see Chart 1). There appears to be little doubt that the 3-hydroperoxy compound **2** is the initial product in all of these autoxidations and is the key intermediate leading to all observed products; it clearly arises by electrophilic attack of oxygen on the "enamine" **1**. A reaction that may ensue is the reduction of the hydroperoxy group to the hydroxy group of **3**, perhaps coupled with oxidation of a molecule of **1** to afford a further molecule of **3**. Products of formula **4** can be satisfactorily accounted for in the manner proposed by Wasserman and Floyd (3); this requires the formation of the enamine tautomer (**2′**) of **2**, followed by intramolecular electrophilic attack of the terminal oxygen of the hydroperoxy group on the enamine, leading to transfer of a hydroxyl group, and then tautomerism and dehydration as shown. Products of formula **5**, which are commonly found as reaction products, particularly when an acid catalyst is present, are best explained by the intramolecular nucleophilic attack of the terminal oxygen of the hydroperoxy group of **2** on the imine function (perhaps protonated), leading to the peroxide shown which can then open, with the assistance of the electrons on nitrogen, to afford **5**. (It is worth noting that the O—O bond of a peroxide, besides being able to break homolytically, may cleave heterolytically in either direction and the terminal oxygen of a hydroperoxy group may be either electrophilic or nucleophilic.) On the basis of the evidence we presented earlier, the formation of products of formula **7** is explained as resulting from the further autoxidation of **3**, the reduction product of **2**, by electrophilic attack of oxygen on its enamine tautomer **3′** leading to the hydroperoxy intermediate which then undergoes cyclization and cleavage in the manner shown, a sequence which is the complete analog of that leading to **5**. This route is different in detail from the one proposed by Wasserman and Floyd (3), but is consistent with the pattern of behavior we have described for other reactions in this series and provides a ready explanation for the isolation of compounds of type **8** reported by these authors if it is supposed **7** and **8** arise from a common peroxide intermediate which is cleaved in the first case with the assistance of electrons on nitrogen, and in the second case, leading to **8**, with the assistance of electrons on the 3-hydroxy function. It may be noted further that intermolecular electrophilic attack at the exocyclic double bond of an enamine such as **2′** or **3′** is, of course, a route that is always open (6), but in compounds of formula **1** the indole is effectively the exclusive "enamine" tautomer available and reaction occurs at C-3, and when the hydroperoxy function is present as in **2′**, intramolecular attack, transferring a *hydroxyl* group to the enamine is the preferred reaction mode (and leads on to **4**). It is when neither of the latter situations prevails, as is the case in **3**, that intermolecular electrophilic attack on the C-2 substituent becomes a significant reaction, leading to the introduction of a *hydroperoxy* function in the present case, and to the sequence of reactions which afford **7** and **8**. The obvious and generally accepted route to dimeric products of form **6** requires the coupling of tautomers **3** and **3′**, utilizing the nucleophilic character of the latter, followed by intramolecular nucleophilic attack by a hydroxyl group on the imine function (possibly protonated) formed in the intermediate. As written, this sequence implies the initial reduction of **2** to **3**, but the chronology is not obligatory since the corresponding coupling between the tautomers **2** and **2′** could occur first and be followed by the reduction and cyclization steps. Dave and Warnhoff (1*d*) have reported results which suggest that the route requiring initial reduction of **2** is favored, but do not establish this point conclusively. In any event, there is no evidence for the formation of dimeric products of type **6** except when the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

2-substituent is methyl. Previous explanations for the difference between the autoxidation behavior of 2,3-dialkylindoles (**1**) where the 2-substituent is methyl and that of analogs where the 2-substituent is some other alkyl moiety, although they have differed in mechanistic details, have all depended on assumptions regarding the relative readiness with which intermediates such as **2** and **3** form their enamine tautomers. The above discussion suggests that these explanations must be at best incomplete since at least some enamine tautomer must be present to generate **6**. The more attractive explanation that presents itself in the light of all of the above evidence is that the bimolecular coupling process is inhibited when the substituent (R) on the imine is larger than methyl and the substituent (R″) on the enamine is consequently larger than hydrogen. As a result, alternative pathways, particularly those resulting from intramolecular processes, prevail when the 2-substituent in **1** is larger than methyl, and only 2-methyl derivatives lead to dimeric products of type **6**.

We believe that the course of all of the reactions within the category we have been concerned with can now be accounted for with the minimum of mechanistic assumptions. It is clear that other reaction pathways may also be available in specific cases, and that the products we have described may themselves be subject to further autoxidation, one illustration being provided in the very recent work of Dave and Warnhoff (1*d*).

Experimental

Melting points were determined on a Thomas–Kofler micro hot stage. Spectrometers used routinely were: a Perkin–Elmer Model 237B for i.r. spectra (carbon tetrachloride solvent unless otherwise indicated) and the wavelengths (in μ) of significant peaks are reported; a Unicam SP. 800 for u.v. spectra (methanol solvent) and wavelengths (in mμ) of absorption bands are reported, followed by the extinction coefficient (ε) in parentheses; a Varian HA-100, A-60, or T-60 for n.m.r. spectra (chloroform-*d* solvent unless otherwise indicated) and chemical shifts are reported on the τ scale, followed in parentheses by an account of the multiplicity and number of protons concerned; a CEC 21-490 for mass spectra and the *m/e* values of significant peaks are reported, followed in parentheses by their relative intensities. An AEI MS-902 mass spectrometer was used to make accurate mass measurements. The 220 MHz spectrum was recorded on the Varian HR-220 at the Canadian 220 MHz N.M.R. Center.

Autoxidation of 2-Methyl-3-ethylindole (1c)

The preparation of 2-methyl-3-ethylindole was based on the method of Pikl and Julian (8*a*): the phenylhydrazone of 2-pentanone was heated with a catalytic amount (*ca.* 1%) of cuprous chloride at 180–200° for 4 h, and 2-methyl-3-ethylindole was obtained as an oil (in 22% yield from 2-pentanone) by vacuum distillation of the reaction mixture. It showed: i.r. ($CHCl_3$) 2.89; n.m.r. 2.20–3.05 (complex; 5), 7.28 (q, J = 7 Hz; 2), 7.73 (s; 3), 8.80 (t, J = 7 Hz; 3). Picrate m.p. 154–157° (lit. (8*b*) m.p. 148–150°).

A 4% solution of 2-methyl-3-ethylindole in benzene was stirred in an open beaker and fresh solvent was added periodically to keep the volume approximately constant. After 1 week the product was precipitated as a white powder by the addition of petroleum ether; the yield corresponded to about 13% conversion and the mother liquor contained principally unchanged **2***c*. The product, **6***c*, was recrystallized three times from a benzene–hexane solution and obtained as colorless prisms, m.p. 157–160° (prior sublimation).

Anal. Calcd. for $C_{22}H_{20}N_2O_2$: C, 75.40; H, 7.48; N, 7.99. Found: C, 75.11; H, 7.60; N, 8.08.

Mass spectrum: 350 (8), 332 (1), 191 (4), 160 (32), 159 (100), 144 (38); i.r. 2.80, 2.94, 6.20; u.v. 244 (14 500), 297 (4300); n.m.r. 2.6–3.3 (complex; 7), 3.63 (d, $J \simeq 8$ Hz, with further fine splitting; 1), 6.72 (s; 1), 7.62 (s; 2), 7.8–8.5 (complex; apparently two overlapping quartets, $J \simeq 8$ Hz, with further splitting; 4), 8.60 (s; 3), 8.90 (t, J = 8 Hz; 3), 9.09 (t, J = 8 Hz; 3).

Autoxidation of 2-Ethyl-3-methylindole (1d)

2-Ethyl-3-methylindole was prepared by a method similar to that described for **1***c*: the phenylhydrazone of 3-pentanone was heated under nitrogen with a catalytic amount of cuprous chloride to 100–140° for 3 days and the reaction mixture was vacuum distilled. After recrystallization from 60–70° petroleum ether, the product (**1***d*) was obtained in 50% yield as crystals m.p. 64–68° (lit. (9) m.p. 66°); i.r. 2.87; n.m.r. 2.20–3.10 (complex; 5), 7.26 (q, J = 7 Hz; 2), 7.78 (s; 3), 8.78 (t, J = 7 Hz; 3).

A 1% solution of 2-ethyl-3-methylindole in benzene was stirred in the manner described above. After 1 day the solid (corresponding to 70% conversion) which had precipitated was collected on a filter, washed, and dried. This material, m.p. 109–111° after recrystallization from acetone, was identified as 2-ethyl-3-hydroperoxy-3-methylindolenine (**2***d*); mass spectrum: 191 (38), 173 (100); u.v. 219 (17 000), 225 (inflection; 12 500), 259 (3300).

Anal. Calcd. for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.33. Found: C, 69.16; H, 6.84; N, 7.25.

A 1% solution of **2***d* in 20 ml ethyl acetate containing 2 ml acetic acid was kept in the absence of air for 2 days. Solvent was removed under reduced pressure and the brown residue was dissolved in methylene chloride and washed free of acetic acid. The solid obtained from the methylene chloride was chromatographed on a column of neutral alumina and eluted with benzene. This afforded a crystalline product (yield corresponding to 45% conversion), which was recrystallized from benzene and obtained as colorless needles, m.p. 150–152°, identified

as 2-acetyl-3-methylindole (lit. (10) m.p. 146.5°); i.r. 2.89, 6.05; u.v. 237 (15 000), 310 (19 500); n.m.r. 0.77 (broad; 1), 2.1–3.0 (complex; 4), 7.40 (s; 6; in presence of benzene this signal moved upfield and split into two singlets of equal intensity).

*Autoxidation of 2-Ethyl-3-hydroxy-3-methylindole (**3d**)*

2-Ethyl-3-hydroxy-3-methylindole was prepared by shaking an ethereal solution of the hydroperoxy compound **2***d* (1.00 g) with a solution of sodium hydrosulfite (2.6 g) in 30 ml of 10% aqueous sodium hydroxide for 50 min. Evaporation of the ether layer afforded a yellow solid (0.71 g) which, after two recrystallizations from acetone–hexane, formed colorless needles, m.p. 79–83°; i.r. 2.77, 3.15 (weak); u.v. 219 (19 000), 224 (inflection), 256 (3600); n.m.r. 2.3–3.0 (m; 4), 6.35 (broad; 1), 7.53 (q, J = 7 Hz; 2), 8.53 (s; 3), 8.83 (t, J = 7 Hz; 3); the high resolution mass spectrum showed the molecular ion of mass 175.0996 (Calcd. for $C_{11}H_{13}NO$: 175.0997), but combustion analysis gave poor and unreproducible results, the best of which was:

Anal. Calcd. for $C_{11}H_{13}NO$: C, 75.40; H, 7.48; N, 7.99. Found: C, 75.76; H, 7.04; N, 8.04.

A solution of 2-ethyl-3-hydroxy-3-methylindolenine (0.25 g) in 200 ml of benzene was stirred in an open beaker for 36 h. After a small amount of amorphous precipitate had been removed by filtration, evaporation of the benzene left a brown tar from which 3-hydroxy-3-methyloxindole (**7***d*) (40 mg; 18%), m.p. 159–165° (lit. m.p. 161.5–162.5° (3); 163–165° (11)), was recovered by crystallization from benzene and recrystallization from benzene–acetone; i.r. ($CHCl_3$) 2.80, 2.91, 5.78; u.v. 252 (6000), 286 (1350); n.m.r. (acetone-d_6) 2.5–3.3 (complex; 4), 8.53 (s; 3).

We thank the National Research Council of Canada for an operating grant in support of this research and for a scholarship (to G.I.D.).

Kinetic Study of the Acetate-catalyzed Aldol Reaction Between Chloral and Alkyl Methyl Ketones

B. C. MENON AND EBERHARD KIEHLMANN
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received July 6, 1971

A kinetic study of the acetate-catalyzed crossed aldol reaction of chloral with butanone, 2-heptanone, and 4-methyl-2-pentanone, respectively, in glacial acetic acid at 60° has been carried out. A comparison of the condensation rates with those for the acetate-catalyzed deuterium exchange of the ketones in glacial acetic acid at 60° indicates that the carbon—carbon bond formation in the aldol reaction is the rate-determining step. The relative rate constants for the crossed aldol reaction and the deuterium exchange of the corresponding ketones are best interpreted in terms of steric rather than polar effects.

On a entrepris une étude cinétique de la réaction aldolique catalysée par acétate, du chloral avec la butanone, l'heptanone-2, et la méthyl-4 pentanone-2, respectivement dans l'acide acétique glacial à 60°. Une comparaison des vitesses de condensation avec celles obtenues pour l'échange de deutérium catalysé par acétate des cétones dans l'acide acétique glacial à 60° indique que la formation du lien carbone—carbone dans la réaction aldolique est l'étape déterminante. Les constantes de vitesse relative pour la réaction aldolique et l'échange de deutérium des cétones correspondantes sont mieux interprétées en termes d'effets stériques que polaires.

Canadian Journal of Chemistry, 49, 3648 (1971)

The mechanistic aspects of aldol reactions have been the subject of intensive studies by various investigators. The fundamental studies by Bonhoeffer and Walters (1) and Bell and Smith (2, 3) firmly established the two-step enolization–addition mechanism through kinetic and deuterium exchange experiments with acetaldehyde.

Although the aldol reaction is catalyzed by acids and bases, the latter are more frequently employed. The base-catalyzed mechanism (4–6) may be described by eqs. 1 to 5. For the formation of aldols in concentrated solutions of acetaldehyde (7), propanal (8), and butanal (9), the proton abstraction step 1 is rate-limiting ($k_1 < k_2$). On the other hand, the formation of the new carbon—carbon bond [2] is the rate-limiting step ($k_1 > k_2$) in many aldol reactions involving ketones, for example the ethoxide-catalyzed condensation of aromatic aldehydes with acetophenones (10), the formation of diacetone alcohol from acetone (3), the condensation of benzaldehyde and acetone (11), and the condensation of formaldehyde with acetone (12).

As a continuation of our interest in the crossed aldol reaction between chloral and alkyl methyl ketones in glacial acetic acid – acetate medium (13), we have now carried out a kinetic study of the aldol reaction of chloral with butanone, 2-heptanone, and 4-methyl-2-pentanone, respectively, in glacial acetic acid – acetate medium, as well as the deuteration of these ketones under conditions similar to the aldol reaction. A comparison of these two sets of rate constants should settle, among other things, the question of the rate-limiting step in the crossed aldol reaction.

Experimental

Reagents

The commercially available ketones were purified by fractional distillation. Pure anhydrous chloral (b.p. 98°) was obtained by distillation of commercially available material (Chloral, Practical, MCB) from phosphorus pentoxide (14). Acetic acid-d_4 (minimum isotopic purity 99.5%) was obtained from Mallinckrodt Chemical Works and used without further purification. Anhydrous sodium carbonate was heated to 125° for 20 h and subsequently cooled in a desiccator.

Rate Measurements

Deuterium Exchange

A weighed amount of anhydrous sodium carbonate was placed in a 5.0-ml volumetric flask and dissolved by introducing a small volume of acetic acid-d_4. A weighed amount of the ketone was then added followed by additional acetic acid-d_4 until the volume of the solution reached the calibration point. After thorough shaking, 0.5-ml samples were transferred by syringe to each of a number of 2.0-ml glass ampoules. The ampoules were sealed and placed in a constant-temperature bath at 60 ± 0.1°. Individual ampoules were withdrawn at various time intervals, the reaction was stopped by cooling in ice–water, and the contents of the ampoules were transferred into dry n.m.r. tubes.

[1] 
R and R′ = alkyl or aryl

[2] 
R″ and R‴ = alkyl, aryl or hydrogen

[3] 
[4] 
[5] 
Exchange was followed to approximately one to two half-lives by integrating the proton signals of the reacting sites in question, using the peak areas of the β- or γ-proton signals as internal standard.[1] Each signal was integrated three times and an average was taken. The variation in individual integrations is ±15%, a common observation in this type of rate measurements (15–18).

Aldol Reaction

A weighed amount of anhydrous sodium carbonate was dissolved in a small volume of glacial acetic acid in a 5.0-ml volumetric flask, and known amounts of ketone and chloral were added, followed by more acetic acid until the volume of the solution reached the calibration point. After thorough shaking, 0.5 ml of the solution was transferred by syringe into each of several glass ampoules. The ampoules were sealed and placed in a constant temperature bath at 60 ± 0.1°. Individual ampoules were withdrawn at appropriate time intervals, and the concentration of the ketols formed by condensation at C-1 and -3, respectively, was determined by several integrations of the respective g.l.c. peak areas (SE-52 at 120°) and reference to a calibration curve prepared from pure product samples at known concentrations. As discussed in a previous paper (13), the crossed aldol reaction of chloral with alkyl methyl ketones under these reaction conditions is irreversible and not accompanied by dehydration. Hence the rate of the reaction can be monitored by measuring the concentration of ketol as a function of time.

[1]In the case of 4-methyl-2-pentanone a correction has been made for the partial overlap of the highly split methine signal with both the methylene peak and the α-methyl peak. See ref. 15 for details.

Results and Discussion

Rates of Deuterium Exchange

Pseudo-first-order rate constants were obtained by fitting experimental values to eq. 6 by

[6] $$N_H^t = N_H^0 \, e^{-kt}$$

means of a linear, least-squares program for the IBM 360/50 computer. In eq. 6 N_H^t and N_H^0 represent, respectively, the number of α-hydrogens at a given reacting site at time t and at time zero, relative to the internal standard, the non-exchanging β- or γ-hydrogens. In all cases studied, good fits were obtained for exchanges followed to one or two half-lives (Fig. 1), thereafter the scatter became serious. Table 1 lists the pseudo-first-order rate constants obtained for the acetate-catalyzed deuterium exchange of butanone, 2-heptanone, and 4-methyl-2-penta-

none. The rate constants are reproducible with an error of ±7%.

The observed first-order rate constants for all the ketones varied with the acetate concentration according to eq. 7. For all ketones k_0 was substantial, pointing to considerable acid-catalyzed exchange.

$$[7] \qquad k_{obsd} = k_0 + k_{AcO^{\ominus}}(AcO^{\ominus})$$

It is interesting to compare our results on deuterium exchange with those obtained in different solvent/catalyst systems by previous workers. The value of $k^{CH_2}/k^{CH_3} > 1$ for butanone is in line with that obtained by Warkentin and Cox (16) for the acetate-catalyzed deuterium exchange of butanone in aqueous solution. The high reactivity of the methylene protons of butanone has been explained by Warkentin and Barnett (15) as being due to a polar effect which overcomes the steric effect resulting in rate acceleration. For 2-heptanone our $k^{CH_2}/k^{CH_3} \approx 1.00$ is quite different from the value ($k^{CH_2}/k^{CH_3} < 0.3$) reported by Rappe and Sachs (17) for the sodium carbonate-catalyzed deuterium exchange in aqueous solution. A possible explanation for this discrepancy may be that given by Warkentin and Cox (16), who have suggested that the enolization is dependent on the nature of the catalyzing base, in close similarity to bimolecular eliminations in which product ratios have been found to depend on the base employed. The highly diminished reactivity of methylene relative to methyl protons in 4-methyl-2-pentanone is obviously due to a preponderance of steric effects controlling the course of the reaction (18).

As has been stated before, the observed rate constants contain a term due to considerable

TABLE 2. Rate data for the crossed aldol reaction between CH_3COCH_2R and chloral in acetic acid – acetate at 60°

R	Concentration of CH_3COONa (M)	$k_{obsd}^{CH_2}$($\times 10^4\ M^{-1}\ h^{-1}$)	$k_{obsd}^{CH_3}$($\times 10^4\ M^{-1}\ h^{-1}$)
CH_3*	0.5132	1.96	1.33
$CH_3(CH_2)_3$†	0.5132	0.42	1.97
$(CH_3)_2CH$‡	0.5132	~0	3.41

*[Ketone] = 1.4500 M; [chloral] = 1.2720 M.
†[Ketone] = 0.8722 M; [chloral] = 0.6750 M.
‡[Ketone] = 1.129 M; [chloral] = 0.8202 M.

acid-catalyzed exchange. As reported by Rappe and Sachs (18), the reactivity sequence found for the acid-catalyzed exchange of the methyl protons of methyl alkyl ketones containing various alkyl groups is opposite to that for the base-catalyzed deuteration rates of the corresponding ketones. Consequently, the lack of a pronounced reactivity trend for deuterium exchange in our acetic acid – acetate medium may be due to a partial cancellation of the polar and/or steric effects which are responsible for the reactivity trends observed by Rappe in acidic and basic medium, respectively.

Rates of Aldol Reaction

The experimental data for the acetate-catalyzed crossed aldol reaction between chloral and alkyl methyl ketones were found to fit the second-order rate expression [8] where a, b, and

$$[8] \qquad t = \frac{2.303}{k(a-b)} \log \frac{b(a-x)}{a(b-x)}$$

x are the concentrations in mol/l of ketone, chloral, and ketol, respectively (Fig. 2). The second-order rate constants for the reaction of chloral with butanone, 2-heptanone, and 4-methyl-2-pentanone, respectively, in glacial acetic acid – acetate medium, obtained by fitting the experimental data to eq. 8 by means of a linear least-squares program, are listed in Table 2.

The acetate-catalyzed crossed aldol reactions between chloral and alkyl methyl ketones in glacial acetic acid were found to be very slow and accompanied by discoloration of the reaction mixture on prolonged heating. As a result of these limitations the kinetics were followed to only about 15 to 20% completion of the reaction. Although the absolute uncertainty in rate constants is not known, the rate ratios observed are reliable and give valuable information regarding the orientation of the aldol reaction.

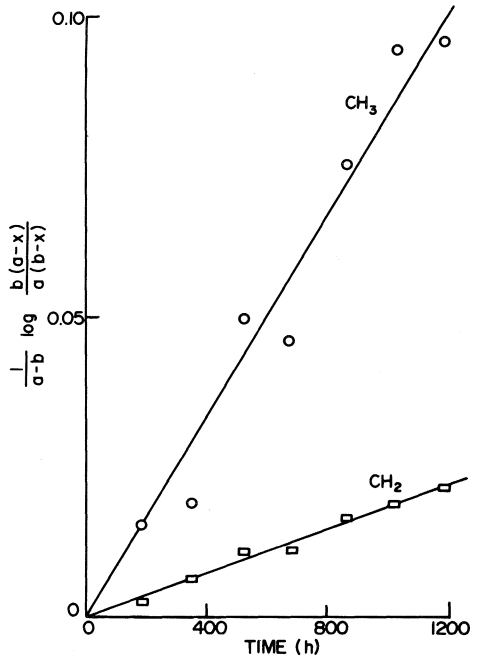

FIG. 2. Kinetics of the crossed aldol reaction of chloral with 2-heptanone in CH_3COOH–CH_3COONa at 60°; [CH_3COONa] = 0.5132 M.

A comparison of the rates of deuteration of the investigated ketones with those of their aldol reactions with chloral under the same conditions of catalyst concentration shows the rates of deuteration, and hence the enolization step, to be much faster than the rates of aldol reaction (Tables 1 and 2). This is a strong indication that the rate-limiting step in these crossed aldol reactions under the conditions employed is the step involving the carbon—carbon bond formation rather than the enolization step.

It is apparent that the major factor that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

determines the relative reactivities of the two sites in the same molecule is steric hindrance which in turn could be a conglomerate of internal, nonbonded interactions and solvation (Table 2). With the exception of butanone the aldol reaction rate is greater on the methyl side than on the methylene side. In 4-methyl-2-pentanone the steric hindrance due to the isopropyl group on the methylene side is so pronounced that no observable reaction takes place at this site. The greater reactivity of the methylene group in butanone parallels its behavior during the deuteration and may be explained on similar grounds (see above).

The relative reactivities of the methyl groups show a marked increase as one goes from butanone and 2-heptanone to 4-methyl-2-pentanone. The high reactivity observed in the latter case may be due to the intermediate possessing some carbanion character (as opposed to enol character) as a result of steric hindrance to enolization and/or to solvation[2] by the sec-butyl group. The slower rates of deuteration in the case of 4-methyl-2-pentanone relative to 2-heptanone could be taken as support for this explanation (Table 1).

The results of the present investigation support conclusions arrived at from product studies of the crossed aldol reactions (13). Under identical experimental conditions of the aldol reaction, it has been reported that methyl condensation becomes more facile in the order 4-methyl-2-pentanone (61% ketol yield) > 2-heptanone (40.8%) > butanone (31.7%), and that the reactivity of the methylene group in alkyl methyl ketones drops off rapidly with increasing bulk of the alkyl groups, for example from butanone (40.3% ketol yield) via 2-heptanone (12.2%) to 4-methyl-2-pentanone (0%).

[2]The authors are indebted to one of the referees for suggesting solvation as an alternate explanation.

The financial support of these investigations by the National Research Council of Canada, Ottawa, Canada, is gratefully acknowledged.

Isolation of 2(*S*)-Dichloroacetamido-3-(*p*-acetamidophenyl)propan-1-ol from a Chloramphenicol-producing *Streptomyces* Species[1]

CHI-KIT WAT,[2] V. S. MALIK,[3] AND L. C. VINING

Atlantic Regional Laboratory, National Research Council of Canada and Department of Biology, Dalhousie University, Halifax, Nova Scotia

Received July 22, 1971

Cultures of a chloramphenicol-producing *Streptomyces* to which 2(*S*)-amino-3(*R*)(*p*-nitrophenyl)-propan-1,3-diol (*p*-nitrophenylserinol) was added produced a new metabolite which has been identified as 2(*S*)-dichloroacetamido-3-(*p*-acetamidophenyl)propan-1-ol (**1**). The structure was confirmed by chemical synthesis. No radioactivity was incorporated into **1** when ^{14}C-labeled *p*-nitrophenylserinol was used, suggesting that **1** is formed not by metabolism of the supplement but by diversion of intermediates normally used for chloramphenicol biosynthesis.

Des cultures de *Streptomyces* produisant du chloramphénicol, auxquelles ont avait ajouté du 2(*S*)-amino-3(*R*) (*p*-nitrophényl) propan-1,3-diol (*p*-nitrophénylsérinol) ont produit un métabolite nouveau, identifié comme étant le 2(*S*)-dichloroacétamido-3-(*p*-acétamidophényl) propan-1-ol (**1**). On a confirmé la structure par synthèse chimique. On n'a pas remarqué l'incorporation de radioactivité dans **1** lors de l'utilisation de *p*-nitrophénylsérinol marqué au ^{14}C, ce qui suggère que **1** est formé, non pas par métabolisme du supplément mais par diversion des intermédiaires utilisés normalement dans la biosynthèse du chloramphénicol.

Canadian Journal of Chemistry, **49**, 3653 (1971)

Under some culture conditions *Streptomyces* 3022a, a chloramphenicol-producing actinomycete, metabolizes its own antibiotic. The first product formed is *p*-nitrophenylserinol which may then be *N*-acetylated or degraded further to *p*-nitrobenzyl alcohol or *p*-nitrobenzoic acid (1). In experiments where *p*-nitrophenylserinol was added to cultures of the actinomycete we observed the formation of an additional metabolite. This has been isolated and shown to have structure **1** (Scheme 1).

The t.l.c. of the neutral extract from cultures supplemented with *p*-nitrophenylserinol showed a zone which absorbed u.v. light but differed in R_f value from similar zones given by known metabolites of *Streptomyces* species 3022a. The substance was not formed when *p*-nitrophenylserinol was omitted from the culture. It was isolated by preparative t.l.c. and purified. The mass spectrum showed a molecular ion at *m/e* 318.0524. Prominent M + 2 (65% of M^+) and M + 4 (12%) ions indicated that the molecule contained two atoms of chlorine and should have the composition $C_{13}H_{16}N_2O_3Cl_2$. The presence of a *p*-acylaminophenylalkyl moiety was deduced from the following evidence.

The u.v. spectrum with λ_{max} 245 nm closely resembled that of acetanilide (λ_{max} 240 nm) except for the bathochromic displacement which could be attributed to alkyl substitution of the benzene ring. The base peak at *m/e* 106.0662 in the mass spectrum of the compound corresponded to an ion of composition C_7H_8N to which structure *c* (Scheme 2) was assigned. The i.r. absorption maxima occurred at 1610 (ring C=C stretching), 3090–3310 (OH or NH stretching), 1685 and 1670 (amide C=O), and at 1542 and 1515 cm^{-1} (amide N–H deformation).

The number and position of peaks in the 1500–1800 cm^{-1} region of the spectrum suggested that the molecule contained two amide but no ester or carboxyl groups. The p.m.r. spectrum of the compound in acetone-d_6 indicated the presence of a 1,4-disubstituted benzene ring (4H; AA′BB′ system; centered at τ 2.63, which is appreciably upfield from the value, τ *ca.* 2.1, found for *p*-nitrophenylalkyl derivatives). It also showed a single hydrogen (multiplet; τ 5.98) attached to a carbon atom vicinal to a hydroxymethyl (2H; doublet; spacing 4.8 Hz; τ 6.41) and a benzylic methylene (2H; doublet; spacing 6.5 Hz; τ 7.13) group, and characteristic signals for an acetamidomethyl (3H; singlet; τ 7.95) and a dichloroacetyl (1H; singlet; τ 3.70) group. A moderately abundant fragment ion in the mass spectrum at *m/e* 287, corresponding to the loss

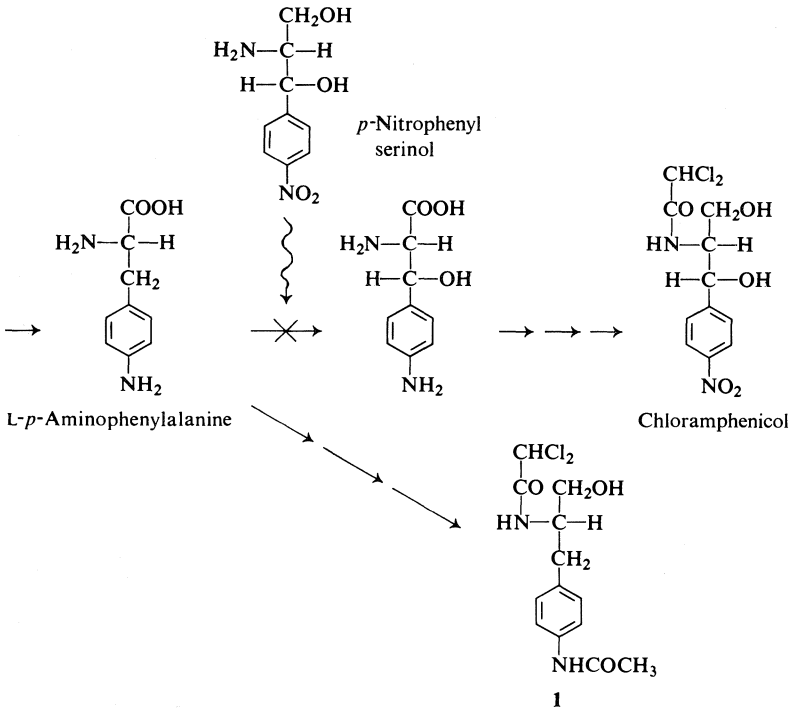

SCHEME 1. Suggested biogenetic relationship between chloramphenicol and 2(*S*)-dichloroacetamido-3-(*p*-acetamidophenyl)propan-1-ol in cultures of *Streptomyces* species 3022a supplemented with *p*-nitrophenylserinol.

of CH_3O from the molecular ion was consistent with a hydroxymethyl group being at C-1. Ions derived by expulsion of 31 mass units were prominent in the mass spectra of chloramphenicol and other phenylserinol derivatives. Absence of hydroxyl substitution at C-3 can also be deduced from the mass fragmentation pattern. Phenylalkyl compounds with this feature show a strong M-18 ion and the molecular ion is weak or absent.

This evidence establishes the basic structure as 2-amino-3-(*p*-aminophenyl)propan-1-ol. One amino group is blocked by an acetyl and the other by a dichloroacetyl substituent. The only remaining uncertainty is the location of the two acyl substituents, and the configuration at the asymmetric carbon. The acetyl group is placed at the *p*-position and the dichloroacetyl at position-2 to account for the principal ions in the mass spectral fragmentation pattern (Scheme 2). To confirm the structural assignments and establish the configuration at C-2, structure **1** was synthesized.

L-*p*-Aminophenylalanine was acetylated with acetic anhydride in glacial acetic acid to give the acetanilide, then converted with dichloroacetyl chloride in aqueous alkali to the 2-*N*-dichloroacetyl derivatives. The p.m.r. spectrum of this intermediate showed characteristic signals of the ABX system expected for a dichloroacetamido substituted carbon bearing a single hydrogen and vicinal to a benzylic methylene. The carboxyl group was reduced with diborane and the product, recovered and purified by preparative t.l.c., was shown to be identical in all respects with the natural compound. The manner of synthesis establishes that the product possesses an asymmetric center at C-2 which requires that the five aliphatic hydrogens on C-1, -2, and -3 constitute an ABMXY system. The simplicity of the p.m.r. spectrum given by the natural product is thus deceptive.

When ^{14}C-*p*-nitrophenylserinol was added to cultures of the actinomycete neither **1** nor chloramphenicol was labeled. Each must have been made *de novo* by the organism rather than by metabolism of *p*-nitrophenylserinol. The absence of **1** in unsupplemented cultures suggests that *p*-nitrophenylserinol inhibits one of the steps leading to chloramphenicol, probably the hydroxylation of *p*-aminophenylalanine to *p*-aminophenylserine (Scheme 1). The accumulated

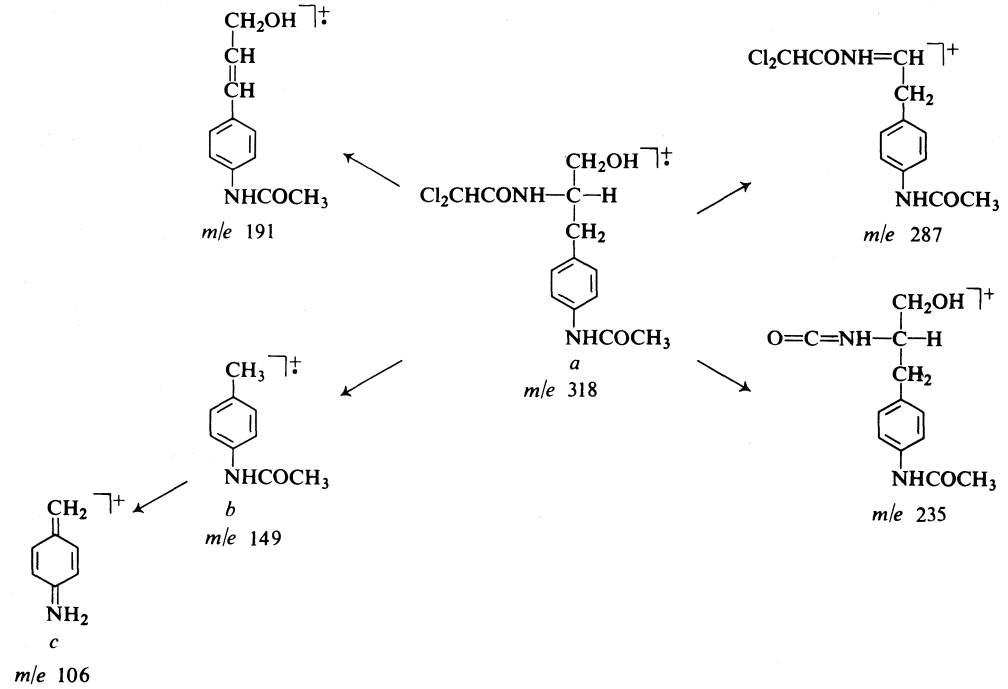
For personal use only.



SCHEME 2. Suggested fragmentation of 2(*S*)-dichloroacetamido-3-(*p*-acetamidophenyl)propan-1-ol in the mass spectrometer.

p-aminophenylalanine could then be modified by dichloroacetylation and reduction as in the chloramphenicol pathway (2), but would undergo acetylation instead of oxidation at the *p*-amino group.

Experimental

Melting points were measured on a Fisher–Johns hot plate and are uncorrected. The p.m.r. spectra were recorded with a Varian Associates A-60A spectrometer. Mass spectra were obtained with a Consolidated Electrodynamics Corporation model 21-110B double-focusing instrument used in the electrical detection mode with 8 kV accelerating voltage and 70 eV electron energy. The sample was vaporized directly into the ion source by raising the source block temperature to 200–220°. Accurate mass measurements were made by the peak-matching method using a perfluorokerosene reference.

Culture

A single spore isolate (strain 13*s*) of *Streptomyces* sp. 3022a was used. Its history and methods used to maintain and culture it have been described (1). Cultures were grown in GNY medium (25 ml), consisting of glycerol (2%), Difco dehydrated nutrient broth (0.8%), Difco dehydrated yeast extract (0.3%), and K_2HPO_4 (0.5%) in distilled water, dispensed in 125 ml Erlenmeyer flasks. *p*-Nitrophenylserinol (2.5 mg per flask) was added before autoclaving.

Isolation

Cultures were centrifuged and the supernatant solution at p*H* 8.5 extracted with ethyl acetate. The concentrated extract was applied to 20 × 50 cm preparative t.l.c. plates spread with a 2 mm thick layer of silica gel HF_{254} (E. Merck & Co., Darmstadt) and chromatographed in chloroform–methanol (7:1). The quenching zone (R_f 0.43) located between chloramphenicol (R_f 0.50) and *N*-acetyl-*p*-nitrophenylserinol (R_f 0.34) was scraped from the plate and the adsorbent was leached with acetone. The eluted substance was taken up in hot ethyl acetate and crystallized as prisms. After recrystallization from water it was obtained as fine needles which melted initially at 167–168°, then crystallized and remelted at 177.5°; $[\alpha]^{26°}$ in methanol (*c*, 0.725) 20.3° at 365 nm, 3.31° at 436 nm; −1.65° at 546 nm, −1.79° at 578 nm, −1.65° at 589 nm; λ_{max} (MeOH) 245 nm (log ε 4.26); ν_{max} (KBr) 3310, 3240, 3130, 3090, 3000, 1685, 1670, 1610, 1542, 1515, 1445, 1410, 1370, 1322, 1270, 1224, 1208, 1140, 837, 826, 810 cm^{-1}; $M^{\pm}$ at *m/e* 318 (2% of most abundant peak) and characteristic fragment ions at *m/e* 287 (2%), 235 (2%), 191 (78%), 149 (60%), and 106 (100%). Accurate mass measurement of selected ions gave *m/e* 318.0524 ($C_{13}H_{16}N_2O_3Cl_2$ requires 318.0538), 191.0945 ($C_{11}H_{13}NO_2$ requires 191.0946), and 106.0662 (C_7H_8N requires 106.0657).

Synthesis

p-Amino-L-phenylalanine (3 g) prepared as described by McGrath *et al.* (2), was acetylated with acetic anhydride (1.5 ml) in glacial acetic acid (25 ml) under the conditions described by Weichert for the racemic amino acid (3). *p*-Acetamido-L-phenylalanine, m.p. 234–237°, was obtained in 62% yield. To a well-stirred and cooled (ice bath) solution of the product (2.22 g) in 0.5 *N* sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

hydroxide (20 ml), dichloroacetyl chloride (1.7 ml) was added drop by drop. The p*H* was maintained above 8 by periodic addition of sodium hydroxide solution and stirring was maintained for 30 min after all of the dichloroacetyl chloride was added. The reaction mixture was brought to p*H* 3 with dilute hydrochloric acid and the precipitate (1.5 g) collected. It was chromatographed on a column (3 × 50 cm) of Sephadex G-25 (fine) using the solvent system benzene – ethyl acetate – ethanol – acetic acid – water (4 : 1 : 2 : 1 : 3). The eluate was collected in 5 ml fractions and the material from fractions 94–145 contained the product. It was recrystallized from water to give *p*-acetamido-α-*N*-dichloroacetyl-L-phenylalanine (3) as prisms (0.8 g) m.p. 105–111°; $\alpha_D^{26°}$ + 72.4° (*c*, 0.29 in methanol; λ_{max}(MeOH) 245 nm (log ε, 4.26); ν_{max}(KBr) 1710, 1670, 1542, 1505 cm^{-1}; τ (acetone-d_6) 7.93 (acetyl CH_3) 4.42 (dichloroacetyl CH), AA′BB′ system centered at 2.73, ABX system with AB and X nuclei centered at 6.85 and 5.20 respectively (calcd. J_{AB} = 14.4, J_{AX} = 8.0, J_{BX} = 5.0 Hz). Double irradiation of the A, B, and X signals confirmed the couplings.

Anal. Calcd. for $C_{13}H_{14}O_4N_2Cl_2$: C, 46.86; H, 4.23; N, 8.41; Cl, 21.28. Found: C, 46.67; H, 4.12; N, 8.34; Cl, 21.36.

The acid (0.67 g) was added to a solution of diborane (0.16 mmol/ml) in tetrahydrofuran prepared as described by Brown *et al.* (4) from boron trifluoride etherate (7.1 ml) and sodium borohydride (0.627 g) in tetrahydrofuran (60 ml), and cooled to 0°. After 2 h acetone (5 ml) was added drop by drop to destroy excess diborane, then water (20 ml). Solvent was removed *in vacuo* and the products separated by preparative t.l.c. 2-Dichloroacetamido-3-(*p*-acetamidophenyl)propan-1-ol crystallized from water as needles (12 mg) which melted at 166°, became solid, and remelted at 179.5°. It had $[\alpha]^{26°}$ in methanol (*c*, 0.72) 20.6° at 365 nm, 3.33° at 436 nm, −1.53° at 546 nm, −1.80° at 578 nm, and −1.66° at 589 nm, did not depress the m.p. of the natural sample on admixture, and showed no differences from it in u.v., mass, p.m.r., or i.r. absorption spectra.[4]

Anal. Calcd. for $C_{13}H_{16}N_2O_3Cl_2$: C, 48.92; H, 5.05; N, 8.78; Cl, 22.21. Found: C, 49.09; H, 4.94; N, 8.68; Cl, 22.05.

We thank Mr. D. J. Embree and J. Van Ingen for determining mass and p.m.r. spectra. We are also grateful to Dr. W. D. Jamieson and Dr. A. G. McInnes for assistance in interpreting the spectra.

Yields of Free Ions in the X Radiolysis of Some Simple Saturated and Unsaturated Hydrocarbon Liquids: Effects of Molecular Structure and Temperature[1]

M. G. Robinson, P. G. Fuochi,[2] and G. R. Freeman
Chemistry Department, University of Alberta, Edmonton 7, Alberta

Received July 5, 1971

Pulse techniques were used at temperatures ranging from 120 to 293 °K. A quasifree electron conductance transient (k/u overshoot) was observed in liquid methane, but not in ethane, propane, cyclopropane, ethylene, propylene or butene-1. The free ion yield in methane, $G_{fi} = 0.8$ at 120 °K, is much larger than those in the other liquids, which at 183° K are: ethane, 0.13; propane, 0.076; cyclopropane, 0.04; ethylene, 0.017; propylene, 0.04; butene-1, 0.027. The activation energies of free ion formation are, in kcal/mol: ethane, 0.6; propane, 0.8; ethylene, 0.5; propylene, 1.0; butene-1, 1.0. The results are interpreted in terms of the coulombic interaction model. The distances that the secondary electrons penetrate the liquid away from their parent ions are greater when the hydrocarbon molecules are more sphere-like, and are reduced by the presence of a π bond in the molecule. Cyclopropane behaves somewhat like an olefin in this regard, a fact that is explained by the unusual bonding in the C_3 ring. In the present liquids the only ionization events that contribute appreciably to the free ion yield are those in which the electron penetrates $\gtrsim 100$ Å from the parent ion.

Les techniques de radiolyse pulsée ont été utilisées à des températures allant de 120 a 293 °K. Une conductance éphémère due à des électrons quasi libres a été observée dans le méthane liquide; l'éthane, le propane, le cyclopropane, l'éthylène, le propylène ni le butène-1 ne présentent de phénomène similaire. Le rendement en ions libres, G_{fi}, déterminé pour le méthane à 120 °K a une valeur de 0.8; pour les autres liquides, ce rendement vaut à 180 °K: 0.13 pour l'éthane, 0.076 pour le propane, 0.04 pour le cyclopropane, 0.04 pour le propylène et 0.027 pour le butène-1. L'énergie d'activation, en kcal/mol, concernant la formation d'ions libres est respectivement de 0.6 pour l'éthane, 0.8 pour le propane, 0.5 pour l'éthylène, 1.0 pour le propylène et 1.0 pour le butène-1. Les résultats sont interprétés sur la base du modèle d'interaction coulombique. La distance qu'un électron secondaire parcourt depuis l'ion parent est plus grande lorsque les molécules d'hydrocarbures sont d'autant plus spheroïdes; par ailleurs la présence d'orbitales π dans les molécules d'hydrocarbures réduit la pénétration d'un électron secondaire. A ce point de vue, le cyclopropane qui possède un genre particulier de liens C—C se comporterait plutôt comme une oléfine. Pour les liquides étudies, les ionisations qui contribuent d'une façon appréciable au rendement en ions libres sont celles pour lesquelles les distances de pénétration des électrons sont au moins de 100 Å.

Canadian Journal of Chemistry, 49, 3657 (1971)

Introduction

The influence of molecular structure on the radiation-induced free ion yield in liquid hydrocarbons has been demonstrated by both conductivity and scavenging studies (1–5). However, the precise nature of the effect is not understood. Liquids that are made up of sphere-like molecules, such as argon and neopentane, give high yields of free ions. Associated with the high yield of free ions is a short lived (μs) conductance transient, believed to be due to quasifree electrons, that is observed by a pulse radiolysis technique (2, 3). Liquids comprised of nonspherical molecules, such as *n*-hexane and *n*-pentane, have low yields of free ions and do not exhibit the short lived radiation induced transient.

In an earlier communication the prediction that liquid methane, which has nearly spherical molecules, should have a high free-ion yield was confirmed (6). A striking difference between the yields in the liquids methane and ethane was observed. The detailed results for these hydrocarbons are presented here together with data obtained for propane, some simple mono-olefins and the pseudo olefin, cyclopropane.

Recent studies have shown that electron scavenging in ethylene and propylene is much less efficient than that in ethane and propane (7). The smaller scavenging efficiencies seem to

reflect smaller ion–electron separation distances in the spurs in the π-bonded systems compared to those in the alkanes. Theory predicts that the free ion yields in the olefins should be correspondingly small, and this expectation is confirmed by the present work.

Experimental

Materials

The ethane, ethylene, propane, propylene, and butene-1 were Phillips Research Grade. Cyclopropane and methane were obtained from Matheson, the methane being Ultra Pure Grade. Each compound was purified by vacuum distillation retaining the middle fraction, and freeze–thaw–pump cycles. Prior to use the hydrocarbons were electrolyzed as liquids at 183 °K (120 °K for methane) for 2 h at 800 V/cm. Each sample was then distilled into a side-bulb attached to the conductance cell, frozen at 77 °K, and the cell-unit was sealed off with a flame.

Equipment and Technique

(a) Conductance Cell

The conductance cell was similar to that used by Tewari and Freeman (3). It was modified for ease of removal from the Dewar and to give a better seal in the Dewar by using O-rings, and making a Kovar seal around the collector lead (Fig. 1). The collector lead was insulated with heat-shrink polyethylene tubing and the Kovar was filled with paraffin wax to prevent condensation of moisture inside it.

The electrode spacing in each cell used was 5 mm and the effective area of the collecting electrode was 1.14 cm^2. The cell constants were measured using standard KCl solutions.

(b) The Quasifree Electron Conductance Transient

The height of the quasifree electron conductance transient is critically affected by traces of electron scavenging impurities such as oxygen (2, 3). However, traces of oxygen can be removed from hydrocarbons by preirradiating the sample in the conductance cell to a dose of 10^{18}–10^{19} eV/g (2). A ^{60}Co source was used for preirradiations. The presence of the quasifree electron transient in the sample after a 1 μs pulse of 1.7 MeV X-rays was sought using the circuit shown in Fig. 2*a*. The sensitivity of this circuit was much greater than that used earlier (3), and enabled currents down to 1 nA to be measured with a response time of 2 μs.

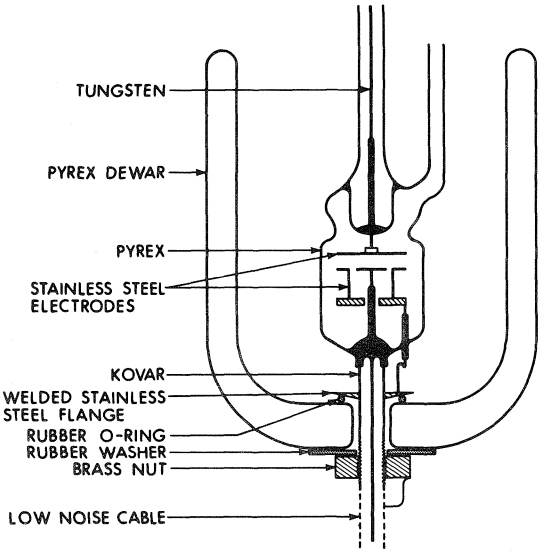

FIG. 1. Conductance cell.

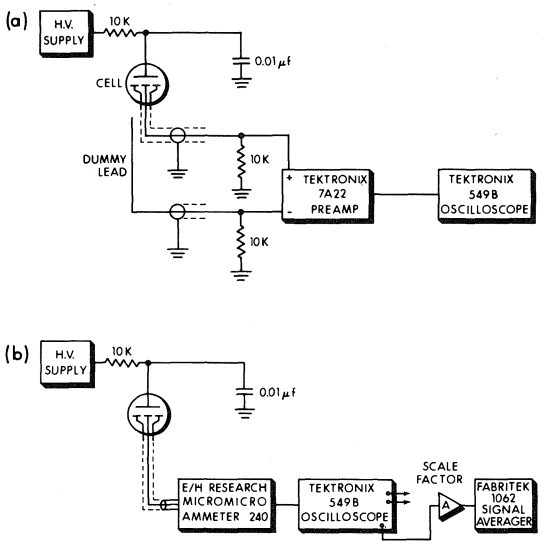

FIG. 2. Schematic diagrams of the circuits used in the measurement of: (*a*) quasifree electron conductance transient (response time 2 μs). (*b*) k/u for ion–ion neutralization (response time ≤0.2 s). Blank and beam pulse control and current monitoring same as in Fig. 3.

(c) Measurement of (k/u) for Ion-Ion Neutralization

The ion–ion neutralization reactions had half lives of the order of magnitude of a second. The decay of the conductance after a 1 ms pulse of X-rays was measured with the circuit shown in Fig. 2*b*. For each run sixteen alternate signals and blanks (no pulse from the Van de Graaff) were measured, averaged and subtracted by the Fabritek 1062 Signal Averager. Currents ≥0.1 pA were measured with response time ≤0.2 s, the response time being shorter for larger currents. Values of the ratio of the neutralization rate constant k to the sum of the charge mobilities u were calculated from the current decay curves (2).

(d) Determination of the Free-ion Yield

The free-ion yields were measured by the charge clearing method (1, 2). The circuit used was similar to that described by Tewari and Freeman (3) but modified to give a greater sensitivity. A schematic diagram of the improved circuit is shown in Fig. 3. Signals were generated by 1 μs pulses of 1.7 MeV X-rays. Alternate signals and blanks were fed into a low drift, high sensitivity integrator (Fig. 3*b*) and averaged with the Fabritek 1062. Normally the clearing field (0.3 to 6 kV) was applied for 1.7 s, beginning approximately 5 μs after the X-ray pulse, and the resulting radiation-induced current

was integrated. A Tektronix 549B oscilloscope with a type 1A7 plug-in monitored the signals and provided suitable delays. Sensitivities as high as 0.125×10^{-12} C/cm were achieved with this system.

For methane the X-ray pulse was applied after the beginning of the clearing field pulse, to prevent the possible loss of quasifree electrons by neutralization during the 5 μs period between the X-ray and voltage pulses in the normal technique.

Dosimetry

A measurement of the dose per X-ray pulse for each hydrocarbon was effected by correlating the charge collected at the gold target and corresponding thermoluminescent dosimetry measurements. An Ortec model 439 Current Digitizer was used to monitor the charge collected from the gold target for, typically, 100 pulses. The same X-ray pulses irradiated several lithium fluoride crystals which were placed in front of and behind the Dewar which contained the conductivity cell. The dose absorbed by these crystals was measured with a Harshaw model 2000 Thermoluminescence Analyzer. Calibration of the lithium fluoride crystals was effected by γ-radiolysis and comparison of the thermoluminescence response (nC) with the dose from the γ-source, measured by Fricke dosimetry (eV ml^{-1}). The dose per pulse was varied between 1 and 3 (10^{10} eV/ml).

Physical Properties of the Hydrocarbons

The densities of the hydrocarbons at the different temperatures were obtained from ref. 8, those at the lowest temperatures by extrapolation. The density of butene-1 at 118 °K was measured and found to be 0.81 g/cm³, which indicated that all densities obtained by extrapolation were accurate to within 3% and most, obtained by shorter extrapolations, would be within 1% of the true value. The dielectric constants were calculated from the Debye equation (9), using appropriate densities, refractive indices (10), and dipole moments (11). The physical properties are summarized in Table 1 and Fig. 4.

Results

Quasifree Electron Conductance Transient

A quasifree electron conductance transient, previously called a k/u overshoot (2, 3) was observed in liquid methane (Fig. 5*a*). The magnitude of the transient increased as the sample was irradiated up to a dose of 1×10^{18} eV/ml, then remained constant at 6.3×10^{-19} mho cm³/eV. The height of the conductance peak was proportional to field strength from 6 to 200 V/cm. The 2 μs response time of the measuring circuit was too slow to permit meaningful k/u measurements to be made.

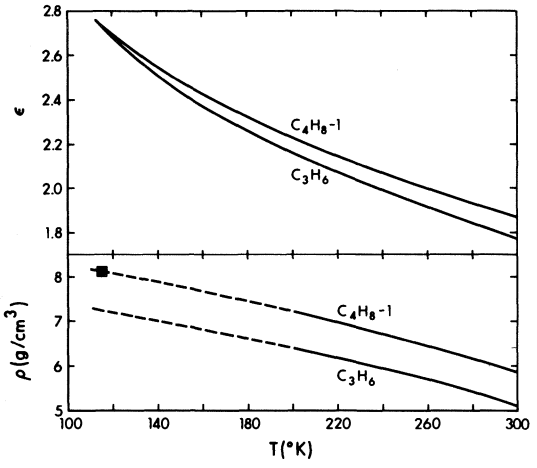

FIG. 4. Densities and dielectric constants of propylene and butene-1 as functions of temperature. ρ:— from ref. 8; --- estimated; ■ measured. ε: calculated from the Debye equation.

A quasifree electron transient was not observed in any of the other liquids, either before or after γ-radiolysis, at sensitivities down to 1 nA/cm and field strengths up to 2000 V/cm (Fig. 5*b*). The magnitude of the transient in the liquids ethane, propane, cyclopropane, ethylene, and propylene at 183 °K was $<3 \times 10^{-23}$ mho/cm³ eV, at least four orders of magnitude smaller than that in methane at 120 °K.

k/u for Ion–Ion Neutralization at 183 °K

The apparent value of k/u increased with increasing applied voltage, probably due to the neutralization of progressively larger fractions of the ions at the electrodes. In ethane the apparent values at 10 and 220 V/cm were 1.6 and 10 (10^{-6} V cm), respectively; in propane the corresponding values were 1.5 and 8 (10^{-6} V cm), respectively. The values at zero field strength would therefore be near to the theoretical value 1.0×10^{-6} V cm in both liquids.

The induced conductances of ethylene, propylene, and cyclopropane were too small to permit the measurement of k/u in those liquids. However, the apparent value in cyclopropane at 200 V/cm was 8×10^{-6} V cm, similar to those in ethane and propane at the same field strength.

The measurement of low conductances was complicated by the existence of a voltage hysteresis in the cell, presumably due to polarization of the glass envelope in the combined electric and radiation fields. The effect of the hysteresis was minimized by giving a few pulses of radiation to the cell at each new voltage, before taking readings.

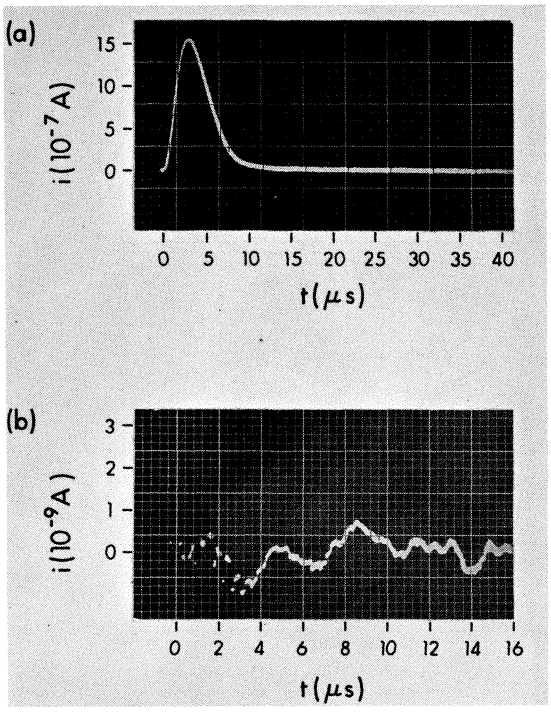

FIG. 5. (*a*) Oscilloscope trace of current *vs.* time for the quasifree electron conductance transient in methane at 120 °K. The X-ray pulse duration was 1 μs and the sample dose was 2.2×10^{10} eV/ml. Applied field 206 V/cm. (*b*) Corresponding oscilloscope trace for ethane at 183 °K. Sample dose (1 μs) $\approx 3 \times 10^{10}$ eV/ml. Applied field = 2000 V/cm.

Free Ion Yields

In Fig. 6 are shown typical yields of ions collected at the electrodes as functions of applied voltage in methane, ethane, propane, and ethylene. The curves obtained for the C_2–C_4 hydrocarbons contained plateaus; cyclopropane, propylene, and butene-1 gave curves similar to that shown for ethylene in Fig. 6. The plateaus correspond to the free ion yields. No plateau was obtained for methane, because in this case the electric field was present during the radiation pulse, and the free ion yield increases with increasing applied field strength (12, 13). The free ion yield in methane in the absence of an applied field at 120 °K, obtained by extrapolation (13), is $G_{fi} = 0.8 \pm 0.1$.

The values of G_{fi} obtained in the different liquids at several temperatures are listed in Table 2. In a given hydrocarbon the yield increases with increasing temperature. At a given tempera-

ture the yields in the liquids decrease in the order $CH_4 \gg C_2H_6 > C_3H_8 > c\text{-}C_3H_6 \approx C_2\text{-}C_4$ olefins.

The free ion yields in ethylene were the most difficult to measure because they were the lowest. However, repeated runs on three samples showed that the values were reproducible within ± 0.002 G units over the temperature range studied.

Discussion

Quasifree Electron Transient

The only liquid in the present series that displayed the quasifree electron conductance transient was methane. This conforms to the previously noted correlation between the magnitude of the transient (k/u overshoot) and the sphericity of the molecules (2, 3). The correlation exists for nonpolar compounds that do not scavenge electrons.

Free Ion Yields

The liquid that displays the quasifree electron conductance transient gives a much larger free ion yield than those that do not display the transient, under similar irradiation conditions (Table 2). This agrees with earlier observations on other systems (2, 3).

Free ion yields calculated from the coulombic interaction model (14), using the semi-empirical distribution of thermalized electron–ion separation distances (14, 15), are in reasonable agreement with the experimental results for ethane and propane. However, the calculated value for methane is too low and those for cyclopropane and the olefins are too high. The semiempirical distribution is apparently suitable for saturated compounds whose molecules are distinctly not sphere-like, but is unsuitable for liquids made up of sphere-like molecules or unsaturated compounds. Sphere-like molecules give rise to longer ion–electron separation distances, while double bonds shorten the separation distances. Different distributions must therefore be devised.

A simple form of distribution function that is convenient to use (4, 16) is the single parameter three dimensional Gaussian

$$[1] \quad N(y)/N_0 = (4y^2/\pi^{1/2}b^3) \exp(-y^2/b^2)$$

where $N(y)/N_0$ is the fraction of the ion–electron pairs that have an initial distance y between the ion and the thermalized electron, and the parameter b is the most probable value of y. The free ion yield G_{fi} is then given by eq. 2

$$[2] \quad G_{fi} = G_{tot} \int_0^\infty \left(\frac{4y^2}{\pi^{1/2}b^3}\right) \times \exp\left(-\frac{y^2}{b^2} - \frac{\xi^2}{\varepsilon y k T}\right) dy$$

where G_{tot} is the total ionization yield, ξ is the electronic charge, ε is the dielectric constant of the liquid, k is Boltzmann's constant, and T is the absolute temperature. By substituting values of G_{fi}, G_{tot}, ε, and T into eq. 2 one obtains a value of b.

Relative values of b in different liquids reflect, in an approximate way, the relative ranges of the secondary electrons in the liquids. The initial energy distributions of the secondary electrons in the different liquids are probably similar to each other, so the relative values of b allow one to compare rates of energy loss by the electrons in the different liquids. The comparison is only qualitative, because the Gaussian might not be an exact description of the electron range distribution.

Values of b for the present liquids at the different temperatures are given in Table 2. For purposes of comparison the product of the electron range b and the density d of the medium has

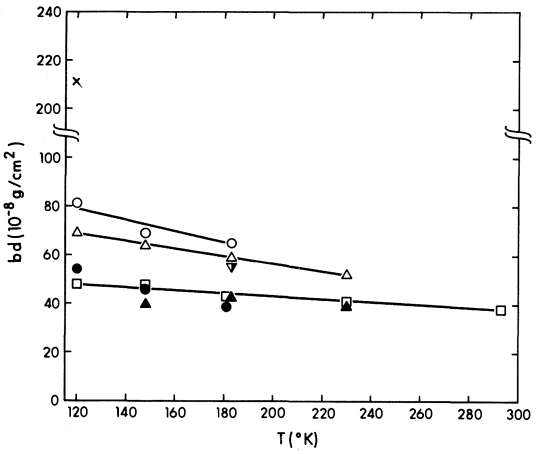

FIG. 7. Values of *bd* as functions of temperature for the different liquids. ×, CH_4; ○, C_2H_6; ●, C_2H_4; △, C_3H_8; ▲, C_3H_6; ▽, *c*-C_3H_6; □, C_4H_8-1.

more theoretical significance than does the range alone (4, 14, 17). Values of *bd* are listed in Table 2 and plotted in Fig. 7.

The values of *bd* decreased somewhat with increasing temperature (Fig. 7). The decrease might simply indicate that the Gaussian function is sharper than the real distribution function, the latter having a longer tail towards higher *y* values. A power function might be more suitable than the Gaussian (18). However, values of *bd* at the same temperature can be meaningfully compared. One can see from Fig. 7 that the relative values of *bd* are in the order $CH_4 \gg C_2H_6 > C_3H_8 > c\text{-}C_3H_6 >$ olefins. The progressively decreasing values of *bd* for the C_1-C_3 alkanes correlate with a sequence of molecular properties. Methane is relatively sphere-like and is almost isotropically polarizable; ethane is much less sphere-like than methane and it is not isotropically polarizable; propane is still less sphere-like, is not isotropically polarizable, and has a small dipole moment (Table 1). The significance of this correlation of *bd* with molecular properties is not understood. The correlation might be partly due to the effect of the molecular properties on the packing and relative orientation of the molecules in the liquid.

The presence of a π bond in the molecule decreases the value of *bd* further (Fig. 7). The π bond apparently increases the secondary electron energy loss cross section of the molecules, or increases the ease of formation of a localized state of the electron in the liquid, or both.

The behavior of cyclopropane falls between those of propane and propylene (Fig. 7). The partial olefinic nature of cyclopropane is well known in organic chemistry (19) and has been observed in radiation chemistry through its charge scavenging reactions and kinetics (7). An unusual type of bonding accounts for the chemical properties of the three-membered ring (20–22), and probably also accounts for the strength of the electron–molecule energy transfer interaction (at low energies) and for the H_2 transfer reaction with alkane positive ions observed by Ausloos and Lias (23).

Temperature Coefficients of the Free Ion Yields

Consider the following general mechanism for the ionic reactions in a radiation-induced conductance system.

[3] $\quad A \rightarrow [B^+ + C^-]$

[4] $\quad [B^+ + C^-] \rightarrow$ Products (geminate neutralization)

[5] $\quad [B^+ + C^-] \rightarrow B^+ + C^-$ (free ions)

[6] $\quad B^+ + C^- \rightarrow$ Products (random neutralization)

[7] $\quad B^+ \rightarrow$ electrode

[8] $\quad C^- \rightarrow$ electrode

The square brackets around products or reactants indicate that the species are in a spur. Only the free ions contribute to the induced conductance. Measurement of the free ion yield gives information about the competition between reactions 4 and 5.

The Arrhenius temperature coefficient of the free ion yield has little direct significance (*cf.* eq. 2), but it allows us to fit the present temperature effects into the framework of a chemist's experience. Arrhenius plots of the free ion yields in ethane, propane, ethylene, propylene, and butene-1 are shown in Fig. 8. In all these liquids at the temperatures studied $G_{fi} \leq 0.03 G_{tot}$ (Table 2), so the ratio of "rate constants" of reactions 4 and 5 is approximately proportional to G_{fi}

$$[9] \quad \frac{k_5}{k_4} = \frac{\text{rate of [5]}}{\text{rate of [4]}} \approx \frac{\text{rate of [5]}}{\text{rate of [4] + [5]}} \approx G_{fi}/G_{tot} \propto G_{f_1}$$

Thus, from the slopes of the curves in Fig. 8 one obtains $E_5 - E_4$, which equals E_5 because E_4 is presumably zero. The "activation energy" E_5

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

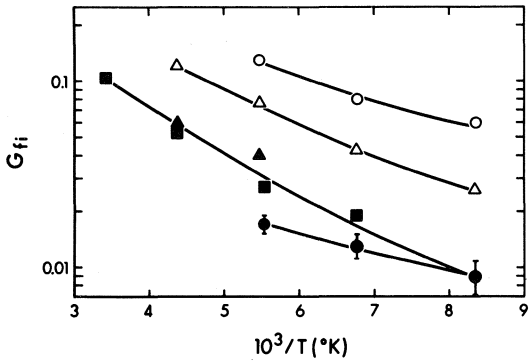

FIG. 8. Effect of temperature on the free ion yield. Arrhenius plots for: ○, ethane; ●, ethylene; △, propane; ▲, propylene; and ■. butene-1. The error bars drawn through the ethylene points were estimated from repeated runs on three samples.

seems to increase gently with increasing temperature (Fig. 8). The average values in the liquids at the temperatures studied are listed in Table 3. They range from 0.5 to 1.0 kcal/mol and are only 2–3 times the mean values of RT, which were 0.3–0.4 kcal/mol.

The coulombic attraction energy E_b between the ion and electron at separation distance b, the most probable value of y in a Gaussian $N(y)$ distribution, is about 2 kcal/mol in each of the liquids (Table 3).

$$[10] \qquad E_b = N_A\xi^2/\varepsilon b$$

where N_A is Avogadro's number. This energy is 2–3 times greater than the observed value of E_5 (Table 3) and is further evidence that the free ions originate from the long range tail of the $N(y)$ distribution.

The distances at which the ion–electron coulombic attraction energies equal E_5 range from 140 Å in butene-1 to 360 Å in ethylene (Table 3). Thus the competition between reactions [4] and [5] is only effective at distances $\gtrsim$100 Å under the present conditions. At smaller distances reaction 4 occurs to the virtual exclusion of reaction 5. The same conclusion was derived for free ion formation in *n*-hexane (24) and is in agreement with earlier expectations (12, 14).

The large kinetic solvent isotope effects for the neutral hydrolysis of acetic and propionic anhydride show unusual temperature dependency; the former passing through a maximum at about 15°, the latter showing a minimum at 30°. This unusual temperature dependency is the consequence of widely different values of the apparent ΔC_p^* in H_2O and D_2O: the value for acetic anhydride in H_2O being -74 ± 2 cal deg^{-1} mol^{-1} but -32 ± 4 in D_2O. The corresponding values for propionic anhydride being -31 ± 2 in H_2O but -94 ± 10 in D_2O. The implications of these differences are discussed.

L'importance des effets isotopiques cinétiques dans l'hydrolyse en milieu neutre d'anhydride acétique et propionique dépend étrangement de la température; le premier passe par un maximum à environ 15° tandis que le dernier présente un minimum à 30°. Cette dépendance inhabituelle par rapport à la température est la conséquence des valeurs très différentes du ΔC_p^* apparent dans H_2O et D_2O: la valeur pour l'anhydride acétique dans H_2O étant de -74 ± 2 cal deg^{-1} mol^{-1} mais de -32 ± 2 dans D_2O. Les valeurs correspondantes pour l'anhydride propionique sont de -31 ± 2 dans H_2O mais -94 ± 10 dans D_2O. Les conséquences de ces différences sont discutées.

Introduction

The spontaneous hydrolysis of carboxylic acid anhydrides have been widely studied (1–10). The reaction is characterized by large kinetic solvent isotope effects (k.s.i.e. $= k_{H_2O}/k_{D_2O}$) and large negative entropies of activation ($\Delta S^{\ddagger}$). Such results were interpreted as being consistent with the requirements of a general base catalyzed mechanism, BAc2, and were taken to imply (11) that more than one water molecule was tightly constrained in the transition state. Our interest in the effect of temperature on solvolytic rates led initially to an investigation of the temperature dependency of the large kinetic solvent isotope effect for acetic anhydride.

The experimental problem simply required that we extend the careful investigation of Gold (5) over a wide temperature range and obtain a complementary set of rate data in D_2O. The results were so surprising that we were led to extend our investigation to study the hydrolysis of propionic anhydride and to other anhydrides. In this paper we report our findings for the hydrolysis of acetic and propionic anhydride.

Experimental

Commercial samples of acetic anhydride and propionic anhydride were refluxed over magnesium turnings for 24 h. The anhydrides were fractionated and collected at b.p. 140–140.5° for acetic anhydride and b.p. 162–163° for propionic anhydride. Water was purified by preliminary distillation, ion exchange over Rexyn R 208-1-300 H—OH resin and finally distilled in a CO_2-free silica glass still. A specific conductance of 3×10^{-6} ohm^{-1} cm^{-1} at 20° was readily obtained. Heavy water was obtained from Merck, Sharpe and Dohme or A.E.C. of U.S.A. The D_2O was distilled off NaOH (0.001 M) into a Stuart-Wormwell still (12) including a quartz condenser and fractionated under pure nitrogen. D_2O was collected with a specific conductance below 5×10^{-7} ohm^{-1} cm^{-1} at 10°. Mole% D was determined by density measurement (pycnometry) (13) and found to exceed always 99.7 mol% D.

Potassium chloride (approximately 10^{-4} M) was added as backing electrolyte to the water to produce a reaction solution with a cell resistance of about 50 000 ohm. The conductance cell, nearly filled with this backing electrolyte, was held at constant temperature to better than ±0.002°. To a further 20 ml of thermostated backing electrolyte was added 3 μl of reactant and then vigorously shaken. It was found that 2–3 ml of this "concentrated" reactant solution added to the backing electrolyte in each cell (cell constant ~0.2) produced optimal initial resistance readings. Conductance–time data were collected by the Auto-RAM system (14) and pseudo first order rate constants were calculated as follows.

Calculation

Solvolysis of an acid anhydride molecule produces only the parent acid as product (4).

$$(RCO)_2O + H_2O \xrightarrow{k_{obs}} 2RCO_2H \xrightarrow{K_a} 2RCO_2^- + 2H^+$$

If the product were a strong acid then Onsager

TABLE 1. Empirical constants for the rate temperature relation 6 for solvolysis of acetic anhydride and propionic anhydride

Substrate	Solvent	A_1	$-A_2$	$-A_3$	$n_{T_1}{}^{T_2}$
Acetic anhydride	H_2O	110.42086	6925.2658	36.2782	$29_2{}^{25}$
	D_2O	48.94343	4276.5775	15.2112	$34_5{}^{40}$
Propionic anhydride	H_2O	47.32806	4110.1487	14.6943	$33_1{}^{39}$
	D_2O	138.76453	8233.3958	46.2346	$24_{12}{}^{49}$

conductance behavior could be assumed but acetic and propionic acids are weak electrolytes. The following conductance equations provided a satisfactory analysis of the conductance–time data (5, 15, 16). Ostwald's dilution law expressed in conductance terms represents the variation in conductance with concentration of the weak electrolyte. At the substrate concentrations used ($\sim 10^{-4}$ M) this was considered to be reliable.

$$[1] \qquad K_a = \Lambda^2 c/\Lambda_0(\Lambda_0 - \Lambda)$$

where K_a is the acid ionization equilibrium constant, c is the electrolyte concentration, Λ is the equivalent conductance, and Λ_0 the limiting equivalent conductance. By definition

$$[2] \qquad \Lambda = 10^3 C_K/Rc$$

where C_K is the cell constant and R is the resistance of the cell (ohms). Combining eqs. 1 and 2, one gets

$$[3] \qquad c = \frac{10^3 C_K}{\Lambda_0 R}\left\{1 + \frac{C_K}{K_a \Lambda_0 R}\right\}$$

Equation 3 relates the experimental resistance to the electrolyte concentration c provided the constants C_K, Λ_0, and K_a are known or can be estimated ($\pm 10\%$) reliably.

The Guggenheim equation (17) for calculation of first order rate constant is[3]

$$[4] \qquad C_{t+\Delta} - C_t = \frac{C_0}{2}\cdot(1 - e^{-k\Delta})\cdot e^{-kt}$$

where C_0 = stoichiometric concentration of anhydride at time, $t = 0$; C_t = concentration of acid at time t; $C_{t+\Delta}$ = concentration of acid at time $t + \Delta$; Δ = constant time interval, approximately $2\cdot t_1/2$; k^0 = observed first order rate constant.

Combining eqs. 3 and 4 and manipulating gives

$$[5] \quad \log\left\{\frac{1}{R_{t+\Delta}} - \frac{1}{R_t}\right\} + \log\left[1 + \frac{10^3 C_K}{\Lambda_0 K_a}\left\{\frac{1}{R_{t+\Delta}} + \frac{1}{R_t}\right\}\right] = \log\left[\frac{C_0\Lambda_0}{2.10^3 C_K}(1 - e^{-k\Delta})\right] - \frac{k^0 t}{2.3026}$$

Resistance data were collected in pairs, at the constant time interval Δt apart. Then rate constant k^0 was calculated by a linear least squares fit to eq. 5. For solvolysis of acetic anhydride and propionic anhydride in H_2O and D_2O; the cell constants were known, Λ_0 was calculated from available values of limiting ionic equivalent conductances (18, 19), K_a values were available for acetic acid in H_2O (20), acetic acid in D_2O (21), propionic acid in H_2O (22). K_a for ionization of propionic acid in D_2O was estimated by interpolation of ΔpK_a from the ΔpK_a *vs.* pK_a (H_2O) plot Robinson, Paabo, and Bates (23).

Excellent first order kinetic behavior was observed over five half-lives and the observed rate constant was calculated over a period of four half-lives. A precision in the rate constant, estimated by the standard deviation in k^0 for individual runs was $\pm 0.25\%$. Kinetic runs were made in quadruplicate as a further test of reproducibility; the differences between the four rate constants rarely exceeded $\pm 0.5\%$.

TABLE 2. Kinetic solvent isotope effect as a function of temperature

Temperature (°C)	Acetic anhydride	Propionic anhydride
0	2.837	3.188
5	2.892	3.024

		25	0.913_3	9 963±33	39.03±0.11	32±4
Propionic anhydride	H_2O	25	1.522	9 508±14	39.54±0.05	31±2
		35	2.626	9 196±31	40.57±0.10	31±2
Propionic anhydride	D_2O	25	0.556_0	9 687±99	40.94±0.33	94±10
		35	0.952_3	8 749±53	44.04±0.17	94±10

Rate constants were measured[4] over the largest attainable temperature range in order to fit the rate constant – temperature data to an accurately reproducible curve using the kinetic modification of the Clarke and Glew equation (24, 25).

$$\log_{10} k^0 = A_1 + A_2/T + A_3 \log_{10} T + A_4 \cdot T + \cdots$$

Empirical parameters, A_1, A_2, A_3 for a three term fit to eq. 6 enabled recalculation of rate constants agreeing within the experimental error, see Table 1, with the observed rate constants. Rate constants were interpolated at 5° intervals over the experimental temperature range for the solvolysis in both solvents. Hence the kinetic solvent isotope effect and its temperature effect are presented in Table 2 as the ratio of the smoothed curve values of the observed first order rate constants ($k_{H_2O}{}^0/k_{D_2O}{}^0$); see Fig. 1.

Assuming the applicability of the transition state theory, the approximation: $d\Delta C_p^{\ddagger}/dT = 0$ and that the observed rate constant can be treated as that of a single rate determining step, then pseudo-thermodynamic parameters, $\Delta G^{\ddagger}$, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $\Delta C_p^{\ddagger}$ can be formally derived from parameters A_1, A_2, and A_3. These data are presented in Table 3.

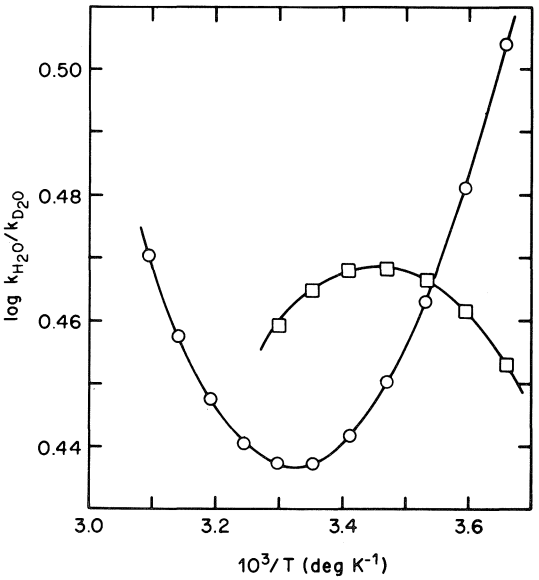

FIG. 1. Temperature dependence of k.s.i.e. for the hydrolysis of acetic anhydride (○) and proprionic anhydride (□).

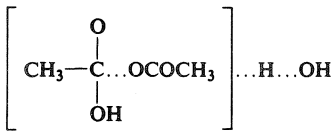
Discussion

The neutral hydrolysis of acetic anhydride has been regarded as reacting by the BAc2 mechanism (7, 9, 11, 26, 27) given formal representation as

$$(RCO)_2O + 2H_2O \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [\ ] \xrightarrow{k_3} 2CH_3COOH$$

where the bracketed intermediate is isomeric with



or there may be a further equilibrium involved with a correspondingly more complex rate equation. In the presence of acids or stronger bases still other rate equations will apply. The postulated transition state admits of a large number of variations (5), the simplest kinetic expression for the

[4]Rate determinations were made in randomized order of increasing and decreasing temperatures.

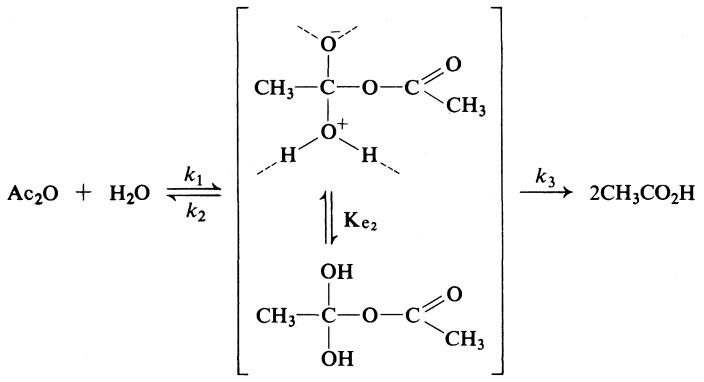

SCHEME 1

observed rate in terms of a steady state approximation being

$$[7] \qquad k^0 = \frac{k_1 k_3}{k_2 + k_3} = \frac{k_1}{1 + \alpha}$$

where $\alpha = k_2/k_3$ and the corresponding kinetic isotope effect is given by

$$[8] \qquad \frac{k^0(H_2O)}{k^0(D_2O)} = \frac{k_1(H_2O)\,(1 + \alpha(D_2O))}{k_2(D_2O)\,(1 + \alpha(H_2O))}$$

If the equilibrium term is significant (Scheme 1), further terms must be included in the k.s.i.e. In 60% dioxane/water, Bunton *et al.* (9) showed by ^{18}O exchange studies that $\alpha = 0.007$ at 25 °C where $\alpha/2 = k_e/k_h$ and k_e was the rate of exchange and k_h the rate of hydrolysis.[5] Where α is small as in the above instance, the formation of the intermediate is the rate controlling step and hence eq. 3, above, reduces to $k_0 = k_1$. In that event no complexity would be expected in the temperature dependence of k.s.i.e. or in $\Delta C_p^{\ddagger}$. Similar values of α were reported for benzoic anhydride and camphoric anhydride (9) but for no anhydride were the ^{18}O exchange for benzoyl chloride relative to the rate of hydrolysis increased markedly as the proportion of water in an organo–water mixture increased (29). Hence, Bunton's oxygen exchange data cannot be taken to exclude the possibility that α approximates unity under our conditions. Bender and Heck (30) have reported that the corresponding value of α in 25% acetonitrile/water mixture for the hydrolysis of ethyl trifluoracetate approximated to unity while the corresponding value of k.s.i.e. in water is 3.6 and $\Delta S^{\ddagger}$ is -35 cal mol^{-1} deg^{-1}. These derived data are consistent with the formation of an intermediate in which the transfer of the proton is advanced: in the limiting case α is large and $k_{obs} = K_e k_3$. While the k.s.i.e. is a little larger than found for the anhydrides, the $\Delta S^{\ddagger}$ values are about the same as shown in Table 3.

It is perhaps significant in the present comparison that the temperature dependence of the k.s.i.e. for methyl trifluoroacetate (32) and for ethyl and isopropyl trifluoroacetate (32) all appear to decrease linearly. The results obtained for acetic and propionic anhydrides show marked departure from such simple temperature dependency and is different in the two examples (Fig. 1). Such differences in temperature dependency greatly weakens any deductions based on the similarity of $\Delta S^{\ddagger}$ or the k.s.i.e. Granted the simple kinetic expression (equation 7) is satisfactory, differences in the temperature dependence of k.s.i.e. would be expected if k_2/k_3 were not too far removed from unity and the difference $\Delta H_2 - \Delta H_3$ is less than 1 kcal. The contrast between the temperature dependence of the k.s.i.e. for the two anhydrides and for the trifluoroacetates which presumably react by the same general mechanism may be attributed to a difference in the value of this ratio.

Further evidence that limiting conditions cannot be applied to the hydrolysis of the anhydrides

[5]Bunton has noted (28) that in order to obtain significant values of α from oxygen exchange experiments two conditions must be satisfied: (*1*) that an intermediate returns (*2*) that the lifetime is sufficient for the oxygens to become equivalent by proton transfer. He notes that there are a number of experimental facts which can be interpreted as casting doubts as to the attainment of the second criterion.

TABLE 4. Kinetic solvent isotope effects as pseudothermodynamic differences*

Substrate	Temperature (°C)	$\delta_I\Delta H^{\ddagger}$ (cal mol^{-1})	$\delta_I\Delta S^{\ddagger}$ (cal deg^{-1} mol^{-1})	$\delta_I\Delta C_p^{\ddagger}$ (cal deg^{-1} mol^{-1})
Acetic anhydride	15	-74 ± 42	-2.34 ± 0.14	42 ± 6
	25	362 ± 64	-0.91 ± 0.22	42 ± 6
Propionic anhydride	25	179 ± 113	-1.40 ± 0.38	-63 ± 12
	35	-447 ± 84	-3.47 ± 0.27	-63 ± 12

*$\Delta X_{D_2O} - \Delta X_{H_2O} = \delta_T\Delta X$.

is evident in the unprecedent differences in the values of $\Delta C_p^{\ddagger}$ for the two anhydrides in H_2O and D_2O (Table 3). The large value of $\delta_I\Delta C_p$ found in this study and the fact that the differences had opposite signs for small differences in structure underlines the complexity of the rate controlling processes. We do not have, as yet, comparable values for $\Delta C_p^{\ddagger}$ for the trifluoroacetates, but Bates and Robinson and co-workers have published a study of the temperature dependence of the ionization of acetic acid (33) in H_2O and D_2O and the corresponding data for the autoprotolysis of the two waters (34). For acetic acid $\delta_I\Delta F = 758$ cal; $\delta_I\delta H$ 400 cal/mol; $\delta_I\Delta S = -1.3$ cal deg^{-1} mol^{-1}, and $\delta_I\Delta C_p = 2$ cal deg^{-1} mol^{-1}. Since the latter term is small, $\delta_I\Delta H$ does not change markedly over the experimental range. In the autoprotolysis of water $\delta_I\Delta C_p = -8.2$ cal deg^{-1} mol^{-1} but in this case we are comparing different species in different environments. In the hydrolysis of acetic anhydride, $\Delta H^{\ddagger}$ is less in D_2O than in H_2O at 15 °C but greater at 25 °C. Just the opposite trend is found for the hydrolysis of propionic anhydride.

These derived parameters do not provide a basis for deciding the kind of mechanistic complexity involved but are good indicators that such complexity is present. The simplest hypothesis would seem to be that for hydrolysis in water α approximates to unity. Scott and Robertson (35) have shown in a recent paper that for a rate sequence equivalent to eq. 9 the apparent heat capacity is a complex term

$$[9]\quad \Delta C_p^{\ddagger} = \Delta C_{p_1}^{\ddagger} + \frac{\alpha}{1+\alpha}(\Delta C_{p_1}^{\ddagger} - C_{p_2}^{\ddagger}) \times \frac{\alpha}{(1+\alpha)^2}(\Delta H_2^{\ddagger} - \Delta H_3^{\ddagger})^2/RT$$

where the last term on the r.h.s. of eq. 9 is spurious and necessarily positive. Given the above possibility and in the absence of information as to the value and temperature dependence of k_2/k_3 it will be apparent that the derived values of $\Delta C_p^{\ddagger}$ do not admit of a simple interpretation in terms of solvent reorganization.

Nuclear Magnetic Resonance Studies of Multi-site Chemical Exchange. II. Hindered Rotation in *N,N*-Dimethyl Carbamyl Fluoride

L. W. Reeves and K. N. Shaw

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received March 1, 1971

The matrix formulation of the Bloch equations including chemical exchange reported earlier is extended to include indirect spin–spin coupling in first-order spectra. The ABX ($J_{AB} = 0$) spin system is treated in detail and particular attention is paid to the determining effect on the nuclear magnetic resonance (n.m.r.) lineshapes of the relative signs of the coupling constants J_{AX} and J_{BX}. The hindered rotation for *N,N*-dimethyl carbamyl fluoride in CCl_4 as solvent has been studied using a complete ^1H n.m.r. lineshape analysis and the activation parameters obtained are: $\Delta G^{\ddagger} = 18.1 \pm 0.6$ kcal mol^{-1}, $\Delta H^{\ddagger} = 17.7 \pm 0.6$ kcal mol^{-1}, and $\Delta S^{\ddagger} = -1.4 \pm 2.1$ cal deg^{-1} mol^{-1} at 25 °C.

The complete lineshape fits give very precise values of the relative shifts (16.5 mol% in CCl_4) of the methyl groups and of the coupling constants J_{AX} (0.30 ± 0.05 Hz) and J_{BX} (0.80 ± 0.05 Hz) at all temperatures. A 40% change in J_{BX} (1.10 ± 0.05 Hz) is observed in neat DMCF from a lineshape fit at −15 °C. The origin of changes in chemical shifts with temperature and J_{BX} with solvent is discussed.

La forme matricielle des équations de Bloch appliquée à l'échange chimique et rapportée précédemment est développée pour tenir compte des couplages spin–spin indirects dans les spectres au premier ordre. Le système de spin ABX (avec $J_{AB} = 0$) est traité en détail, en portant une attention particulière à l'effet déterminant des signes relatifs des constantes de couplage J_{AX} et J_{BX} sur la forme des raies du spectre r.m.n.

L'étude de la rotation restreinte du fluorure de *N,N*-diméthyle carbamyle en solution dans CCl_4 par une analyse complète de forme de raies r.m.n. du proton a donné les paramètres d'activation: $\Delta G^{\ddagger} = 18.1 \pm 0.6$ kcal mol^{-1}, $\Delta H^{\ddagger} = 17.7 \pm 0.6$ kcal mol^{-1} et $\Delta S^{\ddagger} = -1.4 \pm 2.1$ cal deg^{-1} à 25 °C.

Le calcul complet des formes de raies donne des valeurs très précises pour les déplacements relatifs (16.5 mol% dans CCl_4) des groupes méthyles et les constantes de couplage J_{AX} (0.30 ± 0.05 Hz) et J_{BX} (0.80 ± 0.05 Hz) à toutes les températures. Une variation de 40% de J_{BX} (1.10 ± 0.05 Hz) est observée dans le DMCF pur d'après un calcul de forme de raies à −15 °C. L'origine des variations de déplacement chimique avec la température et de J_{BX} avec le solvant est discutée.

Canadian Journal of Chemistry, **49**, 3671 (1971)

Introduction

The Bloch equations (1) have been modified to include chemical exchange effects (2–4), in first-order spectra, and have allowed a simple phenomenological description of n.m.r. lineshape characteristics. In the first paper in this series (5), a concise matrix formulation of the modified Bloch equations has been presented as a basis for a series of experimental studies of a wide range of chemical systems. This formulation accommodates a general first-order *n*-site exchange system and a complete description of all rate processes is contained in a single $n \times n$ matrix. Such a theoretical approach allows an efficient routine analysis for rate constants and activation parameters.

The effect of chemical exchange on spin–spin multiplets in first-order n.m.r. spectra was recognized in the original work of Gutowsky *et al.* (2, 6), and various approximate analytical expressions have been developed to derive kinetic data for specific cases (7–10). Only recently, however, have complete lineshape analyses been applied to multi-site exchange systems with *J*-coupling (11–15). Inconsistent analyses are still appearing in the literature, however, and very little reliable kinetic data is available. Thus this paper outlines the inclusion of *J*-coupling for the representative ABX ($J_{AB} = 0$) spin system. It is shown that, from a complete lineshape analysis in the first-order limit, the detailed form of chemical exchange and additional relaxation processes and also the relative signs of indirect spin–spin coupling constants may be readily determined. The experimental case chosen, namely the hindered rotation in *N,N*-dimethyl carbamyl fluoride (DMCF), is particularly problematical because of a very small chemical shift between two environmental sites and relatively small J_{AX} and J_{BX} values.

A unified theory of exchange modified n.m.r. lineshapes has been presented by Binsch (16). This theory using the Liouville operator formalism is inclusive of the cases discussed in this

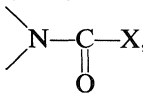
paper, but a detailed description of the lineshapes for first-order spectra (of the form observed for *N,N*-dimethyl amides) is included here to allow a lucid illustration of the inclusion of *J*-coupling and, in particular, to emphasize the effects of the relative signs of the coupling constants as discussed briefly in an earlier paper (12). The matrix formulation presented here follows directly from the stochastic exchange model discussed in the first paper in this series (5) and all the equations used are also applicable to second-order (tightly coupled) spin systems. That is, the diagonal matrix $\mathbf{\Omega}$, *cf.* eq. 19 in ref. 5, defining the Larmor frequencies for spin-sites in the first-order limit is replaced by an off-diagonal matrix with elements formally derived in terms of a superoperator (17–19) in a simple product function basis; and the intensity and population vectors $\boldsymbol{I}$ and $\boldsymbol{P}$, respectively, *cf.* eq. 20 in ref. 5, have zero elements corresponding to combination transitions. This independently developed matrix formulation is particularly amenable to numerical lineshape calculations and has been used for efficient iterative lineshape fitting, similar to that described in this paper, and will be discussed for specific examples of multi-site chemical exchange involving second-order spin systems in future publications.

Hindered rotation about the N—C bond in amides has been the subject of numerous n.m.r studies (20); but to date, reliable data for closely related chemical systems are very limited. Thus *N,N*-dimethyl carbamyl fluoride has been studied as a member of a series of halo-substituted amides to allow a correlation of the barriers to rotation with bonding parameters from molecular orbital calculations. Also, although this compound is well known as a specific enzyme inhibitor (21, 22), no information is available on its electronic structure as compared with other amides of importance in biological systems (23). The parent compound carbamyl fluoride is stable only at a low temperature (24) and hence the barrier to rotation cannot be measured for this particular amide, as is the case for other carbamyl halides and carbamyl pseudo-halides. The electronic interactions of interest, namely those between the carbonyl and amide groups and a given C-substituent X in the general structures



characteristics for the parent amides and a corresponding *N,N*-dimethyl amide series. As the latter amides are readily accessible, this particular series has been chosen for a quantitative comparison of bonding characteristics in C-substituted amides.

Chemical Exchange Spin-sites, ABX Spin System

A normal multi-site n.m.r. exchange system, in the first-order limit, is considered in terms of distinct sites (2, 5) of differing Larmor frequency, ω_i, such that each site may be associated with a specific molecular electronic environment and corresponding relative chemical shift, Ω_i. This concept of exchange sites may now be extended to spin systems including *J*-coupling. As the simple first-order ABX ($J_{AB} = 0$) spin system includes all the features of a general analysis, and is applicable to a study of hindered rotation in *N,N*-dimethyl carbamyl fluoride, this particular system will be considered in detail. The spin Hamiltonian for this system may be expressed in the form

$$[1]\quad H = H_0 + H_\Omega + H_J^{(1)} = -\omega_0[I_{zA} + I_{zB} + I_{zX}] + \Omega[I_{zA} - I_{zB}] + \Omega_X I_{zX} + J_{AX} I_{zA} I_{zX} + J_{BX} I_{zB} I_{zX}$$

H_0 is a generalized Zeeman term and ω_0 is a reference Larmor frequency (rad s^{-1}). An independent frequency variable x may now be defined as $x = \omega - \omega_0$ (5), where ω is the frequency of the irradiating r.f. magnetic field. H_Ω is the chemical shift term in which $\Omega_A = -\Omega$ and $\Omega_B = \Omega$ with $\omega_0 = (1/2)(\omega_A - \omega_B)$ and $\Omega_A = \omega_A - \omega_0$. $H_J^{(1)}$ is the *J*-coupling term as $H_J^{(2)} = (1/2)\{J_{AX}[I_A^+ I_X^- + I_A^- I_X^+] + J_{BX}[I_B^+ I_X^- + I_B^- I_X^+]\}$ may be neglected in a first-order ($J_{ij} \ll |\Omega_i - \Omega_j|$) determination of spectral transition frequencies and intensities (25). The $H_J^{(2)}$ term, however, has been shown to give rise to a spin–spin relaxation mechanism which may be described by Bloch type equations for a weakly coupled spin system (26). The effect of such a relaxation in addition to chemical exchange is not included in the present work. In the usual I_Z-representation with simple product basis functions, ϕ_l, the Hamiltonian given in eq. 1 is diagonal and hence all terms correspond to secular energies determining the transition frequencies listed in Table 1. As is well known, two relative sign combinations are possible for J_{AX} and J_{BX} (25) and thus it is initially assumed that $J_{AX} > 0$ and $J_{BX} > 0$. The AB-part of the ABX spectrum consists of the four transitions (each

TABLE 1
(*a*) Transition frequencies for ABX ($J_{AB} = 0$) spin system

Transition number*	Transition type	Energy levels†	Frequency x
1	A	(1,3), (2,4)	$-\Omega-\frac{1}{2}J_{AX}$
2	A	(5,7), (6,8)	$-\Omega+\frac{1}{2}J_{AX}$
3	B	(1,2), (3,4)	$\Omega-\frac{1}{2}J_{BX}$
4	B	(5,6), (7,8)	$\Omega+\frac{1}{2}J_{BX}$
1	X	(1,5)	$-\Omega_X-J_+$‡
2	X	(3,7)	$-\Omega_X-J_-$

2	αβα	6	αββ
3	βαα	7	βαβ
4	ββα	8	βββ

of which is doubly degenerate for $J_{AB} = 0$) shown in Fig. 1(*a*), where the *J*-couplings with the X-spin determine effective Larmor frequencies $x = -\Omega \pm (1/2)J_{AX}$ and $x = \Omega \pm (1/2)J_{BX}$. These frequencies may be associated with four distinct exchange sites, analogous to the two environmental sites with Larmor frequencies $x = \pm\Omega$. Thus in general, in the presence of exchange, a basic environmental (chemical shift) site with an associated X-spin state may be referred to as *spin site-j*, with Larmor frequency x_j. In this manner, for the couplings as given above, spin site-1 corresponds to a basic A-site associated with an α X-spin state as shown by the eigenfunctions corresponding to the energy levels determining the transition frequency $x_1 = -\Omega - (1/2)J_{AX}$: (ααα, βαα) and (αβα, ββα). For a molecular system not having a preferred conformation (equal population exchange system) all transition intensities in the AB-part of the spectrum are equal, as are those in the X-part, in the absence of exchange. The X-part of the ABX spectrum consists of the four transitions shown in Fig. 3(*a*).

In terms of a stochastic theory (3, 27) for exchange effects in a first-order spin system, the nuclear magnetization associated with spin site-*j* may be considered in terms of a spin isochromat (28) $M(x_j,\phi_j)$ with Larmor frequency x_j and phase ϕ_j (27) and a magnitude proportional to

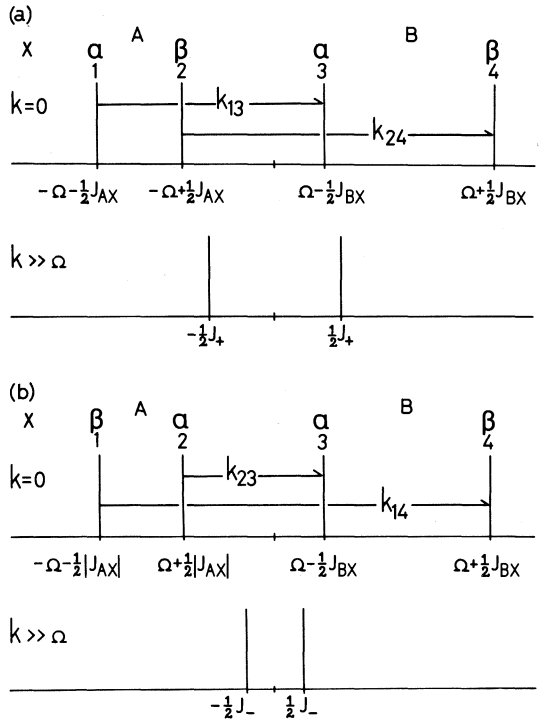

FIG. 1. AB-part of first-order ABX ($J_{AB} = 0$) spectrum in the limits of no exchange and fast exchange ($k \gg \Omega$): (*a*) $J_{BX} > J_{AX} > 0$ and $J_+ = (1/2)(J_{BX} + J_{AX})$; (*b*) $J_{BX} > 0$, $J_{AX} < 0$ with $J_{BX} > |J_{AX}|$ and $J_- = (1/2)(J_{BX} - |J_{AX}|)$. The basic A and B environmental sites are indicated along with the X-spin state corresponding to each AB-exchange spin-site.

the fractional population P_j (5). In the absence of exchange, these spin isochromats precess independently about the direction of the static applied magnetic field and a transverse relaxation time T_{2j} describes the coherent isochromat dephasing (28), and Lorentzian distribution of Larmor frequencies about x_j, associated with local magnetic field inhomogeneity. In the presence of chemical exchange, characterized by a rate constant k, individual spin isochromats are involved in a random transfer between spin-sites. Conversely, it may be considered that each spin isochromat experiences a randomly fluctuating local magnetic field with a fundamental frequency component k rad s^{-1}. Thus an exchange process gives rise to an incoherent isochromat dephasing and a modulation of the Larmor frequencies x_j. The assumptions inherent in a stochastic description of exchange effects may now be summarized as follows:

(*i*) the isochromat $M(x_j,\phi_j)$ remains in spin

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

site-j with a mean lifetime τ_j until a random instantaneous transfer to a different site takes place due to a chemical exchange process, such that precessional effects in the transfer interval may be neglected;

(*ii*) the site lifetime τ_j is independent of the associated spin–spin and spin–lattice relaxation times, T_{2j} and T_{1j}, respectively;

(*iii*) individual spin isochromats relax independently except for site transfer effects; and

(*iv*) for $M(x_j,\phi_j)$ in spin site-j there is a constant probability per unit time, k_{ji}, for transfer *from site-j into site-i*, this probability being inversely proportional to the fractional site population P_j.

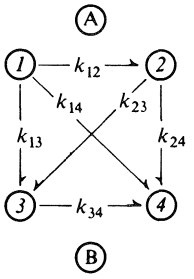
Under these assumptions, the spin-site lifetime τ_j and associated rate constants are related by

$$[2] \qquad \sum_i k_{ji} = \tau_j^{-1}$$

where i ($i \neq j$) includes all allowed transfer sites connected with site-j, and $\tau_j > T_{1j}$. Also, in accordance with the principle of detailed balance for rate processes, spin-site populations and rate constants for any two sites satisfy the condition

$$[3] \qquad P_i k_{ij} = P_j k_{ji}$$

In terms of this stochastic model, an intramolecular mutual exchange in an ABX spin system (for example, hindered internal rotation) is described by a single first-order rate constant and will be assumed to give a transfer of nuclear magnetization between *spin-sites* distinguished by the chemical shifts for A- and B-spins, $-\Omega$ and $+\Omega$, respectively. All possible transfers between the four AB spin-sites may be represented by



In accordance with assumption (*i*) above, it must be assumed that the X-spin state is *unchanged* during an AB spin-site transfer and hence the allowed transfers are $1 \leftrightarrow 3$ and $2 \leftrightarrow 4$ as readily seen by comparison of the eigen-functions associated with the transitions *1*, *3* and *2*, *4* in Table 1. That is, transitions *1* and *3* are A- and B-spin transitions, respectively, where all eigen-functions involved have an α X-spin part as shown in Fig. 1(*a*). For a mutual intramolecular exchange, this stochastic model is consistent with a quantum-mechanical treatment (29, 30) in that it may be considered that the molecular system following a nuclear spin-site transfer has a spin Hamiltonian differing only in interchanged magnetic properties for the A- and B-spins. An exchange operator E defined by $E|\alpha\alpha\xi_X\rangle = |\alpha\alpha\xi_X\rangle$ and $E|\alpha\beta\xi_X\rangle = |\beta\alpha\xi_X\rangle$, where ξ_X is the X-spin part of the product basis function, then determines exactly those transitions involved in AB spin-site transfers as allowed above. In an intramolecular exchange, the nuclear spin states for an individual molecule following a spin-site transfer are determined completely by the original states. This is actually the fundamental difference between such a process and an intermolecular exchange in which the overall state of an individual molecule following spin transfer depends upon the original state of this molecule and also the state of the interacting molecule. Therefore, if the X-spin undergoes an intermolecular exchange all AB spin-site transfers as depicted above are allowed as the X-spin state may now be *changed* in this exchange process. For example, spin-sites *1* and *2* differ only in the X-spin state as shown in Fig. 1(*a*). Such a spin-site transfer may also be considered to correspond to a spin–lattice relaxation mechanism for the X-spin; and in particular, the correlation time τ_C for a quadrupolar relaxation process may be comparable to the AB spin-site lifetime τ_j. Such a mechanism also leads to the effective transfers $1 \leftrightarrow 4$, $2 \leftrightarrow 3$, and $3 \leftrightarrow 4$. The effect of this additional relaxation process will depend upon the parameters $(\tau_C J_{AX})^{-1}$ and $(\tau_C J_{BX})^{-1}$, and hence in many first-order spin systems in the liquid phase such an effect may be described by a pseudo-secular contribution to the transverse relaxation time T_{2j}.

General lineshape characteristics for chemical exchange in the AB-part of a first-order ABX spectrum are concisely described through a 4×4 rate matrix, $\mathbf{K}$, as defined in the first paper of this series (5). In the zero saturation limit, a complex lineshape function $G(x)$ may then be expressed in the form

$$[4] \qquad G(x) = A\, \boldsymbol{I}.\mathbf{S}.[\mathbf{\Lambda} + (1/T_2 + ix)\mathbf{I}]^{-1}.\mathbf{S}^{-1}.\boldsymbol{P}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in which $\mathbf{\Lambda}$ is the diagonal matrix corresponding to a matrix $[\mathbf{K} - i\mathbf{\Omega}]$, the diagonal matrix $\mathbf{\Omega}$ being defined by the spin-site Larmor frequencies, x_j, in terms of the independent frequency variable x. $\mathbf{S}$ is the matrix which diagonalizes $[\mathbf{K} - i\mathbf{\Omega}]$, *viz.*, $\mathbf{\Lambda} = \mathbf{S}^{-1}.[\mathbf{K} - i\mathbf{\Omega}].\mathbf{S}.\boldsymbol{P}$ is the spin-site fractional population column vector and $\boldsymbol{I}$ is a transition intensity row vector. It has been implicitly assumed that T_{2j} is the same for all spin-sites in defining the relaxation matrix $\mathbf{T}_2$ as the scalar matrix $(1/T_2)\mathbf{I}$, where $\mathbf{I}$ is the 4×4 unit matrix. This simplification is usually valid in that non-secular relaxation processes (26, 29), as described by off-diagonal elements in $\mathbf{T}_2$, are negligible. However, it is to be noted that the relaxation processes associated with the J-coupled X-spin, and considered in terms of effective spin-site transfers above, are equivalently described by such off-diagonal elements. In this manner, quadrupolar relaxation effects are very simply incorporated in to eq. 4.

The matrix $\mathbf{K}$ describing intramolecular exchange effects in the AB-part of the equal population ABX ($J_{AB} = 0$) spin system with $J_{BX} > J_{AX} > 0$, and spin-sites as ordered in Fig. 1(*a*), is given (5) in terms of the rate constant k s^{-1} as

$$\mathbf{K} = \begin{pmatrix} k & 0 & -k & 0 \\ 0 & k & 0 & -k \\ -k & 0 & k & 0 \\ 0 & -k & 0 & k \end{pmatrix}$$

In accordance with eq. 2, the diagonal element K_{jj} is equal to the inverse spin-site lifetime τ_j^{-1}. The elements of the diagonal $\mathbf{\Omega}$ matrix are simply the transition frequencies listed in Table 1, and the vectors $\boldsymbol{P}$ and $\boldsymbol{I}$ have equal elements 0.25 and 1.0, respectively. Equation 4 now allows a very efficient computation of the steady-state n.m.r. absorption mode lineshape function, $V(x)$, as the real part of $G(x)$. Lineshapes have been calculated for the AB-part of the ABX spectrum defined by: $\Omega = 4.0$ Hz, $J_{AB} = 0$, $J_{AX} = 2.0$ Hz, $J_{BX} = 5.0$ Hz, and $T_2 = 0.64$ s (0.5 Hz full width at half-maximum), and are shown in Fig. 2(*a*) for rate constants in the range $0 \leqslant k \leqslant 200$ s^{-1}. These lineshapes are normalized independently of k, through the constant A in eq. 4, and the spectrum limits are ± 20 Hz. In the limit of fast exchange ($k \gg \Omega$) the spectrum reduces to a doublet. This feature is characteristic of an A_2X spin system

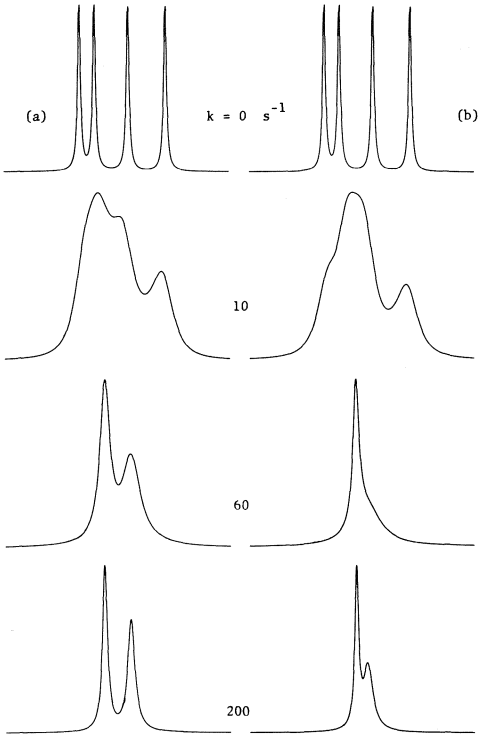


FIG. 2. Intramolecular exchange lineshape function, $V(x)$, for the AB-part of first-order ABX ($J_{AB} = 0$) spectrum; (*a*) $J_{BX} > J_{AX} > 0$; (*b*) $J_{BX} > 0$, $J_{AX} < 0$ and $J_{BX} > |J_{AX}|$.

and is consistent with the expectation that in this limit basic A- and B-sites become equivalent. As shown in Fig. 1(*a*), for J_{AX} and J_{BX} of the *same sign* the doublet splitting is J_+, where $J_+ = (1/2)(J_{BX} + J_{AX})$.

Now for a spin system with J_{AX} and J_{BX} of *different sign*, the spin–spin coupling term in the Hamiltonian given in eq. 1 may be expressed as $-|J_{AX}|I_{zA}I_{zX} + J_{BX}I_{zB}I_{zX}$, where it is assumed that $J_{AX} < 0$ and $J_{BX} > 0$. The allowed transition frequencies are defined by substituting $-|J_{AX}|$ for J_{AX} in Table 1; and the AB-part of the spectrum for this spin system is shown in Fig. 1(*b*), in which the ordered transitions *1* and *2* now correspond to β and α X-spin states, respectively. In this case, the matrix $\mathbf{K}$ is

$$\mathbf{K} = \begin{pmatrix} k & 0 & 0 & -k \\ 0 & k & -k & 0 \\ 0 & -k & k & 0 \\ -k & 0 & 0 & k \end{pmatrix}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and this matrix determines the lineshapes shown in Fig. 2(*b*) for the parameters previously given. In the region of coalescence ($k \sim \Omega$) and in the fast exchange limit, for a given rate constant k, these lineshapes are distinctly different from those for J_{AX} and J_{BX} of the same sign, *cf.* Fig. 2(*a*). Therefore, in general, the *relative signs* of J_{AX} and J_{BX} may be determined directly by lineshape fitting of an exchange modified ABX spectrum. To date, this feature has apparently only been recognized in a few instances (12, 31). Of course, a further consequence of J_{AX} and J_{BX} having different signs is that the doublet splitting in the fast exchange limit is J_-, where $J_- = (1/2)(J_{BX} - |J_{AX}|)$ for $J_{BX} > |J_{AX}|$, as shown in Fig. 1(*b*).

The corresponding rate matrices, **K**, for a more general unequal population exchange system have elements determined by the relationship given in eq. 3. Thus for $J_{BX} > J_{AX} > 0$ it follows that $K_{31} = -k$ and $K_{13} = -(P_A/P_B)k$, where k is the first-order rate constant for transfer from spin-site *1* and P_A is the sum of fractional populations for the spin-sites associated with the A-type basic environmental exchange site. In this manner the doublet in the fast exchange limit is centered at $x = (1 - 2P_A)\Omega$ and it has a splitting given by $(1 - 2P_A)J_- + J_+$, which is equivalent to the weighted average coupling $P_AJ_{AX} + P_BJ_{BX}$. For $J_{BX} > 0$ and $J_{AX} < 0$, this doublet is centered as above but the splitting is now given by $(1 - 2P_A)J_+ + J_-$, where J_+ and J_- are as previously defined.

Exchange effects in the X-part of the ABX ($J_{AB} = 0$) spectrum under consideration are also described by 4 × 4 matrices **K** and **Ω** analogous to those already discussed. The X-part spectra in the absence of exchange and in the fast exchange limit ($k \gg J_{\mp}$) are represented as shown in Fig. 3. The corresponding absorption mode lineshapes (for the particular set of parameters previously defined) are shown in Fig. 4, and again the relative signs of J_{AX} and J_{BX} give rise to marked differences in the computed lineshapes. An example in the literature closely related to the ABX spin system is ^{15}N-formamide analyzed as an ABXY ($J_{AB} \neq 0$) system (32). Inspection of the X-part of the experimental spectrum at 75 °C clearly shows that J_{AX} and J_{BX} have the same sign, as now verified by double resonance methods (33, 34).

With respect to experimental n.m.r. lineshape fitting, an analysis of *both* the AB- and X-parts of an ABX spectrum allows a check on the internal consistency of the fitting procedure used to obtain rate constants for a given exchange process. Also, in general, lineshape fitting is most reliable in the region of coalescence. Now the coalescence condition for the AB-part of the spectrum is determined by the chemical shift difference 2Ω, whereas the same condition for the X-part is determined by the parameter $J_- = (1/2)(J_{BX} - J_{AX})$ (or $J_+ = (1/2)(J_{BX} + |J_{AX}|)$); and hence, if J_- (or J_+) and 2Ω differ significantly, a dual analysis may allow an accurate measurement of the specific rate constant k over an extended temperature range, which is critical in the determination of reliable activation parameters from the usual Arrhenius plot.

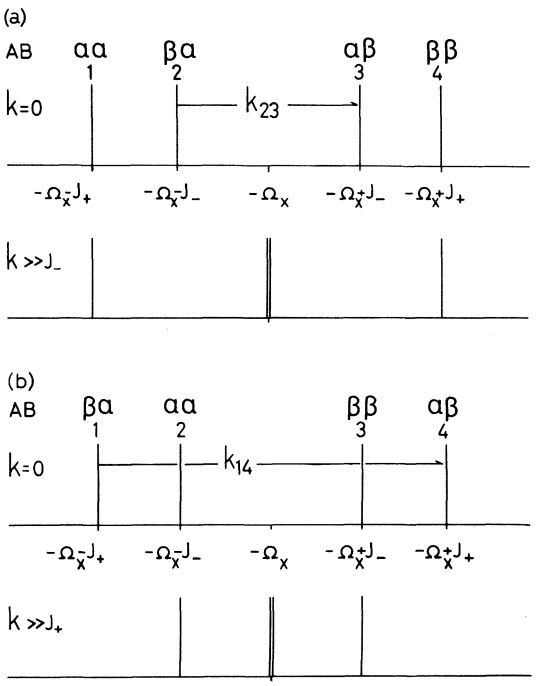

FIG. 3. X-part of first-order ABX ($J_{AB} = 0$) spectrum in the limits of no exchange and fast exchange ($k \gg J_{\mp}$): (*a*) $J_{BX} > J_{AX} > 0$ and $J_{\pm} = (1/2)(J_{BX} \pm J_{AX})$; (*b*) $J_{BX} > 0$, $J_{AX} < 0$ with $J_{BX} > |J_{AX}|$ and $J_{\pm} = (1/2)(J_{BX} \pm |J_{AX}|)$. The AB-spin states corresponding to each of the X-spin sites are shown for the ordered transitions.

Experimental

(A) Preparation of N,N-Dimethyl Carbamyl Fluoride (DMCF)

This compound was prepared by an exchange reaction between equimolar amounts of *N,N*-dimethyl carbamyl

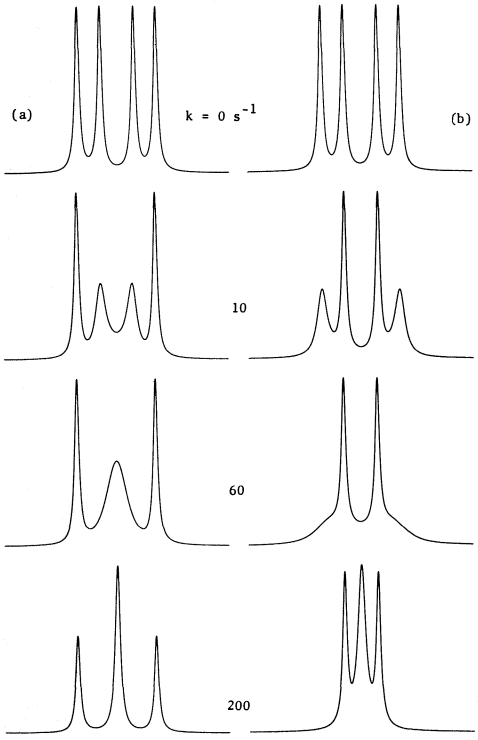

FIG. 4. Intramolecular exchange lineshape function, $V(x)$, for the X-part of an ABX ($J_{AX} = 0$) spectrum: (*a*) $J_{BX} > J_{AX} > 0$; (*b*) $J_{BX} > 0$, $J_{AX} < 0$, and $J_{BX} > |J_{AX}|$.

bromide (DMCB) and AgF, using acetonitrile as solvent, at room temperature. The yield was low (~15%), however, and hence use of SbF_3 as a fluorinating agent (35) allows a more efficient preparation. DMCB was obtained by saturating ~10 g of *N,N*-dimethyl carbamyl chloride with HBr (36) at 0 °C. A N_2 stream was used to remove any HCl or Cl_2 formed and significantly increased the product yield. DMCF was purified by a spinning-band column distillation at 760 mm and 121 °C, the final product giving the elemental analysis: C 39.81 (39.58), H 6.58 (6.59) and F 20.68 (20.88), the values in parentheses being the calculated mole percentages for C_3H_6NOF.

(B) Variable Temperature Nuclear Magnetic Resonance Spectra

The ^1H n.m.r. spectra were obtained at 100 MHz with a Varian HA-100 spectrometer equipped with a V-6031 variable-temperature probe and temperature controller. The V-6031 controller maintains a preset temperature for the N_2 gas heating or cooling the sample, and the gas temperature is sensed at about 5 cm from the sample volume in the spectrometer receiver coil. Thus the sample temperature was measured before and after recording a spectrum using a standard methanol (or glycol) sample and interpolation of the —OH chemical shifts obtained in HA-mode using the data of Van Geet (37). The temperature thus determined is estimated to be accurate to ±0.3 °C and was shown to be stable, within these limits, over a period of about 20 min. The spectra were recorded at sweep rates of 0.02 or 0.05 Hz s^{-1} to best approximate steady-state conditions, and with a low amplitude r.f. field (~0.02 mG) to minimize lineshape distortion due to saturation effects (5). At each temperature, to ensure reproducibility, at least four spectra were digitized and stored using a Fabritek FT-1074 computer interfaced with the HA-100. The interface unit, constructed in our laboratory, consists of a high input impedence differential amplifier for isolation of the A-D converter, logic circuitry for direct frequency calibration of the digital data and a digital/analog read-out for control of the HA-100 recorder. All frequencies were measured, using the V-4315 counter, with reference to TMS as an internal standard. An optimum H_0 field homogeneity was maintained over the temperature range −20 to 80 °C corresponding to a 0.4 Hz resolution (T_2 = 0.8 s) and a reference lineshape that best approximated a symmetrical Lorentzian shape. Dioxane (~2 mol%) was used to give an internal reference line, at a convenient frequency with respect to DMCF, and this linewidth was used to define the effective transverse relaxation time in the absence of chemical exchange, T_2, for DMCF. Wilmad PS-505 5 mm thin-walled sample tubes were used to attain reproducible spinning characteristics and field homogeneity control.

Lineshape measurements were made for DMCF as a 16.5 mol% solution in CCl_4. this solvent being chosen to minimize solvent–solute interactions (38). Solute–solute interactions are minimized in dilute solution. A dilution of DMCF is limited, however, by a decrease in the already small *N*-methyl chemical shift difference, 2Ω, for solute concentrations below the above value. The n.m.r. sample was degassed by the usual freeze–pump–thaw method, and sealed under N_2 at ~1 atm to prevent refluxing at the elevated temperatures required.

(C) Computation of Lineshapes

The ^1H n.m.r. spectrum of DMCF corresponds to the A_3B_3 part of a first-order A_3B_3X ($J_{AB} = 0$) spectrum and hence may be analyzed as the AB-part of an ABX ($J_{AB} = 0$) system, as described in detail in the preceding section.

A Fortran-IV program designated GPLONK has been developed for the efficient iterative fitting of theoretical absorption mode multi-site exchange lineshapes to digital data. This program is based upon eq. 22*a* of ref. 5, which follows directly from the matrix formulation of the complex lineshape function, $G(x)$, *cf.* eq. 4 above. The input consists of (*i*) N experimental intensities (40–100) with arbitrary indexing, (*ii*) frequency calibration data, (*iii*) a baseline correction parameter, (*iv*) a specific normalization data point, (*v*) the linewidth of the internal reference line, and (*vi*) data defining the initial matrices K and Ω, and also the vectors $\boldsymbol{P}$ and $\boldsymbol{I}$, in eq. 4 above. The iterative fitting relies upon a rapidly convergent search using optimized parameter increments, where the rate matrix is varied following the general procedure outlined in ref. 5. An optional variation of spin-site frequencies is available, for the checking of temperature dependence. "Best fit" parameter values correspond to the usual sum of squares of deviations (39), while the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

lineshape fitting error is most conveniently considered as $\varepsilon = (1/N)\Sigma^{N}_{i=1}\,[V'(x_i) - V(x_i)]/V|x$, where $V'(x_i)$ and $V(x_i)$ are the normalized experimental and theoretical intensities, respectively, for the frequency x_i. For the 4 spin-site DMCF exchange system, the time for a complete fit and setting up of control arrays for a CALCOMP plotter on an IBM 360/75 system is less than 6 s, and this time is essentially independent of the number of data points involved as it is governed by the 4 × 4 matrix diagonalization and inversion in eq. 4 above.

(D) Calculation of Activation Parameters

The activation energy, E_a, for the hindered rotation in DMCF was determined from a least-squares fit to the usual Arrhenius equation

$$\log k = -E_a/2.303\,RT + \log A \qquad [5]$$

where k is the first-order rate constant describing the rotation at temperature T and A is the frequency factor for the rate process. A thermodynamical formulation of reaction rates (40) shows that the enthalpy and entropy of activation are given as

$$\Delta H^{\ddagger} = E_a - RT \qquad [6]$$

and

$$\Delta S^{\ddagger} = R\,[2.303 \log (Ah/kT) - 1] \qquad [7]$$

respectively, assuming E_a to be temperature independent. In eq. 7 h is Planck's constant and k is the Boltzmann constant. The free energy of activation, $\Delta G^{\ddagger}$, is then determined as $\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$ at 298 °K. The overall errors quoted for the activation parameters have been estimated from the statistical limits of 95% confidence for E_a and A (39) and a study of the systematic errors (41, 42) involved in the determination of the k values used in eq. 5.

Results and Discussion

In the A_3B_3 part of the A_3B_3X spectrum for DMCF the methyl group *trans* to the carbonyl oxygen, A_3, is assigned to low field of the B_3 group; as the former methyl group, in the planar molecular ground state, is within a shielding region associated with the magnetically anisotropic carbonyl group (43). A similar assignment for DMF (12) has been shown to be correct through use of the nuclear Overhauser effect (44); and also, the magnitude of the *trans* coupling constant, J_{BX} according to the above assignment, is shown to be greater than that of the *cis* coupling, J_{AX}, which is normal (33, 45) for substituted amides. The couplings determined for a dilute solution of DMCF in CCl_4 are $J_{AX} = 0.30 \pm 0.05$ Hz and $J_{BX} = 0.80 \pm 0.05$ Hz, the corresponding values for DMF being 0.35 and 0.06 Hz. Comparison with the related acetyl compounds CH_3CFO (J_{HF} = 7.6 Hz (42)) and CH_3CHO (J_{HH} = 2.9 Hz) shows the effects of the interposed N atom and the N—C partial double bond character, due to delocalization of the N lone pair electrons, in the amide systems. Assuming the hybridization (s-character) to be similar for π-bonding in DMCF and DMF, the relative magnitudes of J_{BX} and changes with respect to the acetyl systems may be considered to be directly related to the detailed form of the π-bonding in the  and  groups.

Thus it is seen that the N–C double bond character is significantly greater for DMF, as $J_{BX}(DMF)/J_{HH} = 4.8$ and $J_{BX}(DMCF)/J_{HF} = 9.5$, and hence the barrier to hindered rotation about this bond is predicted to be higher in DMF. In fact, this is shown to be the case as the activation energy for hindered rotation in DMF is 20.8 ± 0.6 kcal mol^{-1} (12) and the activation energy for DMCF has now been determined as 18.3 ± 0.6 kcal mol^{-1}, *cf.* Table 3.

The couplings J_{AX} and J_{BX} in DMCF are temperature independent within ±0.05 Hz, as defined by the iterative lineshape fitting procedure; and for the 16.5 mol% CCl_4 solution, these couplings averaged to 0.55 ± 0.05 Hz at 78.2 °C in excellent agreement with the value expected for an A_6X spectrum in the fast exchange limit. Furthermore, the observed exchange modified lineshapes unambiguously lead to the conclusion that the signs of these couplings are the same. For example, in the region of coalescence at 44.9 °C the "best-fit" errors for the same and different signs were 1.2 and 2.0%, respectively, exemplifying the precision that may be attained through a total lineshape analysis. A typical experimental lineshape at this temperature is shown along with the corresponding "best-fit" theoretical lineshape in Fig. 5. At this point, it should be mentioned that the spin–spin couplings between methyl protons and the ^{14}N spin have been neglected in the lineshape analysis. Although a ^1H–$\{^{14}N\}$ double resonance study of N-substituted amides indicated that these couplings were negligibly small, the data available from further studies using ^{15}N-amides (34) leads to the ^{14}N coupling constants J_{NA} and J_{NB} of 0.7 and 0.8 Hz, respectively. However, it may safely be assumed that the methyl protons are completely decoupled by the quadrupolar ^{14}N spin–lattice relaxation process (46, 47).

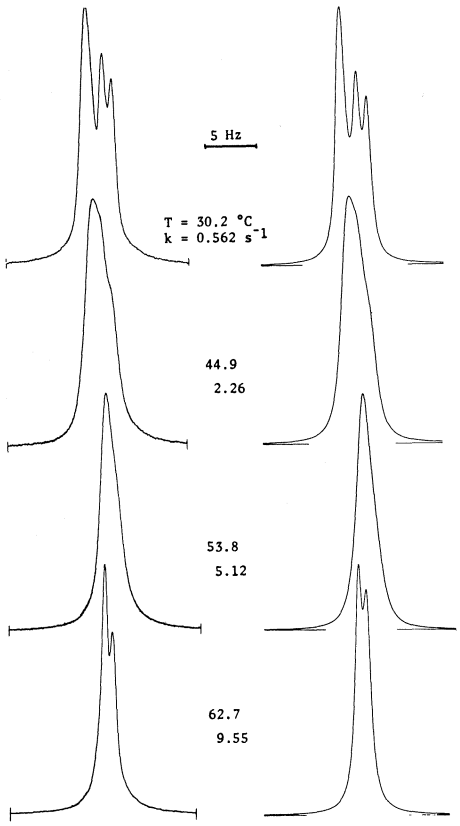

FIG. 5. Comparison of experimental and theoretical exchange lineshapes for DMCF.

In general, indirect spin–spin couplings are relatively insensitive to intermolecular interactions. In the case of a highly polar amide such as DMCF (μ = 4.02 D (48)) in a non-polar solvent, however, electrostatic solute–solute interactions may stabilize the polarized ground-state resonance form $\overset{\oplus}{N}{=}C(O^-)—F$. An increased contribution from this structure then leads to an enhanced coupling between the ^{19}F spin and methyl protons due to the change in N—C double bond character. Such an effect has been observed in that J_{BX} = 1.10 ± 0.05 Hz for neat DMCF, as determined from a complete lineshape fit at −15 °C. This is an increase of about 40% over the same coupling for dilute CCl_4 solutions *cf.* Table 2, and thus it appears that the CCl_4 solvent breaks down a specific solute–solute interaction, probably leading to a simple dimeric form (11), between DMCF molecules. As this coupling constant is unchanged on further dilution, as shown in Table 2, it may be assumed that the dimer concentration is minimal for the 16.5% solution chosen for an accurate determination of kinetic parameters.

J_{BX} = 1.1, J_{AX} = 0.4 Hz

Chemical shifts are usually more sensitive to intermolecular interactions, and indeed the chemical shifts for the methyl groups in DMCF (and the shift difference 2Ω) are solvent-, concentration-, and temperature-dependent, as shown in Table 2 and Fig. 6. These chemical shifts are predominantly due to the combined effect of the magnetic susceptibility anisotropies associated with the C—F and C=O bonds. It may be considered that the NCO and NCF bond angles are both close to 120° for approximately regular sp^2 hybridization of the C atom,[1] and thus the small methyl chemical shift difference (~0.01 p.p.m.)

[1]The structure of DMCF has not been determined experimentally, but comparison of the structural data available for formamide (49), acetaldehyde (50), and acetyl fluoride (51) leads to ∠NCO = 128° and ∠NCF = 112.5°. These bond angles also correspond to a minimum energy configuration in the CNDO/2 s.c. approximation (52).

implies that the charge distributions localized in these two bonds are of similar forms as the methyl groups *cis* and *trans* to the carbonyl group are in shielding regions having very nearly identical characteristics. This is to be compared with the shielding regions for the methyl groups in DMF, due to a carbonyl group only, giving $2\Omega = 17.5$ Hz at 100 MHz ($\sim$0.2 p.p.m.). As the C=O magnetic anisotropy is due to the axially asymmetric π-electron distribution in this group, it follows that delocalization of fluorine $2p\pi$-electrons, as represented by the resonance form N—C(O$^-$)=$\overset{\oplus}{F}$, may be significant in the ground-state of DMCF. The small temperature dependence of 2Ω may be ascribed to an intermolecular dipolar association which affects the magnetic anisotropies of the C=O and/or C—F groups and which varies to a small extent with temperature. It should be noted that this temperature dependence, as determined from the complete lineshape analysis for DMCF in CCl_4, is only 0.008 p.p.m. over the temperature range -15.1 to 78.2 °C. All chemical shift variations, within $\pm$0.05 Hz, were shown to be regular and reproducible over multiple lineshape fits, *cf.* Fig. 6.

The first-order rate constants, k s^{-1}, describing the hindered rotation about the N—C bond for DMCF as a 16.5 mol% solution in CCl_4 are listed in Table 3. These rate constants are average values obtained from multiple complete lineshape fits at each temperature. The corresponding temperature dependent chemical shifts are those given in Table 2, while the couplings J_{AX} and J_{BX} were assumed to be temperature independent. Because of the very small chemical shift difference 2Ω involved, the temperature interval for reliable k determinations is reduced to 66 °C and the overall k variation is only of the order of 200. The errors for the representative lineshape fits shown in Fig. 5 are maximal for very slow and very fast exchange[2] as accurately reproducible spectra for the DMCF four-site exchange system are very difficult to obtain in these limits, even with the stability afforded by a field-frequency locked spectrometer. For example, the average k value at 30.2 °C is 0.550 s^{-1} whereas six lineshape fits at this temperature gave values ranging

[2]These deviations may also arise from inherent inadequacies in the formulation of the lineshape function $V(x)$, such as the assumption of equal transverse relaxation times for all spin-sites in the absence of exchange. These relaxation times may be modified by time-dependent anisotropic chemical shift and anisotropic dipole–dipole interactions (54) and also by a cross-relaxation arising from these two interactions in DMCF.

from 0.362 to 0.944 s^{-1} with fitting errors of 3.5–6.2%. The resultant Arrhenius plot, however, is most satisfactory and is shown in Fig. 7. The activation parameters derived from the temperature independent Arrhenius constants, E_a and log A, and evaluated at 25 °C are given in Table 3.

For hindered rotations in amides the entropy of activation $\Delta S^{\neq}$ derived through complete n.m.r. lineshape analyses is normally relatively small; and in general, as increasing care is taken to remove systematic errors in obtaining kinetic data for a given rate process using n.m.r. methods the values of E_a and log A tend to increase (12, 41) leading to a value of $\Delta S^{\neq}$ close to zero. This entropy change is most probably due to a difference in the solvation structures, formed by dipolar solute–solvent association, for the ground and transition states of an amide. Such an association between the strongly polar DMCF and CCl_4 is possible, to some degree, through induced polarization of the solvent molecules. Therefore, if a solvation effect is dominant, a small increase in entropy is expected on formation of the transition state in amides as the dipole moment for this state is smaller than the moment for the ground state (52). For example, the calculated dipole moments, using s.c. theory, for the ground and transition states of carbamyl fluoride in minimum energy configurations are 3.98 and 3.41 D, respectively, which may be compared with the experimental value of 4.06 D (24). The entropy of activation determined here for DMCF, $\Delta S^{\neq} = -1.4 \pm 2.1$ cal deg^{-1} mol^{-1}, is formally negative but may only be considered to be very small. For the hindered rotation under consideration, a free energy change is expected to be determined primarily by intramolecular effects and hence this activation parameter is much simpler to interpret than the energy of activation which is sensitive to intermolecular effects. It is well known that there is a general tendency in rate processes in solution for enthalpy and entropy changes to compensate each other (53) so that the effective change in free energy is reduced and hence becomes less sensitive to external effects. The free energy of activation for DMCF has been determined as $\Delta G^{\neq} = 18.2 \pm 0.6$ kcal mol^{-1} and this particular parameter will be used in a forthcoming correlation of the bonding characteristics in a complete series of C-substituted *N*,*N*-dimethyl amides.

Nuclear Magnetic Resonance Studies of Multi-site Chemical Exchange. III. Hindered Rotation in Dimethylacetamide, Dimethyl Trifluoroacetamide, and Dimethyl Benzamide

L. W. Reeves, R. C. Shaddick, and K. N. Shaw
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received March 16, 1971

The experimental application of a multi-site exchange theory developed recently has been made to three restricted rotation barriers in amido-type systems. Inclusion of 8 spin-sites in the analyses of the line shapes for spectra of *N,N*-dimethyl trifluoroacetamide and dimethyl acetamide leads to improved values for the activation parameters. Variation of chemical shifts with temperature is included in the iterative fitting procedure. The determination of the relative signs of long range couplings and the inclusion and measurement of unresolved couplings has been accomplished. The barrier for hindered rotation in *N,N*-dimethyl benzamide has been re-investigated including the effect of relatively large chemical shift changes with temperature. The internal consistency of the measurements from all aspects indicates that systematic errors common in the determination of energy barriers by steady-state nuclear magnetic resonance (n.m.r.) have been largely eliminated and hence the activation parameters obtained form a reliable addition to a compilation of experimental data pertaining to the bonding in a related series of simple C-substituted amides.

L'application expérimentale d'une récente théorie de l'échange entre plusieurs sites a été faite pour trois barrières de rotation restreinte dans des structures du type amide.

L'analyse des formes de raies d'un système à huit sites des spectres de la *N,N*-diméthyle trifluroacétamide et de la diméthyle acétamide conduit à des valeurs plus précises des paramètres d'activation. Le procédé d'ajustement par iteration tient compte de la variation du déplacement chimique avec la température. Les signes relatifs des constantes de couplage à longue distance ont été déterminés, en incluant les couplages non résolus qui ont été mesurés.

La barrière de rotation restreinte du *N,N*-diméthyle benzamide a été réexaminée en tenant compte de la variation assez importante du déplacement chimique avec la température.

La consistance interne des différentes mesures indique que les erreurs systématiques communes à la détermination des barrières d'énergie par r.m.n. ont été fortement réduites. Les paramètres d'activation ainsi obtenus constituent donc une contribution sérieuse à l'ensemble des données expérimentales se rapportant au mode de liaison dans une série d'amides simples C-substituées.

Introduction

Although long range spin–spin couplings present in amido-type structures have been measured for some time in high resolution n.m.r. (1, 2), until very recently these couplings have been either ignored, eliminated by double irradiation decoupling (1, 6), or treated by approximate methods (3–5) in kinetic studies of the hindered rotation about the amide N—C bond. Since the chemical shifts modulated by the internal rotation are usually quite small in these molecules, the neglect of long range *cis* and *trans* coupling constants across the N—C bond can, in principle, lead to serious errors in rate constants describing the rotation. Under steady-state n.m.r. decoupling conditions, the lineshape distortion associated with the decoupling process is difficult to assess quantitatively and hence kinetic studies using this method are usually unreliable. For example, a recent double resonance study of dimethyl formamide and a normal n.m.r. study of the corresponding d_1 compound under similar solvent and concentration conditions gave free energies of activation of 21.7 and 23.0 kcal mol^{-1}, respectively, even though it is widely recognized that this particular activation parameter is least sensitive to intermolecular interactions and systematic experimental errors (3, 5). These values are to be compared with results obtained independently from complete lineshape analyses which are consistent within the experimental errors involved, namely, 20.8 ± 0.6 (7) and 20.5 ± 0.6 (8) kcal mol^{-1} at the same temperature 298 °K. In the former lineshape analysis, the hindered rotation was represented by two spin transfer processes between 4 sites defined by the chemical shift difference for the *N*-methyl protons and the *cis* and *trans* couplings to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

formyl proton. It was also recognized that the relative signs of these coupling constants could be determined through the lineshape analysis, but a conclusive experimental verification of this point (and vindication of the exchange model used) was precluded by the very small couplings involved. The initial papers in this series (9, 10) present a complete matrix formulation of general multi-site chemical exchange in first-order spin systems. Through the definition of spin-sites long range couplings are simply incorporated into the lineshape analysis. This matrix formulation of exchange has been applied to the study of n.m.r. line shapes for the methyl group signals of *N,N*-dimethyl carbamyl fluoride (10). The chemical shift difference for *cis* and *trans* methyl protons is very small and varies from 2.2 to 1.4 Hz at 100 MHz at different temperatures. Temperature dependent chemical shifts in amido type systems are not uncommon (11) and must be allowed for in accurate kinetic studies. The further complication of *cis* and *trans* coupling to the extent of 0.3 and 0.9 Hz made the line shape fitting procedure difficult. However, it was possible not only to determine relative signs of these coupling constants, but also by iterative fitting to reliably reproduce relative spin-site positions to ± 0.05 Hz. In two of the three molecules studied in this work long range coupling is present, and in one case, was not resolved under the best operating conditions of the spectrometer. Thus a full rate matrix corresponding to 8 spin-sites is required to compute and fit the lineshapes for these molecules to obtain reliable primary kinetic data.

The aim of the present series of papers thus far is to study the hindered rotation in a related series of simple C-substituted amides, using complete lineshape analyses of steady-state n.m.r. spectra, in an attempt to compile reliable data that may be used in conjunction with that available from semi-empirical s.c.f.-l.c.a.o.-m.o. calculations and other spectroscopic techniques to develop a more complete description of the electronic charge distributions and bonding characteristics in these molecules. Although a large amount of kinetic data has appeared in the literature following the initial study by Holm and Gutowsky on *N,N*-dimethyl formamide, as has already been pointed out (4, 10), until very recently little of these data can be used in semi-quantitative correlations and many of the simpler molecules have yet to be studied. Along with the data now appearing from other laboratories using total lineshape analyses, it is hoped that in the near future a meaningful and detailed correlation of the activation parameters with bonding characteristics of a series of related amides in liquids may be presented.

Experimental

All n.m.r. spectra were recorded on a Varian HA-100 spectrometer with the lock channel activated at the tetramethylsilane (TMS) or hexamethyldisiloxane (HMDS) proton resonance, (added to the extent of ~1% to all solutions). Careful checks on the line width and shape (ideally Lorentzian) in the absence of chemical exchange ensured a line width at half height of less than 0.5 Hz, but often it was as low as 0.2 Hz. Spectra were recorded on a 50 to 100 Hz sweep width and 1000 s sweep time. Each recording of a spectrum was in the limit of negligible saturation as verified by changing r.f. power and noting changes in signal amplitude.

The variable temperature equipment, standard on the HA-100 spectrometer, was used at temperatures other than ambient (30°). The V-6031 controller maintains a preset temperature for the N_2 gas heating or cooling the sample and the gas temperature is sensed at about 5 cm from the sample volume in the spectrometer receiver coil. Thus the temperature was determined before and after recording a spectrum by using a standard methanol or glycol sample and measuring the methyl to —OH and methylene to —OH chemical shifts, respectively, and the calibration data of Van Geet (12). The temperature thus determined is estimated to be accurate to ± 0.3 °C and was shown to be stable, within these limits, over a period of about 20 min. By using standardized sample tubes and constant optimized tube spinning and N_2 gas flow rates, the effects of thermal gradients as indicated by the line shapes symmetry across the small sample volume within the receiver coil are minimal.

N,N-dimethyl benzamide was purchased from K and K Laboratories. *N,N*-dimethyl acetamide was obtained from Aldrich Chemicals and purified by distillation under reduced pressure. *N,N*-dimethyl trifluoroacetamide was prepared by bubbling dimethyl-amine into ~10 g of methyl trifluoro-acetate kept at 0 °C. The saturated solution was allowed to stand for 12 h to complete the reaction and the trifluoroacetamide was distilled from the reaction mixture at 760 mm and 134 °C in 85% yield. The product was further purified by distillation under reduced pressure. In all cases the purity was checked by n.m.r. spectra taken at high gain. No impurities greater than ~0.5% by volume were detected in any sample used for study.

The matrix formulation of the Bloch equations including chemical exchange reported earlier has been used to generate the steady-state n.m.r. line shapes in the absence of saturation. A computer program GPLONK incorporates these equations to iteratively fit the experimental intensities for at least 60 digital data points, including enough base line to reliably define zero intensity. The absorption mode line shape function is given by the imaginary part of

$$G(x) = -i\omega_1 M_0 I[\mathbf{R}_2 + i\mathbf{w}]^{-1}.\boldsymbol{P}$$

which occurs as eq. 18 in ref. 9. $\mathbf{R}_2$ includes a spin-site

transfer rate matrix **K** as previously defined (10), **w** is an ($n \times n$) diagonal frequency deviation matrix, ***P*** is a site population ($n \times 1$) vector, and ***I*** is a row vector with each of the ($1 \times n$) elements unity. The independent variable x for describing frequency appears only in the diagonal matrix **w**, and complete diagonalization of the matrix $[\mathbf{R}_2 + i\mathbf{w}]$ allows the rapid numerical evaluation of the imaginary part of $G(x)$ by procedures previously outlined.

The activation energy, E_a, for hindered rotation is determined from a least-squares fit to the usual Arrhenius equation

$$\log k = -E_a/2.303\ RT + \log A$$

where k is the first-order rate constant describing the rotation at temperature T and A is the frequency factor. The enthalpy and entropy of activation are then given by (13)

$$\Delta H^* = E_a - RT$$

and

$$\Delta S^* = R[2.303 \log Ah/kT - 1]$$

respectively, where h is Planck's constant and k is the Boltzmann constant. The free energy of activation, ΔG^*, is then determined as $\Delta G^* = \Delta H^* - T\Delta S^*$ at 298 °K. The overall errors quoted for the activation parameters have been estimated from the statistical limits of 95% confidence for E_a and log A and a study of the systematic errors involved in the determination of the k values and the temperature T used in the Arrhenius equation.

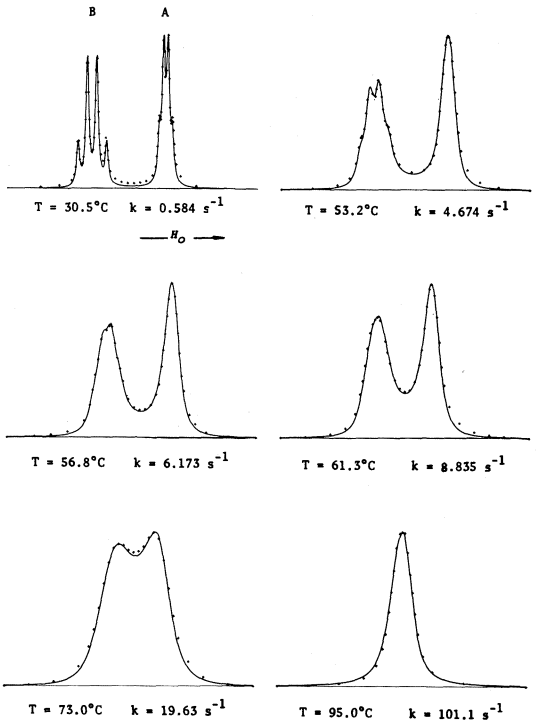

FIG. 1. Line shape fits of the methyl group spectra of DMTFA at a series of temperatures. The solid lines are computed spectra, with the rate constants given below each plot, and the dots are experimental intensities from normalized spectra.

Results and Discussion

Dimethyl Trifluoroacetamide

The molecule *N,N*-dimethyl trifluoroacetamide (DMTFA) has a proton magnetic resonance spectrum which, in the slow exchange limit, consists of two chemical shifted quadruplet signals. This is shown in Fig. 1. The quadruplet signals arise from long range coupling from the $-CF_3$ group to the *trans* and *cis* methyl groups. The spectrum is the A_3B_3 part of an $A_3B_3X_3$ system of nuclei, but with $J_{AB} = 0$. The methyl group *trans* to the carbonyl oxygen (*cis* to $-CF_3$), A_3, is expected to show a smaller coupling J_{AX} as compared with the *trans* coupling, J_{BX}, as is normal for substituted amides (7, 14, 15). On this basis, as shown in Fig. 1 at $T = 30.2$ °C, the A_3 methyl group is assigned to high field of the B_3 group. Such an assignment is opposite to those made for *N,N*-dimethyl formamide (DMF) (7) and *N,N*-dimethyl carbamyl fluoride (DMCF) (10). The very small methyl proton chemical shift difference for DMCF has been interpreted in terms of similar magnetic shielding cones for the C=O and C—F groups, which are approximately symmetrically placed with respect to the N—C bond and reduce the effective shielding in the region about the methyl group *cis* to the carbonyl oxygen. Hence, the reversal of the methyl chemical shifts in DMTFA may be considered as due to the particular form of the magnetic anisotropy of the C—CF_3 group giving rise to a shielding region about the methyl group *trans* to the carbonyl oxygen. Such a reversal is consistent with each of the C—F bonds having a significant anisotropy, as already shown in DMCF, and the removal of substituent symmetry about the N—C bond. It is possible that, due to the close proximity of $-CH_3$ and $-CF_3$ groups, a through-space coupling could increase the magnitude of J_{AX} such that $J_{AX} > J_{BX}$. Such a mechanism has been proposed for the coupling of H and F nuclei separated by five bonds (16). However, the measured coupling constants for DMTFA are 1.5 and 0.7 Hz and these may be compared with those for DMF: $J_{AX} = 0.4 \pm 0.1$ and $J_{BX} = 0.9 \pm 0.1$ Hz (7) and therefore the through-bond coupling ratios J_{trans}/J_{cis} are the same for the above assignments. Similar ratios of coupling constants have also been determined for *N*-methyl, *N*-alkyl trifluoroacetamides (17); an example being $J_{AX} = 0.8$ and $J_{BX} = 1.6$ Hz

For personal use only.

for N—CH_3, N—$(CH_2)_3$—RH_3. Very recently (18), the coupling J_{BX} has been measured for trifluoroacetamide in acetone as 1.8 Hz, with $J_{AX} < 0.2$ Hz. These couplings may be compared with those for ^{15}N-formamide in acetone $J_{AX} = 1.45 \pm 0.05$ Hz and $J_{BX} = 13.35 \pm 0.05$ Hz, and again all ratios are consistent with the assumption that $J_{BX} > J_{AX}$ for DMTFA. The hindered rotation process about the N—C bond modulates the chemical shift difference between the *cis* and *trans* methyl groups and the rotation involves all 8 spin-sites represented by the individual components of the spin multiplets. Labelling sites 1 to 8 from low to high field, the population vector has elements [1/16, 3/16, 3/16, 1/16, 1/16, 3/16, 3/16, 1/16]. These elements allow for the equal population environmental sites (10). Since the spin states of the —CF_3 group are long lived (T_1 long), the labels of the spin-sites 1 to 4 (and 5 to 8), which correspond to the spin states of the —CF_3 group with appropriate statistical weights persist during the chemical exchange. The chemical exchange therefore, via the hindered rotation, permutes the frequencies of 1 and 5, 2 and 6, 3 and 7, and 4 and 8 if J_{AX} and J_{BX} have the same sign; or, 1 and 8, 2 and 7, 3 and 6, and 4 and 5 if J_{AX} and J_{BX} are opposite in sign. The line shapes generated by the multi-site exchange theory are quite different and a relative sign determination can be made from the experimental fit. In the fast exchange limit the remaining quadruplet has a splitting (1/2) ($J_{AX} + J_{BX}$) if the couplings have the same sign or (1/2) ($|J_{BX}| - |J_{AX}|$) for $|J_{BX}| > |J_{AX}|$ if they have opposite signs. The former result is observed experimentally.

The transfer rate matrix defined in eq. 3*a* of the earlier paper (9) is explicitly written out below

$$\begin{array}{c|cccccccc} & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 1 & k & & & & -k & & & \\ 2 & & k & & & & -k & & \\ 3 & & & k & & & & -k & \\ 4 & & & & k & & & & -k \\ 5 & -k & & & & k & & & \\ 6 & & -k & & & & k & & \\ 7 & & & -k & & & & k & \\ 8 & & & & -k & & & & k \end{array}$$

The transverse relaxation times, in the absence of rotation, are assumed to be equal for all sites and to be directly related to the half width taken from a sharp peak in the spectrum added as a line shape reference (dioxane). The rate matrix written out above assumes that J_{AX} and J_{BX} have the same sign, while the corresponding matrix for opposite relative signs is written out below

$$\begin{array}{c|cccccccc} & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ 1 & k & & & & & & & -k \\ 2 & & k & & & & & -k & \\ 3 & & & k & & & -k & & \\ 4 & & & & k & -k & & & \\ 5 & & & & -k & k & & & \\ 6 & & & -k & & & k & & \\ 7 & & -k & & & & & k & \\ 8 & -k & & & & & & & k \end{array}$$

In the computation of lineshapes determined by the above rate matrices, the numerical procedure is based upon a single diagonalization of a complex matrix and an inversion of the associated transformation matrix. To increase the efficiency of the large number of computations involved in an iterative line shape fitting, these 8 × 8 matrices may be converted to block-diagonal form. The overall diagonalization then reduces to that for four 2 × 2 matrices, one such matrix being defined by the elements (1,1), (1,5), (5,1), and (5,5) of the matrix for J_{AX} and J_{BX} of the same sign. The population vector corresponding to this particular sub-matrix is now [1/16, 1/16]. Of course, this factoring of the rate matrix is due to the methyl groups exchanging between the two basic environmental (chemical shift) sites. In this manner, the cycle time for iterative fitting of the 8-site exchange line shape is of the order of 0.4 s on an IBM 360-75 computer.

The experimental line shapes at all temperatures are reproduced by the matrix which assumes that J_{AX} and J_{BX} have the same sign. In Fig. 1, the continuous line is the computed line shape and the data points were obtained from a normalized experimental spectrum. The values of J_{AX} and J_{BX} are 0.70 ± 0.05 and 1.50 ± 0.05 Hz, respectively, with no temperature or discernable solvent dependence. The error limits correspond to the minimum increment for these parameters in the line shape fitting. Fits for multiple spectra at the lower temperatures were reproducible within these limits. The effective positions of all 8 lines in the absence of exchange, used in the iterative line shape fit, are plotted as Fig. 2 to illustrate the consistency of the data and to obtain the temperature dependence of the chemical

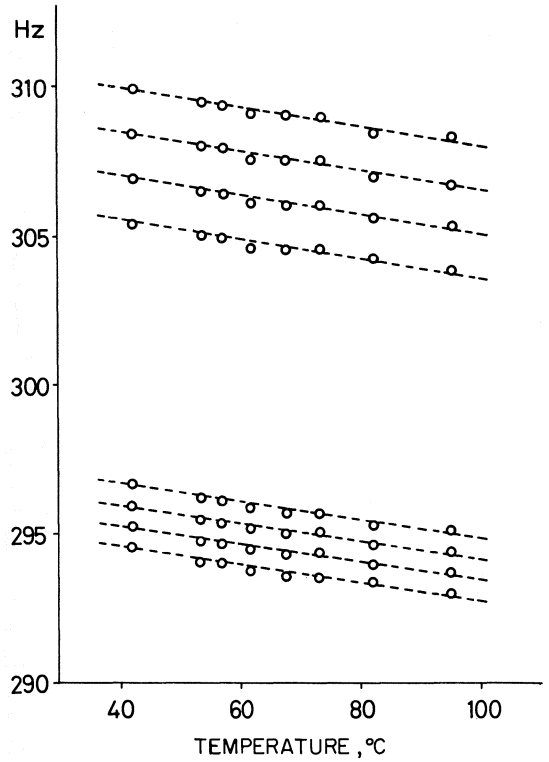

FIG. 2. Peak positions of the methyl proton signals in DMTFA as a function of temperature from the complete line shape fit data. These peak positions are measured in Hz from internal TMS.

shifts. The solvent was CCl_4 and the concentration of DMTFA was 11.25 mol%, with 1.9% dioxane and 1% TMS.

The rate constants and kinetic parameters obtained for the hindered internal rotation in DMTFA are given in Table 1 using the reaction rate theory described in the experimental section. All activation parameters are calculated at 298.2 °K and the Arrhenius plot is shown on a composite diagram, see Fig. 7. The rate constants determined using an approximate analysis (1) have been included in Table 1, and it is seen that there is a discrepancy of a factor of 2–4 in these constants as compared with the complete line shape study. This systematic error in the primary data leads to a very low energy of activation $E_a = 9.3 \pm 0.6$ kcal mol^{-1}. The spin-echo method (19, 20) is an alternative and independent technique for the study of chemical exchange, and the rate constants previously determined (21) for DMTFA are also listed in Table 1. Again there are discrepancies, although certainly reduced, and in this case the rate constants are low in both the slow and fast exchange limits. This is contrary to the error characteristics previously discussed for a spin-echo study of DMF (3), but may be due to the use of a simplified two-site theory to fit the DMTFA data in that the heteronuclear couplings J_{AX} and J_{BX} (J_{BX} comparable with 2Ω in determining site Larmor frequencies) should be included in a complete description of the modulation of the Carr–Purcell echo train (17, 22). It should be noted, however, that the free energies of activation derived from complete line shape analysis, approximate line shape analysis, and spin-echo decay are 18.05 ± 0.30, 18.0 ± 0.6, and 17.6 ± 1.5 kcal mol^{-1}, respectively, while the activation energies vary from 9.3 to 20.6 kcal mol^{-1}. Once again the compensation of effective $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values, corresponding to large systematic experimental errors in the determination of rate constants, leads to an approximately constant $\Delta G^{\ddagger}$ value (5).

Dimethyl Acetamide

A solution which contained 14.9 mol% of *N*,*N*-dimethyl acetamide (DMA) in CCl_4 as solvent was prepared with 1.7 mol% dioxane as a line shape standard and 1% hexamethyl disiloxane for a lock signal. A number of previous studies have been made of the hindered rotation barrier in this molecule (1, 4, 23–27), and the results show the usual inconsistencies some of which have been discussed in detail (4). The deviations in the values obtained for the free energies of activation from independent studies with similar solvents and solute concentrations are well outside the quoted experimental error bounds. Such deviations, however, are not unexpected in view of the fact that *cis* and *trans* scalar couplings between the *N*-methyl and $-CH_3$ groups have either been ignored or reduced by specific deuteration and the only total lineshape study (4) relies upon an approximate two-site model for the double quadruplet A_3B_3 part of an $A_3B_3X_3$ spectrum with $J_{AB} = 0$. In organic solvents, these couplings are not resolved as multiplets under the best operating conditions of the spectrometer. The most obvious spectral feature which reveals the presence of these long range couplings is the difference in apparent line width of the two methyl peaks in the region where exchange is minimal (very slow rotation).

They can be readily included, however, as distinct Larmor frequencies corresponding to a full 8 spin-site rate matrix and the generated line shapes may then be used to determine the unresolved couplings to a high degree of precision. The rate matrix has the same form as the case of DMTFA, with the relative sign ambiguity for J_{AX} and J_{BX}. In this case it is very difficult to decide relative signs because of the very small couplings, but more consistent line shape fits were obtained for J_{AX} and J_{BX} of the same sign. These features are illustrated by the experimental points and computed line shapes which are presented in Fig. 3. The methyl group *trans* to the carbonyl oxygen, A_3, is assigned to low field of the B_3 group. Such an assignment is consistent with that for DMF (7). The relatively small magnetic anisotropy of the C—H bond (28), and hence the $-CH_3$ group, is not expected to significantly modify the form of the magnetic shielding in the *N*-methyl region due to the C=O group. This is shown by the *N*-methyl chemical

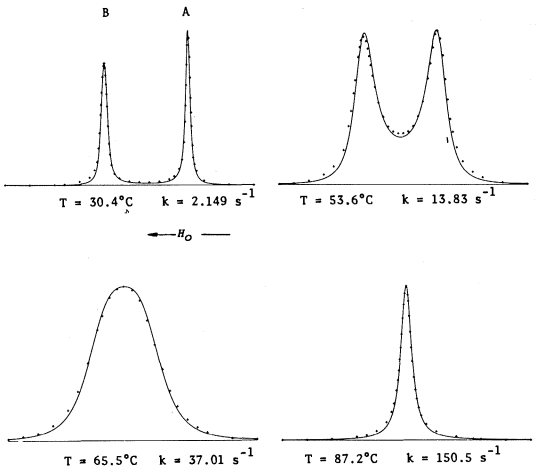

FIG. 3. Line shape fits of the methyl group proton spectra of DMA. Inequality in the heights of the methyl peaks is indicative of unresolved long range coupling. The inclusion of these unresolved couplings in a full 8 site analysis enables the values to be determined.

shift differences for CCl_4 solutions of DMF and DMA: 17.5 and 17.0 Hz, respectively, at 100 MHz and $T = 30$ °C. A temperature dependence of these chemical shifts was required for minimal error in the fits and is illustrated in Fig. 4. In the fast exchange region the extrapolation of the chemical shifts *vs.* temperature from the slow exchange region sufficed to obtain excellent consistency between the experimental and com-

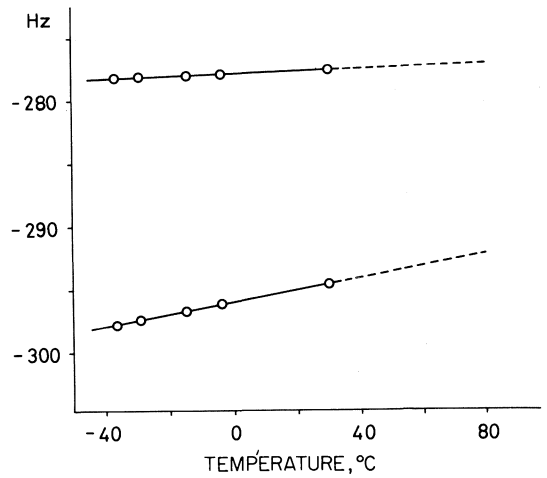

FIG. 4. Chemical shift of the methyl protons in DMA as a function of temperature (TMS internal standard). The dotted lines indicate the chemical shift data for the fast exchange limit, used to complete the line shape fits in this region.

puted spectra. The best fit data also give the values $J_{AX} = 0.10 \pm 0.05$ Hz (*cis*) and $J_{BX} = 0.40 \pm 0.05$ Hz (*trans*) at all temperatures. The J_{AX} coupling has been determined for the first time, while the J_{BX} value may be compared with that for aqueous solutions of DMA and *N*-methyl acetamide (29): $J_{trans} = 0.5$ Hz.

The kinetic data for DMA is given in Table 2. The energy of activation is 16.85 ± 0.41 kcal mol^{-1} and this value is to be compared with the values determined by recent less rigorous analyses (4, 27) for dilute solutions of DMA: $E_a = 20.6 \pm 0.3$ and 22 ± 1 kcal mol^{-1}. The increase in the former energy of activation (and free energy of activation 18.6 as compared with 17.3 kcal mol^{-1}) may be due to a relatively strong dipolar association of the amide with the solvent dimethyl sulfoxide. The latter increased value, however, is apparently a direct consequence of the particular analysis as all kinetic parameters previously determined by this method (24) are consistently high.

Dimethyl Benzamide

The methyl signals of *N*,*N*-dimethyl benzamide (DMB) are especially solvent-, concentration-, and temperature-dependent, but there is no long range coupling involving the *N*-methyl groups to complicate the line shape fits. There is a serious lack of consistent data on this barrier (1, 30) and only estimates of $\Delta G^{\ddagger}$ from coalescence of the methyl signals (3) can be made. DMBA was dissolved in CS_2 at a concentration of 2 mol% and 2% of $CHCl_3$ was added for a line shape standard, while the lock signal was provided by ~1% TMS.

TABLE 2. Kinetic data for DMA (14.9 mol% in CCl_4)

Temperature (°C)	k (s^{-1})
30.4	2.149
35.6	3.350
42.4	5.623
53.6	13.83
65.5	37.01
68.3	40.74
72.8	59.57
75.4	92.94
77.2	95.82
87.2	150.5

$E_a = 16.85 \pm 0.41$ kcal mol^{-1}
$\Delta S^{\ddagger} = -3.59 \pm 1.23$ cal deg^{-1} mol^{-1}
$\Delta H^{\ddagger} = 16.26$ kcal mol^{-1}
$\Delta G^{\ddagger} = 17.33$ kcal mol^{-1} (298.2 °K)

The rate matrix is trivial in this equal population two-site case, but the variation of Larmor frequencies required that total chemical shifts be selected and iterated to improve the final fits of the experimental to theoretical line shapes. The variation in chemical shifts with temperature is presented as Fig. 5 and typical line shape fits as Fig. 6. The best kinetic parameters are shown in Table 3.

Figure 7 is a composite diagram of Arrhenius plots for the three molecules studied here.

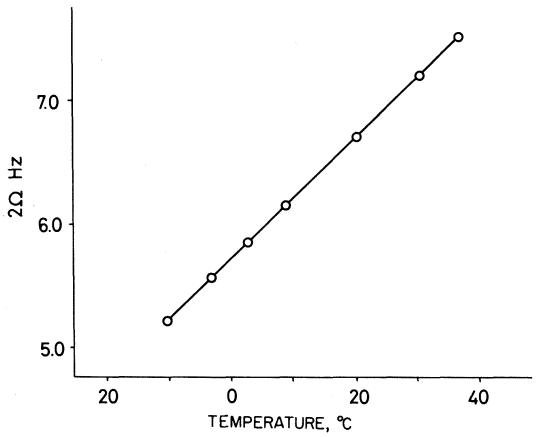

FIG. 5. Relative chemical shifts in DMBA as a function of temperature in the solutions studied. These shift differences were obtained by iterative fitting of the full line shape with chemical exchange.

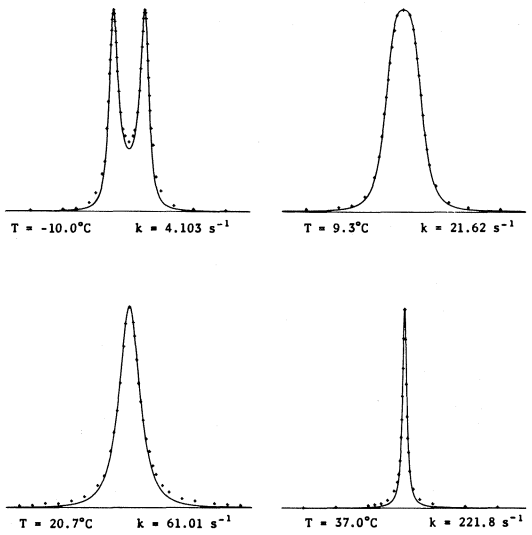

FIG. 6. Complete line shape fits for DMBA at several temperatures with adjusted chemical shifts.

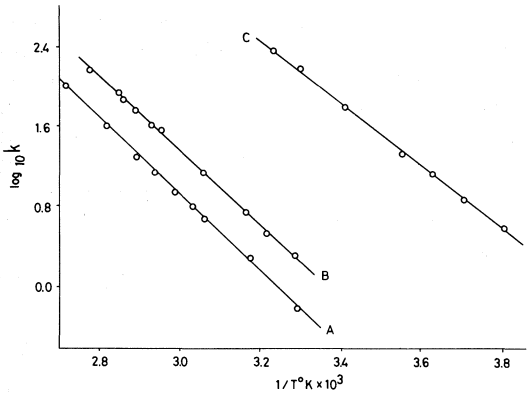

FIG. 7. Arrhenius plots for the rate constants for (*A*) DMTFA (*B*) DMA, and (*C*) DMBA for solutions described in the text.

3.0	13.01
−2.9	7.589
−10.0	4.103

E_a = 14.00 ± 0.25 kcal mol^{-1}
$\Delta S^{\ddagger}$ = −4.69 ± 0.88 cal deg^{-1} mol^{-1}
$\Delta H^{\ddagger}$ = 13.40 kcal mol^{-1}
$\Delta G^{\ddagger}$ = 14.80 kcal mol^{-1} (298.2 °K)

Conclusion

The general problem of the factors which influence the barriers to rotation in an amido system is obviously complex. The role of steric as well as electronic factors are difficult to separate and indeed the reliability of energies of the transition state for comparative purposes, other than at infinite dilution in the gase phase is suspect. The recent review of Kessler (5) points out the factors which, qualitatively speaking, seem to be important. In dilute solution, and hence in the absence of appreciable intermolecular effects for a range of non-polar solvents, it is possible to correlate $\Delta G^{\ddagger}$ with parameters describing the electronic charge distribution in amides and the interaction of a C-substituent with the N—C═O bonding system (31). A similar correlation with parameters describing substituent inductive effects and steric interactions of a bulky substituent has already been attempted (4). In this present series of papers, the precision of the line shape fit data does begin to place some degree of confidence in the values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. When more related amido systems have been studied to give precise line shape fit data over a range of solvents, the interpretation of these activation parameters in terms of solvation of the ground and transition state can be attempted (32). It may then be possible to develop a more general model for the structure of amides in solution by comparison of the free energies of activation $\Delta G^{\ddagger}$, which may be considered to describe intramolecular interactions to a good approximation, and $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ which are expected to give more detailed information on intermolecular interactions.

The Penetrating Power of β-Decay Recoils of Epithermal Energies in Organic Matter

N. H. SHAFRIR

Department of Nuclear Science, Technion, Israel Institute of Technology, Haifa, Israel

Received May 5, 1971

A method for the measurement of the extent of dislocation of the β-decaying nucleus from its equilibrium position is described. An ionized layer formed at the surface of an aqueous solution of an ionic surface-active substance served as a source of β-disintegrating atoms. The primary adsorbed surface-active ions give rise to an electrical double layer within the liquid phase. When the solution contains β-active ions, some will join the electrical double layer near the surface as counter ions. It was found that radioactive β-recoils arising in an adsorbed surface layer are able to leave the surface, collected on a negatively charged plate, and counted. In order to reach the gas phase, the β-recoils have to penetrate the primary organic adsorption layer. When the expanded adsorption layer is gradually compressed, particles of lower energy are stopped, resulting in decreased recoil activity. Extrapolation to zero β-recoil activity gives an approximate value for the mass per unit area of organic material which stops completely atoms of certain initial energy. For particle energies between 2 to 22 eV, a linear dependence is found between the maximum β-recoil energy and the "penetrating power". The corresponding organic stopping layers for this energy region are between 1.0 to about 1.6×10^{-7} g/cm^2.

On décrit une méthode pour mesurer l'étendue de déplacement du noyau altérant β à partir de sa position d'équilibre. On s'est servi d'une couche ionisée formée à la surface d'une solution aqueuse d'une substance ionique de surface active comme source d'atomes désintégrants β. Les ions à surface active adsorbés en premier lieu causent la formation d'une double couche électrique au sein de la phase liquide. Quand la solution contient des ions actifs β, quelques uns d'entre eux vont se joindre à la double couche électrique près de la surface sous forme de contre-ions. On a découvert que les particules radioactives de recul β naissant dans une couche superficielle adsorbée peuvent quitter la surface, être recueillis sur une plaque chargée négativement et ensuite comptés. Pour se rendre à la phase gazeuse, les particules de recul β doivent d'abord pénétrer la première couche d'adsorption organique. Quand la couche étendue d'absorption est comprimée graduellement, les particules de plus faibles énergies sont arrêtées, causant une diminution d'activité pour la particule de recul. On obtient par extrapolation à activité nulle de la particule de recul β, une valeur approximative pour la masse par unité de surface, de matériel organique capable d'arrêter complètement les atomes possédant une certaine énergie initiale. On trouve une dépendance linéaire entre l'énergie maximale de la particule de recul β et le pouvoir pénétrant pour des particules dont l'énergie se situe entre 2 et 22 eV. Les couches d'arrêt organiques correspondant à cette région d'énergie se situent approximativement entre 1.0 et 1.6×10^{-7} g/cm^2.

Canadian Journal of Chemistry, 49, 3692 (1971)

Introduction

One of the important primary effects of nuclear transformations is the subsequent motion of the transmuted atom, in accord with the conservation of momentum and energy. The recoil energy involved can in many cases be calculated exactly. The extent of dislocation of the reaction product from its original equilibrium position depends on the fraction of the kinetic recoil energy spent for internal excitation and ionization, and on the range–energy relationship for the reaction products in the medium in question.

In the case of β-disintegration, the resulting decay products will be in the epithermal region. At present there appear to be no experimental data on the penetrating power of atoms in the eV energy region. Previous relevant measurements concerning neutrino studies (1–3), studies of surface processes by means of recoil atoms from β-decay and K-capture (4), and separation of β-decay products by recoil (5), gave only very vague information about the stopping of these particles. A few years ago some preliminary results on the penetrating power of atoms in the eV region in organic matter were reported by us (6). In these measurements a soluble ionized layer formed at the surface of an aqueous solution of an ionic surface-active substance served as a source for β-disintegrating atoms. The primary adsorbed surface active ions gave rise to an electrical double layer within the liquid phase. Ions of opposite charge were collected near the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

surface. When some of the normal counter ions were replaced by β-disintegrating ions, they partly join the electrical double layer near the surface. It was found that β-recoils originating from this layer were able to leave the surface and could then be collected under atmospheric pressure. In order to reach the gas phase the β-recoils have to penetrate the primary organic adsorption layer. The thickness of the organic stopping layer can be changed gradually by alternating the adsorption conditions. Organic surface layers of the order of 0.1 $\mu g/cm^2$ are thus obtained, which are suitable for the stopping of heavy β-decay recoils in the eV region. These measurements were refined and extended to a number of β–γ disintegrating nuclides with maximum recoil energies between 2 and 22 eV.

The experiments were performed under conditions which almost completely exclude any energy-sharing processes. Thus the whole initial kinetic energy of the recoil particle remained as translational energy.

Principle of the Method

Aqueous solutions of ionic surface-active substances form an ionized surface layer at the solution–air interface. The primary adsorbed surface-active ions charge the surface electrically, giving rise to an electrical double layer. In this way counter ions of opposite sign are coadsorbed at the surface. When the solution contains β active ions of opposite charge to those of the surface active species, some of them will join the secondary adsorption side of the electrical double layer near the surface. The extent of coadsorption of the radioactive ions relative to that of the normal, non-isotopic counter ions, will depend on the physico-chemical characteristics of the radioactive ions. These values were previously determined in connection with adsorption and coadsorption studies of ionic surface-active substances at the water–air interface by means of α-disintegration recoils (7, 8).

In the preliminary experiments (6) it could be shown that a certain fraction of β-disintegration recoils arising in an ionized adsorbed surface layer are able to leave the surface and enter the gas phase even if their initial kinetic energy is only of the order of 1 eV. When leaving the liquid surface, a certain fraction of β-recoils will carry a positive charge which can then be collected on a negatively charged plate under atmospheric pressure. Choosing for the experiments β-decay systems which result in radioactive decay products, the β-recoils arriving at the collector plate can be determined by their decay characteristics.

The usual solid β-disintegration recoil source is a monoatomic film adsorbed on a cleavage plane or on a polished, carefully cleaned and degassed metal surface. In this case the adsorption energy of the atoms will be of the order of 1 eV. Thus, in the case of recoils with kinetic energies of a few eV, they will, on escaping from the surface, lose an appreciable fraction of their energy, and their original energy distribution will therefore be seriously distorted.

On the other hand, the energy of escape from the electrical double layer is small in comparison with the energies of a large part of the β recoil spectrum so that most of the recoil atoms are able to leave their place of formation, losing only a small fraction of their initial kinetic energy.

In order to reach the gas phase, the β-recoils have to penetrate the primary organic adsorption layer. The thickness, or mass per unit area of the organic stopping layer can be changed gradually by alternation of the composition of the solution. This results in changes in the primary adsorption conditions at the surface of the solution. An expanded primary adsorption layer can be compressed by raising the ionic strength of the solution at constant concentration of the surface active substance, or by raising the bulk concentration of the surface-active substance in the region below the critical micell concentration at constant ionic strength. As a result of this compression, an increase in the mass per unit area of the organic stopping layer occurs. In Fig. 1 a schematic representation of the electrical double layer formed at the surface of the solution of an ionic-surface active substance is shown.

Figure 1*A* shows the case of a fully expanded surface layer. Adsorption conditions can be controlled so that, although the organic ions cover the surface in horizontal positions, their density at the surface is high enough to cover the surface completely, not leaving any empty islands between them. Under these conditions a minimum stopping layer is obtained. Figure 1*B* illustrates an intermediate stage of compression, resulting in an intermediate stopping layer. Figure 1*C* gives a schematic representation of a

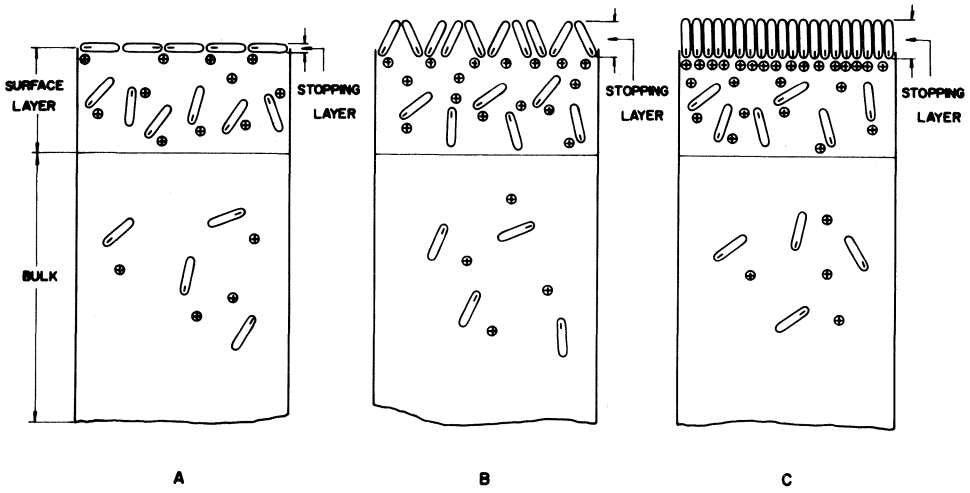

FIG. 1. Schematic representation of an electrical double layer formed at the surface of an aqueous solution of an ionic surface-active substance. A, fully expanded surface layer; B, intermediate stage of compression at surface layer; C, fully compressed surface layer.

fully compressed layer where the organic ions are closely packed and cover the whole surface in vertical position. In this case maximum stopping thickness is obtained.

Electrical double layers of this kind can, to a good approximation, be described by using the Stern picture (9), which is a combination of the rigid Helmholtz layer and the diffuse Gouy–Chapman layer (10, 11). According to this picture the charge at the surface will have a plane distribution, whereas the charge within the solution will be distributed partly parallel to this plane at a distance of the order of one atom and partly toward the bulk of the solution at depths up to a number of molecular layers in a diffusive way.

The surface concentration of the primary adsorbed organic ions and molecules which constitute the stopping layer is determined by measuring the surface tension of the solution *vs.* the concentration of the aqueous solution of the surface-active substance at various ionic strengths. From these results the surface excess of the surface-active substance (Γ) can be calculated by means of a suitably modified Gibbs adsorption equation. Because of the strong adsorption, the surface excess can in fact be taken to be equal to the surface concentration, *i.e.* $C_S = \Gamma(\text{mol/cm}^2)$. As a change in the primary adsorption conditions results in a change in the amount of coadsorption, a suitable normalization of the collector activity, which represents the number of recoils which have reached the collector, has to be made before the results of the individual measurements can be compared. The method of normalization depends on the type of system under investigation.

Experimental

The experimental arrangement used was essentially a modification of an apparatus used for the study of adsorption at ionized surface layers of aqueous solutions of surface-active substances (7, 8, 12–14), as shown in Fig. 2. A is a 5 mm deep lucite cell which contains the solution. On the bottom of the cell is a circular platinum wire B with a connection to the outside. B is connected to the positive pole of a d.c. voltage source. One mm above the liquid surface and the top of the cell, a stainless steel ring C is placed to which a negative potential is applied. In this way edge effects could be neglected. Thus only those β-recoil atoms which leave the surface within the inner edge of the stainless steel ring reach the stainless steel collector D. D is connected to the negative pole of a d.c. supply. The potential between the solution and the collector was 1100 V in order to ensure saturation collection (see Fig. 3), whereas the potential of the ring with respect to the solution was always one third of this value; thus a homogeneous field was maintained. In one experimental series where the half life of the β-recoil was extremely short, so that no effective collection could be performed, a thin window proportional counter was used instead of the collector. In this case β-recoils reaching the counter were detected directly by their α-decay characteristics.

The solution, at the surface of which the β-recoil source was coadsorbed, was 10^{-3} *N* nitric acid containing as ionic surface active substance, an extremely pure, specially synthesized sample of sodium dodecyl sulfate (12–14).

TABLE 1. Disintegration characteristics of the β-decaying nuclides and their recoils, used in the stopping experiments

β-decaying nuclide			β-decay recoil		
Nuclide	$E_{max}(\beta^-)$ (MeV)	Half life	Nuclide	E_{max}(recoil) (eV)	Half life
^{212}Pb	0.589	10.6 h	^{212}Bi	2.38	60.6 min
^{210}Bi	1.16	5.01 day	^{210}Po	6.4	138.4 day
^{211}Pb	1.39	36.1 min	^{211}Bi	8.5	2.12 min
^{212}Bi	2.25	60.6 min	^{212}Po	21.3	3.10^{-7} s

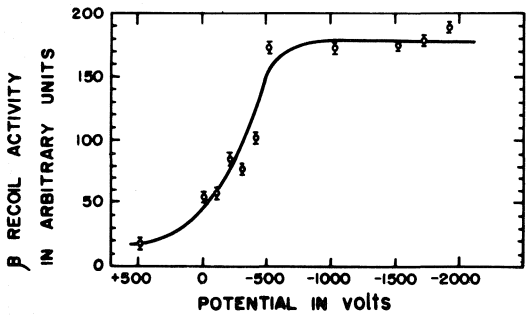

FIG. 3. β-recoil activity *vs.* collector potential.

The β-decaying nuclides and their respective recoils used in the stopping experiments are summarized in Table 1. The maximum β-energies given in this table are for highest energy β-transitions. The respective maximum recoil energies in the table are calculated from the following expression derived directly from the principle of momentum conservation

$$[1] \qquad E_{max}(\text{Recoil}) = \frac{m_0 E_0}{m_R} + \frac{E_0^2}{2m_R c^2}$$

where E_0 is the maximum β-energy, m_R the recoil mass, m_0 the rest mass of the electron, and c the velocity of light.

The β-decay processes of all the nuclides used in this work are accompanied by γ-emission, which imparts recoil momentum to the daughter nucleus in two ways: first, a small amount by direct recoil; and second, a much greater amount by internal conversion. In all the transitions listed, the nuclear excited states have half-times of the order of 10^{-10} to 10^{-13} s. However, if the atoms undergoing the γ-decay have escaped from the surface as a result of the preceding β-decay, they will be away from the surface of the solution by a distance of the order of tens of Å, thus the penetrating power of the recoils through the organic surface layer will not be influenced by the additional recoil energy.

The effect of γ-emission on the recoiling atom well away from the surface will only be to scatter a certain percentage away from the collector, thus lowering the collection yield.

Activities of the respective beta decaying nuclides were dissolved in extremely pure 10^{-3} *N* nitric acid after which the chosen amount of sodium dodecyl sulfate was dissolved in the radioactive solution. ^{212}Pb and ^{211}Pb were introduced into the system by dissolution of the activities from the collecting cathode of a ^{228}Th emanation chamber or a ^{227}Ac emanation chamber, respectively. Collection experiments were started after transient equilibria between ^{212}Pb or ^{211}Pb and their respective decay products were reached.

The collection of the ^{212}Bi atoms above the solution was continued for 2 h. In this way about 75% of the maximum collectable ^{212}Bi activity was accounted for. During that time, and in fact after the first 20 min, secular equilibrium is established between ^{208}Tl, which becomes enriched on the collector in appreciable amounts, and the transient equilibrium activities of the solution. It is a well known fact that ^{208}Tl$^+$ is able to reach the collector under these conditions because of the recoil energy associated with it as a result of the α-decay branching of ^{212}Bi and because of its positive charge (7, 8, 12, 13).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

After removal of the collector, its total activity was measured over a definite time interval. After the 3.1 min activity of ^{208}Tl had decayed, the activity of the collector was followed for a further hour and identified as ^{212}Bi by its half life. From this result the β-recoil activity (^{212}Bi) was calculated for a certain reference time.

For normalization of the β-recoil activity with respect to changes in the coadsorption conditions, the simultaneous measurement of the above mentioned α-recoil activity was found to be suitable. As the highest values of the mass per unit area of the stopping layers used are negligible in comparison with the range of ^{208}Tl in the solution which in water is of the order of 10^{-5} g/cm^2 (15, 16), changes in the α-recoil activity indicate changes in the adsorption conditions and are not influenced by alterations in the thickness of the stopping layer. Thus the ^{208}Tl activity on the collector indicates the amount of coadsorbed $^{212}Bi^{3+}$ ions as a result of variation of the primary adsorption conditions. Consequently this dependence can be used directly for the normalization of the β^--recoil activities (^{210}Po, ^{212}Po) resulting from the β^--decay of coadsorbed Bi^{3+} ions, with respect to changes in adsorption conditions. For the normalization of the β^--recoil activities ^{211}Bi and ^{212}Bi, which result from the β^--decay of coadsorbed Pb^{2+} ions the same procedure is applied, but an additional correction is made for the relative coadsorptions of Pb^{2+} ions with respect to Bi^{3+} ions. This correction is based on the preferential ionic adsorption factor which has been determined experimentally for similar systems (12–14). Thus measurement of the α-recoil activity (^{208}Tl) for all the adsorption conditions used in the experiments served for the normalization of the measured β-recoil activities for the case of all four nuclides.

^{211}Bi atoms were collected above the solution for 15 min, thus reaching their saturation activity. The β-recoil activity (^{212}Bi) was determined by α-spectroscopy using a Si solid state detector in conjunction with a 256 channel pulse height analyzer.

The preparation of the ^{210}Bi and ^{212}Bi activities to be introduced into the solution was somewhat different. Both nuclides were collected in vacuum on a negatively charged platinum plate from extremely thin deposited layers of ^{210}Pb and ^{212}Pb, respectively, by making use of the β-recoil properties. The activities thus collected were then dissolved in 10^{-3} *N* nitric acid and used in the experiments as described previously.

The collection of ^{210}Pb atoms above the solution was continued for one day, and the collected activity determined by α-spectroscopy using a Si detector. The recoils obtained from the β-disintegration of ^{212}Bi were counted directly above the solution as mentioned before, when reaching the detector, by α-counting using an end window proportional counter.

The surface tension of the solutions of various concentrations of sodium dodecyl sulfate was measured with a du Noüy tensiometer. The ionic strength of the solution was controlled by additions of sodium nitrate; thus no new species were added to the system.

All the experiments were performed in a gloved box giving several advantages in addition to prevention of radioactive contamination. Dust would be well excluded, excellent air thermostation could be achieved by making the inner walls of the box thermal conducting and the relative humidity was kept high, thus minimizing surface evaporation. The evaporation was furthermore kept low by the small gas space over the surface in the experimental apparatus, which was about 2.4 cm^3. The box was thermostated at 25.0 ± 0.5 °C.

Results

Collection Experiments

In the preliminary series of measurements, collection conditions and the charge on the ^{212}Bi recoils were investigated under the experimental conditions described above. In this series the β-recoil activity was measured as a function of the collector potential under constant adsorption conditions. The concentration of sodium dodecyl sulfate was 10^{-4} mol/l, the nitric acid content of the solution 10^{-3} mol/l and the ionic strength 3×10^{-3} mol/l. Under these conditions the organic stopping layer had a thickness of 2.1×10^{-10} mol/cm^2.

The results of these measurements are shown in Fig. 3. From this it can be seen that saturation collection of the positively charged fraction of the β-recoils is reached at approximately −500 V under these experimental conditions, *i.e.*, at a field strength of approximately 1600 V/cm.

The number of β-recoils which reach the collector at zero collecting potential represents the overall amount of β-recoils which are able, under these experimental conditions, to reach the collector by a pure diffusion mechanism. These recoils consist of charged and uncharged species.

The number of β-recoils which reach the collector at the maximum applied retarding potential of +500 V represents the fraction of uncharged β-recoils, since the maximum applied retarding potential is very large in comparison with the most energetic β-recoil. It can be seen from these results that about one-third of the β-recoils are uncharged, whereas about two-thirds of them are positively charged. The fraction of negatively charged β-recoils can be assumed to be negligible.

Furthermore, it can be seen from Fig. 3 that the efficiency of collection of β-recoils when saturation has been achieved by a sufficient negative potential is three to four times as large as the collection efficiency by diffusion alone.

Stopping Layer Thickness

The thickness of the organic stopping layer which is practically identical with the excess of the dodecyl sulfate species (DS) at the surface, can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

calculated with the aid of a suitably modified Gibbs adsorption equation from surface tension/conc. measurements. The Gibbs equation for the system under investigation can be written as

$$[2] \quad -d\gamma/RT = \Gamma_{Na^+}\, d\ln a_{Na^+} + \Gamma_{DS^-}\, d\ln a_{DS^-} + \Gamma_{H_3O^+}\, d\ln a_{H_3O^+} + \Gamma_{HDS}\, d\ln a_{HDS^+} + \Gamma_{NO_3^-}\, d\ln a_{NO_3^-} + \Gamma_{Rad^{n+}}\, d\ln a_{Rad^{n+}} + \Gamma_{OH^-}\, d\ln a_{OH^-}$$

where γ = surface tension in dyn/cm, a = molar activity, Γ = surface excess in mol/cm^2, and T = absolute temperature. The symbol Rad^{n+} represents the added radioactive species. The contribution of the sixth term (Rad^{n+}) is negligible, because of the extremely low concentration of the cations. As the surface adsorption of NO_3^- relative to that of the surface-active anions is extremely small, the fifth term may be omitted too. If the ionic strength and the pH are kept constant, the first (Na^+), the third (H_3O^+), and the last (OH^-) terms of the Gibbs equation become zero, and

$$[3] \quad d\ln a_{DS^-} = d\ln a_{HDS}$$

At 25 °C the adsorption isotherm reduces, therefore, to

$$[4] \quad -d\gamma/RT = (\Gamma_{DS^-} + \Gamma_{HDS})(1 - 0.585\sqrt{m_{DS^-}})\, d\ln m_{DS}$$

where m is molarity. For very dilute solutions

$$[5] \quad -d\gamma/RT = (\Gamma_{DS^-} + \Gamma_{HDS})\, d\ln C_{DS^-}$$

and $d\ln C_{DS} = d\ln C_{DS^-}$ are valid. After denoting the sum of the surface excesses of the two existing dodecyl sulfate species by Γ_{DS}, the final result is obtained

$$[6] \quad -d\gamma/RT = \Gamma_{DS}\, d\ln C_{DS}$$

From eq. 6 the surface concentration $C_s \simeq \Gamma_{DS}$ in mol DS/cm^2 can be found and translated into g/cm^2.

Stopping Measurements

In a series of stopping measurements the β-recoil activity was determined as a function of the moles per unit area of the stopping layer. The smallest number of moles per unit area with which stopping experiments could be made was limited by the lowest value of the ionic strength which was permissible. The lower limit of this value is determined by the pH of the solution. Because of the appreciable radiocolloid formation which would occur (8), pH values higher than three are not permissible.

The mass per unit area of the stopping layer was varied according to the β-recoil under investigation, between 2.1 to 6.1 × 10^{-10} mol DS/cm^2, which corresponds to about 0.6 to 1.6 × 10^{-7} g/cm^2. A value of 10^{-4} mol/l was chosen for the sodium dodecyl sulfate concentration of the solution: thus even at the highest ionic strength used, the measurements are still made below the critical micell concentration.

The number of moles DS per unit area was calculated from the surface tension/conc. measurements, making use of eq. 6. The results obtained were found in good agreement with the values given by Matijevic *et al.* (17).

As an illustration, the results of the β-recoil stopping measurements for the system ^{212}Pb/^{212}Bi are shown in Fig. 4. From this it can be seen that when the mass per unit area is raised, the normalized β-recoil activity decreases continuously. This can be explained by the complete stopping of the lower energy part of the β-recoil spectrum. From extrapolation of the curve to

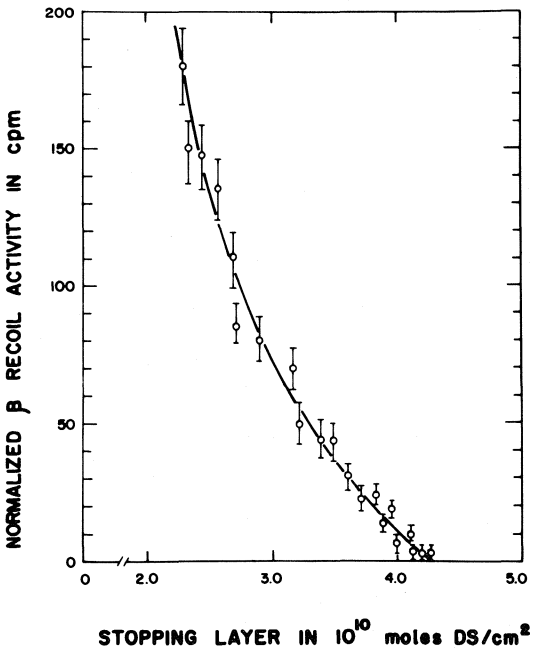

FIG. 4. Normalized β-recoil activity obtained from the system ^{212}Pb/^{212}Bi *vs.* the number of mol DS/cm^2 of the stopping layer.

TABLE 2. Experimentally determined organic stopping thicknesses for very heavy β-recoils in the energy domain 2 to 22 eV

β-decay recoil	E_{max}(recoil) (eV)	Organic stopping layer thickness	
		10^{10} mol/cm^2	10^7 g/cm^2
^{212}Bi	2.38	4.15–4.37	1.10–1.16
^{210}Po	6.4	4.6–4.85	1.22–1.29
^{211}Bi	8.5	4.7–4.95	1.25–1.31
^{212}Po	21.3	5.85–6.15	1.55–1.63

zero β-recoil activity an approximate value can be found for the number of moles of dodecyl sulfate per unit area which completely stops atoms of maximum β^--recoil energy 2.38 eV. These atoms may be said to have the shortest path through the organic stopping layer and to originate from the uppermost coadsorbed layer only. The stopping value seems to lie approximately between 4.15 to 4.37 $\times$ 10^{-10} mol DS/cm^2, which corresponds to about 1.10 to 1.16 $\times$ 10^{-7} g/cm^2 or organic material.

In Table 2 the results of the stopping measurement performed in a similar way, for all the four β-recoils under investigation are given.

Discussion

The energy loss of heavy particles with velocities $v < e^2/\hbar = 2.2 \times 10^8$ cm/s is accompanied by a quasiadiabatic interpenetration of the respective electron fields and most of the energy is transferred by nearly elastic collisions. The most successful approach to the nuclear stopping mechanism has been made by Lindhard *et al.* (18) who brought the theoretical predictions very close to the experimental results (15, 16) by introducing a screened potential based on a statistical model of the interacting atoms. Their treatment is based on a universal nuclear stopping cross section due to shielded nuclear collisions, calculated from a Thomas–Fermi model of the interaction between an ion and an atom. However, at extremely low energies, *i.e.* for values of the dimensionless Lindhard energy parameter $\varepsilon < 10^{-2}$, the Thomas–Fermi treatment is a crude approximation, when the ion and the atom do not come close to each other and thus the nuclear scattering and stopping becomes uncertain. For still lower velocities, as in the case of β-decay recoils, studied in this investigation where the initial particle velocity is of the order of 10^{-3} $e^2/\hbar$, the effective collision cross section will tend to coincide with the gas kinetic cross section, corresponding to a rate of energy loss proportional to the energy of the recoil.

The only semiquantitative treatment of this problem has been made by Jacobsen, who because of the complexity of the problem neglected the deviation of the particle path from a straight line (19). Unfortunately under these conditions no comparison between this approach and experiment can be made.

Because of the diffusion-like phenomenon of the penetration of particles through material in this extremely low energy domain the usual definition of range is not applicable. Instead we prefer to call the approximate layer of material through which the particles are able to dislocate themselves the "extent of dislocation" of the β-recoils. In Fig. 5 the results obtained for maximum β-recoil energies between 2 and 22 eV are given. It is seen that in this energy domain a nearly linear dependence between recoil energy and dislocation distance in organic matter as represented by the stopping layer thickness was found.

In the light of the considerations mentioned it seems to be safe to conclude that, under the physical and experimental circumstances which have been described, atoms resulting from β-decay which leave the surface of the solution do so only as a result of their β-recoil energy.

Another possibility which should be discussed is that some of the atoms obtained in the solution as a result of α-decay, *e.g.* ^{208}Tl, having initial kinetic energies of the order of 100 keV, could transfer their kinetic energy by a central collision more or less completely to a β-recoil atom, which

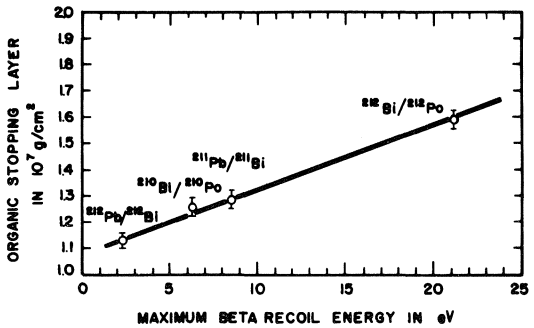

FIG. 5. Dislocation distance of heavy β-recoils in organic material as a function of particle energy.

could then be ejected from the solution. This seems to be quite improbable for two reasons. Firstly, if this mechanism should have some quantitative importance, it should in a similar way eject some of the coadsorbed β-disintegrating ions, *e.g.* ^{212}Pb. However, such activities could not be detected on the collector. Secondly, if one calculates the mean distance between the β-recoil atoms, *e.g.* ^{212}Bi-ions at the surface, knowing their specific activity in the solution, their preferential ionic adsorption at the surface layer relative to the adsorption of hydrogen and sodium ions (12, 13), and the general adsorption conditions used, one finds that this distance is of the order of 10^3–10^5 Å. This means that the direct collision mechanism is rather improbable.

Finally, it may be said that the method described here proved to be suitable for measurements of the stopping of β-recoils. Experiments using surface-active ions with greater chain lengths as well as insoluble ionized surface films are in progress.

The technical assistance of F. Lichtenstern and E. Mionis and the crew of the technical service of the Department is acknowledged.

Etude des oxydes mixtes de lanthanides et de vanadium(V)

H. Brusset, F. Madaule-Aubry, B. Blanck, J. P. Glaziou, et J. P. Laude

Institut de Chimie, École Centrale des Arts et Manufactures, Grande Voie des Vignes, 92–Chatenay-Malabry, France

Reçu le 23 septembre 1970[1]

Ce travail présente une étude par voie sèche d'oxydes mixtes de vanadium(V) et de lanthanides. L'étude a porté sur tous les éléments de terres rares à l'exclusion du cérium et du prométhium.

Tous les orthovanadates TVO_4 ont été préparés et leurs paramètres de maille redéterminés. Des composés nouveaux ont été synthétisés: $4T_2O_3.V_2O_5$ pour tous les lanthanides étudiés, $5T_2O_3.V_2O_5$ pour les éléments allant du samarium à l'ytterbium et $6T_2O_3.V_2O_5$ pour le praséodyme et le néodyme. L'identification de ces composés a été menée par diffractométrie de rayons X.

This work presents a study of the mixed oxides of vanadium(V) and lanthanides by dry methods. The study includes all elements of the rare earth group except cerium and promethium.

All orthovanadates of the formula TVO_4 were prepared and their lattice parameters redetermined for all lanthanides. New materials were synthesized: lanthanides $4T_2O_3.V_2O_5$, for elements from samarium to ytterbium the compounds $5T_2O_3.V_2O_5$. and for praseodymium and neodymium the compounds $6T_2O_3.V_2O_5$. Identification of these materials was carried out by X-ray diffraction.

Canadian Journal of Chemistry, 49, 3700 (1971)

Dans le cadre d'une étude systématique des oxydes doubles contenant un élément de terre rare (1–4) nous nous sommes intéressés aux vanadates de lanthanides.

En effet, si sont bien connus les orthovanadates TVO_4 (où T représente l'un quelconque des lanthanides) et si quelques composés polyvanadiques ont été préparés à partir de solutions aqueuses (5, 6), la littérature ne mentionne aucun résultat concernant des études faites par voie sèche et correspondant à des mélanges d'oxydes T_2O_3 et V_2O_5 en proportions autres qu'équimoléculaires.

Nous avons entrepris l'étude de tous les systèmes binaires T_2O_3–V_2O_5, où T représente l'un des éléments suivants: lanthane, praséodyme, néodyme, samarium, gadolinium et dysprosium; l'existence de composés nouveaux analogues à ceux mis en évidence pour les éléments ci-dessus a été vérifiée pour les autres terres rares, à l'exclusion du prométhium et du cérium, c'est à dire l'europium, le terbium, l'holmium, le thulium et le lutécium. Nous avons laissé de côté le prométhium parce qu'il ne présente pas d'isotope stable; quant au cérium, seul l'orthovanadate a pu être préparé: l'oxyde Ce_2O_3, en effet, se réoxyde spontanément dès la température ambiante et l'étude de ce système aurait nécessité une autre technique que celle que nous avons employée pour les autres. Des traitements thermiques de mélanges CeO_2–V_2O_5 n'ont pas permis d'obtenir d'autres composés que $CeVO_4$.

[1]Revision reçue le 7 juin 1971.

Produits de départ et techniques expérimentales

Nous avons utilisé l'hémipentoxyde de vanadium V_2O_5 pur à 99.9%, livré par Riedel–Dehaën, et les sesquioxydes de terres rares T_2O_3 purs à 99.9% de chez Touzart et Matignon, sauf dans le cas du praséodyme où nous disposions du peroxyde Pr_6O_{11} et du terbium où il s'agissait de Tb_5O_9.

Nous avons vérifié par fluorescence X (spectromètre Philips PW 1200, anticathode de tungstène, cristal analyseur LiF) que les oxydes de terres rares ne contenaient pas, en petite quantité, d'autre lanthanide, ce qui s'est avéré exact dans tous les cas, sauf celui de l'oxyde d'erbium dont le spectre de fluorescence X a montré des pics d'intensité très faible correspondant aux raies $L\alpha_1$ du thulium, de l'holmium et du fer.

Nous disposons pour l'identification des phases cristallines d'un diffractomètre à poudres Philips PW 1310 utilisé avec un tube à anticathode de cuivre et un filtre de nickel. Les pointés des angles concernent la radiation $K\alpha_1$ du cuivre, $\lambda = 1.5405$ Å.

Tous les diffractogrammes des oxydes de départ ont été réalisés et sont en bon accord avec ceux donnés par l'ASTM (7); le pentoxyde de vanadium se présente sous sa seule forme cristalline connue, orthorhombique. Il en est de même pour les sesquioxydes (cubiques) de dysprosium, holmium, erbium, thulium, ytterbium, lutécium.

Le sesquioxyde de samarium se présente comme un mélange des formes monoclinique et cubique. Après chauffage pendant 24 h à 1500 °C les raies de la forme cubique ont toutes disparu.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Les sesquioxydes d'europium et de gadolinium qui peuvent cristalliser sous forme cubique et monoclinique apparaissent sous la seule forme cubique.

Les peroxydes Pr_6O_{11} et Tb_5O_9 après chauffage pendant 6 h sous courant d'hydrogène, ont donné naissance aux sesquioxydes correspondants: Pr_2O_3 hexagonal et Tb_2O_3 cubique.

Nd_2O_3 se présente comme un mélange de formes hexagonale et cubique, cette dernière en faible proportion et disparaissant après chauffage à 800 °C.

Quant au sesquioxyde de lanthane, commercial, c'est un mélange de La_2O_3 hexagonal et d'hydroxyde $La(OH)_3$ (provenant de l'hydratation de l'oxyde par la vapeur d'eau atmosphérique). Celui-ci disparait après chauffage à 600 °C pendant 15 h. Dans l'étude du système concernant le lanthane, nous avons utilisé du sesquioxyde préalablement chauffé à 800 °C et conservé à l'étuve ainsi que les échantillons de mélanges d'oxydes.

Les systèmes binaires ont tous été étudiés de la même façon: les mélanges d'oxydes, préalablement broyés finement, ont été effectués au sein de l'acétone; cette technique s'est montrée plus rapide et plus efficace que le passage au broyeur-mélangeur, l'acétone s'évaporant avant tout traitement ne modifie pas les résultats. Les mélanges ainsi obtenus ont été chauffés pendant des durées variables (généralement 24 h) à des températures comprises entre 600 et 1500 °C dans des creusets de platine fermés (mais non scellés) pour les mélanges riches en oxyde de vanadium.

Le refroidissement des produits de réactions s'est fait à la vitesse de refroidissement propre des fours, ceux-ci ne permettant pas d'opérations de trempe.

Nous avons utilisé un four à moufle Paris-Labo pour les chauffages à l'air jusqu'à 1100 °C, et, pour les températures supérieures, un four à moufle de la Compagnie Industrielle des Fours, à résistance de superkanthal équipé d'un programme de chauffe dont la température maximale de fonctionnement est 1500 °C. Pour les traitements effectués sous atmosphère contrôlée (azote, hydrogène), nous avons utilisé deux fours tubulaires: un petit four de laboratoire Leune jusqu'à 900 °C, à tube de quartz, un four Hermann Moritz jusqu'à 1600 °C utilisant des résistances de carbure de silicium. Nous ne nous en sommes servis que pour des chauffages sous azote, avec un tube en mullite.

Après refroidissement, tous les produits obtenus ont été examinés par diffraction des rayons X au moyen du diffractomètre Philips.

Les sesquioxydes de praséodyme et terbium pouvant donner lieu à des dioxydes, les traitements thermiques qui les concernent ont été menés sous atmosphère inerte d'azote.

Les conditions expérimentales avec lesquelles nous avons opéré ne nous ont pas permis de constituer les diagrammes d'équilibres des systèmes binaires T_2O_3–V_2O_5, mais plutôt de déterminer les conditions d'apparition de phases nouvelles figurant dans ces diagrammes. Néanmoins, comme les oxydes de terres rares sont réfractaires et que les composés nouveaux sont apparus du côté des mélanges riches en terres rares, et donc qui n'ont pas fondu lors du traitement, il est probable qu'après un refroidissement relativement rapide, étant donnée la lenteur des réactions entre solides, l'examen des phases cristallines donne une bonne idée des phases en équilibre à la température maximale de chauffe.

Résultats

Les premiers résultats, concernant les systèmes relatifs au gadolinium et à l'erbium, ont été publiés par ailleurs (1).

Dans tous les cas, on observe la formation de l'orthovanadate TVO_4 et d'un composé défini nouveau, contenant quatre atomes de terre rare pour un atome de vanadium, dont la formule dualistique peut s'écrire $4T_2O_3.V_2O_5$. Nous désignerons ce type de composé sous le nom de "composés A".

D'autre part, les systèmes se classent en deux catégories: (*i*) ceux qui font intervenir le praséodyme et le néodyme montrent en outre la formation de composés de formule globale $6T_2O_3.V_2O_5$ ("composés B"). (*ii*) les autres systèmes, à l'exception de celui du lanthane, présentent la formation de composés de formule globale $5T_2O_3.V_2O_5$ ("composés C"), sauf peut-être dans le cas du lutécium.

Dans aucun des systèmes étudiés nous n'avons observé la formation de solution solide.

a Composés formés

(1) Orthovanadates

Dans tous les cas, nous avons préparé l'orthovanadate TVO_4 par chauffage des mélanges équimoléculaires T_2O_3–V_2O_5 à 1500 °C pendant 24 h, mais la réaction est complète dès des températures inférieures à 800 °C. Une étude par analyse thermique différentielle des phénomènes observés lors du chauffage et du refroidissement du mélange équimoléculaire Gd_2O_3–V_2O_5 montre (Fig. 1), à l'échauffement, un pic exothermique vers 668 °C, et aucun phénomène au refroidissement. Le produit final est constitué uniquement par de l'orthovanadate $GdVO_4$. La netteté et la reproductibilité du phénomène observé, qui se produit à une température voisine de la température de fusion, déterminée dans les mêmes conditions, de l'oxyde V_2O_5 (673 ± 5 °C) laissent supposer que la réaction de formation de l'orthovanadate de gadolinium se fait, non pas entre deux solides, mais entre un solide (Gd_2O_3) et un liquide (V_2O_5). La réaction s'effectuerait brusquement dès homogénéïsation du mélange par la fusion de V_2O_5.

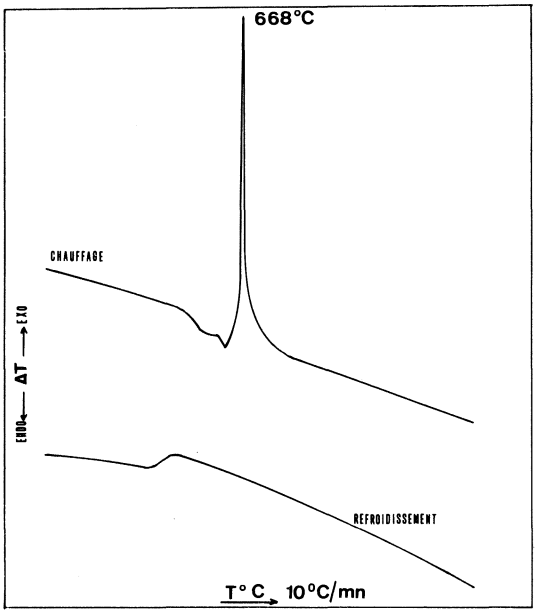

FIG. 1. Etude de la formation de l'orthovanadate de gadolinium par analyse thermique différentielle.

Or, comme nous le montrent les Figs. 4, 5 et 6, dans tous les systèmes étudiés, l'orthovanadate se forme d'abord lors des chauffages à basses températures, les composés définis nouveaux se formant ensuite (ou à température supérieure) par réaction entre l'orthovanadate et l'oxyde en excès. Le phénomène décrit ci-dessus permettrait d'expliquer cette formation privilégiée.

De même, alors que dans le cas du cérium nous n'avons pu mettre en évidence aucun composé nouveau à partir des mélanges CeO_2–V_2O_5, nous avons toujours observé la formation de $CeVO_4$. En particulier, le mélange $2CeO_2.V_2O_5$ mène à $CeVO_4$ pur pour un chauffage de 800 °C pendant 24 h.

Orthovanadates quadratiques

Les orthovanadates de terres rares, du cérium au lutécium, forment une série isomorphe, cristallisant avec la structure du zircon dans le système quadratique, groupe d'espace $I4_1/amd$ et ont été étudiés par Milligan et Vernon (8), et plus récemment par Schwarz (9) ou Aïa (10). Certains diagrammes (Nd, Ce, Eu, Dy, Ho) ont été publiés par le National Bureau of Standards (11).

Tous nos diagrammes sont en bon accord avec ceux mentionnés ci-dessus, sauf pour ceux de Milligan et Vernon (8) qui présentent un décalage angulaire systématique se traduisant par un écart sur les paramètres de maille. Le Tableau 1 donne, à titre d'exemple, le diffractogramme relatif à $SmVO_4$.

TABLEAU 1. Diffractogramme relatif à $SmVO_4$

*F, raies de forte intensité; f, raies de faible intensité; m, raies d'intensité moyenne; Max, raie d'intensité maximale.

Nous avons procédé, dans tous les cas, à un affinement par moindres carrés des paramètres cristallins a et c à partir du diagramme indicé, chaque distance réticulaire d étant affectée d'un coefficient de pondération $w = 1/\tau^2$ où τ est l'écart type (12); nous avons choisi $\tau = \Delta d/0.798$, assimilant Δd (erreur expérimentale) à la déviation moyenne. Δd a été calculée à partir de l'évaluation de l'erreur expérimentale sur les angles 2θ; nous avons choisi $\Delta(2\theta) = 0.05°$ d'après la reproductibilité des mesures. Cet affinement a été fait au moyen d'un programme général d'affinement des paramètres de maille à partir des diagrammes de poudres écrit par l'un de nous (F.M.) pour ordinateur IBM 1130. La convergence était généralement réalisée après un ou deux cycles d'affinement.

Le Tableau 2 donne les résultats obtenus, ainsi que, pour chaque orthovanadate, les valeurs données par l'article le plus récent.

Les erreurs données sont calculées comme la déviation moyenne sur les paramètres, soit $0.798\,\tau$ si τ est l'écart-type, obtenu par la méthode des moindres carrés.

Orthovanadate de lanthane

Il n'appartient pas à la série isomorphe quadratique, mais est voisin du phosphate de lanthane, qui, lui, cristallise dans le système monoclinique avec la structure de la monazite. Une étude structurale de ce composé est en cours au laboratoire (par Boursier). Des monocristaux de $LaVO_4$ ont été obtenus par le refroidissement du mélange $4V_2O_5.La_2O_3$, maintenu pendant 5 h à 1100 °C (13). Cette méthode est d'ailleurs tout à fait en accord avec les résultats que nous avons obtenus pour le système La_2O_3–V_2O_5 (*cf.* plus bas).

Des clichés de diffraction des rayons X par les méthodes de Weissenberg et de précession ont montré que le cristal appartient au groupe d'espace $P2_1/n$, avec des paramètres de maille tout à fait en accord avec les valeurs trouvées par Aïa (10). Si on fait un changement de coordonnées de façon à se trouver dans les conditions des tables internationales de cristallographie, on obtient le groupe d'espace $P2_1/c$.

Le diagramme de poudres du composé obtenu par chauffage du mélange équimoléculaire $La_2O_3.V_2O_5$, identique à celui obtenu après broyage des monocristaux préparés suivant la méthode ci-dessus, a alors été indicé au moyen d'un programme, écrit par l'un de nous (F.M.) pour IBM 1130, qui, à partir des paramètres de maille et des extinctions systématiques, génère tous les triplets d'indices possibles à l'intérieur des limites données et les attribue aux raies observées en tenant compte des incertitudes expérimentales.

Le Tableau 3 donne ce diffractogramme indicé; un affinement par moindres carrés mène ensuite aux valeurs des paramètres

	a (Å)	*b* (Å)	*c* (Å)	β (deg)

Données de Aïa	7.07	7.26	6.61	102.6

(2) Composés A: $4T_2O_3.V_2O_5$

On les observe pour tous les éléments.

Les diffractogrammes de ces composés sont voisins, sans que l'on puisse retrouver exactement le même nombre de raies, ce qui permettrait de conclure à une série isomorphe. Il semble que les structures de ces produits soient voisines mais le passage d'un élément au suivant s'accompagne de déformations modifiant les symétries cristallines. Cette symétrie est en tout cas basse, car des essais systématiques d'indiçage ont échoué pour les systèmes cubique, quadratique, hexagonal et orthorhombique, en utilisant entre autres les méthodes de Bjurström (15) et Ito (16), dans le cas du composé de l'erbium.

Toutefois, dans le cas du lutécium, un chauf-

fage à 1500 °C (température maximum que nous pourrons atteindre) pendant 96 h n'a pas permis d'obtenir le composé A pur. Le diffractogramme du produit obtenu montre les raies caractéristiques de $LuVO_4$, de Lu_2O_3 et des raies nouvelles qui ne peuvent être attribuées qu'au composé A; le diagramme correspondant est donc sans doute incomplet. L'ensemble des diagrammes de diffraction obtenus (ainsi que celui du composé analogue de l'yttrium que nous avons aussi préparé, le diagramme donné par Levin (14) n'étant pas suffisamment détaillé) figurent dans un tableau déposé en archives.[2]

La Fig. 2 présente un schéma récapitulatif des spectres de diffraction de tous les composés A étudiés, qui met en évidence les ressemblances et les différences de ces spectres. On constate que ces composés peuvent se classer par groupes de

[2]Les photocopies des documents archivés peuvent être obtenues, sur demande adressée aux archives des documents non publiés, à la Bibliothèque scientifique nationale, au Conseil national de recherches du Canada à Ottawa.

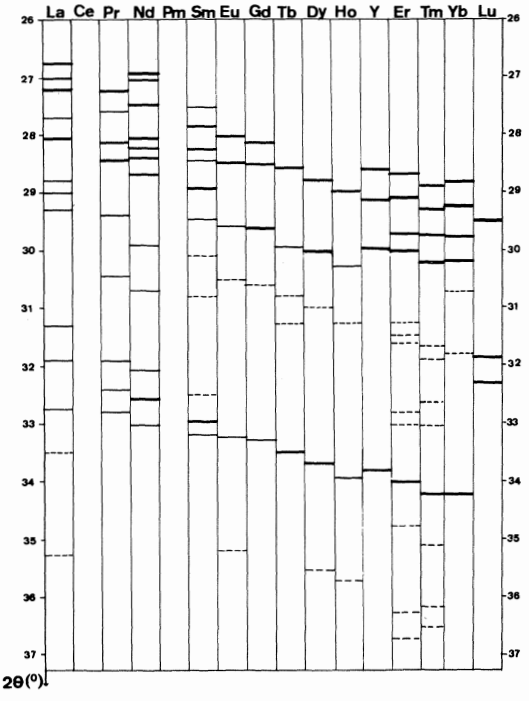

FIG. 2. Caractéristiques générales des spectres de diffraction des composés A: ▬ raies intenses; — raies moyennes; --- raies faibles.

deux ou trois fort voisins: (*i*) composés de l'europium et du gadolinium; (*ii*) composés du terbium, du dysprosium et de l'holmium; (*iii*) composés de l'erbium, du thulium et de l'ytterbium.

Les autres éléments étudiés conduisent à des composés riches en raies, difficiles à classer.

Le rapport atomique $T/V = 4$ a été vérifié par fluorescence X.

(3) Composés B: $6T_2O_3.V_2O_5$

Ces composés n'ont pu être préparés que pour le praséodyme et le néodyme. Les deux diagrammes de diffraction obtenus sont présentés Fig. 3 et peuvent être obtenus au dépôt des données non publiées.[2]

Bien qu'ils présentent certaines analogies en ce qui concerne les positions angulaires des raies intenses, le diagramme relatif au néodyme est beaucoup plus riche en raies moyennes et faibles que celui qui concerne le praséodyme et on ne peut conclure à l'isomorphisme.

(4) Composés C: $5T_2O_3.V_2O_5$

On les observe pour tous les éléments, du samarium à l'ytterbium. Leurs diffractogrammes

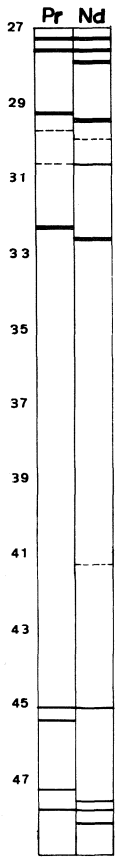

FIG. 3. Caractéristiques générales des spectres de diffraction des composés B: ▬ raies intenses; — raies moyennes; --- raies faibles.

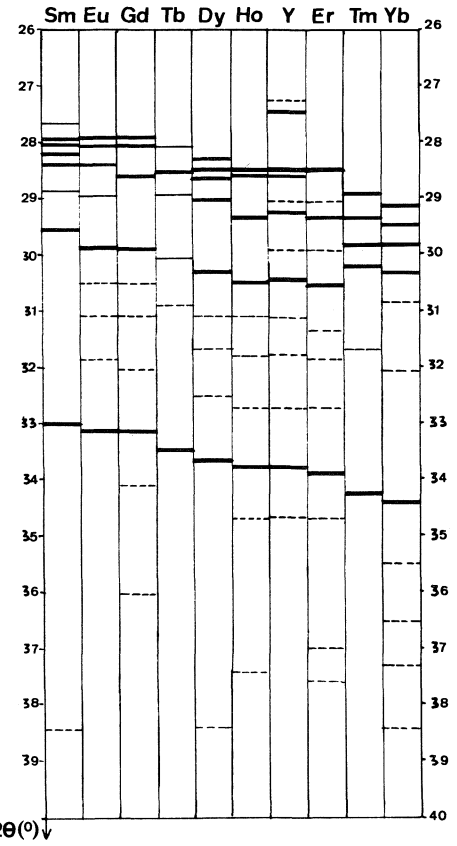

FIG. 4. Caractéristiques générales des spectres de diffraction des composés C: ▬ raies intenses; — raies moyennes; --- raies faibles.

ainsi que celui concernant l'yttrium (14) sont récapitulés par la Fig. 4, ils peuvent être obtenus au dépôt des données non publiées.[2] Il n'apparait pas plus de similitudes entre ces diagrammes qu'entre ceux qui concernent les composés A, en particulier en ce qui concerne le nombre de raies intenses.

La symétrie cristalline ici aussi est probablement basse: les raies sont nombreuses et des essais d'indiçage n'ont pas abouti. Dans le cas du lutécium, il est probable qu'il se forme complètement à une température supérieure à 1500 °C. Quelques raies nouvelles (outre les raies de $LuVO_4$ et de Lu_2O_3) apparaissent dans le diffractogramme du mélange $5Lu_2O_3.V_2O_5$ chauffé à 1500 °C pendant 96 h.

Dans le cas des trois types de composés A, B, C, seule la préparation de monocristaux permettrait de résoudre le problème posé par leur structure, puisqu'ils ne sont analogues à aucun des types classiques d'oxydes mixtes.

La teneur en vanadium est faible, et ces oxydes qui se présentent sous forme de céramiques sont réfractaires et difficilement attaquables. D'autre part, il n'est pas certain que le nombre d'atomes d'oxygène soit exactement celui qui correspond à la stoechiométrie. En effet, des études à partir de l'oxyde Pr_6O_{11} ont mené à des composés A′ et B′ correspondant à des rapports Pr/V respectivement de 4 et 6, mais dont les diagrammes de diffraction, quoique très voisins de ceux des composés A et B obtenus à partir de Pr_2O_3, ne leur sont pas tout à fait identiques, en ce qui concerne le nombre et l'intensité relative des raies. Ceci laisse prévoir la possibilité de teneurs en oxygène variables pour un même nombre T/V.

b Description des systèmes binaires

Les Figs. 5, 6, et 7 résument les résultats

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

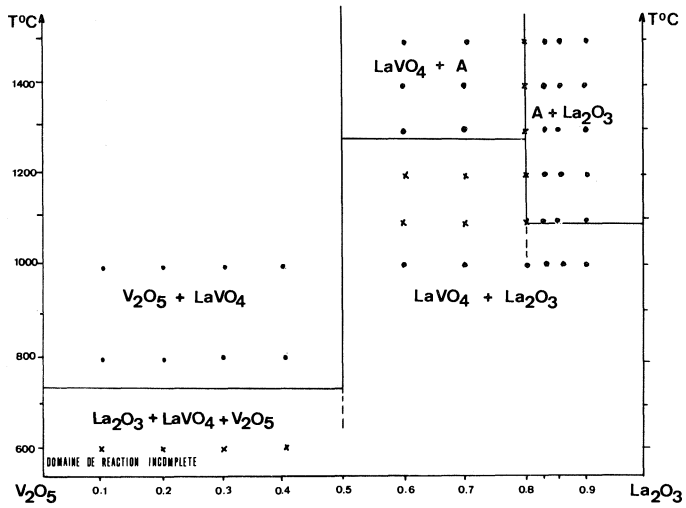

FIG. 5. Phases observées dans le système La_2O_3–V_2O_5; ● représente une expérience; × indique un produit qui contient 3 phases (réaction incomplète).

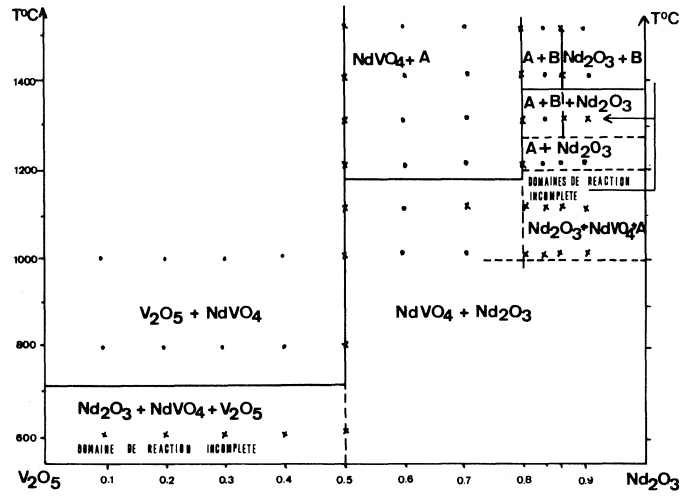

FIG. 6. Phases observées dans le système ND_2O_3–V_2O_5; ● représente une expérience; × indique un produit qui contient 3 phases (réaction incomplète).

obtenus. On observe trois types de systèmes: Fig. 5, La_2O_3–V_2O_5; Fig. 6, Nd_2O_3–V_2O_5 analogue à Pr_2O_3–V_2O_5; Fig. 7, Yb_2O_3–V_2O_5 typique des systèmes des éléments au-delà du samarium (et semblable à celui de Levin (14) pour l'yttrium).

Dans tous les cas on observe: (*i*) la facile formation de l'orthovanadate TVO_4, généralement dès les premières températures étudiées (600 °C); (*ii*) l'absence de toute solution solide; (*iii*) l'absence de tout composé défini dans le sous-sytème TVO_4–V_2O_5. Le bas point de fusion de V_2O_5 justifie alors son emploi comme fondant pour la préparation de monocristaux d'orthovanadates (13); (*iv*) la présence, dans les domaines riches en oxydes de terres rares, d'échantillons présentant trois phases cristallines, ce qui montre une réaction incomplète.

La température pour laquelle la formation des composés A est totale varie entre 1100 et 1400 °C sans que l'on puisse mettre en évidence une variation de cette température avec le numéro atomique. Dans le cas du lutécium cette température est supérieure à 1500 °C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

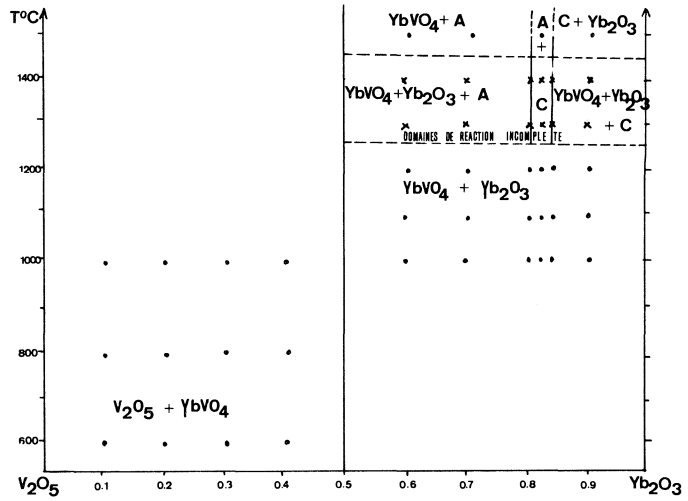

FIG. 7. Phases observées dans le système Yb_2O_3–V_2O_5; ● représente une expérience; × indique un produit qui contient 3 phases (réaction incomplète).

Les composés B se forment à une température supérieure à celle des composés A, tandis que les composés C se forment à une température voisine de celle des composés A, ou plus basse (cas du samarium, du dysprosium, de l'erbium).

Enfin le système relatif au gadolinium (1) présente un domaine de plus à cause de l'existence des deux variétés allotropiques, cubique et monoclinique de Gd_2O_3. Il en est de même du samarium, mais l'oxyde utilisé pour préparer les échantillons de départ étant un mélange des deux formes, nous avons observé la présence de ces deux formes après les traitements à basse température.

Conclusion

En conclusion, nous avons réalisé l'étude dans tout le domaine de composition des huit systèmes binaires: La_2O_3–V_2O_5, Pr_2O_3–V_2O_5, Nd_2O_3–V_2O_5, Sm_2O_3–V_2O_5, Gd_2O_3–V_2O_5, Dy_2O_3–V_2O_5, Er_2O_3–V_2O_5, Yb_2O_3–V_2O_5 et montré l'existence de composés définis nouveaux de formule globale $4T_2O_3.V_2O_5$ dans le cas de tous les éléments de terres rares sauf le cérium et le prométhium, de formule $6T_2O_3.V_2O_5$ pour le praséodyme et le néodyme, de formule $5T_2O_3.V_2O_5$ pour tous les éléments allant du samarium à l'ytterbium (groupe yttrique). Cette formation est probable, au-dessus de 1500 °C, dans le cas du lutécium.

Ces composés, de basse symétrie cristalline, ont été identifiés par leur diffractogramme de poudre, et l'étude s'en poursuit actuellement au laboratoire. Nous nous attachons, en particulier, à déterminer la symétrie cristalline des composés du type A, qui sont représentés pour l'ensemble des lanthanides, par essais d'indiçage dans le système monoclinique et par formation de solutions solides entre deux tels composés, ce qui perme tra de déterminer combien de séries isomorphes ils constituent.

An *ab initio* Molecular Orbital Study of Bonding in Fluorocarbonium Ions[1]

N. C. Baird and R. K. Datta
Department of Chemistry, University of Western Ontario, London, Ontario

Received June 7, 1971

Ab initio molecular orbital calculations are reported for the series of carbonium ions $(CH_3)^+$, $(FCH_2)^+$, and $(F_2CH)^+$ and for their neutral molecule counterparts CH_4, CH_3F, and CH_2F_2. The energies and wavefunctions for the carbonium ions have been calculated both with and without including the carbon $2p_\pi$ orbital in the minimal basis set in order to unravel the inductive destabilization and resonance stabilization due to fluorine substitution. The increase in bonding energy with multiple fluorine substitution is less than linear, due primarily to nonadditivity in the dative carbon–fluorine π bonding. The "saturation" effect noted previously for the hydride abstraction reaction enthalpies is shown to be due primarily to stability effects in the neutral molecules themselves rather than to energetic effects of the carbonium ions.

Des calculs d'orbitale moléculaire *ab initio* sont rapportés pour une série d'ions carboniums $(CH_3)^+$, $(FCH_2)^+$ et $(F_2CH)^+$ ainsi que pour leurs molécules neutres correspondantes CH_4, CH_3F et CH_2F_2. Les énergies et les fonctions d'onde pour les ions carboniums ont été calculées à la fois en incluant ou non l'orbitale du carbone $2p_\pi$ dans l'ensemble de base minimum afin de démêler la déstabilisation inductive et la stabilisation de résonance dues à la substitution du fluor. L'accroissement de l'énergie de liaison avec la substitution multiple du fluor est moins que linéaire; ceci est dû en premier à la non-additivité dans la liaison π dative carbone–fluor. Il est montré que l'effet de "saturation" noté auparavant pour les enthalpies de réaction d'abstraction de l'hydrure est dû en premier à des effets de stabilité dans les molécules neutres en soi plutôt que des effets énergétiques des ions carboniums.

Canadian Journal of Chemistry, 49, 3708 (1971)

Introduction

The thermochemical stabilities of organofluorine molecules and ions is of both theoretical curiosity and of experimental importance, since the bonding energies in such systems are distinctly nonadditive with respect to multiple fluorine substitution. For example, perfluorobenzene is some 37 kcal/mol *less* stable than that extrapolated from the change in the heat of formation (ΔH_f) in benzene compared to fluorobenzene, whereas the stabilities of the fluoromethanes *increase* upon multiple fluorine substitution (1). In addition to these nonadditivity effects in neutral molecules, some unusual trends are encountered in the closed-shell positive and negative hydrocarbon ions which contain fluorine. Given that the electronegativity of fluorine is much greater than that of carbon, one would expect fluorine substitution to destabilize carbonium ions and to stabilize carbanions. In actual fact, the opposite effects are often encountered, presumably because the p_π lone pair electrons of fluorine can stabilize the π bonding in carbonium ions, whereas the same electrons destabilize the π bonding in carbanions (2, 3).

In this paper, the electronic and geometrical structure of the fluoromethyl carbonium ion $(FCH_2)^+$ and the difluoromethyl carbonium ion $(F_2CH)^+$ are investigated by *ab initio* molecular orbital calculations in an attempt to unravel the stabilizing and destabilizing effects. These ions have been studied in some detail experimentally, since, together with $(F_3C)^+$, they appear predominant in the mass spectrum of many fluorocarbons (4).

Method of Calculation

All calculations reported herein have been obtained using the nonempirical ("*ab initio*") s.c.f.-l.c.a.o.-m.o. theory of Roothaan (5). Each molecular orbital is expanded as a linear combination of a minimal basis set (1s orbitals centered on hydrogen; 1s, 2s, and 2p orbitals centered on carbon and fluorine) of Slater-type orbitals (STOs). All integrals over the STOs are computed using the STO-3G expansions of Pople and co-workers (6), in which each STO is expanded as a linear combination of 1s or 2p Gaussian-type orbitals (GTOs). The computer

For personal use only.

program used on a CDC-6600 computer to execute the calculations employs subroutines from the POLYATOM system[2] to compute integrals over the GTOs.

The following "standard" geometry information is used except where indicated otherwise: angles about tetravalent carbon (neutral molecules), tetrahedral; angles about trivalent carbon (carbonium ions), 120°; C—H bond distance, 1.083 Å; C—F bond distance, 1.360 Å. For the neutral molecules considered, the s.t.o. exponents used for the orbitals of C and H are those deduced as optimum for CH_4 by Pople and co-workers (7), whereas in all positive ions, the exponents for the σ orbitals of C and H are those optimum for $(CH_3)^+$ (see Table 1) (7). The values recommended by Pople and co-workers (7) for the $n = 1$ and $n = 2$ orbitals are used for all F atom orbitals in neutral compounds, and for the σ orbitals in the positive ions (Table 1). The exponents for the p_π orbitals of C and of F in the fluorocarbonium ions (Table 1) are partially optimized by calculations for $(FCH_2)^+$ using an assumed C—F distance of 1.25 Å. Simple energy minimization of the F $2p_\pi$ exponent (with no π orbital on C) leads to the value 2.53 (Table 1). Using the latter as a starting value, two sets of successive reoptimizations of first the C $2p_\pi$ exponent followed by the F $2p_\pi$ leads to the values reported in Table 1 which are probably accurate to ±0.02.

TABLE 1. Slater-type orbital exponents used in calculations

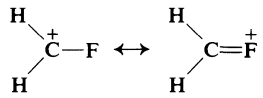
Atom	Orbital	Exponent value: Carbonium ions	Exponent value: Neutral molecules
C	1s	5.67	5.67
	2s, $2p_\sigma$	1.77	1.75
	$2p_\pi$	1.44	1.75
H	1s	1.33	1.18
F	1s	8.65	8.65
	2s, $2p_\sigma$	2.56	2.56
	$2p_\pi$	2.63	2.56
		2.53*	

*Used only for $(FCH_2)^+$ at 1.38 Å in the calculation with no C $2p_\pi$ orbital (see text).

Results and Discussion

Given the unusual geometry effects encountered in neutral fluorocarbons (8) (small FCX bond angles and short C—F bond distances), a geometry search was first executed for $(FCH_2)^+$ using the energy minimization criterion. Since variation of the FCH bond angles led to an optimum value within 2° of the "expected" 120° value, the latter value was employed in all subsequent calculations. Next the C—F bond distance and $2p_\pi$ orbital exponents of both C and F were simultaneously varied in a "brute force" minimization procedure, yielding the optimum values of 1.44, 2.63, and 1.26 Å, respectively.

The calculated carbon–fluorine bond length of 1.26 Å is very short for a linkage of this type (the average value in neutral fluoroethylenes and in fluorobenzenes being 1.33 Å (8)) and is indicative of relatively strong dative π bonding from F to C in the positive ion, as represented symbolically by the resonance structures



A measure of the strength of this π bonding was obtained by recalculating the wavefunction and energy for $(FCH_2)^+$ using the same molecular geometry and orbital exponents but eliminating the carbon atom $2p_\pi$ orbital from the basis set. The optimum energy calculated for this species, in which the fluorine $2p_\pi$ lone-pair of electrons is forced to remain localized on fluorine and the π bonding artificially "destroyed", is −136.1837 a.u., or some 75.1 kcal/mol less stable than the structure in which π bonding is active. A similar calculation for the difluoromethyl carbonium ion $(F_2CH)^+$, with the same bond angles, bond lengths, and orbital exponents as that for $(FCH_2)^+$ yields energies of −233.7933 and −233.5845 a.u. with and without the carbon $2p_\pi$ orbital included; thus the π bonding energy in (F_2CH^+) of 131.0 kcal/mol is less than double that in the monofluoro ion by some 19 kcal/mol. Note that these π energies are much larger than those found in the isoelectronic boron fluorides (9).

A somewhat more realistic evaluation of the π bond strength in $(FCH_2)^+$ is obtained by

[2]Available as program 47A from the Quantum Chemistry Program Exchange, Indiana University, Bloomington, Indiana, U.S.A.

TABLE 2. Mulliken population analyses for $(FCH_2)^+$ wavefunctions

Atom	Orbital*	Population† (electrons) Calculation *A*	Calculation *B*	Calculation *C*
C	1s	1.994	1.994	1.994
	2s	1.259	1.299	1.340
	$2p_\sigma$	1.213	1.216	1.207
	$2p_{\sigma'}$	0.795	0.947	0.964
	$2p_\pi$	0.394	0	0
	Total	5.654	5.456	5.505
H	1s	0.746	0.747	0.743
F	1s	1.999	1.999	1.999
	2s	1.938	1.944	1.962
	$2p_\sigma$	1.965	1.950	1.974
	$2p_{\sigma'}$	1.346	1.155	1.075
	$2p_\pi$	1.606	2.000	2.000
	Total	8.854	9.048	9.010

*The coordinate axis is such that the $2p_{\sigma'}$ orbitals on C and F lie along the C—F bond axis.
†Calculation *A* refers to the ion with C $2p_\pi$ included at $R_{CF} = 1.26$ Å; calculations *B* and *C* are for the ion without the C $2p_\pi$ orbital at $R_{CF} = 1.26$ Å and $R_{CF} = 1.38$ Å, respectively.

TABLE 3. Total energies and excess atomic charges for molecules and ions

Species	Calculation type*	Total energy (a.u.)	Excess charges (*e*) C	H	F
CH_4	—	−39.73139	−0.114	+0.028	—
CH_3F	—	−137.14671	+0.054	+0.029	−0.138

*See notes to Table 2 for details.

comparing the ion energy obtained with C $2p_\pi$ included at its optimum geometry ($R_{CF} = 1.26$ Å) and π exponents (Table 1) with the ion energy calculated without the C $2p_\pi$ orbital and using the optimum C—F distance and F $2p_\pi$ exponent. Energy minimization for this species yields an optimum energy of —136.2080 a.u. at $R_{CF} = 1.38$ Å and a F $2p_\pi$ exponent of 2.53; thus the ability of the $2p_\pi$ orbital on carbon to conjugate with the fluorine $2p_\pi$ lone pair yields an ion which is 60 kcal/mol more stable and has a bond length which is 0.12 Å shorter than the "imaginary" species in which the π electrons are localized on fluorine.

Further insight into the nature of the bonding in such carbonium ions is provided by the Mulliken population analysis (10) of the *ab initio* wavefunctions (Tables 2 and 3). Note first that the C—H bonds in the set of carbonium ions $(CH_3)^+$, $(FCH_2)^+$, and $(F_2CH)^+$ are all polar in the sense $C^{\delta-}H^{\delta+}$ to almost the same degree, since the hydrogen atom net charges all lie in the range $+0.27 \pm 0.02\,e$ (+0.25, +0.25, and +0.29 *e*, respectively).

Although each hydrogen atom bound to carbon carries about $\frac{1}{4}$ of the positive charge regardless of environment, the net charges and individual orbital populations associated with carbon and with fluorine are influenced substantially by the number of fluorine substituents and by the extent of π bonding permitted. When no $2p_\pi$ orbital is available on carbon in $(FCH_2)^+$, the population of each fluorine orbital except $2p_{\sigma'}$ is essentially equal to two (2.00, 1.96, 1.97, and 2.00 for the 1s, 2s, $2p_\sigma$, and $2p_\pi$ orbitals, respectively). The electrons in the C—F σ bond in this case are almost equally shared, since the $2p_{\sigma'}$ population on F is 1.08 *e* and the fluorine

net charge $-0.01\ e$. The σ bond reorganizes to become quite polar in the sense $C^{\delta+}F^{\delta-}$ when the C $2p_\pi$ orbital is available, although the net increase in electron density of all the σ orbitals of fluorine of $0.24\ e$ only partially compensates for the flow of 0.39 π electrons from F to C, yielding a net *positive* charge on fluorine of $+0.15\ e$. A similar phenomenon occurs in the difluoromethyl ion, in which the net charge of $-0.04\ e$ for each F drops to $+0.11\ e$ when π bonding occurs. Thus the polarization of the C—H σ electrons and the C—F π electrons toward carbon ensures a "delocalization" of the positive charge, and the net charges on carbon in the series $(CH_3)^+$, $(FCH_2)^+$, and $(F_2CH)^+$ are +0.26, +0.35, and $+0.52\ e$, all well below the "classical" +1 electron description.

At first glance, the net transfer of only $0.39\ e$ from F to C in the $(FCH_2)^+\pi$ network seems incompatible with the high energy calculated for this π bond. In fact, the following argument shows that *substantial polarization of an electron pair does not lead to a correspondingly low covalent bond strength.* If the polarization or ionicity i of a two-electron two-center bond is defined as the difference between the population q_u of an orbital ϕ_u, and the value 1.0, then

$$i = |q_u - 1|$$

$$q_u = 2(C_u^2 + C_uC_vS_{uv})$$

where S_{uv} is the overlap integral between the orbitals, and the values of C_u and C_v are interconnected by the normalization condition

$$C_u^2 + C_v^2 + 2C_uC_vS_{uv} = 1$$

In contrast, the covalent bond strength is the bond order $2C_uC_v$ relative to the completely covalent value of $1/(1 + S_{uv})$; *i.e.*

$$B = 2C_uC_v/(1 + S_{uv})$$

The essential point is that B is not linearly related to i; for small S values,[3]

$$B \sim \sqrt{1 - i^2}$$

which illustrates that even when the ionic character is large, the covalent bond strength remains quite high. In the case of $(FCH_2)^+$, for which i is 61%, the covalent bond strength B is a little over 70%. It is interesting that this B value is in good agreement with the bond shortening of 0.12 Å calculated above, since the latter corresponds to a π bond character of ~67% if one assumes that the bond order – bond length derivative established for carbon–carbon bonds applies also to carbon–fluorine linkages.[4] The analogy between carbon–carbon and carbon–fluorine π bonding also extends to the effects of multiple substitution, *i.e.* the total π energy in $(F_2CH)^+$ is significantly less than twice that in $(FCH_2)^+$, in the same way that the π energy in the allylic anion is much less than twice that in ethylene.

Although the discussion above has centered upon the ability of fluorine atoms to stabilize a carbonium ion by dative π bonding, the energetic destabilization due to the inductive effect is also of great importance in determining the overall behavior of the substituent. Unfortunately it is not possible to "turn off" the inductive effect in m.o. calculations to determine its energetic effect, so that the energetic consequences of the inductive effect can be deduced only on a relative basis. To this end, the total molecular energies (in atomic units) of $(CH_3)^+$, $(FCH_2)^+$, and $(F_2CH)^+$, all calculated using the same geometries and exponents and *without* the presence of the carbon $2p_\pi$ orbital are compared below:

$(CH_3)^+$	$E = -38.7917$	$\Delta E = -97.3920$
$(FCH_2)^+$	$E = -136.1837$	$\Delta E = -97.4008$
$(F_2CH)^+$	$E = -233.5845$	

Note in particular that the energy increase in going from $(FCH_2)^+$ to $(F_2CH)^+$ is almost identical to the difference between $(CH_3)^+$ and $(FCH_2)^+$; the small difference of 0.0088 a.u. (~5.5 kcal/mol) indicates that, whatever the magnitude of the inductive destabilization of

[3]See ref. 11 for the plot of B *vs.* i when S is included; the value of ~70% for B when $i \sim 61\%$ is taken from this plot.

[4]The rate of change of bond length with bond order is about 0.18 for $C(sp^2)$–$C(sp^2)$ linkages; see ref. 12. As a referee has pointed out, the fact that the transferability of the bond order – bond length derivative works here does not imply that this will be true for all fluorocarbon systems.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

one fluorine atom, the net effect for two such units is only slightly *less* than double that for one.

In contrast, the increase in π bond energy in the transition $(FCH_2)^+$ to $(F_2CH)^+$ is 19.2 kcal/mol less[5] than for the pair $(CH_3)^+$ to $(FCH_2)^+$, and this larger change in the resonance effect dominates the variations in the overall energy changes. In terms of the total energies (with the C $2p_\pi$ orbital "active"),

$$\left.\begin{array}{ll}(CH_3)^+ & E = -38.7917\\ (FCH_2)^+ & E = -136.3034\end{array}\right\} \Delta E = -97.5117$$

$$\left.\begin{array}{ll}(FCH_2)^+ & E = -136.3034\\ (F_2CH)^+ & E = -233.7933\end{array}\right\} \Delta E = -97.4899$$

The decrease in the overall ΔE by difluoro substitution compared to monofluoro substitution of 0.0218 a.u. or 13.7 kcal/mol is in excellent agreement with the corresponding decrease in the experimental heat of formation change of 11 kcal/mol for this series:

$$\left.\begin{array}{ll}(CH_3)^+ & \Delta H_f = +261^6\\ (FCH_2)^+ & \Delta H_f = +197^3\end{array}\right\} \Delta\Delta H_f = 64 \text{ kcal/mol}$$

$$\left.\begin{array}{ll}(FCH_2)^+ & \Delta H_f = +197^3\\ (F_2CH)^+ & \Delta H_f = +144^3\end{array}\right\} \Delta\Delta H_f = 53 \text{ kcal/mol}$$

Both the calculated and the experimental results predict that the inherent stability of the methyl carbonium ion itself is increased by substitution of a second fluorine atom, although the energy gain is not quite as large as that obtained upon introduction of the first fluorine. This interpretation is in marked contrast to that given by Martin, Lampe, and Taft (2) who concluded that a "saturation effect" occurs, with the result that the total stabilization for $(F_2CH)^+$ is slightly *less* than that for $(FCH_2)^+$, and that for $(F_3C)^+$ is much less than for either the monofluoro or difluoro ions. This discrepancy occurs because Martin *et al.* did not really compare the energies of the ions themselves to each other, but rather compared the energy changes in the hydride abstraction reactions

$$CH_{4-n}F_n \rightarrow (CH_{3-n}F_n)^+ + H^-$$

In fact, their conclusion that the stabilization energy of the ion decreases with multiple fluorine substitution does not reflect any energetic property of the ions themselves, but rather is due to the *increasing stability of the neutral molecules* $CH_{4-n}F_n$ as n increases. In summary, the failure of the enthalpy change for the hydride abstraction reaction to increase continuously with n is due mainly to the greater than additive increase with n of the bonding energy of the neutral molecules $CH_{4-n}F_n$ with only a minor contribution due to the less than additive increase in bonding energy of the $(CH_{3-n}F_n)^+$ carbonium ions. It is interesting to note that both trends are reproduced by the *ab initio* energies (Table 3).

Since no correlation energy effects are included and only a minimal basis set of orbitals is employed in the present calculations, it would not be surprising if the absolute energies calculated for each of the hydride abstraction reactions above were greatly in error. In actual fact, the values obtained for ΔH (259, 198, and 195 kcal/mol for $n = 0$, 1, 2, respectively) are in fair agreement with the experimental results (262, 236, and 234 kcal/mol, respectively) if the experimental energy for the hydride ion[7] is used rather than the theoretical value; the latter is well-known to be quite inaccurate when a minimal basis set is used.

In conclusion, it appears that minimal basis set *ab initio* calculations are well-suited to the analysis of substituent effects in carbonium ions, both in terms of predicting overall trends in stability and in terms of decomposing the energy into contributions from inductive and resonance effects. Similar calculations on substituent effects in carbanions are currently in progress.

Axial:Equatorial Rate Ratios. 1. Eliminations Leading to the Exocyclic Methylene Group

J. F. KING AND M. J. COPPEN
Department of Chemistry, University of Western Ontario, London, Ontario

Received June 18, 1971

Phenyl *cis*-4-*t*-butylcyclohexanemethyl sulfoxide (**4**) thermolyzes to 1-*t*-butyl-4-methylenecyclohexane (**5**) at 116 and 130° about five to six times faster than its *trans* (equatorial) epimer **6**. *cis*-4-*t*-Butylcyclohexanemethyl bromide (**7**) undergoes elimination with potassium *t*-butoxide in *t*-butyl alcohol at 100° about nine times faster than its *trans* (equatorial) epimer **8**. The rate difference found for the sulfoxides **4** and **6** is the first clear demonstration of steric acceleration (without any contribution from any reagent repulsion effect) in the formation of an exocyclic carbon–carbon double bond in a simple anchored cyclohexane system. The faster elimination from **7** (*vs.* **8**) is ascribed primarily to steric acceleration; the experiment neither requires nor excludes the influence of non-bonding repulsions between the substrate and the attacking base.

Le phényl *t*-butyl-4 *cis* cyclohexaneméthyl sulfoxyde (**4**) se transforme par thermolyse à 116 et 130° en *t*-butyl-1 méthylène-4 cyclohexane (**5**); la vitesse est de cinq à six fois plus grande que pour l'épimère (équatorial) *trans* **6**. Le *t*-butyl-4 bromométhyl-1 cyclohexane (**7**) subit une réaction d'élimination sous l'action du *t*-butoxyde de potassium dans l'alcool *t*-butylique à 100° et la vitesse est de neuf fois plus grande que pour l'épimère (équatorial) *trans* **8**. La différence de vitesse trouvée pour les sulfoxydes **4** et **6** constitue la première preuve d'une accélération stérique (sans aucune contribution d'effets de répulsion du réactif) dans la formation d'une double liaison carbone–carbone exocyclique appartenant à un système cyclohexanique rigide. L'élimination plus rapide dans **7** (*vs.* 8) est due principalement à une accélération stérique; les résultats obtenus n'impliquent et n'excluent pas l'influence des répulsions de non-liaison entre le substrat et la base qui vient d'attaquer.

Canadian Journal of Chemistry, 49, 3714 (1971)

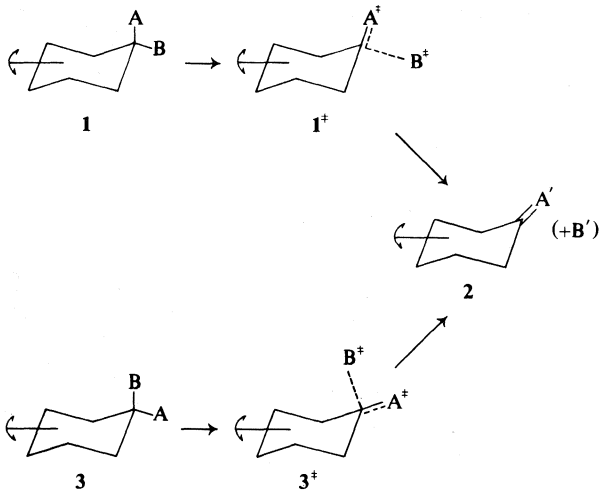
Introduction

Since the appearance of Barton's pioneering paper two decades ago (1), conformational analysis has become part of the very fabric of organic chemistry, being used routinely to explain or predict both the products and relative rates of reactions. Rationalization of relative rates in conformational terms requires some kind of description of the geometry of transition states, and it seemed to us that if we only knew enough about how conformational factors affect reaction rates, we could apply this knowledge to learn about transition state geometry, *i.e.* as a tool in the general problem of elucidating reaction mechanisms.

We have begun our attempts to apply conformational phenomena to mechanistic study using reactions of substituted cyclohexyl compounds because these appeared to be the best understood of any in conformational terms. In this, the first paper of a projected series, we describe our experiments on reactions of the type **1** → **2** ← **3**, as in Scheme 1.[1] Prior to this study, what was known about the system **1** → **2** ← **3** derived from study of the chromic acid oxidation of cyclohexanols (3–8). The work described in this account was done primarily to see if the analysis that had evolved from the cyclohexanol oxidations was general, *i.e.* could be extended to include reactions in which the central atom of A, A‡, and A′ was something other than oxygen. We also sought

[1]We use the symbol (**i**) below to indicate a rigid or anchored (2) cyclohexane ring. This symbol makes it easy to dépict reaction schemes involving anchored six-membered rings without further specifying the structure, *i.e.* whether it is part of a simple *trans*-decalin, a more complex fused ring (*e.g.* steroid), or 4-*t*-butylcyclohexyl system. At the same time the symbol (**i**) diminishes the likelihood of misunderstanding by clearly distinguishing between a simple cyclohexyl system, which is normally readily converted to the other chair conformation, from an anchored cyclohexyl system, which is not.

(**i**)



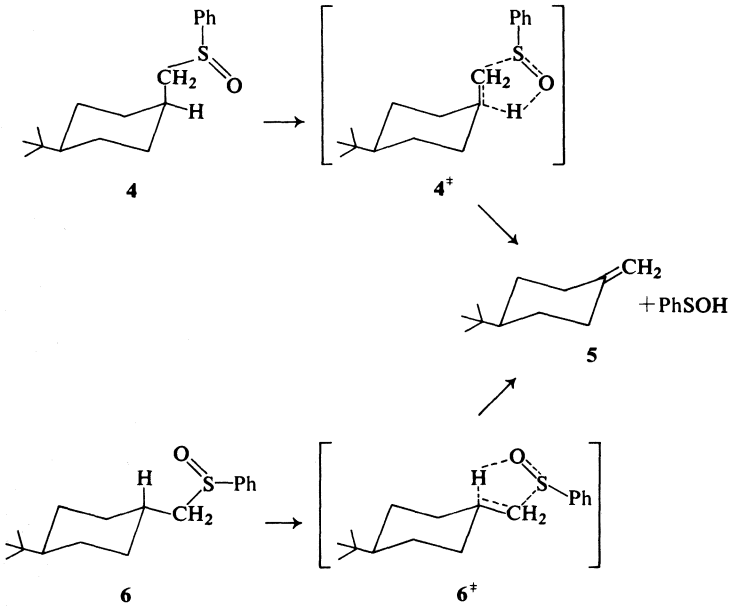
SCHEME 1

to obtain clear demonstration of the "steric acceleration effect" in a simple axial cyclohexyl compound in which the only other axial functions are hydrogens, and in addition to determine the significance, if any, of the "reagent repulsion effect" (see below). The second, and accompanying paper demonstrates the application of this "method of axial:equatorial rate ratios" to a reaction in which we have been interested, for entirely independent reasons, for some time, namely the formation of sulfenes by dehydrohalogenation of sulfonyl chlorides.

As is mentioned above, the oxidation of cyclohexanols with chromic acid has been studied extensively (3–8). It was found that axial alcohols react faster than their equatorial epimers, and further, that, except for an extremely hindered hydroxyl group (8), the greater the steric compression on the hydroxyl group the faster the reaction (4). This was explained (4) as deriving from a *steric acceleration effect*, which may be described in terms of the structures in Scheme 1. When A = OH and B = H, **1** has higher energy than **3** (*i.e.* $G(\mathbf{1}) > G(\mathbf{3})$), because of the higher total non-bonding interaction energy associated with the axial disposition of the hydroxyl function compared with the equatorial. On going from the starting material to the transition state, the non-bonding interaction energy difference, $G(\mathbf{1}^{\ddagger}) - G(\mathbf{3}^{\ddagger})$, is reduced as the geometries of $\mathbf{1}^{\ddagger}$ and $\mathbf{3}^{\ddagger}$ approach that of the product **2**; *i.e.* $G(\mathbf{1}^{\ddagger}) - G(\mathbf{3}^{\ddagger}) < G(\mathbf{1}) - G(\mathbf{3})$. Hence $G(\mathbf{1}^{\ddagger}) - G(\mathbf{1}) < G(\mathbf{3}^{\ddagger}) - G(\mathbf{3})$, or, since $G(\mathbf{1}^{\ddagger}) - G(\mathbf{1})$ is simply $\Delta G_1^{\ddagger}$, the free energy of activation for **1**, and $G(\mathbf{3}^{\ddagger}) - G(\mathbf{3})$ is $\Delta G_3^{\ddagger}$, the free energy of activation for **3**, this is more simply stated: $\Delta G_1^{\ddagger} < \Delta G_3^{\ddagger}$, *i.e.* the axial isomer **1** reacts faster than its equatorial epimer **3**.

Barton (1) had previously pointed out that "if the rate determining step is attack upon the carbon–hydrogen bond rather than upon the carbon–oxygen bond" then reaction of axial alcohols would be subject to smaller steric hindrance than that of the equatorial epimers. In terms of Scheme 1 (A = OH, B = H, and $B^{\ddagger}$ = a hydrogen partially bonded to the hydrogen-abstracting reagent), this would mean that in the process $\mathbf{3} \rightarrow \mathbf{3}^{\ddagger}$, the total non-bonding energy increases more than it does in process $\mathbf{1} \rightarrow \mathbf{1}^{\ddagger}$. This basic notion has been applied in numerous contexts for some time; for the purposes of specific reference in this paper we shall call this the *reagent repulsion effect*. As data on the cyclohexanol oxidation became available it grew apparent that for that reaction at least, the steric acceleration effect was definitely the more important, and perhaps the only significant, steric effect. In general, however, until the magnitude of the putative reagent repulsion effect in all reactions of the type $\mathbf{1} \rightarrow \mathbf{2} \leftarrow \mathbf{3}$ can be estimated, it would appear advisable to keep it in mind as a possibility which requires consideration. Alternatively, of course, one could design a system in which reagent repulsion is clearly impossible or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



SCHEME 2

obviously of no consequence. This is, in fact, the approach adopted in the first of the reactions discussed in this paper.

Evidence available when this work was begun (9–12), and added to subsequently (13–15), strongly indicates that the thermolysis of simple alkyl (or aryl alkyl) sulfoxides with at least one β-hydrogen atom leads to the olefin and the sulfenic acid via a cyclic concerted process in which the sulfoxide oxygen acts as the proton-abstracting agent. Reactions **4** → **5** ← **6** in Scheme 2 illustrate the specific example of the sulfoxide thermolysis corresponding to the general system in Scheme 1. The transition states for the *cis*-sulfoxide **4** and the *trans*-sulfoxide **6** are depicted by **4**‡ and **6**‡, respectively. It is evident that the contribution of any reagent repulsion effect in this system would be inconsequential, whereas the steric acceleration effect would be predicted to show up undiminished. On the basis of the foregoing analysis it would be expected that relative rates of the thermolysis of **4** and **6** would be a direct measure of the steric acceleration in this system, and hence could give some notion of the significance of this effect in the general system **1** → **2** ← **3** in which the central atom of A and A′ is carbon.

A second system of the general type **1** → **2** ← **3** was also studied briefly, namely the dehydrohalogenation of the axial and equatorial cyclohexanemethyl bromides **7** and **8** to 1-*t*-butyl-4-methylenecyclohexane (**5**). It was hoped that in addition to providing another example of the Scheme 1 system in which A is carbon and B is hydrogen, that it might also lead to definite information concerning the reagent repulsion effect.

After our work was well underway another effect relevant to our study of axial:equatorial rate ratios was suggested in order to account for the products of hydride reduction and Grignard addition to carbonyl compounds (16, 17); for the specific example of additions to cyclohexanones this would be an example of the reaction **1** ← **2** → **3**, *i.e.* the *reverse* of the general reaction that we are concerned with in this paper. Felkin and co-workers (16–18) have postulated the existence of torsional strain in the transition state between the partial bond joining the attacking nucleophile to the erstwhile carbonyl carbon and any bonds to the α-carbons that eclipse (or nearly eclipse) this partial bond. This hypothesis, which we shall call the "Felkin postulate", was used to account, among other things, for the well-known predominance of the equatorial alcohol in the hydride reduction of unhindered anchored cyclohexanones, the torsional strain in this instance being between the hydride hydrogen to carbon bond and the two C—H bonds between the α-carbons

TABLE 1. Rates of thermolysis of the phenyl *cis*- and *trans*-4-*t*-butylcyclohexanemethyl sulfoxides (**4** and **6**) in benzene

Compound	Configuration	Temperature (°C)	$k \times 10^6$ (s^{-1})	k_{Ax}/k_{Eq}
cis-**4**	Axial	129.9	32	5.4
trans-**6**	Equatorial	129.9	5.9	
cis-**4**	Axial	116.4	6.4	5.8
trans-**6**	Equatorial	116.4	0.11	

and their axial hydrogens. These authors specifically suggest that the torsional strain is significant even in transition states in which the partial bond is weak; in terms of Scheme 1 this refers to that situation in which $\mathbf{1}^{\ddagger}$ is close to **2** on the reaction coordinate.

In the present context the Felkin postulate would suggest that as $\mathbf{1}^{\ddagger}$ and $\mathbf{3}^{\ddagger}$ become more and more like **2** (as one changes the reaction conditions or the nature of A or B), the energy difference between $\mathbf{1}^{\ddagger}$ and $\mathbf{3}^{\ddagger}$ will not become negligible because of the differences in torsional strain. If this be the case then the axial:equatorial rate ratio will not reduce to a simple reflection of the difference in energy between the two starting materials ($G(\mathbf{1}) - G(\mathbf{3})$).

The work described in this paper neither alters the status of the Felkin postulate nor makes specific use of it. The topic is mentioned as a possible effect which could influence axial:equatorial rate ratios in general and also as an illustration of the complexities and uncertainties that may still surround even semi-quantitative theoretical interpretation of axial:equatorial rate ratios. We wish to emphasize that application of the method of axial:equatorial rate ratios at present is an essentially empirical procedure in which the validity of the argument is directly related to the similarity between the unknown and model systems. In order to make non-trivial application of the method, the unknown and model reactions must be chemically different but sterically analogous. Obviously, enough must be known of the important factors governing axial:equatorial rate ratios to be sure that unknown and model reactions are really sterically analogous and that the unknown system will not be controlled by a hitherto unknown effect. The primary aim of our study (which is described in part in this paper) was to assemble an array of carefully chosen model systems for comparison with reactions of unknown course. It was hoped that we might also either uncover any further influences of importance in anchored cyclohexyl systems, or else reduce the likelihood of their existence to the point that useful mechanistic conclusions could be drawn by applying the method of axial:equatorial rate ratios.

Results and Discussion

Thermolysis of cis and trans Phenyl 4-t-Butylcyclohexanemethyl Sulfoxides (4 and 6)

The axial and equatorial sulfoxides **4** and **6** were obtained in a straightforward manner from the corresponding 4-*t*-butylcyclohexylcarbinols, via the methanesulfonates and the phenyl sulfides (see Experimental). Model experiments with phenyl cyclohexanemethyl sulfoxide showed that thermolysis in benzene at 130° gave, in addition to methylenecyclohexane, a second material (perhaps 1-methylcyclohexene) running slightly more slowly on v.p.c.; formation of this second material was completely suppressed by addition of calcium carbonate to the reaction. The rates of the thermolyses were followed by v.p.c. determination of the 1-*t*-butyl-4-methylenecyclohexane (**5**). The reactions were found to be cleanly first order to >60% reaction; variation in the amount of calcium carbonate had no effect on the rate.

As may be seen in Table 1, the axial sulfoxide **4** reacts five to six times faster than its equatorial epimer **6** in benzene solution in the temperature range 116–130°. By way of comparison it should be noted that Eliel and co-workers (7) found that the oxidation of *cis*-4-*t*-butylcyclohexanol with chromic acid in 75% acetic acid at 25° proceeds 3.23 times faster than the *trans* (equatorial) epimer. The increase in the ratio k_{Ax}/k_{Eq} on going from 129.9 to 116. 4° with the sulfoxides suggests that the ratio at 25° might well be distinctly greater than 6; the data, however, are probably not accurate enough to justify extrapolation to lower temperatures (or estimation of enthalpies and entropies of activation).

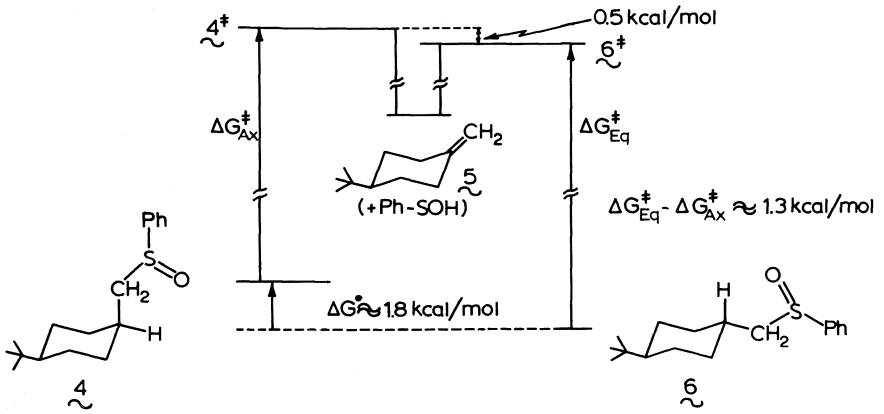

FIG. 1. Energy diagram for the thermolyses of the *cis*- and *trans*-phenyl 4-*t*-butylcyclohexanemethyl sulfoxides (**4** and **6**) at 130°.

The approximate relative free energies in the thermolyses of the sulfoxides **4** and **6** are summarized in Fig. 1. The $\Delta G°$ value (*i.e.* $G_{Ax} - G_{Eq}$) for the —CH_2SO—Ph group is assumed to be about 1.8 kcal/mol, *i.e.* comparable to that found with other —CH_2X groups, *e.g.* —CH_2CH_3, 1.75 kcal/mol (19) and CH_2OCH_3, 1.80 kcal/mol (20); it is also further assumed that the value is not much different at 130°. At that temperature the rate ratio, k_{Ax}/k_{Eq}, is 5.9, corresponding to a difference in free energy of activation ($\Delta G^{\ddagger}_{Eq} - \Delta G^{\ddagger}_{Ax}$) of 1.3 kcal/mol, indicating a roughly 0.5 kcal/mol difference in energy between the two transition states **4**‡ and **6**‡.

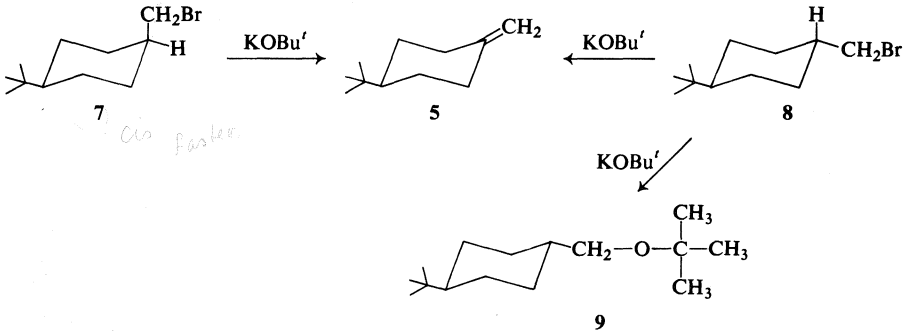
For any reaction in which the rate difference between two epimers derives exclusively from steric acceleration as defined here, it is evident from Fig. 1 that the rate difference cannot be greater than ΔG^0, the difference in the free energies of the starting materials; *i.e.* as the two transition states approach the same energy, $\Delta G^{\ddagger}_{Eq} - \Delta G^{\ddagger}_{Ax}$ tends toward $\Delta G°$, or, taking the Felkin postulate into account, $\Delta G°$ less the energy of the torsional strain difference. With the sulfoxide thermolysis the maximum possible difference in $\Delta G^{\ddagger}$ would be ~1.8 kcal/mol, whereas the difference that is actually observed is 1.3 kcal/mol or about 70% of this value. For the chromic acid oxidation of cyclohexanols the rate ratio of 3.23 at 25° quoted earlier corresponds to a difference in $\Delta G^{\ddagger}$ of about 0.7 kcal/mol or about 80% of 0.87 kcal/mol, the $\Delta G°$ value for the hydroxyl groups in hydroxylic media (19). If the extent of the reaction in the transition state in the thermolysis and oxidation reactions should happen to be roughly comparable, then the difference in rate between the axial and equatorial alcohols in chromic acid oxidation would seem almost entirely ascribable to steric acceleration, with little or no room for contribution by reagent repulsion. Alternatively the difference between $\Delta\Delta G^{\ddagger}$ and $\Delta G°$ could be ascribed entirely to Felkin's torsional strain in the transition state **1**‡; this would still leave very little leeway for any effect of reagent repulsion.

E2 Reaction of cis- and trans-4-t-Butylcyclohexanemethyl Bromides (7 and 8)

With the aim of obtaining further data on k_{Ax}/k_{Eq} for exocyclic eliminations, we briefly investigated the reaction of the *cis*- and *trans*-4-*t*-butylcyclohexanemethyl bromides (**7** and **8**) with strong base. These compounds were readily prepared from the cyclohexylcarbinols via the *p*-nitrobenzenesulfonate esters (see Experimental).

Each bromide was found to react with potassium *t*-butoxide in *t*-butyl alcohol at 100°. As shown in Scheme 3 the axial bromide (**7**) gave 1-*t*-butyl-4-methylenecyclohexane (**6**) (~80% yield) with no sign of any of the *t*-butyl ether. The equatorial isomer (**8**) however, gave a mixture estimated to contain about 30% of **6** and about 70% of *t*-butyl 4-*t*-butylcyclohexanemethyl ether (**9**) (total yield of this mixture also 80%), the product of a presumed S_N2 displacement at the equatorial primary carbon. As will be described in a subsequent paper in this series, we have observed that the formation of **8** from the *p*-nitrobenzenesulfonate takes place about 20 times faster than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



SCHEME 3

that of the axial isomer **7** under the conditions studied. For the S_N2 reaction of **7** and **8** with potassium *t*-butoxide we estimate $k_{Ax}/k_{Eq} < 0.3$; only an upper limit was obtainable because of the absence of any detectable amount of the ether from **7**.

The rate of the reaction of the bromides **7** and **8** with a large excess of potassium *t*-butoxide was obtained by following the rate of release of bromide ion. With **7** this gives the rate of elimination directly, but with **8** this yields the sum of the rates of substitution and elimination. At 100° with a base concentration of 0.76 *M* in *t*-butyl alcohol the rate of bromide ion release from the axial bromide **7** corresponded to a second order rate constant of 9.4×10^{-4} l mol^{-1} s^{-1}. With the equatorial bromide (**8**) the corresponding rate constant was 3.5×10^{-4} l mol^{-1} s^{-1}, which, from the product ratio given above, corresponds to a second order rate constant for the *elimination* of 1.1×10^{-4} l mol^{-1} s^{-1}. To show that the reaction rate depended on base concentration, another pair of determinations was carried out with the solution 0.41 *M* in potassium *t*-butoxide; this led to rate constants for the elimination of 9.0×10^{-4} and 1.0×10^{-4} l mol^{-1} s^{-1} for **7** and **8** respectively.

Approximate though these measurements are, they clearly show that the axial bromide **7** undergoes elimination (evidently bimolecular) distinctly more rapidly than its equatorial epimer **8**, by about nine times, in fact. This value corresponds to a difference in $\Delta G^{\ddagger}$ of about 1.6 kcal/mol, which is close to, but still less than, the maximum difference derivable exclusively from steric acceleration, which may be estimated as detailed above to be about 1.8 kcal/mol. It had been hoped that the considerable bulk of the *t*-butoxide ion might lead to a difference in $\Delta G^{\ddagger}$ of more than 1.8 kcal/mol, thereby requiring the postulation of another effect, *viz.* reagent repulsion, in addition to steric acceleration. In the absence of further data it is not unreasonable to ascribe the faster elimination of the axial bromide (**7**) primarily to steric acceleration; reagent repulsion is neither required nor entirely excluded.

Experimental

Melting points, which were determined on a Kofler hot stage, and boiling points are uncorrected. Unless otherwise stated, i.r. and n.m.r. spectra were determined in carbon tetrachloride solution (Fisher Spectranalyzed grade), and were determined on a Beckman IR-10 instrument and a Varian A-60 spectrometer, respectively; the chemical shifts are recorded in p.p.m. downfield from internal tetramethylsilane. The u.v. spectra were determined on a Jasco model O.R.D./U.V.5 spectropolarimeter. The t.l.c. was carried out using Camag silica gel DF 5. The refractive indices were determined with a thermostatically controlled Bausch and Lomb refractometer. Organic extracts were dried with anhydrous magnesium sulfate. The silica gel used for column chromatography was B.D.H. (for Chromatographic Adsorption). Dry ether refers to ether (Mallinckrodt anhydrous) freshly distilled from lithium aluminum hydride (Metal Hydrides). Petroleum ether refers to the fraction of b.p. 30–60°. The v.p.c. was carried out on F and M model 700 apparatus; *I* refers to injector temperature, *O* to oven temperature, and *D* to detector temperature; helium (40 ml/s) was used as the carrier gas. The degassing and sealing of Carius tubes was carried out according to the following procedure. Then tube was placed in liquid nitrogen until the sample was frozen, and then evacuated with a vacuum pump (10^{-2}–10^{-3} mm). The direction connection to the pump was closed and the sample removed from the liquid nitrogen and allowed to thaw and let stand for about 10 min with occasional gentle shaking. The tube was then put back in the liquid nitrogen, pumped, warmed, shaken as before, and then cooled and evacuated for a third time, after which the tube was sealed off at the torch.

cis-4-t-Butylcyclohexanemethyl Methanesulfonate

cis-4-*t*-Butylcyclohexylcarbinol (2.3 g) prepared as described by Buchanan *et al.* (21), and methanesulfonyl

chloride (1.3 ml, Eastman, redistilled) were dissolved in methylene chloride (15 ml, Fisher Spectranalyzed grade) and cooled in an ice bath. To this cooled solution, triethylamine (3 ml, Fisher Reagent grade, redistilled) in methylene chloride (5 ml) was added slowly. The reaction mixture was left standing at room temperature for 10 min, then poured into water, and extracted twice with methylene chloride. The combined methylene chloride layers were washed successively with water, sulfuric acid (10%) and water, and dried. Evaporation of the methylene chloride gave a white solid (2.1 g). Crystallization from methylene chloride – pentane gave *cis*-4-*t*-butylcyclohexanemethyl methanesulfonate as fine plates, m.p. 45.5–46°. The i.r. bands were found at ν_{max} 1370 (s), 1350 (s), 1250 (vw), 1180 (s), 990 (sh), 970 (sh), 950 (s), 940 (sh) cm^{-1}. The n.m.r. spectrum had bands at 0.84 (s, $-C(CH_3)_3$), 2.90 (s, $-OSO_2CH_3$), and 4.12 p.p.m. (d, $-CH_2OSO_2CH_3$, J 7.5 Hz).

Anal. Calcd. for $C_{12}H_{24}O_3S$: C, 58.01; H, 9.74; S, 12.89. Found: C, 57.82; H, 9.93; S, 13.05.

trans-4-Butylcyclohexanemethyl Methanesulfonate

This was prepared from *trans*-4-*t*-butylcyclohexylcarbinol (21) by the same procedure as for *cis*-4-*t*-butylcyclohexanemethyl methanesulfonate. Crystallization from methylene chloride – pentane gave *trans*-4-*t*-butylcyclohexanemethyl methanesulfonate as large plates, m.p. 71.5–72°. The i.r. bands were found at ν_{max} 1370 (s), 1350 (s), 1240 (vw), 1180 (s), 995 (sh), 980 (sh), 950 (s), 910 (vw) cm^{-1}. The n.m.r. spectrum had bands at 0.84 (s, $-C(CH_3)_3$), 2.85 (s, $-OSO_2CH_3$), and 3.90 p.p.m. (d, $-CH_2OSO_2CH_3$, J 5.5 Hz).

Anal. Calcd. for $C_{12}H_{24}O_3S$: C, 58.01; H, 9.74; S, 12.89. Found: C, 58.20; H, 9.88; S, 12.98.

Cyclohexanemethyl Methanesulfonate

This was prepared from cyclohexylcarbinol (Aldrich) by the same procedure as for *cis*-4-*t*-butylcyclohexanemethyl methanesulfonate. Crystallization from methylene chloride – pentane gave cyclohexanemethyl methanesulfonate as needles, m.p. 45–46.5°. The i.r. bands were found at ν_{max} 1350 (vs), 1180 (s), 980 (s), 945 (s), 900 (m) cm^{-1}. The n.m.r. spectrum had bands at 2.96 (s, $-OSO_2CH_3$) and 3.92 p.p.m. (d, $-CH_2OSO_2CH_3$, J 6 Hz).

Anal. Calcd. for $C_8H_{16}O_3S$: C, 49.97; H, 8.39; S, 16.67. Found: C, 50.14; H, 8.32; S, 16.56.

Phenyl cis-4-t-Butylcyclohexanemethyl Sulfide

cis-4-*t*-Butylcyclohexanemethyl methanesulfonate (1.3 g) was dissolved in dioxane (5 ml, Fisher Reagent grade, redistilled) and added to a solution of sodium thiophenoxide prepared by mixing sodium (0.5 g), ethyl alcohol (15 ml, 95%), thiophenol (2.5 g, Fisher Reagent grade) in dioxan (50 ml). This mixture was refluxed for 12 h under a nitrogen atmosphere and then poured into a mixture of ether and 5% aqueous sodium hydroxide. The ethereal layer was washed with 10% sulfuric acid (until the washings were acidic), then with water, and dried. Evaporation of the ether gave a white solid (1.3 g). Crystallization from pentane gave phenyl *cis*-4-*t*-butylcyclohexanemethyl sulfide as spars, m.p. 48–49°. The i.r. bands were found at ν_{max} 3060 (vw), 1585 (w), 1240 (w), 1090 (vw), 1030 (w) cm^{-1}. The n.m.r. spectrum had bands at 0.82 (s, $-C(CH_3)_3$), 2.86 (d, $-CH_2SC_6H_5$, J 7.5 Hz), and 7.1 p.p.m. (m, $-SC_6H_5$).

Anal. Calcd. for $C_{17}H_{26}S$: C, 77.79; H, 9.99; S, 12.21. Found: C, 78.01; H, 10.18; S, 12.16.

Phenyl trans-4-t-Butylcyclohexanemethyl Sulfide

This was prepared from *trans*-4-*t*-butylcyclohexanemethyl methanesulfonate by the same procedure as for phenyl *cis*-4-*t*-butylcyclohexanemethyl sulfide. Crystallization from pentane gave phenyl *trans*-4-*t*-butylcyclohexanemethyl sulfide as fine needles, m.p. 40–41°. The i.r. bands were found at ν_{max} 3060 (vw), 1585 (w), 1270 (vw), 1240 (vw), 1090 (vw), 1070 (sh), 1030 (vw) cm^{-1}. The n.m.r. spectrum had bands at 0.82 (s, $-C(CH_3)_3$), 2.70 (d, $-CH_2SC_6H_5$, J 6 Hz), and 7.1 p.p.m. (m, $-SC_6H_5$).

Anal. Calcd. for $C_{17}H_{26}S$: C, 77.79; H, 9.99; S, 12.21. Found: C, 78.04; H, 10.10; S, 12.18.

Phenyl Cyclohexanemethyl Sulfide

This was prepared from cyclohexanemethyl methanesulfonate by the same procedure as for phenyl *cis*-4-*t*-butylcyclohexanemethyl sulfide. Crystallization from pentane gave phenyl cyclohexanemethyl sulfide as spars m.p. 19–21°. The i.r. bands were found at ν_{max} 3070 (w), 1585 (m), 1260 (w), 1240 (w), 1090 (w), 1070 (sh), 1030 (w) cm^{-1}. The n.m.r. spectrum had bands at 2.70 (d, $-CH_2SC_6H_5$, J 6 Hz) and 7.1 p.p.m. (m, $-SC_6H_5$).

Phenyl cis-4-t-Butylcyclohexanemethyl Sulfoxide (4)

To a solution of phenyl *cis*-4-*t*-butylcyclohexanemethyl sulfide (2.9 g) in glacial acetic acid (200 ml) at 15° was added aqueous hydrogen peroxide (10 ml, 30%). The reaction mixture was left standing at 15° for 1 h and then poured into water. The resulting mixture was extracted twice with ether. The combined ethereal layers were washed with water and then with a saturated solution of sodium bicarbonate and dried. Evaporation of the ether gave an oil (3.0 g). Crystallization from pentane gave phenyl *cis*-4-*t*-butylcyclohexanemethyl sulfoxide (4) as fine needles, m.p. 60–61°. The i.r. bands were found at ν_{max} 3060 (vw), 1580 (vw), 1370 (m), 1240 (w), 1090 (m), 1070 (sh), 1050 (vw), 1025 (sh), 1000 (sh) cm^{-1}. The n.m.r. spectrum had bands at 0.84 (s, $-C(CH_3)_3$), 2.70 (m, $-CH_2SOC_6H_5$), and 7.5 p.p.m. (m, $-SOC_6H_5$).

Anal. Calcd. for $C_{17}H_{26}OS$: C, 73.31; H, 9.41; S, 11.51. Found: C, 73.61; H, 9.59; S, 11.71.

Phenyl trans-4-t-Butylcyclohexanemethyl Sulfoxide (6)

This was prepared from phenyl *trans*-4-*t*-butylcyclohexanemethyl sulfide by the same procedure as for phenyl *cis*-4-*t*-butylcyclohexanemethyl sulfoxide (4). Crystallization from methylene chloride – pentane gave phenyl *trans*-4-*t*-butylcyclohexanemethyl sulfoxide (6) as fine plates, m.p. 107–108°. The i.r. bands were found at ν_{max} 3060 (vw), 1580 (vw), 1370 (m), 1260 (w), 1240 (w),1090 (m), 1070 (sh), 1050 (vs), 1030 (sh), 1000 (sh) cm^{-1}. The n.m.r. had bands at 0.84 (s, $-C(CH_3)_3$), 2.50 (m, $-CH_2SOC_6H_5$), and 7.5 p.p.m. (m, $-SOC_6H_5$).

Anal. Calcd. for $C_{17}H_{26}OS$: C, 73.31; H, 9.41; S, 11.51. Found: C, 73.63; H, 9.45; S, 11.50.

Phenyl Cyclohexanemethyl Sulfoxide

This was prepared from phenyl cyclohexanemethyl sulfide by the same procedure as for phenyl *cis*-4-*t*-

butylcyclohexanemethyl sulfoxide (**4**). Crystallization from methylene chloride – pentane gave phenyl cyclohexanemethyl sulfoxide as fine needles, m.p. 56–57°. The i.r. bands were found at ν_{max} 3060 (w), 1580 (vw), 1270 (vw), 1100 (sh), 1080 (m), 1070 (sh), 1050 (s), 1020 (sh), 1000 (sh) cm^{-1}. The n.m.r. spectrum had bands at 2.71 (d, $—CH_2SOC_6H_5$, J 6 Hz) and 7.5 p.p.m. (m, $—SOC_6H_5$).

Anal. Calcd. for $C_{13}H_{18}OS$: C, 70.20; H, 8.16; S, 14.41. Found: C, 70.38; H, 8.09; S, 14.37.

1-t-Butyl-4-methylenecyclohexane (5)

This was prepared from 4-*t*-butylcyclohexane following the general procedure of Greenwald *et al.* (22). The i.r. bands were found at ν_{max} 3080 (w), 1650 (m), 1370 (m), 1245 (w), 1225 (w), 990 (w), 910 (sh), 900 (s) cm^{-1}. The n.m.r. spectrum had bands at 0.86 (s, $—C(CH_3)_3$) and 4.5 p.p.m. (broad s, $C{=}CH_2$).

Measurement of the Rate of the Reaction of the Pyrolysis of Phenyl cis- and trans-4-t-Butylcyclohexanemethyl Sulfoxides (4 and 6)

The phenyl 4-*t*-butylcyclohexanemethyl sulfoxide (*ca.* 250 mg) and naphthalene (*ca.* 140 mg, B.D.H. laboratory reagent, added as a standard for the v.p.c. assay) were weighed and dissolved in benzene (Fisher Spectranalyzed Grade, freshly distilled from calcium hydride) and the resulting solution made up to 10 ml at 25 °C. Aliquots (1 ml) of this solution with solid calcium carbonate (*ca.* 20 mg) were degassed and sealed under vacuum. These aliquots were then put into an oil bath whose temperature was controlled by a Fisher "Proportional Temperature Control" thermostat to ±0.2°. Timing was started at the time of immersion in the oil bath. After an appropriate time interval the aliquot was removed from the oil bath and placed under rapidly running cold water. The aliquot was then cooled in Dry Ice – acetone and opened. The thawed solution was then poured down a column of silica gel (*ca.* 5 g) and the column washed with 10 ml of benzene – *n*-pentane (1:1). This short column removed any unpyrolysed sulfoxide but did not alter the ratio of 1-*t*-butyl-4-methylenecyclohexane to naphthalene (known mixture ratios being the same before as after the above work-up). The resulting solution was then analyzed by v.p.c. using a 10% silicon rubber GE.SE.33 on Chromosorb WAW.DMSC 80–100 mesh column (6′ × ¼″ diameter) v.p.c. *I*, 165°; *O*, 120°; *D*, 178°). The amount of 1-*t*-butyl-4-methylenecyclohexane produced in the reaction was estimated by a comparison of the areas under the peak corresponding to naphthalene. This ratio was compared to ratios of known composition analyzed under the same conditions.

Two samples, one of the *cis*-sulfoxide **4**, the other of the *trans*-epimer **6** were sealed in ampoules as described above (except that the naphthalene was omitted), heated at 130° for 50 h, chromatographed as above, and the solvent evaporated. The n.m.r. spectra of the two materials were identical with that of an authentic specimen of 1-*t*-butyl-4-methylenecyclohexane (**5**) except for the presence of a small amount of an impurity containing hydrogens on an aromatic ring.

cis-4-t-Butylcyclohexanemethyl p-Nitrobenzenesulfonate

cis-4-*t*-Butylcyclohexylcarbinol (3.0 g) was dissolved in pyridine (5 ml, redistilled) and the resulting solution cooled in an ice bath. To this cooled solution *p*-nitrobenzenesulfonyl chloride (4.0 g, Eastman Organic) in dry pyridine (5 ml) was added slowly. The resulting solution was left standing in the ice bath for 20 min. The mixture was then poured into water and extracted twice with methylene chloride. The combined methylene chloride layers were washed with 10% sulfuric acid until the washings were acidic and then washed with water and dried. Evaporation of the methylene chloride gave a yellow solid. Crystallization from methylene chloride – carbon tetrachloride gave *cis*-4-*t*-butylcyclohexanemethyl *p*-nitrobenzenesulfonate as yellow needles, m.p. 108–109°. The i.r. bands were found at ν_{max} 3100 (vw), 1605 (w), 1535 (s), 1405 (sh), 1380 (vs), 1365 (vs), 1350 (vs), 1315 (m), 1240 (vw), 1185 (vs), 1100 (m), 1020 (vw), 975 (m), 950 (s), 930 (sh), 900 (sh), 685 (m), 615 (m) cm^{-1}. The n.m.r. spectrum had bands at 0.78 (s, $—C(CH_3)_3$), 4.20 (d, $—CH_2OSO_2—$, J 8 Hz), and 8.10 to 8.55 (q, $—OSO_2-C_6H_4NO_2$, J_{AB} 9 Hz, δ_A 8.22, δ_B 8.47).

Anal. Calcd. for $C_{17}H_{25}NO_5S$: C, 57.44; H, 7.09; N, 3.94; S, 9.02. Found: C, 57.47; H, 7.04; N, 3.88; S, 8.91.

trans-4-t-Butylcyclohexanemethyl p-Nitrobenzenesulfonate

This was prepared from *trans*-4-*t*-butylcyclohexylcarbinol by the same procedure as for *cis*-4-*t*-butycyclohexanemethyl *p*-nitrobenzenesulfonate. Crystallization from methylene chloride – carbon tetrachloride gave *trans*-4-*t*-butylcyclohexanemethyl *p*-nitrobenzenesulfonate as fine needles, m.p. 138–139°. The i.r. bands were found at ν_{max} 3100 (vw), 1650 (w), 1535 (s), 1360 (sh), 1350 (s), 1310 (m), 1230 (w), 1185 (vs), 1095 (m), 985 (w), 950 (s), 685 (m), 615 (m) cm^{-1}. The n.m.r. had bands at 0.81 (s, $—C(CH_3)_3$), 3.98 (d, $—CH_2OSO_2—$, J 6 Hz), and aromatic absorption from 8.0 to 8.53 analyzed as an AB quartet: δ_A 8.15, δ_B 8.45 p.p.m. (J_{AB} 9 Hz).

Anal. Calcd. for $C_{17}H_{25}NO_5S$: C, 57.44; H, 7.09; N, 3.94; S, 9.02. Found: C, 57.35; H, 7.16; N, 3.93; S, 9.08.

cis-4-t-Butylcyclohexanemethyl Bromide (7)

cis-4-*t*-Butylcyclohexanemethyl *p*-nitrobenzenesulfonate (2.0 g) was dissolved in dry acetone (100 ml). Lithium bromide (1.5 g) and calcium carbonate (1.0 g) were added to the solution and the resulting mixture refluxed for 24 h. The reaction mixture was then poured into water and extracted twice with petroleum ether and the extract dried. Evaporation of the petroleum ether gave an oil (1.3 g). The oil was adsorbed onto silica gel (40 g). Elution with petroleum ether afforded the crude bromide as an oil. Distillation (b.p. 58–60°/0.6 mm) gave *cis*-4-*t* butylcyclohexanemethyl bromide as an oil, n_D^{25} 1.5900. The i.r. bands were found at ν_{max} 1300 (w), 1240 (sh), 1230 (m), 1030 (broad, w), 960 (w), 680 (m) cm^{-1}. The n.m.r. spectrum had bands at 0.85 (s, $—C(CH_3)_3$) and 3.41 p.p.m. (d, $—CH_2Br$, J 8 Hz).

Anal. Calcd. for $C_{11}H_{21}Br$: C, 56.66; H, 9.08; Br, 34.27. Found: C, 56.65; H, 9.16; Br, 34.31.

trans-4-t-Butylcyclohexanemethyl Bromide (8)

This was prepared from *trans*-4-*t*-butylcyclohexanemethyl *p*-nitrobenzenesulfonate by the same procedure as for *cis*-4-*t*-butylcyclohexanemethyl bromide, except

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

that the reaction mixture was refluxed for only 2 h. Column chromatography (silica gel, elution with petroleum ether) followed by distillation (b.p. 58–60°/0.6 mm) gave *trans*-4-*t*-butylcyclohexanemethyl bromide as an oil, n_D^{25} 1.4858. The i.r. bands were found at ν_{max} 1300 (w), 1255 (m), 1235 (m), 1200 (vw), 1150 (vw), 980 (w), 900 (w), 655 (m) cm^{-1}. The n.m.r. spectrum had bands at 0.84 (s, $-C(CH_3)_3$) and 3.29 p.p.m. (d, $-CH_2Br$, J 5.5 Hz).

Anal. Calcd. for $C_{11}H_{21}Br$: C, 56.66; H, 9.08; Br, 34.27. Found: C, 56.67; H, 9.31; Br, 34.38.

t-Butyl trans-4-t-Butylcyclohexanemethyl Ether (9)

trans-4-*t*-butylcyclohexanemethyl bromide (215.5 mg) was dissolved in potassium *t*-butoxide – *t*-butyl alcohol (0.412 *M*, 20 ml) and the resulting solution degassed three times and sealed under vacuum (.001 mm). This sealed ampoule was then left standing at 100° for 24 h. The reaction mixture was poured into water and extracted with methylene chloride and then with ether. The methylene chloride and ether layers were neutralized with 2% sulfuric acid, washed with water, combined, and then dried. Evaporation of the solvent gave an oil (152 mg). Separation (t.l.c. cyclohexane–ether (4:1)) gave the crude ether (100 mg) as a solid. Recrystallization from pentane gave *t*-butyl *trans*-4-*t*-butylcyclohexanemethyl ether as fine needles, m.p. 31–32°. The i.r. bands were found at ν_{max} 1230 (w), 1200 (s), 1075 (m), 1020 (w) cm^{-1}. The n.m.r. spectrum had bands at 0.84 (s, $-C(CH_3)_3$), 1.10 (s, $-OC(CH_3)_3$), and 3.30 p.p.m. (d, $-CH_2OC(CH_3)_3$, J 5 Hz).

Anal. Calcd. for $C_{15}H_{30}O$: C, 79.58; H, 13.36. Found: C, 79.29; H, 13.20.

Measurement of the Rate of the Reaction of cis- and trans-4-t-Butylcyclohexanemethyl Bromide (7 and 8) with Potassium t-Butoxide in t-Butyl Alcohol at 100°

(a) Titration of the Bromide Ion Produced

Potassium *t*-butoxide was prepared by dissolving freshly cut potassium (free of the oxide crust and washed three times in pentane) in *t*-butyl alcohol (freshly distilled from calcium hydride) under a nitrogen atmosphere. The solution was standardized by titration with hydrochloric acid (0.1 *N*, B.D.H., concentrated Volumetric Solution). The *cis*- or *trans*-4-*t*-butylcyclohexanemethyl bromide solution was prepared by weighing the bromide (*ca.* 200 mg) and dissolving it in *t*-butyl alcohol (freshly distilled from calcium hydride) and making the solution up to 50 ml at 30°.

To a solution of the bromide (5 ml) was added the *t*-butoxide solution (5 ml), this mixture was then degassed three times and sealed under vacuum. The sealed solutions were then thoroughly mixed and placed in an oil bath whose temperature was controlled by a Fisher "Proportional Temperature Control" thermostat to 100.0 ± 0.2°. Timing was started at the time of immersion in the oil bath. After an appropriate time interval the aliquot was removed from the oil bath and placed in an ice bath. The sample was then opened and poured into water containing nitric acid (5 ml, 6 *N*) and the bromide ion titrated with silver nitrate. The pseudo first order rate constant was calculated from the slope of a plot of log (100 − % reaction) *vs.* time for six such determinations varying from <20 to >60% reaction; the apparent second order rate constant for bromide ion formation was obtained by dividing the pseudo first order rate constant by the potassium *t*-butoxide concentration. The apparent second order rate constants so obtained for the reaction of the *cis* bromide **7** were 9.4×10^{-4} l mol^{-1} s^{-1} ($KOBu^t$ 0.76 and substrate 1.96×10^{-2} *M*) and 9.0×10^{-2} l mol^{-1} s^{-1} ($KOBu^t$ 0.41 and substrate 1.66×10^{-2} *M*); for the *trans* bromide **8** the apparent second order rate constants for bromide ion release were 3.2×10^{-4} ($KOBu^t$ 0.41 and substrate 1.81×10^{-2} *M*) and 3.5×10^{-4} l mol^{-1} s^{-1} ($KOBu^t$ 0.76 and substrate 1.96×10^{-2} *M*).

(b) Product Analysis of the Reaction of cis- and trans-t-Butylcyclohexanemethyl Bromide with Potassium t-Butoxide

The bromide (*ca.* 250 mg) was dissolved in the *t*-butoxide solution (20 ml, 0.412 *M*), degassed three times, sealed under vacuum, and left at 100° for 24 h. The ampoule was cooled, opened, poured into water, and extracted with methylene chloride and ether. The methylene chloride and ethereal layers were neutralized with 2% sulfuric acid, washed with water, combined, and dried.

cis-4-*t*-Butylcyclohexanemethyl bromide (250 mg) gave an oil (130 mg), the n.m.r. spectrum of which showed a band at 4.45 ($C{=}CH_2$) and no bands in the region 2.5–4.4 p.p.m. ($-CH_2Br$ and $-CH_2OC(CH_3)_3$). *trans*-4-*t*-Butylcyclohexanemethyl bromide (215.5 mg) gave an oil (152 mg), the n.m.r. spectrum of which showed bands at 3.03 (d, $-CH_2OC(CH_3)_3$) and 4.45 ($C{=}CH_2$) in the ratio of 2.24:1 (*i.e.* 69:31%), but no band at 3.38 p.p.m. (CH_2Br). The apparent second order rate constants for the bromide ion formation from the *cis*-bromide (**7**) were therefore taken directly as the rate constants for the bimolecular elimination. The rate constants for the bimolecular elimination for the *trans*-bromide **8** were taken as 31% of the rate constants for the bromide ion release *i.e.* 1.0×10^{-4} and 1.1×10^{-4} l mol^{-1} s^{-1}, respectively.

This work was supported by grants from the National Research Council of Canada and the Alfred P. Sloan Foundation.

Axial:Equatorial Rate Ratios and the Mechanism of Formation of Sulfenes by Dehydrohalogenation of Alkanesulfonyl Chlorides[1]

J. F. KING AND T. W. S. LEE

Department of Chemistry, University of Western Ontario, London, Ontario

Received June 18, 1971

The method of axial: equatorial rate ratios has been applied to the study of the mechanism of formation of sulfenes via the reaction of alkanesulfonyl chlorides with base. The axial *trans*-2-decalinsulfonyl chloride (**6**) and the equatorial *trans*-2-decalinsulfonyl chloride (**8**) were synthesized. The axial sulfonyl chloride **6** was found to react 71 times faster than the equatorial epimer **8** with triethylamine in the presence of aniline at $-25°$, a reaction which evidently proceeds via the sulfene **7**. With water at 50° without added base (a reaction believed to take place by direct attack on the sulfur atom) **8** reacts about 14 times faster than **6**. It is concluded that the formation of the sulfene **7** from **6** by the action of triethylamine cannot take place by a mechanism involving a slow S_N2 reaction followed by a fast bimolecular elimination, and that the most likely route for **6**, and other alkanesulfonyl chlorides as well, is the E2 reaction.

La méthode des rapports de vitesse axial:équatorial a été utilisée pour étudier le mécanisme de la formation des sulfènes via la réaction des chlorures d'alkanesulfonyles avec une base. Le chlorure de la *trans*-2-décalinsulfonyle axiale (**6**) et le chlorure de la *trans*-2-décalinsulfonyle équatoriale (**8**) ont été synthétisés. Le chlorure de sulfonyle axial **6** réagit 71 fois plus vite que l'épimère équatorial **8** avec la triéthylamine en présence d'aniline à $-25°$ (réaction qui se fait via le sulfène **7**). Dans l'eau à 50°, sans l'adjonction d'une base, (réaction supposée se faire par une attaque directe sur l'atome de soufre) le composé **8** réagit environ 14 fois plus vite que le composé **6**. Ces résultats prouvent que la formation du sulfène **7** à partir de **6**, par l'action de la triéthylamine, ne peut se faire par un mécanisme impliquant une réaction S_N2 lente suivie d'une élimination bimoléculaire rapide. A partir du composé **6**, et d'autres chlorures d'alkanesulfonyle, le mécanisme le plus probable est celui faisant intervenir une réaction E2.

Canadian Journal of Chemistry, **49**, 3724 (1971)

Introduction

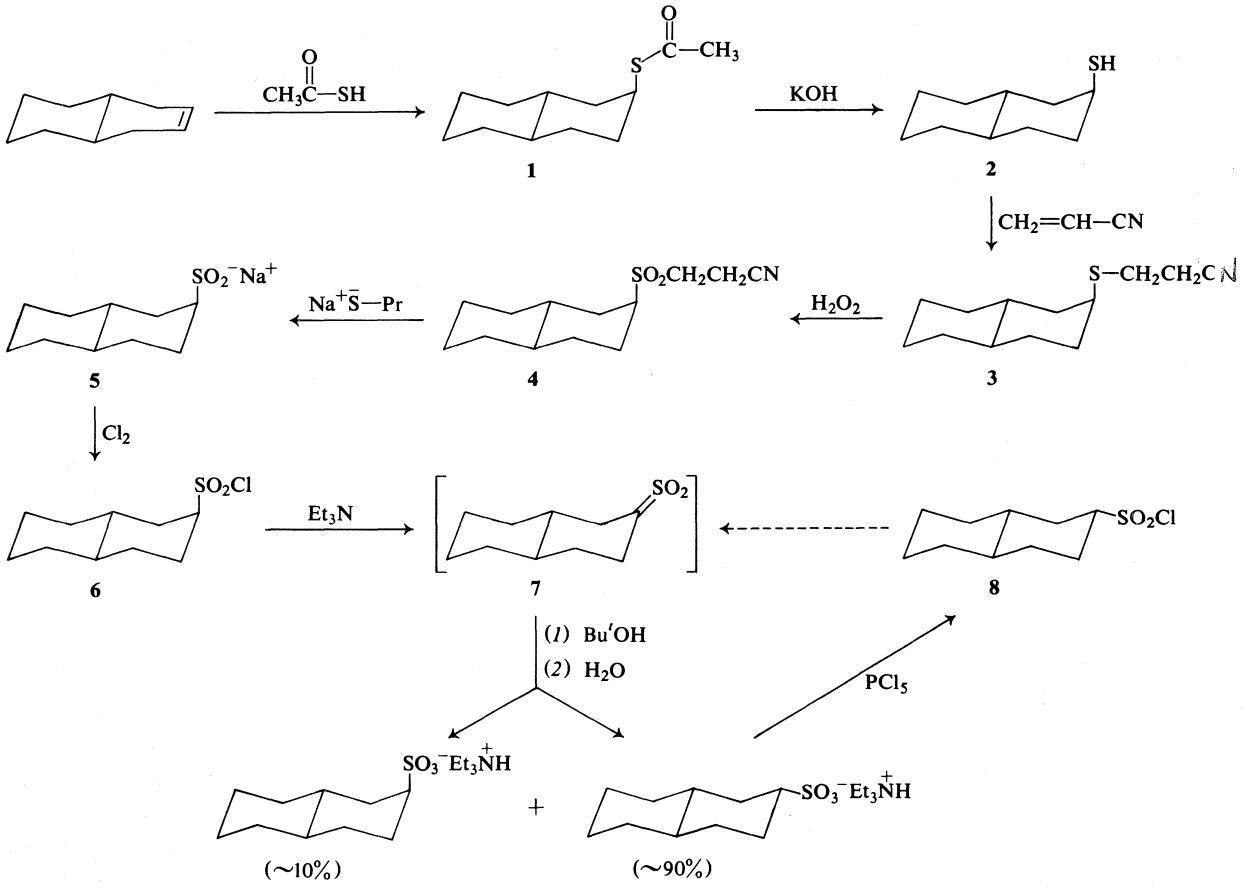
The work described in the accompanying paper (1) was started in the hope of ultimately using the relative rates of axial *vs.* equatorial epimers in the study of reaction mechanisms. It seemed that the method of axial:equatorial rate ratios might be applied to a problem already being studied in our laboratory, namely the mechanism of formation of sulfenes by dehydrohalogenation of alkanesulfonyl halides, eq. 1.

[1] $$RR'CHSO_2Cl + R_3''N \rightarrow RR'C{=}SO_2 + R_3''\overset{+}{N}H\ Cl^-$$

Accordingly, we have synthesized a pair of anchored axial and equatorial sulfonyl chlorides and measured their rates of reaction. A preliminary account which includes other aspects of the study of the mechanism of sulfene formation via eq. 1 has been published (3); it will be necessary in this account to refer to the other phases of this investigation (mainly kinetic studies) but full discussion of these will be taken up in a subsequent paper.

Among the possible mechanisms for sulfene formation according to eq. 1, two appeared particularly likely: (*i*) a one-step concerted elimination, *i.e.* E2 reaction, and (*ii*) substitution of chloride by the tertiary amine followed by elimination. The second mechanism though less obvious, and perhaps less probable than the first, cannot be dismissed out of hand; evidently the same first step, *i.e.* displacement of chloride by the tertiary base, is found in the pyridine catalyzed hydrolysis of benzenesulfonyl chloride (4). Since mechanism (*ii*) has two steps, it is possible, in principle, for either step to be rate controlling. That version of mechanism (*ii*) in which the intermediate sulfonammonium ion is formed rapidly and is attacked in the slow step by tertiary base to give the sulfene, would be *second* order in the tertiary amine; the reaction has been found to show only first order dependence on the tertiary amine concentration (3), thereby excluding that possibility. The kinetic data, however, do not

[1]Axial:Equatorial Rate Ratios Part 2, and Organic Sulfur Mechanisms Part 10. References 1 and 2 are respectively parts 1 and 9 of these series.



SCHEME 1

distinguish between mechanism (*i*) and the version of mechanism (*ii*) in which the attack of the tertiary amine in the sulfonyl chloride is slow and the subsequent elimination rapid. The problem of distinguishing between these possible mechanisms would appear to be quite simple by the method of axial:equatorial rate ratios.

As was shown in the accompanying paper (1) the actual formation of a double bond exocyclic to a cyclohexane ring has been found to be faster from an axial precursor than from its equatorial epimer. One would therefore predict that formation of the sulfene from a substituted cyclohexanesulfonyl chloride by a direct E2 mechanism would be distinctly faster from the axial sulfonyl chloride than from the equatorial isomer. On the other hand if the rate-controlling step were a substitution reaction, the reaction would be slower for the axial than for equatorial compound. The latter conclusion can be supported by relevant examples which will be detailed in the discussion of the mechanism section.

To apply this method it was necessary to obtain a pair of anchored axial and equatorial sulfonyl chlorides. A convenient route to the stereospecific synthesis of an axial sulfonyl chloride was suggested by the observation of Bordwell *et al.* (5) that free radical addition of thioacetic acid to anchored cyclohexenes gave apparently exclusively the axial thiolester. Of the various possible anchored cyclohexane systems that might be synthesized taking advantage of the stereospecificity of the thioacetic acid addition, the 2-substituted *trans*-decalin system was chosen because the symmetry of the olefinic starting material (Δ^2-*trans*-octalin) was such that attack onto either face of the double bond would lead to the same product.

Results and Discussion

Synthesis of the Axial and Equatorial trans-2-Decalinsulfonyl Chlorides (6 and 8)

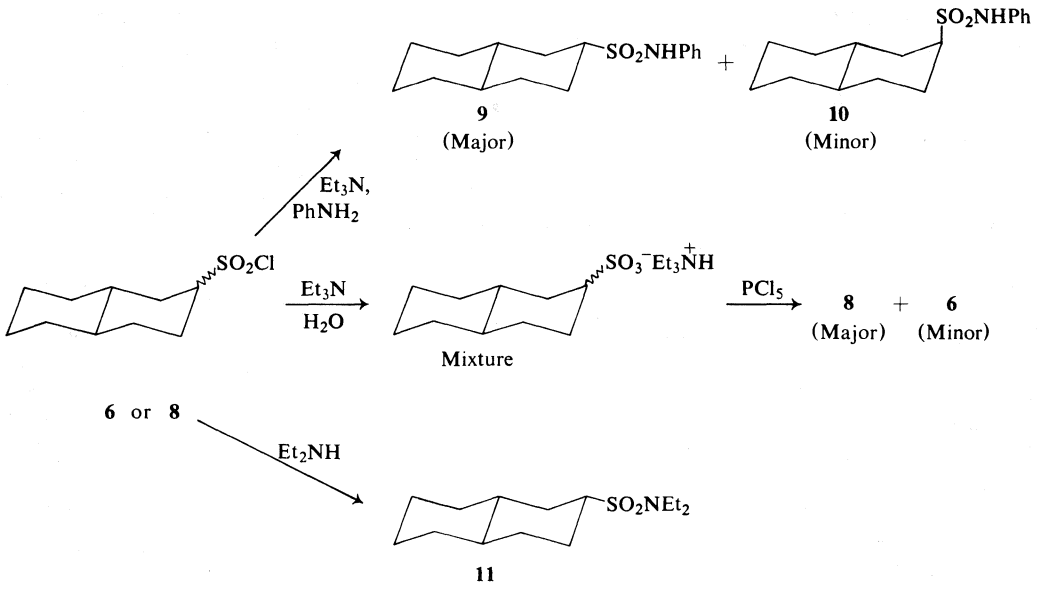
The synthesis of the axial and equatorial sulfonyl chlorides (**6** and **8**) is summarized in Scheme 1. *trans*-Δ^2-Octalin, prepared by the recipe of Johnson *et al.* (6), when treated with thioacetic acid, gave a high yield of the axial thiolacetate **1**. The usual analytical and spectroscopic data were in full agreement with the assigned structure. Of particular significance was a band at 3.98 p.p.m. in the n.m.r. spectrum appropriate to the methine bearing the acetylthio function; the relatively narrow half-width (8 Hz) of this band clearly shows the proton to be equatorial (7, 8).

Attempts to generate **6** by direct chlorination of the thiolester **1** or the corresponding mercaptan **2** gave products which from their i.r. spectra evidently contained a sulfonyl chloride but from which we were unable to obtain **6** in anything like pure form. We thereupon took advantage of the useful procedure of Truce and Roberts (9) for converting a mercaptan to the corresponding sulfinic acid. This involved formation of the acrylonitrile adduct **3**, oxidation to the sulfone **4**, and finally elimination to form the sodium sulfinate **5**; **5** on chlorination gave the axial sulfonyl chloride **6** as a fairly pure oil which after short-path distillation was obtained as a low-melting solid recrystallizable from cold pentane. Any possibility of epimerization in the process was precluded by the observation of the characteristic narrow signal for the equatorial methine proton in the n.m.r. spectrum of **6**; the analogous narrow signal also appeared in the spectrum of **3** but was obscured, presumably by the signal for the methylene group on the other side of the sulfonyl function, in the sulfone **4**.

It was anticipated that the axial sulfonyl chloride **6** would generate the sulfene **7** on treatment with base, and that trapping of the sulfene **7** would lead to a mixture of the axial and equatorial sulfonic acids (or derivatives) in which the equatorial epimer would predominate. Accordingly, **6** was treated with triethylamine in *t*-butyl alcohol presumably giving initially a mixture of the *t*-butyl sulfonate esters, which, after the addition of water and standing for an interval, gave the mixture of triethylammonium sulfonates. The salt mixture was converted to the mixture of sulfonyl chlorides (**8** and **6**), from which the equatorial isomer **8** was obtained in the form of crystals melting at 28–29°. The mode of synthesis, elemental analysis, and n.m.r. and i.r. spectra unambiguously show that this material has the equatorial sulfonyl chloride structure **8**. The axial methine hydrogen in **8** appears as a broad hump (half-width 25 Hz) around 3.5 p.p.m., in contrast to the much sharper peak at 3.9 p.p.m. found in the spectrum of **6**. The i.r. spectrum of **8**, though in general rather similar to that of **6**, shows a characteristic strong sharp band at 600 cm^{-1}; **6** on the other hand has a similar band at 645 cm^{-1}. These bands proved useful in determining the relative quantities of **6** and **8** in mixtures of these materials; the relative intensities of the 645 and 600 cm^{-1} peaks were simply compared with those found with mixtures of known composition prepared from pure samples of **6** and **8**. In this way it was possible to show that the mixture of **6** and **8** obtained from **6** via the reaction of triethylamine and *t*-butyl alcohol followed by treatment with water (as in Scheme 1) consisted of about 90% of **8** and 10% of **6**. *t*-Butyl alcohol was used as the sulfene trap in this reaction because it was hoped that its greater bulk might lead to the formation of a smaller proportion of the axial product than would be formed using a smaller sulfene trap, *e.g.* water. In agreement with this simple notion, it was found that reaction product when water was used as the trap was apparently somewhat smaller (80:20); one cannot be certain, however, that the apparent difference, even if real, derives from the relative rates of formation of the equatorial and axial products from the sulfene and does not have some other source, *e.g.* differences arising in the formation of the sulfonyl chlorides from the salt mixture.

Kinetic and Product Analysis Studies on the Axial and Equatorial Sulfonyl Chlorides (6 and 8)

As has been mentioned already, the present study is part of our investigation of the mechanism of formation of sulfenes via dehydrohalogenation of alkanesulfonyl chlorides, as in eq. 1. In the other part of this work (which is at least partly accessible elsewhere (3, 10)) it was found that alkanesulfonyl chlorides react smoothly with tertiary amines in 1,2-dimethoxyethane, and that the extent of reaction is easily determined by potentiometric titration of the chloride ion produced. A temperature of −25° was convenient, or even necessary, for some of the reactions studied, *e.g.* phenylmethanesulfonyl chloride and triethylamine; other reactions, *e.g.* **6** and **8** with triethyl-



SCHEME 2

amine, were measured at that temperature for comparison, even though their rates are also readily measurable at room temperature. With a 20-fold excess of triethylamine and a 100-fold excess of aniline as the sulfene trap, the reaction showed satisfactory pseudo first order kinetics to >80% reaction. Under these conditions the axial sulfonyl chloride **6** reacts 71 times faster than its equatorial epimer **8**.

Though a substantial body of evidence now available indicates that the action of triethylamine on alkanesulfonyl chlorides bearing at least one α-hydrogen yields the sulfene, it was felt that it was of some importance to have specific evidence that the sulfene **7** was in fact being generated from the sulfonyl chlorides **6** and **8**. Since there is only one α-hydrogen in **6** and **8**, we thought that a deuterium-labelling experiment would be much less conclusive than it has been with other substrates (11, 12), and we therefore turned to another experiment to demonstrate the intermediacy of the sulfene **7**.

A classic test to determine if an intermediate is common to two reactions is to see if the two reactions give product mixtures of identical composition when the reaction conditions are identical. Accordingly both **6** and **8** were treated with triethylamine and aniline in dimethoxyethane using the same relative amounts of the reagents as in the kinetic runs but with the mixture 30 times more concentrated. The product from **6**, obtained in about 80% yield, was evidently a mixture of the equatorial and axial sulfonanilides (**9** and **10**, respectively, as in Scheme 2). Unfortunately we were able to obtain only the axial isomer **10** in crystalline form, though the sample of the presumed equatorial epimer **9** that was isolated from t.l.c. showed the spectroscopic features expected for that structure (see Experimental). In the mixture from the axial sulfonyl chloride **6**, the anilides **9** (presumed) and **10** were estimated to be present in the ratio 60 to 40; similar treatment of the equatorial sulfonyl chloride **8** gave a 75% yield of a mixture estimated to be 65% **9** and 35% **10**.

The use of water rather than aniline as the sulfene trap gave a mixture of the triethylammonium sulfonates which was converted to the mixture of the sulfonyl chlorides (**6** and **8**) so that its composition could be estimated by i.r. spectroscopy as described earlier. The sulfonyl chloride mixture obtained from **6** (in 83% yield) was estimated to consist of 20% of **6** and 80% of **8**, whereas that from **8** (88% yield) was evidently about 30% **6** and 70% **8**. When **6** or **8** was treated with diethylamine the product (obtained in 86 and 81% yields, respectively) was apparently more or less entirely the equatorial *N*,*N*-diethylamide **11**.

The similarity of the product mixtures obtained from either the axial sulfonyl chloride **6** or its equatorial epimer **8** in the reactions summarized

in Scheme 2 is regarded as good evidence for the existence of a common intermediate, *viz.* the sulfene **7**. One likely source of the slight discrepancies (*e.g.* 80:20 *vs.* 70:30 in the reaction with water) is experimental uncertainty; in this example the difference might well derive, for example, from a somewhat less efficient conversion of the axial sulfonate to the sulfonyl chloride with the material from the reaction of **6** with triethylamine and water. It is also possible, however, that the differences noted are real, though small. Such a circumstance is perfectly consistent with the sulfene mechanism if the sulfene is attacked by the trap before the initially-formed sulfene – triethylammonium chloride aggregate has either dispersed or equilibrated. Under such circumstances the sulfene trap might be attacking in the one case a sulfene with the triethylammonium ion still more or less in the axial position, and in the other a sulfene with the cation on the other side of the plane of the sulfene grouping; in that event a measurable difference in the stereochemistry of the products would not be surprising. The possibility of very rapid attack on sulfenes before the medium has fully equilibrated has been mentioned previously to account for small deviations from strict stoichiometry in the deuteration experiments (11).

Another feature of the deuteration study just referred to was that the action of tertiary amines led to the incorporation of one deuterium atom when the reaction was carried out in the presence of a deuterated sulfene trap, *i.e.* that the base invariably led to sulfene formation (11). When the sulfonyl chloride was treated with D_2O or methanol-*d* in the *absence* of base, however, no deuterium was taken up, and it was inferred that another mechanism of hydrolysis was operating under these conditions, presumably direct displacement of the chloride by water or the alcohol. It was therefore expected that if the analogous situation were to obtain in the hydrolysis of **6** and **8**, an entirely different axial:equatorial rate ratio would be observed in the absence of base. The reactions of **6** and **8** with water without added base were found to be extremely slow and to follow first order kinetics only to about 40 to 50% of completion. Even so, however, it was possible to obtain at least a rough idea of the relative rates of reaction of **6** and **8**; for the hydrolysis at 50° the value so obtained was $k_{Ax}/k_{Eq} \approx 0.07$, *i.e.* about 1/1000 of the ratio found with the triethylamine induced reaction at −25°.

The Mechanism of the Dehydrohalogenation of Alkanesulfonyl Chlorides

For the reasons presented in detail in the accompanying paper, we would expect that a concerted bimolecular elimination (E2 reaction) of hydrogen chloride would be distinctly faster with the axial sulfonyl chloride **6** than with its equatorial epimer **8**. This has of course been found, the ratio in fact being substantially larger than those discussed in the other paper (1). These results are therefore consistent with the E2 mechanism of sulfene formation, in the reaction of triethylamine with the axial sulfonyl chloride **6**, at the very least. The large axial:equatorial rate ratio for the sulfonyl chlorides probably derives primarily from the relatively large conformational free energy of the chlorosulfonyl group, taken with an evidently "product-like" transition state for the reaction (3).

Another possible mechanism which was mentioned in the introduction involves slow substitution of the chloride by direct attack of the tertiary amine, followed by rapid bimolecular elimination from the intermediate sulfonylammonium ion to form the sulfene. In such a reaction the bulky chlorosulfonyl group, in which the sulfur is tetrahedrally substituted, would become in the transition state an even bulkier group in which five substituents would be placed roughly at the apices of a trigonal bipyramid. From the following evidence it can be concluded that such a mechanism would lead to $k_{Ax}/k_{Eq} < 1$.

It would appear to be a general phenomenon that those reactions exocyclic to a cyclohexane ring, which involve expansion of the function on going from starting material to transition state, proceed more readily with the equatorial compound than with its axial epimer. The hydrolysis of esters of cyclohexanecarboxylic acids and the formation and saponification of esters of cyclohexanols are examples which have been extensively studied (see ref. 13). Of the few other examples which have been reported, one seems exceptional. The reaction of an axial amino group with 2,4-dinitrochlorobenzene apparently goes about 50% faster than that of its equatorial epimer, an observation that has been suggested to owe its origin to relatively strong hydrogen bonding in the equatorial amino function (14).

This apparent exception, as well as other considerations, suggested that our general study of axial:equatorial rate ratios and their application to the study of reaction mechanisms should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

include an investigation of reactions exocyclic to the cyclohexane ring. As has been mentioned in the accompanying paper (1), we have in fact already looked at some examples involving change in the coordination number of an exocyclic atom; the details will be described in a subsequent account. The particular observations relevant to the present discussion concern the relative rates of S_N2 reactions of cyclohexanemethyl bromides and *p*-nitrobenzenesulfonates. In the one case k_{Ax}/k_{Eq} was estimated (1) as <0.3 and in the other k_{Ax}/k_{Eq} for the reaction of the *p*-nitrobenzenesulfonates with lithium bromide in acetone at 45° was found to be about 0.05 (15). Both sets of results strongly suggest that a direct displacement reaction at the sulfonyl sulfur of **6** and **8** would lead to $k_{Ax}/k_{Eq} \ll 1$.

The closest analogue of the hypothetical slow S_N2 reaction followed by rapid elimination mechanism, however, was obtained directly from the sulfonyl chlorides **6** and **8** themselves. Hydrolysis of **6** and **8** in the absence of base, which, as has been mentioned above, is believed to proceed by direct displacement on the sulfur, showed just the sort of axial:equatorial rate ratio expected: $k_{Ax}/k_{Eq} \approx 0.07$.

The above examples lead to a conclusion which we suggest is inescapable, namely that if the sulfene formation from the axial sulfonyl chloride **6** were proceeding by a rate-determining attack on the sulfur atom followed by a rapid elimination to form the sulfene, then it would have to take place more slowly than the same reaction with the equatorial compound **8**. Since the opposite is, in fact, observed experimentally we must conclude that the reaction of **6** does not proceed via "S_N2 plus E" mechanism.

These data taken by themselves do not *require* the E2 mechanism for the reaction of the equatorial isomer or of any other sulfonyl chloride. The following pieces of evidence of a totally different kind, however, are also in agreement with the E2 mechanism: (*a*) the formation of mono-exchanged products with diethylamine (11) and *n*-butylamine (16), (*b*) the distinctly negative ρ value obtained from a Hammett plot for the reaction of substituted phenylmethanesulfonyl chlorides with pyridine (3, 10), and (*c*) a linear Brønsted-type relationship in the reaction of a number of sterically different tertiary amines with methanesulfonyl chloride (16). These observations when taken with the axial:equatorial rate ratios combine to suggest very strongly that the E2 mechanism is the general mode of formation of sulfenes by the action of amines on alkanesulfonyl halides.

As a final note we wish to point out that in addition to illuminating the specific problem of the mechanism of sulfene formation, the present study serves as an illustration of the potential usefulness of the method of axial:equatorial rate ratios in the study of reaction mechanisms.

Experimental

The general experimental procedures were as described in the accompanying paper (1), with the following additions. 1,2-Dimethoxyethane (DME) (Eastman, "white label") was refluxed over lithium aluminum hydride and distilled before use, triethylamine (Eastman, "white label") was distilled from calcium hydride before use. Pentane and acrylonitrile (Eastman, "yellow label") were distilled before use. Aniline (McArthur Chemical Co. Ltd.) was distilled from zinc dust.

1,2α,3,4,4aα,5,6,7,8,8aβ-Decahydro-2-naphthyl Thiolacetate (1)

Thioacetic acid (7 g, 0.092 mol) was added to *trans*-Δ^2-octalin (10 g, 0.077 mol prepared by the method of Johnson and co-workers (6)) and the reaction mixture was stirred vigorously for 15 min. The reaction was complete after another 30 min at 50°. The excess of thioacetic acid was removed by distillation under reduced pressure. The oily residue was distilled *in vacuo* to give the thiolacetate **1** (15 g, 96%), b.p. 94° (0.8 mm), $n_D^{25.6}$ 1.5152. The n.m.r. spectrum (CCl_4) showed a broad and partially resolved band at 0.8–2.0, a singlet at 2.24, and a narrow band at 3.98 p.p.m. (half-width 8 Hz). The i.r. spectrum ($CHCl_3$) showed very strong absorption at 1670 cm^{-1}; other major bands below 1600 cm^{-1} were: 1446 (s), 1351 (m), 1120 (s), 955 (m), 874 (w), 835 (w), 641 cm^{-1} (m).

Anal. Calcd. for $C_{12}H_{20}SO$: C, 67.88; H, 9.49; S, 15.10. Found: C, 67.87; H. 9.50; S, 15.09.

1,2α,3,4,4aα,5,6,7,8,8aβ-Decahydro-2-naphthalenethiol (2)

The axial thiolacetate **1** (10 g), ethyl alcohol (50 ml), and 20% aqueous potassium hydroxide (50 ml) were mixed and allowed to reflux for 1 h. The reaction mixture was then acidified with acetic acid and the oily thiol extracted three times with ether. The ethereal phase was washed twice with water, dried, and evaporated. The residue obtained was distilled *in vacuo* to yield the axial mercaptan **2** (7.2 g, 90%), b.p. 54–55° (0.5 mm), n_D^{26} 1.5144. The n.m.r. spectrum (CCl_4) showed a partially resolved broad band at 0.8–2.0 and a narrow band at 3.5 p.p.m. (half-width, 11 Hz). The i.r. spectrum (CH_2Cl_2) showed major peaks below 1600 cm^{-1} at 1450 (s), 1355 (m), 1245 (m), 1144 (m), 1058 (w), 974 (m), 940 cm^{-1} (m).

The axial mercaptan **2** was characterized as the phenylurethane which was obtained by mixing a sample of **1** (0.5 g) with phenylisocyanate (0.35 g) and allowing the reaction to stand overnight. The product was obtained as white needles, m.p. 170–171°.

Anal. Calcd. for $C_{17}H_{23}NSO$: C, 70.54; H, 8.01; N, 4.84; S, 11.08. Found: C, 70.54; H, 8.08; N, 4.86; S, 11.10.

3-(1,2α,3,4,4aα,5,6,7,8,8aβ-Decahydro-2-naphthylthio)-propionitrile (3)

Acrylonitrile (10 g) was added dropwise with stirring and ice-bath cooling to axial mercaptan **2** (6.5 g, 0.38 mol) which had been mixed with a small quantity of sodium methoxide (0.05 g). The resulting reaction mixture was then stirred at room temperature for 1 h. Any precipitate formed at this point was filtered off and the filtrate distilled under reduced pressure to remove the excess acrylonitrile. Distillation of the resulting residue *in vacuo* yielded the product **3** (8.3 g, 97.5%), b.p. 120–121° (0.01 mm), n_D^{25} 1.5186. The n.m.r. spectrum (CCl_4) showed a broad band at 0.8–2.0, a multiplet centered at 2.62, and a narrow band at 3.24 p.p.m. (half-width, 8 Hz). The i.r. spectrum (CH_2Cl_2) showed an absorption band at 2260 cm^{-1} due to the cyano group and other major peaks below 1600 cm^{-1} at: 1450 (s), 1355 (m), 1245 (m), 1145 (w), 948 (w), 840 cm^{-1} (w).

Anal. Calcd. for $C_{13}H_{21}NS$: C, 69.80; H, 9.48; N, 6.27; S, 14.35. Found: C, 69.77; H, 9.48; N, 6.38; S, 14.31.

3-(1,2α,3,4,4aα,5,6,7,8,8aβ-Decahydro-2-naphthylsulfonyl)propionitrile (4)

To a solution of the axial sulfide **3** (2 g) in acetic acid (2.5 ml), hydrogen peroxide (30%, 2.6 g) was added slowly. The reaction mixture was allowed to stand at room temperature for 1 week. When the reaction was completed, the viscous reaction mixture was poured into water and the product extracted three times with methylene chloride. The combined organic phase was then washed with dilute sodium bicarbonate solution, twice with water, and dried. Removal of methylene chloride yielded the product **4** which was recrystallized from pentane (2.02 g, 86%), m.p. 97–98°. The n.m.r. spectrum ($CDCl_3$) showed a broad band at 0.8–2.7 and a multiplet at 2.7–3.5 p.p.m. The i.r. spectrum (CH_2Cl_2) showed a peak due to the cyano group at 2250 (m) and strong absorption bands of the sulfonyl group at 1310 (vs) and 1130 (vs); other major i.r. peaks below 1600 cm^{-1} were 1145 (m), 845 (w), 660 cm^{-1} (w).

Anal. Calcd. for $C_{13}H_{21}NSO_2$: C, 61.15; H, 8.29; N, 5.48; S, 12.55. Found: C, 61.01; H, 8.14; N, 5.46; S, 12.59.

Sodium 1,2α,3,4,4aα,5,6,7,8,8aβ-Decahydro-2-naphthalenesulfinate (5)

A solution of sodium propanethiolate was prepared by dissolving metallic sodium (0.18 g, 7.5 mmol) in a mixture of 1-propanethiol (0.495 g, 7.5 mmol) and absolute alcohol (5 ml). This solution was then added slowly to a stirred solution of the axial sulfone **4** (2 g) dissolved in absolute alcohol (30 ml). The resulting reaction mixture was allowed to reflux for 5 h, after which the alcohol was evaporated under reduced pressure. The salt obtained was washed twice with dry ether and dried to give the sodium sulfinate (1.4 g, 70%). The i.r. spectrum (Nujol) of the salt showed major bands below 1600 cm^{-1} at 1001 (s), 960 (s), 750 cm^{-1} (w).

1,2α,3,4,4aα,5,6,7,8,8aβ-Decahydro-2-naphthalenesulfonyl Chloride (6)

The axial sulfinate salt **5** (1.3 g) was dissolved in water (40 ml) with a little acetic acid (0.05 ml) added. Methylene chloride (40 ml) was also added to the solution to form a lower layer. This two-phase solution was then cooled in an ice-bath before passing in the chlorine gas. The chlorination was evidently complete when the aqueous phase became clear and the organic phase turned greenish yellow. The two layers were then separated and the aqueous phase extracted twice with methylene chloride. The combined methylene chloride phase was washed successively with dilute sodium bisulfite solution, sodium bicarbonate solution, and twice with water. Drying and evaporating of the organic phase yielded the axial sulfonyl chloride **6** (1.1 g, 80%). Purification of the compound was carried out by short-path distillation *in vacuo* followed by recrystallization from pentane, m.p. 31–32°. The n.m.r. spectrum (CCl_4) showed absorption at 0.8–2.8 (diffuse broad band) and 3.91 p.p.m. (narrow band of equatorial proton at C-2, half-width 10 Hz). The i.r. spectrum (KBr cell, CH_2Cl_2) showed major peaks below 1600 cm^{-1} at: 1450 (s), 1360 (vs), 1300 (w), 1230 (w), 1210 (m), 1165 (vs), 1142 (m), 1120 (m), 1055 (m), 1025 (w), 980 (w), 970 (w), 932 (m), 845 (m), 645 (s), 565 (s), 550 (m), 490 (m), 460 (m), 440 (w), 420 (m), 360 cm^{-1} (w).

Anal. Calc. for $C_{10}H_{17}SO_2Cl$: C, 50.73; H, 7.24; S, 13.54; Cl, 14.97. Found: C, 50.63; H, 7.22; S, 13.60; Cl, 15.03.

1,2β,3,4,4aα,5,6,7,8,8aβ-Decahydro-2-naphthalenesulfonyl Chloride (8)

To a mixture of the axial sulfonyl chloride (**6**) (10 g) and tert-butyl alcohol (30 g) in methylene chloride (25 ml), triethylamine (25 ml) was added with stirring. The resulting reaction mixture was then allowed to stand overnight at room temperature and then extracted three times with water. The aqueous phase was then evaporated under reduced pressure and dried to yield the sulfonate salt mixture (11 g). This was mixed with phosphorus pentachloride (20 g) and dry benzene (200 ml) and allowed to reflux for 1 h with constant stirring. After cooling, the reaction mixture was filtered and the filtrate washed with several portions of ice-water. Drying and evaporating the benzene phase yielded the crude product (4.1 g, 41%). This product contained a trace of impurity which was removed by t.l.c. (benzene:ether, 9:1). The product **8** was further purified by distillation *in vacuo* and recrystallization from pentane; m.p. 28–29°. The n.m.r. (CCl_4) showed absorption at 0.8–2.7 (diffuse broad band) and 3.5 p.p.m. (broad band of axial proton at C-2, half-width, 25 Hz). The i.r. (KBr cell, CH_2Cl_2) showed major peaks below 1600 cm^{-1} at 1450 (s), 1360 (vs), 1310 (w), 1240 (w), 1210 (m), 1165 (vs), 1145 (m), 1120 (w), 1055 (m), 1020 (w), 970 (m), 930 (m), 880 (w), 845 (w), 600 (s), 585 (w), 560 (m), 555 and 545 (s), 495 (m), 475 (m), 450 (sh), 440 (m), 360 cm^{-1} (w).

Anal. Calcd. for $C_{10}H_{17}SO_2Cl$: C, 50.73; H, 7.24; S, 13.54; Cl, 14.97. Found: C, 50.98; H, 7.16; S, 13.55; Cl, 15.09.

The Reaction of the Axial Sulfonyl Chloride (6) with Triethylamine and Aniline

Triethylamine (4 ml) was added quickly to a solution of the axial sulfonyl chloride **6** (0.3 g) and aniline (15 g) dissolved in 1,2-dimethoxyethane (10 ml). The reaction mixture was allowed to stand at room temperature for 2 h before it was acidified with dilute hydrochloric acid solution. Evaporation of the 1,2-dimethoxyethane under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

reduced pressure was followed by extraction of the organic product with methylene chloride. The organic phase was dried and evaporated to give an oily material. Purification of the product as well as separation of the compound into two epimeric sulfonanilides were carried out by t.l.c. (benzene:ether, 9:1); of the total purification product (0.34 g, 78%), 40% was the axial sulfonanilide **10** and 60% evidently the equatorial sulfonanilide **9**.

The sulfonanilide **10** was further purified by recrystallization from methanol, m.p. 141°. The n.m.r. spectrum ($CDCl_3$) showed a complex broad band at 0.8–2.6, a narrow band due to the equatorial proton at 3.4 (half-width, 10 Hz) and multiplet of aromatic protons at 7.18–7.52 p.p.m. The major i.r. peaks below 1700 cm^{-1} were: 1600 (s), 1500 (s), 1450 (m), 1400 (m), 1340 (s), 1220 (s), 1150 (vs), 1032 (w), 912 cm^{-1} (s).

Anal. Calcd. for $C_{16}H_{23}NSO_2$: C, 65.50; H, 7.90; N, 4.77; S, 10.93. Found: C, 65.68; H, 8.05; N, 4.90; S, 11.09.

The equatorial sulfonanilide **9** was not obtained crystalline. It was purified by t.l.c. The n.m.r. spectrum ($CDCl_3$) showed complex broad band at 0.8–2.5, a relatively broad band appropriate to the axial proton at 3.15 (half-width, 16 Hz) and an aromatic absorption band at 7.18–7.52 p.p.m. The i.r. spectrum (CH_2Cl_2) also showed peaks at positions similar to that of the epimeric compound: 1600 (s), 1500 (s), 1450 (m), 1400 (m), 1340 (s), 1220 (m), 1150 (vs), 1035 (w) and 925 cm^{-1} (s).

*The Reaction of the Equatorial Sulfonyl Chloride **8** with Triethylamine and Aniline*

The above reaction was repeated with the equatorial sulfonyl chloride **8** as the substrate. The reaction mixture was allowed to remain at room temperature for 24 h before the isolation of products. The products were identified and compared by t.l.c. with the pure products obtained from the preceding experiment. The yield of the product was 75% and the ratio of axial sulfonanilide **10** to equatorial sulfonanilide **9** was estimated to be 35:65.

*The Reaction of the Axial Sulfonyl Chloride **6** with Diethylamine*

Diethylamine (1.5 ml) was added into a solution of **6** (0.3 g) in methylene chloride (10 ml). The reaction mixture was allowed to remain at room temperature for 1 h before it was washed with dilute hydrochloric acid and water and dried. Removal of solvent yielded the sulfonamide **11** as an oily material (0.34 g, 86%) which was recrystallized from pentane to give white plates, m.p. 62–63°. The n.m.r. spectrum (CCl_4) showed a broad band at 0.8–2.2 as well as a triplet at 1.2(J = 7.0 Hz) and a quartet at 3.28 p.p.m. (J = 7.0 Hz). The i.r. spectrum (CH_2Cl_2) showed major bands below 1600 cm^{-1} at 1450 (s), 1380 (m), 1350 (m), 1315 (vs), 1200 (s), 1130 (vs), 1053 (m), 1018 (s), 935 (s), 845 (w), 785 cm^{-1} (m).

Anal. Calcd. for $C_{14}H_{27}NSO_2$: C, 61.50; H, 9.95; N, 5.12; S, 11.73. Found: C, 61.64; H, 9.70; N, 5.11; S, 11.84.

*The Reaction of the Equatorial Sulfonyl Chloride **8** with Diethylamine*

The above reaction was repeated under the same conditions, with **8** (0.3 g) except that the reaction time was 2 h. The product obtained was again an oily material which was purified by recrystallization from pentane to give **11** as white plates (0.32 g, 81%), m.p. 62–63°; mixed m.p. with the sample of **11** from the preceding reaction 62–63°. The n.m.r. spectrum (CCl_4) and i.r. spectrum (CH_2Cl_2) were also identical with those of **11** obtained from the preceding reaction.

*The Triethylamine-catalyzed Reaction of the Axial Sulfonyl Chloride **6** with Water*

A mixture of triethylamine (4 ml) and water (3 ml) was added to a solution of **6** (0.3 g) dissolved in dioxane (10 ml). The reaction mixture was allowed to stand at room temperature for 30 min before it was evaporated to dryness under reduced pressure. The residue was dissolved in water, washed twice with ether, and the aqueous phase evaporated to dryness. The product obtained was then mixed with phosphorus pentachloride (1.5 g) and refluxed in dry benzene (20 ml) for 1 h. The reaction mixture was filtered and the filtrate washed several times with ice-cold water and dried. Evaporation of benzene yielded a mixture of the epimeric sulfonyl chlorides (**6** and **8**) (0.25 g, 83%) which was partially purified by t.l.c. (benzene:ether, 9:1); the two epimeric compounds could not be separated. The n.m.r. spectrum ($CDCl_3$) showed diffuse broad band at 0.8–2.75 and multiplet at 3.4–4.2 p.p.m. The i.r. spectrum (KBr cell, CH_2Cl_2) also showed the characteristic absorption bands of **6** and **8**, especially the 645 cm^{-1} peak of axial epimer **6** and the 600 cm^{-1} peak of equatorial epimer **8**. The ratio of **6** to **8** in the product mixture was estimated to be 2:8 by comparing the i.r. spectrum of the product mixture with those of known mixtures of the pure sulfonyl chlorides.

*The Triethylamine-catalyzed Reaction of the Equatorial Sulfonyl Chloride **8** with Water*

The above reaction was repeated with **8** (0.3 g) as the substrates; the reaction was allowed to run for 12 h. The product obtained was again a mixture of epimeric sulfonyl chlorides (0.265 g, 88%). The i.r. spectrum (KBr cell, CH_2Cl_2) of the purified mixture was found to be almost identical with that of a mixture of 30% of **6** and 70% of **8**.

*Measurement of the Rates of Reaction of the Axial and Equatorial Sulfonyl Chlorides (**6** and **8**) with Triethylamine and Aniline*

A stock solution of the sulfonyl chloride ($\sim 4.0 \times 10^{-3}$ M) in DME (250 ml) was prepared, and the concentration determined by allowing the solution to react with triethylamine for at least 10 half-lives and titrating the chloride ion as described below; the value so obtained was at least 98% of that expected from the weight used in making up the stock solution. A stock solution of the base was prepared by dissolving triethylamine (2.020 g) and aniline (9.313 g) in DME.

To determine the pseudo first order rate constant 25 ml portions of each stock solution were precooled and mixed (as described below), the reaction allowed to run at $-25.0 \pm 0.2°$ for an appropriate time interval whereupon the reaction was quenched by the addition of the calculated amount of dilute nitric acid solution. The resulting solution was then transferred to a 150 ml beaker and the free chloride ion titrated potentiometrically with 0.005 N $AgNO_3$ using a Radiometer PHM 25 pH meter; during the titration the beaker was cooled in ice water. The pseudo first order rate constant was obtained from

the slope (as determined by the method of least squares) of a plot of the logarithm of the concentration of unreacted substrate *vs.* time; good straight line plots of six or more points (from zero reaction to >80% reaction) were obtained by this procedure.

The precooling and mixing of the solutions was carried out as follows. The sulfonyl chloride stock solution (25 ml) was placed in a 100 ml round-bottomed flask equipped with two necks, one about 15 cm long ending in a Quickfit B24 female joint, the other about 5 cm long with a B14/23 neck. The latter was fitted with a simple adaptor consisting of a tube 12 cm long bent into an acute angle (*ca.* 60°) and bearing a male B14/23 joint at each end. The stock solution of the bases (25 ml) was pipetted into a 25 ml Erlenmeyer flask with a B14/23 neck which was then attached to the free end of the adaptor so that the contents of the Erlenmeyer flask at this stage stayed separate from the solution in the round-bottomed flask. The long neck of the larger flask was stoppered and the whole assembly almost completely immersed in the cooling liquid (ethyl alcohol) in the compartment of a Kryothermat KT-62 apparatus (Polyscience Corporation, Evanston, Ill.). After ½ h, when both solutions had reached −25°, the two solutions were mixed as quickly as possible by rotating the adaptor in the neck of the round-bottomed flask so that the base solution poured from the Erlenmeyer into the round-bottomed flask; the timing was begun from this instant.

Using the above procedure and with $[Et_3N] = 40 \times 10^{-3}$ *M*, $[PhNH_2] = 0.20$ *M*, and [**6**] $= 1.97 \times 10^{-3}$ *M*, the pseudo first order rate constant for the axial sulfonyl chloride (**6**) was found to be 1.27×10^{-4} s^{-1}. For the equatorial sulfonyl chloride **7** with [**7**] $= 2.00 \times 10^{-3}$ *M* the pseudo first order rate constant so obtained was 1.78×10^{-6} s^{-1}.

*Measurement of the Rates of Solvolysis of the Axial and Equatorial Sulfonyl Chlorides (**6** and **8**) in Aqueous Dimethoxyethane at 50.0°*

A solution (100 ml) of the sulfonyl chloride (0.010 *M*) in DME:H_2O 5:1 by volume was allowed to stand at 50.0 ± 0.1°. Aliquots were removed at intervals and the chloride ion content determined potentiometrically as above. The rate constant was obtained from the slope of a plot of log [unreacted sulfonyl chloride] *vs.* time. The plot was linear only to about 50% reaction after which the slope diminished appreciably, especially with **8** which reacts only very slowly (<35% reaction after 4 days at 50°). The first order rate constants so obtained were, for the axial sulfonyl chloride **6**, 1.1×10^{-6} s^{-1}, and for the equatorial sulfonyl chloride **8**, 1.6×10^{-5} s^{-1}.

Radiation Chemistry of Dithionates

G. S. MURTHY,[1] R. L. EAGER,[2] AND K. J. MCCALLUM

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received November 25, 1970[3]

The salts $Na_2S_2O_6$, $Na_2S_2O_6.2H_2O$, $K_2S_2O_6$, BaS_2O_6, and $BaS_2O_6.2H_2O$ were irradiated at room temperature with ^{60}Co gamma rays. When the irradiated salts were dissolved in water sulfite ions, sulfate ions, and acid were found as irradiation products. The dependence of yield upon absorbed dose was studied. The *G*-values found ranged from unity to 20. Thermal annealing of the irradiated salts had only a slight effect on product yields. For BaS_2O_6 there is a large increase in product yields after a dose of 28.3×10^{22} eV per mol has been absorbed. A mechanism involving SO_3^- and $S_2O_6^-$ radical ions is proposed.

Les sels $Na_2S_2O_6$, $Na_2S_2O_6.2H_2O$, $K_2S_2O_6$, BaS_2O_6, et $BaS_2O_6.2H_2O$ furent irradiés, à la température de la pièce, avec des rayons gamma du ^{60}Co. Lorsque les sels irradiés furent dissous dans l'eau des ions sulfite, des ions sulfate et acide furent trouvés comme produits d'irradiation. La dépendance du rendement à la dose absorbée fut étudiée. Les valeurs de *G* trouvées se situaient entre 1 et 20. Le recuit thermique des sels irradiés eut seulement un petit effet sur les rendements des produits. Pour BaS_2O_6 il y a une grande augmentation des rendements des produits après l'absorption d'une dose de 28.3×10^{22} eV par mol. Un mécanisme impliquant les ions radicalaires SO_3^- et $S_2O_6^-$ est proposé.

Canadian Journal of Chemistry, 49, 3733 (1971)

Introduction

As part of a study of the radiation chemistry of inorganic sulfur compounds results are reported here on the effects of ^{60}Co gamma rays on alkali dithionates. Chantry *et al.* (1) found a single absorption line with a *g* value of 2.004 in the e.s.r. spectra of gamma irradiated single crystals of sodium dithionate. They postulated that this line was due to the SO_3^- radical ion. The presence of this species in BaS_2O_6 which had been thermally decomposed was postulated by Gilevich and Potopovich (2). To explain their results they postulated that the dithionate ion thermally decomposed to yield the radical ion SO_3^-. This species could in turn react with dithionate ions to form species such as $S_2O_5^-$, SO_4^{2-}, SO_3, and SO_2. The resulting solid upon solution in water would, therefore, yield sulfate, sulfite, and acid, which they found as products. Gilevich and Potopovich found that their thermally decomposed barium dithionate sample gave an e.s.r. spectrum consisting of a sharp peak with a *g* value of 2.011 ± 0.001 and a shoulder with a *g* value of 2.003 ± 0.001. They attributed these paramagnetic signals to the presence of SO_2^- and SO_3^- radical ions respectively.

[3]Revision received July 22, 1971.

Experimental

Reagents

The hydrated dithionates were prepared from sulfur dioxide and manganese dioxide using the methods of Larson *et al.* (3) or of Brauer (4). The anhydrous salts were obtained by heating the appropriate hydrates at 105–110 °C in a hot air oven for a period of 15–20 h. The purity of the dithionates was checked by chemical tests and by comparing their infrared spectra with those reported in the literature (5, 6). The amount of water of crystallization in the hydrates was found to agree with the theoretical values. Distilled water, again distilled from alkaline permanganate and then from an alkaline acid dichromate solution, was used for dissolving the irradiated samples.

Irradiations and Dosimetry

The irradiation source was a Gamma Cell 220 ^{60}Co Irradiation Unit manufactured by Atomic Energy of Canada Limited. For the $K_2S_2O_6$ irradiations the dose rates were of the order of 1000 rad/min. For the other irradiations the dose rates were of the order of 5000 rad/min. Originally all of the samples were irradiated in screw cap bottles. For BaS_2O_6, and to a lesser extent $Na_2S_2O_6$, the odor of sulfur dioxide could be detected when the bottles were opened. Samples of $Na_2S_2O_6$ and of BaS_2O_6 were then irradiated in sealed Pyrex glass tubes. The results for $Na_2S_2O_6$ were identical for both sealed tubes and screw cap bottles. With BaS_2O_6 the sulfate yields were the same for both types of containers but the acid and sulfite yields were lower for the samples irradiated in screw cap bottles. These results indicated that for BaS_2O_6 sufficient sulfur dioxide escaped to cause a significant decrease in the sulfite and acid yields. All of the BaS_2O_6 results reported here are for irradiations in sealed tubes whereas for $Na_2S_2O_6$ most of the results were obtained using screw cap bottles. For the other salts

no odor of sulfur dioxide was detected and screw cap bottles were used for all of the irradiations. The samples were irradiated in the presence of air at a temperature of 25 ± 5 °C. The absorbed dose was measured using ferrous sulfate dosimetry assuming a *G*-value of 15.5 for the production of ferric ion. Allowance was made for the difference in the electron densities of the sample and the dosimeter.

Analytical Procedures

The irradiated salt was dissolved in deaerated triple distilled water and analyzed for sulfite, sulfate, and acid. No odor of hydrogen sulfide could be detected.

Acid was determined by a micro-titration with a standard sodium hydroxide solution using phenolphthalein as an indicator. A blank was done on a solution of the unirradiated dithionate.

Sulfate was determined by using a nephelometric method (7) in which a barium sulfate precipitate is formed. By prior treatment of the sample with hydrogen peroxide, which oxidized sulfite to sulfate, both sulfate and sulfite could be determined and the sulfite found by difference. Standard samples containing known amounts of sulfate, sulfite, and dithionate were used to prepare calibration curves.

Thermal Annealing Studies

The effect of product yields by thermally annealing the irradiated salts prior to their solution in water was studied by placing the irradiated salts in Pyrex tubes which were immersed for varying periods of time in a constant temperature bath.

Results

The anhydrous salts, $Na_2S_2O_6$, $K_2S_2O_6$, and BaS_2O_6 all showed a light brown coloration in the earlier stages of irradiation. With increasing absorbed dose the color of $Na_2S_2O_6$ did not change whereas for $K_2S_2O_6$ and BaS_2O_6 the color gradually changed to dark brown. Upon exposure to the atmosphere the light brown color of irradiated $Na_2S_2O_6$ was bleached to a white color. This latter behavior was not observed with the other irradiated salts. It was established that the bleaching effect for the $Na_2S_2O_6$ samples was due to reaction with water vapor. A sample of irradiated $Na_2S_2O_6$ was divided into two portions, one portion was placed in a desiccator containing anhydrous calcium chloride, the other portion in a desiccator containing some liquid water. The sample over the calcium chloride remained unchanged during a period of five days whereas the sample over the water started to bleach to a white color within a period of a few minutes and within 2 h no trace of the brown color was observable.

Annealing studies were made with samples of $Na_2S_2O_6.2H_2O$ and $BaS_2O_6.2H_2O$ which had received absorbed doses of 22.5×10^{22} and 23.8×10^{22} eV mol^{-1}, respectively. After annealing for 2 h at 55 °C the yellow color of both salts was unchanged. At the end of 4 h of annealing at 55 °C the color of both salts had changed to a light purple. For longer annealing periods or at higher temperatures, 85 °C for $Na_2S_2O_6.2H_2O$ and 80 °C for $BaS_2O_6.2H_2O$, the intensity of the purple color increased. The yields of products were only slightly affected by annealing. As an example, a 6 h annealing period at 85 °C reduced the sulfate, sulfite, and acid yields from the $Na_2S_2O_6.2H_2O$ sample by 2.5, 5.9, and 1.7%, respectively. For $BaS_2O_6.2H_2O$ at 80 °C the corresponding values were 1.6, 0.96, and 0.68%, respectively. Annealing experiments were not made using $Na_2S_2O_6$ and BaS_2O_6 because for these salts the evolution of SO_2 became appreciable even at 50 °C.

With BaS_2O_6 the odor of SO_2 was detected in the early stages of irradiation whereas for $Na_2S_2O_6$ the odor of SO_2 was not detected until much larger doses had been absorbed. Neither

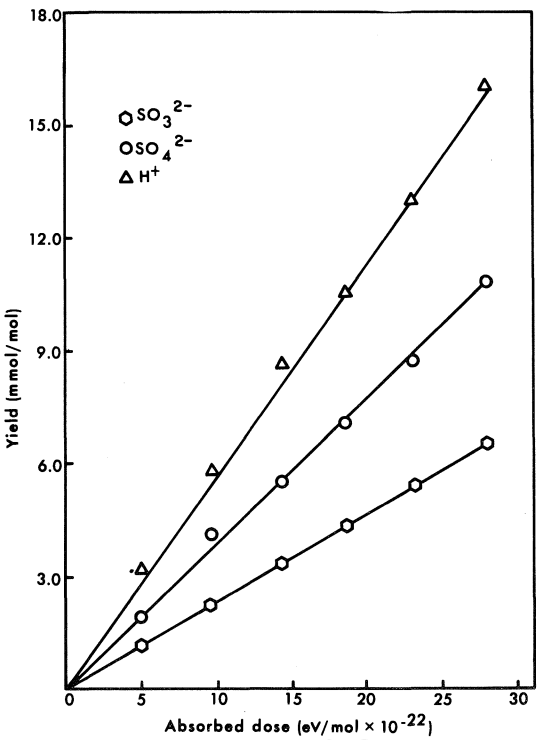

FIG. 1. Yields of SO_3^{2-}, SO_4^{2-}, and acid as a function of dose for $Na_2S_2O_6$.

TABLE 1. *G*-values of products

Compound	Dose (eV per mol × 10^{-22})	Acid	SO_3^{2-}	SO_4^{2-}
$Na_2S_2O_6$	27.6	3.45	1.45	2.30
$Na_2S_2O_6.2H_2O$	33.2	7.29	4.40	3.93
$K_2S_2O_6$	12.4	7.58	1.33	3.89
BaS_2O_6*	28.3	10.6	4.06	2.60
BaS_2O_6	41.8	—	6.85	12.87
$BaS_2O_6.2H_2O$	50.5	16.6	8.31	12.00

*At the point just before the sudden increase in yield of SO_3^{2-} and SO_4^{2-}.

$Na_2S_2O_6.2H_2O$ nor $BaS_2O_6.2H_2O$ appeared to evolve SO_2 at any time during the irradiations.

Electron spin resonance spectra were obtained from irradiated samples of the various dithionates. The samples were microcrystalline and a detailed analysis of their spectra was not made. All of the spectra indicated a paramagnetic species with a *g* value of 2.004. Irradiated BaS_2O_6 samples yielded spectra with at least six absorption peaks whose relative heights varied with the microwave power, indicating the presence of more than one paramagnetic species. With prolonged irradiations the BaS_2O_6 spectra became simpler. It may be concluded from these observations that the SO_3^- radical ion was present in all of the irradiated samples. The presence of other radical species also appears likely.

The yields of sulfite and sulfate, in mmoles, and of acid in milliequivalents, produced per mole of salt are shown plotted against absorbed dose in eV per mol in Figs. 1, 2, 3, 4, and 5 for $Na_2S_2O_6$, $Na_2S_2O_6.2H_2O$, $K_2S_2O_6$, BaS_2O_6, and $BaS_2O_6.2H_2O$, respectively. In Table 1 are given some *G*-values for the products. These were calculated from the curves given in Figs. 1–5.

Discussion

The yields of products resulting from the γ-irradiation of solid dithionates followed by solution in water shows the following behavior;

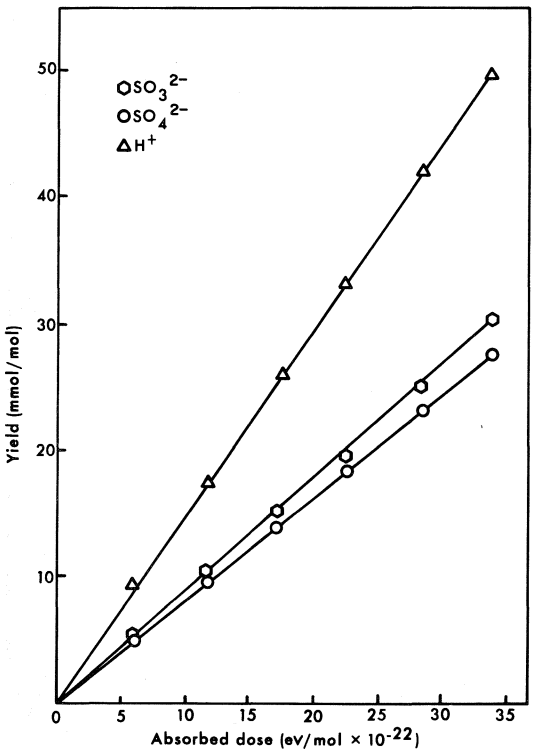

FIG. 2. Yields of SO_3^{2-}, SO_4^{2-}, and acid as a function of dose for $Na_2S_2O_6.2H_2O$.

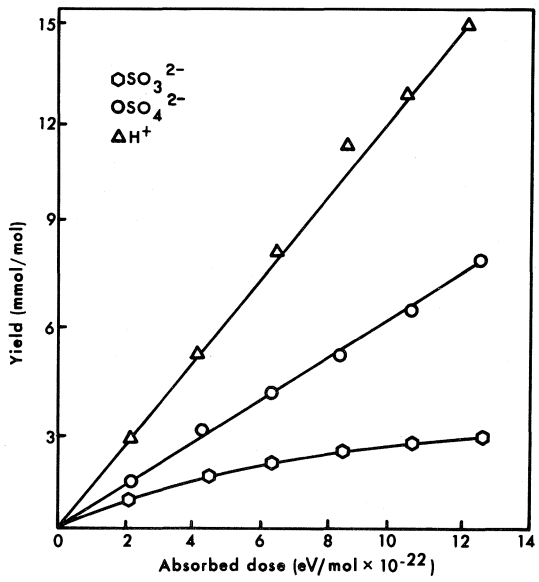

FIG. 3. Yields of SO_3^{2-}, SO_4^{2-}, and acid as a function of dose for $K_2S_2O_6$.

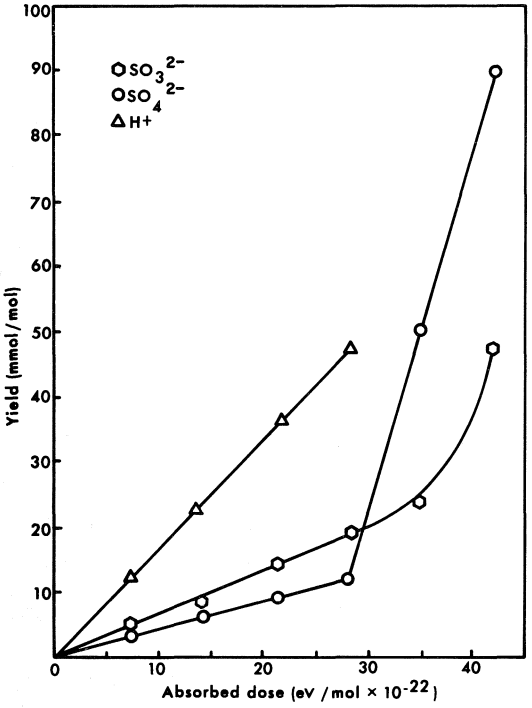

FIG. 4. Yields of SO_3^{2-}, SO_4^{2-}, and acid as a function of dose for BaS_2O_6.

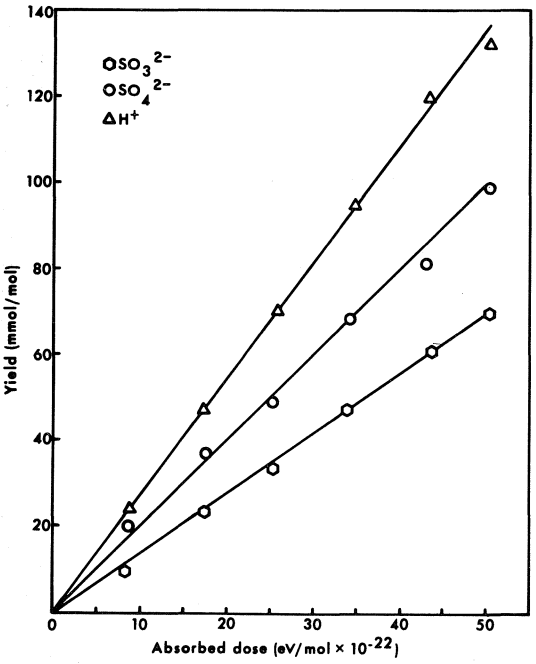

FIG. 5. Yields of SO_3^{2-}, SO_4^{2-}, and acid as a function of dose for $BaS_2O_6.2H_2O$.

the products are acid, sulfite, and sulfate; annealing of the solid salts prior to solution has little effect on the yields; for a given absorbed dose the yield of products is greater for the hydrates than for the corresponding anhydrous salts; for BaS_2O_6 there is a large increase in product yields, especially sulfate, after a dose of 28.3×10^{22} eV per mol has been absorbed.

The simplest overall reaction in which acid, sulfite, and sulfate are formed when irradiated dithionates are dissolved in water appears to be

[1] $S_2O_6^{2-} + H_2O \rightarrow 2H^+ + SO_3^{2-} + SO_4^{2-}$

Reaction 1 predicts that the ratio of sulfite to sulfate yields will be unity and that the ratio of the acid yield to the sum of the sulfite and sulfate yields will also be unity. In Table 2 the experimentally observed values of these ratios are shown, also given are the sum of the *G*-values for sulfite and sulfate. It is seen that the stoichiometry of reaction 1 is only approximately obeyed.

Possible interactions of the incident radiation with dithionate ions are

[2] $S_2O_6^{2-} \rightsquigarrow SO_3^- + SO_3^-$

[3] $S_2O_6^{2-} \rightsquigarrow S_2O_6^- + e^-$

Upon solution in water the following overall reactions would appear to be plausible

[4] $2SO_3^- + H_2O \rightarrow 2H^+ + SO_4^{2-} + SO_3^{2-}$

[5] $2S_2O_6^- + 3H_2O \rightarrow 6H^+ + SO_3^{2-} + 3SO_4^{2-}$

It is not likely that reactions of $S_2O_6^-$ and of the electron accompanying its formation will result in a yield of acid which is higher than the sum of the sulfite and sulfate yields. In the formation of the two $S_2O_6^-$ radical ions two electrons were also produced which will undergo subsequent reactions. For example, they may react with neighboring $S_2O_6^{2-}$ ions as follows

[6] $S_2O_6^{2-} + e^- \rightarrow SO_3^- + SO_3^{2-}$

Reaction 6 combined with reactions 3, 4, and 5 results in the stoichiometry represented by reaction 1.

The *G*-values found are larger than those often encountered in the irradiation of solids. This is particularly so for BaS_2O_6 and the hydrates. The increased yields from the hydrates could be due to some of the SO_3^- and $S_2O_6^-$ radical ions reacting with the water of hydration rather than undergoing the recombination reactions discussed above. It is also possible that the radiation

*At the point just before the sudden increase in yield of SO_3^{2-} and SO_4^{2-}.
† At maximum absorbed dose.

absorbed by the water molecules resulted in a more efficient production of final products. This might occur because the radiolytic products of the water reacted with neighboring $S_2O_6^{2-}$ ions to produce intermediate radicals which did not recombine as readily as was the case for the anhydrous salts. However, for BaS_2O_6 the only satisfactory explanation seems to be that a chain reaction can occur. The following reaction would appear to be a possibility

[7] $SO_3^- + S_2O_6^{2-} \rightarrow SO_3^{2-} + SO_3 + SO_3^-$

For $Na_2S_2O_6$ and $K_2S_2O_6$ there are two cations per anion whereas in BaS_2O_6 there is only one cation per anion. Hence for BaS_2O_6 there is a greater probability of a SO_3^- radical ion being adjacent to a dithionate ion, thus the chain lengths should be longer with a consequent higher product yield, as was found experimentally. In the hydrates the SO_3^- radical ions could also react with water molecules producing chain carriers with a resulting increase in product yields.

The small effect thermal annealing has upon product yields can be explained as follows. The pair of SO_3^- radical ions produced in reaction 2 can either remain in close proximity to one another, or as the result of acquiring sufficient kinetic energy during their formation, they may come to rest relatively far apart. If the SO_3^- radical ions which are in close proximity to one another recombine in times which are short compared to the irradiation times and to the lapse of time before the samples are dissolved in water, then only isolated SO_3^- radical ions will remain in the solid. Similarly the electron produced in reaction 3 may remain in the close proximity of the $S_2O_6^-$ radical ion with the result that they eventually recombine. Alternatively, the electron may come to rest at some distance from the $S_2O_6^-$ radical ion with the possibility of their recombination being quite small. Hence at the time of annealing only isolated intermediates are present in the dithionate substrate and consequently very little recombination can occur. *i.e.*, the effect of thermal annealing is small.

The large increase in product yields shown by BaS_2O_6 after an absorbed dose of 28.3×10^{22} eV per mol is rather unusual and an explanation is not immediately obvious. However, the following is suggested as a possibility. Reactions 2 and 3 produce the radical ion species SO_3^- and $S_2O_6^-$ which, if they survive, produce products upon solution in water, otherwise recombination reactions result in a reduced yield of products. If the extent of the recombination reaction is appreciable then a decrease in the recombination rate would result in an appreciably increased rate of production of products. In the early stages of an irradiation the probability of reactions 2 or 3 occurring in the neighborhood of a SO_3^- or $S_2O_6^-$ remaining from a previous interaction of the incident radiation with a $S_2O_6^{2-}$ ion is quite small. With increasing absorbed dose however, the probability of such a special coincidence increases.[3] Thus with increasing absorbed doses $S_2O_6^-$ radical ions formed as the result of reaction 3 occurring have an increasing probability of undergoing reactions such as the following

[8] $S_2O_6^- + SO_3^- \rightarrow SO_3^{2-} + 2SO_3$

[9] $S_2O_6^- + S_2O_6^- \rightarrow SO_3^{2-} + 3SO_3$

These newly formed $S_2O_6^-$ radical ions, as a result of undergoing reaction 8 or 9 do not have an opportunity to recombine with the electrons produced at the time of their formation and

[3]A simplified mathematical treatment leads to the conclusion that the probability is proportional to the square of the absorbed dose.

hence the yield of products is increased. Reactions 8 and 9 predict that the ratio of SO_4^{2-} to SO_3^{2-} will be greater than 1:1 in agreement with the results found in the irradiation of BaS_2O_6 when the absorbed doses are greater than 28.3×10^{22} eV per mol. At an absorbed dose of 28.3×10^{22} eV per mol the sum of the SO_3^{2-} and SO_4^{2-} yields from BaS_2O_6 is 31 mmol per mol, *i.e.*, approximately one SO_3^{2-} or SO_4^{2-} precursor species for every 32 $S_2O_6^{2-}$ ions. Using a primitive cubic structure as a simple example a given structural unit has 26 relatively close neighbors. Hence it does not seem unreasonable to expect that at these doses the newly formed $S_2O_6^-$ radical ions have a large probability of being adjacent to either SO_3^- or $S_2O_6^-$ radical ions formed earlier.

The effect was not noticed with the other salts. For $Na_2S_2O_6$ and $K_2S_2O_6$ at the largest absorbed doses given the sum of the SO_3^{2-} and SO_4^{2-} yields were 17 and 11 mmol per mol, respectively. Hence, it is conceivable that had the irradiations been carried to higher doses a sudden increase in yield of products would also have been observed. With the hydrates, $Na_2S_2O_6.2H_2O$ and $BaS_2O_6.2H_2O$ if, as proposed earlier, the reactive intermediates react with water of hydration then the extent of recombination is relatively small and there is no opportunity for a sudden increase in the rate of production of products.

A similar type of behavior had been noticed previously by Eager and Mahadevappa in the irradiation of various alkali thiosulfates except that a *falling off* in the yield of products, particularly sulfate, was observed (8). The falling off in yield occurred at approximately the same absorbed dose values which in the present work resulted in a sudden increase in yield. The explanation offered above for the increase in product yields for $Ba_2S_2O_6$ is also probably applicable for the decreased yields found with the thiosulfates. Assuming that SO_3^- radical ions are formed in the irradiated thiosulfates then if additional SO_3^- radical ions are formed in the immediate vicinity of a SO_3^- radical ion already present the two SO_3^- radical ions could react to form the dithionate ion, $S_2O_6^{2-}$. After a certain absorbed dose the probability of this happening becomes large enough so that continuing irradiation results in an appreciable decrease in the number of SO_3^- radical ions present. Since SO_3^- radical ions are likely precursors of sulfate, the observed yield of sulfate shows a sudden decrease with increasing absorbed dose.

We thank the National Research Council of Canada for financial support of this work.

On the Blue Complexes Formed in Acidic Solutions of Hexaammineruthenium(II)

F. BOTTOMLEY AND S. B. TONG
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received June 18, 1971

The blue complex formed by reaction of hexaammineruthenium(II) dichloride and hydrochloric acid has been characterized by analytical, spectroscopic, electrochemical, and chemical methods as a chloro-bridged ruthenium(II)–ruthenium(III) dimer, $[Ru_2(NH_3)_6Cl_4H_2O]Cl$. With hydrobromic acid the analogous complex $[Ru_2(NH_3)_6Br_4H_2O]Br$ is formed. Reactions of the complexes with ammonia and hydrohalic acids are reported.

Le complexe bleu, obtenu en faisant réagir le dichlorure d'hexaammineruthénium(II) avec l'acide chlorhydrique a été caractérisé par des méthodes analytiques, spectroscopiques, électrochimiques et chimiques; il s'agit d'un dimère ruthénium(II)–ruthénium(III) avec un pont chloro, $[Ru_2(NH_3)_6Cl_4H_2O]Cl$. Avec l'acide bromhydrique, le complexe correspondant, $[Ru_2(NH_3)_6Br_4H_2O]Br$, est obtenu. Les réactions de ces complexes avec l'ammoniaque et les acides halogénhydriques sont rapportées.

Introduction

The formation of deep blue solutions is a notable feature of ruthenium chemistry. These solutions were obtained in two distinct ways: (*a*) by reduction of chloro-complexes of ruthenium(III); (*b*) by reaction of ammine complexes of ruthenium(II) with acids. Although there are differences in the electronic state of the ruthenium in the starting material, in the ligands, and in method of preparation, it seemed possible the species responsible for the blue color was similar in all cases. Earlier investigations and discussions of the nature of the species were mainly based on solution studies (1–5). Recently two complexes have been isolated. Wilkinson and coworkers (6, 7) obtained the blue cluster anion $Ru_5Cl_{12}^{2-}$ by reduction of ruthenium(III) chloride in methanol. Lever and Powell (8) obtained a blue complex, tentatively formulated as $[Ru(NH_3)_3Cl_2H_2O]Cl$, from the reaction between hexaammineruthenium(II) dichloride and hydrochloric acid. We have reinvestigated this complex, and extended the reaction to hydrobromic acid, to determine the nature of the blue species.

Results

Hot aqueous hydrochloric acid solutions of hexaammineruthenium(II) dichloride rapidly become blue and on cooling a blue micro-crystalline material precipitates. Great difficulty was experienced in obtaining a product with reproducible chemical and physical properties. Using the criteria of maximum intensity of the absorption in the electronic spectrum and a minimum magnetic moment for the complex, the preparation was repeated under various conditions until both criteria were satisfied. The method described in the experimental section was regularly repeated and yielded deep blue micro-crystals of $[Ru_2(NH_3)_6Cl_4H_2O]Cl$. A similar procedure using hexaammineruthenium(II) dibromide and hydrobromic acid gave deep blue-green micro-crystals of $[Ru_2(NH_3)_6Br_4H_2O]Br$. Attempts to prepare a pure iodo-complex failed due to the insolubility of hexaammineruthenium(II) di-iodide in hydriodic acid.

Both the chloro- and bromo-complexes are hygroscopic and moderately air stable when dry, slightly soluble in water, methanol, and dimethylformamide (with slow decomposition), insoluble in ethanol, and decomposed by dimethylsulfoxide. The chloro-complex has a conductivity expected for a 1:1 electrolyte in DMF, but the conductivity of the bromo-complex is high (Fig. 1), possibly because this complex is decomposed by DMF more rapidly than the chloro-complex. Their infrared spectra in the region 4000–700 cm^{-1} showed absorption bands due to co-ordinated ammonia (these occurring at frequencies in the range normally observed for ruthenium(III) rather than ruthenium(II) (9)). In addition, a pronounced broad shoulder which appeared at 3430 (chloro-complex) or 3460 cm^{-1} (bromo) on the high energy side of the NH_3 band was assigned to co-ordinated water (Table 1). In the low frequency region (700–200 cm^{-1}) there were a number of

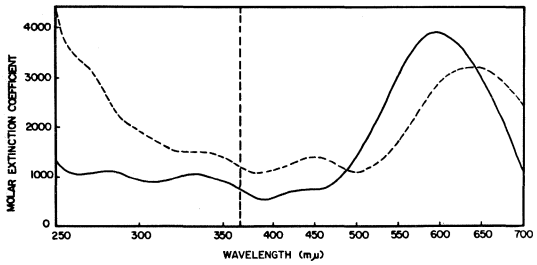

FIG. 2. Electronic spectra of $[Ru_2(NH_3)_6X_4H_2O]X$ (X = Cl, —; X = Br, ---) (aqueous solution).

bands, but no definite assignments could be made. In particular, ruthenium-chloride or bromide stretching frequencies could not be identified with certainty. The electronic spectra of the complexes (aqueous solution) are shown in Fig. 2. The three high energy absorption bands were observed in the spectra of different samples and in spectra taken as Nujol mulls and therefore are not due to impurity. This spectrum agrees with that described briefly in the literature (3).

$[Ru_2(NH_3)_6Cl_4H_2O]Cl$ has a magnetic moment of 2.05 B.M. at 21 °C and the bulk susceptibility obeys the Curie–Weiss law over the temperature range 80–294 °K with $\theta = -18.6°$. $[Ru_2(NH_3)_6Br_4H_2O]Br$ has a magnetic moment of 2.00 B.M. at 21 °C. The results are in agreement with a total of one unpaired electron per two ruthenium atoms for both complexes.

Potentiometric titration of either complex with cerium(IV) showed 50% of the ruthenium was easily oxidizable and the shape of the titration curve was similar to that for oxidation of hexaammineruthenium(II) (Fig. 3). The shape of the curve above the inflexion point indicated further oxidation took place, although no definite break was observed. Potentiometric titration of chloropentaammineruthenium(III) with cerium(IV) resulted in curves similar to the upper portion of Fig. 3. Presumably oxidation to ruthenium(IV) occurred, with loss of ammonia from the complex. Similar behavior was observed in radiolysis experiments (10). $[Ru_2(NH_3)_6Cl_4H_2O]Cl$ gave a polarographic reduction wave at −0.28 V *vs.* s.c.e. in 1 *M* hydrochloric acid, at a concentration of 3 × 10^{-4} *M*. The results were complicated by a catalytic hydrogen discharge such that the discharge appeared at potentials 0.2 V more positive than in the absence of $[Ru_2$-

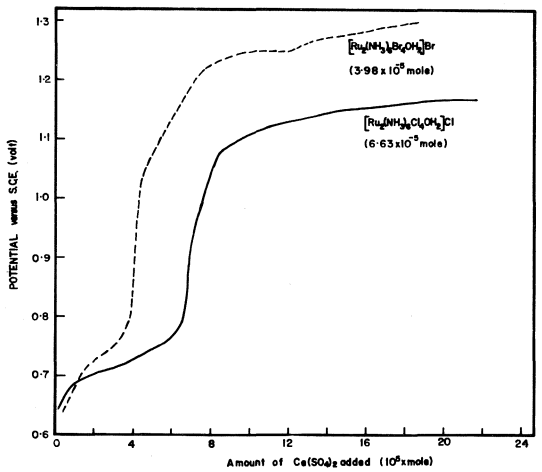

FIG. 3. Potentiometric titration curves for $[Ru_2(NH_3)_6X_4H_2O]X$ (X = Cl, —; X = Br, ---).

$(NH_3)_6Cl_4H_2O]Cl$. Under similar conditions $[Ru^{III}(NH_3)_5Cl]Cl_2$ gave a wave at −0.25 V *vs.* s.c.e. (with no catalytic hydrogen discharge). An $E_{1/2}$ of −0.27 V was reported for reduction of $[Ru^{III}(NH_3)_5Cl]Cl_2$ under conditions different from those used in this work (11). The wave height for $[Ru_2(NH_3)_6Cl_4H_2O]Cl$ corresponded to approximately 41% of the ruthenium in the complex being present as ruthenium(III) by comparison with $[Ru^{III}(NH_3)_5Cl]Cl_2$).

$[Ru_2(NH_3)_6Cl_4H_2O]Cl$ reacted with hydrochloric acid and oxygen at room temperature over several days to give a 73% yield of trichlorotriammineruthenium(III) (8). Without oxygen reaction was extremely slow. $[Ru^{III}(NH_3)_3Cl_3]$ was insoluble in all common solvents. Its infrared spectrum (Table 1) showed three absorption bands assignable to metal–nitrogen stretching frequencies and three bands assignable to metal–chlorine stretching frequencies, and the complex therefore has been assigned the *mer*-configuration, although we are aware of the error which may arise when assignment of stereochemistry is based solely on solid-state infrared data (12).

On heating $[Ru_2(NH_3)_6Cl_4H_2O]Cl$ with aqueous hydrochloric acid, ammonia was lost from the complex, but we were unable to obtain $[Ru^{III}Cl_5H_2O]^{2-}$ (8). The infrared spectrum of the product showed absorption bands assignable to co-ordinated ammonia as well as water, and microanalytical results indicated a significant nitrogen content. The bulk magnetic susceptibility was lower than expected for ruthenium(III), indicating the complex may be polymeric. At room temperature $[Ru_2(NH_3)_6Br_4H_2O]Br$ and hydrobromic acid did not give $[Ru^{III}(NH_3)_3Br_3]$, but on heating $[Ru^{III}Br_5H_2O]^{2-}$ was formed in 81% yield.

In aqueous ammonia at room temperature $[Ru_2(NH_3)_6X_4H_2O]X$ (X = Cl, Br) gave solutions having the deep wine-red color characteristic of ruthenium red (13). Addition of potassium iodide to the solution gave hexaammineruthenium(II) diiodide (30% yield), showing the presence of ruthenium(II) in the complex. Addition of the appropriate acid to the red solution regenerated the blue solution (8), and several repetitions of the ammonia/acid treatment ultimately gave chloropentaammineruthenium(III) dichloride (68%) or bromopentaammineruthenium(III) dibromide (79%). These same complexes were obtained by heating the red solution and then adding the appropriate acid. There was no reaction between $[Ru_2(NH_3)_6Cl_4H_2O]Cl$ and triphenylphosphine in refluxing methanol.

Discussion

The chemical and physical evidence presented above shows that $[Ru_2(NH_3)_6X_4H_2O]X$ (X = Cl, Br) contain halo-bridged ruthenium(II) and ruthenium(III) ions. The reason for the deep-blue color presumably lies in the presence of mixed oxidation states. Whether any particular ruthenium ion should be regarded as ruthenium(II) or ruthenium(III) is not clear. The deep color of, for example, ruthenium red, has been ascribed to "oscillating valencies", but recent results indicate that each ruthenium ion has a distinct oxidation state (14).

Assuming octahedral co-ordination about the ruthenium, the analytical and infrared results indicate the ruthenium ions are bridged by a single halide. Although this is the only formulation in agreement with all the results, it cannot be regarded as conclusive in the absence of a full structure determination. Some information on the structure of the chloro-complex may be obtained from its reactions. The high yield of $[Ru^{III}(NH_3)_3Cl_3]$ obtained from $[Ru_2(NH_3)_6Cl_4H_2O]Cl$ and hydrochloric acid means that each ruthenium ion in this complex must be co-ordinated by three ammonia molecules. Assuming the *mer*-stereochemistry assigned to $[Ru^{III}(NH_3)_3Cl_3]$ from infrared evidence is correct and no rearrangement occurred during

reaction, the three ammonia molecules will have the *mer*-configuration. Even allowing free rotation about the Ru—Cl—Ru axis, this restriction on the ammonia configuration still permits six isomers of formula $[Cl_2(NH_3)_3RuClRu(NH_3)_3ClH_2O]Cl$ and twelve isomers are possible if the two ruthenium ions have distinct, separate, oxidation states. For the bromo-complex, it is not possible to make even a partial assignment of geometry. Repeated attempts to obtain suitable crystals of either the chloro- or bromo-complex for X-ray work have not been successful to date.

Ruthenium metal was not observed in the preparation of the complexes unless solutions were heated for an extended period. It is assumed, therefore, that ruthenium(III) was formed by oxidation of ruthenium(II) by the solvent water, rather than by disproportionation, although no visible evolution of hydrogen gas was observed.

Lever and Powell (8) tentatively proposed the formula $[Ru(NH_3)_3H_2OCl_2]Cl$ for the blue chloro-complex and obtained other salts of the complex cation. We have reformulated the complex, but we find that slow evaporation of the filtrate after removal of the chloro-complex yields a small quantity of crystals with an Ru:Cl ratio of 1:3. This complex is presently under investigation.

No related mono-chloro-bridged complexes of the type discussed here are available for comparison. The only chloro-bridged ruthenium complex of known structure, $[(Bu_3^nP)_4Ru_2Cl_5]$, has a tri-chloro-bridge (15). Shilov postulated a di-chloro-bridged complex as the blue intermediate in reduction of ruthenium trichloride in tetrahydrofuran (4). The blue $Ru_5Cl_{12}^{2-}$ isolated by Wilkinson and co-workers (6, 7) is obviously unrelated to the complexes described here and hence the blue colors observed in ruthenium chemistry are not indicative of the presence of one species, but at least two unrelated complexes give blue solutions.

Experimental

Ruthenium trichloride was obtained from Johnson, Matthey and Mallory, Montreal, and used as received. All other chemicals were reagent grade. Analyses were by Bernhardt Microanalytical Laboratories, Mulheim, W. Germany. Except where indicated, all operations were carried out under argon and all solvents were deoxygenated before use.

Hexaammineruthenium(II) Dichloride and tris-o-Phenanthrolinenickel(II) Dichloride Tetrahydrate

These were prepared by literature methods (8, 16).

Anal. Calcd. for $Cl_2H_{18}N_6Ru$: Cl, 25.86; H, 6.62; N, 30.65. Found: Cl, 26.05; H, 6.36; N, 31.05.

Anal. Calcd. for $C_{36}Cl_2H_{32}N_6NiO_4$: C, 58.25; Cl, 9.55; H, 4.34; N, 11.32. Found: C, 58.38; Cl, 9.73; H, 5.00; N, 11.45.

Hexaammineruthenium(II) Dibromide and Diiodide

These were prepared by metathesis from the chloride salt.

Anal. Calcd. for $Br_2H_{18}N_6Ru$: H, 5.00; N, 23.15. Found: H, 5.06; N, 23.68.

Anal. Calcd. for $H_{18}I_2N_6Ru$: H, 3.97; N, 18.39. Found: H, 4.21; N, 18.68.

μ-Chloro-trichloroaquohexaamminediruthenium Chloride

To a solution of hexaammineruthenium(II) dichloride (0.70 g) in water (9 ml) were added 5 drops of concentrated ammonia. The solution was heated to 80 °C and concentrated hydrochloric acid (6 ml) rapidly added. The solution became blue and was filtered hot, leaving a small quantity of dark material. The filtrate was allowed to stand at 5 °C for 12 h, the blue micro-crystalline product filtered off, recrystallized from methanol at low temperature, washed with ethanol and ether, and dried in vacuo over P_2O_5. Yield 0.26 g (56%).

Anal. Calcd. for $Cl_5H_{20}N_6ORu_2$: Cl, 35.48; H, 4.03; N, 16.82. Found: Cl, 35.45; H, 4.05; N, 16.85.

μ-Bromo-tribromoaquohexaamminediruthenium Bromide

This was prepared, in 59% yield, in a similar manner to the chloro-complex, from hexaammineruthenium(II) dibromide and hydrobromic acid (48%).

Anal. Calcd. for $Br_5H_{20}N_6ORu_2$: Br, 55.34; H, 2.79; N, 11.64. Found: Br, 55.08; H, 2.78; N, 11.59.

Reaction of $[Ru_2(NH_3)_6X_4H_2O]X$ (X = Cl, Br) with Ammonia

(a) At Room Temperature

$[Ru_2(NH_3)_6Cl_4H_2O]Cl$ (0.080 g) in 1:1 aqueous ammonia (5 ml) was stirred until the solution became wine-red. To the solution was added potassium iodide, the resultant yellow precipitate of hexaammineruthenium(II) diiodide filtered off, recrystallized from dilute ammonia, washed with ethanol, and ether and dried in vacuo. Yield 0.050 g (33%).

Anal. Calcd. for $H_{18}I_2N_6Ru$: H, 3.97; N, 18.39. Found: H, 3.94; N, 18.30.

The electronic and infrared spectra of the product agreed closely with the literature (9, 17). By an analogous procedure $[Ru_2(NH_3)_6Br_4H_2O]Br$ gave $[Ru^{II}(NH_3)_6]I_2$ in 27% yield.

(b) At Elevated Temperature

A solution of $[Ru_2(NH_3)_6Cl_4H_2O]Cl$ (0.10 g) in 1:1 aqueous ammonia (9 ml) was stirred until it became wine-red and the solution gently heated for 10 min. Addition of concentrated hydrochloric acid (12 drops) gave a yellow solution which on cooling deposited yellow crystals of chloropentaammineruthenium(III) dichloride. These were removed by filtration, recrystallized from dilute hydrochloric acid, washed with ethanol and ether, and air dried. Yield 0.08 g (68%).

Anal. Calcd. for $Cl_3H_{15}N_5Ru$: H, 5.17; N, 23.93. Found: H, 5.15; N, 24.11.

The infrared and electronic spectra were in good agreement with the literature (9, 18).

In a similar manner $[Ru_2(NH_3)_6Br_4H_2O]Br$, NH_3 and HBr gave $[Ru^{III}(NH_3)_5Br]Br_2$ in 79% yield.

Anal. Calcd. for $Br_3H_{15}N_5Ru$: H, 3.55; N, 16.44. Found: H, 3.91; N, 16.55.

The infrared and electronic spectra were in good agreement with the literature (9, 18).

Reaction of $[Ru_2(NH_3)_6X_4H_2O]X$ (X = Cl, Br) with Acid

(a) At Room Temperature

Oxygen was passed through a solution of $[Ru_2(NH_3)_6Cl_4H_2O]Cl$ (0.090 g) in concentrated hydrochloric acid (20 ml) for five days at room temperature. The orange trichlorotriammineruthenium(III) was removed by filtration, washed with ethanol and ether, and air dried. The insoluble crude product was purified by warming to 60 °C in 1:1 aqueous ammonia, filtered off, washed well with water, ethanol, and ether, and air dried. Yield 0.068 g (73%).

Anal. Calcd. for $Cl_3H_9N_3Ru$: H, 3.51; N, 16.25. Found: H, 3.58; N, 16.25.

The electronic spectrum (Nujol mull) showed two bands at 297 and 375 mμ.

(b) At Elevated Temperature

A solution of $[Ru_2(NH_3)_6Cl_4H_2O]Cl$ (0.0513 g) in concentrated hydrochloric acid (10 ml) was refluxed for 1 h. The solution was filtered hot and cesium chloride added to the filtrate, giving a red precipitate, which was removed by filtration, washed with cold water, ethanol, and ether, and air dried. Yield 0.0882 g.

Anal. Found: Cl, 27.53; N, 2.58.

The electronic spectrum of the complex showed one band at 334 mμ. The infrared spectrum showed bands at 3300, 3240, 1610, 1305 (shoulder), 1292, 1273, and 780 cm^{-1} (weak), attributable to co-ordinated ammonia and at 3500 and 1650 cm^{-1}, attributable to co-ordinated water.

A solution of $[Ru_2(NH_3)_6Br_4H_2O]Br$ (0.069 g) in hydrobromic acid (48%, 10 ml) was heated until it became red. The solution was filtered hot and cesium chloride added to the filtrate. The red $Cs_2[Ru^{III}Br_5H_2O]$ was removed by filtration, washed with a little cold water, ethanol, and ether, and air dried. Yield 0.064 g (81%).

Anal. Calcd. for $Br_5Cs_2H_2ORu$: Br, 50.93. Found: Br, 50.55.

The infrared spectrum showed two broad bands in the region 3500–3650 cm^{-1} and a broad band in the region 1600–1650 cm^{-1} attributable to co-ordinated water.

Infrared spectra were recorded on a Beckman IR-12 spectrophotometer as Nujol or hexachlorobutadiene mulls between potassium bromide or polyethylene plates. Electronic spectra were recorded on a Coleman Model EPS-3T instrument. Room temperature magnetic moments were by the Gouy method. Conductivity measurements in dimethylformamide solution were made on a Beckman Model RC-18A conductivity bridge. Potentiometric titrations were carried out using a Leeds and Northrup research potentiometer, with a saturated calomel reference electrode and ceric sulfate as oxidant. Polarographic curves were recorded on a Princeton Applied Research Model 170 electrochemistry system. The analysis was carried out in a Kalousek vessel with a saturated calomel reference electrode (s.c.e.) and the dropping mercury electrode had an outflow velocity of 2.95 mg s^{-1} and a drop time of 2.97 s at a mercury column pressure of 75 cm.

We wish to thank Dr. A. B. P. Lever of York University, Ontario, for the low temperature magnetic moments, Dr. D. Barnes of this department for the polarographic measurements, the National Research Council of Canada for financial support, and Johnson, Matthey and Mallory for a generous loan of ruthenium.

Transient Phenomena in Dissociation of Diatomic Molecules[1]

R. K. BOYD
Department of Chemistry, University of Guelph, Guelph, Ontario

AND

GEORGE BURNS
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received April 30, 1971

A model suitable for studies of non-equilibrium effects in chemical reactions (13) was used to predict incubation times for the dissociation of O_2 in Ar between 2900 and 7200 °K. It was found that the model accounts satisfactorily for the experimental data. On the other hand previously used theories underestimate these incubation times by a factor of five to ten; the discrepancy is traced to assumptions used in previous investigations. When the same model is applied to the dissociation of Br_2 in Ar and Cl_2 in Ar, it correlates well a variety of experimental data, obtained over a wide temperature range.

Un modèle convenable pour les études des effets de nonéquilibre (13) a été utilisé pour prédire les temps d'incubation pour la dissociation de O_2 dans Ar entre 2900 et 7200 °K. Il a été trouvé que le modèle calculé est satisfaisant d'après les données expérimentales. D'autre part, les théories antérieurement utilisées sous-estiment ces temps d'incubation par un facteur de cinq à dix; le désaccord est retracé grâce aux suppositions utilisées dans des examens antérieurs. Lorsque le même modèle est appliqué à la dissociation de Br_2 dans Ar et de Cl_2 dans Ar, il met bien en corrélation la variété des données expérimentales obtenues audessus d'une plus grande échelle de température.

Canadian Journal of Chemistry, 49, 3744 (1971)

1. Introduction

Wray (1) showed that the dissociation of oxygen in shock waves is preceded by a measureable induction period. He proposed that such an "incubation time" (1) is due to coupling of the vibrational relaxation to dissociation of O_2. This phenomenon is predicted by the theories of Hammerling, Teare, and Kivel (2), Marrone and Treanor (3) and Heims (4). Brau, Keck, and Carrier (5) pointed out that these theories (2–4) are of a phenomenological nature, and applied their diffusion theory of dissociation reaction to predict the incubation times in oxygen. Although the Brau *et al.* calculations agreed well with the experiments (1) at very high temperatures, their predicted incubation times deviated from experiment at lower temperatures, being about five to ten times smaller than the experimental data at 5000 °K. Use of the Morse potential function instead of the truncated harmonic oscillator function in these calculations did not alter the above discrepancy. It was suggested (5) that the discrepancy may be due to experimental error, since it was relatively difficult to obtain accurate incubation times at lower temperatures (1). However, recently, Watt and Myerson (6) succeeded in obtaining accurate measurements of the incubation times and rate constants down to 2900 °K. When these new results were compared (6) with theoretical calculations of Brau *et al.* (5) the observed absolute values of incubation times were still an order of magnitude greater than calculated.

In the present work, we developed further a model for dissociation used previously (7), applied it to the O_2–Ar system below 7200 °K, and showed that the incubation times so obtained are of the order of vibrational relaxation times, and agree well with all the available experimental data (1, 6). The reaction profiles were generated, and the results compared with the previous theoretical treatments. On the other hand, when the model is used to treat the halogen recombination–dissociation reactions, it was found that it correlates well the available experimental data (7–11).

2. Non-equilibrium Dissociation–Recombination

The model for dissociation of diatomic molecules (7) assumes that the density of representative points in the vibrational phase space of n diatomic molecules, which have a total vibra-

For personal use only.

tional energy E_v, is uniform at any given time throughout the course of the reaction. For this reason, it may be referred to as a "uniform phase density (u.p.d.) model".

If, in this model, the diatomic oscillators were in equilibrium with each other, and were unable to interact with other degrees of freedom, they could have been described by a microcanonical ensemble defined by n and E_v. The vibrational temperature, T_v, of the oscillators would have been a time independent observable. Such a microcanonical ensemble would have occupied a hypersurface of constant energy cut out of a uniform ensemble in $6n$ dimensional phase space. However, according to the model, the oscillators *do* interact with other degrees of freedom, and their total vibrational energy is a function of time. Thus, we consider a non-equilibrium ensemble, which moves through the uniform ensemble as the total energy of oscillators changes with time during the course of the reaction. It is assumed that such a non-equilibrium ensemble maintains uniform density of the representative points at any given time in phase space, and thus can be described by an "observable" T_v. The density of representative points in the vibrational phase space for such a non-equilibrium ensemble is then

$$\rho(H,t) \approx \exp\,[-H(t)/kT_v(t)]$$

The assumption that a time-dependent vibrational temperature exists (Bethe–Teller approximation) at relatively low shock wave temperatures is not unreasonable. It is commonly used if dissociation of diatomic molecules can be neglected, and it can be shown (12) that it holds exactly, within the harmonic oscillator approximation. Therefore one may expect that the u.p.d. model would describe satisfactorily some of the shock wave processes, provided that the temperature is so low that the dissociation reaction and vibrational relaxation are *weakly* coupled; this feature is discussed further below.

One expects that, during the dissociation, the uppermost levels very close to the dissociation limit would be depopulated with respect to the lower energy levels, whose distribution function is described by the assumed T_v. It is here assumed that this depopulation is limited to a very narrow energy region, and that the molecular distribution function over these levels is time-dependent during the course of reaction.

The other assumptions of the u.p.d. model were described previously (7, 13). While in the previous investigation the back reaction was neglected, in the present work both dissociation and recombination are considered. The vibrational relaxation equation now takes the form (14)

$$[1] \qquad \frac{d\varepsilon_v}{dt} = \frac{(\varepsilon_\infty - \varepsilon)}{\tau_v} - \frac{(\bar{E}_d - \varepsilon_v)}{[X_2]}\left(\frac{d[X_2]}{dt}\right)_d + \frac{(\bar{E}_r - \varepsilon_v)}{[X_2]}\left(\frac{d[X_2]}{dt}\right)_r$$

The first term on the right side of eq. 1 describes the relaxation of the unperturbed oscillator, with a characteristic vibrational relaxation time τ_v. The average vibrational energy ε_v is related to the vibrational temperature T_v via the harmonic oscillator approximation, $\varepsilon_v = R\theta/[\exp(\theta/T_v) - 1]$, where $\theta = h\nu_0/k$; ε_∞ is the value of ε_v for the special case where $T_v = T$, the instantaneous value of the translational temperature.

The subscripts $_d$ and $_r$ denote the dissociation and recombination directions, respectively; thus for example, $(d[X_2]/dt)_d$ is the rate for the dissociation of X_2, the diatomic molecule. $\bar{E}_d$ is the average energy lost by the vibrational mode when one oscillator dissociates; similarly, $\bar{E}_r$ is the average energy supplied to the vibrational mode by the recombination of two atoms. At equilibrium, detailed balance requires that $\bar{E}_d = \bar{E}_r$; in the present work, it is assumed that during the entire course of the reaction $\bar{E}_d = \bar{E}_r \simeq D$, the dissociation energy. That is to say, dissociation is considered to occur only from states very close to the top of the vibrational ladder. The second term in eq. 1 is thus the perturbation term arising from the fact that a dissociating molecule has considerably more vibrational energy than the average; as pointed out by Treanor and Marrone (14), the effect is analogous to "evaporation cooling", where only the most energetic molecules escape into the vapor phase. The last term is the "condensation heating" perturbation term.

For a closed system, the nett chemical rate may be described as the difference of the two

For personal use only.

reaction rates

$$[2] \quad -\mathrm{d}[X_2]/\mathrm{d}t = k_d[M][X_2] - k_r[M][X]^2$$

The quantities k_d and k_r are the rate coefficients; they are, in general, functions of the internal distribution functions of the corresponding chemical species. However, in the present work, the recombinative rate coefficient is assumed to be an observable obtained from measurements after all transients have died, and thus is taken to be a time-dependent constant. This is not too unreasonable an assumption, since transient phenomena in recombinations, which have *not* been observed, involve relaxation of highly excited diatomic molecules, and are expected to be extremely fast.

The dissociative rate coefficient k_d, on the other hand, cannot be defined here by one non-zero eigenvalue, and depends on both T and T_v. The functional form of this dependence is obtained (7, 13, 15) from the two assumptions, used above in eq. 1 concerning the existence of a unique T_v and of "reactive" states X_2* very close to the dissociation limit. The fractional population of such states is given by

$$[3] \quad [X_2^*]/[X_2] = g^* \exp(-D/RT_v)/Q_v(T_v)$$

where g^* is an effective degeneracy for the reactive states, and $Q_v(T_v)$ is the vibrational partition function. The one-way rate coefficient k_d is now given by

$$[4] \quad k_d = \kappa(T)[X_2^*]/[X_2]$$

where $\kappa(T)$ is the "microscopic" rate constant describing the rate of dissociation of X_2*. Then, for given values of $[X_2]$ and of T, eqs. 3 and 4 give

$$[5] \quad k_d(T,T_v)/(k_r K_{eq}) = [Q_v(T)/Q_v(T_v)] \exp[D/R(1/T - 1/T_v)]$$

Equation 5, with $Q_v(T)/Q_v(T_v)$ replaced by the high-temperature limit (T/T_v), is the form given previously (7, 13, 15). Evaluation of the rate coefficient k_d thus requires knowledge of k_r; this problem has been discussed previously (16).

Different collision partners M, (Ar, X_2, and X), have different efficiencies for the various processes (dissociation, recombination, and relaxation). In terms of the present model, a complete description would require three values of the de-excitation collision probability P_{10} (12) which governs the value of τ_v (eq. 1), and three values of k_r. It is also necessary to know the equilibrium constant corresponding to the arbitrary "hypersurface in phase space" (17) used to distinguish reactants from products. In the present case, K_{eq} is essentially the usual equilibrium constant for the process $X_2 \rightleftharpoons 2X$.

The available experimental information is, however, far from sufficient to establish the values of six parameters, so that further simplifications had to be made. The number of independent parameters was reduced to three by making the somewhat serious approximation that, for all collision partners i,j

$$[6] \quad (P_{10})_i/(P_{10})_j = \kappa_i/\kappa_i = k_{r,i}/k_{r,j}$$

The resulting relative collision efficiencies will thus correspond to weighted averages for the relaxation and reactive processes. It should be emphasized that this approximation is *not* an essential feature of the present model, but was imposed, as a necessity, by the lack of experimental information.

Using these additional assumptions, the total chemical rate can now be expressed by a linear combination of terms

$$[7] \quad -\mathrm{d}[X_2]/\mathrm{d}t = \sum_i k_{d,i}(T, T_v) \cdot [M_i][X_2] - \sum_i k_{r,i}(T) \cdot [M_i][X]^2$$

The relaxation time τ_v in eq. 1 is now a composite function (12) of the three $(P_{10})_i$. Since each $k_{d,i}$ is a function of T_v, which is in turn a function of the concentration of all species i via eq. 1, eq. 7 does *not* represent a decomposition of the total chemical rate into separable contributions from each collision partner i, except in the limit $T_v = T$. This feature has received considerable attention (18–21). The time-dependence of the $k_{d,i}$ must be taken into account in the integration of eq. 7.

3. Method of Computation

It is the purpose of the present work to compute reaction profiles which may be directly compared with the raw experimental observations. To do this, the relaxation eq. 1 and the chemical rate eq. 7 must be integrated simultaneously with the shock conservation equations. The latter can be integrated implicitly by a modification of the iterative technique described previously (10); the modification required is a correction to the enthalpy of X_2 for the disequilibrium of the vibrational mode. This correction was calculated,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in this work, from the harmonic oscillator approximation, and was a function of the vibrational temperature.

In order to compute theoretical profiles of X_2 optical density *vs.* time, the vibrational temperature and X_2 concentration must be used, together with extrapolated or available extinction coefficient data. The integration must be performed over a rectangular slit function which is typically 1 mm wide; the resulting averaged signal should correspond to the optical density "seen" by the photomultiplier in a shock tube experiment using molecular absorption spectrophotometry. The latter must be further integrated over an RC time constant, to simulate the further distortion of the step function, at the shock front, by the amplification chain. This final profile should correspond to the profile observed on the oscilloscope screen in a typical shock-wave absorption experiment. It should agree with the experimental profile to within the accuracy of the model.

In a similar fashion, profiles of X atom concentration, two-body emission intensity (10), T, T_v, and total gas density, were computed. Further details of these computations are given in the Appendix.

4. Results

The computations were performed on an IBM 360/50 computer; ideal shock wave conservation equations were used.

(A) O_2–Ar System

In the case of oxygen, the main interest lies in the observable incubation times (1, 6). This is because the available theoretical prediction of incubation times (5) underestimates the experimental values by a factor of five to ten at temperatures below 5000 °K. Application of the present model to this problem requires knowledge of vibrational relaxation times, molecular extinction coefficients, and rate constants obtained under conditions such that relaxation is much faster than reaction.

For the case of O_2 dilute in argon, vibrational relaxation times and molecular extinction coefficients at 1470 Å have been measured (22) over the temperature range of interest. The values of $k_{r,Ar}$ were obtained from recent low-temperature recombination rate constants (23) and the results obtained by Wray (24), who studied recombination of atoms in shock-dissociated ozone. In the present work, rate constants, which were obtained (24) under such conditions that corrections for reaction

$$O + O_3 \rightarrow 2O_2$$

were necessary, were omitted. Furthermore, it was assumed that it is possible to use the data of Watt and Myerson (6) to calculate the recombination rate constants from the rate quotient law; this assumption is further discussed below. The data were combined to give the equation

$$[8] \qquad \log_{10} [k_r] = 13.4–1.70 \log_{10} T$$

over the range 200 to 5000 °K (Fig. 1); k_r is in $l^2\ mol^{-2}\ s^{-1}$.

When integrated over a 5 μs RC time-constant (6), the profile of oxygen atom concentration [O], computed for the conditions of the experiment reported in most detail (Fig. 4, ref. 6), agreed well with the experimental profile. Both incubation times and dissociation rates were in good agreement, the latter providing a check on the self-consistency of the computation. In Fig. 2, computed incubation times are plotted as a function of translational temperature. The computed values are in excellent agreement with the experimental results over the range 2900 to 7200 °K. These incubation times are three to four times longer than Camac's relaxation times (22). Our calculations indicate that up to 7200 °K, the time at which the rate of formation of oxygen atoms settles down to a steady value corresponds to practically complete relaxation (Fig. 3); that is, according to the present model, during the "normal" dissociation period (6), the fraction of O_2 in the dissociating states is very nearly at the equilibrium value. This fact justifies inclusion of the Watt and Myerson data (6) in calculation of eq. 8.

The computed profiles of optical density at 1470 Å yielded rate constants in agreement with the [O] profile values. At 5000 °K, the rate constants obtained by Wray (1) are about a factor of 2 higher than those of Watt and Myerson (6). The reason for this discrepancy is not known, but the present calculations suggest that it is *not* due to disequilibrium of internal modes, which *would* have tended to give high values from Wray's technique (7, 13). The computed incubation times for $\log (I_0/I)$, at 1470 Å, were about 20% longer than those for [O]. This qualitative trend is in agreement with the predictions of Brau, Keck, and Carrier (5).

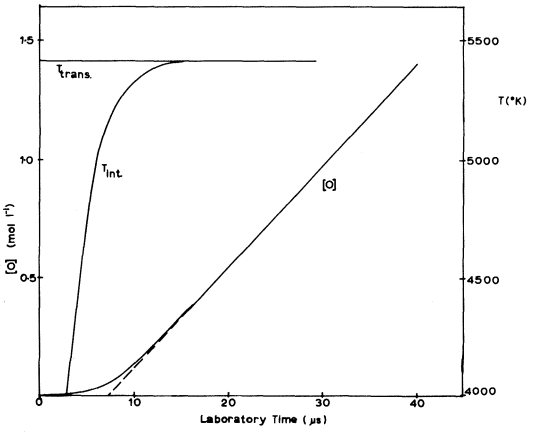

FIG. 3. Computed profiles of some gas properties. 1% O_2 in argon, total initial pressure 10^{-3} atm; shock velocity 2.45×10^5 cm s^{-1}.

(B) Br_2–Ar System

The success of the u.p.d. model in predicting well the incubation times for O_2–Ar system prompted our application of the model to other systems. Specifically the Br_2–Ar system seemed to be of particular interest. It was shown previously (7, 13) that the u.p.d. model reconciles, adequately, various experimental data on bromine dissociation–recombination reaction. However, in the past, 10% Br_2–Ar mixtures were tested; such mixtures produce extremely small experimental reaction slopes, and are thus not very useful in testing the present model. Moreover, in the past (7, 13) the back reaction has not been taken into account in calculations of dissociation profiles. In the present work both of these limitations were eliminated. For dilute mixtures, reaction profiles up to a few percent dissociation were generated; for 10% Br_2–Ar mixtures, total reaction profiles were obtained.

The high dilution (1%) data, which show least

For personal use only.

scatter, appear to be those of Warshay (9); since these raw experimental results were not available to us, the following procedure was adopted. Seven profiles of two-body emission intensity were computed for comparison with the results obtained in Series A of ref. 10, over the range 1370 to 1900 °K; only the first few microseconds of each profile were matched, in order to define the initial slopes. The computed profiles of Br_2 optical absorption, corresponding to the best fits of the emission profiles, were then used to compute "initial slope" rate constants, for comparison with the results of Warshay (9).

The values of the relaxation time for Br_2 in Ar, and of the extinction coefficients of Br_2, were the same as used previously (7, 13). The flash-photolysis recombination rate constants, obtained (8) over the range 298 to 1300 °K, were expressed in the form

$$[9] \quad \log_{10} [k_{r,\text{flash}}] = 7.99 + 536.99/T - 3.238 \times 10^4/T^2$$

(where k_r is in $l^2\ mol^{-2}\ s^{-1}$), and extrapolated up to 1900 °K. These rate constants are believed (7, 13) to represent the contribution from argon only. The efficiency of molecular bromine is known (11), relative to that of argon, in the overall dissociation process; the efficiency of Br atoms was used as the fitting parameter.

Before integration over slit-width and electronics risetime, the computed absorption profiles showed sharp "spikes" immediately behind the shock front (7, 13). This reflects the fact that initially $T_v = 298$ °K; since the Br_2 absorption coefficient is a *decreasing* function of T_v (7, 8), these spikes are due to the relatively rapid rise of T_v, immediately behind the shock front, causing in turn a rapid decrease in the extinction coefficient. When integrated over a slit-width and rise-time, the spikes degenerate to small humps; a typical profile is shown in Fig. 4. It is difficult to eliminate subjectivity in estimating initial slopes, unless some well-defined procedure is adopted (10, 25); the procedure indicated in Fig. 4 was used in the present work. The initial slopes were converted to dissociation rate constants, and are shown in Fig. 5.

These results are similar to those obtained previously (7, 13) for mixtures containing 10% of Br_2, but involve reasonably large values of the initial slopes. The present extension of the u.p.d. model also permits matching of experimental

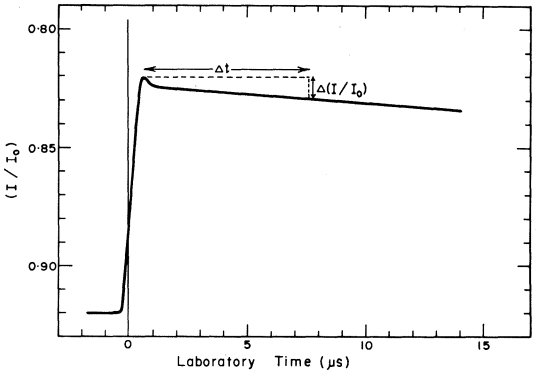

FIG. 4. Computed profile of transmitted light intensity; 1% Br_2 in argon; total initial pressure 47.6 Torr; shock velocity 1.73×10^5 cm s^{-1}; T (shock front) = 1530 °K; 0.1 cm slit width, zero time taken when shock front is at center of slit; RC time-constant = 0.1×10^{-6} s.

profiles to complete equilibrium. The most reliable data are the profiles of two-body emission obtained in Series C of ref. 10. The quality of the individual fits obtained, using the present procedure, was similar to that obtained previously (10) using a more orthodox approach. The efficiency of Br atoms, relative to that of argon, was found in the present work to be 10 ± 6, over the temperature range of the experiments (10).

Figure 6 shows the variation of the vibrational and translational temperature in a typical case. It can be seen that the two temperatures, T and T_v, approach each other as the reaction proceeds to the equilibrium. There is a maximum in the vibrational temperature, when the flow of energy into vibration from the translational heat-bath is just balanced by the loss of vibrational energy through dissociation of highly energized oscillators. In all cases studied here, this "steady state" value occurs at a time when recombination is unimportant. The concept of such a "steady state" in the vibrational distribution function was used (13) to explain the temperature dependence of the "initial slope" rate constants obtained by the shock wave emission technique, which monitors the product Br atoms. However, the use of this "steady state" assumption is not necessary in the present work, since the model yields [Br], T_v, and T directly as a function of time.

(C) Cl_2–Ar System

The temperature dependence of rate coefficients for Cl atom recombination in argon was

FIG. 5. FIG. 6. Time dependence of translational and vibrational temperatures; 9% Br_2 in argon; total initial pressure 11.7 Torr; shock velocity 1.215×10^5 cm s^{-1}; Br atom efficiency, relative to argon, is 12.0.

discussed elsewhere (26, 27). It is presently assumed that Cl recombines via the "semi-relaxed" (13, 27) mechanism. The vibrational relaxation time of Cl_2 in Ar, $\tau_v(Cl_2\text{–Ar})$, was calculated using the method described elsewhere (28). Vibrational relaxation times needed for these calculations are available in the literature (22, 29). Although $\tau_v(Cl_2\text{–Ar})$ has not been measured, and thus cannot be compared to $\tau_v(Cl_2\text{–Ar})$ presently calculated, the value obtained is not unreasonable; furthermore the method (28) predicts $\tau_v(Cl_2\text{–He})$ in good agreement with experiment (30). The optical extinction coefficients for Cl_2 at 3850 and 3640 Å have been reported (31, 32). For the purposes of computation, the (unknown) total pressures were chosen in such a way that no more than 5% of dissociation occurred in the first 5 μs of the reaction. Just as in the case of Br_2 in Ar, the computed Cl_2–Ar dissociation rate coefficients display a pronounced negative temperature dependence, in agreement with experiments (31, 32) (Fig. 7).

5. Discussion

The principal finding of the present investigation is that the u.p.d. model for dissociation predicts well the observed incubation times for O_2 dissociation in argon below 7200 °K. On the other hand the previously used model (5) fails to agree with the experimental results at lower temperatures.

The dissociation of a diatomic molecule may be described by a transport matrix possessing a set of eigenvalues. However, because the signal-to-noise ratio and time resolution of shock wave data are limited, the experiment can usually be

satisfactorily described by the *two* lowest non-zero eigenvalues, λ_1 and λ_2; certainly, from the experimental point of view, only two rate parameters (dissociation rate coefficient and internal relaxation time) are obtainable. One of the eigenvalues is associated with internal relaxation and the other with dissociation.

Commonly it is assumed that the internal relaxation is governed by the relaxation between the two lowest vibrational energy levels. In this case,

$$\lambda_2 = \lambda_{int} \simeq k_{10} + k_{01}$$

where k_{10} and k_{01} are rate constants for transitions between the lowest and first excited vibrational levels (12). For convenience in discussion, we here consider the case where recombination may be ignored, so that $\lambda_1 = \lambda_{diss} \simeq k_d$, the dissociation rate coefficient. It was emphasized in Section 2 above that a condition for the validity of the principal assumptions of the present model is that the coupling between dissociation and relaxation must be weak, *i.e.* $\lambda_1 \ll \lambda_2$. We are indebted to a referee for pointing out that this condition may be made quite explicit for the case of the modified Bethe–Teller eq. 1, used in the present model; such an equation may be shown to be valid only if λ_1 and λ_2 are well separated, and, in addition, are the only two eigenvalues of importance.

The diffusion theory of dissociation (5), which considers excitations of highly activated molecules in the dissociation limit, does not satisfactorily reproduce the experimental results under these conditions. That the theory may fail at low shock temperature was recognized by its authors (5). Specifically, in this theory, the magnitude of the vibrational relaxation transient time, and hence λ_2, depends upon the diffusion coefficient which had been defined from classical trajectory calculations within $3kT$ of the dissociation limit; it is reasonable that the diffusion time among uppermost vibrational levels be faster than k_{10}^{-1}. It is not surprising, therefore, that the incubation times obtained from the diffusion theory are smaller than those calculated in the present work, and observed experimentally, at lower temperatures.

The chief difference between the halogen and the oxygen systems is that of the negative temperature coefficients in recombination–dissociation rates. For O_2, the low temperature recombination rate coefficients agree well with those obtained in shock wave experiments, in the sense that a smooth graph of k_r (or k_d/K_{eq}) over the entire temperature range is obtained (Fig. 1). On the other hand, the negative temperature coefficients obtained for the halogens in shock waves are consistently higher than those obtained in lower temperature experiments. This discrepancy in the negative temperature coefficients is quite general, and is not limited to the few cases discussed in this work. In other examples, Br_2 in excess of He, Ne, Kr, O_2, and N_2 was similarly compared (13), and in all cases the shock wave data produced a high negative temperature dependence, while the negative temperature coefficients, obtained from flash photolysis data at lower temperatures, were considerably smaller. Similar results were obtained for iodine in a large excess of argon (33). An indirect comparison of flash and shock rate data, obtained from studies of iodine recombination over a wide pressure range of diluent argon, also predicts a discrepancy between the negative temperature coefficients (34).

For the O_2–Ar system, because the low and high temperature recombination–dissociation data are in essential agreement, the vibrational temperature decays to translational temperature within the transient time (Fig. 3). Consequently k_d, the time-dependent rate coefficient, decays, within the same time, to its time-independent value,

For personal use only.

($k_r K_{eq}$), which in the absence of recombination may be identified with λ_1. On the other hand, the negative temperature coefficients obtained for the halogens, at low and at high temperatures, differ markedly. This would then imply that the vibrational temperature behind the shock wave reaches a "steady state", which is below the translational temperature (Fig. 6). This means that k_d, after an initial transient associated with vibrational relaxation, reaches what is almost a steady state value, obtained from shock wave results. This value of k_d is smaller than the corresponding ($k_r K_{eq}$), as can be seen from Fig. 8. This conclusion implies that for halogens in shock waves, the dissociation is governed not by one but by several nearly degenerate eigenvalues.

It must be pointed out that this interesting conclusion is based on two important assumptions: (*1*) that the available experimental data are correct and (*2*) that the extrapolation of the low temperature data into the shock wave temperature range (Figs. 5 and 7) is acceptable. We are unable to question the first of these assumptions at the present time. As to the second assumption, it could only be said that one does not anticipate the observed sharp change in the negative temperature coefficient on theoretical grounds; this is confirmed by the results of trajectory calculations on the 2Br + Ar system (35). It may be of interest to point out that the above conclusion does not depend upon detailed assumptions of the u.p.d. model; just about any other reasonable non-equilibrium model for dissociation would arrive at similar conclusions if the above two assumptions are accepted. However, the shapes of T_v *vs.* t (Figs. 3 and 6) and k_d *vs.* t (Fig. 8) are correct only to within the limitations of the u.p.d. model. We do not feel that the predicted time dependencies (Figs. 3, 6, and 8) are exact descriptions of actual phenomena: the u.p.d. model used is only a simple and approximate scheme. Nonetheless, it is highly intriguing that it predicts a variety of experimental data (Figs. 2, 3, 5, 7) with a surprising accuracy. It should also be pointed out that, in the case of *complete* reaction profiles, the scatter in the fitting parameter (Br atom efficiency), obtained using the u.p.d. model is identical to that obtained previously ($\pm 60\%$) using a more orthodox procedure (ref. 10, eq. 12).

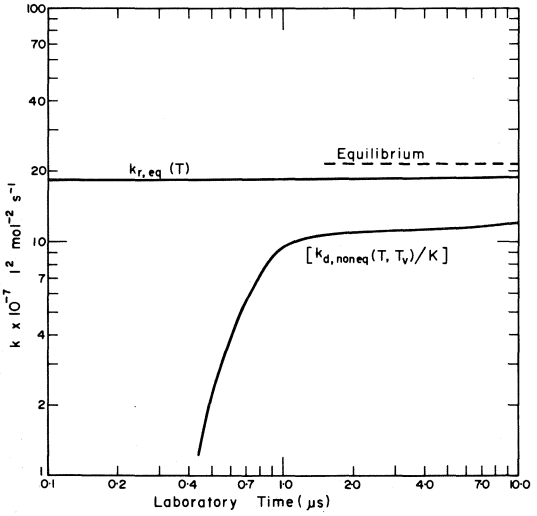

FIG. 8. Time dependence of rate coefficients for Br_2–Ar system. Conditions identical to those of Fig. 6. Variation in k_r is due to variation in the translational temperature only.

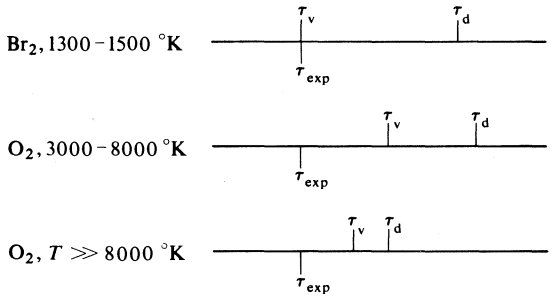
Another difference between the oxygen and halogen systems (especially bromine) is the fact that the latter display marked discrepancies in the absolute values of rate coefficients obtained using various techniques (Fig. 5). Use of the present model has permitted quantitative reconciliation of these results, but it seems worthwhile to point out here the qualitative features of the present model which led to this result. The crucial difference between the bromine and oxygen systems is one of time scales. Wray (1) discussed his results on incubation times in O_2 in terms of τ_v and τ_d, the characteristic times for relaxation and dissociation, respectively; these are inversely related to λ_2 and λ_1 above. For present purposes, a third characteristic time τ_{exp}, defining the time resolution of the experiment, is introduced; this is normally of the order of 10^{-6} s. The following very schematic diagram is useful in comparing the two systems.



For the Br_2 system at lower temperatures, τ_v and τ_d are well separated, so that little or no coupling exists between relaxation and dissocia-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

tion; thus dissociation rates obtained by monitoring two-body emission from product Br atoms agree well (10) with the flash photolysis results at their common temperature. However, τ_v and τ_{exp} are so close that an experimental technique, which is sensitive to the instantaneous vibrational distribution function of Br_2, will tend to give spurious results. Thus, since the molecular extinction coefficient is a function of T_v, this technique gives results which disagree with those of the other two independent methods (10, 13). Qualitatively (7, 13), the fact that non-equilibrium effects give apparently *high* values for the rate coefficients (9) follows from the form of the dependence of the extinction coefficient on T_v; at the wavelength used (9), the extinction coefficient decreases with increasing T_v (8, 9) behind the shock front, thus producing a spurious contribution, to the initial rate of change of optical density with time, which is of the *same* sign as that caused by dissociation of Br_2. Since the method of data reduction used (9) explicitly assumes that relaxation is effectively instantaneous within the shock front (36), this *total* initial slope is assigned entirely to the dissociation contribution. This effect is the origin of the "hump" shown in Fig. 4, and referred to in Section 4 above. When the appreciable noise levels present in such experiments are considered, it is clear that such "humps" would not be clearly observable, but would contribute to spuriously high values for the initial slopes (7, 13).

For the O_2 system, at the lower end of its temperature range, all three characteristic times are well separated. Therefore, the vibrational relaxation (22) and dissociation (1, 6) may be conveniently studied independently of one another, and observable incubation times occur. At higher temperatures, however, considerable dissociation–relaxation coupling is observed (1).

Appendix

Computational Procedure

Let us define the rate of the dissociation reaction as $[(\partial[X_2]/\partial t)_\rho]_{r.g.t.}$, where ρ is the total density and r.g.t. refers to the real gas time, which differs from the laboratory time (l.t.) in shock wave reactions. We have

$$[A1] \qquad [X_2] = (1 - \alpha)\phi C_1/\rho_{12}$$

$$[A2] \qquad [X] = 2\alpha\phi C_1/\rho_{12}$$

$$[A3] \qquad [M] = (1 - \phi)C_1/\rho_{12}$$

where ϕ is the mole fraction of X_2 in unshocked gas, C_1 is the total molecular concentration ahead of the shock front. Furthermore, $\rho_{12}(t) = \rho_1/\rho_2(t)$, where ρ_1 is the total gas density ahead of the shock front and $\rho_2(t)$ is the total gas density behind the shock front. Then

$$[A4] \quad -[(\partial[X_2]/\partial t)_\rho]_{r.g.t.} = (\phi C_1/\rho_{12})(d\alpha/dt)_{r.g.t.}$$

which is the chemical rate described by eq. 8. Then, making the appropriate substitutions from eqs. A1 to A3, eqs. A4 and 8 give

$$[A5] \quad (d\alpha/dt)_{l.t.} = (1/\rho_{12})(d\alpha/dt)_{r.g.t.} = (C_1/\rho_{12}{}^3)k_{r,Ar}[1 + (F - 1)\phi + \alpha\phi(2E - F)][K_{eq}G(1 - \alpha)\rho_{12} - 4\phi C_1\alpha^2]$$

where E and F are the reaction efficiencies, relative to Ar, of X and X_2 respectively; G is the r.h.s. of eq. 5 and $K_{eq} = k_d/k_r$.

The vibrational relaxation equation with the assumption $(\bar{E}_d - \varepsilon_v) = (E_r - \varepsilon_v) \simeq D$ is

$$[A6] \quad (d\varepsilon_v/dt)_{r.g.t.} = [(\varepsilon_\infty - \varepsilon_v)/\tau_v + (D/[X_2])[(\partial[X_2]/\partial t)_\rho]_{r.g.t.}$$

Substituting eqs. A7 and A8 into A6

$$[A7] \qquad \varepsilon_v = R\theta/(\exp(\theta/T_v) - 1)$$

$$[A8] \qquad \varepsilon_\infty = R\theta/(\exp(\theta/T) - 1)$$

where R is the gas constant, we obtain

$$[A9] \quad (dT_v/dt)_{l.t.} = (d\varepsilon_v/dt)_{r.g.t.}(T_v/\theta)^2 \times (R\rho_{12})^{-1}(\exp(\theta/T_v))^{-1} \times (\exp(\theta/T_v) - 1)^2$$

where $(d\varepsilon_v/dt)_{r.g.t.}$ is given by eq. A6.

Since ρ_{12}, T, α, and P, the total pressure, are all functions of time behind the shock front, it is necessary to use the hydrodynamic conservation equations and the ideal gas equation of state. We have integrated eqs. A5 and A9 using a 4th order Runge–Kutta procedure. The conservation equations were integrated implicitly using an

iterative technique (10). In this way, laboratory time profiles for all relevant parameters, describing the reacting gas, were generated. Such profiles took no account of finite slit-width and electronics rise-time. For this reason appropriate integrations over known slit-width (1 mm) and electronic rise-time (0.1–0.2 $\times$ 10^{-6} s) were made.

NOTES

Methyl Cyanodithioformate as a Reactive Dienophile in Diels–Alder Reactions

D. M. VYAS AND G. W. HAY[1]

Department of Chemistry, Queen's University, Kingston, Ontario

Received June 1, 1971

A Diels–Alder reaction between cyclopentadiene and methyl cyanodithioformate afforded a 60:40 mixture of the isomers **2***a* and *b*. The n.m.r. studies of these compounds and the products of $LiAlH_4$ reduction, **3***a* and *b*, established that the major isomer, **2***a*, was 3-*exo*-cyano-3-methylthio-2-thiabicyclo-[2.2.1]hept-5-ene, and that **3***a* was the corresponding 3-*exo*-aminomethyl compound.

Une réaction de Diels–Alder entre le cyclopentadiène et le cyanodithioformate de méthyle conduit à un mélange 60:40 des isomères **2***a* et *b*. Une étude r.m.n. de ces composés et des produits de réduction par $LiAlH_4$, **3***a* et *b*, prouve que le produit majoritaire, **2***a*, est le cyano-3 *exo* méthylthio-3 thia-2 bicyclo[2.2.1]heptène-5; le produit **3***a* est l'aminoéthyl-3 *exo* correspondant.

Canadian Journal of Chemistry, **49**, 3755 (1971)

Introduction

A number of simple carbonyl compounds have been shown to function as dienophiles in the Diels–Alder reaction (1–4). However the analogous thiocarbonyl system, which has proved to be highly dipolarophilic (5), has provided very few examples of dienophilic activity. Through the pioneering research of Middleton (6), and Schonberg and König (7) the dienophilic nature of thiophosgene, thiofluorenone, perfluorothioacetone, and other fluorothiocarbonyls has been demonstrated. All of these last named compounds are highly toxic and, until recently, most were very difficult to obtain. More recent investigations have shown that thiobenzophenone (8), thioacetophenone (9), dichlorosulfine (10), and thioketene (11) react with dienes to give Diels–Alder adducts even under moderate conditions. Obviously the dienophilic potential of compounds with the carbon–sulfur double bond has been unexploited synthetically, not least because of their typical unpleasant odor and toxicity. Here presumably lies a wide field of preparative application of these compounds.

During the development of methods for the synthesis of unsaturated, deoxy sugars with sulfur in the ring, via the Diels–Alder reaction we have discovered that methyl cyanodithioformate (**1**) possesses a marked dienophilic activity. This has been demonstrated in our laboratory by the formation of Diels–Alder adducts with a wide range of dienes differing in reactivity from that of cyclopentadiene to that of 1,3-butadiene. The reagent is easily synthesized (12, 13) and is deep purple in color, a property which is useful to indicate the completion of the reaction, or to signal the occurrence of a retro-Diels-Alder reaction during the workup of the adducts. Such a dienophile has the advantage over the fluorothiocarbonyl compounds and others of introducing a potentially more useful functional group (cyano) into the product.

This paper reports the synthesis and proof of structures of stable derivatives of 2-thiabicyclo [2.2.1]hept-5-ene, synthesized via a facile Diels–Alder reaction using methyl cyanodithioformate as the dienophile.

Results and Discussion

At 0 °C, **1** reacted immediately with cyclopentadiene to give an almost quantitative yield of **2***a* and *b*[2] in a 60:40 ratio based on the peak integrations of the n.m.r. spectra. A portion of **2***a*, the major isomer, crystallized leaving a syrupy mixture (**2***ab*) which was rich in **2***b*. A slow isomerization of **2***b* to *a* was observed on standing at room temperature.

[1]To whom correspondence should be addressed.

[2]Each of **2***a*, *b*, and **3***a*, *b* was obtained as a racemic mixture. To conserve space the structural formula for only one of the enantiomers has been given in each case.

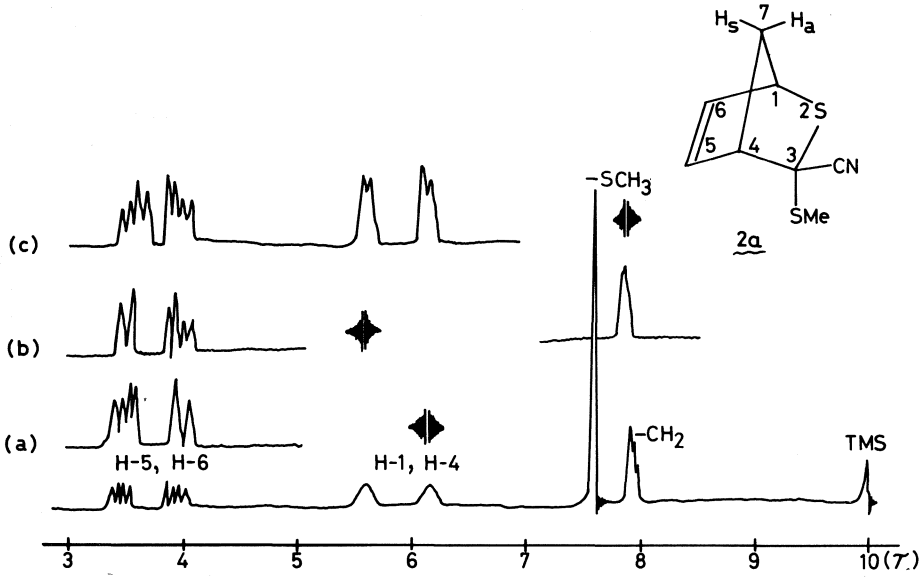

FIG. 1. The 60 MHz n.m.r. spectrum of **2***a* in deuteriochloroform with the assignments of protons as indicated. (*a*) Resonance of the H-5 and -6 protons during the simultaneous irradiation at 6.15 τ. (*b*) Resonance of the H-5, -6, and C-7 methylene protons during simultaneous irradiation at 5.61 τ. (*c*) Resonance of the H-1, -4, -5, and -6 protons during simultaneous irradiation at 7.93 τ.

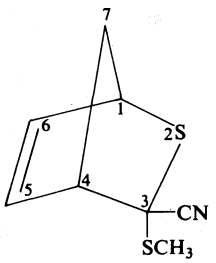
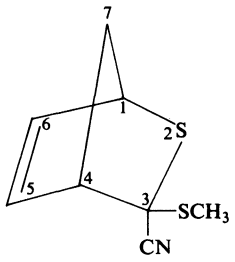


2*a*



2*b*

In the 60 MHz n.m.r. spectra of **2***a* (Fig. 1) the bridgehead, methylene bridge, and vinylic protons were identified from the chemical shifts when compared to those of other Diels–Alder adducts of cyclopentadienes (8, 14), and the peak integrations. Only one of the two low-field quartets was affected by irradiation at either 6.17 or 5.63 τ (Figs. 1*a* and *b*) whereas the multiplet centered at 7.93 τ was reduced to a broad singlet by irradiation at both frequencies. Moreover, it was observed that irradiation at 7.93 τ (Fig. 1*c*) collapsed the multiplets centered at 6.15 and 5.61 τ to indistinct doublets without affecting the quartets centered at 3.50 and 3.97 τ. These data are consistent with the product being a 1,4- but not a 1,2-adduct. The latter type of compound shows significant and characteristic differences in the n.m.r. spectrum which reflect the dissimilar proton interactions inherent in such structures (15). Thus, the quartets centered at 3.50 (1H) and 3.97 τ (1H) were attributed to the resonance of the vinyl protons (H-5, -6; $J_{5,6} \simeq 6$ Hz), the multiplets centered at 5.61 (1H) and 6.15 τ (1H) were assigned to the bridgehead protons (H-1, -4; $J_{4,5} \simeq J_{1,6} \simeq 3$ Hz), and the multiplet centered at 7.93 τ (2H) was derived from the methylene bridge hydrogens. The $-SCH_3$ hydrogens gave rise to the sharp singlet at 7.64 τ (3H).

The elemental analysis, and i.r. and mass spectra, of **2***a* were consistent with the proposed structure. The mass spectrum revealed not only a distinct molecular ion ($[M]^+$) peak at *m/e* 183 but also ions with *m/e* 136, 117, 109, 66 (base peak) which, in terms of the probable fragmentation route, were attributed to $[M-SCH_3]^+$, $[H_3CSC(CN)S]^{\cdot+}$, $[M-SCH_3-HCN]^+$, and cyclopentadienyl radical cation.

The 60 MHz n.m.r. spectrum of the residual syrup, **2***ab* (Table 1), resembled that of **2***a* but was more complex; the recognizable signals from **2***a* being overlapped by others from the second component. However, two distinct, 3-proton

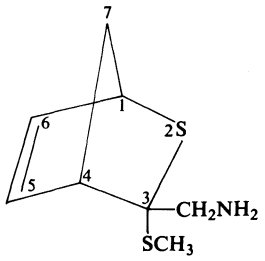
singlets were observed at 7.64 and 7.56 τ, and these were assigned to the $-SCH_3$ protons of **2***a* and *b*, respectively.

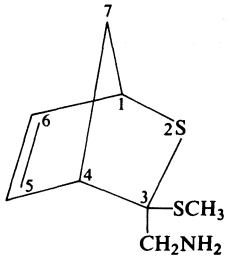
There remained the problem of establishing the stereochemistry at C-3. The shielding of *endo* ring protons or those of *endo* methyl groups in norbornene and 2-thiabicyclo[2.2.1]hept-5-ene systems as a consequence of the vinylic diamagnetic anisotropy (16) is well established (17–20) in n.m.r. studies. This effect causes the *exo* protons to resonate at a lower field than the *endo* protons. Although **2***a* lacks a hydrogen atom or a methyl group at C-3 it is evident from the chemical shifts (Table 1) that the $-SCH_3$ protons in **2***a* resonate 0.08 p.p.m. upfield to those of **2***b*. This shielding is very much smaller than that observed in comparable carbocyclic compounds (14). The Drieding model of **2***a* indicated that the $-SCH_3$ group may lie on the boundary of the shielding region of the double bond, and hence the protons, although in an *endo* position, experience a minimal diamagnetic shift.

However, for an unequivocal designation of the stereochemistry at C-3 in **2***a*, lithium aluminum hydride reduction of **2***a* to **3***a* and **2***ab* to **3***ab* was performed. The i.r. spectrum of each of **3***a* and *ab* exhibited absorption at 3.00 (broad doublet), 3.26, and 6.30 μ but not at 4.50 μ confirming that the cyano had been reduced to an amino methyl group.

Compound **3***a* gave a simple 60 MHz n.m.r. spectrum (Table 1), in which all of the proton resonances were clearly identified from their chemical shifts and peak integrations. On comparing the spectrum of **3***a* with that of **3***ab* (Table 1), the resonance signals corresponding to $-CH_2NH_2$, $-SCH_3$, and $-NH_2$ protons in **3***b* were readily identified.



3*a*



3*b*

The chemical shifts of the $-SCH_3$ protons of **3***a* and *b* are greater than those of **2***a* and *b* (Table 1), reflecting the increased shielding concommitant with the reduction of the cyano group. In each case the difference between the chemical shifts of the $-SCH_3$ protons of the major and minor isomers was not only in the same direction but also of approximately the same magnitude (**2***a*, *b*: 0.08 p.p.m.; **3***a*, *b*: 0.12 p.p.m.), indicating that the configuration at C-3 was unaffected by the reduction and that both **2***b* and **3***b* have an *exo*-SCH_3 group. This requires that the $-CH_2NH_2$ protons of **3***b* lie within the shielding zone of the ring double bond and hence, as observed (Table 1), resonate at a higher field than those of **3***a*. The difference between the chemical shifts of $-CH_2NH_2$ protons in **3***b* and *a* is 0.35 p.p.m., identical to that observed between the *endo*- and *exo*-CH_3 protons of 3-cyano-3-methylnorbornene (14).

These data lead to the conclusion that **2***a* is a racemic mixture of 3-*exo*-cyano-3-methylthio-2-thiabicyclo[2.2.1]hept-5-ene, and that **3***a* is a racemic mixture of the corresponding 3-*exo*-aminomethyl compound.

Experimental

General Conditions

All melting points were determined on a Fisher–Johns melting point block and are uncorrected. All evaporations were conducted under reduced pressure. The i.r. spectra were recorded on a Perkin–Elmer Model 180 spectrometer using the following conditions: $CHCl_3$ solution; 0.1 mm path length; scan time setting 1:1, coarse adjustment 10:1, split program 7, time constant 2. The n.m.r. spectra were obtained in $CDCl_3$ solution using either a Varian T-60 or a Bruker HX-60 60 MHz spectrometer. Mass spectra were obtained with a Jeol JMS 01SC spectrometer.

*Methyl Cyanodithioformate (**1**)*

This compound was prepared according to Simmons *et al.* (13).

*Racemic Mixture of 3-exo-Cyano-3-methylthio-2-thiabicyclo[2.2.1]hept-5-ene (**2a**)*

Compound **1** (5.88 g) in 20 ml CH_2Cl_2 was added with stirring to 4 g freshly distilled cyclopentadiene in 20 ml CH_2Cl_2 at 0 °C. An immediate loss of the deep purple color of **1** ensued. Evaporation of the solvent and excess diene gave a pale yellow syrup (9.10 g) which, after solution in a minimum volume of CH_2Cl_2 and addition of petroleum ether (b. p. 30–60 °C) to incipient cloudiness, afforded, upon cooling, 4.3 g **2***a* as colorless prisms, m.p. 85–86 °C. The n.m.r. spectrum of **2***a* as obtained on the Varian T-60 spectrometer with an internal TMS standard is given in Fig. 1. The determination of chemical shifts and peak integrations, and the decoupling experiments (Figs. 1*a–c*), were performed with the Bruker HX-60 using an internal TMS lock. The i.r. spectrum had major peaks at 3.25 (w), 3.35 (s), 3.40 (s), 3.42 (s), 3.52 (s), 4.50 (s), 6.00 (w), 7.00 (s), and 7.50 (s) μ. The mass spectrum showed major components at *m/e* 183, 136, 117, 109, and 66 (base peak).

Anal. Calcd. for $C_8H_9NS_2$: C, 52.46; H, 4.85; N, 7.46; S, 34.97. Found: C, 52.61; H, 4.85; N, 7.81; S, 34.92.

The residual syrupy mixture, **2***ab*, gave the n.m.r. spectrum (Varian T-60, internal TMS standard) which consisted of many overlapping peaks (Table 1), except two distinct singlets at 7.64 and 7.56 τ. The i.r. spectrum showed the same number and location of absorption peaks as that of **2***a*.

*Racemic Mixture of 3-exo-Aminomethyl-3-methylthio-2-thiabicyclo[2.2.1]hept-5-ene (**3a**)*

Compound **2***a* (2.2 g) in 20 ml anhydrous ethyl ether was added dropwise to 1.8 g $LiAlH_4$ in 50 ml anhydrous ethyl ether, and stirred at room temperature until the reaction subsided (45 min). The $LiAlH_4$ was destroyed in the usual fashion and the product isolated from the ether extracts by evaporation after drying over anhydrous $MgSO_4$. The yield was 1.5 g yellow–orange syrup, **3***a*, the chemical shifts of the n.m.r. spectrum (Varian T-60, internal TMS lock) of which are recorded in Table 1. The i.r. spectrum exhibited absorbance at 3.00 (m, broad doublet), 3.26 (m), 3.35 (s), 3.40 (s), 3.50 (s), 6.30 (m, broad), 6.97 (s), and 7.51 (s) μ.

A phenylurethane derivative of **3***a* was prepared according to Shriner *et al.* (21), m.p. 138–139 °C.

Anal. Calcd. for $C_{15}H_{18}N_2OS_2$: C, 58.82; H, 5.88; N, 9.12. Found: C, 58.81; H, 5.89; N, 9.33.

The mixture, **2***ab*, was reduced in the same manner. The i.r. spectrum of the product, **3***ab*, was indistinguishable from that of **3***a*. The n.m.r. spectrum (Varian T-60, internal TMS lock) data for **3***ab* is given in Table 1.

Proton Magnetic Resonance Studies of Some 1-X-2,4-Dinitrobenzenes

MICHAEL D. STEPHENS,[1] JOHN D. REINHEIMER, AND ALLAN H. KAPPELMAN
Department of Chemistry, The College of Wooster, Wooster, Ohio

Received June 11, 1971

Shaefer's additivity rules for coupling constants have been applied to trisubstituted benzenes. If a resonance interaction between substituents is possible, the observed coupling constants are larger than those predicted. For other substituents, the additivity rules are followed.

Les règles d'additivité de Shaefer, relatives aux constantes de couplage, ont été appliquées aux composés benzéniques trisubstitués. S'il y a possibilité d'une interaction de résonance entre les substituants, les constantes de couplage observées sont alors plus grandes que celles prévues. Pour les autres substituants, les règles d'additivité sont respectées.

Introduction

A predictive additivity scheme for coupling constants in substituted benzene compounds has been proposed (1). The scheme has developed from correlations between substituents and coupling constants and is based specifically upon coupling parameters of mono-substituted benzene compounds. Schaefer *et al.* (2), have applied this predictive additivity scheme to a series of 1,2,4 trisubstituted benzene compounds and found very good and consistent agreement between the predicted and observed ortho coupling constants. The present study presents a series of eight 1-X-2,4-dinitrobenzene compounds and compares the observed coupling constants with the predicted.

Experimental

The 2,4-dinitrohalobenzenes and 2,4-dinitroacetanilide spectra were recorded on a Varian HA 100 n.m.r. spectrometer using an internal lock on the solvent. These and the other spectra were recorded on a Varian A 60 with an external water lock. The spectra are ABC and were analyzed using the LAOCN3 computer program of Castellano and Bothner-By (3). The compounds were recorded as both 5 and 10% solutions in acetone with no observable change in coupling constants. Acetone was the solvent for the series; 2,4-dinitrophenol was recorded in acetone, methanol, acetonitrile and CCl_4–acetone (7:3 v/v) to study coupling constant consistency in different solvent systems. A few drops of D_2O were added to samples where proton exchange was expected. All solvents were spectral grade and the compounds were obtained commercially.

Results and Discussion

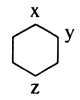
The chemical shift parameters for these compounds are given in Table 1. The predicted coupling constants are determined by the following eqs. 1–3 (2), where the ΔJ values for the

$$[1]\quad J_o = J_{56} = \Delta J_{23}{}^{x} + \Delta J_{34}{}^{y} + \Delta J_{23}{}^{z} + J_o{}^{b}$$

$$[2]\quad J_m = J_{35} = \Delta J_{35}{}^{x} + \Delta J_{24}{}^{y} + \Delta J_{26}{}^{z} + J_m{}^{b}$$

$$[3]\quad J_p = J_{36} = \Delta J_{36}{}^{x} + \Delta J_{36}{}^{y} + \Delta J_{36}{}^{z} + J_p{}^{b}$$

substituents are derived from the respective monosubstituted compounds. The numbering system is somewhat confusing. In columns 1 and 2 of eqs. 1–3, the numbers refer to the tri-substituted benzene,



where x is regarded as C-1. The final column is the normal coupling constant for unsubstituted benzene, while columns 3, 4, and 5 are numbered from the group labelled x, y, or z. Thus, J_{56} would be J_{23} if x is on C-1, J_{34} if y is on C-1 and J_{23} if z is on C-1. The tabulated data of reference (2) place x, y, and z on C-1. The observed and predicted coupling constants are given in Table 2. McConnell's theoretical work (4) and later empirical studies (5, 6) indicate that in aromatic systems spin–spin coupling is transmitted almost exclusively through the σ bonding orbitals with the π bonding systems having a slight effect on long range coupling and accounting for approximately 0.5 Hz of the ortho coupling constant. Previous studies (5–7) of monosubstituted and disubstituted benzene compounds have shown direct correlation between substituent inductive effect and changes in coupling constants. The predictive additivity scheme has developed from

†The error in the computer calculated constants is less than 0.02 Hz for compounds **1**, **2**, **5**, **8**; less than 0.04 Hz for **3** and **7**; less than 0.06 Hz for **4** and **6**.
‡100 MHz spectrum.

these correlations and has been successfully applied to disubstituted benzenes (1, 2, 8–10) with few exceptions (1, 10). In our study the 2,4-dinitrohalobenzenes, compounds **6–8**, show very good agreement between the predicted and observed ortho and meta coupling constants. Compounds **1–3**, with OCH_3, NH_2, and OH substituents, deviate from additivity and although the necessary monosubstituted values are not available to calculate the predicted values for 4 and 5 ($NHNH_2$ and $NHCOCH_3$), a comparable deviation is expected. A deviation of 0.2 Hz for coupling constants is considered significant (1). The maximum error in the computed coupling constants is 0.06 Hz, so the observed deviations are well beyond experimental error.

What can be the causes of these deviations from the predicted coupling constants? Several possible explanations, in terms of poor ΔJ values, hydrogen bonding, or bond order may be advanced. The first possibility is not regarded as likely, because there are few cases for disubstituted benzenes in the literature where experimental and predicted results disagree (1, 10). The second explanation, that of intramolecular hydrogen bonding to the ortho nitro group, has been advanced by Castellano and Kostelnik (1). They found a deviation of 0.4 Hz for J_{56} for ortho nitrophenol. They argued that the bond lengths and bond angles of the benzene ring were distorted, causing the observed deviation. The deviations for $-NH_2$, $-OH$, $-NHNH_2$, and $NHCOCH_3$ can be explained on this basis, but no hydrogen bonding should occur with the $-OCH_3$ substituent. However, the smallest calculated deviation, 0.20 Hz occurs with this group. A change of solvent from one of small hydrogen bonding capability may effectively change the intramolecular hydrogen bond. The solvent effect of carbon tetrachloride – acetone (7:3), acetonitrile, and methanol on the spectra of 2,4-dinitrophenol was investigated. The coupling constants changed 0.05 Hz. This change is much less than 0.4–0.6 Hz deviations observed. These findings indicate that the intramolecular hydrogen bonding is not affected by the solvent, or that the intramolecular hydrogen bonding is not the correct explanation for the deviations. The third explanation, that of bond fixation, is based on the donor and acceptor nature of the substituent and nitro groups. The resonance interaction, as given in Fig. 1, increases the bond order at C_5—C_6 relative to unsubstituted benzene. Several authors (11) have drawn direct correlation between bond order and coupling constants in fused aromatic systems with coupling constants increasing as bond order increases. This indicates that those substituents for which this donor–acceptor interaction can occur should have greater coupling constants. The halogens, with their relatively small donor capacity, will not interact with the ortho or para nitro groups and this bond fixation will not occur. The deviation from additivity in the meta coupling constants cannot be easily explained by the resonance configurations. However, the data of

*Coupling constants in Hz.
†The errors in the computer coupling constants are given in footnote † of Table 1.

Smith and Kmet (12) show the same general trend as ours; namely, that J ortho and J meta are both increased when resonance interaction between p-substituted groups can occur.

It is significant to note that Schaefer did not study compounds where a strong resonance effect could occur. As in Schaefer's study, our para coupling constants show no consistent change with change of structure.

Conclusion

Solubility considerations did not allow the use of CCl_4. The use of the additivity scheme for this series of compounds is open to challenge since the monosubstituted values used in this scheme were determined in CCl_4. Schaefer *et al.* (2) indicate that values 0.1 Hz greater than predicted will occur in an acetone solvent system. The lack of large changes in coupling constants of 2,4-dinitrophenol in different polar solvent systems indicates that an explanation involving more than intramolecular hydrogen bonding is necessary to explain the observed deviation of ortho coupling constants from the additivity scheme encountered in this study. The extent of solvent–solute hydrogen bonding will vary in these solvent systems but the small changes in coupling parameters support the resonance interpretation as a partial explanation for the observed deviations.

The solubility of O_2 in liquid paraffin was determined over the temperature range from 31 to 90 °C under an O_2 pressure of 736 Torr. The solubility was also determined at 35 °C over the pressure range from 290 to 834 Torr.

La solubilité de O_2 dans de la paraffine liquide a été déterminée sur l'intervalle de température allant de 31 à 90 °C et sous une pression d'O_2 de 736 Torr. La solubilité a également été déterminée à 35 °C sur l'intervalle de pression allant de 290 à 834 Torr.

Canadian Journal of Chemistry, 49, 3762 (1971)

Introduction

In the course of flash photolysis experiments using O_2 as a triplet state quencher in viscous solutions, it became necessary to know the solubility of O_2 in liquid paraffin from approximately 30 to 90 °C, in order to determine concentrations in solution from gas pressure data.

Liquid paraffin is a colorless, transparent,

oily liquid that is obtained from crude petroleum by refining. A high degree of refinement is indicated by freedom from unsaturated and aromatic hydrocarbons and other impurities. Existing O_2 solubility data (1) cover only a 20 °C temperature range. Also it is highly probable that variations occurred in the liquid paraffin used by different workers because its properties are dependent on its source and the techniques employed in producing it (2).

Experimental

Liquid paraffin (LP, Anachemia AC7014) as received had an average molecular weight of 390, viscosity and density at 20 °C of 126 cs and 0.871 g/cm^3, respectively, and a refractive index of 1.4748 at 21.4 °C.

The experimental method for measuring gas solubilities was based on that described by Gubbins, Carden, and Walker (3). It consisted of equilibration of the liquid with the gas phase, transfer of samples to a gas stripping cell, and subsequent analysis of the extracted gas by chromatography.

The liquid paraffin samples were prepared in a flask immersed in a constant temperature bath maintained within ±0.1 °C. The paraffin was first degassed, then O_2 was added with stirring until the pressure stabilized at 736 Torr. Solubility measurements were normally begun after approximately two hours of stirring in the O_2 atmosphere. Similar results were obtained when stirring was continued up to 16 h. Between withdrawal of successive samples, the bulk of the sample was allowed to equilibrate for ½ h.

The samples were transferred to the stripping cell by means of a gas tight syringe. As a check for air ingress during transfer, a run was performed with liquid paraffin saturated with carrier gas, and this showed negligible oxygen.

The liquid was stripped by a stream of helium carrier gas passed through the stripping cell. With liquid paraffin solvent it was necessary to heat the stripping cell to approximately 60 °C in order to reduce the viscosity and prevent a frothing problem.

The oxygen was determined gas chromatographically using a 2 meter column of "Molecular Sieve" type 5A, 40–60 mesh, at 50 °C, in conjunction with a thermal conductivity detector. The gas chromatograph was calibrated periodically by injecting measured volumes of O_2 directly on the column.

As a check on the experimental method, the solubility of O_2 in monochlorobenzene was determined.

Results

The value of the Bunsen absorption coefficient, α (cm^3 of gas at standard temperature and pressure dissolved by 1 cm^3 of solvent at the temperature of the measurement and under a partial pressure of 760 Torr), for O_2 in C_6H_5Cl at 25 °C, obtained using the described method was 0.172 ± 0.005, in good agreement with the value 0.173 found by Horiuti (1).

Table 1 gives the values of the absorption coefficient, β (cm^3 of gas at standard temperature and pressure dissolved by 1 cm^3 of solvent at the temperature and partial pressure of the measurement), measured at constant temperature for varying O_2 pressures. Henry's constant, $K_H = P/X$, where P is the partial pressure of O_2 above the solution, in Torr, and X is the mole fraction of O_2 in the solution, is also given, based on solvent average molecular weight = 390.

The data in Table 1 show that Henry's law holds over this pressure range within experimental error.

Since Henry's Law holds, the values of O_2 solubility in liquid paraffin have been given in terms of the Bunsen absorption coefficient.

Table 2 gives the experimental results.

Table 3 summarizes the results found in the literature.

Discussion

The values obtained in this work for O_2 solubility in liquid paraffin are comparable to those values found by other workers, as shown in Table 3.

Baldwin and Daniel (4) measured O_2 solubilities for a series of solvent extracted mineral oils derived from the same crude, and found that the solubility decreased considerably with increasing mean molecular weight from 100 ($\alpha \simeq 0.34$) to 400 ($\alpha \simeq 0.14$) after which the decrease was slight. Values found for O_2 solubility in *n*-hexane (1), *n*-heptane (5), *n*-octane (5), and *n*-nonane (5) fit in with their results as does the value for liquid paraffin given in this work.

A Regenerable, Solid-Phase Coupling Reagent for Use in Peptide Synthesis[1]

J. BROWN[2] AND R. E. WILLIAMS
Biochemistry Laboratories, National Research Council of Canada, Ottawa, Canada

Received August 17, 1971

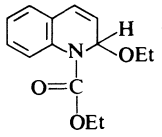
The incorporation of the peptide reagent EEDQ (1) into an insoluble polymeric form is described. The utility of this reagent in peptide syntheses is investigated and its application in automated processes considered.

L'introduction du réactif peptidique EEDQ (1) sous une forme polymérique et insoluble est décrite. L'utilité du réactif dans la synthèse des peptides est étudiée et son utilisation dans une réaction automatisée est envisagée.

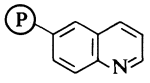
Canadian Journal of Chemistry, 49, 3765 (1971)

Automatic large-scale peptide syntheses have been, for the most part, hampered by the lack of a suitable reagent for carrying out the peptide bond forming step. A recent report has described an inexpensive reagent 'EEDQ' (**1**)[3] which forms the peptide bond with essentially no racemization (1). A fully automatic solid-phase synthetic sequence making use of this type of reagent is conceivable if the basic element of the reagent (the quinoline moiety) is converted to an insoluble derivative **2**. The coupling reactions could then be carried out in a solid-phase type of reaction. The spent reagent could be easily recovered by virtue of its insolubility and regenerated to be used again.

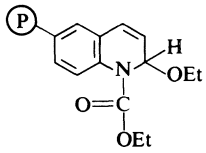
The incorporation of the quinoline nucleus into a suitable insoluble polymeric material was accomplished by the free-radical initiated polymerization of 6-isopropenylquinoline (2 parts by weight), styrene (3 parts), and divinylbenzene (0.08 parts) in benzene solution. The resulting polymer, after having been washed with petrol (30–60°) and dried, was obtained as a colorless granular powder insoluble in all common organic solvents. It contained 1.33 m*M* nitrogen (as N_2) per gram.



1
EEDQ



2a



P— = Polymer

2b

The polymer was converted into the active reagent by reaction overnight in methylene chloride (6 ml/g) in the presence of a slight excess of ethyl chloroformate, triethylamine, and ethanol (2). The reagent was recovered by repeated suspensions in chloroform, washing with petrol (30–60°) and vacuum filtration. The reagent could be stored in this form for at least 3 months if protected from moisture.

Assay of the resin for the number of reagent sites available for reaction was carried out by coupling an excess of N^{α}-DNP-L-leucine and

[1]NRCC No. 12205.

[3]Abbreviations: EEDQ, *N*-ethoxycarbonyl-2-ethoxy-1,2 dihydroquinoline; DCC, dicyclohexylcarbodiimide; Cbz, benzyloxycarbonyl; DNP, 2,4-dinitrophenyl; HOSu, *N*-hydroxysuccinimide. All chemicals were of reagent grade quality. All amino acid derivatives used gave satisfactory elemental analyses and suitable spectroscopic data.

glycine ethyl ester in methylene chloride. The dipeptide product (R_f 0.35) was isolated by t.l.c. (silica gel, EtOAc/C_6H_6, 2/8, v/v) and the amount formed calculated from the optical density at 340 nm of an ethanol solution (N^{α}-DNP-L-leucylglycine ethyl ester, $\varepsilon_{340} = 16\ 100$). The number of millimoles of product formed per gram of activated resin was found to be 0.20 ± 0.04.

Racemization caused by the polymeric and monomeric reagents during coupling was compared by application of the Young test (3) to each. Couplings of N^{α}-Benzoyl-L-leucine and glycine ethyl ester (released from its hydrochloride by triethylamine) were done in methylene chloride solution under identical experimental conditions. Comparison of the specific rotations of the crude neutral fractions with that of pure *N*-benzoyl-L-leucylglycine ethyl ester ($[\alpha]_D = -34.0°$ (3)) indicated the following results: the monomeric reagent (EEDQ) had produced $95.0 \pm 0.1\%$ L dipeptide, the polymeric reagent had produced $91.9 \pm 0.7\%$, and DCC with 2 equiv of HOSu[3] (4) had produced $91.1 \pm 0.1\%$. The reagent therefore seems to be slightly less effective in the polymeric form than in the monomeric form (EEDQ) but gave results at least comparable to those produced by the widely-used DCC/HOSu combination.

The use of the resin for the simplified preparation of peptides can be illustrated by this preparation: N^{α}-Cbz-L-phenylalanine (150 mg), glycine ethyl ester hydrochloride (70 mg), and triethylamine (70 μl) were mixed and shaken at room temperature for 1 h. Activated polyquinoline reagent (approximately 0.3 m*M* active reagent sites per gram) (3.3 g) was added in one portion and the mixture shaken overnight. Product isolation involved filtration of the mixture to remove the resin, washing the resin with ethyl acetate, combining the filtrates, and evaporating to dryness. The residue was taken up in ethyl acetate, filtered and evaporated to dryness (160 mg) (83.5%) (m.p. 102–105 °C, $[\alpha]_D = -16.4°$ (*c* 1.96, EtOH)). This crude residue was crystallized once from ethyl acetate – petrol (30–60°) to yield pure product (136 mg) (71.0%) m.p. 107–108 °C (uncorrected), $[\alpha]_D = -16.6°$ (*c* 1.97, EtOH)), (lit. (5), m.p. 105–106 °C, $[\alpha]_D = -16.7°$ (*c* 2.0, EtOH)). The yield (83.5%) and purity of the crude product suggests that further deblocking and coupling steps could profitably be carried out on this product if the synthesis were to be adapted to an automated synthesis of small blocked peptides.

Finally, that the reagent can be regenerated is best illustrated by the fact that all racemization tests and preparative scale experiments were carried out by repeated use and regeneration of the same 5-g sample of polyquinoline resin.

Nuclear Magnetic Resonance Studies of the Solution Chemistry of Metal Complexes. II. Protonation of the Peptide Linkages of Bis(glycylglycinato)cobaltate(III)[1]

DALLAS L. RABENSTEIN

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 7, 1971

Protonation of bis(glycylglycinato)cobaltate(III) in acidic aqueous solutions has been investigated by proton magnetic resonance spectroscopy. Chemical shift measurements indicate that the site of protonation is the peptide oxygen rather than the Co(III)-coordinated, deprotonated peptide nitrogen as previously proposed, and that the two peptide linkages are protonated in a stepwise fashion rather than simultaneously. Equilibrium constants for the stepwise protonation equilibria have been derived from the n.m.r. data. The equilibrium constant for the first protonation step has also been determined by p*H* titration.

La protonation du cobaltate(III) du bis(glycylglycinate) en solutions acides aqueuses a été étudiée par résonance magnétique nucléaire. La mesure des déplacements chimiques indique que le site de protonation est l'oxygène du peptide beaucoup plus que l'azote du peptide déprotoné coordiné au cobalt(III) comme il a été proposé antérieurement, et que les deux liaisons peptidiques sont protonées par étapes aussi bien que simultanément. Les constantes d'équilibre de la protonation équilibrée par étapes ont été obtenues à partir des résultats de r.m.n. La constante d'équilibre pour la première étape de protonation a été également déterminée par la mesure du p*H*.

Canadian Journal of Chemistry, **49**, 3767 (1971)

Introduction

The nature of metal ion binding by peptides and proteins is of interest in view of the importance of metal ions in biological systems. Undoubtedly the specificity with which the biological functions of such molecules are influenced by metal ions is due, in part at least, to specificity in the binding of the metal ions to the potential coordination sites (2). Binding of metal ions to the peptide linkage has been the subject of much research (3–12). Binding can occur via the peptide oxygen, the protonated peptide nitrogen, and the deprotonated peptide nitrogen.

Structural studies of several bis(glycylglycinato)cobaltate(III) complexes ($Co(gg)_2^-$) have revealed that the Co(III) is bound to each peptide at the nitrogen atoms of the amino and deprotonated peptide groups and at a carboxylic oxygen atom (13).[2] Studies on the solution chemistry of $Co(gg)_2^-$ have shown that in acidic solutions the peptide linkages are protonated (14). The rapidity of the protonation reaction and the lack of any major change in the optical rotatory dispersion spectrum indicate that protonation occurs without any ligand rearrangement. It has been inferred from these results that protonation occurs at the coordinated peptide nitrogen atoms of $Co(gg)_2^-$, although McKenzie pointed out that these results are not evidence that protonation does not occur at some other site on the peptide, such as peptide oxygen or carboxyl oxygen (12).

In this paper, the results of a proton magnetic resonance study of the protonation of $Co(gg)_2^-$ in acidic aqueous solutions are reported. These

[1]For Paper I in this series, see ref. 1.

[2]Throughout this paper, fully protonated glycylglycine is abbreviated H_3gg^+, zwitterionic glycylglycine is abbreviated H_2gg, and the mono- and dianions are abbreviated Hgg^- and gg^{2-}, respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

results suggest that protonation of $Co(gg)_2^-$ to yield $Co(Hgg)_2^+$ is a stepwise process, and that protonation occurs at the peptide oxygen rather than the coordinated peptide nitrogen. Equilibrium constants for the stepwise protonation equilibria are derived from the n.m.r. data. While this study was in progress, the crystal structure of the $Co(Hgg)_2^+$ species was reported (15).

Experimental

Sodium bis(glycylglycinato)cobaltate(III) tetrahydrate was prepared by the method of McKenzie (12), from tris(carbonato)cobaltate(III) (16). Solutions of $NaCo(gg)_2 \cdot 4H_2O$ were prepared determinately in H_2O and D_2O, and the p*H* of these solutions was varied with concentrated HNO_3 and 13.1 *M* DCl, respectively.

The n.m.r. spectra were obtained on a Varian A56/60A spectrometer, operating at a probe temperature of 25 °C with a standard Varian variable temperature accessory. Chemical shifts are reported in Hz relative to the central resonance of the triplet of the tetramethylammonium ion (TMA) as an internal standard, negative shifts representing resonances downfield from TMA. The TMA resonance is close to the resonances of the carbon-bonded protons of $Co(gg)_2^-$, making it possible to use expanded sweep widths (100 Hz) to achieve maximum accuracy in chemical shift measurements. The central resonance of the TMA triplet is 3.17 p.p.m. downfield from sodium 3-(trimethylsilyl)-1-propane sulfonic acid (TMS*). Nuclear magnetic resonance spectra were taken of 0.5 ml solutions of known p*H* or known H^+ concentration. At p*H*'s > 0.2, samples were prepared by adding acid to solutions of $NaCo(gg)_2 \cdot 4H_2O$, and measuring the p*H* with a p*H* meter (Orion model 801) equipped with a glass electrode and a saturated calomel reference electrode. Samples were withdrawn from the solutions at the appropriate p*H* values. At p*H*'s < 0.2, samples were prepared directly in n.m.r. tubes at known H^+ concentrations by adding the appropriate amounts of $NaCo(gg)_2 \cdot 4H_2O$, solvent and acid. The H^+ concentrations of these solutions were corrected to approximately account for the H^+ consumed upon protonation of $Co(gg)_2^-$. No attempt has been made to convert all acidities to either an activity scale or a concentration scale because of the uncertainty in the ionic strengths. This approach is justified because the equilibrium constants were calculated using only data in the region where measurements were made with the p*H* meter. Even so, good agreement is obtained between the theoretical curves and the experimental points in more acidic solutions.

Results

The proton n.m.r. spectra of the α-methylene protons[3] and the β-methylene protons of $Co(gg)_2^-$ were observed over a range of acidities in both H_2O and D_2O. The spectra obtained at p*H* 9.4 are shown in Fig. 1. The resonance patterns for both methylene groups are broad at this p*H* and at the other p*H*'s studied, with the upfield pattern sharpening significantly on going from the H_2O to the D_2O solution.

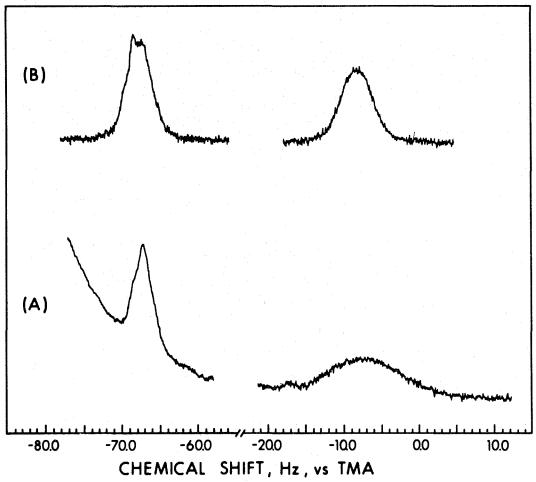

FIG. 1. 60 MHz proton n.m.r. spectra of the methylene protons of $Co(gg)_2^-$ at p*H* 9.4 in H_2O (*A*) and D_2O (*B*). 25 °C.

From the crystal structure of $Co(gg)_2^-$ (Fig. 2) (13), the spectrum of the α-methylene protons is expected to be an AB pattern due to the nonequivalent environments experienced by the two protons of each methylene group, while the spectrum of the β-methylene protons is expected to be an ABXY pattern in H_2O due to spin coupling of the non-equivalent methylene protons with the protons of the $—NH_2$ group. In D_2O the spectrum of the β-methylene protons is expected to be an AB pattern if spin coupling to the deuterium of the $—ND_2$ group is too small to observe. The multiplet patterns ob-

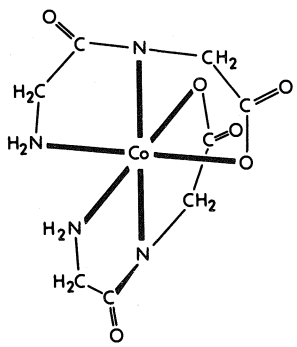

FIG. 2. Structure of $Co(gg)_2^-$ (13).

[3]The methylene groups of glycylglycine are labelled as follows: $H_2NCH_{2(\beta)}CONHCH_{2(\alpha)}CO_2H$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

served for the carbon-bonded protons, however, are more complex than simple AB patterns, possibly due to additional spin interaction with the nitrogen of the peptide ($I = 1$) or the Co(III) ($I = 7/2$) (17). Such interaction is expected to broaden the resonances as observed. In any case, the resonance pattern at higher field is significantly sharpened by changing the amino group of the peptide from $-NH_2$ to $-ND_2$, while the resonance pattern at lower field is not appreciably affected by the change. Based on the changes in the resonance patterns resulting from substitution of deuterium for the amino protons, the higher field multiplet pattern (−7.7 Hz *vs.* TMA) is assigned to the β-methylene protons of $Co(gg)_2^-$ and the lower field multiplet pattern (−67.2 Hz *vs.* TMA) to the α-methylene protons. These are the same assignments arrived at by Barnet *et al.* on the basis of the n.m.r. spectra of similar Co(III) complexes of L-alanylglycine and glycyl-L-alanine (15).

The p*H* dependence of the chemical shifts of the α- and β-methylene protons of $Co(gg)_2^-$ (measured at the center of the resonance patterns) is shown in Fig. 3. The p*H* dependence of these protons in glycylglycine is also shown for comparison. At p*H* 2.6 the resonances of the methylene protons of $Co(gg)_2^-$ start shifting downfield, indicating that some protonation has occurred at this p*H*. As the p*H* is further decreased, the resonances continue to shift downfield. At all p*H*'s, a single, averaged resonance pattern is observed for each of the methylene groups, indicating that interchange between the variously protonated forms via proton exchange is rapid on the n.m.r. time scale.

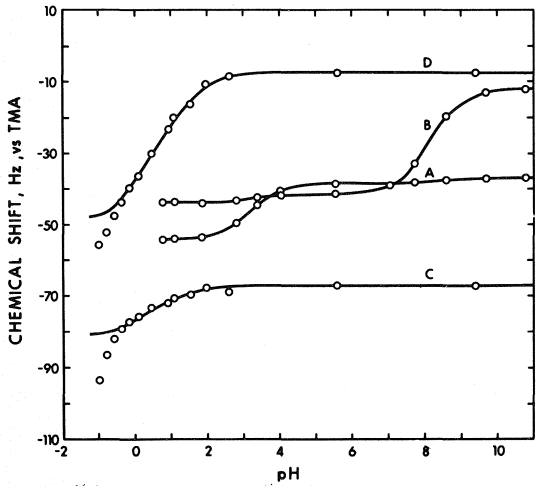

FIG. 3. Chemical shift behavior of methylene protons of glycylglycine as a function of p*H*. Curve *A*, α-methylene protons of glycylglycine; *B*, β-methylene protons of glycylglycine; *C*, α-methylene protons of $Co(gg)_2^-$; *D*, β-methylene protons of $Co(gg)_2^-$.

The observed chemical shifts in the p*H* region where protonation is occurring are the sums of the chemical shifts of the variously protonated species, weighted according to the relative concentrations of each of the species. Thus the observed shifts are a measure of the concentrations of the species present, from which the protonation equilibria can be quantitatively described. Attempts to account for the observed shifts in terms of the simultaneous protonation of both peptide linkages (eq. 1) were unsuccessful, and

[1] $$Co(gg)_2^- + 2H^+ \rightleftharpoons Co(Hgg)_2^+$$

indicated that protonation to form $Co(Hgg)_2^+$ occurs in two steps (eqs. 2 and 3).

[2] $$Co(gg)_2^- + H^+ \rightleftharpoons Co(Hgg)(gg)$$

[3] $$Co(Hgg)(gg) + H^+ \rightleftharpoons Co(Hgg)_2^+$$

These protonation equilibria are described by equilibrium constants K_{a1} and K_{a2} (eqs. 4 and 5).

[4] $$K_{a1} = \frac{[H^+][Co(gg)_2]}{[Co(Hgg)(gg)]}$$

[5] $$K_{a2} = \frac{[H^+][Co(Hgg)(gg)]}{[Co(Hgg)_2]}$$

The observed chemical shifts in this p*H* region are related to the chemical shifts of the species presented by eq. 6.

[6] $$\delta_{obs} = P_{Co(gg)_2}\delta_{Co(gg)_2} + P_{Co(Hgg)(gg)} \times \delta_{Co(Hgg)(gg)} + P_{Co(Hgg)_2}\delta_{Co(Hgg)_2}$$

where $P_{Co(gg)_2}$, $P_{Co(Hgg)(gg)}$, and $P_{Co(Hgg)_2}$ are the populations of the species indicated ($P_{Co(gg)_2} + P_{Co(Hgg)(gg)} + P_{Co(Hgg)_2} = 1$). δ_{obs} is related to equilibrium constants K_{a1} and K_{a2} by eq. 7

[7] $$(\delta_{obs} - \delta_{Co(gg)_2})\frac{1}{[H^+]^2} + (\delta_{obs} - \delta_{Co(Hgg)(gg)})\frac{1}{[H^+]K_{a1}} + (\delta_{obs} - \delta_{Co(Hgg)_2})\frac{1}{K_{a1}K_{a2}} = 0$$

which is obtained from eqs. 4, 5, and 6.

For personal use only.

The equilibrium constants and the chemical shifts of the methylene protons in the mono- and diprotonated species were evaluated from the observed chemical shifts. The procedure involved first evaluating the chemical shift of the β-methylene protons in the Co(Hgg)(gg) species and K_{a1} from the observed β-methylene chemical shifts in the pH region where the second protonation is not extensive. The chemical shift of the β-methylene protons in the $Co(Hgg)_2^+$ species and K_{a2} were then evaluated from the observed chemical shifts at lower pH's where the diprotonated species is also present.

The chemical shift of the β-methylene protons in Co(Hgg)(gg) and K_{a1} were evaluated using eq. 8, which is obtained when the second protonation is neglected.

[8] $$(\delta_{Co(gg)_2} - \delta_{obs})/[H^+] = \delta_{obs}/K_{a1} - \delta_{Co(Hgg)(gg)}/K_{a1}$$

K_{a1} was obtained from the slope and $\delta_{Co(Hgg)(gg)}$ from the intercept of the linear portion of a plot of $(\delta_{Co(gg)_2} - \delta_{obs})/[H^+]$ *vs.* δ_{obs}. Linear behavior was obtained for the data at pH's greater than 1.4. This corresponds to the pH range over which the second protonation is not significant and, consequently, the range over which eq. 8 is valid. The chemical shift of the β-methylene protons in Co(Hgg)(gg) obtained from this plot is -24 ± 0.5 Hz and the K_{a1} is $3.5 \pm 0.25 \times 10^{-2}$ ($pK_{a1} = 1.46$).

$\delta_{Co(Hgg)_2}$ and K_{a2} were evaluated from the β-methylene chemical shifts at lower pH's from the slope and intercept respectively of a plot of $(\delta_{Co(gg)_2} - \delta_{obs})/[H^+]^2 + (\delta_{Co(Hgg)(gg)} - \delta_{obs})/K_{a1}[H^+]$ *vs.* δ_{obs} (from eq. 7). The values of $\delta_{Co(Hgg)(gg)}$ and K_{a1} determined above were used in the evaluation of $\delta_{Co(Hgg)_2}$ and K_{a2}. The chemical shift obtained in this way for the β-methylene protons in the di-protonated species is -49 ± 4 Hz and the K_{a2} is 0.8 ± 0.15 ($pK_{a2} = 0.097$).

The chemical shifts of the α-methylene protons in the mono- and di-protonated species were determined from the observed chemical shifts of the α-methylene protons using eq. 6. Populations were calculated from the previously determined equilibrium constants. The chemical shifts calculated by this procedure for the α-methylene protons in the mono- and di-protonated species are -71 and -81 Hz, respectively.

The solid curves drawn through the experimental data for the α- and β-methylene protons of $Co(gg)_2^-$ in Fig. 3 were calculated using the equilibrium constants and the chemical shifts for these protons in the mono- and di-protonated species determined above. At high acid concentrations, the experimental points deviate from the calculated curves. This is attributed to protonation of the peptides to form higher protonated species, possibly by protonation at the carboxyl oxygen.

The value of K_{a1} was also determined by a pH titration technique to check the results from the n.m.r. study. Fifty ml of 0.0491 M $NaCo(gg)_2 \cdot 4H_2O$ was titrated with 1.348 M HNO_3 to a pH of 1.00. K_{a1} was calculated from the amount of acid consumed by protonation of the complex to form Co(Hgg)(gg) at various pH's down to pH 1.00. The amount of acid required to change the pH of the solution was determined from a titration curve for 50.00 ml of H_2O. The pH titration study yielded a K_{a1} of $3.7 \pm 0.2 \times 10^{-2}$ ($pK_{a1} = 1.43$).

Discussion

Protonation of $Co(gg)_2^-$ to form $Co(Hgg)_2^+$ shifts the resonance frequency of the multiplet pattern due to the β-methylene protons by a larger amount ($\Delta\delta = 42$ Hz) than the resonance frequency of the multiplet pattern due to the α-methylene protons ($\Delta\delta = 14$ Hz), indicating that the β-methylene protons are nearer the sites of protonation. These results suggest, then, that protonation of the peptide linkage in $Co(gg)_2^-$ occurs at the peptide oxygen rather than the peptide nitrogen as previously suggested (12). While this study was in progress, it was reported that the peptide oxygens of $Co(Hgg)_2^+$ are also protonated in the crystalline state (15). Based on the n.m.r. spectra of $Co(gg)_2^-$ in 2 M $HClO_4$, these workers also concluded that the peptide oxygens are protonated in the solution phase.

Gillard *et al.* have also investigated the protonation of $Co(gg)_2^-$. The pK_a of the protonated complex, presumably for the reaction represented by eq. 1, was reported to be about 1.2 (20), although more recent n.m.r. evidence suggested a pK_a of about 0.5 (21). In the present work, it was found that the chemical shift data for protonation of $Co(gg)_2^-$ could not be fitted by a simultaneous protonation of both peptide linkages. Rather, the chemical shift data suggest a stepwise protonation of the peptide linkages of $Co(gg)_2^-$. Similar stepwise protonation behavior has also been observed for protonation

TABLE 1. Ionization constants for the peptide protons in selected metal complexes of polyglycine peptides

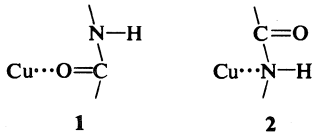
*Glycylglycylglycine; $H_2ggg^- = H_2NCH_2CONHCH_2CONHCH_2CO_2^-$; $Hggg^{2-} = H_2NCH_2CON^-CH_2CONHCH_2CO_2^-$; $ggg^{3-} = H_2NCH_2CON^-CH_2CON^-CH_2CO_2^-$.

of the deprotonated, metal-coordinated peptide linkages in several other metal complexes of polyglycine peptides (6, 7, 11).

Other metal ions that promote the ionization of the peptide hydrogens in polyglycine peptides upon complexation include Ni(II) and Cu(II). Equilibrium constants for the ionization of the peptide protons in several Ni(II)- and Cu(II)-peptide complexes are given in Table 1. Examination of the equilibrium ionization constants listed in Table 1 reveals that the peptide protons in protonated $Co(gg)_2^-$ are much more acidic than those in the protonated Ni(II)- and Cu(II)-peptide complexes. These differences are probably due to a combination of differences in the sites of metal binding and protonation at the peptide linkage and structural changes following proton ionization. Based on evidence from the kinetics of proton-transfer between the mono- and di-protonated Cu(II)-triglycine complexes, Pagenkopf and Margerum (8) suggested that the peptide oxygen of the protonated peptide linkage is coordinated in the Cu(II)-triglycine complexes (Structure **1**), although Kim and Martell (6, 7) have reported that the protonated peptide nitrogen is coordinated in Cu(II)-polyglycine peptide complexes (Structure **2**). The peptide oxygens in the



1 **2**

crystalline complex $Cu(H_2ggg)Cl{\cdot}1.5\,H_2O$, where H_2ggg^- is $H_2NCH_2CONHCH_2CONHCH_2CO_2^-$, are coordinated to the Cu(II) (Structure **1**) (18). The peptide oxygens are also coordinated in the protonated Ni(II)-triglycine complex (10, 11, 19), in contrast to $Co(Hgg)_2^-$ where protonation is at the peptide oxygen and the deprotonated peptide nitrogen is metal coordinated.

The Crystal and Molecular Structure of $(PPh_3)_2PtO_2.2CHCl_3$

P.-T. CHENG, C. D. COOK, S. C. NYBURG, AND K. Y. WAN
Lash Miller Chemical Laboratories, University of Toronto, Toronto 181, Ontario

Received June 21, 1971

The X-ray crystal structure analysis of the chloroform adduct of the bis(triphenylphosphine) platinum di-oxygen complex $(PPh_3)_2PtO_2.2CHCl_3$ is reported. The crystals belong to the monoclinic system $a = 15.492(7)$, $b = 13.520(5)$, $c = 19.187(6)$ Å; $\beta = 98.97(6)°$. Space group $C2/c$. $Z = 4$ molecules per cell.

A total of 2740 independent X-ray reflections were measured and refinement gave a final conventional R of 6.6%.

The molecule has a two-fold axis of symmetry through the Pt atom with O—O normal to the axis. The O—O distance of 1.505(16) Å is in accord with that found with other transition elements when oxygen is taken up irreversibly to form di-oxygen complexes.

On a déterminé par diffraction de rayons-x la structure cristalline du composé d'addition du chloroforme et du dioxo bis(triphénylephosphine) platine $(PPh_3)_2PtO_2.2CHCl_3$. Ce composé cristallise avec une maille monoclinique de dimensions: $a = 15.492$ (7), $b = 13.520$ (5), $c = 19.187$ (6) Å et $\beta = 98.97$ (6)°, dans le groupe d'espace $C2/c$ avec quatre molécules par maille.

L'affinement de la structure conduit à un facteur d'accord final $R = 6.6\%$ pour les 2740 réflexions mesurées. La molécule a un axe d'ordre deux passant par l'atome de platine avec O—O perpendiculaire à cet axe. La distance O—O de 1.505 (16) Å est comparable à celles trouvées pour d'autres éléments de transition quand l'oxygène est fixé irréversiblement pour former des complexes bioxygénés.

Canadian Journal of Chemistry, 49, 3772 (1971)

Introduction

Crystallographic data are slowly accumulating on the oxygenated synthetic oxygen carriers of iridium(I) and platinum(0). Ibers and co-workers (1–5) have obtained data for three trigonal-bi-pyramidal iridium(I) complexes, $(PPh_3)_2Ir(CO)(X)(O_2)$, (X = Cl,I) and $(PPh_3)_2Ir(O_2)^+$ and have rationalized the observed variations in O—O bond lengths (Table 1) by reference to a simple three-center m.o. scheme. Kakudo and co-workers (6) have reported that the O—O bond length in the molecule $(PPh_3)_2PtO_2.1.5C_6H_6$ is 1.45 Å.

The trigonal complex $(PPh_3)_2PtO_2$ has been the subject of structural studies in these laboratories and data have been obtained for two derivatives $(PPh_3)_2PtO_2.C_6H_5CH_3$ and $(PPh_3)_2PtO_2.2CHCl_3$. Details of the former structure have already been reported (7) and although the crystallographic data were only marginal in quality, an O—O bond length of 1.26 ± 0.05 Å was indicated. This length is considerably shorter than would be anticipated for this irreversible oxygen carrier and prompted the present investigation of the complex $(PPh_3)_2PtO_2.2CHCl_3$.

Reaction of $(PPh_3)_2.Pt(C_2H_4)$ or $Pt(PPh_3)_3$ with oxygen in aromatic hydrocarbons or chlorinated alkanes as solvent (S) yields solvated complexes $(PPh_3)_2Pt(O_2)S_x$. We have determined a number of x values by integration of the ^1H or ^{19}F n.m.r. spectra of the complexes in suitably deuterated solvents. We have found that for toluene, $x = 1$ and for chloroform, $x = 2$. For the Pt complex containing tris-*p*-fluorophenylphosphine with fluorobenzene as solvent, $x = 2$.

Oxygen is taken up irreversibly by all the platinum(0) complexes we have examined and this suggests that these derivatives are more akin to the iridium(I) iodo complex $(PPh_3)_2Ir(CO)(I)(O_2)$ rather than the chloro derivative $(PPh_3)_2Ir(CO)(Cl)(O_2)$ which reacts with oxygen in a reversible manner (see Table 1). It is interesting to note that significant changes in nature of the aryl phosphine employed (*e.g.* tris-*p*-chloro, tris-*p*-fluoro, tris-*p*-methyl, and tris-*p*-methoxy) have no observable effect on the reversibility of the oxygen uptake whereas in the iridium(I) system a change in the coordinated halogen has a profound effect upon the chemical behavior and the observed bond length of the oxygen molecule.

Experimental

The ethylene adduct (8) $[(PPh_3)_2Pt.C_2H_4]$ was dissolved in oxygen-saturated chloroform. The solution was allowed to stand in an oxygen-filled desiccator when the oxygen adduct was deposited as bright orange crystals.

The crystals, which are quite stable, analyze for $(PPh_3)_2PtO_2.2CHCl_3$.

Anal. Calcd. for $(PPh_3)_2PtO_2.2CHCl_3$: C, 46.07; H, 3.26; Cl, 21.48. Found: C, 49.54; H, 2.80; Cl, 21.77.

Good crystal specimens could be selected from the above preparations. These were needles having z (monoclinic as long axis and with {110} forms well developed. Unit cell dimensions were determined by measuring 2θ, χ, and ϕ settings of high angle principal reflections on an FACS-1 Picker four-circle diffractometer. The results were averaged for four crystals. The data are as follows:

$C_{38}H_{32}O_2Cl_6P_2Pt$ f.W. = 990

Monoclinic, $a = 15.492(7)$, $b = 13.520(5)$, $c = 19.187(6)$ Å, $\beta = 98.97(6)°$. $V = 3970$ Å^3, $\rho_o = 1.62(1)$, $Z = 4$, $\rho_c = 1.66$ (25 °C; CuKα, $\lambda = 1.542$ Å, μ(CuKα) = 120.2 cm^{-1}).

Intensity data were collected by automated diffractometer using CuKα radiation in 2θ scan mode at 2° min^{-1} with $4° \leqslant 2\theta \leqslant 115°$. The scanning range at low 2θ was 2° with 10 s background count at the 2θ limits. The crystals were found to be somewhat unstable under X-irradiation, reflections falling in intensity typically by 1% h^{-1}. Accordingly four separate crystals, all mounted about the z-axis were used; on average the intensity fell by about 10% during data collection from each crystal.

All the crystals were needles of volume about 0.07 mm^3 and absorption corrections were applied to all the intensity data. The weighting function used for intensity was (9)

$$\sigma^2(F^2) = (I/[(LP).A]^2) + CF^4$$

where $0.05 \leq A \leq 0.33$ is the absorption factor with C as 0.02 to allow for crystal instability. Of the 2740 independent reflections collected, 156 had $I < \sigma(I)$ and were considered unobserved.

Determination of the Structure

The three-dimensional Patterson function was used to determine the space group. Both Cc and $C2/c$ generate peaks along the line $0, 2y, \frac{1}{2}$ but only $C2/c$ has related peaks at $2x$, $2y$, $2z$ and at $2x, 0, \frac{1}{2}$. In this way the space group was established as $C2/c$ and the Pt atom coordinates found as $(0.0, 0.028, \frac{1}{4})$. Since these are of form $0, y, \pm\frac{1}{4}$ the Pt atoms lie on diad axes governing the symmetry of the molecule as a whole. (The alternative symmetry 1 in $C2/c$ for $Z = 4$ is in any case ruled out on chemical grounds.)

Refinement using the full matrix least squares programs ORFLS and XFLS (10) was routine. Scattering factors were those derived from Hartree–Fock wave functions (11) allowance being made for anomalous scattering. The conventional R factor at this stage, using isotropic temperature factors, was 9.0%. A difference Fourier map based on isotropic refinement containing all non-hydrogen atoms showed each of the three chlorine atoms of $CHCl_3$ to be disordered on two sites. We concluded that the occupancy of the chlorine atoms at these six sites was 0.5 because this gave the lowest residual, $R = 0.066$, when anisotropic refinements were completed. When the ratios were fixed at 0.4, 0.6 or 0.6, 0.4 either the residual increased or refinement could not be carried out. Final F_o and F_c values have been placed in the Depository for Unpublished Data.[1] The positional and thermal parameters with standard deviations as obtained in the least squares refinement are given in Tables 2 and 3. Since the final difference Fourier map did not show any significant peaks, all hydrogen positions were calculated using C . . . H = 1.07 Å.

The β_{ij} in Table 3 are the coefficients in the expression $\exp[-(h^2\beta_{11} + k^2\beta_{22} + l^2\beta_{33} + 2hk\beta_{12} + 2kl\beta_{13} + 2kl\beta_{23})]$.

The bond distances and angles in the molecule are shown in Fig. 1, the average standard deviations of the sp^2 carbon angles being 1°.

Discussion of the Structure

A diagram of the molecule viewed normal to the twofold axis is given in Fig. 2. Bond lengths of interest are marked in.

The twofold axis through Pt requires the oxygen molecule to lie either wholly on this axis or,

alternatively, to lie normal to this axis through the O—O midpoint. The latter is the case. The O—O distance of 1.505(16) Å is in accord with the general observation that when oxygen is taken up reversibly by transition metal complexes the O . . . O distance is 1.3–1.4 Å but when taken up irreversibly, as here, it is about 1.5 Å. However, they cannot be compared directly since the Ir and Rh complexes are trigonal bipyramidal and the Pt complexes are trigonal (see Table 1).

In the present case the situation is somewhat complicated by what appear to be hydrogen bonds between the oxygen atoms and the neighboring carbon atoms of chloroform molecules at a C . . . O distance of 3.049(17) Å (see Fig. 2). Such short C . . . O distances are not unknown (12) and an analogous case appears in the molecular complex diethyl ether: $HCBrCl_2$ with a distance of 3.10(10) Å between the ether oxygen atom and the carbon atom of bromodichloromethane (13). In the present case, the derived H-positions for the two half-occupied chloroform molecules are virtually identical. These yield a C—H . . . O angle of 161°. The influence of this hydrogen bond, if real, on the O . . . O distance will possibly be better understood when we have recollected X-ray data for the toluene complex, since in the latter hydrogen bonding is ruled out. That

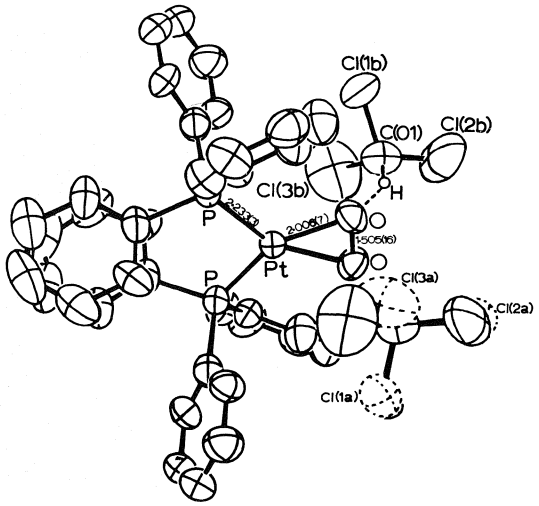

FIG. 2. Molecule of $(Ph_3P)_2PtO_2.2CHCl_3$ with 50% probability thermal ellipsoids. In order to make one of the hydrogen atoms clearly visible the corresponding $CHCl_3$ molecule has been drawn in only one of its two disordered positions. For the other $CHCl_3$ molecule both positions are given (full and broken lines, respectively).

electronic, the difference in O . . . O bond lengths must be due to the effect of solvent molecules. Ligand–solvate molecule interactions have not previously been introduced into discussions of oxygen bond lengths in complexes of this type although they may well be significant.

The Pt . . . O distance, 2.006(7) Å, is similar to that found in other platinum complexes, namely, 2.07 Å in bis(triphenylphosphine)carbonatoplatinum(II) (14), 2.01(1) in bis(triphenylphosphine)-peroxidoacetonatoplatinum(0) (15), 2.0 in potassium bis(oxalato)platinum dihydrate (16) 2.20,-2.24(3) in trimethyl (salicylaldehydato)platinum-(IV) (17), 2.01(3) in $Pt(O_2)(PPh_3)_2 1.5C_6H_6$ (6) and 2.02 in potassium bis(acetylacetonato)chloroplatinate(II) (8). With the exception of the salicylaldehydato complex, the Pt . . . O distance seems to be little affected by whether the oxygen atoms are bonded to each other or not.

The two phosphorus atoms and two oxygen atoms lie closely coplanar with the Pt atom. The angle between planes O—Pt—O′ and P—Pt—P′ is only 0.1°. Coefficients for the best least squares planes through the "central coordination moiety" and the three phenyl rings are listed in Table 4. In no case does the maximum deviation from planarity exceed 0.015 Å. There are no unusually short interatomic contacts in the crystal, except around the oxygen atoms: a close interatomic distance of 2.38 Å between O and H(16) and a close intermolecular distance of 2.39 Å between O and H(35) (at $\frac{1}{2} - x, \frac{1}{2} + y, \frac{1}{2} - z$).

The Catalytic Decomposition of Isopropyl Alcohol Vapor on Manganese (II) Oxide

D. G. KLISSURSKI,[1] E. F. MCCAFFREY, AND R. A. ROSS
Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received June 17, 1971

The vapor phase decomposition of isopropyl alcohol has been studied from 210 to 365 °C on manganese(II) oxide. Rates of conversion to acetone and propylene were measured with partial pressures of isopropyl alcohol from 0.3 to 22 mm. The catalyst selectivity towards dehydrogenation was around 0.80 between 320 and 365 °C while at 306 °C it was somewhat less and depended on the alcohol partial pressure. Propylene and hydrogen additions had no effect on the reaction rate while the reaction order with respect to isopropyl alcohol partial pressure was 0.4 to 0.6 except at 306 °C when it decreased with increase in the alcohol partial pressure. The effects of acetone and water additions were shown respectively to be exerted mainly on the dehydrogenation and dehydration reactions while at acetone pressures above 4 mm, considerable amounts of by-products including mesityl oxide and heavier ketones were clearly detected. The apparent activation energy of the overall decomposition as calculated from the experimental rates was 26 ± 0.5 kcal mol^{-1}. The results have been interpreted to be in general agreement with the concept that the rate-limiting step is linked to the direct interactions on the catalyst surface and it has been established that the reaction is significantly more complex than previously recognized. The physical properties of the manganese(II) oxide were determined by X-ray and nitrogen adsorption techniques while infrared, n.m.r., and gas chromatographic methods were used to analyze the products of catalysis.

On a étudié la décomposition de l'alcool isopropylique en phase vapeur, entre 210 et 365 °C, sur l'oxyde de manganèse(II). Les taux de conversion en acétone et propylène furent mesurés au moyen des pressions partielles d'alcool isopropylique entre 0.3 et 22 mm. La sélectivité du catalyseur pour la déshydrogénation se situait autour de 0.80 entre 320 et 365 °C, alors qu'à 306 °C elle était légèrement inférieure et dépendait de la pression partielle de l'alcool. Des additions de propylène et d'hydrogène n'ont eu aucun effet sur la vitesse de la réaction, alors que l'ordre de la réaction par rapport à la pression partielle d'alcool isopropylique était de 0.4 à 0.6, excepté à 306 °C où il diminuait avec l'augmentation de la pression partielle d'alcool. On a constaté que les effets de l'addition d'acétone et d'eau s'exerçaient principalement sur les réactions de déshydrogénation et de déshydratation, alors qu'à des pressions d'acétone de plus de 4 mm, des quantités considérables de produits secondaires incluant l'oxyde de mésityle et des cétones plus lourdes étaient clairement détectées. L'énergie d'activation apparente de la décomposition totale, telle que calculée à partir des vitesses expérimentales était de 26 ± 0.5 kcal mol^{-1}. Les résultats ont été interprétés comme étant en accord général avec le concept que l'étape limitante est reliée aux interactions directes à la surface du catalyseur et il a été établi que la réaction est singulièrement plus complexe qu'on l'avait prévu. Les propriétés physiques de l'oxyde de manganèse(II) ont été déterminées par les techniques de rayons-X et d'adsorption d'azote, alors qu'on a utilisé l'infrarouge, la r.m.n. et la chromatographie en phase gazeuse pour analyser les produits de catalyse.

Canadian Journal of Chemistry, 49, 3778 (1971)

Introduction

Few comprehensive kinetic studies of the heterogeneous catalytic properties of manganese(II) oxide or its mixed oxides have been reported and as a first step in an experimental assessment of these properties an examination of the catalytic decomposition of isopropyl alcohol vapor on manganese(II) oxide has been carried out. This reaction is frequently used as a model in studies of variations in catalytic activity and selectivity involving nonmetallic catalysts (1). At temperatures below 500 °C it proceeds mainly in two directions: (*a*) dehydrogenation and (*b*) dehydration.

According to current theories, catalyst activity and selectivity in this reaction may be related to lattice parameters, type of conductivity, and width of forbidden zone as well as to the acidic properties of the surface (2–5). For manganese(II) oxide in particular, a relatively high activity in the dehydrogenation of isopropyl alcohol has been reported (6) but unfortunately no data on the surface area were given and hence the specific activity cannot be estimated. At the same time, the reaction order with respect to isopropyl alcohol or any of the reaction products has not been studied and yet it is generally accepted that

only dehydrogenation proceeds on the surface of this catalyst (6–8).

In the present work the activity and selectivity of manganese(II) oxide in the decomposition of isopropyl alcohol vapor have been examined from 300 to 365 °C. Reaction orders and activation energy have been measured and attention given to the more complex character of the reaction.

Experimental

Apparatus

The all-glass flow system has been described previously (9, 10). A quartz integral reactor was used and tests from 210 to 363 °C showed that isopropyl alcohol did not decompose to any detectable extent in the absence of the catalyst. High-purity nitrogen at atmospheric pressure was used as a carrier gas and the catalyst bed temperature was controlled to $\pm 0.1°$ from 300 to 400 °C by a platinum resistance thermometer connected to an expanded-scale "Sigma" proportional controller.

Reaction products were analyzed at 80 °C by a Beckman GC5 gas chromatograph using stainless steel columns, 72 in. × 0.125 in. o.d., packed with "Carbowax 1540" on "Teflon 6".

To establish the experimental conditions for which the reaction rate was not influenced by external or internal diffusion, the influence of space velocity, catalyst mass, and particle size was studied in the usual manner (9). As a result of these preliminary studies the kinetic measurements were performed at flow rates from 220 to 360 ml min^{-1} (N.T.P.) (space velocities at 342.5 °C, 300 to 500 cc gas (cc catalyst)$^{-1}$ min^{-1}).

All reaction rate measurements were made after the establishment of the steady catalyst activity level.

Materials

(a) Manganese(II) Oxide

Electrolytic grade metallic manganese, 99.999% pure, was dissolved in nitric acid to give a 4 *M* solution at p*H* 6. The solution was kept at 60 °C and 4 *M* ammonium oxalate solution added with vigorous stirring. The precipitate, $MnC_2O_4.2H_2O$, was washed with warm deionized-water until free of nitrate ions and then dried at 80 to 100 °C for 6 h. Calcination to manganese(III) oxide was carried out at 300 °C for 5 h followed by 16 h each at 400 and 600 °C (11–13). Subsequently, analysis by X-ray powder photography confirmed the α-Mn_2O_3 structure (14). Chemical analysis (15) showed 69.98% *w/w* manganese (theory 69.59%) while the specific surface area was 26 ± 2 m^2 g^{-1} (B.E.T.; N_2; −196 °C). Finally the α-Mn_2O_3 was heated for 12 h at 600 °C in a flow of hydrogen (60 ml min^{-1}) and X-ray powder photography of the product confirmed the MnO structure (14). Chemical analysis gave 76.90% *w/w* manganese (theory 77.44%) and the surface area was 23 ± 2 m^2 g^{-1}.

It was established that the specific surface area of the manganese(II) oxide samples did not change after use in the catalytic measurements.

(b) Reagents

Isopropyl alcohol and acetone were "Spectrosol" quality and their u.v. absorption characteristics, Unicam SP800A, were the same as those given on their accompanying certificates. All gaseous reagents and the nitrogen carrier (Canadian Liquid Air Ltd.) were 99.99% pure.

Results

The Effect of Temperature on the Reaction Rate and Products

Experiments were carried out with 9.72 mm partial pressure isopropyl alcohol at various temperatures from 325 to 363 °C in which the rates of conversion of the alcohol to acetone (r_1) and propylene (r_2) were measured along with the overall rate of conversion (r_3) and the selectivity ratio r_1/r_3. Within this temperature range, several other products were formed which accounted for approximately 0.1% of the total conversion. Isopropyl ether and mesityl oxide were positively identified while i.r. and n.m.r. analyses both indicated the presence of an acetylenic compound.

Although the dehydrogenation reaction was predominant, dehydration also took place simultaneously to a significant extent. The average selectivity for dehydrogenation was close to 0.80 at all temperatures with no obvious trend. Earlier it had been accepted (6) that manganese(II) oxide catalyzes the dehydrogenation reaction with a selectivity of 99–100%, a conclusion which is evidently not in agreement with the present results. However, the disagreement may be explained simply by the fact that the reaction rate previously had been measured only from the pressure changes of the gaseous products (7) or by the quantity of hydrogen evolved (6).

In Fig. 1, $\log_{10} r_3$ is plotted against the reciprocal catalyst temperature in the Arrhenius fashion. From the slope of this line the apparent activation energy, E', was calculated at 26 ± 0.5 kcal mol^{-1}. Additional measurements in the interval 210 to 300 °C confirmed this value.

For a catalytic reaction inhibited by the products it has been shown (16) that the relationship between E' and the apparent activation energy E, calculated from rate constants is given by: $E' = E/(r + 1)$, where r is the overall reaction order with respect to the inhibiting products. Because of the complexity of rate constant calculations for some reactions, it was further shown (16) that E could be obtained by plotting the temperature dependence of the flow rate at which a given degree of conversion was achieved, since then: flow rate, $V \propto k$, rate constant.

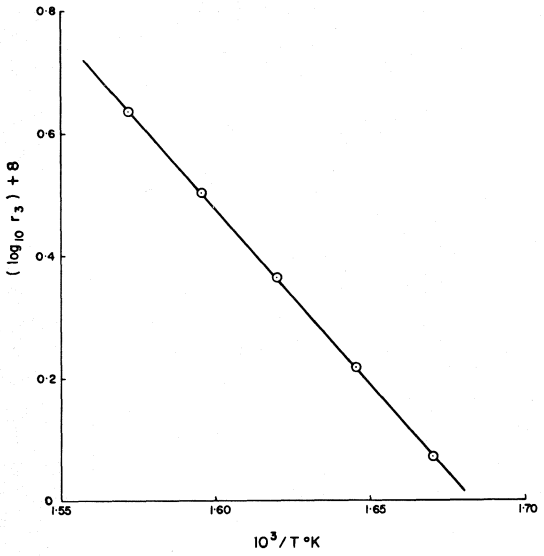

FIG. 1. Arrhenius plot of overall experimental reaction rate (r_3). Partial pressure isopropyl alcohol, 9.72 mm; flow rate, 300 ml min^{-1} (N.T.P.).

Figure 2 shows the mole fraction of isopropyl alcohol converted *vs.* the reciprocal of the flow rate at the temperatures indicated. From these data four separate Arrhenius plots of $\log_{10} V$ against $1/T$ °K were drawn for four different degrees of conversion between 15 and 30%. The plots gave an apparent activation energy of 30 ± 2 kcal mol^{-1}. The slightly higher value found for E and E' indicates the level of the product inhibition effects on the overall reaction rate.

The Effect of Isopropyl Alcohol Partial Pressure on the Reaction Rate

The partial pressure of isopropyl alcohol was varied between 0.3 and 21 mm at 306, 323, and 356 °C at 300 ml min^{-1} (N.T.P.). The results are shown in Table 1. There is a slight trend for dehydration to become more favored with decrease in temperature, particularly so at the highest isopropyl alcohol partial pressures at 306 °C. Logarithmic plots of these data indicate a reaction order for the overall decomposition from 0.4 to 0.6 with respect to isopropyl alcohol partial pressure at 323 and 356 °C. The order lay at the higher end of the range at 356 °C and at the lower end at 323 °C. Previously it has been stated (17) that the rate of reaction of isopropyl alcohol on manganese(II) oxide at "low" temperatures depends little on the alcohol partial pressure al-

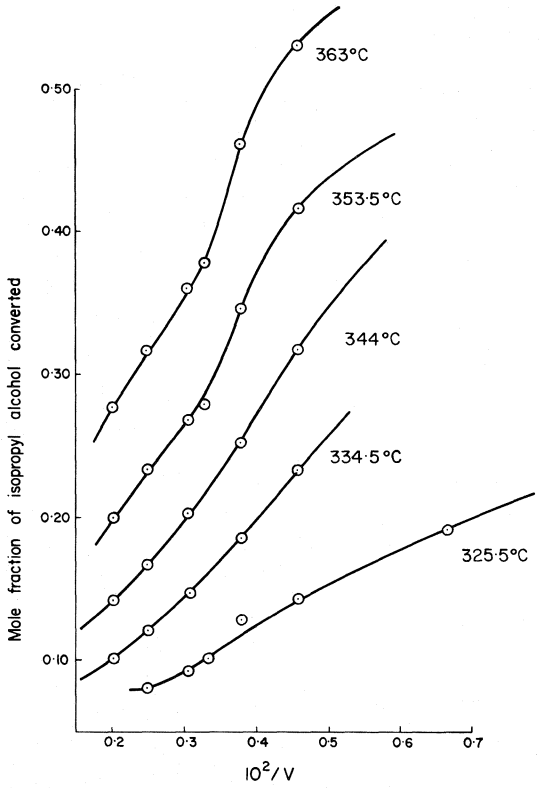

FIG. 2. Changes in mole fraction of isopropyl alcohol converted with variation in flow rate, V, at temperatures shown.

though no data were quoted. At 306 °C, the dependence of the reaction order on isopropyl alcohol partial pressure was more complex. There was a distinct tendency for the order to fall with increase in the alcohol partial pressure, *e.g.* from 0.3 to 10.0 mm the order decreased from 0.6 to about 0.2, Fig. 3. Similar effects have been observed also with $ZnO.Cr_2O_3$ catalysts (18).

The Effect of Hydrogen

In the temperature range studied with hydrogen partial pressures from 1.5 to 40 mm and an isopropyl alcohol partial pressure of 7.78 mm the reaction rate was not influenced by hydrogen partial pressure.

The Effect of Propylene

At 323 °C with 7.78 mm partial pressure isopropyl alcohol and propylene partial pressures from 0.3 to 33 mm no influence of the gas was detected on the rates of either the dehydration or dehydrogenation reactions.

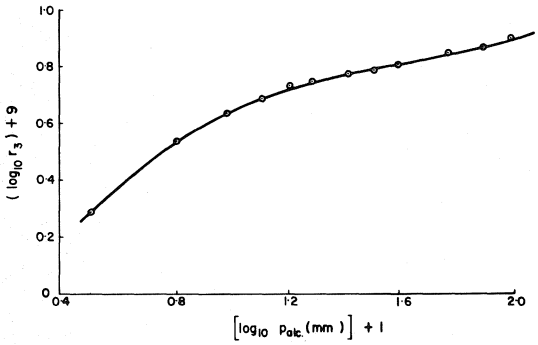

FIG. 3. Variation of overall reaction rate with initial isopropyl alcohol partial pressure at 306 °C.

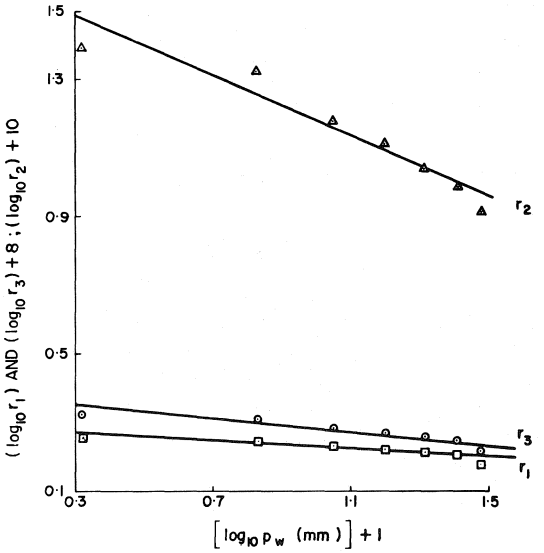

FIG. 4. The effect of the total water vapor partial pressure on r_1, r_2, and r_3 at 323 °C. Partial pressure isopropyl alcohol, 7.78 mm.

The Effect of Water Vapor

The effect of changing the water vapor partial pressure from 0.2 to 3 mm was studied at 323 and 343 °C with isopropyl alcohol partial pressures of 7.78 and 16.83 mm, respectively. At 323 °C, $r_1 \propto (p_w)^{-0.06}$, $r_2 \propto (p_w)^{-0.45}$, and $r_3 \propto (p_w)^{-0.08}$ and at 343 °C, $r_1 \propto (p_w)^{-0.05}$, $r_2 \propto (p_w)^{-0.58}$, and $r_3 \propto (p_w)^{-0.11}$. Figure 4 illustrates these effects for the experiments at 323 °C. After the removal of the added water vapor the catalyst activity recovered to its original value.

The Effect of Acetone

When 27.77 mm of acetone was passed alone over newly prepared manganese(II) oxide at 356 °C at 300 ml min^{-1} (N.T.P.), about 1% initially condensed to give mesityl oxide and six other heavier ketones. After 2 h exposure this activity had fallen to about 0.5%.

At 323 °C and isopropyl alcohol partial pressure 7.78 mm, the acetone partial pressure

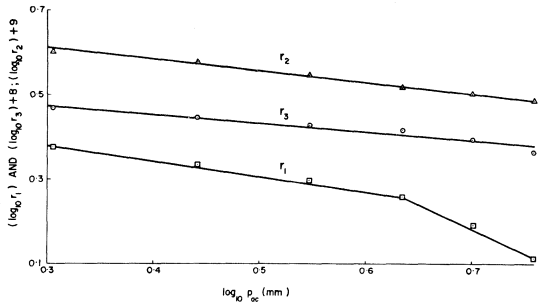

FIG. 5. The effect of the total acetone partial pressure on r_1, r_2, and r_3 at 323 °C. Partial pressure isopropyl alcohol, 7.78 mm.

was varied from 2 to 6 mm. Figure 5 shows the results obtained with respect to r_1, r_2, and r_3. The rates r_2 and r_3 are respectively $\propto (p_{ac})^{-0.06}$ and $(p_{ac})^{-0.10}$ over the entire pressure range while $r_1 \propto (p_{ac})^{-0.36}$ from 2.02 to 4.32 mm but at the higher pressures this index becomes -1.00.

Clear evidence of catalyst poisoning was obtained here. For example, when the last increment of acetone added was entirely removed at the conclusion of the experiments, r_1 was reduced by 17% and r_2 by 13% at the steady level of catalyst activity.

In this series of experiments a small trace of isopropyl ether was detected which increased in quantity with increase in acetone partial pressure but never exceeded 0.1% of the total products. Considerable amounts of other by-products including mesityl oxide principally, and two of the heavier ketones were present. These increased in amount sharply but smoothly with increase in acetone partial pressure such that they accounted for approximately 30% of the total products at 5.74 mm acetone. Their rate of formation was between first and second order with respect to the acetone partial pressure, Fig. 6.

Discussion

The decomposition of isopropyl alcohol on manganese(II) oxide involves principally dehydrogenation, dehydration, and condensation reactions. In the absence of added acetone the overall rate can be equated to the sum of the dehydrogenation and dehydration rates as the contributions of the condensation reactions are then very small. Since the selectivity ratio is almost constant at 0.80 from 320 to 365 °C, the apparent activation energy, E', of 26 ± 0.5 kcal

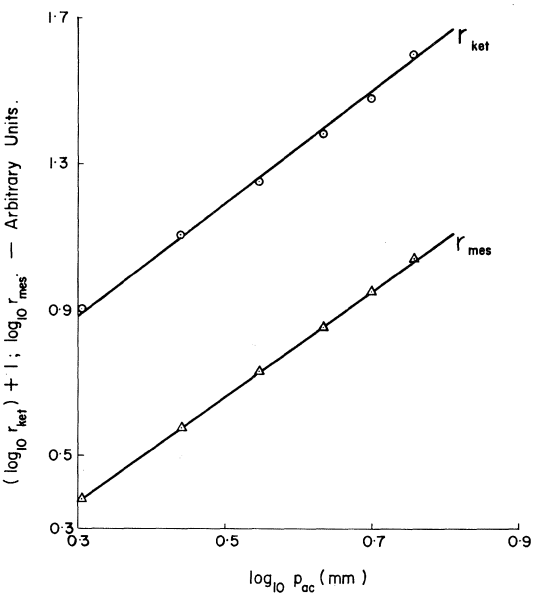

FIG. 6. Variation of the rates of ketone, r_{ket}, and mesityl oxide, r_{mes}, formation with acetone partial pressure at 323 °C. Partial pressure isopropyl alcohol, 7.78 mm.

mol^{-1} applies to both dehydrogenation and dehydration and therefore it may be compared directly with the value of Balandin *et al.* (6), 25.4 kcal mol^{-1}, for the dehydrogenation of isopropyl alcohol on manganese(II) oxide in the same temperature region. Good agreement is obtained also between the value of 30 ± 2 kcal mol^{-1} found here for E from the data of Fig. 2 and the earlier value of 31.9 kcal mol^{-1} calculated (6) from adsorption coefficients. The difference between E and E' is consistent with the effects of the products on the overall reaction rate. Balandin *et al.* interpreted their results as being consistent with desorption of acetone as the rate-controlling step. However, the complexity of the reaction was not then entirely recognized.

Although the decomposition of isopropyl alcohol has been studied frequently using a variety of catalysts (1), few papers have emphasized the kinetics of the reaction and information on the kinetic equations is limited. In dehydrogenation, the possible rate-limiting steps are (*a*) adsorption of the alcohol, (*b*) interaction on the surface, and (*c*) desorption of products. These possibilities have been discussed recently (17) for catalysis on zinc(II) oxide and a kinetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

analysis carried out. Also, in a general form the following equation has been proposed (17) for the catalytic dehydrogenation

$$[1] \qquad \text{rate} = \frac{k_1 k_3 p_{alc}}{k_1 p_{alc} + k_2 p_{ac} + k_3}$$

where k_1, k_2, and k_3 are, respectively, the rate constants for the decomposition of the alcohol, adsorption of acetone, and desorption of acetone while p_{alc} and p_{ac} are the partial pressures of isopropyl alcohol and acetone, respectively. The equation is in agreement with experimental data (18) and was derived on the assumption that at the steady state the rate of desorption of acetone is equal to its rate of adsorption plus the rate of dehydrogenation of the alcohol. By making suitable deductions in the classical manner regarding the relative weights of the component terms in the equation it can be modified (17) to explain the results of experiments with various catalysts where either (*b*) (18) or (*c*) (6, 19) was concluded to be the rate-limiting step. For the dehydration of isopropyl alcohol on metallic oxides a similar kinetic treatment (20) yields an equation for the rate like eq. 1 with rate parameters for water substituted for those of acetone.

The present results show that the order of the overall decomposition reaction with respect to isopropyl alcohol partial pressure depends on the temperature and on the pressure region, Table 1 and Fig. 3. Similar effects have been observed (18) for the reaction of 30–300 mm isopropyl alcohol at 383 °C on a $ZnO.Cr_2O_3$ catalyst. All of these data are in agreement with eq. 1, since if it is accepted (17) that $k_3 + k_1 p_{alc} \gg k_2 p_{ac}$ the equation can be transformed to

$$[2] \qquad \text{rate} = \frac{k_1}{(1/p_{alc}) + k_1/k_3}$$

Hence, with increase in the partial pressure of isopropyl alcohol the dehydrogenation reaction rate will be increasingly less affected by the isopropyl alcohol partial pressure. A similar conclusion can be obtained for the dehydration reaction. The present results show that r_1, r_2, and also r_3 are affected in this fashion by increase in the alcohol partial pressure with the major change reflected in r_1, the rate of dehydrogenation. These features are illustrated in Fig. 7 where Langmuir plots of $1/r_1$, $1/r_2$ and $1/r_3$ are given for the data obtained at 306 °C. It would be expected that

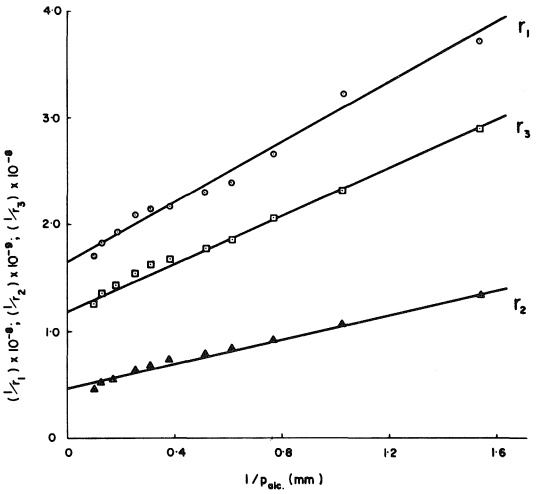

FIG. 7. Langmuir plots of r_1, r_2, and r_3 at 306 °C.

similar results would be found at the higher temperatures if higher partial pressures of isopropyl alcohol could have been used but experimental limitations were prohibitive because of the possibility of cracking reactions occurring (21). The Langmuir pattern observed at 306 °C was also noted with $ZnO.Cr_2O_3$ (18).

The zero order rate dependence of r_1, r_2, and r_3 on the partial pressure of hydrogen is interpreted in terms of a very rapid saturation of any surface sites present which might be amenable to the adsorption of the gas or alternatively that extremely rapid desorption is involved. A similar interpretation may be applied to explain the zero order kinetic relationship found with propylene.

The effect of water vapor partial pressure on the reaction rates, Fig. 4, is indicative of the accepted view (21, 22) that different surface sites are involved in the dehydrogenation and dehydration of alcohols since r_1 is only barely related to p_w while r_2 is substantially inhibited by increase of this partial pressure.

The influence of acetone partial pressure on the mechanism and rate of the reaction on manganese(II) oxide is of a significantly more complex character than has been accepted (6). The rates r_2 and r_3 are only slightly inhibited by increase in acetone partial pressure while r_1 is more significantly affected, particularly at high pressures. Indications are that inhibition of acetone formation would become almost total at acetone partial pressures around 10 mm at 323 °C. Since the rate

For personal use only.

retardation exerted by acetone is largely concentrated on the other path of the reaction from that of the water vapor, the results can be regarded as added confirmation of the hypothesis that different surface loci are involved in the two competitive reactions. At the same time it is important to note (*i*) that at the highest acetone partial pressures a substantial increase takes place in the rates of formation of the observed secondary products such that a kinetic relationship exists between these rates and the acetone partial pressure, Fig. 6, (*ii*) that a measurable reduction in overall catalyst activity is observed after removal of this acetone, and (*iii*) that acetone itself undergoes condensation reactions on the manganese(II) oxide. Hence the intervention of additional surface reactions in these conditions occurs with complex consequences in regard to mechanistic interpretations especially involving r_1.

At present, we have been unable to develop mechanisms which completely satisfy the kinetic results. Nevertheless, some useful conclusions can be made with respect to general if not detailed reaction sequences. Thus the results show fair agreement with the concept (18) that the rate-limiting step is linked to reaction on the catalyst surface. Figure 7 supports this deduction as it expresses a proportionality between the reaction rate and the surface coverage although, taken alone, it does not imply that the slow step in the mechanisms of dehydrogenation and dehydration is reaction of the alcohol. However, some further support for this deduction is evident in the small effect of acetone and water on the overall reaction rate. Thus $r_3 \propto p_w^{-0.1}$ and $p_{ac}^{-0.1}$ but the effect of these products on the separate competitive reactions is more pronounced, $r_2 \propto p_w^{-0.5}$ and $r_1 \propto p_{ac}^{-(0.3-1.0)}$ depending on partial pressure.

The addition of water vapor hardly affects the rate of the dehydrogenation reaction and the overall relationship of r_3 with p_w is mathematically consistent with the catalyst selectivity. Isopropyl ether disappears as the water vapor pressure is increased and the catalyst recovers its original activity when the added water vapor is removed. This indicates the reversible adsorption of water on active dehydration sites and clearly shows that the surface equilibrium is very sensitive to the pressure of water vapor.

The order found with respect to acetone for r_3 when compared with that for r_1 is believed to be due to an increase in the inter-molecular reactions which produce mesityl oxide, isopropyl ether, and the heavier ketones as was observed when the acetone partial pressure was increased. Since r_3 was only slightly affected in these experiments it may be concluded that no significant change in the surface concentration of adsorbed alcohol took place. Hence the effect of added acetone is most probably exerted on a sensitive acetone adsorption/desorption equilibrium condition as the course of catalysis is considerably modified. The secondary reactions and effects present a special interest for further study.

Raman and Infrared Spectra of Crystalline OF_2

J. TREMBLAY AND R. SAVOIE

Centre de recherches sur les atomes et les molécules et Département de Chimie, Université Laval, Québec, Québec

Received June 15, 1971

Raman and infrared spectra of crystalline OF_2 indicate that this solid is not centro-symmetric and contains at least two molecules per primitive cell, on sites of symmetry C_s or C_1.

Les spectres Raman et infrarouges de OF_2 cristallin indiquent que le solide n'est pas centro-symétrique et que la maille primitive contient au moins deux molécules, situées sur des sites de symétrie C_s ou C_1.

Introduction

The OF_2 molecule has been shown by electron diffraction (1) and microwave measurements (2, 3) to be of C_{2v} symmetry, with bond lengths and apex angle of 1.41 Å and 103°, respectively. The infrared spectrum of the gas has also been recorded (4–6). Band contours in the ν_1 (symmetric stretch) and ν_3 (asymmetric stretch) regions have shown that the OF_2 molecule is one of the few triatomic molecules for which $\nu_1 > \nu_3$. In the condensed states, only the Raman spectrum of the liquid has been reported so far (7), which is understandable in view of the corrosive nature of this compound and its low freezing point, 49.4 °K (8).

Our main aim in undertaking the present study was to gather information on the crystal structure of the solid for which no crystallographic data are as yet available. It was expected that this type of compound would be well suited for a spectroscopic investigation since it is not contaminated by isotopic species, except by $^{18}OF_2$ at a negligible concentration of 0.2%.

Experimental

The OF_2 used in our experiments was prepared by reacting gaseous F_2 (98% pure, Matheson Co., Ltd.) with a 3% aqueous solution of NaOH which was continuously changed in the reaction vessel. The evolved gas was first purified by bubbling through distilled water and then by trap-to-trap distillation (9). Bands from probable impurities, such as CF_4 and SiF_4, were not detected in our spectra.

The infrared spectra were recorded on a carefully calibrated Perkin–Elmer (model 621) spectrophotometer and the frequencies cited later are believed to be accurate to ± 1 cm^{-1}. The far-infrared spectrum of the solid in the region 20–200 cm^{-1} was obtained on a commercial interferometer (Research and Industrial Instruments Co., model FS-720) coupled to a Fourier transform computer (FTC-100), with a theoretical resolution of 1 cm^{-1} and a probable frequency accuracy of ± 1 cm^{-1}.

The spectra were recorded using a conventional liquid helium cryostat (10), with cesium iodide or silicon backing plate. A side arm was added to the bottom part of the cryostat, making it possible to deposit the gaseous samples through a Teflon cone which could be slided in and out by a selenoid coil. This technique insured more uniform film deposits on the window and prevented samples from condensing on other cold parts of the cryostat. The temperature, measured with a calibrated carbon resistor, was controlled within a few degrees by a Teflon plug which limited the amount of liquid helium reaching the copper block to which the backing plate was attached (10). Solid films of pure OF_2 were prepared by direct deposition of the sample from a trap at liquid nitrogen temperature. (The vapor pressure of OF_2 at 77 °K is 1.44 mm Hg (9).)

The Raman spectra were recorded on a Spex (model 1400) spectrometer equipped with an argon ion laser (CRL, model 52 A) and a cooled phototube detector (Star Tracker FW-130). This instrument was calibrated with a neon discharge lamp and the frequency accuracy is estimated at ± 1 cm^{-1}. The Raman spectra of solid OF_2 proved to be difficult to obtain because of the colored nature of this compound. (The liquid is yellowish brown whereas the solid still retains a light brown coloration.) No spectrum could be obtained using the 6328 Å of a He–Ne laser (Spectra Physics, model 125) at 70 mW output power. The argon ion laser gave weak Raman spectra, especially since the power output of the laser beam had to be kept quite low (~100 mW) because part of it was absorbed, resulting in local heating of the sample.

The liquid helium cryostat used for the Raman experiments, illustrated in Fig. 1, will be described in some detail since it worked rather well and it could be of general use. The upper part of this cryostat is of conventional design, with an outer section of brass, and the liquid nitrogen and helium vessels made from stainless steel sheets joined by Heliarc welds. The tail section, of Pyrex glass (50 mm diameter) with a flat window at the end, is joined to the main body through

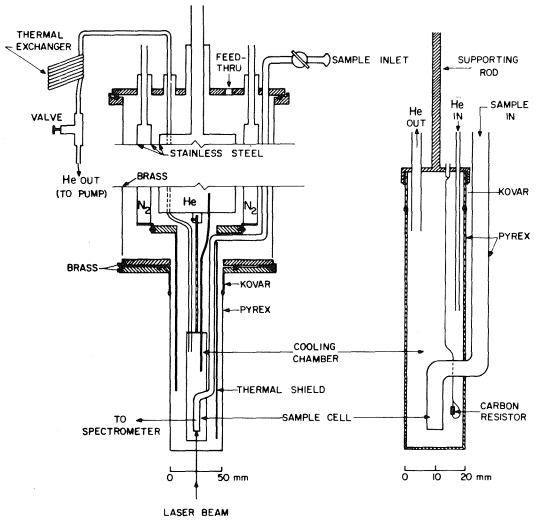

FIG. 1. Liquid helium cryostat for low-temperature Raman studies.

a Kovar seal. The copper thermal shield, bolted onto the bottom part of the liquid nitrogen pot, can be easily dismantled.

The main advantage of this cryostat is that the sample cell (of Pyrex, 6 mm diameter), as well as the sample inlet tube, contain no metal part, thus minimizing the danger of sample decomposition. The sample cell is soldered directly onto the glass cooling chamber (20 mm diameter). The temperature, measured by a carbon resistor near the sample cell, is controlled by the amount of liquid helium which is allowed to fall in the cooling compartment. When this chamber is filled with the refrigerant, the temperature of the sample is obviously close to 4.2 °K, but scattering of the laser beam occurs from the gas bubbles escaping from the liquid helium. Much better spectra can be obtained by restricting the flow of the refrigerant (this is done by partially closing the valve on the helium outlet tube) in such a way that it does not accumulate in the cooling chamber. However, the temperature of the sample is raised by a few degrees under these conditions.

Results and Discussion

The Raman and infrared spectra of crystalline OF_2 at ~10 °K are reproduced in Fig. 2 and observed frequencies are given in Table 1. Drastic changes occurred in the infrared spectrum upon annealing deposited samples by raising the temperature as near as possible to the melting point. This was particularly evident in the ν_3 region where the band at 823 cm^{-1} completely disappeared upon annealing, to be replaced by a sharp peak at 812 cm^{-1} and a very broad band extending from 815 to 850 cm^{-1}. In the ν_1 region, annealing caused each of the two components of the Fermi diad to split. In the Raman study, where the polycristalline solid was obtained by slowly cooling the melt, only minor changes in band intensities resulted from annealing the sample.

The most striking feature in the infrared spectrum of crystalline OF_2 is the broad band on the high-frequency side of the 812 cm^{-1} ν_3 peak. The fact that this band increases in relative intensity when the incident infrared beam was allowed to fall on the sample at non-normal incidence, suggested that it was due to reflection. To confirm this, we recorded the infrared reflection spectrum of a thick sample of solid OF_2, using an optical system similar to that described by Bessette and Cabana (11). A strong reflection band was indeed observed in the 815–850 cm^{-1} region. In the Raman spectrum, a sharp peak is observed at 845 cm^{-1}, its frequency being approximately coincident with the limit of the infrared reflection band. This band is too far away from the main ν_3 Raman doublet at 812/820 cm^{-1} to result from a factor-group splitting (12) of this vibration. We assign it to the longitudinal mode associated with the 812 cm^{-1} transverse vibration. We have already pointed out that transverse–longitudinal splittings are likely to occur in piezoelectric molecular crystals (13). The presence of this longitudinal mode in the Raman spectrum of solid OF_2 is a sure indication that this crystal is non-centrosymmetric (14). Furthermore, the fact that the 845 cm^{-1} Raman band occurs as a sharp peak, whose frequency remained unchanged with the various samples studied, indicates that the solid is, for reasons of symmetry or by accident, completely or nearly optically isotropic. This suggests that solid OF_2 has a cubic crystal structure.

The infrared and Raman spectra of crystalline OF_2 also give an indication as to the number of molecules per primitive cell in this solid. All of the fundamentals show at least two components (ν_1 and ν_2 in the infrared and ν_3 in the Raman), which can only result from a factor-group splitting since all these vibrations are nondegenerate in the free molecule. There are therefore at least two molecules per primitive cell in the crystal.

The far-infrared spectrum of crystalline OF_2 (Fig. 2) shows seven bands in the 40–90 cm^{-1} region, all of these having Raman-active counter-

parts with almost identical frequencies. Although the number of observed lattice fundamentals is lower than the maximum of nine permissible (for $k = 0$ transitions) if the primitive cell contains two molecules, we believe that the number of molecules per primitive cell in crystalline OF_2 is in fact larger than that. This belief is based on the fact that all of the predicted active lattice modes in an infrared or Raman spectrum are seldom observed, except when the number of bands is very small. In this case, for example, since one of the moments of inertia of the OF_2 molecule is about 6 times smaller than the other two (1–3), a librational mode with frequency $\sim 200\ cm^{-1}$ should give at least one peak in either the infrared or Raman spectrum. No such band could be detected. Furthermore, seven active lattice modes in the spectra of a crystal with two molecules per primitive cell would indicate a crystal of low symmetry, which is inconsistent with the behavior of the longitudinal mode associated with the ν_3 fundamental, as mentioned above.

Although vibrational spectra of crystalline solids can seldom be interpreted on the basis of a unique choice of site and unit-cell symmetries, they usually restrict the number of such possibilities (12, 15). In this case, it is found that the site symmetry cannot be C_2 or C_{2v}, since for any possible factor group chosen thereof the ν_1 and ν_2 fundamentals should appear as singlets in the infrared spectrum, contrary to what is observed. Similarly, we can deduce that the crystal structure is not monoclinic, triclinic, or trigonal if the site symmetry is C_s, and that it is not triclinic if the site symmetry is C_1.

It seems inappropriate at this point to pursue our analysis any further, for lack of sufficient information. However, if the crystal has a cubic structure, as was suggested earlier, then a combination of C_s site and T_d crystal symmetries would certainly explain our infrared spectrum. It predicts 8 lattice bands, doublets for ν_1 and ν_2, and a singlet or doublet for ν_3, depending upon which plane of symmetry of the molecule coincides with that of the site. This type of structure, with 12 molecules per primitive cell (16), should however result in a rather complex Raman spectrum: 17 lattice bands are then predicted, whereas 4 bands should be observed in the ν_1 and ν_2 regions, and either 2 or 4 in the ν_3 region (excluding longitudinal modes).

The Effect of Electric Fields on the Radiolysis of Acetylene, and the Mechanism of Cuprene Formation[1]

J. P. BRIGGS[2] AND R. A. BACK

Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received June 29, 1971

Gaseous acetylene at pressures of about 200 Torr was irradiated with γ-rays at doserates between about 10^{11} and 10^{12} eV/cc s, with and without an electric field applied. The deposition of cuprene on the bottom of the reaction vessel was markedly affected by the field, but the rate of cuprene formation as measured by the pressure decrease was unchanged. Examination of the cuprene deposit with an electron microscope showed it to consist of rather uniform spheres averaging about 3000 Å in diameter, with each containing an estimated 2×10^8 molecules of acetylene. The mechanism of cuprene formation is discussed, and it is suggested that it does not proceed through a direct polymerization of acetylene, but involves a secondary polymerization of polyene intermediates, in the gas phase and after their condensation in liquid droplets.

On a irradié de l'acétylène gazeux à des pressions d'environ 200 Torr avec des rayons-γ, à des vitesses de dosage se situant entre 10^{11} et 10^{12} eV/cc s, avec et sans l'application d'un champ électrique. La formation de dépôt de cuprène au fond du récipient de réaction était grandement affectée par la présence du champ, mais la vitesse de formation de cuprène telle que mesurée par la diminution de la pression, est demeurée inchangée. Un examen du dépôt de cuprène au microscope électronique a révélé que celui-ci consiste en sphères plutôt uniformes, d'un diamètre d'environ 3000 Å, contenant chacune un nombre estimé à 2×10^8 molécules d'acétylène. On discute du mécanisme de formation du cuprène et on suggère que celle-ci ne se déroule pas selon la polymérisation directe de l'éthylène, mais qu'elle implique plutôt une polymérisation secondaire d'intermédiaires polyènes, dans la phase gazeuse et après leur condensation dans les gouttelettes liquides.

Superficially, the radiolysis of acetylene appears to be a simple process. The only products of importance at moderate conversions are benzene and cuprene (a $(CH)_n$ polymer) in a ratio of about 1:4 in terms of C_2H_2 consumed. The *G*-value for acetylene disappearance is about 70, approximately independent of dose, doserate, acetylene pressure, and type of radiation. Despite this apparent simplicity and despite extensive studies of the system, the mechanism is not well understood (1–7). The basic problem is an overabundance of mechanisms, as it seems clear that ions, free radicals, and excited C_2H_2 molecules are all capable of initiating polymerization and benzene formation. The difficulty is in deciding which processes in fact are important in the actual radiolysis.

Electric fields, applied during radiolysis, have been used with some success in this laboratory and elsewhere as an aid in the elucidation of mechanism (8–12). It appeared that this technique might be useful in the acetylene radiolysis, in particular in assessing the respective roles of ions, radicals, and excited molecules.

Experimental

Acetylene was irradiated in a variety of cylindrical Pyrex vessels, typically 2 or 3 cm in diameter and 5 to 10 cm long. Electrodes were made of stainless steel or of graphite deposited on the glass surface, and were either parallel plates (at each end of the cylinder) or in a coaxial configuration. Dosimetry was based on measurements of saturation ion-currents in the reaction vessels, taking $W = 25.3$ eV/ion pair (13).

Acetylene (from Matheson) was thoroughly degassed in a mercury-free vacuum line, and acetone impurity was removed by distillation from a trap at −78 °C and passage through activated charcoal. Analysis by gas chromatography showed less than 30 p.p.m. of acetone remaining. In some experiments vessels were baked, filled with acetylene, sealed with a torch and removed from the vacuum line before irradiation. In others, the vessel, mounted in the Gamma-cell, was permanently attached to the vacuum line, and the irradiation was started by the admission of purified acetylene. In these experiments, pressure was measured during the irradiation with an accuracy of about ±10 m Torr, using a Texas Instruments quartz spiral gauge. Since irradiation times were typically several days and total fractional pressure changes only a few percent, careful measurement of small

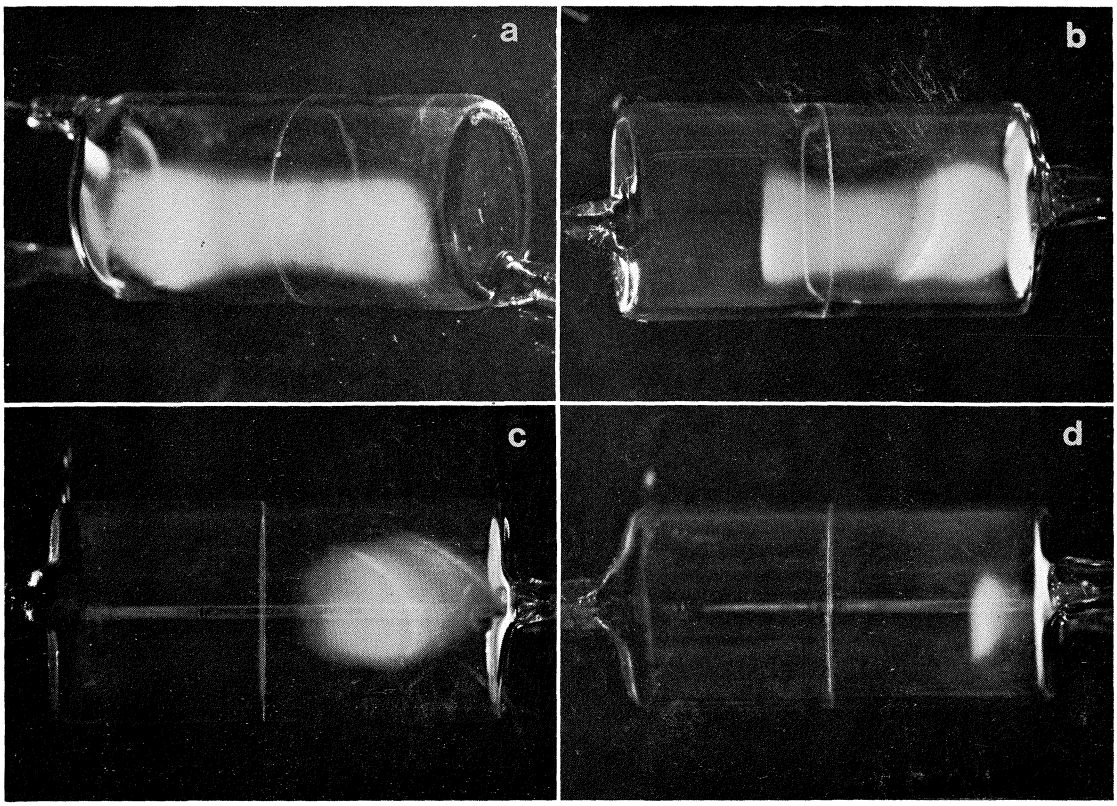

FIG. 1. The effect of applied fields on the deposition of cuprene. The anode is on the right: (*a*), no field; (*b*), 70 V, $i = 0.25\, i_{\text{saturation}}$; (*c*), 300 V, $i = 0.50\, i_{\text{saturation}}$; (*d*), 750 V, $i = 0.88\, i_{\text{saturation}}$.

changes in the temperature of the cell and connecting tubing during the experiments was essential.

Irradiations were carried out in one or the other of two AECL Gamma-cells loaded with about 500 and 9500 Ci of ^{60}Co, which with lead shields gave doserates ranging from about 10^{11} to 10^{12} eV/cc s at the acetylene pressures employed (~200 Torr).

Results

The results consist in essence of two apparently simple observations. The first was that an electric field had an obvious and marked effect on the deposition of cuprene. In the absence of a field, a thin white adherent deposit of cuprene became visible on the bottom surface of a horizontal cylindrical reaction vessel after some hours of irradiation. When a saturation voltage was applied during irradiation to parallel-plate electrodes at either end of the vessel, no such deposit of cuprene was observed, and a discoloration of the anode suggested formation of a thin film on its surface. With field strengths less than that required for saturation, the cuprene deposit did not disappear entirely, but was shifted progressively towards the anode as saturation was approached, with quite a sharp demarkation at the edge of the deposit. The photographs in Fig. 1 and the plot in Fig. 2 illustrate this behavior. These experiments were done with vessels 4.7 cm long and 2.1 cm diameter with parallel graphite electrodes at each end, acetylene pressure of 200 Torr, and a doserate of 10^{11} eV/cc s. At higher doserates, cuprene in the absence of a field was deposited less evenly, probably because of convection currents in the gas, and the effect of the field was less clear cut.

The second simple observation was that the presence of an electric field had virtually no effect on the rate of disappearance of acetylene as reflected by the change in pressure. Typical pressure–time plots are shown in Figs. 3 and 4. The more rapid initial decrease evident in the figures was shown to occur also in the absence of radiation and is presumably due to an adsorption

phenomenon which appeared to be complete in about 2 h. Figure 3 represents two separate experiments under similar conditions, with and without a saturation field applied; the straight lines drawn have identical slopes. Figure 4 represents a single experiment at higher doserate, in which a field was applied, removed for a time, and reapplied. The larger absolute scatter in these data reflects a poorer temperature control than in the later experiments shown in Fig. 3. It is clear from these figures that within the experimental accuracy of perhaps $\pm 5\%$, the rate of pressure change was unaffected by the field. Other experiments under a variety of conditions including applied fields of less than saturation, and well along the saturation plateau, just short of the ion-multiplication

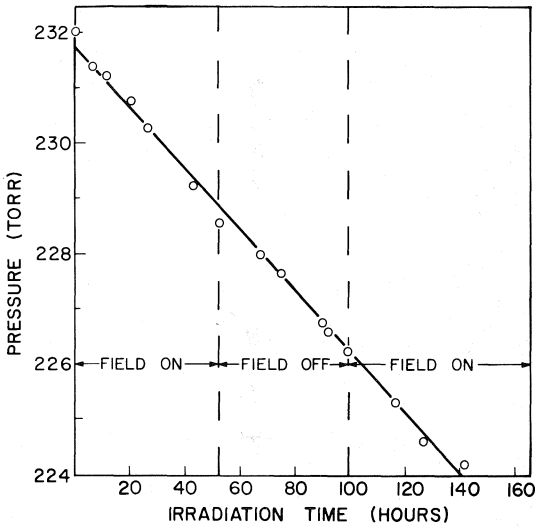

FIG. 4. Pressure–time plot for the radiolysis of acetylene.

region, also showed no effect on the rate of pressure change.

G-values for acetylene disappearance were evaluated from data such as those in Figs. 3 and 4. At an acetylene pressure of about 240 Torr and doserates of 1.1×10^{12} and 1.3×10^{11} eV/cc s, average values of $G(-C_2H_2)$ were about 90 and 125, respectively. This appears to confirm the increase in *G*-value at low intensity reported by Field (3).

Discussion

At first sight our two observations appear to be contradictory, with the first pointing to an ionic mechanism and the latter to a non-ionic one. Further consideration reveals that in fact neither observation permits any such definite interpretation. The shift of the cuprene deposit could have been caused by the action of the electric field on ionic precursors, or on cuprene particles themselves which became charged as a result of an ionic mechanism of polymerization. The particles could, however, equally well have acquired charge incidentally after polymerization by a non-ionic mechanism, as it is well known that small particles in the presence of ions or electrons readily become charged, so that the simple observation that the cuprene deposit was shifted by an applied field does not rule out a non-ionic mechanism of formation. Similarly, the lack of effect of a field on the rate of polymerization

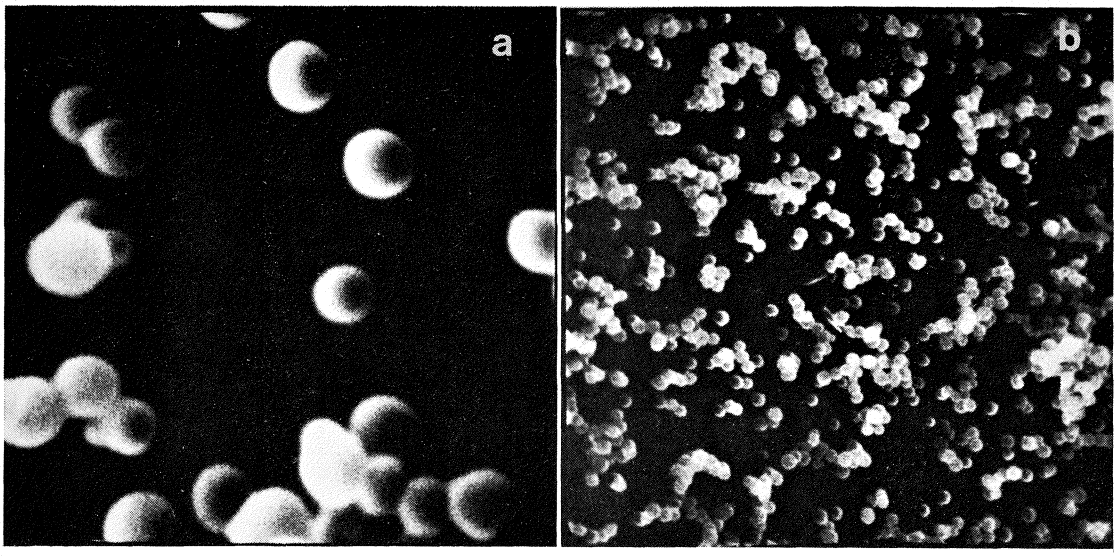

FIG. 5. Electron microscope photographs of cuprene formed in the radiolysis of acetylene. Magnifications about (*a*), 18 000; and (*b*), 3 500.

could be the consequence of a non-ionic mechanism, but is also compatible with a short-chain ionic polymerization in which chains were terminated before the ionic chain carriers could be removed to the electrodes by the field. Such behavior has been noted recently in the H_2–D_2 exchange in the presence of trace impurities (9) and the relatively low G-value for cuprene formation points to a short-chain process in the acetylene radiolysis.

The observation that electric fields approaching the ion-multiplication region caused no enhancement of the rate of polymerization indicates that low-lying excited states of acetylene do not make an important contribution to the reaction (*c.f.* Carmichael *et al.* (10)).

To gain further insight into the formation and behavior of the cuprene particles, photographs were taken with an electron microscope;[3] typical examples are shown in Fig. 5. These showed that cuprene was formed in spherical particles, fairly uniform in size, with an average diameter around 3000 Å. There were no apparent differences between particles formed in the presence and absence of an electric field or any dependence on the strength of the field. The uniform size and the lack of small particles is in accord with earlier studies of cuprene formed by α-radiation. The present photographs, however, show few connecting "stems" nor any indication that the particles were viscous liquid rather than solid, both features of the earlier studies (1, 14).

Some useful deductions can be made from the size of the particles. Assuming a typical solid hydrocarbon density of 0.7, the average particle mass is about 1×10^{-14} g, corresponding to a molecular weight of 6×10^9, and containing 2.3×10^8 molecules of C_2H_2. Taking $G(-C_2H_2)$ for cuprene formation = 80 and W = 25.3 eV/ion pair, then $M/N(-C_2H_2)$ = 20 molecules/ion-pair, so that only one cuprene particle was formed for every 10^7 ion pairs. This means that unless each particle carried an enormous multiple charge (which seems very unlikely), the cuprene particles represented a completely negligible fraction of the charge carriers in the system. This is supported by our observations that ion current measurements with both steady and intermittent fields showed no evidence for massive ions of low mobility. Lifetime measurements with the intermittent field in fact indicated that most of the negative charge carriers in the system were free electrons (15).

The simplest and most plausible explanation of the effect of the field on the deposition of cuprene appears to be a competition between the sedimentation of the particles due to gravity and the

horizontal drift in the electric field. Horizontal and vertical displacements should have been equal when the force on the particle due to gravity equalled that of the electric field, which for a particle with the estimated average mass of 1×10^{-14} g and a single electronic charge should have occurred at a field strength of about 6 V/cm. Assuming that motion of the particles before attaining full size and acquiring charge was negligible, then the average horizontal drift during sedimentation at this field strength should have been about equal to the radius of the vessel, and at higher field strengths should have been proportionately larger. Calculated average horizontal drift is shown as a function of field strength in Fig. 2, together with the observed shift of the edge of the cuprene deposit. The latter is somewhat less than the former at low field strengths although considering the rough and ready nature of our calculations the agreement is not bad. As the field strength is increased, the observed shifts fall much below the calculated ones. One possible explanation of these observations is that the cuprene particles were initially neutral, and appreciable sedmentation occurred before charge was acquired by capture of a negative ion or electron. With increasing field strength, concentration of ions and electrons would be reduced by their removal at the electrodes, so that charge acquisition would be slower and the field therefore less efficient in shifting the particles. It is interesting that in a recent study of carbon formation in flames it was concluded that most of the carbon particles were initially neutral and acquired charge by collision with ions; it was also concluded that the particles each carried only a single electronic charge (16).

While the present results do not permit a decision between an ionic and a non-ionic process, some more general conclusions may be drawn about the mechanism of cuprene formation. A number of facts and observations from this and previous work point to a sequence of reactions rather than a simple direct polymerization of acetylene, and the following 4-stage mechanism is suggested:

(1) A primary polymerization of acetylene to form polyunsaturated hydrocarbons with molecular weights in the C_4 to C_{20} range. Taking a reasonable value of G(chain initiation) = 4, and $G(-C_2H_2) = 80$, appreciable chain transfer to the C_2H_2 monomer would be required to give such low molecular weights; this seems not unlikely. There is also evidence, in the relatively low G-value and its lack of a strong dependence on doserate and acetylene pressure, for some sort of self-termination of the kinetic chain, perhaps by cyclization or other rearrangement of growing polyradicals or ions to yield stabilized unreactive species.

(2) A secondary polymerization of the polyenes formed initially, which would tend to be much more reactive than acetylene. They would rapidly attain a low steady-state concentration, with their rate of formation remaining rate-controlling and the polymerization of acetylene and the polyene intermediates going on virtually as a co-polymerization. In this view of the radiolysis, benzene becomes simply one of a number of unsaturated intermediates, detectable in appreciable amounts because of the ease of formation of the aromatic ring and its relatively low reactivity. Even benzene disappears rapidly by secondary polymerization at quite low conversions (1).

(3) A physical condensation of the polyenes formed by primary and secondary polymerization. The spherical shape of the cuprene particles strongly suggests initial condensation as liquid droplets, which would require a carbon number of about 20 to permit condensation as a liquid at room temperature and a vapor pressure low enough for condensation at the very low conversions at which cuprene is observed.

(4) Rapid and extensive polymerization and cross-linking in the liquid polyene droplets, induced by radiation and leading to the final intractable cuprene product.

While we have written 4 stages in the mechanism, it should be emphasized that all four will proceed simultaneously under steady-state radiolysis. Previous authors have generally assumed, at least tacitly, a direct polymerization of acetylene to cuprene, and have tended to talk in "either-or" terms about an ionic or a non-ionic mechanism. In the more complex system that we are suggesting, it seems probable that both ions and free radicals might play a part, although one or the other might be predominant in a particular stage of the reaction. There are obvious tests of our proposed mechanism. In particular, it should be possible to detect low concentrations of polyene intermediates and to suppress cuprene formation by the removal of such intermediates at sufficiently low conversions. Experiments to do so are planned.

Fermi Resonance of Infrared Vibrations in the —NH_2 Groups of Polynucleotides

G. ZUNDEL, W. D. LUBOS, AND K. KÖLKENBECK

Physikalisch-Chemisches Institut der Universität Muenchen, Sophienstrasse 11, 8 Muenchen 2, Germany

Received June 24, 1971

The —NH_2 group causes an intensive band pair in the i.r. spectra of DNA, r.RNA, poly (A+ U), and poly (G + C). One band occurs at 3330, another at 3180 cm^{-1}. This band pair is due to the NH stretching vibration of the hydrogen-bonded NH group as well as to the harmonic vibration of the —NH_2 bending vibration, whereby these vibrations are coupled via Fermi resonance. This follows on comparison with papers on amines. The weak shoulder in the 3500–3400 cm^{-1} range is to be assigned to the stretching vibrations of the non hydrogen-bonded NH groups. The doublet structure disappears to a large extent in the denaturated DNA, since the strength of the Fermi resonance depends on the strength of the hydrogen bonds and the hydrogen bonds are of differing strength, due to the bending and stretching. The relative intensities of the two bands are interchanged in the corresponding band pair of the —ND_2 groups, for which an explanation can also be given.

Le groupe —NH_2 provoque une paire de bandes intense dans les spectres i.r. du DNA, du r.RNA, du poly (A + U) et du poly (G + C). Une bande apparaît à 3330 et l'autre à 3180 cm^{-1}. Cette paire de bandes est due à la vibration de valence du groupe NH en liaison hydrogène aussi bien qu'à la vibration harmonique de déformation de —NH_2, ces vibrations étantes couplées grâce à la résonance de Fermi. Cela découle de la comparaison avec des publications sur les amines. Le faible épaulement dans la région 3500–3400 cm^{-1} doit être attribué à la vibration de valence des groupes NH pas liés en liaison hydrogène. La structure de doublet disparaît en cas de DNA dénaturé parce que l'intensité de la résonance de Fermi dépend de la force des liaisons hydrogène et les liaisons hydrogène sont de force différente à cause d'élongation et de déformation. Les intensités relatives des deux bandes s'interchangent dans la paire de bandes en cas des groupes —ND_2. Une explication de ce phénomène peut être également donnée.

The explanation of the splitting up of the bands of the —NH_2 group of the polynucleotides in the 3600–3000 cm^{-1} range is as yet most unsatisfactory. We therefore plotted spectra of films of calf thymus DNA, ribosomal RNA, poly (A + U)[1] and poly (G + C)[1] in this range. The vibrations of the —ND_2 groups of these polynucleotides were also investigated for *N*-deuteration. These spectra are shown in Fig. 1. DNA, poly (A + U) and poly (G + C) occur as a double helix under the conditions chosen (1) (see also Experimental). A considerable number of the bases are paired, too, with the r.RNA, for on warming, a high degree of u.v.-hyperchromicity (2, 3) is observed.

Broad bands, one at about 3330 and one at about 3180 cm^{-1} are observed with these polynucleotides. This band pair occurs again with interchanged relative intensities in the *N*-deuterated samples at about 2500 and 2350 cm^{-1}.

[1]The abbreviations used, A, U, G, and C, stand for the salts of polyadenylic acid, polyuridylic acid, polyguanylic acid and polycytidylic acid.

A weak shoulder is found on the slope of this band complex at about 3450 cm^{-1}.

Tsuboi (4) assigns these bands to the antisymmetric and symmetric stretching vibrations of the —NH_2 groups. He refers here to studies by Kyogoku *et al.* (5) of crystals containing 1-methylthymine and 9-methyladenine. This is a possible explanation in the case of these crystals, since according to X-ray investigations (5), both NH groups of the —NH_2 group of the 9-methyladenine are bound in the same way to O atoms of the C=O groups of the 1-methylthymine.

In DNA and the polynucleotides investigated, one NH group of the —NH_2 groups is free, that is, not linked by a hydrogen bond. Kyogoku *et al.* (6) as well as Miller and Sobell (7) investigated model substances such as 9-methyl- and 9-ethyladenine in $CDCl_3$. Here they find bands at 3517 and 3416 cm^{-1} in diluted solutions and assign these to, respectively, the antisymmetric and symmetric stretching vibrations of —NH_2 groups not bonded by hydrogen bonds. A comparison with our findings shows that the weak shoulder in the 3500–3400 cm^{-1} range should be assigned to

the NH stretching vibration of the NH groups not bonded by a hydrogen bond.

Which vibrations, however, cause the intensive band pair? In the case of the model substances, NH stretching vibrations of hydrogen-bonded NH groups in the 3400–3150 cm^{-1} range are observed (6, 7). It could be assumed, accordingly, that both bands are caused by NH stretching vibrations of different bases. This assignment, however, is contradicted by the findings shown in Fig. 2. The spectrum shown by the broken line is that of DNA and the spectrum shown by a continuous line is that of DNA whereby the amine groups occurred as —NHD groups. In the presence of the —NHD groups, only a broad band at about 3315 cm^{-1} is observed instead of the two bands (3333 and 3183 cm^{-1}).[2] If both bands were caused by NH stretching vibrations of different bases, the band pair would also have to be observed in the spectrum of DNA with —NHD groups.

Comprehensive papers by Wolff *et al.* (8–12*a*) give the key to the assignment of this band pair. These authors investigated the hydrogen bonds of primary amines with tertiary acceptor amines. They found a band pair which is in complete conformity with the one observed by us. Wolff *et al.* could demonstrate that this band pair comes into being through coupling of the symmetric NH stretching vibration with the harmonic vibration of the $—NH_2$ bending vibration. The harmonic vibration of the $—NH_2$ bending vibration obtains its intensity through Fermi resonance from the stretching vibration.

We can explain the band pair in the case of the polynucleotides analogously to that in the case of amines. We must only substitute the expression symmetric NH_2 stretching vibration in Wolff's explanation by stretching vibration of the hydrogen-bonded NH group and antisymmetric stretching vibration by stretching vibration of the non hydrogen-bonded NH group.

With the polynucleotides the NH bending vibration is observed in the range 1700–1600 cm^{-1}. This vibration, however, is coupled with a ring vibration and shifts this somewhat towards larger wave numbers. Thus, for instance, in the case of poly-A, when this is *N*-deuterated and thus $—ND_2$ groups are present instead of the $—NH_2$ groups, only the ring vibration Py 8a at 1630 cm^{-1} is found. When the $—NH_2$ groups are present, however, this band is shifted towards 1655 cm^{-1} and a second band is observed at 1610 cm^{-1}. Finally it should be pointed out that the coupling of the $—NH_2$ bending vibration with other ring vibrations of the base residue just like the coupling between CO stretching vibrations (12*b*), depends on the formation of the secondary structure. For when the secondary structure has formed, the transition moment of the $—NH_2$ bending vibration occurs preferably in the base ring plane. This is in part the cause of the secondary structure sensitivity of the bands at about 1700 cm^{-1}. The $—ND_2$ bending vibration should be observed at about 1210 cm^{-1}. This band is, however, masked by the intensive antisymmetric stretching vibration of the $\diagdown PO_2^- \diagup$ groups.

Hence, with the polynucleotides the band pair in the range 3400–3150 cm^{-1} is caused by the NH stretching vibration of the hydrogen-bonded NH group of the $—NH_2$ group and by the harmonic vibration of the bending vibration of the $—NH_2$ group thus coupled by Fermi resonance. The finding that only one band occurs instead of the band pair in the presence of —NHD groups (Fig. 2) is accordingly quite comprehensible, for now the harmonic vibration of the bending vibration is in a different position and can thus no longer couple with the stretching vibration. The weak band of the stretching vibration of the free NH groups, expected at about 3450 cm^{-1}, is not observed in the spectrum in the presence of the —NHD groups for this band merges with the slope of the now more intensive stretching vibration of the hydrogen-bonded NH groups.

According to Wolff and Horn (11, 12*a*), the intensity ratio in the band pair depends on the strength of the hydrogen bonds. The low-frequency band becomes more intensive, the stronger the hydrogen bond. This fact, that the strength of the Fermi resonance and thus the splitting up and intensity ratio depend on the strength of the hydrogen bond, explains the finding (Fig. 3) that

[2]The band observed at 3108 cm^{-1} in the spectrum of the sample in which the amino groups were present as —NHD groups is the stretching vibration of the CH groups of the base residues. This is all the more intensive here since the layer is approximately 10 times thicker than with the sample with the $—NH_2$ groups (see Experimental). With this sample the stretching vibrations of the aliphatic CH groups at 2957 and 2885 cm^{-1} also occur correspondingly more intensively.

with the denaturated DNA, almost no structure of the band complex can be observed. In the denaturated DNA, the hydrogen bonds vary in strength due to the stretching and bending. Thus the coupling between both vibrations also varies in strength. The doublet, therefore, becomes one broad band.

On transition from the $—NH_2$ to the $—ND_2$ band pair (Fig. 1) the two bands often interchange their intensities with the polynucleotides, in conformance with the findings with the amines. This could be caused by the fact that the stretching vibrations and the harmonic vibration of the bending vibrations shift at different degrees of strength on transition from H to D, *i.e.*, that these have somewhat different isotopic factors. Each band would then obtain, respectively, more or less stretching or bending vibration character.

Two bands at about 3380 and 3220 cm^{-1} (Fig. 3*b*) are also found with poly-U, although the latter possesses no $—NH_2$ groups. Here a different explanation applies. According to Miller and Sobell (7), the band of the stretching vibration of the free NH groups is observed at 3380 cm^{-1} with cyclohexyluracil in $CDCl_3$, whereas that of the hydrogen-bonded NH group occurs at 3180 cm^{-1}. With poly-U the band at about 3220 cm^{-1} can accordingly be assigned to the stretching vibration of the hydrogen-bonded NH groups, whereas the band at about 3380 cm^{-1} is the stretching vibration of non hydrogen-bonded NH groups, which hence do not interact so definitely with their environment. The extreme broadening of these bands is due to the fact that poly-U is present in coiled conformation (1).

Experimental

The synthetic polynucleotides were obtained by Boehringer, Mannheim (poly A, U, C), by Miles, Elkhart, Indiana (poly G), and the calf thymus DNA by theWorthington Biochemical Corporation, Freehold, N.J. The RNA is a mixture of RNA with the sedimentation constants 16S and 23S. It is produced according to the phenol extraction method (13) from escherichia coli ribosomes. Poly (A + U) and poly (G + C) were made of equimolar mixtures of aqueous solutions of the individual components. In the case of poly (G + C), the mixtures had to be tempered for 6 h at 50 °C.

Since the danger exists with DNA that the latter denaturates in distilled water already at room temperature, some samples were dried with excess salt. The excess salt was removed by repeated washing of the film with alcohol. The i.r. spectra did not differ from the samples whereby the excess salt was removed by dialysis against distilled water at 4 °C before drying. The paper by Auer and Alexandrowicz (14) provides further confirmation of the fact that under these conditions no denaturation takes place. These authors found no hyperchromicity at all in the u.v. below 20° in the case of calf thymus DNA at a concentration of 10^{-2} mol/l ($\approx$3.5 mg/ml) in an ion-free milieu. Since the DNA concentration was never less in our experiments, no denaturation occurred.

The films were dried on sample supports of Ge as described in (15) and subsequently subjected to spectroscopic investigation in the cells described in (16, 17). The spectra were plotted with photospectrometer type 221 and 325, of the Perkin–Elmer Company, Bodenseewerk, Ueberlingen, W. Germany.

In order to study the DNA with —NHD groups the film was treated with water vapor of a saturated aqueous $BaCl_2$ solution (90% D_2O + 10% H_2O). In this way approximately 10% —NHD was obtained in addition to a large number of $—ND_2$ groups and very few $—NH_2$ groups. Since in this case the number of the NH groups is considerably smaller, the film must be approximately 10 times as thick as for customary investigations, which is demonstrated by intensive CH stretching vibrations.

Ring–Chain Tautomerism of Hydroxyketones

JOSEPHINE E. WHITING[1] AND J. T. EDWARD
Department of Chemistry, McGill University, Montreal, Quebec

Received February 10, 1971[2]

A study of the u.v., i.r., and n.m.r. spectra of 5-hydroxy-2-pentanone and of 6-hydroxy-2-hexanone has shown that in most organic solvents there is a slight preference for the open-chain form of the hydroxyketone over the cyclic hemiketal. Increase in temperature and in polarity of solvent further favors the open-chain tautomer; in water there was no evidence of any cyclic form.

L'étude des spectres d'absorption i.r., u.v., et r.m.n. des composés 5-hydroxy-2-pentanone et 6-hydroxy-2-hexanone a montré que dans la plupart des solvants organiques la forme ouverte de l'hydroxycétone est légèrement préférée à la forme cyclique de l'hémicétal. L'augmentation de la température ainsi que de la polarité du solvant favourise l'existence de ces composés sous la forme ouverte, et dans l'eau on ne remarque que la forme ouverte.

Canadian Journal of Chemistry, 49, 3799 (1971)

It has long been known that γ- and δ-hydroxyaldehydes and ketones can react either as the straight-chain form or as the cyclic hemiacetal or hemiketal (1, 2), and an equilibrium between these forms has been assumed. However, it is only fairly recently that equilibrium constants for some of these examples of ring-chain tautomerism have been measured. Thus Hurd and Saunders (3) showed, from measurements of the u.v. absorption, that in 75% aqueous dioxane 4-hydroxybutanal and 5-hydroxypentanal exist predominantly as the cyclic hemiacetals, containing only 11.4 and 6.1% respectively of free aldehyde. (It is likely that 3–4% of the hydrated aldehyde (4) is also present.)

Substitution of the methylene hydrogens of these ω-hydroxyaldehydes by hydroxyl or hydroxymethyl groups gives the common aldopentoses and hexoses, which are known to be present in solution almost wholly in the cyclic form (5). This is to be expected on conformational grounds (6*a*, 7). The cyclic form can also be favored by being fused to other rings (8).

Although equilibrium constants have been measured for the ring–chain tautomerism of some complex hydroxyketones (*e.g.* α-(β-hydroxyethyl)-aminodesoxybenzoins (9)) and related compounds (10, 11), values for the simple hydroxyketones have been lacking. The present paper records the equilibrium constants for the ring–chain tautomerism (eqs. 1 and 2) of two of

[1] 
1 **2**

[2] 
3 **4**

the simplest possible hydroxyketones, 5-hydroxy-2-pentanone (**2**) and 6-hydroxy-2-hexanone (**4**), and the effects of temperature and solvent polarity on these values. Additionally, we have looked for the possible ring–chain tautomerism of their 2,4-dinitrophenylhydrazones **5** and **6** (eqs. 3 and 4).

[3] 
5

[4] 
6

Cyclic structures have been postulated for the phenylhydrazones of some pyranoses (12) and for the 2,4-dinitrophenylhydrazone of a steroidal δ-hydroxyaldehyde (8), and a ring–chain tautomeric equilibrium has been demonstrated for certain hydroxyhydrazones (10).

Experimental

The i.r. spectra were recorded with Perkin–Elmer Model 337 and 257 spectrophotometers for routine, and with Model 521 spectrophotometer for quantitative work. The n.m.r. spectra were recorded with a Varian A-60 spectrophotometer and u.v. spectra with a Unicam SP800 spectrophotometer equipped with a temperature-controlled cell block. Analyses were done by Dr. C. Daesslé of Montreal and Dr. A. Bernhardt of Elbach über Engelskirchen, West Germany.

Materials

Starting materials were commercial products. Wherever possible spectrograde solvents were used. For the u.v. spectra these were cyclohexane, dioxane, acetonitrile, carbon tetrachloride, chloroform, and methanol. Absolute ethanol, 95% ethanol, freshly distilled water, and freshly distilled reagent grade dimethylsulfoxide, kept over Linde Molecular Sieves Type 3A, were also used. Spectrograde carbon tetrachloride was used as solvent for the quantitative i.r. measurements. Deuterated solvents for n.m.r. were obtained from Stohler Isotopes or Merck, Sharpe, and Dohme.

5-Hydroxy-2-pentanone (2)

4,5-Dihydro-2-methylfuran (1.0 g) was refluxed for 45 min in 0.02 *N* hydrochloric acid (40 ml) until the solution was homogeneous. The solution was cooled and saturated with anhydrous potassium carbonate. The oil that separated was extracted with ether (5 × 20 ml). The combined ether extracts were dried over anhydrous sodium sulfate, filtered, and evaporated at reduced pressure at room temperature to give a pale yellow liquid (10.9 g, 90%). This product was distilled twice at 10^{-3}mm pressure and a bath temperature of 35°, and condensed on a cold finger cooled by Dry Ice – ethanol. The distillate was a clear colorless liquid, ν_{max}(neat) 3440 (ν O—H), 1720 (ν C=O), 1170 (ν C—O of **1**), and 1075 cm^{-1} (ν C—O of **2**).

Anal. Calcd. for $C_5H_{10}O_2$: C, 58.8; H, 9.9. Found: C, 58.6; H, 9.7.

The 2,4-dinitrophenylhydrazone **5**, recrystallized twice from ethanol and dried at room temperature and reduced pressure, had m.p. 150–151°, ν_{max}(KBr) 3500 (ν O—H), 3330 (ν N—H), 1625 (ν C=N), and 1130 cm^{-1} (ν C—O); λ_{max}(EtOH) 362 nm (ε 21 000), λ_{max}(acetone) 366 nm (ε 20 000); n.m.r. in DMSO-d_6: 2.1 (s, 3H, CH_3), 7.7–9.0 δ (m, 3H, Ar).

Anal. Calcd. for $C_{11}H_{14}N_4O_5$: C, 46.8; H, 5.0; N, 19.9. Found: C, 46.6; H, 5.2; N, 20.2.

6-Hydroxy-2-hexanone (4)

The hydroxy-ketone was prepared in similar fashion, in 90% yield, by hydrolysis of 2-methyl-5,6-dihydropyran-3-carboxylic acid (m.p. 118–119°, lit. 119° (1)), obtained by the method of Perkin (1). The product was a clear colorless liquid, ν_{max}(neat) 3430 (ν O—H), 1725 (ν C=O), 1095 (ν C—O of **3**), 1045 cm^{-1} (ν C—O of **4**).

Anal. Calcd. for $C_6H_{12}O_2$: C, 62.0; H, 10.4. Found: C, 62.2; H, 10.5.

The 2,4-dinitrophenylhydrazone **6**, recrystallized twice from ethanol and dried at room temperature and reduced pressure, had m.p. 94–95° (lit. 96–97° (13)), ν_{max}(KBr) 3460 (ν O—H), 3330 (ν N—H), 1618 (ν C=N), 1595 (Ar) and 1110 cm^{-1} (ν C—O); λ_{max}(EtOH) 362 nm (ε 21 000), λ_{max}(acetone) 366 nm (ε 20 000); n.m.r. in DMSO-d_6: 2.1 (s, 3H, CH_3), 7.8–9.0 δ (m, 3H, Ar).

Anal. Calcd. for $C_{12}H_{16}N_4O_5$: C, 48.6; H, 5.4; N, 18.9. Found: C, 48.7; H, 5.3; N, 19.1.

2-Methoxy-2-methyltetrahydrofuran (7)

The compound was prepared by the reported method (14) and was a colorless liquid boiling at 115–116° (lit. 114.5° (14)), ν_{max}(neat) 2849 (C—H of OMe), 1075 (ν C—O), and 1035 cm^{-1} (ν C—O); n.m.r. in CCl_4: 1.35 (s, 3H, CH_3), 3.1 δ (s, 3H, CH_3O); end absorption only in the u.v.

Anal. Calcd. for $C_6H_{12}O_2$: C, 62.0; H, 10.4. Found: C, 62.1; H, 10.3.

5-Ethoxy-2-pentanone (8)

This compound was prepared by reported methods (15). The colorless liquid, b.p. 169–170° (lit. 170–171° (15)), was purified by v.p.c. on an Aerograph 705 Autoprep with 1/12 effluent splitter. The column consisted of 30% Se-30 on Chromosorb W, 20 ft aluminum, 3/8 in. d; H_2 flow 25 ml/min, N_2 flow in detector 25 ml/min, N_2 flow in collector 300 ml/min; column temperature 175°, injector 215°, detector 250°. The liquid had ν_{max}(neat) 2875 (C—H of OEt), 1721 (ν C=O), and 1120 cm^{-1} (ν C—O); λ_{max}(cyclohexane) 278 nm (ε 17.0), λ_{max}(EtOH) 273 nm (ε 19.5), λ_{max}(H_2O) 265 nm (ε 24.6); n.m.r. in CCl_4: 1.1 (t, 3H, CH_3 of OEt), 1.8 (m, 2H, CH_2), 2.1 (s, 3H, CH_3), 2.5 (t, 2H, CH_2), 3.35 (t, 2H, CH_2), 3.4 δ (q, 2H, CH_2).

Anal. Calcd. for $C_7H_{14}O_2$: C, 64.4; H, 10.8. Found: C. 64.6; H, 10.6.

The 2,4-dinitrophenylhydrazone of **8**, recrystallized twice from ethanol and dried at reduced pressure, had m.p. 155–156°, ν_{max}(KBr) 3320 (ν N—H), 1628 (ν C=N), 1595 (Ar) and 1135 cm^{-1} (ν C—O); λ_{max}(EtOH) 362 nm (ε 21 000), λ_{max}(acetone) 366 nm (ε 20 000); n.m.r. in DMSO-d_6: 1.2 (t, 3H, CH_3 of OEt), 2.1 (s, 3H, CH_3), 7.8–9.0 δ (m, 3H, Ar).

Anal. Calcd. for $C_{12}H_{16}N_4O_5$: C, 55.3; H, 6.4; N, 9.9. Found: C, 55.5; H, 6.4; N, 9.8.

Analytical Procedures

For i.r. studies, the intensities of the carbonyl absorption at 1721 cm^{-1} of an equilibrated solution (0.005 to 0.04 *M*) of **1** ⇄ **2** in carbon tetrachloride were compared with those of a standard solution of compound **8** (compound **7** had no absorption in this region) at 22 °C.

For n.m.r. studies, 1–2 *M* solutions of **1** ⇄ **2** and **3** ⇄ **4** in carbon tetrachloride, cyclohexane-d_{12}, chloroform-*d*, acetone-d_6, ethanol-d_6, acetonitrile-d_3, dimethylsulfoxide-d_6, deuterium oxide, and formamide (for **1** ⇄ **2** only), were equilibrated at 37 ± 0.5° for 5 h (equilibrium of most samples was reached within a few minutes, in contrast to the equilibrations reported by Hurd and Saunders (3)). The spectra were recorded with probe temperature 37 ± 1°, sweep width 250 Hz. At least duplicate samples of each concentration and solvent were recorded, and the integration of each spectrum was an average of five scans. Relative concentrations of the cyclic and open-chain forms were calculated from the integrations of the two singlet methyl peaks, the one at lower field (δ_c) having a value close to that of the model compound 8 and hence

7 **8**

being assigned to the open-chain form, the one at higher field (δ_r) having a value close to that of C—Me of model **7**, and hence being assigned to the ring form. Some values of the chemical shifts δ_c and δ_r, in Hz downfield from tetramethylsilane as an internal standard, are recorded in Tables 1 and 2,[3] along with the percentage of the open-chain form obtained from n.m.r. studies.

For the u.v. study, 0.02 to 0.05 *M* solutions of **1** ⇄ **2** and **3** ⇄ **4** were equilibrated in water baths maintained at 15.0 ± 0.1, 24.8 ± 0.1, and 50.1 ± 0.1°; the temperatures of samples in the cell block (*i.e.*, the temperatures at which the spectra were recorded) were 15.4 ± 0.1, 25.0 ± 0.1, and 49.8 ± 0.2°. Samples were equilibrated for 5 h (15 min was in fact enough for most samples). The equilibria were very mobile, and no acid was required to catalyze the reaction. The hydroxyketones and model compound **8** had a band in the region 265–280 nm, depending on the solvent or solvent mixture. Compound **7**, a model for the cyclic forms, had no appreciable absorption at these wavelengths. The extinction coefficients of the hydroxyketones were compared with those of compound **8** in each solvent and solvent mixture, at each temperature. Results are recorded in Tables 1–6. At least two runs, and usually three or four, were made for each determination, and results were usually reproducible to within about 1%.

[3]In most of the solvents of Table 1 chemical shifts were found to be somewhat variable, presumably because of concentration and other effects, and are not recorded.

Results and Discussion

There are two diastereomeric conformations of the cyclic tautomers **1** and **3**; the chain tautomers may exist in a large number of different conformations, only one of which is shown in Scheme 1.

The difference in the free energy content **1***a* and *b* is probably small. The five-membered ring is quite flexible (16), and this prevents calculations

of interaction energies by the methods applicable to the more rigid chair form (6*a*) of cyclohexane. On the other hand, structure **3***a* (OH axial) should be considerably favored over **3***b* because of the anomeric effect (17), and because of the greater size of the methyl group (6*b*).

Inspection of the n.m.r. spectra of the mixtures of compounds **1** ⇄ **2** and **3** ⇄ **4** showed only two methyl signals, one for the open-chain keto form (at lower field) and one for the cyclic form. Evidently the conformational equilibrium between the cyclic forms is fast so that only a single weight average absorption is observed (6*c*). The percentages (at 37°) of the open-chain forms **2** and **4** in different solvents, calculated from the integrated areas of the different methyl signals, are given in Tables 1 and 2, respectively. In these tables are shown also the percentages (at 25°) in these solvents calculated from the u.v. absorption of the tautomeric mixtures; the lower temperature should increase the amount of the cyclic form by about 1–1.5% (see below). It is evident that the results from the two different methods are in rough agreement. Furthermore, they agree roughly with the result obtained by i.r. spectroscopy, which showed 57.7 ± 0.5% of **2** present at 22° in the mixture **1** ⇄ **2**. Because of its greater convenience, the u.v. method was used exclusively to determine the percentages of the open-chain tautomers in aqueous-organic solvents of varying composition (Tables 3, 4, and 5).

It is apparent that the hydroxyketones **2** and **4** show a much smaller tendency to cyclize than do the analogous hydroxyaldehydes studied by Hurd and Saunders (3). This is to be expected, from the lesser reactivity of ketones as compared to aldehydes.

The extent of cyclization is greatly affected by

the nature of the solvent, but cannot be correlated with any of the common measures of solvent polarity. This can be seen by an inspection of Tables 1 and 2, in which the solvents (other than the neat hydroxyketone) are arranged in order of increasing dielectric constant ε: on going from cyclohexane (ε ~ 2) to acetonitrile (ε = 37.5) the percentage of the keto form remains almost constant. Other measures of solvent polarity, such as Kosower's Z values (18) or Dimroth's E_T values (19) (shown in Table 1), are equally poor in correlating with the equilibrium constant: in particular, none would predict the special effect of water, and to a much lesser extent of dimethyl sulfoxide, in stabilizing the keto form. This effect is shown also in mixtures of water with organic solvents (Tables 3–5 and Fig. 1): the proportions of open-chain keto forms **2** and **4** increase rapidly with increasing proportion of water and are approximately 100% in pure water.[4] While water has the highest Z and E_T values (but not the highest dielectric constant) of the solvents in Tables 1 and 2, quantitatively its effect is out of line with these values, and stabilization of the hydroxyketones **2** and **4** by some specific solvation might seem to be indicated. Water is known to hydrogen-bond fairly strongly to the carbonyl group, but so (albeit less strongly) do methanol and ethanol (20), which are shown in Tables 1 and 2 to be comparatively ineffective in stabilizing the hydroxyketo form.

Increase in temperature favors the open-chain over the cyclic form (Table 6 and Figs. 2 and 3), indicating that the reactions **1** → **2** and **3** → **4** are endothermic (ΔH is positive: Table 7). The enthalpy and entropy changes for these reactions become much greater in the more aqueous solvents (Table 7), perhaps because of greater solvation effects. However, the solvation of **2** and **4** (in preference to **1** and **3**) would cause a decrease in entropy, and the reactions **1** → **2** and **3** → **4** are accompanied by large increases in entropy. Any explanation of the remarkable effects of water in favoring the hydroxyketo form must at the moment be highly speculative.

The furanose forms of sugars have generally been regarded as inherently less stable than the pyranose forms, and this has been in accord with the general feeling that six-membered, chair-shaped rings are always more stable than five-membered rings. However, the difference in free energy of five- and six-membered rings is not pronounced: the flexible cyclopentane has greater

[4]In contrast, 1-deoxyfructose (which differs from **4** only in having three additional hydroxyl groups) in water at 20° is only 4.5% in the open-chain form (private communication from Prof. S. J. Angyal, Sydney, Australia). The additional hydroxyl groups would be expected to favor the cyclic form both by inductive and by conformational effects, but the magnitude of combined effects is remarkable.

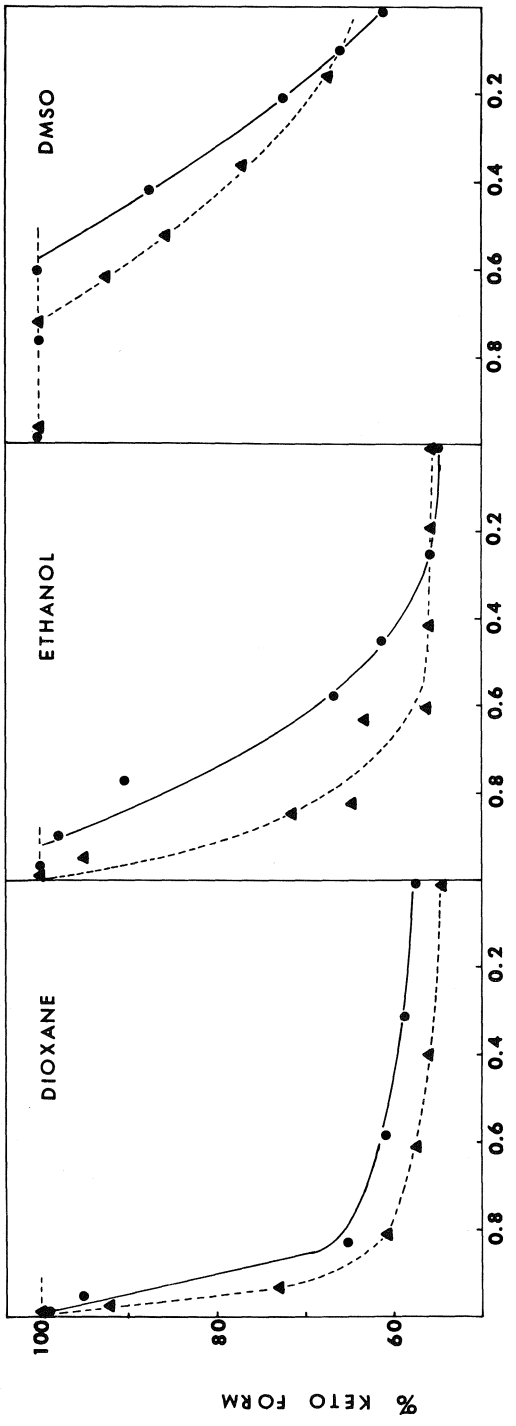

FIG. 1. Effect of mole-fraction of water in aqueous dioxane, aqueous ethanol, and aqueous dimethyl sulfoxide on the percentages of the keto forms 2 (▲) and 4 (●).

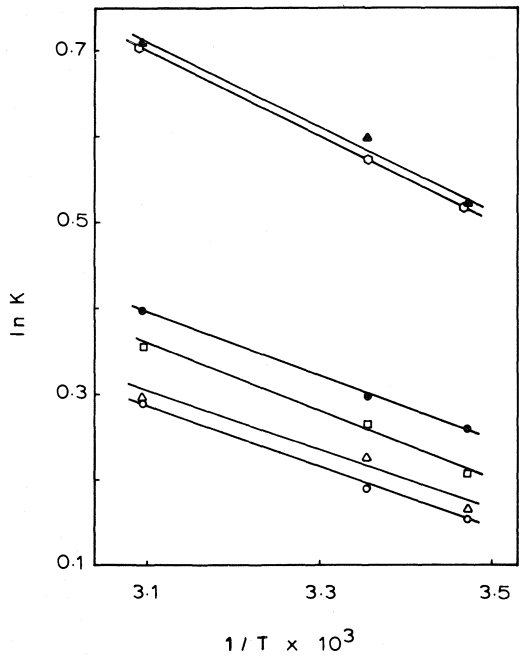

FIG. 2. Effect of temperature on equilibrium **1** ⇄ **2** in dioxane (○), ethanol (△), and dimethyl sulfoxide (⬡), and on equilibrium **3** ⇄ **4** in dioxane (●), ethanol (▲), and dimethyl sulfoxide (□).

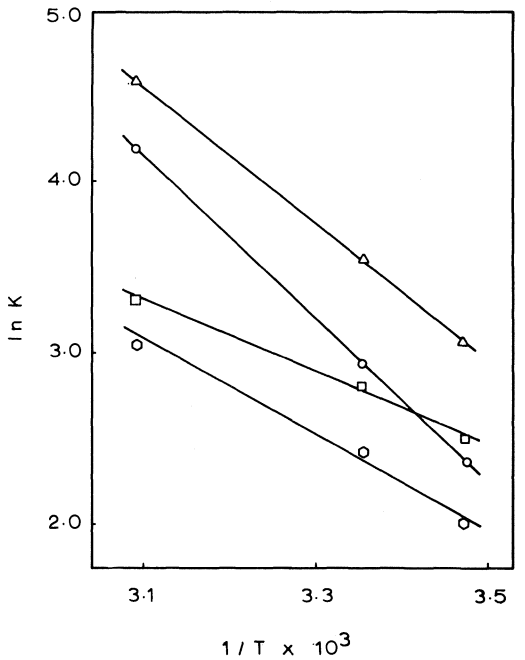

FIG. 3. Effect of temperature on equilibrium **1** ⇄ **2** in dioxane–water, 0.96 mole-fraction water (⬡) and in dimethyl sulfoxide – water, 0.75 mole-fraction water (△), and on equilibrium **3** ⇄ **4** in dioxane–water, 0.95 mole-fraction water (○), and in dimethyl sulfoxide – water, 0.70 mole-fraction water (□).

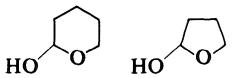
entropy than the rigid cyclohexane, and replacement of a methylene group by an oxygen atom lessens the free energy difference by reducing the eclipsed interactions in the five-membered ring (6*a*). From the data of Hurd and Saunders (3), the difference in free energy changes for the two reactions: cyclization of the hydroxyaldehydes in 75% aqueous dioxane at 25° to tetrahydropyran-2-ol (**9**), and to tetrahydrofuran-2-ol (**10**), is only 0.4 kcal/mol (13*a*). Our data for equilibrium in



9 **10**

carbon tetrachloride show the difference in free energy changes on cyclization of the hydroxyketones to 2-methyl-2-hydroxytetrahydropyran (**3**) and to 2-methyl-2-hydroxytetrahydrofuran (**1**) to be only 0.16 kcal/mol. The difference in free energy favoring the six-membered ring is thus very small; furthermore, it is reversed in dioxane–water (~0.95 mole-fraction H_2O), the furanose form **1** then being favored by 0.3 kcal/mol. (A referee has pointed out the pertinence of the work of Trister and Hibbert (21), who found both five- and six-membered cyclic acetals formed by reaction (equilibrium-controlled) of glycerol with aldehydes. The proportion of five-membered product increased with temperature.)

If the 2,4-dinitrophenylhydrazones **5** and **6** exhibit any ring–chain tautomerism, the cyclic isomers (like **1** and **3**) could exist in two forms; additionally, the open-chain tautomer could exist in *syn* and *anti* forms. However, interconversions of *syn* and *anti* isomers of simple hydrazones can generally be induced by heat or light with relative ease (10). In fact, in DMSO-d_6 the n.m.r. spectra showed only singlets at 2.1 δ, about the value expected for the methyls of the open-chain forms **5** and **6**. The i.r. spectra of the solid hydrazones also indicated the open-chain forms only, showing substantial absorption corresponding to the hydroxyl and C=N functions. Furthermore, the 2,4-dinitrophenylhydrazones in ethanol or acetone had u.v. absorptions identical to that of the 2,4-dinitrophenylhydrazone of the model compound **8**, indicating the predominance of the

For personal use only.

open-chain form in these solvents also. It is evident that 2,4-dinitrophenylhydrazones of hydroxy-ketones show a much smaller tendency than do the parent ketones to form the cyclic tautomer, presumably because the double bond of the hydrazone is stabilized by conjugation with the aromatic ring. In contrast, there is evidence that the 2,4-dinitrophenylhydrazone of a hydroxyaldehyde exists mainly in the cyclic form (8). This accords with the greater tendency of hydroxyaldehydes themselves to cyclize, as noted above.

We are grateful to Prof. S. J. Angyal for helpful discussion, and to a referee for thoughtful criticism and many suggestions. The financial support of the National Research Council of Canada is gratefully acknowledged.

Thermal Tautomerism of Crotonic Acid and Vinylacetic Acid, Neat and in Heavy Water

MARTIN B. HOCKING

Research Department, Dow Chemical of Canada, Limited, [1] *Sarnia, Ontario*

Received July 15, 1971

A distillate containing 25% vinylacetic acid has been obtained from *trans*-crotonic acid. Pure vinylacetic acid has been obtained from this by successive thermal equilibrations and distillations. Vinylacetic acid has been subjected to tautomerization conditions in acidic, neutral, and basic media, the latter in normal and in heavy water. These observations are coordinated in an attempt to arrive at plausible pathways for the various transformations observed.

A partir de l'acide crotonique-*trans*, il est obtenu un distillat contenant 25% d'acide vinylacétique. L'acide vinylacétique pur a été obtenu ultérieurement par équilibration thermique et distillation. L'acide vinylacétique a été soumis à des conditions de tautomérisation en milieu acide, neutre, et basique; cette dernière étant effectuée dans l'eau normale et dans l'eau lourde. Les observations ainsi obtenues sont réunies dans le but de déterminer les mécanismes possibles pour les différentes transformations observées.

Canadian Journal of Chemistry, 49, 3807 (1971)

Introduction

The double bond of an α,β unsaturated carboxylic acid can migrate to a position β,γ to the carbonyl. For instance, Linstead (1) has shown that thermal tautomerization of cyclohexylideneacetic acid yields an equilibrium mixture consisting largely of cyclohexene-1-acetic acid and that hydrosorbic acid in hot strong base exists as an equilibrium mixture of the α,β and β,γ tautomers (2). Similarly, Kon and Linstead (3) found that boiling 3,3-diethylacrylic acid with 60% aqueous potassium hydroxide yielded a considerable proportion of the β,γ unsaturated acid. If the α-hydrogen of the starting acid is replaced by ethyl or methyl the rate at which equilibration to the β,γ unsaturated acid can take place is severely retarded (4). The prime importance of the mobility of the hydrogen α to the carboxyl in these tautomeric changes has been demonstrated by Ives and Rydon who found that deuterium oxide exchanged rapidly with the α-hydrogens of sodium vinylacetate and much less readily with sodium *trans*-crotonate (5–7).

The *trans*-crotonic – vinylacetic tautomeric equilibrium has been shown to lie at about 98% of the former either in hot 50% sulfuric acid (8) or in hot aqueous base (9). These results have been confirmed by the isotopic exchange studies of Ives (6, 7), by the sulfur dioxide catalyzed experiments of Waterman *et al.* (10), and by our own purely thermal equilibration work (11). Butler and Small (12) reported the formation of a small proportion of methyl vinylacetate on the pyrolysis of methyl crotonate, but it was present in the starting material. During the course of this work Ozeki and Kusaka (13) reported that vinylacetic esters had been obtained on attempts to prepare crotonate esters from *trans*-crotonyl chloride via the Einhorn reaction.

The purpose of this report is to discuss our unexpected production of a 25% vinylacetic acid distillate from *trans*-crotonic acid. This work partially supplements and enlarges upon the elegant isotopic exchange studies of Ives and Rydon (5).

Experimental

Practical grade *trans*-crotonic acid was used. Analysis of the mixtures of *cis*- and *trans*-crotonic acids and vinylacetic acid was by integration of the n.m.r. resonance of the methyl double doublets (11) for the first two compounds, and of the two groups of three peaks attributed to the methylene of the latter (n.m.r. data given below). The respective multiplets were sufficiently well-separated from each other for accurate integration. Apart from convenience, this method of analysis assured no fractionation or further isomerization or tautomerization before analysis.

Vinylacetic Acid

This material, required for comparative purposes, was readily prepared by the acid hydrolysis of 3-butenenitrile (14). The n.m.r. spectrum of pure vinylacetic acid in $CDCl_3$ (chemical shifts with respect to internal tetramethylsilane, couplings in Hz measured on a multiplet expanded to 50 Hz sweep width, proton integral

ratios in parentheses) was as follows: acid OH, singlet at 11.45 p.p.m. (0.95); methine proton, multiplet of 13 peaks spread over 40 Hz, centered at 5.88 p.p.m. (1.00); terminal methylene in two multiplets of 9 and 11 peaks separated by 7 Hz, centered at 5.11 p.p.m. (1.98); saturated methylene, six peaks in two groups of three, the centers of which are separated from each other by 6.7 Hz (1.0 and 1.4 Hz for lower field group, 1.3 and 1.3 Hz for higher field group). The spectrum was not amenable to first order analysis.

Vinylacetic Acid from trans-Crotonic Acid

(a) Using a "Todd" Column

trans-Crotonic acid (2.5 kg) was heated at 175° for 24 h. By raising the temperature to 187° the acids were then distilled at atmospheric pressure up a glass column (90 × 2.5 cm) packed with 1/4″ glass helices and fitted with a variable reflux head. At a reflux ratio of 100:1 and a take-off rate of about 20 ml/h the fractions given in Table 1 were obtained during a total operating time of 32 h.

The vinylacetic acid obtained was isolated by a series of thermal equilibration and distillation steps. Table 2 gives the best results obtained in a series of experiments carried out at different temperatures to determine optimum conditions for the equilibration step. The thermally equilibrated material was crystallized at 0° without solvent, and the crystallized *trans* filtered off. The initially enriched vinylacetic acid was distilled at 120 mm (b.p. range 115–120°) up a vacuum-jacketed column (70 × 2.5 cm; reflux 100:1) packed with glass helices. Table 3 outlines the results obtained by carrying out two thermal equilibrations and crystallization–distillations, on the purity and quantity of 250 g of crude vinylacetic acid obtained from crotonic acid.

(b) Using a Concentric Tube Column (15)

trans-Crotonic acid (360 g) was heated at 180° for 20 h and then distilled at atmospheric pressure at a reflux ratio of about 100:1 for a total of 48 h using completely vacuum-jacketed equipment (Table 1). Because this gave a poorer separation the product was not re-equilibrated or re-distilled.

Deuterium Exchange Experiments

Deuterium oxide (99.8%) was purchased from Atomic Energy of Canada. Vinylacetic acid was given a prelimi-

nary exchange treatment with heavy water to obtain carboxyl-deuterated material which was then recovered by extraction with carbon tetrachloride, dried ($MgSO_4$), and vacuum distilled (b.p. 71–73°/20 mm) before use. That only carboxyl deuteration had been effected was confirmed by n.m.r. (Table 5). The *t*-butanol used as an integral standard was dried ($MgSO_4$) and re-distilled at atmospheric pressure immediately before use.

Alkaline Conditions

Run 1 was largely exploratory. An n.m.r. tube containing vinylacetic acid (86 mg; 1 mmol), *t*-butanol (10 μl), heavy water (0.50 g), and sodium hydroxide (40 mg; 1 mmol) was cooled in an ice-water bath and sealed. Relative integrals of the initial n.m.r. spectrum bands and of those in spectra run at later intervals are given in Table 4. Runs 2, 7, and 8 were carried out in the same way as the first except that sodium metal, 41.5 (1.8 mmol), 47.2, and 43.1 mg respectively, was substituted for sodium hydroxide, and the quantity of vinylacetic acid used was raised to 145, 130, and 130 mg respectively.

Neutral and Acid Conditions

Run 3, carried out under "neutral conditions" had the same quantities of the same components as run 1, but without the sodium hydroxide. The n.m.r. tube for run 4 contained vinylacetic acid (145 mg), *t*-butanol (10 μl), heavy water (0.50 g), and concentrated sulfuric acid (8 mg).

Control Experiments

Run 5 was carried out on twice recrystallized *trans*-crotonic acid (128.8 mg; 1.5 mmol) in heavy water (0.50 g) containing *t*-butanol (10 μl) and sodium metal (43 mg; 1.9 mmol) and results are recorded in Table 6. An exchange experiment (run 6) on vinylacetic acid (145 mg; 1.7 mmol) without preliminary carboxyldeuteration, in normal water (0.50 g), was carried out in the presence of *t*-butanol (10 μl) and sodium hydroxide (71 mg; 1.8 mmol). No *cis*-crotonic acid was formed, as determined by n.m.r.

Results

Vinylacetic Acid Preparation

A distillate containing more than 25% vinylacetic acid was obtained by heating *trans*-crotonic acid for a time at 175° followed by distillation at atmospheric pressure (Table 1). The vinylacetic acid could not be isolated by distillation because of the closeness of its boiling point to that of the other main constituent, *cis*-crotonic acid, 169 and 169.3° (16) respectively. It was known (11) that *cis*-crotonic acid is readily thermally isomerized to the significantly higher boiling *trans*-isomer but that at the same time vinylacetic acid is also readily thermally tautomerized to *trans*-crotonic acid (6, 7). However, it was found that at 165° it was possible to preferentially isomerize the *cis*-crotonic acid with very little loss of the vinylacetic acid (Table 2). This mixture was then readily separable by distillation or crystallization or both (Table 3) to give reasonably pure vinylacetic acid (17), confirmed by comparison of its i.r. and n.m.r. spectra and other physical properties with those of an authentic sample (14).

Deuterium Exchange Experiments

Alkaline heavy water, at room temperature, readily exchanged deuterium with the α-hydrogens of carboxyl deuterated vinylacetic acid. After only 24 h, **1** was essentially the only

$CH_2{=}CH{-}CD_2{-}CO_2Na$

1

$CH_2D{-}CH{=}CD{-}CO_2Na$

2

species present (Table 4). The 10% drop in the integral attributed to the terminal methylenic hydrogens is accounted for by tautomerism to *trans*-crotonic acid, as seen by the nearly equivalent rise in the integral for this compound. Tautomeric equilibrium was attained after about 2 months at room temperature, or 4 h at 100°.

In either neutral or acidified heavy water vinylacetic acid was notably resistant to exchange or tautomerism. At room temperature,

periods as long as 27 days under neutral conditions and 10 days when acidified, showed no exchange (Table 5). At 100°, 27% α-hydrogen exchange occurred after 66 h for the neutral experiment, and 23% in 4 h in acid, but no tautomerism was detected in either. The *t*-butanol internal standard used in the acid experiment was almost completely deuterated. As a control experiment substitution of *trans*-crotonic acid for vinylacetic acid in an alkaline heavy water run gave only about 2% terminal methyl deuterium incorporation and none at the α- and β-carbons (Table 6). Heating to 100° for 4 h brought about significant exchange at the α, about 2/3, and the terminal positions, about 1/3, but still very little exchange at the β position. In another control experiment, vinylacetic acid was heated in alkaline normal water and yielded normal *trans*-crotonic acid almost quantitatively.

Discussion

Vinylacetic Acid Formation

The *trans*-crotonic acid – vinylacetic acid tautomeric equilibrium lies about 98% on the side of the former. The high proportion of vinylacetic acid was obtained in distillates consisting largely of *cis*-crotonic acid. This is known (11) to exist in equilibrium with the *trans* and is formed via thermal cracking of the crotonate dimer **3** (Scheme 1). The 25° boiling point differential

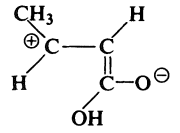
between *cis*- and *trans*-crotonic acids allows the distillation column to become highly enriched in the lower boiling *cis* isomer. *cis*-Crotonic acid (**4**), can also rapidly thermally tautomerize to vinylacetic acid (**5**) (11). The vinylacetic acid thus formed co-distils with the *cis*-crotonic acid to yield the observed 25% vinylacetic acid distillate.

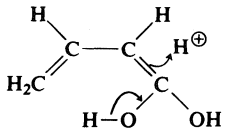
Thus, *cis*-crotonic acid tautomerizes to a higher equilibrium level of vinylacetic acid than the *trans*. Of a *cis–trans* isomeric pair of α,β-unsaturated carboxylic acids, the *cis* is always the most dissociated (18). This is because there is little contribution in the *cis* acid from the resonance form **6**, due to non-coplanarity of the



6

carboxyl carbonyl with the olefinic double bond caused by steric interactions (19). The presence of *cis* steric interactions is also supported by the 20 cm^{-1} higher i.r. frequency shown for the *cis* carbonyl *vs.* the *trans*.

The reduced olefinic conjugation conferred by the non-coplanarity, and the steric strain causing it, give two bases for easy tautomerization of *cis*-crotonic acid. A further contribution might be provided by the intramolecular 1,5 sigmatropic shift of a proton from methyl to carbonyl, for which the molecular geometry of the *cis* acid is correct. The diene gem diol intermediate formed, **7**, would readily collapse to vinylacetic acid.



7

Vinylacetic Acid – Heavy Water Deuterium Exchange

The method of analysis used in the tautomerization experiments readily lent itself to the simultaneous determination of the extent of tautomerization and of deuterium exchange. Ives and Rydon (5–7), in their meticulous study, could not experimentally determine the position of deuterium exchange on tautomeric incorporation. Nevertheless, by an involved kinetic argument necessitating a number of assumptions they concluded that the transformations shown in Scheme 2 were occurring (6, 7). The present work proved this directly. That tautomerization to *trans*-crotonic acid occurred simultaneously to the α exchange, with incorporation of terminal deuterium, was also proven mathematically by Ives (7). We concur with these conclusions.

To determine the equilibrium ratio of incorporated deuterium, Ives (7) also evaluated the ratio $f_2/f_1 = 0.89$, where f_2 is the ratio of the rate of removal of protons to that of deuterions, and f_1 is the ratio of the rates of addition of protons and deuterons. For this evaluation it was necessary to determine rate constants k_1, the rate of deuterium exchange with light vinylacetic acid, and k_2, the rate of tautomerization of vinylacetic acid to *trans*-crotonic acid, which at 100° were found (7) to be $90 \pm 10 \times 10^{-4}$ and 58×10^{-4} min^{-1} respectively.

Plotting our 25° tautomerization data on first order coordinates, Fig. 1, yielded a rate constant k_2 of 1.55×10^{-4} min^{-1}. On attempting to fit our data to the kinetic argument used by Ives for obtaining a value for k_1 it was found that k_1 at 25° was so large relative to k_2 that k_2 was indeterminate by this method. This was probably because of the smaller Arrhenius activation energy usually shown by exchange reactions, than by isomerizations (20). Data from further room temperature (25°) and −5° exchange experiments with frequent early in-

11 (*a* X = CO_2H; *b* X = OR) — **12** (*a* X = CO_2H; *b* X = OR)

SCHEME 3

tegral determinations (Table 4) supported this suggestion and gave values for k_1 directly. Values for *initial* k_1 obtained in this way were 74×10^{-4} and 25×10^{-4} min^{-1} respectively, the former quite close to Ives' value at 100°.

Initial fast deuterium exchange α to the carboxyl in alkaline medium probably occurs via a non-classical carbanionic intermediate 12*a* (Scheme 3), as has been accepted (21, 22) for exchange reactions in allylic ethers. A proton or deuteron could add α or γ to the substituent giving exchanged starting material or tautomerized product respectively. However, allyl alkyl ethers **11***b* were found to tautomerize and γ-monodeuterate rapidly and to α-exchange only slowly, the inverse of our observations with **11***a*.

Methoxyl is inductively withdrawing and in a resonant position increases the substrate electron density by conjugation (23). Therefore, in **11***b*, alkoxyl is electron-attracting. In **12***b*, the alkoxyl is in conjugation with, and hence is raising the electron density on, the diffuse carbanion. Carboxylate anion and carboxyl have only minor changes in net inductive effect when changed from a non-conjugative to a conjugative situation (23). Thus, the overall relative electron affinity changes from $-CO_2H \gg -OR > -CO_2^{\ominus}$ to $-CO_2H > -CO_2^{\ominus} \gg -OR$ on changing from a purely inductive to an inductive plus conjugative position. The progressively greater ease of tautomerization and greater resistance to α exchange observed follow the latter order, suggesting that these substituents are affecting the allyl system conjugatively. To be conjugative this must be occurring through the intermediates **12**. The non-conjugative substitutent effect prior to the formation of **12** must only be on its rate of formation, *i.e.* slower with the ether.

The explanation for the observed difference between the ether and carboxylate now resolves itself to simply a higher γ than α electron density, and thus more ready γ protonation in the former, due to alkoxyl conjugative electron donation to the anion **12***b*, and a higher α than γ electron density in the latter **12***a* promoting α protonation. The intermediate carbanion **12***b* formed from the ether then gives alkoxyl-1-propenyl ether, rather than exchanged starting material **11**. In contrast, the sodium vinylacetate carbanion, **12***a*, gives exchanged starting material and relatively little crotonate.

Infrared Studies on Rotational Isomerism. V. 2-Nitroethanol

PAUL A. GIGUÈRE AND TOKIJI KAWAMURA
Département de Chimie, Université Laval, Québec, Québec

Received July 12, 1971

The i.r. spectra of 2-nitroethanol in the three physical states were measured between 4000 and 250 cm^{-1}. The liquid and the crystal were also studied in Raman effect. In all three states the molecules exist as *gauche* and *trans* isomers, the former being stabilized by a weak intramolecular hydrogen bond. Definite evidence for a third isomer, previously reported in dilute CCl_4 solutions, could not be ascertained from the vapor spectra as a function of temperature. On the other hand this study revealed appreciable decomposition of the vapor above 80 °C, with formation of nitroethylene and also some aldehyde. For that reason it was not possible to evaluate the enthalpy of isomerization. The difficulty of securing a pure sample of 2-nitroethanol is emphasized. Only one crystalline phase was obtained.

On a étudié en i.r. entre 4000 et 250 cm^{-1} le nitro-2 éthanol sous les trois états physiques. En outre on a étudié en Raman le liquide et le cristal. Dans les trois états les molécules existent sous forme d'isomères *trans* et *gauche*. Ce dernier est stabilisé par une faible liaison hydrogène interne. La présence d'un troisième isomère, présumément *gauche*, signalée dans les solutions diluées en solvant inerte, n'a pu être confirmée par une étude de la vapeur en fonction de la température. Celle-ci, par contre, a révélé une décomposition appréciable à partir de 80 °C avec formation de nitroéthylène et d'un peu d'aldéhyde. Pour cette raison il n'a pas été possible d'évaluer l'enthalpie d'isomérisation *gauche–trans*. On souligne la difficulté de préparer un échantillon pur de ce nitroalcool. Une seule phase cristalline a été obtenue.

Canadian Journal of Chemistry, 49, 3815 (1971)

Introduction

The existence of an intramolecular hydrogen bond between the nitro group and the hydroxymethyl group resulting in a six-membered chelate ring in 2-nitroalcohols was first postulated by Malinowski and Urbański (1). This hypothesis has been confirmed definitely by various spectroscopic studies (2–5). Claims to the contrary (6, 7) were later disproved (4). Nevertheless, the question of rotational isomerism in the nitroalcohols is not yet completely understood. For instance, 2-nitroethanol in CCl_4 solutions at high dilution has been reported to exhibit not two, but three distinct O—H stretching bands arising, presumably, from one *trans* and two *gauche* conformers (4, 5). The distinction between the latter two is not clearly established. It has been suggested to arise from two kinds of intramolecular hydrogen bonds involving respectively only one or both of the oxygen atoms of the nitro group. However, that explanation cannot account for certain other observations; in particular the fact that other β-nitroalcohols, such as 2-nitrobutanol, and 2,2-dinitropropanol, show only the two expected O—H bands at 3 μ. In the hopes of elucidating this problem we have extended the present series of investigations (8) to 2-nitroethanol. Previous work on this compound had been restricted mostly to the O—H stretching region.

Fundamentally, it is interesting to know to what extent the rather weak proton-acceptor character of the nitro group is compensated by the greater flexibility of a six-membered ring. On the other hand, introduction of a triatomic substituent leads to a significantly more complex situation than, for instance, in the 2-haloethanols because of greater possibility of coupling between the vibrations and overlapping of the bands. This is particularly true in the region of the skeleton stretching and the various CH_2 deformation modes. Experimentally, the preparation of a pure sample of the nitroalcohol is made more difficult by its thermal instability. It would seem that this aspect of the problem was not always fully appreciated in the past.

Experimental

The sample of 2-nitroethanol (Brickman and Co., Montreal) was stated to be of "practical grade". It was first dried over either sodium sulfate or molecular sieve, and then distilled[1] under reduced pressure (between 10 and 15 Torr) using a Vigreux fractionating column. The middle fraction, distilling at constant temperature (between 110 and 115 °C) was a clear, mobile liquid with, a refractive index n_D^{25} 1.4449. Now, values reported so far for this property range from a minimum of 1.4383 (9) to a maximum of 1.4497 (5), *cf.* also 1.4403^{20} (3). The most reliable seems to be n_D^{20} 1.4440 from the extensive

[1]DANGER OF EXPLOSION! Fortunately this did not materialize.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

work of Burmistrov and Bashinova (10). In fact, in one instance where the distillation was carried out at rather low pressure (~0.5 Torr) and temperature (b.p. about 67°) we obtained a product of refractivity close to that reported by the Russian authors: n_D^{20} 1.4442. By comparison the brown residue of distillation had a higher refractivity; *viz.* 1.4478.

As for stability, the purified product was found, as reported before (10), to remain unaltered for periods of up to 5 or 6 months if kept in the dark. Upon exposure to daylight it took a light yellow color after a few hours, but this did not affect noticeably the i.r. spectrum of the liquid; at least not in the early stages. The spectroscopic samples were prepared as reported previously (11, 12). For the vapor spectra, because of the low volatility of the compound a 10 m folded-path absorption cell with cesium bromide windows (8) had to be used in a static system. The liquid alcohol in a side tube was kept at 10 to 20° below that of the cell enclosure. The latter, made of metal, undoubtedly catalyzed the decomposition of the vapor at temperature above 80 to 100° as revealed by our spectra. Indeed, β-nitroalcohols are known to be prone to decomposition (13) on heating with formation of nitroolefins and aldehydes. On the other hand, the Russian authors (10) found 2-nitroethanol to be stable up to 130° and even 150°, presumably in glass. Still they do recommend distilling it at low pressure (10–30 Torr).

The solid specimen were prepared either by condensation of the vapor on a support at liquid nitrogen temperature or by gradual cooling of a thin liquid film between cesium bromide discs. This always produced a glassy solid which could be devitrified easily by controlled warming. Crystallization usually occurred around −65°. Incidentally, this is well above the currently quoted melting point for 2-nitroethanol, *i.e.* −80° (14). Obviously, this datum must refer to a very impure product or a mixture of isomers. By contrast our crystals were observed to melt at about −54°. Numerous variations in the crystallization procedure, along the lines previously tried for 2-cyanoethanol (15), failed to yield a second crystalline phase. This follows naturally from the presence of both *gauche* and *trans* conformers in the normal crystal.

Discussion of Results

Interpretation of the spectra (Fig. 1) is best carried out by considering first the simplest case of the liquid, then the crystal, and finally the very complex vapor spectra. It must be emphasized again that considerable "mixing" of vibrations is expected; especially in the middle range (1600 to 800 cm^{-1}). Therefore, the assignments listed in Table 1 give an oversimplified picture.

Liquid Spectra

The broad O—H stretching band centered at about 3300 cm^{-1} is indicative of strong intermolecular hydrogen bonding. In thick samples a vague shoulder around 3550 cm^{-1} must belong to a combination tone. The OH bending expected in the neighborhood of 1350 cm^{-1} was not discernible among the NO_2 stretching and the CH_2 wagging bands. As for the OH torsion about the C—O bond, it was barely noticeable as an inflexion at 700 cm^{-1}, on the slope of the very broad band around 590 cm^{-1}. It appeared more clearly in the supercooled (at −180°) liquid.

The two stretching modes of the NO_2 group have been studied extensively in various organic compounds (16). In our spectra, both the symmetric and, to a lesser extent, the antisymmetric bands showed weak satellites. These must be due to rotational *gauche–trans* isomerism as explained before (17). The same feature accounts for the widely separated doublets of the various CH_2 deformation bands; most noticeably in the twisting and rocking bands. For the skeletal stretching and bending modes the assignments proposed here are based on the related cases of the lower nitroparaffins (18, 19), and the halogen 2-substituted ethanols (11, 12).

Crystal Spectra

The main O—H stretching band at 3220 cm^{-1} in the crystal is accompanied by a strong shoulder at 3290 cm^{-1} due, no doubt, to *trans* conformers. In very carefully annealed samples secondary maxima were visible at 3180 and 3320 cm^{-1}. From this it may be inferred that the unit cell must contain more than one molecule of each configuration. As in the liquid the OH bending mode cannot be identified clearly with any of the numerous peaks in the 7 μ region, except possibly the broader one at 1470 cm^{-1}. However, the frequency seems rather high for such an assignment. In contrast the torsional mode gives rise to a well characterized doublet with a 50 cm^{-1} separation, again due to coexistence in the crystal of *gauche* and *trans* molecules. The fact that the two components show roughly the same intensity is considered an indication that both conformers are present in equal number in the crystal lattice.

Most of the other bands exhibit multiplet structure. For instance, the CH_2 twisting modes of the isomers give rise each to a triplet; another confirmation that the unit cell contains more than one molecule of each kind, with in-phase and out-of-phase vibrations. It is noteworthy that some of the stronger components of these multiplets are shifted to *lower* frequency with respect to the liquid. Crystal field effects may be responsible for this, as well as for the much enhanced activity of certain skeletal bending bands: *v.g.* at 591, 498, 415, and 393 cm^{-1}. The presence of the

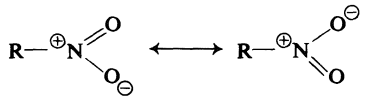
thermodynamically less stable *trans* conformer in the crystal must result from the particular situation that *inter*molecular hydrogen bonds in 2-nitroethanol are much stronger than the *intra*molecular bond of the *gauche* isomer. Indeed, the enhanced electronegativity of the oxygen atoms due to resonance among the canonical structures



makes them better proton acceptors than, say, the halogen atoms in 2-chloro- and 2-bromoethanol. This, coupled with strong dipole–dipole interactions, leads to a high degree of molecular association in condensed phases, as reflected in the low volatility, *viz.* Table 2.

Vapor Spectra

Both the frequency and the separation of the main O—H stretching peak and its weak satellite in the i.r. spectra of the vapor are comparable with those of other 2-substituted ethanols; in particular the 2-chloro- (12). Likewise the OH torsion in the *gauche* conformer occurs at nearly the same frequency in both alcohols. From these it could be inferred that the strength of the intramolecular hydrogen bond in 2-nitroethanol is of the order of 1 kcal mol^{-1}. However, it must be

remembered that such correlations are not too reliable for strongly bent hydrogen bonds. In spite of the greater flexibility of the six-membered chelate ring there is no guarantee that the hydrogen bond in the nitroalcohol is closer to linearity than in the haloethanols.

The various other criteria used previously to evaluate the enthalpy difference between the *gauche* and the *trans* conformers are not applicable here, unfortunately. Indeed, study of the temperature dependence of the relative intensity of structure sensitive bands is precluded by decomposition upon heating. Below 50 or 60° the bands were too weak for reliable intensity measurements, even with a 10-m path. Then, beginning at about 80° dehydration of the alcohol became noticeable as revealed by appearance of the stronger bands of nitroethylene (20). It turns out that most of the conformation sensitive bands, such as the CH_2 twisting and rocking, and the C—N stretching are nearly coincident in both spectra. As for the low-frequency skeleton bending modes, they are very poorly characterized, as may be judged from Fig. 1A. Lastly, the C—O stretching frequency is not appreciably affected by changes in the azimuthal angle of the molecule.

For the same reason intensity measurements on the two O—H stretching peaks at 3670 and 3628 cm^{-1} were hampered by the strong rotational structure of the water bands which altered seriously the contour of the main nitroalcohol doublet. Still, from visual observation it appeared that the relative intensity of the *gauche* and *trans* bands did not change nearly as much with temperature as, for instance, in the 2-haloethanols. Under such conditions it was illusory to look for a third O—H stretching component corresponding to that observed in dilute CCl_4 solutions (4, 5). Conceivably this could be due to a solvent effect. At any rate the hypothesis of two *gauche* conformers involving respectively one, and the two oxygen atoms of the nitro group is not too convincing. As mentioned above it cannot account for the absence of the triplet feature in other nitroalcohols. In addition, stereochemistry shows

TABLE 2

Alcohol	Molecular weight	Boiling point (°C)
2-Nitroethanol	91	198
2-Chloroethanol	80	129
2-Bromoethanol	125	150

that rotation of the NO_2 group about its axis to bring the two oxygen atoms equidistant to the OH group will also bring the proton much closer to the nitrogen atom. The latter is a very poor acceptor in this case, due to the formal positive charge from resonance.

To complicate further the situation, another decomposition reaction occured at temperature above 120° as confirmed by emergence of a strong aldehyde band around 1720 cm^{-1}. The formation of formaldehyde from 2-nitroethanol under various influences, in particular alkylating agents, has been reported before (10). From intensity measurements on the characteristic band of nitroethylene at 800 cm^{-1} the dehydration reaction was found to be endothermic by some 5 kcal. This is only half as large as expected from bond energy considerations.

In conclusion it is clear that a quantitative study of rotational isomerism in 2-nitroethanol would require much more elaborate means than used so far in this series of investigations.

The authors are grateful to the National Research Council of Canada for a continuing research grant. The interest and cooperation of Dr. Michel Schneider were most valuable.

The Reaction of *trans*-Chlorocarbonylbis(triphenylphosphine)iridium(I) with Silver Nitrate

D. N. CASH AND R. O. HARRIS[1]

Scarborough College Chemical Laboratories, Department of Chemistry, University of Toronto, 1265 Military Trail, West Hill, Ontario

Received January 14, 1971[2]

The reaction of *trans*-[$Ir^{I}(CO)(PPh_3)_2Cl$] (1) with $AgNO_3$ in acetone leads to two products. If a small excess of $AgNO_3$ is present, [$Ir^{I}(CO)(PPh_3)_2(NO_3)$] is isolated; while if a larger excess of $AgNO_3$ is present, the novel compound [$Ir(CO)(PPh_3)_2(NO_3)_2Ag$] is isolated as product. The characterization, and some reactions of these complexes are discussed.

L'action du [$Ir^{I}(CO)(PPh_3)_2Cl$]-*trans* (1) sur le $AgNO_3$ dans l'acétone, conduit à deux produits. Si un léger excès d'$AgNO_3$ est présent, le composé [$Ir^{I}(CO)(PPh_3)_2(NO_3)$] est alors isolé; si par contre un plus grand excès d'$AgNO_3$ est présent, le nouveau composé isolé est alors [$Ir(CO)(Ph_3)_2(NO_3)_2Ag$]. La caractérisation ainsi que certaines réactions avec ces complexes sont discutées.

Canadian Journal of Chemistry, **49**, 3821 (1971)

Introduction

In continuing our investigation of the reactions of oxidizing metal salts, particularly nitrates, with iridium(I) complexes (1), we have examined the reaction of [$Ir(CO)(PPh_3)_2Cl$] (2) with silver nitrate, in acetone. Nyholm and Vrieze (3) have reported that this reaction produces silver metal, but gave no conditions. On the basis of our previous work, we expected reaction 1 to occur, giving [$Ir(CO)(PPh_3)_2Cl(NO_3)_2$] as product.

$$[1]\quad [Ir(CO)(PPh_3)_2Cl] + 2AgNO_3 \xrightarrow{\text{acetone}} [Ir(CO)(PPh_3)_2Cl(NO_3)_2] + 2Ag$$

Oxidation was not observed, but instead, metathesis occurred. If only a small excess of silver nitrate was present (eq. 2) the product obtained was [$Ir(CO)(PPh_3)_2(NO_3)$] (**A**). If a large excess of silver nitrate was present (eq. 3) the product [$Ir(CO)(PPh_3)_2(NO_3)_2Ag$] (**B**) was obtained.

$$[2]\quad [Ir(CO)(PPh_3)_2Cl] + AgNO_3 \xrightarrow{\text{acetone}} [Ir(CO)(PPh_3)_2(NO_3)] + AgCl$$
(A)

$$[3]\quad [Ir(CO)(PPh_3)_2Cl] + 2AgNO_3 \xrightarrow[\text{excess } AgNO_3]{\text{acetone}} [Ir(CO)(PPh_3)_2(NO_3)_2Ag] + AgCl$$
(B)

[1]Author to whom communications should be addressed.

[2]Revision received August 11, 1971.

The properties and reactions of both these complexes are discussed below.

Results and Discussion

1. [Ir(CO)(PPh$_3$)$_2$(NO$_3$)] (A)

The complex **A** is obtained (eq. 2) as a bright yellow solid, soluble in chloroform, dichloromethane, and benzene, and insoluble in alcohols, ether, and alkanes. From analysis (Table 1) and i.r. spectrum (Table 2), and from the chemical reactivity noted below, the complex is taken to be the nitrato analogue of the square planar d^8 complex *trans*-[$Ir(CO)(PPh_3)_2Cl$] (2). From the i.r. spectrum, part of which is reproduced in Fig. 1, the nitrato ligand is seen to be co-ordinated to the metal ion (4), although the exact nature of the linkage cannot be deduced by this means (5).

Complexes of d^8 iridium(I) of this type are known to react with molecular oxygen (6), sulfur dioxide (7), olefins such as tetracyanoethylene (8), cupric halides (1), halogens (9), and mercuric salts (3). Complex **A** is similarly reactive. Analysis results and i.r. spectra for all the products of the reactions discussed below are given in Tables 1 and 2, respectively. Except where noted, the i.r. spectrum of each product contained absorptions due to co-ordinated nitrato ligand.

In solution, **A** reacts irreversibly (eq. 4) with molecular oxygen to form [$Ir(CO)(PPh_3)_2(NO_3)(O_2)$] (**C**), which is unstable in solution, decomposing over a period of minutes to uncharacterized products. As a solid, **C** is stable in air for a period of days. Complex **C** reacts rapidly (eq. 5)

in solution with sulfur dioxide gas, as do similar molecular oxygen complexes (10), to produce a bidentate sulfato complex. The product obtained from chloroform – petroleum ether was $[Ir(CO)(PPh_3)_2(NO_3)(SO_4)]\cdot\frac{1}{2}CHCl_3$ (**D**).

$$[4]\quad \underset{\textbf{(A)}}{[Ir(CO)(PPh_3)_2(NO_3)]} + O_2 \xrightarrow{CHCl_3} \underset{\textbf{(C)}}{[Ir(CO)(PPh_3)_2(NO_3)(O_2)]}$$

$$[5]\quad \underset{\textbf{(C)}}{[Ir(CO)(PPh_3)_2(NO_3)(O_2)]} + SO_2 \xrightarrow{CHCl_3} \underset{\textbf{(D)}}{[Ir(CO)(PPh_3)_2(NO_3)(SO_4)]}$$

Complex **A** reacts readily (eq. 6) in the solid state with sulfur dioxide gas, forming $[Ir(CO)(PPh_3)_2(NO_3)(SO_2)]$ (**E**) as product. The green solid **E** loses sulfur dioxide very slowly at room temperature, even under vacuum.

Complex **A** reacts in benzene (eq. 7) with the olefin tetracyanoethylene (TCNE) to give the product $[Ir(CO)(PPh_3)_2(NO_3)(TCNE)]$ (**F**). Complex **F** is soluble in chloroform and dichloromethane, but rapidly decomposes, preventing recrystallization.

$$[6]\quad \underset{\textbf{(A)}}{[Ir(CO)(PPh_3)_2(NO_3)]} + SO_2 \rightarrow \underset{\textbf{(E)}}{[Ir(CO)(PPh_3)_2(NO_3)(SO_2)]}$$

$$[7]\quad \underset{\textbf{(A)}}{[Ir(CO)(PPh_3)_2(NO_3)]} + TCNE \xrightarrow{C_6H_6} \underset{\textbf{(F)}}{[Ir(CO)(PPh_3)_2(NO_3)(TCNE)]}$$

With cupric halides in acetone, **A** reacts (eq. 8) to form the dihalonitrato complexes $[Ir(CO)(PPh_3)_2(NO_3)X_2]$ (where $X^- = Cl^-$ and Br^-). With iodine in benzene solution, **A** reacts (eq. 9) to give a similar diiodo complex.

$$[8]\quad \underset{\textbf{(A)}}{[Ir(CO)(PPh_3)_2(NO_3)]} + 2CuX_2 \xrightarrow[X^- = Cl^-, Br^-]{\text{acetone}} \underset{\textbf{(G)}\ X^- = Cl^-;\ \textbf{(H)}\ X^- = Br^-}{[Ir(CO)(PPh_3)_2(NO_3)X_2]} + 2CuX$$

[9] $[Ir(CO)(PPh_3)_2(NO_3)] + I_2 \xrightarrow{C_6H_6} [Ir(CO)(PPh_3)_2(NO_3)I_2]$
(A) (I)

In acetone, **A** reacts (eq. 10) with mercuric chloride and mercuric nitrate to give the products (when recrystallized from chloroform) $[Ir(CO)(PPh_3)_2(NO_3)Cl(HgCl)]\cdot CHCl_3$ (**J**) and $[Ir(CO)(PPh_3)_2(NO_3)_2(HgNO_3)]$ (**K**), respectively. In chloroform solution, each of these complexes displays only one carbonyl stretching absorption in the i.r. spectrum, which suggests that in each case only one isomer is present. A possible structure is shown in Fig. 3.

In chloroform or dichloromethane solution, **A** reacts readily (eq. 11) with carbon monoxide gas, losing the nitrato ligand, and forming the soluble nitrate salt of the cation $[Ir(CO)_3(PPh_3)_2]^+$. Other salts of this cation have recently been reported (11), prepared by a different route. This illustrates the relatively poor bonding which exists between the nitrato ligand and the d^8 metal ion in complex **A**. Similar reaction of the halide analogues does not result in expulsion of the anion from the co-ordination sphere (12).

[10] $[Ir(CO)(PPh_3)_2(NO_3)] + HgX_2 \xrightarrow{\text{acetone}} [Ir(CO)(PPh_3)_2(NO_3)X(HgX)]$
(A) $X^- = Cl^-, NO_3^-$ (J) $X^- = Cl^-$; (K) $X^- = NO_3^-$

[11] $[Ir(CO)(PPh_3)_2(NO_3)] + 2CO \xrightarrow[CO]{CH_2Cl_2} [Ir(CO)_3(PPh_3)_2](NO_3)$
(A) (L)

The i.r. spectrum of the solid **L** has no absorptions due to co-ordinated nitrato ligand, but does contain absorptions assigned to an ionic nitrate group.

2. [Ir(CO)(PPh$_3$)$_2$(NO$_3$)$_2$Ag] (B)

The complex **B** (eq. 3) is obtained as very small, golden brown crystals, soluble in chloroform and dichloromethane, much less so in benzene, and insoluble in alcohols, ether, and alkanes. Analysis (Table 1) supports the empirical formula given. The i.r. spectrum of the solid (Table 2), part of which is reproduced in Fig. 2, has absorptions at 1499, 1273–1263 (a partially resolved doublet), 995, and 789 cm^{-1}, which have been assigned to co-ordinated nitrato ligands, absorptions at 1992 and 608 cm^{-1} which have been assigned to carbonyl ligand, and absorptions due to triphenylphosphine ligands. A weak but sharp absorption at 814 cm^{-1} has not been assigned, but may be an additional nitrato mode. In solution in chloroform, the carbonyl stretching absorption is found at 2005 cm^{-1}. An attempt to obtain a Raman spectrum was unsuccessful as the colored complex decomposed in the laser beam.

The solid is apparently indefinitely stable in light and air. It is essentially diamagnetic at room temperature (Gouy method), and is non-conducting in dichloromethane solution ($\sim 1.5 \times 10^{-4}$ *M*). Although the complex is not sufficiently soluble for an accurate molecular weight to be determined, a molecular weight measurement (*M*) in chloroform solution ($\sim 3.5 \times 10^{-3}$ *M*) was carried out, and the value $M = 945 \pm 50$ was obtained. This compares with the value $M = 976$ for the empirical formula unit $[Ir(CO)(PPh_3)_2(NO_3)_2Ag]$. The complex is known, however, to decompose slowly in solution (see below). From these observations, complex **B** is believed to be non-ionic and monomeric in non-polar solvents such as chloroform and dichloromethane.

In acetonitrile, a molecular weight (*M*) determination (osmometric) gave the result $M = 335 \pm 20$ (Schwarzkopf, New York). This result can be explained by the dissociation in eq. 12, which produces three particles per formula unit. Acetonitrile is a solvent of high dielectric, which is, moreover, a good solvent for silver ions.

[12] $[Ir(CO)(PPh_3)_2(NO_3)_2Ag] \xrightarrow[(N_2)]{CH_3CN} [Ir(CO)(PPh_3)_2(NO_3)] + Ag^+ + NO_3^-$
(B) (A)

To further investigate the complex **B**, a series of chemical reactions was carried out, parallel to those undergone by complex **A**. The analysis results and i.r. spectra of the products of these reactions are given in Tables 1 and 2, respectively.

Complex **B** reacts in solution with molecular

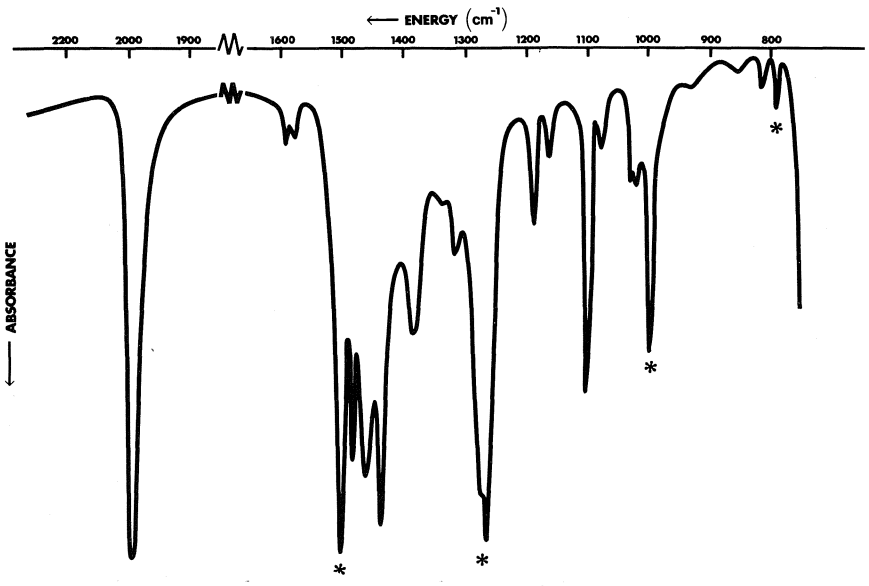

FIG. 2. Infrared spectrum of $[Ir(CO)(PPh_3)_2(NO_3)_2Ag]$, * denotes a nitrato ligand absorption.

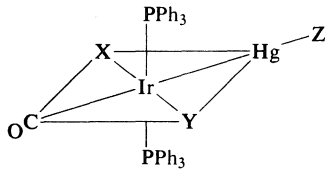

FIG. 3. Structure of one isomer of $[Ir(CO)(PPh_3)_2(X)(Y)(HgZ)]$. (*1*) X = Cl, Y = NO_3, Z = Cl; (*2*) X = NO_3, Y = NO_3, Z = NO_3; (*3*) X = NO_3, Y = NO_3, Z = Cl.

oxygen, and this reaction is slow enough that it may be followed in an open i.r. cell (0.5 mm sodium chloride cavity cell). Over a period of several minutes, absorption at 2005 cm^{-1} due to carbonyl stretching in **B** diminishes, while a new absorption at $\sim$2030 cm^{-1} appears and grows. The new band is due to carbonyl stretching in $[Ir(CO)(PPh_3)_2(NO_3)(O_2)]$ (**C**), which is the product of the reaction. This product is identical to that prepared from **A** (eq. 4). Preparatively, **C** can be prepared from **B** only in poor yield, because **C** is unstable in solution over the time scale of the reaction. It is proposed that this reaction is not a reaction of **B**, but is instead a slow dissociation (eq. 12) producing **A**, followed by the rapid reaction of **A** with molecular oxygen (eq. 4) producing **C**.

Similarly, **B** reacts with tetracyanoethylene in benzene to give a solid which has in its i.r. spectrum absorptions identical to those found for complex **F**, previously formed by the direct reaction of **A** and tetracyanoethylene (eq. 7). Complex **B** reacts in acetone with cupric halides to produce products which are identical to **G** and **H**, previously obtained by the reaction of **A** with cupric halides (eq. 8). It is assumed that all these reactions proceed by an initial dissociation (eq. 12).

As a solid, **B** does not react, however, with sulfur dioxide gas. Complexes of the type $[Ir(CO)(PPh_3)_2X]$ are known to react readily with this gas, even when dispersed as solids in potassium bromide discs (13). The lack of reaction suggests that the iridium ion in **B** is not as nucleophilic as that in **A**. Moreover, the possibility that **B** is a cocrystalline form of **A** and silver nitrate, already at variance with previous results, is further contradicted by this observation.

With iodine, and with mercuric chloride, complex **B** reacts to give products which are not identical to those produced from **A** under the same conditions. Reacting with iodine in benzene solution (eq. 13), **B** gives $[Ir(CO)(PPh_3)_2(NO_3)_2I]$ (**M**) as product, and reacting with mercuric chloride in acetone (eq. 14), **B** gives $[Ir(CO)(PPh_3)_2(NO_3)_2(HgCl)]$ (**N**) as product.

The i.r. spectrum of solid **M** contains absorptions due to co-ordinated nitrato ligands which are very similar, both in frequencies and intensities, to those observed in the i.r. spectra of a series

[13] $$[Ir(CO)(PPh_3)_2(NO_3)_2Ag] + I_2 \xrightarrow{C_6H_6} [Ir(CO)(PPh_3)_2(NO_3)_2I] + AgI$$
(B) (M)

[14] $$[Ir(CO)(PPh_3)_2(NO_3)_2Ag] + HgCl_2 \xrightarrow{\text{acetone}} [Ir(CO)(PPh_3)_2(NO_3)_2(HgCl)] + AgCl$$
(B) (N)

of similar dinitrato complexes $[Ir(CO)(PPh_3)_2(NO_3)_2X]$ (where $X^- = NCO^-$, N_3^-, NCS^-, Cl^-, and Br^-) which we have previously reported (1). The preparative route we then employed did not produce $[Ir(CO)(PPh_3)_2(NO_3)_2I]$, which is found to be stable when formed.

The solution i.r. spectrum of complex **N** contains only one carbonyl stretching absorption, indicating that only one isomer is present. A possible structure is shown in Fig. 3, emphasizing the similarity of **N** to the complexes **J** and **K** which were previously prepared from **A** (eq. 10).

The mechanism of reactions 13 and 14 is unknown. In each case, an insoluble silver halide is formed, and a product results in which there are two nitrato ligands co-ordinated to iridium. The conditions necessary for such a product to be obtained seem to be restricted. When bromine is used in place of iodine in reaction 13, the major product is found to be $[Ir(CO)(PPh_3)_2(NO_3)Br_2]$ (identical to complex **H**). When hydrogen bromide is used in place of iodine, a mixture of carbonyl hydrido-bromo complexes of iridium(III) results, which contain no co-ordinated nitrato ligand.

Reaction of **B** with mercuric nitrate in acetone (eq. 15) gives a product identical to complex **K**, prepared previously by reaction of **A** with mercuric nitrate (eq. 10).

[15] $$[Ir(CO)(PPh_3)_2(NO_3)_2Ag] + Hg(NO_3)_2 \xrightarrow{\text{acetone}} [Ir(CO)(PPh_3)_2(NO_3)_2(HgNO_3)] + AgNO_3$$
(B) (K)

The observations on **B** may now be summarized. Analysis shows the complex to have the empirical formula $[Ir(CO)(PPh_3)_2(NO_3)_2Ag]$. It may be dissolved in, and recovered unchanged from, solution in low polarity solvents such as chloroform and dichloromethane, in which it behaves as a non-ionic, monomeric solute of the formula given. In more ionizing solvents, it dissociates into three particles per formula weight (eq. 12); the postulated dissociation is supported by the chemical reactivity of the complex, which in many of its reactions gives the same products as those given by the complex **A**. In other reactions, however, **B** loses silver, but retains both nitrato groups as co-ordinated ligands.

Its i.r. spectrum shows triphenylphosphine, carbon monoxide, and nitrate to be present as ligands, there being no indication of any ionic nitrate. The absence of any large splitting of the nitrato absorptions suggests that both ligands are present in very similar, if not identical environments. The frequencies of the absorptions indicate both nitrato ligands to be co-ordinated to the iridium ion. However, some interaction of the nitrates with the silver ion is not ruled out. The position of the carbonyl stretching frequency suggests an iridium center part way between the +1 and +3 oxidation state (14).

From the above information, a tentative structure is proposed (Fig. 4). An iridium silver bond is assumed, although in the absence of a Raman spectrum or low frequency i.r. spectrum this cannot be confirmed. Several complexes containing transition metal to silver bonds are known (15); in all previous examples the silver ion is stabilized by co-ordination of some ligand or ligands. In this example, interaction of the silver ion with the

nitrato ligands, or with the π-electrons of the phenyl rings of the phosphines may account for the known stability of **B**. Such interactions are not shown in Fig. 4.

The molecule of Fig. 4 can be considered to be an adduct of $[Ir(CO)(PPh_3)_2(NO_3)]$ with silver nitrate. The d^8 iridium (I) ion may act as a Lewis base towards the silver ion, forming a metal–metal bond. This type of iridium(I) complex is known to act as an electron donor towards molecules such as sulfur dioxide and nitrosonium ion (16). The resulting five co-ordinate, sixteen valence electron system is now stabilized by the addition of a nitrato ligand, forming the six co-ordinate, eighteen valence electron product. A similar product is obtained from the reaction of an iridium(I) complex with an aryldiazonium cation, in the presence of a co-ordinating anion (17).

Experimental

Reagents employed were analar grade or better, and solvents were solvent grade, unless otherwise noted. Iridium was acquired as $(NH_4)_2IrCl_6$ from Johnson Matthey Chemicals, "Specpure" grade. This was converted to $[Ir(CO)(PPh_3)_2Cl]$ (18) by a standard method. The latter was used as prepared, without recrystallization, so long as the i.r. spectrum indicated the absence of iridium(III) impurities.

All i.r. spectra were obtained using a Beckman IR 12 spectrophotometer, calibrated by polystyrene film. Molecular weights were obtained with a Mechrolab 302 osmometer, using M.C.B. spectroquality chloroform as solvent. Microanalysis was by Huffman Laboratories, Colorado.

Estimation of the silver composition of complex **B**, $[Ir(CO)(PPh_3)_2(NO_3)_2Ag]$, was carried out by suspending a preweighed sample (~0.1 g) in acetone (20 ml), to which concentrated nitric acid (2 ml) was added very slowly, with stirring, to decompose the complex. Several volumes of water were added, and the acetone distilled off. The solid residue, containing iridium as insoluble product species, was filtered off, and the filtrate and washings which contained silver nitrate in nitric acid was titrated potentiometrically against a standard bromide solution. The value of percentage silver (Table 2) is an average of several such determinations.

A. $[Ir(CO)(PPh_3)_2(NO_3)]$

Acetone (75 ml) was deoxygenated under argon, and $[Ir(CO)(PPh_3)_2Cl]$ (0.925 g) and $AgNO_3$ (0.45 g) were added. The slurry was warmed and stirred under argon for 1 h, when the yellow-brown product solid was recovered by addition of hot, deoxygenated water (150 ml). The solid was collected in air, washed with water, ethanol, and ether, and dried in air. Yield 0.685 g.

This solid contains silver chloride as well as the desired product. It darkens on standing in air, but the i.r. spectrum shows no change. This initial solid is suitable as a starting material for many of the preparations which follow, provided the further products may be recrystallized.

Complex **A** was purified by dissolving the initial product solid in a minimum of oxygen-free benzene (30 ml) under argon. The filtered bright yellow solution was diluted with several volumes of oxygen-free *n*-pentane. The bright yellow product powder was collected and dried in vacuum. Yield ~0.5 g (~50%).

B. $[Ir(CO)(PPh_3)_2(NO_3)_2Ag]$

Acetone (75 ml) was deoxygenated under argon, and $[Ir(CO)(PPh_3)_2Cl]$ (1.21 g) and $AgNO_3$ (6 g) added. The slurry was cooled in an ice bath and stirred under argon for an hour, when the product was recovered by the addition of oxygen-free water (150 ml). The orange-brown product solid was filtered off, washed well with water, ethanol, and ether, and dried in air. This solid contains silver chloride as well as complex **B**, but may be used as a starting material for the preparations which follow.

Complex **B** was recrystallized by dissolving the initial product solid in a minimum of oxygen-free chloroform (65 ml) under argon. The yellow solution was filtered, and an equal volume of oxygen-free ether added. The rapidly precipitated brown crystals were collected in air, washed with ether, and dried in vacuum. Yield 0.78 g (~60%).

C. $[Ir(CO)(PPh_3)_2(NO_3)(O_2)]$

(*i*) Complex **A** (0.25 g) was dissolved in chloroform (10 ml), and air was bubbled through the solution for several minutes. The orange solution was filtered, and diluted with petroleum ether (70 ml). The rapidly formed orange powder was collected after a few hours, washed with ether, and dried in vacuum. Yield 0.20 g (80%).

(*ii*) Complex **B** (0.1 g) was suspended in chloroform (5 ml), and methanol (25 ml) was added. After several days, dark orange crystals of product were recovered. Yield 0.03 g (30%).

D. $[Ir(CO)(PPh_3)_2(NO_3)(SO_4)]\cdot\frac{1}{2}CHCl_3$

Complex **C** (0.144 g) was dissolved in chloroform (15 ml), and sulfur dioxide gas was bubbled into the orange solution, which rapidly became pale yellow. After filtration, petroleum ether was added (35 ml). After a day at −5 °C, pale yellow crystals were obtained, which were washed with ether and dried in vacuum. Yield 0.135 g (75%).

E. $[Ir(CO)(PPh_3)_2(NO_3)(SO_2)]$

Complex **A**, under vacuum, was placed under an atmosphere of sulfur dioxide. The bright yellow powder was quantitatively converted to the lime green product solid over a period of minutes. Yield 100%.

F. $[Ir(CO)(PPh_3)_2(NO_3)(TCNE)]$

(*i*) Complex **A** (0.20 g) was added to a solution of excess tetracyanoethylene (TCNE) (0.1 g) in benzene (15 ml). The bright yellow solution deposited a pale yellow solid, which was collected in air, washed with a little benzene, then with ether, and dried in vacuum. Yield 0.10 g (~50%).

(*ii*) Complex **B** (0.1 g) was added to a solution of excess TCNE (0.05 g) in benzene (10 ml). After several minutes, the product solid was collected, washed with a little benzene and then ether and dried in air. This solid displays identical absorptions in the i.r. spectrum as the complex **F**. Yield 0.05 g (~50%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

G. [Ir(CO)(PPh$_3$)$_2$(NO$_3$)Cl$_2$]

(*i*) Complex **A** (0.20 g) was added to a slurry of excess $CuCl_2 \cdot 2H_2O$ (0.5 g) in acetone (20 ml), and stirred at room temperature. After 15 min, water (30 ml) was added, and the precipitated solid collected, washed with water, ethanol, and ether, and dried in air. The product was extracted into chloroform (3 × 5 ml), forming a pale green solution, which was filtered from a residue. Addition of methanol (35 ml) gave a pale yellow solid, which was collected after a day, washed with ether, and dried in vacuum. Yield 0.10 g (50%).

(*ii*) Complex **B** (0.20 g) was reacted in an identical manner, giving the same product. Yield 0.12 g (55%).

H. [Ir(CO)(PPh$_3$)$_2$(NO$_3$)Br$_2$]

(*i*) Complex **A** (0.20 g) was reacted with $CuBr_2$ (0.5 g) exactly as in the preparation of **G** above. The product was a bright yellow solid. Yield 0.11 g (50%).

(*ii*) Complex **B** (0.20 g) was reacted with $CuBr_2$ (0.5 g) as above, giving an identical bright yellow solid product. Yield 0.10 g (50%).

I. [Ir(CO)(PPh$_3$)$_2$(NO$_3$)I$_2$]

Complex **A** (0.13 g) was added to excess iodine (0.1 g) dissolved in benzene (15 ml). After stirring at room temperature for several minutes, the solution was filtered and diluted with ether (35 ml). The pale orange solid product was collected after one day, washed with ether, and dried in vacuum. Yield 0.07 g (40%).

J. [Ir(CO)(PPh$_3$)$_2$(NO$_3$)Cl(HgCl)]·½CHCl$_3$

Complex **A** (0.19 g) was added to excess $HgCl_2$ (0.09 g) in acetone solution (15 ml). After several minutes, the solvent was removed from the product white slurry by a water pump. The solid residue was extracted with chloroform (3 × 4 ml) to give a very pale yellow solution, which was filtered from a white residue. Addition of petroleum ether (30 ml) gave a rapidly formed white solid, which was collected after one day, washed with ether, and dried in vacuum. Yield 0.16 g (75%).

K. [Ir(CO)(PPh$_3$)$_2$(NO$_3$)$_2$(HgNO$_3$)]

(*i*) Complex **A** (0.10 g) was added to excess $Hg(NO_3)_2 \cdot H_2O$ (0.20 g) in acetone (15 ml). After stirring for several minutes, the solvent was removed by a water pump. The yellow residue was extracted with chloroform (3 × 4 ml), giving a colorless, opaque solution that was filtered from a yellow residue. The filtrate was diluted with petroleum ether (30 ml) to give a white powder as product. The product was collected, washed with ether, and dried in vacuum. Yield 0.11 g (90%).

(*ii*) Complex **B** (0.12 g) was reacted in an identical manner as (*i*) above, giving an identical product. Yield 0.12 g (90%).

L. [Ir(CO)$_3$(PPh$_3$)$_2$](NO$_3$)

Complex **A** (0.40 g) was suspended in dichloromethane (20 ml), and carbon monoxide gas was bubbled into the slurry, in the absence of oxygen. The solution was filtered after several minutes, and ether (100 ml) was added. After one day at −5 °C, the product was collected, and dried. The solid was recrystallized by dissolving in a minimum amount of ethanol (25 ml), followed by filtration and addition of ether (100 ml). The pale yellow solid product was collected after one day at −5 °C, washed with ether, and dried in vacuum. Yield 0.090 g (20%).

M. [Ir(CO)(PPh$_3$)$_2$(NO$_3$)$_2$I]

Complex **B** (0.16 g) was added to an excess of iodine (0.2 g) in solution in benzene (15 ml). After stirring for several minutes, the solution was filtered from a brown residue, and diluted with ether (75 ml). After one day at −5 °C, orange crystals of product were collected, washed with ether, and dried in vacuum. Yield 0.15 g (90%).

N. [Ir(CO)(PPh$_3$)$_2$(NO$_3$)$_2$(HgCl)]

Complex **B** (0.20 g) and $HgCl_2$ (0.09 g) were added to acetone (15 ml). The slurry rapidly became white, and after stirring for several minutes, was diluted with water (35 ml). The precipitated solid was filtered off, washed with water, and ether and dried in air. Extraction with dichloromethane (3 × 7 ml) gave a colorless solution which was filtered from a white residue, and diluted with petroleum ether (30 ml). A white powder rapidly separated, was collected, washed with ether, and dried in vacuum. Yield 0.10 g (45%).

Other Reactions of Complex B

(i) With Bromine

Complex **B** (0.10 g) was added to a solution of excess Br_2 (0.1 g) in benzene (10 ml). After several minutes, the solution was filtered from a residue, and diluted with ether (35 ml). After one day at −5 °C, bright yellow crystals were obtained, identical to complex **H** above, [Ir(CO)(PPh$_3$)$_2$(NO$_3$)Br$_2$]. Yield 0.06 g (50%).

(ii) With Hydrogen Bromide

Complex **B** (0.10 g) was added to benzene (15 ml) through which HBr gas was being slowly bubbled. After several minutes, the pale yellow solution was filtered from a residue, and diluted with petroleum ether (35 ml). After several hours, a product solid was collected. Yield 0.07 g. The product i.r. displayed no nitrato ligand absorptions, although carbonyl and metal-hydride absorptions characteristic of iridium(III) were observed.

Metal Halide Ammines. 1. Thermal Analyses, Calorimetry, and Infrared Spectra of Cadmium Halide (Cl, Br, I) Derivatives

K. C. Patil and E. A. Secco

Chemistry Department, St. Francis Xavier University, Antigonish, Nova Scotia

Received May 26, 1971

The thermal analyses of cadmium halide hexammines reveal that decomposition occurs by loss of ammonia via the diammine and the monoammine. Calorimetric measurements along with related enthalpic values for the intermediate stable stages of the decomposition reaction are given.

The infrared spectral data of the diammines and monoammines are presented with their assignments.

Les analyses thermiques d'hexammines d'halogénure de cadmium indiquent que la décomposition se fait par perte d'ammoniaque via la diammine et la monoammine. Les mesures calorimétriques ainsi que les valeurs d'enthalpie correspondantes sont données pour les étapes intermédiaires stables.

Les données relatives aux spectres infrarouges des diamines et monoamines sont présentées avec leurs attributions.

Canadian Journal of Chemistry, 49, 3831 (1971)

Introduction

The reaction between cadmium halides (Cl, Br, I) and ammonia in aqueous solution is known to yield ammoniates or ammines of varying compositions depending on the reaction conditions, such as solution concentration and temperature (1–3). Although the kinetics of formation of cadmium halide diammines have been reported (4–6), no study of the mode of decomposition of these ammines has appeared in the literature.

The purpose of this paper is to report on the mode of decomposition, heat of decomposition, relative thermal stability, and infrared spectra of cadmium halide (Cl, Br, I), monoammines, diammines, and hexammines.

Experimental

All the halide diammines were prepared by the addition of liquor ammonia to saturated aqueous solutions ($>0.25\ m$) of the respective cadmium halide. The resulting precipitate was washed free from halide with distilled water, followed by washing with alcohol, and dried at room temperature in air. Dilute aqueous solutions ($<0.25\ m$) of cadmium halide are reported to yield basic halides with ammonia (7).

Cadmium halide hexammines were prepared by refluxing the anhydrous cadmium halide with anhydrous liquid ammonia for 3–4 h. The ammonia was Matheson compressed gas with a stated purity 99.99% grade. The apparatus consisted of a conical Pyrex flask containing a magnetic stirrer fitted to a condensor charged with an acetone – Dry Ice mixture (*ca.* −70 °C).

The heating curves recorded for differential thermal analysis, thermogravimetry, and calorimetry were obtained using the instrumentation described previously (8, 9). The infrared spectra of the compounds were recorded on a Perkin–Elmer Model−180 spectrophotometer using the standard pellet technique with KBr as the matrix material.

Results and Discussion

Thermogravimetry

The results of thermogravimetry are given in Table 1. The proposed reactions for each compound are those which best fit the observed weight loss; the intermediate and final products of decomposition were further confirmed by infrared and correlated with DTA curves.

The decomposition course of all the hexammines occurred via the following sequence

[1] $CdX_2 \cdot 6NH_{3(s)} \rightarrow CdX_2 \cdot 2NH_{3(s)} + 4NH_{3(g)}$

[2] $CdX_2 \cdot 2NH_{3(s)} \rightarrow CdX_2 \cdot NH_{3(s)} + NH_{3(g)}$

[3] $CdX_2 \cdot NH_{3(s)} \rightarrow CdX_{2(s)} + NH_{3(g)}$

[4] $CdX_{2(s)} \rightarrow CdX_{2(g)}$, where (X = Cl, Br, I).

The hexammines are relatively unstable, decomposing to the diammines after a few days in storage at room temperature.

The diammines prepared by aqueous precipitation show the corresponding steps 2, 3, and 4 in their decomposition pattern.

Differential Thermal Analysis

The results of DTA measurements are presented in Table 2 and the discussion is given to accompany the TG results.

The three endotherms corresponding to reaction eqs. 1 to 3 appeared for the bromide and iodide ammines; an additional endotherm due to

the melting of the monoammine is observed in all compounds. The melting temperatures of the monoammines decrease in the order of Cl → Br → I which is interpreted in terms of stronger covalency of the Cd–N bond in going from chloride to iodide ammines.

The DTA curve of the chloride hexammine, Fig. 1, displays two endotherms attributed to steps 1 and 2 leading to the monoammine. The monoammine subsequently decomposed to the anhydrous chloride via two steps

[3*a*] $CdCl_2 \cdot NH_{3(l)} \rightarrow CdCl_2 \cdot \frac{1}{2}NH_{3(s)} + \frac{1}{2}NH_{3(g)}$

[3*b*] $CdCl_2 \cdot \frac{1}{2}NH_{3(s)} \rightarrow CdCl_{2(s)} + \frac{1}{2}NH_{3(g)}$

which accounts for the two endotherms at 330 and 360 °C, respectively. The residue after the 330 °C endotherm was determined thermogravimetrically to correspond to the composition $CdCl_2 \cdot \frac{1}{2}NH_3$. The small exotherm observed at 370 °C is attributed to crystallization of $CdCl_2$, confirmed by X-ray diffraction patterns of the residues immediately prior to the exothermic peak and immediately after this peak. The absence of a crystallization exotherm for $CdBr_2$ and CdI_2 is most likely due to the fact that these anhydrous halides result from a liquid phase decomposition reaction whereas anhydrous $CdCl_2$ results from a solid phase reaction.

Calorimetric Measurements

The calorimetric data, along with the related enthalpy values for decomposition of the halide ammines including two halide hydrates for comparison purposes, are presented in Table 3

*Includes ΔH (fusion) of $CdCl_2 \cdot NH_3$ which overlaps the decomposition reaction.
†All determinations were done in duplicate; ΔH values accompanied by average deviations.
‡ΔH_f° values of compounds used in our calculations are from ref. 3 below. The above ΔH_f° values were calculated using Kopp's Rule approximation, *i.e.* $\Delta C_p^\circ \simeq 0$.

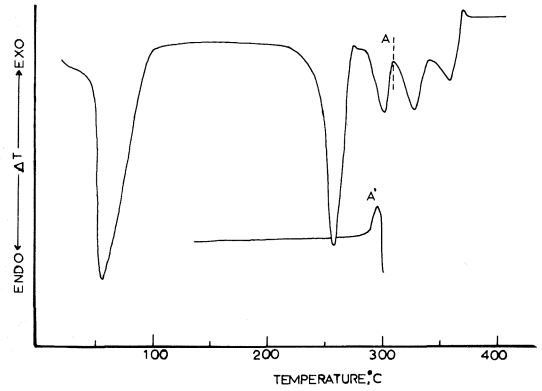

FIG. 1. Differential thermal analysis heating curve *A* for $CdCl_2 \cdot 6NH_3$ and the cooling curve *A'* from 300 °C illustrating the reversibility of the process associated with the third endotherm. The heating curve shows the additional endotherms identified with reactions 3*a* and 3*b* along with the exotherm due to crystallization.

according to the following equations showing the onset and terminal temperatures,

$$[5]\quad CdCl_2 \cdot NH_{3(s)} \xrightarrow{240\text{–}325\ ^\circ C} CdCl_{2(s)} + NH_{3(g)}$$

$$[6]\quad CdCl_2 \cdot 2NH_{3(s)} \xrightarrow{160\text{–}230\ ^\circ C} CdCl_2 \cdot NH_{3(s)} + NH_{3(g)}$$

$$[7]\quad CdCl_2 \cdot 6NH_{3(s)} \xrightarrow{25\text{–}100\ ^\circ C} CdCl_2 \cdot 2NH_{3(s)} + 4NH_{3(g)}$$

$$[8]\quad CdBr_2 \cdot 6NH_{3(s)} \xrightarrow{25\text{–}130\ ^\circ C} CdBr_2 \cdot 2NH_{3(s)} + 4NH_{3(g)}$$

$$[9]\quad CdI_2 \cdot 6NH_{3(s)} \xrightarrow{25\text{–}130\ ^\circ C} CdI_2 \cdot 2NH_{3(s)} + 4NH_{3(g)}$$

$$[10]\quad CdCl_2 \cdot 2\tfrac{1}{2}H_2O_{(s)} \xrightarrow{80\text{–}170\ ^\circ C} CdCl_{2(s)} + 2\tfrac{1}{2}H_2O_{(g)}$$

$$[11]\quad CdBr_2 \cdot 4H_2O_{(s)} \xrightarrow{25\text{–}130\ ^\circ C} CdBr_{2(s)} + 4H_2O_{(g)}$$

Our ΔH_f° values for $CdCl_2 \cdot NH_3$, $CdCl_2 \cdot 6NH_3$, and $CdBr_2 \cdot 6NH_3$ are in excellent agreement with the literature whereas a noticeable disparity is evident in the ΔH_f° values for the other compounds.

The column of values for ΔH per mole of NH_3 or H_2O formed indicates an increasing trend, $CdCl_2 \rightarrow CdBr_2 \rightarrow CdI_2$. This trend is consistent with a prediction by Chatt and co-workers (10) which suggested that the relative affinities of the halide ions for Cd^{2+} are in the direction Cl < Br < I. The order of Cd–halogen bond strength is Cl → Br → I where the difference is reported as 8–10 kcal/mol (11), thus a parallel increasing trend for the ammonia ligands is anticipated. However, in addition to the factors of ionic size and polarizability of the ligand in contributing to the stability of the metal halogen complexes (12), the role of lattice energy must also be recognized in crystalline compounds.

Infrared Spectral Data

The infrared spectra of cadmium halide hexammines (13, 14) and diammines (15, 16) already appear in the literature. In Table 4 the infrared absorption frequencies, with their

*vs = very strong; s = strong; m = medium; w = weak; b = broad; sp = sharp; sh = shoulder.

assignments, are presented for the diammines, monoammines, and the deuterated analogues of the diammines over the 4000–180 cm^{-1} region. The ν_H/ν_D ratios fall in the range 1.31–1.42 for the NH_3 vibrations.

The vibrational assignments are made on the basis of a simple 1:1 model (*i.e.* Cd–NH_3) where the normal modes of vibration are represented by those of a tetrahedral ZXY_3 molecule of C_{3v} symmetry.

Our data show a high degree of internal consistency for the various assignments in all ammines; the data are also in agreement with the existing literature values for the diammines. The symmetric stretching $\nu_{(NH)s}$ for the deuterated analogue is not discernible since its expected weak band at *ca.* 2320 cm^{-1} is masked by ν_3 of CO_2 present in the atmosphere. Slight shifts of 10–30 cm^{-1} are noticeable for $\nu_{(NH)s}$ and $\rho_{(NH_3)r}$ in going from $CdCl_2 \cdot NH_3 \rightarrow CdBr_2 \cdot NH_3 \rightarrow CdI_2 \cdot NH_3$.

The observation of the 370 cm^{-1} band in the monoammines confirms the $\nu_{(M-N)}$ assignment and is a step towards resolving the existing controversy (16, 17) regarding the assignment of $\nu_{(M-N)}$ and $\delta_{(N-M-N)}$ in the hexammines. The bending mode $\delta_{(N-M-N)}$ predicted to be <200 cm^{-1} was not observed in the diammines since this frequency is beyond the limits of our instrument. The slight isotopic shift evident in $\nu_{(M-N)}$, $\nu_H/\nu_D = 1.06$, suggests that this mode involves the entire NH_3 (or ND_3) mass unit; such an assumption leads to a calculated ν_H/ν_D of 1.07.

Electronic Spectra of Nickel Chloride in Molten Amides

M. E. Stone and K. E. Johnson,
University of Saskatchewan, Regina Campus, Regina, Saskatchewan

Received April 28, 1971

Solutions of $NiCl_2$ in molten acetamide and caprolactam have been investigated. The nature of the Ni(II) species present was found to be independent of concentration, over the concentration ranges 0.02 to 0.25 and 0.01 to 0.3 *M*, respectively; however, it was not independent of temperature. In both solvents, Ni(II) occurred mainly in octahedral environments but an increase in temperature apparently resulted in the formation of tetrahedral species.

Des mélanges de $NiCl_2$ avec l'acétamide et la caprolactame ont été étudiés. La nature des espèces Ni(II) est indépendante de la concentration sur les intervalles de concentration allant respectivement de 0.02 à 0.25 et de 0.01 à 0.3 *M*; elle n'est cependant pas indépendante de la température. Dans les deux solvants, Ni(II) se trouve principalement dans un environnement octahédrique; une augmentation de la température a cependant pour conséquence la formation d'espèces tétrahédriques.

Canadian Journal of Chemistry, **49**, 3836 (1971)

Mixtures of $NiCl_2$ with acetamide and caprolactam change color, from pale green to blue, when heated. Since color changes are often indicative of structural changes, the electronic spectra of these systems have been investigated.

Experimental

Spectra were obtained with a Cary 14H recording spectrophotometer, using a single cell. The furnace used to heat the optical cell was an adaptation of that described by Johnson, Mackenzie, and Sandoe (1). Changes included elimination of the mirror system, the light beam being passed directly through the sample. The temperature could be controlled to within ± 1 °C.

In order to correct the spectra for changes in the densities of the systems, the densities of caprolactam and acetamide were determined at various temperatures. This was done by Archimedes method, weighing a silver block in air, water, and the melts. Since the solutions expanded on heating, they decreased in molarity. In order to compare results for a constant composition, all the recorded values of optical density were divided by the density of the solvent at the temperature at which the spectrum was obtained. This treatment was based on the assumption that the densities of the solutions were the same as those of the pure solvents.

The temperature ranges used were 85 to 190 °C for acetamide and 73 to 193 °C for caprolactam; at higher temperatures the solvents discolored. The spectral range for acetamide was found to be 7.0 to 33 kK; for caprolactam it was 6.8 to 31 kK.

Results

The spectra obtained from representative $NiCl_2$/caprolactam and $NiCl_2$/acetamide mixtures by increasing the temperature are shown in Figs. 1 and 2. The densities of caprolactam and acetamide were found to be linear functions of temperature

$$p(\text{caprolactam}) = 1.0462 - 0.0005t,$$

$$p(\text{acetamide}) = 1.0763 - 0.00095t$$

In each case, a least squares fit to a straight line was computed and gave a good correlation factor (0.9645 for caprolactam taking 9 points and 0.9984 for acetamide taking 19 points).

Discussion

(a) Caprolactam Solutions

Over the concentration range 0.01 to 0.3 *M*, the solutions obeyed the Bouger–Beer law that optical density is proportional to concentration. This implies that either: (*i*) a single species was present or (*ii*) there was a mixture of species whose concentration ratios remain constant when the total concentration changed.

The spectra were found to be both linear and internally linear with respect to temperature. That is (*i*) the molar absorptivity at a given wavelength was a linear function of temperature. (*ii*) each spectrum in the set could be considered as a linear combination of two other spectra in the set.

If

$$\delta = [1 - b]\varepsilon(t_1) + b\varepsilon(t_2) - \varepsilon(t_3),$$

where $\varepsilon(t)$ = molar absorptivity at a given wavelength at temperature t, then a value of b could be calculated such that δ was small compared to ε at all wavelengths.

Spectra which are both linear and internally linear with respect to temperature can arise from a single species (2). If the system under investigation had contained a single Ni(II) species, it would most likely have been a distorted octahedron, since other geometries usually correspond to spectra with higher molar absorptivities. A tetragonal distortion (D_{4h}) would have led to increased intensity and splitting of the ^3T levels, particularly $^3T_{2g}$ (F) (3). Increased intensity was observed (Table 1) but the $^3T_{1g}$ (P) ← $^3A_{2g}$ (F) and $^3T_{2g}$ (F) ← $^3A_{2g}$ (F) transitions did not appear to split.

Internal intensity can be interpreted (4) as the result of an equilibrium between two species, the spectrum of each of which is independent of temperature. As the temperature is changed, so the relative concentrations of the species change and with them the total spectrum of the mixture. However, the concentration changes arising from a chemical equilibrium are generally not linear with respect to temperature and, therefore, the total spectrum would not be expected to change linearly with temperature. Brynestad and Smith (4) have considered this problem and conclude that spectra which are both linear and internally linear with respect to temperature are not due to species in equilibrium. If they are due to a mixture, then it is a mixture of species for which the composition is independent of temperature; the extinction coefficients of the absorbing species are temperature dependent.

When the spectra of the $NiCl_2$/caprolactam solutions are compared to that of Ni$(Cap)_6Cl_2$ in ethanol at room temperature (Table 2), the former will be seen to resemble the latter in some regions but to have greater absorption in the 12–24 kK region. This absorption increases with temperature. The total spectrum of a mixture of two species should show temperature changes due to both of them. Although the weakest band (12 kK) changes little, the large increases in intensity in the bands at 8, 15, and 22 kK in the $NiCl_2$/caprolactam spectrum can be compared to those observed for octahedral Ni(II) in $KMgCl_3$ (6). Thus the mixture could have contained an octahedral species. In this case, it must also have contained a species which gave rise to the band at 17 kK. Such a band is characteristic of a tetrahedral species. However, the spectrum of tetrahedral Ni(II) in $[NiBr_4]^{2-}$ has been previously found (7) to decrease in height with increasing temperature,

*Acm = acetamide.

although the results were not corrected for changes in melt density. Other tetrahedral species may behave differently but it seems unlikely that the large increase in intensity of the 17 kK band is not due to an increase in concentration.

It seems then that, in the caprolactam solutions, Ni(II) existed in an equilibrium mixture of octahedral and tetrahedral sites, the latter being favored by increasing temperature. The change in the concentration of octahderal sites would be small, leading overall to small intensity increases in the bands due to the octahedral species since the intensity of bands from each O_h site increased with temperature. In turn, these changes were modified by the sharper increase in overlapping T_d bands at ~9 kK ($^3A_2$(F) ← $^3T_1$(F)) and 17 kK ($^3T_1$(P) ← $^3T_1$(F)).

The results obtained show some similarity to those given by Angell and Gruen (8) for Ni(II) in an 11 *M* aqueous $MgCl_2$ solution at 125–180 °C. In this range, the molar absorptivity is linear with respect to temperature, although the relationship does not hold at higher temperatures (*i.e.*, up to 314 °C). The spectra were interpreted as representing a mixture of octahedral and tetrahedral complexes, so it seems that concentration changes in the Ni(II) species can be linear with respect to temperature over limited ranges.

Thus, the most plausible explanation of the spectra is that they arose from Ni(II) in a mixture of octahedral and tetrahedral environments. Since the main tetrahedral band is affected only slightly by octahedral bands, its optical density gives a measure of the concentration of the tetrahedral species. A plot of log optical density *vs.* $10^3/T$ should be linear with slope $\Delta H/2.303\bar{R}$ (9). The peaks at 14.3, 16.0 and 17.0 kK were analyzed in this way, giving the graphs shown in Fig. 3. These are linear over a region from 100 to 160 °C and are parallel to each other. The latter suggests that one tetrahedral species only is present in that temperature range. At lower temperatures, the equilibrium, if there is one, involves different species. The average value of ΔH between 100 and 160 °C is 2.2 kcal mol^{-1}. This figure is very low for an $O_h \rightarrow T_d$ Ni(II) transition, since previous workers (8, 10) obtained values of 7–17 kcal mol^{-1}. However, ΔH must vary with temperature and the type of ligand involved (see later), so the value of 2.2 kcal mol^{-1} may not be unreasonable. If the system in the 70 to 100 °C range is treated as an equilibrium mixture, then ΔH is calculated to be about 7.3 kcal mol^{-1}.

(b) Acetamide Solutions

Solutions of $NiCl_2$ in acetamide in the range of 0.02 to 0.25 molar were found to obey the Bouger–Beer Law. Unlike the caprolactam solutions, they gave spectra which were neither linear nor internally linear with respect to temperature. The spectrum obtained at 85 °C closely resembled that of $[Ni(Acm)_4(H_2O)_2]$-

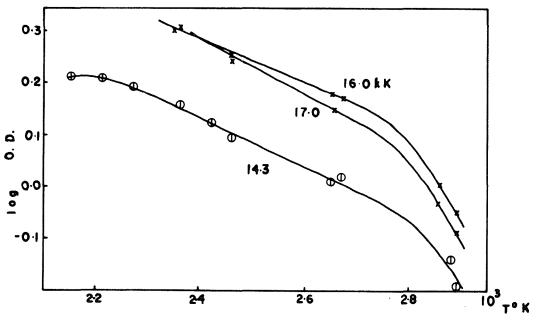

FIG. 3. Plot of $\log_{10}$ (optical density) *vs.* $10^3/T$ °A for $NiCl_2$ in caprolactam (0.064 *M*).

Cl_2 in ethanol (Table 2) and presumably corresponded to an octahedral Ni(II) site in the melt.

At higher temperatures, the spectra were similar to those obtained from the caprolactam solutions and, therefore, tetrahedral Ni(II) was probably present in the system. Since the spectra were not internally linear with respect to temperature, there could not have been a simple equilibrium between octahedral and tetrahedral species for each of which ε was independent of temperature. There could have been: (*i*) an equilibrium between octahedral and tetrahedral species for one or both of which ε varied with temperature, or (*ii*) a gradual distortion of the octahedral species toward tetrahedral symmetry. Although several octahedral $\rightleftarrows$ tetrahedral equilibria have been investigated and the temperature dependencies of the molar absorptivities have been neglected, it is possible that they are appreciable here. Temperature dependence should be greatest for centrosymmetric octahedral or pseudo-octahedral complexes, for which the transitions gain intensity by vibronic coupling. A gradual distortion would be expected to be accompanied by splitting of octahedral bands. Since this is not observed, an equilibrium is most likely.

This study does not tell us whether Cl^- is in the first coordination sphere of Ni(II) in molten amides. The ligand field parameter Δ (given by $^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$) is the same for the melts as for the compounds in EtOH solution where 6 oxygen atoms form the first links (5). The substitution of Cl which is somewhat lower in the spectrochemical series might reduce Δ a little and would also constitute a lowering of symmetry but by how much? Probably the octahedral species involve coordination by 6 amide groups and the tetrahedral species arise when a Cl substitutes for an amide, there not being enough room for 5 amides and one Cl about Ni(II). It might be interesting, within the limited temperature ranges available, to examine mixtures containing bromide instead of chloride, and alkali salts (MX).

The authors would like to thank the National Research Council of Canada for financial support.

The Temperature Dependence of Transition State Volumes in Hydrolysis Reactions

MOYRA J. MACKINNON AND J. B. HYNE

Department of Chemistry, The University of Calgary, Calgary, Alberta

Received July 19, 1971

The temperature dependence of the transition state volume, $d\bar{V}^t/dT$, in a number of hydrolysis reactions is derived from pressure/rate data and partial volume temperature dependence. The values obtained for $d\bar{V}^t/dT$ vary from near zero for *p*-methylbenzyl chloride to about 0.3 ml mol^{-1} deg^{-1} for isopropyl bromide. The interpretation of the experimental and derived values for these hydrolyses is discussed in terms of charge development with accompanying solvation effects about the solute.

La dépendance du volume de l'état de transition de la température $d\bar{V}^t/dT$, dans un nombre de réactions d'hydrolyse provient de la pression/vitesse donnée et de la dépendance de la température du volume partiel. Les valeurs obtenues pour $d\bar{V}^t/dT$ varient près de zéro pour le chlorure de *p*-méthylbenzyle à environ 0.3 ml mol^{-1} deg^{-1} pour le bromure d'isopropyle. L'interprétation de ces données expérimentales pour ces hydrolyses est discutée en terme de développement de charge accompagnant les effets de solvatation autour du soluté.

Canadian Journal of Chemistry, 49, 3840 (1971)

Introduction

The temperature dependence of a transition state partial molal volume, $d\bar{V}^t/dT$, may be obtained from the temperature dependence of the activation volume, $d\bar{V}^*/dT$, and of the partial molal volume of the initial state, $d\bar{V}^g/dT$, thus

$$\frac{d\Delta V^*}{dT} = \frac{d\bar{V}^t}{dT} - \frac{d\bar{V}^g}{dT}$$

Although a few values of $d\Delta V^*/dT$ have previously been obtained experimentally (1–7), these have not been combined with partial molal volume temperature dependence data to study the transition states of these reactions. In this investigation a number of hydrolysis reactions varying in their degree of charge development in the transition state were studied and the derived values of $d\bar{V}^t/dT$ interpreted in terms of reaction mechanism.

Experimental

Materials

Water

House distilled water was passed through Illco-Way deionizing resin and then redistilled in Pyrex apparatus from which carbon dioxide was excluded. The conductivity of the water was $8 \times 10^{-7}\ \Omega^{-1}\ cm^{-1}$ at 25 °C.

Benzyl Chloride

Eastman White Label benzyl chloride was twice distilled at 10^{-3} mm Hg with collection of the middle third fraction of each distillation, $n_D^{23.0\,°C} = 1.5391$.

p-Methylbenzyl Chloride

p-Methylbenzyl chloride supplied by Aldrich Chemical Company was distilled twice at 10^{-3} mm Hg with collection of the middle third fraction each time. Analysis of the purified sample by gas–liquid chromatography showed less than 0.1% impurity, $n_D^{20} = 1.5331$.

Allyl Chloride

Matheson, Coleman and Bell allyl chloride was twice distilled under vacuum with collection of the middle third fraction each time (2), $n_D^{23.2\,°C} = 1.4155$.

n-Butyl Bromide

n-Butyl bromide supplied by Fisher Scientific Company was distilled at atmospheric pressure and a middle fraction used. Analysis by gas–liquid chromatography showed less than 0.01% impurity in the purified sample, $n_D^{23.0\,°C} = 1.4385$.

Isopropyl Bromide

Isopropyl bromide supplied by British Drug Houses was distilled at atmospheric pressure with collection of the middle third fraction, $n_D^{23.6\,°C} = 1.4251$.

Methanesulfonyl Chloride

Methanesulfonyl chloride supplied by Eastman Organic Chemicals was twice distilled under vacuum with collection of the middle third fraction each time. Analysis by gas–liquid chromatography showed less than 0.4% impurity, $n_D^{22.6\,°C} = 1.4513$.

Kinetics

The rates of hydrolysis of *p*-methylbenzyl chloride were studied in water at 1.045 and 20.00 °C over a pressure range from 1 to 2041 atm. The hydrolysis rates of *n*-butyl bromide were studied at 55.00 and 69.94 °C over a pressure range of 1 to 3402 atm. The rates for methanesulfonyl chloride were obtained at 5.00 and 21.00 °C between 1 and 2041 atm. Temperature control was maintained to ±0.01 °C in an oil bath with thermoregulator and lamp heater with an auxiliary refrigerating unit for temperatures below 20 °C.

In all reactions the rate of production of HCl resulting from the hydrolysis was followed conductimetrically, the experimental details having been previously reported (8,9). Graphical analysis of the conductivities by the Guggen-

heim method (10) yielded pseudo first-order rate constants. The high pressure systems and controls have also been previously described (8).

The hydrolysis of benzyl chloride (8), isopropyl bromide (1), and allyl chloride (2) have been studied by previous workers and their rate/pressure data were used in the determinations of $d\overline{V}^t/dT$ for these compounds.

Partial Molal Volumes

The method for determination of partial molal volumes by injection from a micro-syringe has been previously reported (11). Degassed water was used as the solvent and the temperature of the oil bath maintained to about ±0.01 °C. For temperatures below 25 °C cooling was obtained by a coil connected to an auxiliary thermostatted cryostat.

The required partial molal volumes of the reactants were obtained at two different temperatures which were as far apart as was experimentally possible for the compounds under investigation. If the upper temperature was too high it was found that the results were not reproducible due to the formation of gas bubbles.

Each determination was done at least four times. The first determination corresponded to a substrate concentration equal to that used for the kinetic runs ($\gtrsim 5 \times 10^{-4}$ *M*) where no solubility effects were found. The value of the partial molal volumes obtained with fresh solvent for each determination did not differ from those obtained with three or four repeated injections into the same solvent.

The required densities of the compounds at the temperature of injection were obtained from the literature except in the case of *p*-methylbenzyl chloride. A density value for this substrate was determined with a micro-pycnometer which had been calibrated with distilled water.

Results

Kinetics

The rate constants as a function of pressure for the hydrolysis of *p*-methylbenzyl chloride at 1.05 and 20.00 °C are presented in Table 1, and for *n*-butyl bromide at 55.00 and 69.94 °C in Table 2. Corresponding data for methanesulfonyl chloride hydrolysis at 5.00 and 21.00 °C are given in Table 3. Each rate constant is the average of at least three determinations with indicated errors being average deviations. These rate constants yield values of ΔV^* at different temperatures as shown in Table 4 together with corresponding literature values of ΔV^* for several other hydrolysis reactions. Our values of ΔV^* were obtained by fitting the rate–pressure data to a quadratic expression (12) with the indicated errors being standard deviations from this quadratic fit. In the case of isopropyl bromide, ΔV^*

was recalculated from the literature rate constants (1) using the quadratic expression in order that the extracted value would be comparable with the other ΔV^*'s which were obtained by this method.

Partial Molal Volumes

Table 5 presents partial molal volumes in water as a function of temperature for the same compounds for which ΔV^* data are shown in Table 4. The densities of the solutes needed in the calculation of the partial molal volumes were obtained from the literature as follows: benzyl chloride (13), allyl chloride (14), isopropyl bromide (14), *n*-butyl bromide (16), and methanesulfonyl chloride (15). The density of *p*-methylbenzyl chloride was determined at 25.1 °C = 1.06_6 g/ml, and at 23.5 °C = 1.07_0 g/ml.

Each partial molal volume in the table is the average of at least four determinations with the errors being average deviations.

Using the data in Tables 4 and 5, values of $d\overline{V}^t/dT$ may be calculated for each of the compounds under consideration by use of the equation

$$\frac{d\Delta V^*}{dT} = \frac{d\overline{V}^t}{dT} - \frac{d\overline{V}^g}{dT}$$

Table 6 presents $d\Delta V^*/dT$, $d\overline{V}^g/dT$ and $d\overline{V}^t/dT$ for the compounds in this investigation. Accumulation of uncertainties in the activation volume and the initial state partial molal volumes results in $d\overline{V}^t/dT$ values having rather large error limits. These values of $d\overline{V}^t/dT$ are shown in Fig. 1 with the required limits of uncertainty indicated for each compound. Despite the magnitude of the uncertainty in the extracted values of the temperature dependence of the transition state volume there is, nevertheless, a clear trend and a significant difference between the various hydrolyses as indicated in Fig. 1.

TABLE 5. Partial molal volumes in water at various temperatures

Compound	Temperature (°C)	Partial molal volume (ml/mol)

	21.0	73.6±0.3

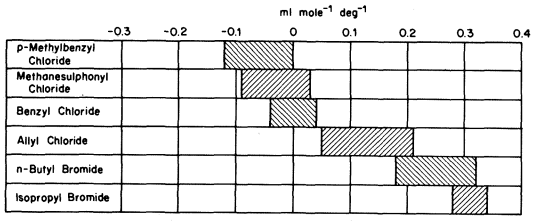

FIG. 1. Range of $d\overline{V}^t/dT$ values for transition states of several hydrolysis reactions

Discussion

A number of experimental values of $d\Delta V^*/dT$ have been previously reported (1–6) and Laidler (7) has discussed the variation of this second derivative activation parameter for several reactions involving different types of charge development or reduction in the activation process. However, since $d\Delta V^*/dT$ represents the temperature dependence of a difference, $d\overline{V}^t/dT - d\overline{V}^g/dT$, a definitive interpretation of $d\Delta V^*/dT$ variations can only be obtained through knowledge of the magnitude of the two component parts. Dissection of pseudothermodynamic parameters into their initial and transition state components has proved useful and informative in the cases of the first derivative parameters ΔH^* (17) and ΔV^* (11). Interest is currently being shown in the corresponding dissection of the second temperature derivative of the reaction rate ΔC_p^* (18) although no published data are yet available. The dissection of $d\Delta V^*/dT$ requires $d\overline{V}^g/dT$ and yields $d\overline{V}^t/dT$. This extracted value of $d\overline{V}^t/dT$ represents a further transition state property the value of which is likely to reflect the detailed nature of the solvent shell around the transition state.

Before entering into a detailed examination of the behavior of $d\Delta V^*/dT$ and its component parts, it is worth observing that despite the general utility of ΔV^* as a diagnostic probe of reaction mechanism (19), it is remarkably insensitive to changes in reaction substrate in the group of hydrolyses presented in Table 4. Apart from the one case of *p*-methylbenzyl chloride, negative ΔV^* values lie in the narrow range of −9 to −12 ml/mol for compounds with hydrolysis mecha-

nisms as different as *n*-butyl bromide and methanesulfonyl chloride. Indeed, changes in a particular ΔV^* of the same order of magnitude can be effected by *temperature* changes of some 30 to 40 °C (*vide* allyl chloride), once again emphasizing the need for caution in interpreting small changes in ΔV^* as being reflections of mechanism variations.

The experimentally determined values of $d\Delta V^*/dT$ presented in Table 6 themselves illustrate an interesting division of the hydrolysis reactions into those with negative activation volume temperature dependence and those with zero or positive temperature coefficients. Negative values for $d\Delta V^*/dT$ have commonly been associated with the development of polarity and hence electrostriction in the activation process resulting in a "tighter" transition state solvation shell whose volume is less responsive to temperature change than is the initial state. Contrariwise positive $d\Delta V^*/dT$ values have been attributed to solvation shell "loosening" in the activation process resulting from charge dispersal or decrease in polarity compared with the initial state. In all of the hydrolyses cited in Table 6 there can be little question that the transition state in the rate determining step is more polar than the initial state since in all cases the halide ion is a final product of the hydrolysis of a covalently bonded initial state. Accordingly, the zero or positive values for *n*-butyl bromide and isopropyl bromide suggest that there may well be other factors besides relative degrees of polarity or charge development in the initial and transition states involved in the determination of the temperature dependence of the volume of activation.

In discussing the results of the dissection of $d\Delta V^*/dT$ into its component parts as presented in Table 6, it must be recognized that the extracted $d\bar{V}^t/dT$ values are subject to considerable uncertainty by virtue of the accumulation of errors in the experimentally determined $d\Delta V^*/dT$ and $d\bar{V}^g/dT$ values from which the transition state parameter is derived. This question of confidence limits is always a problem with second derivative parameters and particularly so when they are obtained from the difference of two other derivatives. Despite the obvious need for caution, however, there is justification for recognizing the validity of the *trend* in $d\bar{V}^t/dT$ values demonstrated schematically in Fig. 1.

Clearly there is a trend in values from close to zero to significantly positive as the reacting substrate structure is varied from *p*-methylbenzyl chloride to isopropyl bromide. Generally speaking this order of substrate follows the decreasing degree of charge development expected in moving from the initial state to the top of the transition state energy barrier. The less developed and accessible the polarity of the system at the transition state the less tightly bound will be the solvation shell. Hence the response of the total volume of the transition state—substrate and kinetically significant solvation sheath—to temperature is expected to be greater for the less polar transition states.

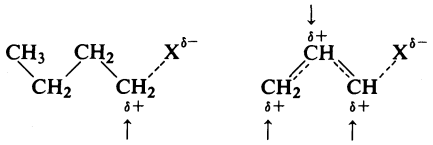
A comparison of our relative values of $d\bar{V}^t/dT$ with partial molal volume temperature dependence of models such as the tetraalkylammonium bromides shows a similar trend (20). Me_4NCl with a tighter solvent shell than the larger and more hydrophobic Bu_4NBr, shows a value of $d\bar{V}^g/dT$ of about 0.11 ml mol^{-1} deg^{-1} compared to 0.25 ml mol^{-1} deg^{-1} in the case of Bu_4NBr.

The possibility of the change from chloride to bromide as the leaving anion being responsible for at least some of the change in $d\bar{V}^t/dT$ behavior must be examined. Millero and Drost-Hansen (21) compare values of $d\bar{V}^g/dT$ for tetraalkylammonium chlorides and the corresponding bromides and establish that there is no significant difference in the expansibility of the chlorides

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

compared to the bromides. This would seem to indicate that, within our uncertainty limits, the change from chloride to bromide is unlikely to be the major reason for the change in behavior of $d\bar{V}^t/dT$.

The effect of charge on polarity development on volumes can be modified, however, by solvent accessibility to the polar site. Attention has already been drawn to the *positive* value of $d\Delta V^*/dT$ for *n*-butyl bromide and isopropyl bromide. Despite the expected greater degree of polarization in the secondary alkyl halide compared with the primary *n*-butyl bromide, the temperature dependence of the transition state volume of isopropyl bromide is at least as great as that for the primary alkyl bromide. This may well be a reflection of the reduced solvent accessibility to the developing carbonium type center in the isopropyl case compared with the smaller but less screened positive charge character on the *n*-butyl methylene center. The fact that the temperature dependences of the initial and transition state volumes in these two cases are virtually identical also suggests that the dominant factor in determining the thermal expansivity of both states is more likely a hydrophobic type of interaction between solute and solvent. The importance of solvent accessibility to the developing polarity in the activation process is also highlighted in the data for allyl chloride particularly when compared with *n*-butyl bromide. In the allyl chloride case the developing polarity in the transition state can be delocalized over the entire hydrocarbon chain thus providing a far greater degree of solvent accessibility to the available charge than is possible in the saturated *n*-butyl chain.



Accordingly, it might be expected that the degree of solvent electrostriction around the allyl transition state compared with the initial state would be greater than in the *n*-butyl case, leading to the relatively low value range for $d\bar{V}^t/dT$ for allyl chloride.

While *negative* values for $d\bar{V}^t/dT$ are not conclusively shown by virtue of the uncertainties associated with the first three hydrolyses in Table 6 the trend in values certainly suggests that negative values are a real phenomenon. This, of course, would mean that the volume of the transition state *decreased* with increase in temperature. It should be recalled that in hydrolyses we are dealing with a highly structured solvent, water, and that the degree of structuredness of the solvent is very temperature dependent. Any solute exerting an electrostrictive effect on water must compete with the water–water structure making interactions. As these are reduced by thermal agitation the electrostrictive effect of the solute will result in a greater degree of collapse of the environmental water "lattice" with a corresponding reduction in volume at higher temperatures. The concept of the competition between the structure making quasi crystalline field forces of liquid water and the electrostrictive attractions of a dissolved solute is, of course, a basic feature of the Frank and Wen (22) model of solvation shell structure.

Conclusion

There are now a number of good illustrations of the increased sensitivity of second derivative activation parameters to reaction mechanism variations compared with that of first derivative parameters (1, 2, 23). The principal difficulty associated with the use of these second derivatives lies in the problem of obtaining data of sufficient accuracy to permit extraction of parameters with reasonable confidence limits. The results on the second derivative parameter $d\Delta V^*/dT$ and its dissection into initial and transition state components presented here both illustrate the caution that should be exercised and the usefulness of the parameter in providing further insight into the important problem of solute–solvent interactions in the kinetics of reactions in solution.

The Reaction of Active Nitrogen with Carbonyl Chloride

R. R. Baker and C. A. Winkler
Department of Chemistry, McGill University, Montreal, Quebec

Received June 22, 1971

The reaction between active nitrogen and $COCl_2$ in an unheated reaction vessel has been studied over a large range of initial reactant conditions. Analytical studies have shown CO and Cl_2 to be the only reaction products, effectively produced in equal amounts. The maximum extent of reaction corresponded to no more than 10% of the available N atoms. The reaction was found to change from first order in both N and $COCl_2$ for $[COCl_2]_0/[N]_0 < \sim 0.1$, to zero order in $COCl_2$ and second order in N, with $[COCl_2]_0/[N]_0 > \sim 0.3$. The reaction appears to be initiated by energy transfer from an excited N_2 species.

La réaction entre l'azote actif et le $COCl_2$, dans un récipient réactionnel non-chauffé, a été étudiée en fonction des conditions des corps réagissant. Des études analytiques ont montré que CO et Cl_2 étaient les seuls produits de la réaction et qu'ils se formaient en égale quantité. L'avancement maximum de la réaction correspond à 10% au plus des atomes d'azote disponibles. La réaction passe du premier ordre en N et $COCl_2$ pour $[COCl_2]_0/[N]_0 < \sim 0.1$, à l'ordre zéro en $COCl_2$ et à l'ordre deux en N pour $[COCl_2]_0/[N]_0 > \sim 0.3$. La réaction semble induite par un transfert d'énergie à partir des espèces excitées de N_2.

Canadian Journal of Chemistry, 49, 3846 (1971)

Introduction

In reactions of active nitrogen the primary step may involve the direct attack of N atoms on the additive or its acquisition of energy from an excited molecular nitrogen species (1–3). The primary step in the reaction of active nitrogen with carbonyl chloride appears to be of the latter type, followed by secondary reactions with N atoms.

Experimental

A fast flow apparatus was used, essentially similar to those described in earlier studies (*e.g.* 4–6). Active nitrogen was produced by either a microwave unit, or by a condensed discharge between electrodes, in a discharge tube so designed that the active nitrogen traversed the same path in passing from either discharge to the reaction vessel (7). A Wood's horn light trap was interposed between the discharge unit and the reaction vessel. The reaction vessels were Pyrex tubes (cleaned with HF) about 70 cm long, with internal diameters in the range 2.0 to 3.1 cm. Carbonyl chloride was introduced into the reaction vessel at points 20 to 40 cm downstream from the discharge. Temperatures in the reaction zone were measured with a thermocouple sheathed in a thin glass tube.

Nitrogen atom flow rates could be adjusted over a rather wide range by adding traces of suitable discharge catalysts (H_2, O_2, or I_2) to the N_2 before it entered the discharge tube (6). The N atom flow rate at various positions in the reaction vessel could be determined by titration with NO (8) that was added through a movable jet.

Chlorine in the reaction products was trapped over a frozen solution of KI at liquid nitrogen temperatures, and its amount estimated, after melting the solution, by titration of the liberated I_2 with standard $Na_2S_2O_3$ solution. Carbon monoxide was estimated chromatographically, using a Gow-Mac W–Ni four filament thermal conductivity detector, in samples taken from the reaction vessel with a Toepler pump.

A stream of purified (6) Linde "Bone Dry" nitrogen entered the discharge tube directly, or after it had been mixed with traces of an appropriate catalyst gas. Carbonyl chloride (Matheson, 99.0% purity) was purified by bulb-to-bulb distillation, and was stored over mercury in the dark, to avoid its possible contamination with traces of Cl_2 formed by photochemical decomposition.

Results

The reaction was accompanied by a pink emission that extended in the reaction vessel for a distance that corresponded roughly with the time required for "complete" reaction. The temperature of the reaction zone was always higher than the temperature of the Lewis–Rayleigh afterglow in the absence of $COCl_2$, and ranged from 0.2 °K higher for low reactant flow rates (N atoms, 1.5×10^{-6} mol s^{-1}; $COCl_2$, 1.0×10^{-6} mol s^{-1}) to 50 °K higher for the highest flow rates used (N atoms and $COCl_2$ each 12×10^{-6} mol s^{-1}).

Analytical Studies

Cl_2 and CO were the only detectable products from the reaction, presumably produced in equal amounts. However, from a limited number of CO analyses, it appears that the recovery of Cl_2 was always about 5–10% lower than that of CO, over a range of N atom and $COCl_2$ flow

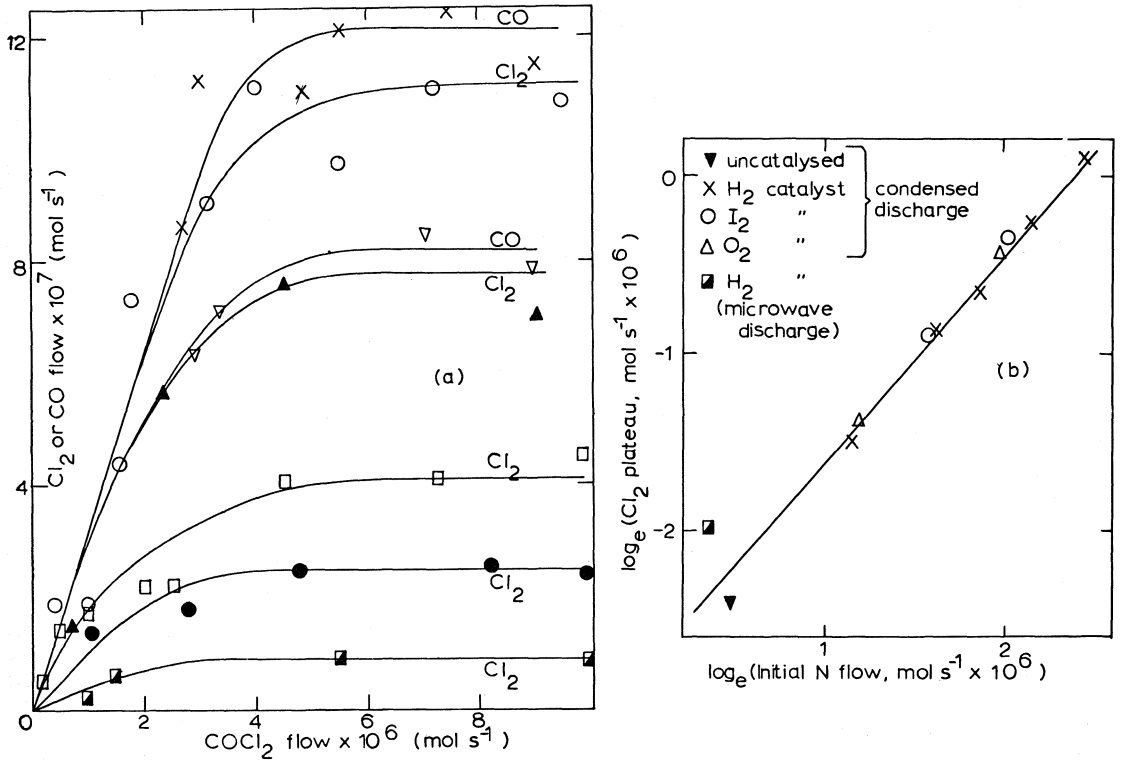

FIG. 1. (*a*) Yield of products from $COCl_2$ plus active nitrogen reaction. H_2 as catalyst: initial N atom flow = 11.7×10^{-6} mol s^{-1}, product = CO, ×; product = Cl_2, ○; initial N atom flow = 8.8×10^{-6} mol s^{-1}, product = CO, ▽; product = Cl_2, ▲. I_2 as catalyst, initial N atom flow = 4.9×10^{-6} mol s^{-1}, product = Cl_2, □. O_2 as catalyst, initial N atom flow = 3.3×10^{-6} mol s^{-1}, product = Cl_2, ●. No catalyst, initial N atom flow = 1.6×10^{-6} mol s^{-1}, product = Cl_2, ◪. These are typical data, obtained using a condensed electrode discharge, and an unheated reaction vessel of 2.0 cm internal diameter, at a total pressure of 2.3 Torr. N_2 flow = 180×10^{-6} mol s^{-1}. (*b*) Dependence of Cl_2 plateau on N atom flow rate.

rates (Fig. 1*a*). The discrepancy is thought to be due to some absorption of Cl_2 by the stopcock grease.

The plateau value for Cl_2 formation never exceeded roughly 10% of the initial N atom flow rate, independently of the nature of the discharge catalyst used and the type of discharge, for flow rates of N atoms between 1.4 and 11.7×10^{-6} mol s^{-1} (Fig. 1*b*). The least squares gradient of Fig. 1*b* is 1.1, from which it may be concluded that the maximum production of Cl_2, hence the maximum destruction of $COCl_2$, is proportional to [N]. To determine the ratio of N atom consumption, Δ[N], to Cl_2 production, $\Delta[Cl_2]$, the flow rates of N atoms, in the absence and in the presence of $COCl_2$, were determined at a point 50 cm downstream from the $COCl_2$ inlet, corresponding to a reaction time (0.10 s) in excess of that required for complete reaction. From differences in the two titrations, an average value of $\Delta[N]/\Delta[Cl_2] = 6.6 \pm 1.2$ was obtained over the range of experimental conditions used.

Kinetics Studies

The kinetics of the reaction were followed by titrating unreacted N atoms with NO (8) after various extents of reaction. The maximum loss of NO by its reaction with Cl atoms formed during the reaction was estimated from the known rate constants (3, 9) and with the assumptions that $[M] = [N_2]$ and $[Cl]_{max} = 2\Delta[Cl_2]$. A ratio of about 10^4 was calculated for the relative rates of reactions 1 and 2 for the conditions of the experiments,

[1] $$N + NO \rightarrow N_2 + O$$

[2] $$Cl + NO + M \rightarrow NOCl + M$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The maximum loss of NO by reaction 2 would therefore be negligible during the titration.[1]

(i) Recombination of N Atoms

With a condensed electrode discharge in the absence of a dissociation catalyst, small amounts of $COCl_2$ ($<1.2 \times 10^{-6}$ mol l^{-1}) decreased the rate of N atom decay. Previous studies (11–13) have shown that, for conditions similar to those of the present study, the recombination of N atoms proceeds by first and second order heterogeneous processes, and a third order homogeneous process. Analysis of the present data (13), with corrections for the reaction of N atoms with $COCl_2$, indicated that the first order process was effectively zero, and that the presence of $COCl_2$ did not significantly alter the third order rate constant, but that it did reduce to zero the second order heterogeneous rate constant (Fig. 2).

Similar results were obtained with H_2, admitted through the discharge (Fig. 2). For these experiments, no correction was necessary for the insignificant extent to which N atoms react with H_2 at 300 °K (14–16).

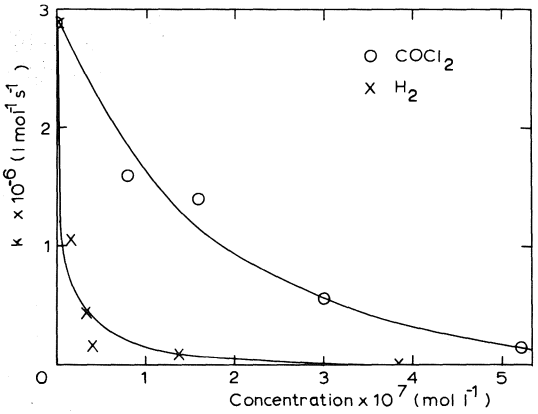

FIG. 2. Effect of $COCl_2$ and H_2 on the second order rate constant for the heterogeneous recombination of N atoms.

[1]The actual loss should be much less than the maximum, since NO will be generated by the fast reactions 3 and 4, with rate constants at 300 °K of 2 and 7×10^9 l mol^{-1} s^{-1}, respectively (10).

[3] $\quad Cl + NOCl \rightarrow NO + Cl_2$

[4] $\quad COCl + NOCl \rightarrow NO + Cl_2 + CO$

The overall effect is that reaction 2 acts mainly to catalyze the recombination of Cl atoms, or Cl and COCl radicals, with little or no net loss in NO.

(ii) Reaction of $COCl_2$

In the kinetic studies of the active nitrogen + $COCl_2$ reaction, H_2 was introduced into the discharge in sufficient quantities that the second order rate constant for the heterogeneous recombination of N atoms was zero. The presence of $COCl_2$ then increased the rate of N atom decay, as expected (typical data are shown in Fig. 3*a*). The rate of consumption of N atoms by $COCl_2$ was obtained as the difference between the decay curves in the presence and absence of $COCl_2$. A short induction period was observed in many of the reaction mixtures studied. Consumption of N atoms by $COCl_2$ was complete after about 0.06–0.08 s, leaving residual N atoms in the reaction vessel.

The orders of the reaction with respect to N atoms and $COCl_2$ were determined by plotting log (maximum rate) against log [N] and log [$COCl_2$], respectively. For a given value of $[N]_0$, the reaction order changed with the value of $[COCl_2]_0$ (Fig. 3*b*). With $[COCl_2]_0/[N]_0 < \sim 0.1$, the reaction was first order in both $COCl_2$ and N. With $[COCl_2]_0/[N]_0 > \sim 0.3$, it became zero order in $COCl_2$ and second order in N.

Discussion

Since the maximum extent of reaction, even with excess $COCl_2$, corresponded to less than 10% of the available N atoms, and the N atom decay profiles showed induction periods, it is concluded that N atoms do not attack $COCl_2$ directly. As with NH_3 and SO_2 (refs. 2, 3, and ref. 1, pp. 505–511), it is probable that the primary reaction of $COCl_2$ involves energy transfer from an excited molecular species, possibly $N_2(A^3\Sigma_u^+)$.

The observed changes in reaction order with changes in the initial concentrations of reactants (Fig. 3*b*) indicate that N and $COCl_2$ compete for some reaction intermediate, and that reaction with N predominates at low $[COCl_2]_0/[N]_0$, while reaction with $COCl_2$ predominates at high $[COCl_2]_0/[N]_0$. The kind of mechanism that would satisfy the above considerations may be represented briefly.

N_2* represents an electronically excited species produced in the discharge, $COCl_2^{+}$ represents a vibrationally excited molecule, $COCl_2$* represents an electronically excited molecule capable of dissociation, and M represents an inert molecule. The alternative reactions of $NCOCl_2$ with N

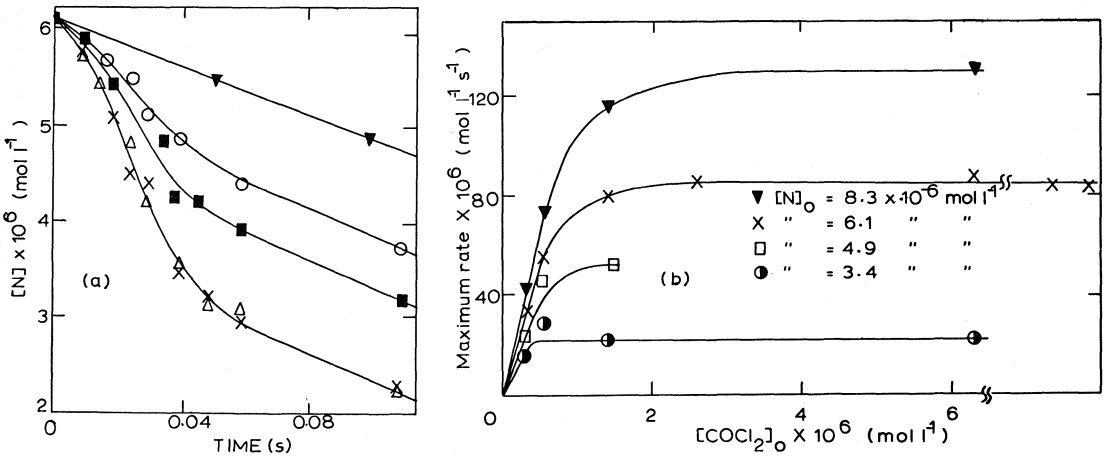

FIG. 3. (*a*) N atom decay in the presence of $COCl_2$. Typical data, obtained using a condensed electrode discharge system, catalyzed with H_2, 2.0 Torr total pressure, in a 3.1 cm internal diameter, unheated, reaction vessel. $[COCl_2]_0$ values, in mol $l^{-1} \times 10^6$, are: ▼, 0; ○, 0.31; ■, 0.55; ×, 2.6; △, 6.3. (*b*) Variation of maximum rate with $[COCl_2]_0$.

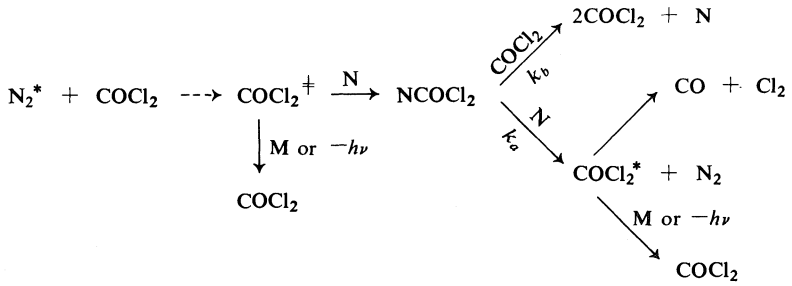

and $COCl_2$ have rate constants k_a and k_b, respectively. The observed pink reaction flame might result from emission by $COCl_2$* or, more probably, by Cl_2 ($^3\Pi_{0u}{}^+$) produced by recombination of Cl atoms (17).

If it is assumed that (*i*) the majority of $COCl_2{}^‡$ molecules are deactivated, and (*ii*) $[N_2{}^*]_0$ is constant for the different initial values of $[N]_0$ used (18–20), stationary state treatment of this mechanism yields

$$[5] \qquad \frac{d\Delta[N]}{dt} = \frac{\text{constant } [COCl_2][N]^2}{k_a[N] + k_b[COCl_2]}$$

Equation 5 is capable of predicting the observed changes in reaction order as follows.

(*i*) When $[COCl_2]_0/[N]_0$ is very small, such that $k_a[N] \gg k_b[COCl_2]$, eq. 5 reduces to

$$[6] \qquad \frac{d\Delta[N]}{dt} = \frac{\text{constant}}{k_a}[COCl_2][N]$$

and $d\Delta[N]/dt$ is first order in N and $COCl_2$, as observed when $[COCl_2]_0/[N]_0 < \sim 0.1$.

(*ii*) When $k_a[N] \ll k_b[COCl_2]$,

$$[7] \qquad \frac{d\Delta[N]}{dt} = \frac{\text{constant}}{k_b}[N]^2$$

and $d\Delta[N]/dt$ is second order in N, and zero order in $COCl_2$, as observed when $[COCl_2]_0/[N]_0 > \sim 0.3$.

The present data give a value of $2.06 \pm 0.16 \times 10^6$ l mol^{-1} s^{-1} for the constant in eq. 5, and $k_a/k_b = 0.11 \pm 0.01$.

Réaction des acétoxy-1 époxy-2,3 cyclohexanes *cis* et *trans* avec le tributylcarbéthoxyméthinephosphorane[1]

H. Favre et J. P. Lapointe
Département de Chimie, Université de Montréal, Montréal, Québec

Reçu le 9 juin 1971

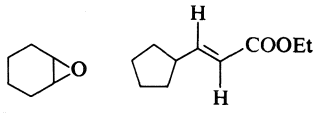
La réaction de l'acétoxy-1 époxy-2,3 cyclohexane *cis* (**3**) avec le tributylcarbéthoxyméthinephosphorane conduit à quatre composés: le cyclopentène-1 carbaldéhyde (**5**), le (cyclopentène-1 yl)-3 propénoate d'éthyle (**6**), l'(acétoxy-2-*c* cyclopentyl)-3 propénoate d'éthyle *trans* (**7**), et son isomère **8** dans le rapport 8–20–12–60, avec un rendement de 70%. Un mélange 38–62 des acétoxy-époxydes **3** et **4** donne les mêmes résultats.

Four different products were obtained by the reaction of *cis*-1-acetoxy-2,3-epoxycyclohexane with tri-*n*-butyl-carbethoxymethylidenephosphorane: cyclopent-1-enaldehyde (**5**), ethyl-3-(cyclopent-1-enyl)-propeonate (**6**), *trans*-ethyl-3-(2-*c*-acetoxycyclopentyl)propeonate (**7**), and its isomer **8**, in a 8–20–12–60 ratio, with a yield of 70%. The same products were obtained when a mixing of acetoxyepoxydes **3** and **4** were used in a 38–62 ratio.

Canadian Journal of Chemistry, **49**, 3851 (1971)

Gerkin et Rickborn (1) ont montré que l'action du tributylcarbéthoxyméthinephosphorane (Bu_3-P=CHCOOEt) (2) sur l'époxyde de cyclohexène **1** conduisait principalement à l'ester α,β-éthylénique **2**. Il était intéressant d'examiner si la réaction se faisait lorsqu'un groupe acétoxy se trouvait en α de l'époxyde et de déterminer la stéréospécificité de la réaction, le cas échéant.

L'acétoxy-époxyde *cis* **3** est connu (3, 4). Sa réaction avec le tributylcarbéthoxyméthinephosphorane conduit aux quatre composés **5**, **6**, **7**, et **8** avec un rendement de 70%, dans le rapport 8–20–12–60.



1 **2**

L'aldéhyde **5**, qui est connu (5), est caractérisé par son spectre de r.m.n.: un proton aldéhydique et un proton vinylique, et sa dinitro-2,4 phénylhydrazone.

La structure de l'ester doublement insaturé **6** découle des données spectrales suivantes. Groupe carbonyle à 1720 cm^{-1} en i.r.; en u.v., un λ_{max} à 270 mμ établit la conjugaison du groupe carbonyle et des deux doubles liaisons; le spectre de r.m.n., en plus du groupe —OEt, signale la présence des trois protons vinyliques.

Le composé principal de la réaction est l'acétoxy-ester **8**. Les spectres i.r. et de r.m.n. établissent la présence des groupes —COOEt et —OAc. Le spectre de r.m.n. indique de plus que la double liaison, conjuguée avec le groupe ester, d à 5.73 (J = 16 Hz) et dd à 6.8 (J = 16 et 7.8 Hz), est de configuration *trans*, d'après la constante de couplage de 16 Hz. Les positions respectives et la configuration *trans* des substituants portés par le cycle se déduisent de la transformation, ozona-

tion, suivie d'une réduction par l'hydrure de lithium et d'aluminium, du composé **8** en méthylol-2 cyclopentanol-1 *trans*, qui est connu (6).

Le quatrième composé de réaction ne s'obtient pas pur, mais en mélange avec l'acétoxy-ester **8**. L'ozonation, suivie de la réduction par l'hydrure de lithium et d'aluminium d'un mélange **7**–**8** 16–84 conduit aux deux diols **9** et **10** dans le rapport 16–84. Le spectre de r.m.n. du mélange **7**–**8**, de proportions 44–56, est semblable à celui du composé **8** pur, sauf pour une bande nouvelle à δ 5.19, attribuable à C*H*—OAc de l'isomère *cis*, à côté de la bande à δ 4.90 du composé *trans* **8**.

Nous avons préparé les diols **9** et **10** par réduction de l'éthoxycarbonyl-2 cyclopentanone par l'hydrure de lithium et d'aluminium. On sait que cette réduction conduit à des alcools insaturés et aux diols **9** et **10** (7, 8); nous montrons dans ce travail que les deux diols **9** et **10** se forment dans le rapport 23–77.

Une preuve supplémentaire de la configuration *cis*–*trans* des composés **7** et **8** repose sur la réduction du composé **8** et du mélange des composés **7** et **8** en acétoxy-esters saturés, respectivement **12** pur et un mélange de **11** et **12**. La réduction par l'hydrure de bore sodium du céto-ester **13** conduit à un mélange d'hydroxy-esters, qui par acétylation donne les acétoxy-esters **11** et **12**, dans le rapport 12–88. Le dosage, qui ne peut se faire par c.p.g., est fait par spectroscopie de r.m.n., en tenant compte des multiplets correspondant aux protons C*H*—OAc, apparaissant à δ 5.15 pour l'ester *cis* **11**, et à 4.75 pour son isomère *trans* **12**. Le composé majoritaire de réduction est l'isomère *trans*, à l'image de la réduction de la propyl-2 cyclopentanone qui donne 74% d'isomère *trans* (9). Il se trouve (tableau 1) ainsi que les trois isomères *cis* **7**, **9**, et **11** présentent, en r.m.n., une bande C*H*—OR (R = —H ou —Ac) à champ plus faible que les isomères *trans* correspondants. En revanche, les acétates de méthoxycarbonyl-2 cyclopentyles *cis* et *trans*, en mélange, ne se distinguent pas l'un de l'autre.

Un mélange 38–62 des acétoxy-époxydes **3** et **4** conduit exactement aux mêmes résultats que l'acétoxy-époxyde *cis* pur, soit aux composés **5**, **6**, **7**, et **8**, dans le rapport 10–21–10–59, et avec un rendement de 75%.

Ce travail montre que la conversion **3**–**4** → **7**–**8** se fait, et qu'elle se fait sans rétention totale de la configuration de départ. La présence de l'aldéhyde **5** dans le milieu réactionnel justifie les conclusions mécanistiques de Rickborn et Gerkin (10), formation d'aldéhyde intermédiaire.

TABLEAU 1. Déplacements chimiques du proton >C*H*— OR dans les isomères *cis*–*trans*

Partie expérimentale

Les spectres i.r. ont été mesurés à l'aide d'un spectrophotomètre Beckman IR-8 ou Perkin–Elmer 621, u.v. à l'aide d'un spectrophotomètre Spectronic 505 de Bausch and Lomb; de r.m.n. à l'aide d'appareils Jeol C 60H et JNM-4H-100, le tétraméthylsilane étant pris comme référence; de masse à l'aide d'un spectromètre Hitachi–Perkin–Elmer RMU-6D. Un appareil F and M 700 a servi à la c.p.g. Les points de fusion ont été déterminés en tubes capillaires, à l'aide d'un thermomètre étalonné avec des substances standards. Les analyses élémentaires sont de Schwarzkopf Microanalytical Laboratory, New York et de C. Daesslé, Microanalyses, Montréal.

(1) Acétoxy-1 époxy-2,3 cyclohexanes cis et trans (3 et 4)

L'isomère *cis* se prépare par époxydation du cyclohexène-2 ol-1 à la manière de Henbest et Nicholls (11). L'époxy-alcool (17.5 g) est acétylé, avec un rendement de 58%, par 175 ml d'anhydride acétique dans 175 ml de pyridine anhydre, durant 70 h. Une extraction à l'éther conduit à l'acétate **3**, qui distille à 117–118° sous 25 mm.

L'isomère *trans* **4**, en mélange avec son isomère *cis*, se prépare selon la méthode générale de Henbest et Nicholls (11), par époxydation de l'acétate de cyclohexène-2 yle, avec un rendement de 45%.

La c.p.g. (QF1 3% sur Anachrome ABS, en tube de verre de 6 m de longueur, température 162°) montre que l'isomère *cis* s'obtient pur et que le mélange des isomères *trans* et *cis* est constitué de 62% d'isomère *trans* et de 38% d'isomère *cis*.

Spectre de r.m.n. de l'isomère *cis* (CCl_4): δ 2.06 (s, 3, —OCOCH_3); 3.12 (m, 2, —C*H*—C*H*—); 5.0 (m, 1, >C*H*—OAc). Spectre de r.m.n. du mélange *cis*–*trans* (CCl_4): 2.06 et 2.08 (s, 3, —OCOCH_3); 3.15 et

2.92 (2m, 2, —C*H*—C*H*— respectivement *cis* et *trans*); 4.95 (m, 1, C*H*—OAc).

(2) Réaction de l'acétoxy-1 époxy-2,3 cyclohexane cis avec le tributylcarbéthoxyméthinephosphorane

Dans un ballon de 500 ml à trois tubutures, muni d'un réfrigérant, d'un agitateur, d'une ampoule à brome, sous atmosphère d'azote, on met une solution de 36.9 g (0.1 mol) de bromure de tributylcarbéthoxyméthylènephosphonium, préparé selon (2), dans 140 ml de benzène anhydre. A cette solution on ajoute goutte à goutte 62.8 ml (0.1 mol) d'une solution de 1.6 *M* de butyllithium dans l'hexane. Ensuite, on ajoute rapidement 15.6 g (0.1 mol) d'acétoxy-1 époxy-2,3 cyclohexane *cis* (3). On chauffe à l'ébullition à reflux pendant 24 h. La solution refroidie est lavée trois fois avec de l'eau, séchée sur sulfate de sodium anhydre, et évaporée sous vide de 11 mm. Le résidu d'évaporation est une huile rouge, 37.5 g. Une chromatographie sur colonne de silice avec de l'éther comme éluant, permet de séparer le résidu en deux fractions: l'oxyde de tributylphosphine et les quatre composés de réaction **5**–**8**. L'analyse par c.p.g. est la suivante, sur colonne de D.E.G.S. 10% sur Chromosorb W, N. A., 3.6 m 200°: **5**, 8 ± 2%, temps de rétention 1.5 min; **6**, 20 ± 2%, 3.9 min; **7**, 12 ± 2%, 12.1 min; **8**, 60 ± 2%, 13.6 min. La distillation du résidu sous 0.35 mm permet de séparer l'aldéhyde **5** des esters **6**–**8**. L'aldéhyde **5**, très volatil, se retrouve dans une trappe à −81°, accompagné d'hexane et de benzène. Les esters **6**–**8** distillent entre 100 et 120°, sans séparation. Leur séparation se fait par chromatographie sur gel de silice; avec un mélange d'éther–hexane 25–75 comme éluant: l'ester **6** sort en premier lieu, pur, suivie de l'ester **8** pur, et finalement des esters **7** et **8** en mélange.

Cyclopentène-1 carbaldéhyde (5)

La fraction résultant de la distillation contient 45% d'aldéhyde **5**, 23% d'hexane et 32% de benzène, par dosage par c.p.g. Spectre i.r. (CCl_4): 2715, C—H de CHO; 1680 cm^{-1}, C=O. Spectre de r.m.n.: (CCl_4): δ 6.76 (s, 1, proton vinylique); 9.77 (s, 1, proton aldéhydique). L'analyse par c.p.g. (colonne de D.E.G.S. sur Chromosorb W, N.A., 3.6 m, 195°) ne donne qu'un pic pour l'aldéhyde **5** rehaussé par adjonction de l'aldéhyde authentique, préparé selon (5). Dinitro-2,4 phénylhydrazone p.f. 213–214°, seul ou en mélange avec un échantillon authentique de p.f. 215–216° (5, 12).

(Cyclopentène-1 yl)-3 propénoate d'éthyle trans (6)

Le p.éb. 110° sous 0.35 mm. Spectre u.v. (EtOH 95%) λ_{max} 270 mμ, (ε 14 400). Spectre de masse (70 éV), ion moléculaire à *m/e* 166. Spectre i.r. (CCl_4): 1720 (C=O), 1635 cm^{-1} (C=C). Spectre de r.m.n.: (CCl_4): δ 5.6 (d, 1, *J* = 16 Hz, —CH=C*H*—COOEt); 7.43 (d, 1, *J* = 16 Hz, —C*H*=CH—COOEt); 6.13 (m, 1, —CH_2—C*H*=C); 4.13 (q, 2, *J* = 6.8 Hz, —O—C*H*$_2$—CH_3); 1.26 (t, 3, *J* = 6.8 Hz, —O—CH_2—C*H*$_3$); les méthylènes du cycle apparaissent à 2.4 et 2.0 respectivement 4H et 2H.

Anal. calc. pour $C_{10}H_{14}O_2$: C, 72.26; H, 8.49. Trouvé: C, 71.99; H, 8.25.

(Acétoxy-2-t cyclopentyl)-3 propénoate d'éthyle trans (8)

Le p.éb. 110° sous 0.35 mm. Spectre i.r. (CCl_4): 1720 (C=O de COOEt); 1735 (C=O de OAc); 1650 cm^{-1} (C=C). Spectre de r.m.n. (CCl_4): δ 5.73 (d, 1, *J* = 16 Hz, —CH=C*H*—COOEt; chaque pic du doublet est dédoublé, *J* = 1.5 Hz); 6.8 (dd, 1, *J* = 16 et 7.8 Hz, −C*H*=CH—COOEt); 4.87 (m, 1, C*H*—OAc); 4.11 (q, 2, *J* = 7.2 Hz, —O—C*H*$_2$—CH_3); 2.66 (m, 1, C*H*—CH=); 2.0 (s, 3, —OCOC*H*$_3$); 1.26 (t, 3, *J* = 7.2 Hz, —OCH_2-C*H*$_3$); les méthylènes du cycle apparaissent à 2.0 et 1.76 (6H).

Anal. calc. pour $C_{12}H_{18}O_4$: C, 63.70; H, 8.02. Trouvé: C, 63.62; H, 7.95.

(Acétoxy-2-c cyclopentyl)-3 propénoate d'éthyle trans (7)

Il fut obtenu en mélange avec son isomère **8**; les proportions, déterminées par c.p.g. comme plus haut, sont de 45–55. Spectre i.r. (CCl_4): 1720 (C=O de COOEt); 1735 (C=O de OAc); 1650 cm^{-1} (C=C). Spectre de r.m.n. (CCl_4): δ 5.76 (d, 1, *J* = 16 Hz, —CH=C*H*—COOEt); 6.81 (dd, 1, *J* = 16 et 7.8 Hz, —C*H*=CH— COOEt); 4.90 et 5.19 (2m, 0.55 et 0.45 respectivement, >C*H*—OAc); 4.13 (q, 2, *J* = 7.2 Hz, —O—C*H*$_2$—CH_3); 2.69 (m, 1, >C*H*—CH=); 2.0 (s, 3, —OCOC*H*$_3$); 1.28 (t, 3, *J* = 7.2 Hz, —OCH_2C*H*$_3$); les méthylènes du cycle apparaissent à 2.03 et 1.82 (6H).

(3) Réaction d'un mélange des acétoxy-époxydes 3 et 4 avec le tributylcarbéthoxyméthinephosphorane

Le mode opératoire est décrit à la section 2, plus haut. Le mélange 38–62 des époxydes **3** et **4** décrit à la section 1, 10.9 g conduit à 10 g de composés de réaction, dosés par c.p.g.: **5**, 10 ± 2%; **6**, 21 ± 2%; **7**, 10 ± 2%; **8**, 59 ± 2%.

Les esters **6** et **8** sont obtenus purs par chromatographie sur gel de silice, de même que les esters **7** et **8** en mélange (preuves par spectroscopie de r.m.n. et i.r., ainsi que par c.p.g., à partir des échantillons authentiques décrits plus haut).

(4) Méthylol-2 cyclopentanols-1 cis et trans (9 et 10)

(a) Par réduction de l'éthoxycarbonyl-2 cyclopentanone

A une solution contenant 11 g (0.29 mol) d'hydrure de lithium et d'aluminium dans 400 ml d'éther anhydre, on ajoute goutte à goutte une solution de 21.8 g (0.14 mol) d'éthoxycarbonyl-2 cyclopentanone dans 80 ml d'éther anhydre. L'addition se fait en 1.5 h. Le mélange est ensuite porté à l'ébullition à reflux pendant 30 min, puis refroidi; l'excès d'hydrure est décomposé en ajoutant de l'eau goutte à goutte. On ajoute ensuite 200 ml d'une solution aqueuse de sel de la Rochelle à 20%. La phase éthérée est décantée et la phase aqueuse extraite deux fois par de l'éther. Les phases éthérées sont réunies, lavées avec une solution aqueuse saturée, de chlorure de sodium, séchées sur sulfate de sodium anhydre et évaporées. Après distillation, on obtient 5.2 g d'alcools insaturés, (36.5% de rendement), d'après le spectre de r.m.n. et la c.p.g. La phase aqueuse obtenue plus haut à la fin de la réaction est extraite par de l'éther d'une manière continue, durant 3 jours et permet de recueillir 5.6 g de diols **9** et **10** (rendement 34.6%).

La c.p.g. sur colonnes de (*a*) diglycérol 8% sur Chromo-

sorb W 80/100, A.W.; (*b*) Polyester de Craig 3% sur Chromosorb G 80/100, A.W. indique que les diols sont identiques avec les diols obtenus par réduction par l'hydrure de lithium et d'aluminium des acétates d'éthoxycarbonyl-2 cyclopentyle *cis* et *trans*; les configurations de ces esters sont connues à la suite des travaux de Pascual *et al.* (13, 14).[2] Les diols **9** et **10** sont dans le rapport 23–77.

Les deux diols **9** et **10** se séparent en c.p.g. préparative, sur colonne de Polyester de Craig 15% sur Chromosorb A 60/80, N.A.W. 3 m, 165°, He comme gaz porteur de débit 65 ml/min.

*Le méthylol-2 cyclopentanol-1 cis (**9**)* est homogène en c.p.g. Spectre i.r. ($CHCl_3$): 3400 cm^{-1} (—OH). Spectre de r.m.n. ($CDCl_3$): 4.32 (m, 1 C*H*—OH); 3.73 (d, 2, J = 5.8 Hz, —CH_2OH); 3.55 (s, 2, —O*H*, échangeable avec D_2O); de 1.67 à 1.94, 7, CH_2 et CH du cycle.

*Le méthylol-2 cyclopentanol-1 trans (**10**)* est homogène en c.p.g. Spectre i.r. ($CHCl_3$): 3400 cm^{-1} (—OH). Spectre de r.m.n. ($CDCl_3$): 3.97 (m, 1, C*H*—OH); 3.60 (m, 2, —CH_2OH); 3.08 (s, 2, —O*H*, échangeable avec D_2O); 1.72 (m, 7, CH_2 et autre CH du cycle).

*(b) A partir de l'ester **8***

On dissout 163 mg d'ester **8** pur dans 20 ml d'éther de pétrole (p. éb. 30–40°) et refroidit cette solution dans un bain d'acétone et de glace sèche. On ozonise jusqu'à coloration bleue persistante, puis retire le tout du bain froid. Après décoloration, on évapore le solvant sous vide de 11 mm. On reprend le résidu d'ozonides par 5 ml de tétrahydrofuranne et ajoute goutte à goutte cette solution à une solution composée de 165 mg d'hydrure de lithium et d'aluminium dans 5 ml de THF. On agite 20 min à 25°, détruit l'excès d'hydrure par addition d'eau–THF 1–1. On sature la phase aqueuse de carbonate de sodium. La phase tétrahydrofurannique se sépare de la phase aqueuse; on la décante, la sèche sur sulfate de sodium anhydre, évapore le solvant. Le résidu (110 mg) est distillé sous vide de 0.25 mm. Le méthylol-2 cyclopentanol-1 *trans* (**10**) est identique (c.p.g. i.r., r.m.n.) avec celui décrit en (*a*)).

*(c) A partir des esters **7** et **8** en mélange*

Un mélange des esters 7 et **8**, 16–84, c'est une fraction tirée de la chromatographie sur gel de silice des produits réactionnels décrits à la section 1, est ozoné et réduit comme en section (*b*) plus haut. Il conduit à un mélange des diols **9** et **10**, dans les proportions de 16–84 par dosage par c.p.g.

*(5) (Acétoxy-2 cyclopentyl)-3 propionate d'éthyle cis et trans (**11** et **12**)*

*(a) Réduction de l'ester **8***

On agite en atmosphère d'hydrogène, durant 45 min, une solution d'ester **8** (280 mg) dans 10 ml d'éthanol 95%, en présence de 25 mg d'oxyde de platine. La solution est filtrée sur de la terre de diatomée, le solvant évaporé sous vide de 11 mm. On distille le résidu et recueille 160 mg d'ester **12**, p.éb. 125° sous 1.5 mm. Spectre i.r.: (CCl_4): 1728 cm^{-1} (C=O). Spectre de r.m.n. (CCl_4): 4.80 (m, 1, >C*H*—OAc); 4.11 (q, 2, —OCH_2CH$_3$); 2.3 (m, 2, —CH_2COOEt); 2.00 (s, 3, —OCOCH_3); 1.25 (t, 3, —OCH$_2$CH_3); 1.75 (m, 9, autres H).

Anal. calc. pour $C_{12}H_{20}O_4$: C, 63.14; H, 8.83. Trouvé: C, 63.35; H, 8.60.

*(b) Réduction des esters **7** et **8** en mélange*

Comme en section (*a*), l'hydrogénation d'un mélange 46–54 des esters **7** et **8** conduit aux esters **11** et **12** dans le rapport 45–55 déterminé par spectroscopie de r.m.n. Dans le spectre de r.m.n. les bandes à 5.15 et 4.75, correspondant aux protons *cis* et *trans* C*H*—OAc, sont dans le rapport 45–55; les autres bandes du spectre sont semblables au spectre du composé *trans* pur décrit en section (*a*).

(c) Réduction de l'(oxo-2 cyclopentyl)-3 propionate d'éthyle

A une solution de 5 g d'(oxo-2 cyclopentyl)-3 propionate d'éthyle, préparé selon (15), dans 20 ml de méthanol, refroidie entre −5 et 0°, on ajoute par petites portions 1 g de borohydrure de sodium. La solution est ensuite agitée durant deux heures à cette température. On acidifie la solution par une solution aqueuse d'acide sulfurique 30%, jusqu'à coloration bleue du papier rouge Congo. On évapore le méthanol sous vide de 11 mm. On extrait plusieurs fois le résidu par de l'éther. On lave jusqu'à neutralité les solutions éthérées réunies par des lavages avec une solution saturée de chlorure de sodium. On sèche sur sulfate de sodium anhydre, évapore le solvant et traite le résidu par 35 ml de pyridine et 35 ml d'anhydride acétique durant 70 h à température de 25°. On traite par de l'eau glacée et extrait par de l'éther. On lave la solution éthérée avec une solution aqueuse d'acide chlorhydrique à 2%, puis avec une solution aqueuse saturée de bicarbonate de sodium, enfin avec une solution saturée de chlorure de sodium. On sèche sur sulfate de sodium anhydre, évapore le solvant sous vide de 11 mm et distille le résidu. On recueille 4.2 g du mélange des esters **11** et **12**, p.éb. 119° sous 1.8 mm. Spectre i.r. (CCl_4): 1730 cm^{-1} (C=O). Le spectre de r.m.n. est semblable à celui décrit en section (*b*), sauf que le rapport des bandes à δ 5.15 et 4.75, correspondant à C*H*—OAc, est de 12–88, établissant ainsi la teneur du mélange à 12% d'ester **11** et 88% d'ester **12**.

Le mélange des esters **11** et **12** ne se fractionne pas en c.p.g. sur colonnes de QF1, d'U.C.W. ou de Carbowax 20M TPA.

Nous remercions le Ministère de l'Education de la Province de Québec, le Ministère des Pêcheries et des Forêts du Canada (Comité consultatif national de

[2]Les diols **9** et **10** furent obtenus par réduction par l'hydrure de lithium et d'aluminium des éthoxycarbonyl-2 cyclopentanols *cis* et *trans* (6). Nous avons de notre côté préparé les méthoxycarbonyl-2 cyclopentanols *cis* et *trans* selon la méthode (13, 14) et réduit les acétates correspondants. Le spectre de r.m.n. d'un mélange 64–36 des acétates **14** et **15** est le suivant $CDCl_3$: 5.40 (m, 1 C*H*—OAc); 3.68 et 3.75 (2s, 3, —OCH_3 des isomères *cis* et *trans*); 2.90 (m, 1, C*H*COOMe); 2.00 et 2.03 (2s, 3, —OCOCH_3 des isomères *cis* et *trans*); 1.92 (m, 6, CH_2 du cycle); le spectre de r.m.n. de l'isomère *cis* pur sert à attribuer les pics des isomères *cis* et *trans*. La réduction de mélange *cis–trans* 64–36 par l'hydrure de lithium et d'aluminium donne un mélange des diols **9** et **10**, 63–37. Les acétates **14** et **15** se séparent en c.p.g., temps de rétention de 15.6 et 14.7 min respectivement (Polyester de Craig, 3% sur Chromosorb G 80/100, A.W., DMCS; 3.6 m, température 140°, N_2 28 ml/min.

Kinetic Isotope Effect Studies on the Reaction of Benzyl Nitrate with Base in Various Solvents

CAROL A. POLLOCK[1] AND P. J. SMITH[2]

Department of Chemistry, Bishop's University, Lennoxville, Quebec

AND

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received July 16, 1971

The role of solvent and base on the nature of the transition state for the concerted one-step carbonyl elimination reaction of benzyl nitrate has been examined using rate and kinetic isotope effect techniques. The primary hydrogen–deuterium isotope effect was found to increase with increasing strength of the abstracting base, k^H/k^D = 5.94 and 6.41 at 30° for reaction with EtO^-/EtOH and *t*-BuO^-/*t*-BuOH, respectively. The nitrogen isotope effect decreased with increasing strength of the abstracting base, 2.07, 1.82, and 1.54% for reaction with OH^-/40 vol % EtOH–H_2O, EtO^-/EtOH, and *t*-BuO^-/*t*-BuOH, respectively. The conclusion is reached that an increase in the strength of the abstracting base leads to a more reactant-like transition state with decreased rupture of both the C—H and O—N bonds. The role of solvent on the nature of the transition state was examined by determining rates and nitrogen isotope effects for reaction in various ethanol–water and ethanol – dimethyl sulfoxide mixtures. The nitrogen effect was found to remain essentially constant in solvent mixtures ranging from 65 vol % EtOH–H_2O on the one hand to 80 vol % EtOH–DMSO on the other hand where the rate constants differed by a factor of 100 fold. It is concluded that solvent plays only a very minor role in determining transition state structure for the concerted elimination reaction of a neutral substrate with base.

Le rôle du solvant et de la base sur la nature de l'état de transition pour la réaction d'élimination concertée en une étape du groupement carbonyle du nitrate de benzyle a été examiné en utilisant des techniques de vitesse et de cinétique d'effet isotopique. L'effet isotopique primaire hydrogène–deutérium croît avec la force croissante de la base qui permet l'élimination, k^H/k^D = 5.94 et 6.41 à 30° pour la réaction avec respectivement EtO^-/EtOH et *t*-BuO^-/*t*-BuOH. L'effet isotopique de l'azote décroît avec la force croissante de la base 2.07, 1.82, et 1.54% pour la réaction avec respectivement OH^-/40 vol % EtOH–H_2O, EtO^-/EtOH et *t*-BuO^-/*t*-BuOH. On arrive à la conclusion qu'un accroissement dans la force de la base d'élimination amène à un état de transition plus réactif avec une rupture décroissante de chacune des liaisons C—H et O—N. Le rôle du solvant sur la nature de l'état de transition a été examiné par détermination des vitesses et des effets isotopiques de l'azote pour la réaction dans de nombreux mélanges éthanol–eau et éthanol–diméthylsulfoxyde. On trouve que l'effet de l'azote reste essentiellement constante dans les mélanges de solvant, allant de 65 vol % EtOH–H_2O d'un côté à 80% vol EtOH–DMSO d'un autre côté, dans lesquels les constantes de vitesse diffèrent par un facteur de cent. On en conclut que le solvant ne joue qu'un petit rôle mineur dans la détermination de la structure de l'état de transition pour une réaction d'élimination concertée entre un substrat neutre et une base.

Canadian Journal of Chemistry, 49, 3856 (1971)

Introduction

It is generally accepted that the concerted one-step (E2) elimination reaction can proceed by a spectrum of transition states differing in the extent of carbon–hydrogen and carbon – leaving group bond rupture (1, 2). The nature of the transition state could range from one that is E1-like (**1**) with considerable C_α—X bond rupture and a negligible degree of C_β—H bond weakening all the way to an E1cb-like transition state (**3**) with extensive C_β—H bond rupture and very little C_α—X bond rupture. An infinite number of intermediate transition states (**2**) is considered to be possible. Furthermore, it has been proposed that the E2 mechanism can merge

smoothly on the one hand to the carbonium ion mechanism (E1) and on the other hand to the carbanion mechanism (E1cb).[3]

Within recent years considerable experimental data has been accumulated from the study of several one-step processes and interpreted in the light of a variable transition state for the E2 reaction. The studies dealt mainly with the 2-phenylethyl and related systems and included eclipsing effects (4), substituent effects (5), leaving group isotope effects (6), primary hydrogen–deuterium isotope effects (7), and secondary isotope effects (8) for the reaction with OD^- in D_2O *vs.* OH^- in H_2O (k^{OD^-}/k^{OH^-}).

The determination of the relative extent of C—H and C—X bond rupture at the transition state using isotope effects is dependent on the interpretation of the magnitude of these effects in terms of the degree of decrease of the appropriate force constant(s) (bond-weakening) in going from the initial to the transition state. The interpretation of the C—X isotope effect has generally been considered to be straightforward with the magnitude of the effect being dependent upon the extent of bond rupture at the transition state. Katz and Saunders (9), however, have shown from a theoretical treatment that small isotope effects for the leaving group can be associated with reactions in which C—X bond rupture is quite far advanced at the transition state. Saunders suggests that qualitative interpretation of isotope effects should be possible, however, when systematic changes in some structural or environmental feature of a reaction are made.

Several theoretical discussions (10–12) have led to the accepted view that the magnitude of the primary hydrogen–deuterium isotope effect is at a maximum when the transition state is symmetrical and that smaller isotope effects are a result of either reactant-like or product-like transition states. A knowledge of the type of transition state from Hammett ρ or k^{OD^-}/k^{OH^-} determinations is essential, therefore, before one can interpret a small isotope effect in terms of the degree of carbon–hydrogen bond-weakening.

Westheimer's curve (plot of k^H/k^D *vs.* the degree of proton transfer to base at the transition state) has been realized by several groups of workers for entirely unrelated reaction systems. Kresge *et al.* (13) determined the isotope effect, $k^{H_3O^+}/k^{D_3O^+}$, for the hydrolysis of several vinyl ethers in aqueous solution at 25° and obtained a uniform trend when $k^{H_3O^+}/k^{D_3O^+}$ was plotted against log $k^{H_3O^+}$ with a maximum being observed. Other workers (14, 15) have realized similar behavior for base-catalyzed proton removal from carbon. For example, Longridge and Long (15) from a study of hydrogen exchange from azulenes, observed a maximum hydrogen–deuterium isotope effect when the proton was transferred between bases of similar strengths, as measured by ΔpK_a values.[4] Finally, Cockerill (7*b*), in a study of the elimination reaction of dimethyl-2-phenylethylsulfonium bromide with hydroxide ion in various water – dimethyl sulfoxide mixtures, obtained a curve with a maximum when k^H/k^D was plotted against mol % dimethyl sulfoxide.

The present available studies show that the transition state for an E2 process is dependent on leaving group (17, 7*c*), acidity of the β-hydrogen (17, 7*c*), dihedral angle (18), solvent, and base. Until very recently the latter two variables have always been changed simultaneously and it was difficult to assess the contributions of each. Recent studies (7*b*, 19), however, have been carried out on neutral and "onium" substrates in mixed solvents where the basic species was kept constant. It was found that whereas solvent plays an important role in determining transition state geometry for the reaction of the charged reactant it appears to have very little effect when the substrate is neutral.

The carbonyl elimination reaction of benzyl nitrate with ethoxide ion (eq. 1) has previously

[1] $$C_6H_5CH_2ONO_2 + {}^-OEt \rightarrow C_6H_5CHO + {}^-NO_2 + EtOH$$

been shown (6*a*) to be a concerted process by the absence of deuterium exchange with solvent and a N^{14}:N^{15} isotope effect of 2.0%. Furthermore, a recent determination (20) of the nitrogen isotope effect associated with the carbonyl elimination reaction ($E_{CO}2$) of a series of para-substituted

[3]In a recent paper (3), O'Ferrall has suggested that at the borderline between the mechanisms, a continuity of transition states need not be expected.

[4]Bordwell and Boyle (16) in two recent papers have examined the question of the use of rho values, the Bronsted, β, and hydrogen–deuterium effects as guides to transition state structures in deprotonation reactions. They conclude that these parameters are either very insensitive to large changes in transition state structure or that the transition states are essentially unaltered for widely different substrates.

benzyl nitrates at 20° in a solvent of 90 vol % EtOH–H_2O has shown the nitrogen effect to be appreciably sensitive to the nature of the para-substituent (2.26 and 1.62% for the *p*-CH_3 and *p*-CF_3 substituents, respectively).

Accordingly, we have carried out a study on the $E_{CO}2$ reaction of benzyl nitrate with different bases in different solvents in order to shed more light on the role of solvent and base in determining transition state geometry. The results are discussed in the light of a theory proposed by Thornton (21) which allows one to predict the effect of base strength on the nature of the transition state.

Results and Discussion

Isotope Effect Studies on the Reaction of Benzyl Nitrate with Different Bases

The nitrogen and hydrogen–deuterium isotope effects for the carbonyl elimination reaction of benzyl nitrate with hydroxide ion[5] in 40 vol % EtOH–H_2O, ethoxide ion in ethanol, and *t*-butoxide ion in *t*-butanol were determined at 30° and the results are shown in Tables 1 and 2, respectively. A summary of the isotope effects together with the pertinent rate constants is shown in Table 3.

In all the base-solvent systems studied, except for *t*-butoxide in *t*-butanol, the carbonyl elimination reaction producing nitrite ion was in competition with an S_N2 process giving nitrate ion; *i.e.* % $E_{CO}2 < 100$, Tables 2 and 5. It is possible, however, using methods described previously (6*a*) to determine both the deuterium and nitrogen isotope effects associated with the elimination process. The total rate was followed by acid–base titration and the rate constant for the carbonyl elimination reaction, k_{Eco2}, was evaluated from the relative yields of nitrite and nitrate ions determined by the selective reduction of these ions to ammonia. In all cases the ratio of nitrite to nitrate remained constant during the course of a kinetic run.

The nitrogen isotope effect for the carbonyl elimination reaction in each solvent system was obtained by comparing the N^{14}/N^{15} ratio of benzyl nitrate of natural isotopic abundance with that of nitrite ion formed in the desired elimination reaction of the ester carried to some known extent of completion. Selective reduction of the nitrite ion to ammonia accomplished the separation of the nitrogen of this ion from that of the nitrate ion formed in the simultaneous S_N2 displacement reaction (6*a*). The ammonia was then converted into nitrogen gas which was first purified and then analyzed mass spectrometrically. The isotopic abundance for the reactant was obtained by analysis of the nitrogen gas similarly formed from nitrite plus nitrate produced in a reaction which had been allowed to proceed to completion.

The isotope effect measurements, Table 3, were determined under different solvent conditions. It is reasonable to assume, however, that the abstracting base increases in strength from the aqueous medium[6] to the medium of ethoxide in ethanol and finally to the *t*-butoxide – *t*-buta-

[5]It has been shown (22) that the % base present as hydroxide is 90% in this solvent mixture.

[6]The active base in the 40 vol % EtOH–H_2O solvent could be either hydroxide ion or ethoxide ion. It is reasonable to assume that it is hydroxide since England and Burns (22) have shown that the percent base present as hydroxide in this solvent mixture is 90.

nol solution. This view is supported by values of the *H*-function reported by Bowden (23) and is in accord with the observed rate constants for elimination ($10^3 k_{E_{CO}2}$ (30°) = 481, 0.438, and 0.028 1 mol^{-1} s^{-1} for reaction in *t*-butanol, ethanol, and 40 vol % EtOH–H_2O, respectively).

The nitrogen isotope effects decrease from a value of 2.07% obtained for the reaction in the EtOH–H_2O solvent to a value of 1.83% in EtOH and finally to 1.54% in *t*-butanol. Since the magnitude of the leaving group isotope effect depends on the extent to which the composite force constant of the O—N bond is decreased in going from the initial to the transition state (24), the largest effect associated with the reaction of benzyl nitrate with the weakest base, "hydroxide", indicates, therefore, that there is *more* O—N bond rupture in the transition state for this process than for the reactions promoted by the stronger bases, ethoxide and *t*-butoxide.

An interpretation of the magnitude of the primary hydrogen–deuterium effects, Table 3, in terms of the extent of C—H bond rupture requires a prior knowledge of the nature of the transition state with respect to the degree of proton transfer to base; *i.e.* whether the proton is *more than* or *less than* one-half transferred. The large nitrogen isotope effects observed in the three solvent systems (the theoretical maximum is approximately 3.8% at 30° (6*a*)) together with the large Hammett ρ value of +3.6 (20), measured for the ethoxide promoted reaction, suggest a transition state where the proton is more than one-half transferred, since the only way a large positive ρ can result in a reaction in which C—N bond rupture is well advanced would be for the transfer of the proton to be very well advanced as well. This conclusion receives support from the fact that the reaction of 2-phenylethyltrimethylammonium ion with ethoxide (7*c*) has similar values for ρ and the nitrogen effect. For this process Steffa and Thornton (8) have established that the proton is more than one-half transferred to base at the transition state by determining the secondary effects, k^{OD^-}/k^{OH^-}.

Consequently, the smaller value of k^H/k^D obtained for the reaction of benzyl nitrate with ethoxide than with *t*-butoxide suggests that the proton is *more transferred* to base in the transition state for the "weaker base" promoted reaction (k^H/k^D = 5.94 and 6.41 for reaction of benzyl nitrate with ethoxide and *t*-butoxide, respectively).

The nitrogen and hydrogen–deuterium isotope effects obtained for the reaction of benzyl nitrate with several bases lead to the conclusion that both the oxygen–nitrogen and carbon–hydrogen bonds are ruptured to a greater extent at the transition state for reactions promoted by bases of *decreasing* strengths. In other words, the more one bond is broken in the transition state the more also is the other. In the light of this conclusion, it is difficult to visualize a smooth transition from a carbanionic-like E2 transition state to the E1cb mechanism as visualized by Bunnett (1) for a particular reaction where substituents, base, or solvent are varied systematically since increased C—H rupture leads to an attenuated O—N bond weakening. This is in accord with the theoretical predictions of O'Ferrall (3) mentioned in the Introduction.

A theoretical treatment of Thornton (21) dealing with the effects of structural changes in the reactant on the nature of the transition state is in accord with the conclusion that a decrease in the strength of the abstracting base involved in an E2 reaction will lead to a more product-like transition state with increased C—H and O—N bond weakening. Thornton expressed the view that the geometrical change for an elimination reaction will be determined largely by the substituent effect on the parallel motion along the reaction co-ordinate where the relative lengths of the arrows below

represent the relative extent to which each atom has moved when the reacting system has reached the transition state. Thornton showed that the

more difficult it is for two atoms to move apart, the greater will be the extent to which they need to separate before arriving at the state of maximum energy which separates reactants and products. With respect to the effect of base strength on the transition state geometry, it is easy to see that the weaker the base the more difficult will be the motion resulting in a transfer of the proton from carbon to base. A decrease in the strength of the base will, therefore, result in an increase in the extent of proton transfer to base and an increase in the extension of the O—N bond at the transition state since the reaction co-ordinate motion which results in the separation of hydrogen from carbon also involves a separation of nitrogen from oxygen.

The question arises concerning the relative carbanion character of the product-like transition states (increased C—H and O—N bond rupture) compared with the more reactant-like transition states. It is generally considered that for reactions characterized by large positive ρ values a decrease in ρ and an increase in k^H/k^D indicates a transition state which has less C—H bond rupture and, therefore, decreased carbanion character (5*b*). It follows from our conclusion where a decrease in C—H bond rupture is accompanied by a decrease in O—N bond rupture that the carbanion character of a transition state is dependent on the *relative* change of each of these bond lengths for a transition state where there is coupling of the motions of the bonds as illustrated by Thornton's representation of the E2 transition state. Thornton (21) considered this situation and he suggested that by making H move more relative to O, and C_α move more relative to X the transition state becomes more product-like with relatively more carbanion character at C_α than carbonium ion character at O; that is, the transition state becomes more E1cb-like.

Our conclusion that an increase in C—H bond weakening leads also to an attenuated increase in O—N bond rupture in the transition state would suggest that for a particular reaction series systematic changes in substituents, base, etc. would not lead to a changeover from the concerted to the stepwise (E1cb) mechanism for elimination. We suggest that only in those cases where coupling is poor would one expect a carbanion intermediate. The combination of a poor leaving group (25), stabilization of charge at the β-carbon (25), and a dihedral angle displaced from 180 or 0° (18) is expected to favor the formation of a carbanion intermediate involved in the elimination process.

Nitrogen Isotope Effect Studies on the Role of Solvent on Transition State Geometry for the $E_{CO}2$ Reaction of Benzyl Nitrate

The nitrogen isotope effect was determined for the carbonyl elimination reaction of benzyl nitrate at 30° in various ethanol–water and ethanol – dimethyl sulfoxide mixtures. The isotope effect results are shown in Table 4 while a summary of these effects together with the pertinent kinetic data is shown in Table 5. The overall rate constants when multiplied by the ratio $[NO_2^-]/([NO_2^-] + [NO_3^-])$, % $E_{CO}2$, give the rate constant for the elimination process, k_{Eco2}.

The rate constant for elimination is seen to decrease with increasing water content of the medium; *i.e.* k_{Eco2} = 0.438 and 0.0284 in 100% EtOH and 40 vol % EtOH–H_2O, respectively. This trend is consistent with the predicted effect (26) of an increase in solvent polarity on a reaction of an ion with a neutral substrate. Furthermore, the variation in the elimination to substitution ratio, % $E_{CO}2$, with solvent composition is also in accord with changes in polarity of the reaction solution (26). Another factor which could account for the decrease in rate constant is that the abstracting base becomes more or better solvated as the reaction mixture acquires a greater water content. This increase in solvation would make it more difficult for the base to promote elimination and hence the decrease in rate constants. This factor will be discussed in more detail below.

It is of interest to note, however, that a discontinuity exists in the plot of log k_{Eco2} *vs.* volume% EtOH–H_2O, Fig. 1, when the solvent composition is approximately 50 vol % EtOH–H_2O and the percent base present as hydroxide is greater than 80 (22). This discontinuity can be ascribed to the fact that the "abstracting" base involved in the elimination process has been changed from a "strong" base, ethoxide, to a "weaker" base, hydroxide, which becomes kinetically significant only in solutions with a composition of greater than 50% water. This view is supported by the nitrogen isotope effect results where a similar discontinuity is observed. The constancy of the nitrogen results for solvent compositions ranging from 100 vol % EtOH–H_2O to 65 vol % indicates that the abstracting base remains constant in this solvent composition region while the increase in nitrogen effect for the 50 and 40 vol % EtOH–

H_2O mixtures suggest that the abstracting base is a weaker one (21).

The only reasonable conclusion that one can draw concerning the invariance of the nitrogen isotope effect results determined for reactions carried out in solvents ranging from 100 % EtOH to 65 vol % EtOH–H_2O is that the transition state structure remains essentially constant. It should be noted that the polarity of the solvent is changed considerably over this range of solvent composition; *i.e.*, dielectric constant of EtOH and 60 vol % EtOH–H_2O is 23.2 and 44.7, respectively (27). Consequently, it appears that the effect of solvent on the nature of the transition state is negligible for reaction between an ion and a neutral molecule. A similar conclusion was reached by Cockerill *et al.* (19) who studied the elimination reaction of the 2-arylethyl bromides with potassium *t*-butoxide in *t*-butyl alcohol – dimethyl sulfoxide mixtures and found that ρ and k^H/k^D did not vary.

The possibility exists that the observed variation in rate constants and nitrogen isotope effects with solvent composition could be due to changes in base strength arising from alterations in the solvation of hydroxide ion. In other words, the discontinuities could well arise from a competi-

tion of hydroxide ions of different solvation for the α-hydrogen atom. The formation of the $E_{CO}2$ transition state should require a displacement of only one solvent molecule as hydroxide ion in ethanol–water is probably solvated by a combination of two or three ethanol and water molecules.[7] Consequently, it happens that as water is added to the reaction medium the type of solvation of the partially neutralized hydroxide ion in the transition state should change; *i.e.*, as ethanol molecules are replaced by water molecules the base, hydroxide ion, would become effectively weaker. This should lead, however, to a continuous change[8] in both the second order rate constant for elimination and the nitrogen isotope effect as the solvent composition is varied which is not observed. Furthermore, it is unlikely that the nitrogen isotope effect determined in 100% EtOH, where ethoxide is base, would be the same as the isotope effect determined in 65 vol % EtOH–H_2O if the base present in the aqueous solution is a highly solvated hydroxide ion. It is concluded that the discontinuities arise due to a change in base, ethoxide ion to hydroxide ion, and are not a result of changes in base "structure", solvation of hydroxide.

In order to eliminate the problem of changing the base as well as the solvent which was encountered in the study of the reaction of benzyl nitrate with base in the ethanol–water mixtures, the nitrogen isotope effects and the rate constants associated with the reaction of benzyl nitrate with ethoxide ion[9] in various ethanol – dimethyl sulfoxide mixtures were determined, Table 5. It is seen that the rate constant for elimination increases regularly, Fig. 1, as more dimethyl sulfoxide is added to the ethanol solvent, $k_{E_{CO}2}$ is 0.000438 and 0.0273 in ethanol and 70 vol % ethanol – dimethyl sulfoxide, respectively. This variation in rate can simply be ascribed to the fact that dimethyl sulfoxide has the ability of desolvating the abstracting base, ethoxide; *i.e.*, dimethyl sulfoxide competes with the ethoxide ion for the ethanol molecules. Since the abstracting base must be partially desolvated in order to form the transition state, it follows that the variation in the ease of desolvation as influenced by additions of dimethyl sulfoxide will lead to variations in rate as observed. Once the transition state is formed, however, the base it contains is substantially the same species (a partially neutralized ethoxide ion) regardless of medium composition.

That the base is essentially constant for ethoxide in ethanol and for the several ethanol – dimethyl sulfoxide mixtures is borne out by the nitrogen isotope effect results in Table 5 where it is seen that the isotope effect remains essentially constant when the solvent composition is varied; *i.e.*, 1.82 and 1.90 in EtOH and 80 vol % EtOH–DMSO, respectively. The constancy of the nitrogen isotope effects, and hence the constancy of O–N bond rupture at the transition state, obtained under the different solvent conditions is as predicted by Thornton (21) when the base remains the same. The conclusion is reached, therefore,

[7]Hydroxide ion is believed to be hydrogen bonded to three water molecules (28).

[8]Smith and Bourns (29), in a study of the reaction of 9-fluorenyl nitrate with acetate in ethanol–H_2O mixtures, found the nitrogen isotope effect equal to 1.0091, 1.0105, 1.0131 for reaction in ethanol, 92 vol % EtOH–H_2O, 85 vol % EtOH–H_2O, respectively.

[9]It is unlikely that bases other than ethoxide; *i.e.*, nitrite or dimsyl ion, induce elimination as they are probably kinetically insignificant under the reaction conditions employed.

that the role of solvent in determining transition state structure is very minor for an elimination reaction involving a neutral substrate.

Experimental

Materials

Benzyl Nitrate and Benzyl Nitrate α-d_2

These compounds were prepared by the procedure described by Buncel and Bourns (6*a*). The benzyl nitrate α-d_2 was shown by n.m.r. to be at least 99% deuterated.

Absolute Ethyl Alcohol

This solvent was dried by the method of Lund and Bjerrum (30) and stored under anhydrous conditions.

Absolute t-Butyl Alcohol

This solvent was dried by refluxing over and distilling from sodium metal. The process was repeated twice and the *t*-butyl alcohol was stored under anhydrous conditions.

Dimethyl Sulfoxide

This solvent was distilled once from calcium hydride under reduced pressure, was filtered through a 4 ft molecular sieve (B.D.H. grade 5A) column and then fractionally redistilled under reduced pressure.

Mixed Solvents

These were prepared to give the desired solvent by per cent volume to volume.

Sodium Ethoxide and Potassium t-Butoxide

These bases were prepared by the action of the appropriate metal with the desired solvent under strictly anhydrous conditions in a nitrogen atmosphere. The base solutions in the mixed solvents were prepared by diluting the appropriate alkoxide with either dimethyl sulfoxide or water. The water used in the dilutions was CO_2 free.

Kinetic Measurements

The rate constants for the overall reactions as well as the rate constants for elimination were determined as described by Buncel and Bourns (6*a*).

Nitrogen Isotope Effects

Complete Reaction and Collection of Ammonia

A weight of benzyl nitrate and an accurately measured volume of base were allowed to react to completion. A 5 ml aliquot was extracted and added to the Kjeldahl distillation and since it is the total nitrogen that is required, the nitrite and nitrate were both distilled into the same flask containing excess sulfuric acid. The acid was back-titrated with standard alkali, using bromocresol green as indicator; followed by the immediate addition of 3 ml of 0.01 *N* sulfuric acid to prevent loss of ammonia. The titration gave the total number of moles of product formed which was usually greater than 99% of the number of moles of reactant.

Partial Reaction

A weight of benzyl nitrate was calculated so that when the reaction had proceeded to the desired extent of reaction, the nitrite produced would yield a volume of nitrogen of approximately 3 ml at standard conditions. The substrate was weighed into a reaction flask which was placed in a constant temperature bath and allowed to equilibriate. Similarly, the base of desired concentration and solvent composition was placed in the constant temperature bath. After approximately 30 min, the reactants were mixed and the reaction was allowed to proceed for a pre-determined time, as calculated from the kinetic data. The reaction flask was then removed from the bath and its contents emptied into a separatory funnel containing ice, water and diethyl ether. The aqueous layer was extracted four times with ether. The combined ether extracts were then washed four times with water and these washings were added to the aqueous layer which was then concentrated to a small volume, 25 ml, on rotary evaporator.

The concentrated solution was then added to a Kjeldahl distillation flask and the nitrite ion was converted into ammonia which was distilled into excess standard sulfuric acid and back titrated as described for the preparation of the complete samples. The resulting ammonium sulfate solution was concentrated to 3 ml in preparation for its conversion to ammonia.

In all of the partial reactions where the nitrite ion was reduced to ammonia in preparation for its conversion to nitrogen gas and mass spectrometer analysis, the amount of nitrate ion was determined by the procedure described above, so that the ratio $[NO_2^-]/([NO_2^-] + [NO_3^-])$ could be used in the evaluation of nitrogen isotope effect for the $E_{CO}2$ process.

In all cases the ammonium sulfate solutions were concentrated to 3 ml in preparation for conversion to nitrogen by the procedure described by Buncel and Bourns (6*a*).

For the reaction with *t*-butoxide in *t*-butanol, the usual method of quenching was unsatisfactory due to the fast rate of the reaction. In this case, the desired extent of reaction was achieved by adding the appropriate amount of base, corresponding to the extent of reaction required, and allowing the reaction to proceed for 30 half-lives. In these cases, the concentrations of the reactants were sufficiently low so that no more than 1% reaction occurred during the mixing of the reacting solutions.

The kinetic isotope effect was calculated by using the expression suggested by Baliga and Bourns (31)

$$\frac{k^{14}}{k^{15}} = \frac{\ln 1 - \dfrac{f'(1-p)}{1-fp}}{\ln 1 - \dfrac{rf'(1-p)}{1-f'p}}$$

where f' is the mole fraction of the ester which has undergone reaction, p is the fraction of the total reaction which is substitution and r is $(N^{14}/N^{15})_{reactant}/(N^{14}/N^{15})_{NO_2^-}$. This is a modification of an expression derived by Stevens and Attree (32), and takes into account the fact that the reactant is being consumed by reactions other than those where the isotope effect is being measured.

The N^{14}/N^{15} ratio was found to be the same for nitrate ion collected during the early stages of the reaction, 134.187 and 134.232, as for the average value found for the completes, $NO_2^- + NO_3^-$. *i.e.*, 134.212. Consequently, substitution occurs without fractionation thus making the use of f' valid.

Synthesis of Some Stable 7-Halo-1,4-thiazepines. Potential Substituted Penam Precursors

P. BLONDEAU,[1] R. GAUTHIER,[2] C. BERSE, AND D. GRAVEL
Department of Chemistry, University of Montreal, Montreal 101, Quebec

Received July 19, 1971

The synthesis of some new 3-carbomethoxy-5-oxoperhydro-1,4-thiazepines is described. Halogenation studies led to the preparation of three potential substituted penam ring precursors: 6,7-dibromo-3-carbomethoxy-5-oxoperhydro-1,4-thiazepine, 3-carbomethoxy-6,7-dichloro-5-oxoperhydro-1,4-thiazepine, and 3-carbomethoxy-7-chloro-6,6-dimethyl-5-oxoperhydro-1,4-thiazepine. Preliminary studies on the reactivity of these α-halothioethers showed that methanolysis to the corresponding methoxy-thiazepines may be carried out in nearly quantitative yields in the case of the first two derivatives; the third compound, on the other hand, led to an open-chain dehydrohalogenated product where C-7 is converted to the corresponding dimethyl acetal.

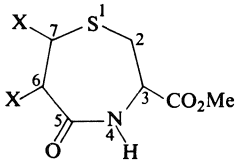
La synthèse de quelques nouvelles méthoxycarbonyl-3 oxo-5 perhydrothiazépines-1,4 est rapportée. Des études sur l'halogénation de ces composés ont conduit à la préparation de trois précurseurs possibles du noyau penam substitué: la dibromo-6,7 méthoxycarbonyl-3 oxo-5 perhydrothiazépine-1,4, la dichloro-6,7 méthoxycarbonyl-3 oxo-5 perhydrothiazépine-1,4, et la chloro-7 diméthyl-6,6 méthoxycarbonyl-3 oxo-5 perhydrothiazépine-1,4. Des études préliminaires sur la réactivité de ces α-halogénothioethers ont montré que, dans le cas des deux premiers dérivés, la méthanolyse pour donner les méthoxy thiazépines correspondantes peut être effectuée avec des rendements quasi-quantitatifs; le troisième composé, d'autre part, a conduit à un produit de déshydrohalogénation où le C-7 est transformé en diméthyl acétal correspondant.

Canadian Journal of Chemistry, 49, 3866 (1971)

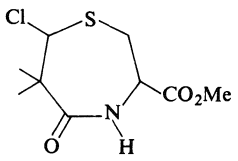
Introduction

During the last few years several reports of total syntheses of penam[3] derivatives have appeared in the literature (1–5). In all cases the β-lactam ring was formed on either a 1,3-thiazolidine or 1,3-thiazoline ring bearing the appropriate substitution.

However, to our knowledge, there is no known synthesis of a penam ring or of a penicillanic acid[3] starting from a seven-membered cyclic precursor. Although there are reports of attempts to achieve such a goal by Knunyants and coworkers (6) and also by Leonard and Wilson (7), this synthetic approach has never been thoroughly investigated due mainly to the unavailability of stable key intermediates such as 7-halo-1,4-thiazepines. It was therefore in an attempt to overcome this limiting factor that a program was initiated first to synthesize some stable 7-halo-1,4-thiazepines and subsequently to systematically investigate the possible modes of forming the elusive 4,7-bond. The model compounds chosen were 3-carbomethoxy-6,7-dihalo-5-oxoperhydro-1,4-thiazepine (**1**) and 3-carbomethoxy-7-chloro-6,6-dimethyl-5-oxoperhydro-1,4-thiazepine (**2**) which upon cyclization could yield substituted derivatives of the penam ring system.



1
X = Br or Cl



2

It could easily be gleaned from the literature that 3-carbomethoxy-7-chloro-5-oxoperhydro-1,4-thiazepines were highly unstable due to their susceptibility to dehydrohalogenate (6, 7). It was hoped, in the case of **1**, that a *trans* dihalo derivative would resist dehydrohalogenation on

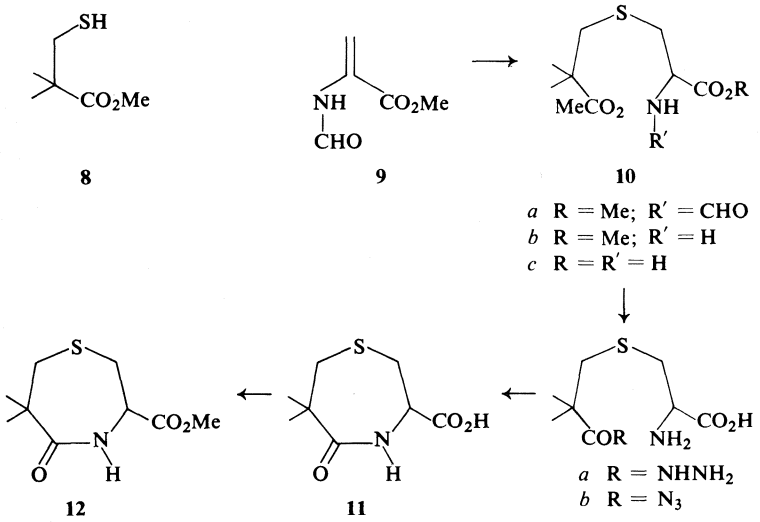

SCHEME 2

stereoelectronic grounds and in the case of **2** that the monochloro derivative would resist elimination to a certain extent due to the lack of β-hydrogens.[4]

Results and Discussion

Synthesis

Synthesis of thiazepine **7** was readily achieved by combining known methods from the literature as outlined in Scheme 1.

In a first step, L-cysteine (**3**) was condensed with methyl acrylate (**4**) following a method reported by Foldi (8) for the case of ethyl acrylate. The resulting addition product **5**, obtained in a 90% yield, was then cyclized (9, 10) in a solution of methanol saturated with ammonia to yield 49% of 3-carboxy-5-oxoperhydro-1,4-thiazepine (**6**). Esterification of the acid **6**, effected by standard treatment with ethereal diazomethane, gave a nearly quantitative yield of the desired ester **7**. (See Experimental for comment on optical purity.)

In the case of the second parent compound **12**, a synthetic approach was devised which is shown in Scheme 2.

In the first instance, synthesis of the methyl mercaptopivalate moiety **8** was achieved by standard methods (11, 12) from hydroxypivalic acid (11). This mercapto ester **8** was then condensed with methyl α-formamidoacrylate (**9**) (13)

[4]Rearrangement in an E_1 process nevertheless remained possible.

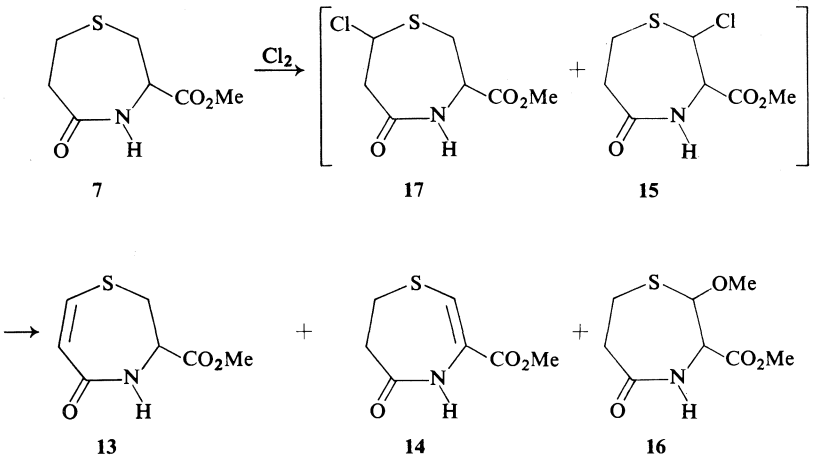

SCHEME 3

under basic conditions (8) to yield 83% of the oily diester **10***a*. Removal of the formyl protecting group was effected in high yield in methanolic hydrogen chloride to give the corresponding amino diester **10***b*. An attempt to cyclize the latter by the methanol–ammonia method (*vide supra*) completely failed as ammonolysis of the amino ester moiety took place in quantitative yield; a prolonged reaction time gave no further change.

Due to the lower reactivity of the ester group on the pivalate moiety, cyclization was achieved using the acyl azide method (14). To that effect, amino diester **10***b* was partially saponified with a sodium carbonate solution to yield 95% of the expected acid-ester **10***c*. The latter compound upon treatment with hydrazine and subsequently with nitrous acid gave the required thiazepine **11** with a 22% yield. Esterification by the usual diazomethane procedure finally gave the parent 3-carbomethoxy-6,6-dimethyl-5-oxoperhydro-1,4-thiazepine (**12**) in quantitative yield.

Halogenation

The reaction scheme expected to introduce halogen at C-6 and -7 proceeded via the 6,7-dehydro derivative **13** which, hopefully, could be halogenated on the double bond to yield the required *trans*-dihalo compound **1**.

Preparation of 3-carbomethoxy-5-oxo-2,3,4,5-tetrahydro-1,4-thiazepine (**13**) was achieved easily using a known chlorination–dehydrochlorination procedure (7). Indeed it is well known that thioethers react with chlorinating agents to give α-chloro thioethers (15) which in turn may be dehydrohalogenated. In the case of 5-oxo-perhydro-1,4-thiazepines, the α-chloro thioether intermediates are quite unstable [5] probably due to the presence of a carbonyl group at the 5-position; under the reaction conditions stipulated by Leonard and Wilson (7) the intermediate α-chloro thioether formed is dehydrohalogenated *in situ* to yield directly the 2,3,4,5-tetrahydro-1,4-thiazepine.

When the above conditions (7) were applied to perhydrothiazepine **7**, three products were obtained after chromatography on silica gel (see Scheme 3).

The desired product, 3-carbomethoxy-5-oxo-2,3,4,5,-tetrahydro-1,4-thiazepine (**13**), was formed in a 37% yield along with 19% of 3-carbomethoxy-5-oxo-4,5,6,7-tetrahydro-1,4-thiazepine (**14**) which results from the dehydrochlorination of the alternate intermediate **15**. Finally, a 1% yield of 3-carbomethoxy-2-methoxy-5-oxoperhydro-1,4-thiazepine (**16**) was obtained suggesting that intermediate **15** had, at least partially, resisted dehydrochlorination and reacted subsequently with the methanolic eluent on the chromatography column.

Concerning the introduction of two halogen atoms on the double bond of **13** in order hopefully to obtain a stable *trans*-6,7-dihalo compound, it

[5] Knunyants and co-workers (6) did report the successful preparation, by the above method, of some 7-halo-5-oxoperhydro-1,4-thiazepines; however, these were unstable and underwent dehydrohalogenation very readily. Repetition of the published procedure by Leonard and Wilson (7) did not yield the expected 7-halo-1,4-thiazepine.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

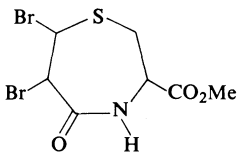
is important to note that Knunyants and coworkers (6) have carried out the bromination of a related thiazepine but without, however, succeeding to isolate the 6,7-dibromo derivative; instead there was always obtained an excellent yield of the corresponding dehydrobrominated product (see Scheme 4).

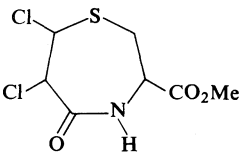
We feel, however, that this result does not militate against the presumed stability of *trans*-6,7-dihalo derivatives since dehydrohalogenation might well have gone through the corresponding acylimine (see Scheme 4) followed by tautomerization to the observed product (16).

Also of importance is the fact that Leonard and Wilson (7) in studying the chlorination at $-60°$ of a pure stereoisomer of the same thiazepine have observed, aside from the normal tetrahydrothiazepine expected, two other compounds resulting from further chlorination and rearrangement of the first reaction product (see Scheme 5).

In both cases cited above, no stable 7-halo perhydrothiazepine could be isolated. However, bromination of thiazepine **13** in dichloromethane yielded 78% of the desired 6,7-dibromo compound **18**, m.p. 133–134°. This compound could be kept for more than 1 month in dichloromethane solution but surprisingly decomposed after a few days when kept in the crystalline state.



18



19

It is interesting to note that the 6,7-dibromo compound **18**, although slightly unstable can be obtained and kept while the 7-chloro derivative **17** could not even be isolated. This behavior could well be due to a *trans* configuration of the bromine atoms thus preventing the stereoelectronically preferred *trans*-coplanar arrangement of H and Br for a potential dehydrohalogenation.

18 X = Br
19 X = Cl

21 X = Br
22 X = Cl

20

Finally, heating the dibromo derivative **18** in the presence of powdered zinc in methanol yielded the original tetrahydrothiazepine **13** quantitatively showing that bromine had been introduced without modification to the basic skeleton of the molecule.

Having succeeded in preparing the 6,7-dibromothiazepine **18** it became interesting to seek conditions whereby chlorination of the tetrahydrothiazepine **13** would occur on the double bond rather than at the sulfur atom, as illustrated previously in Scheme 5. It was expected that a *trans*-6,7-dichloro derivative could show a greater degree of stability than the corresponding dibromo compound.

In the hope of increasing the polar character of the reactants and therefore altering the normal course of the reaction, the chlorination of tetrahydrothiazepine **13** was carried out in anhydrous nitromethane rather than dichloromethane. There was thus obtained a 60% yield of a solid, m.p. 158–160°, identified as 3-carbomethoxy-6,7-dichloro-5-oxoperhydro-1,4-thiazepine (**19**). As in the previous case treatment with zinc in methanol gave the original tetrahydrothiazepine **13**.

Chlorination studies on the second model compound **12** also proved fruitful in yielding 67% of the desired 7-chlorothiazepine **2**. The position of the chlorine atom follows from the n.m.r. spectrum which shows a singlet at δ 4.90 for the C-7 methine proton; in the case of a 2-chloro derivative one would expect a doublet, unless of course the dihedral angle happened to be nearly 90° (17). However, the assigned structure **2** is strongly supported by results of the reactivity studies (see below).

Reactivity

Considering that the reported attempts (6, 7) to form a 4—7 bond starting from either a 7-halo-5-oxoperhydrothiazepine or the corresponding sulfonium ion, led only to the 6,7-dehydrohalogenated product it was necessary to seek mild conditions where elimination could be suppressed in favor of substitution by nitrogen in the 4 position.

Thus, treatment during 12 h of the 6,7-dibromothiazepine **18** in pyridine and methanol afforded an almost quantitative yield of the corresponding dimethoxy compound **20** and none of the desired penam derivative. On the other hand, the same 6,7-dimethoxy compound was obtained in 1 h when silver oxide or silver carbonate (18) was used instead of pyridine; yields were also quantitative in this case.

The action of pyridine and methanol on the 6,7-dichlorothiazepine **19** was also investigated. In this case the reaction is much slower: after 24 h of contact one can isolate a 77% yield of the monosubstitution product **22**. Examination of the fragmentation pattern in the mass spectrum corroborates the assignment made on the basis of n.m.r. data; indeed, a fragment at *m/e* 177 corresponds to the loss of methyl thioformate indicating that methanolysis takes place at C-7. This order of reactivity is also that which is expected *a priori*. Interestingly, it was later found that treatment of dibromo thiazepine **18** with silver carbonate in methanol for 20 min gave 23% of the 6-bromo-7-methoxy derivative **21**.

On the other hand, treatment of the 7-chloro-6,6-dimethyl model **2** with pyridine and methanol as above, yielded only unchanged starting material and no trace of substitution product; identical results were also observed in the case of silver oxide or silver carbonate in methanol at room temperature. However, in refluxing methanol in the presence of silver oxide or silver carbonate, a 95% yield of a new product was obtained after 1 h. The structure, which is easily derived by physical methods, corresponds to the open chain enamide **23**. A comparison of the n.m.r., i.r., and u.v. spectra of the enamide **23** to those of an authentic sample of methyl α-acetamidoacrylate was useful in confirming the assigned structure. Also in substantiation of structure **23**, the enamide was treated with a

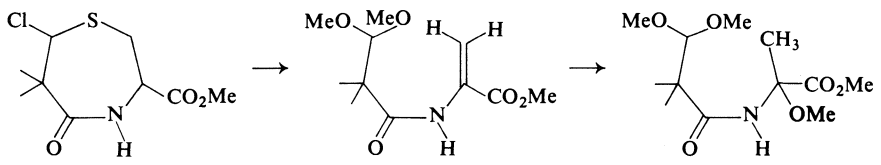
*An intense peak at *m/e* 55 is *characteristic of all* the 6,7-unsubstituted thiazepines reported herein, and most probably corresponds to $[CH_2{=}CH{-}C{=}O]^{\oplus}$. This fragment originates from C−5, −6, and −7 of the ring and its presence or absence is used advantageously to determine the substitution pattern in the chlorination reactions.



2 **23** **24**

methanol saturated with hydrogen chloride solution to give amide **24** resulting from the addition of methanol to the enamide moiety (20).

Although the desired cyclization failed to take place under both sets of conditions used, the two 7-haloperhydrothiazepine models available will now allow a systematic study of the feasibility of this particular reaction to be undertaken.

It may be of interest to add that very recently Edwards *et al.* (19) described the cyclization, under solvolytic conditions, dioxane – water – silver ion, of 5-chloro-azacyclooctan-2-one to 1-azabicyclo[3.3.0]octan-2-one.

Experimental

The i.r. spectra were determined on a Beckmann, model IR-8, spectrometer using chloroform as solvent (unless otherwise indicated). The n.m.r. spectra were determined either on a Varian A-60 or on a Jeol JNM-4H-100 spectrometer. Deuterochloroform was used as solvent unless otherwise indicated; the following abbreviations are employed: singlet (s), doublet (d), triplet (t), and multiplet (m). The u.v. spectra were measured on a Bausch and Lomb Spectronic 505 spectrometer, and the mass spectra on a Hitachi-Perkin-Elmer RMu-6D instrument. Microanalyses were by Midwest Microlab Inc., Indianapolis, Ind. Melting points are uncorrected.

S-(2-Carbomethoxyethyl)cysteine (5)

This compound was prepared following a method reported by Foldi (8) for the synthesis of *S*-(2-carboethoxyethyl)cysteine. Triethylamine (115 ml) and methyl acrylate (**4**) (51.0 g, 600 mmol) were added with stirring at 25° to a solution of *l*-cysteine hydrochloride hydrate (**3**) (87.5 g, 500 mmol) in ethanol (400 ml). The exothermic reaction which ensued was completed in a few minutes as indicated by a negative nitroprusside test. The resulting precipitate was filtered *in vacuo*, washed with boiling ethanol (2 × 100 ml), and then with ether (100 ml) to yield 90% (93 g) of a white solid melting at 208–209°; i.r. (Nujol): 3200–2000, 1730, 1610, and 1580 cm^{-1}; n.m.r. (CF_3COOH): δ 2.85 (m, 4H); 3.35 (m, 2H); 3.82 (s, 3H); 4.55 (m, 1H); 7.55 (broad m, 3H).

3-Carboxy-5-oxoperhydro-1,4-thiazepine (6)

A solution of thioether **5** (41.4 g, 200 mmol) in methanol saturated with ammonia (1.2 l) was stirred at room temperature for 7 days. The solvent was then evaporated to dryness, and the residue dissolved in water (400 ml). The solid which precipitated upon acidification to p*H* 2 with concentrated hydrochloric acid was filtered *in vacuo* and washed with cold water (50 ml). Recrystallization from acetone yielded 49% (17.1 g) of the thiazepine **6**, m.p. 218–219°. The i.r. (Nujol): 3320, 3100–2300, 1715 and 1610 cm^{-1}; n.m.r. (CF_3COOH): δ 2.8–3.4(m, 6H); 4.85 (m, 1H); 8.40 (d, 1H).

Anal. Calcd. for $C_6H_9NO_3S$: C, 41.13; H, 5.18; N, 7.99. Found: C, 41.41; H, 5.27; N, 7.73.

3-Carbomethoxy-5-oxoperhydro-1,4-thiazepine (7)

A solution of perhydrothiazepine **6** (17.5 g, 100 mmol) in methanol (200 ml) was cooled in an ice bath; an ice-cold solution of diazomethane in ether was then slowly added, until the precipitate formed was completely dissolved and evolution of nitrogen ceased. Evaporation of the solvent *in vacuo* and recrystallization of the residue

from ether gave 92% (17.3 g) of thiazepine **7**, m.p. 91–92°. The i.r.: 3380, 1750 and 1670 cm^{-1}; n.m.r.: δ 2.90 (m, 6H); 3.82 (s, 3H); 4.50 (m, 1H); 6.65 (m, 1H).

Anal. Calcd. for $C_7H_{11}NO_3S$: C, 44.42; H, 5.86; N, 7.40. Found: C, 44.54; H, 5.98; N, 7.67.

The optical purity of this compound and its derivatives has not been determined; however, following observations made in a related series where the methanol–ammonia method was used, it is probable that the compounds are at least partly racemized.

*Methyl α-Formamidoacrylate (**9**)*

Compound **9** was prepared according to the method described by Frankel and Reichmann (13); m.p. 50–52° (lit. 53° (13)). The yield for the addition of formamide on pyruvic acid was only 10%, although Frankel and Reichmann report a 20% yield for this reaction.

Bromopivalic Acid

Bromopivalic acid was prepared, as reported by Greene and Hagemeyer (11), from hydroxy pivalic acid and 48% hydrobromic acid. The yield obtained was 70%, m.p. 44° (lit. 75% yield, m.p. 46–48° (11)).

Mercaptopivalic Acid

Thiourea (47 g, 620 mmol) was added to a solution of bromopivalic acid (110 g, 608 mmol) in absolute ethanol (250 ml), and the resulting mixture heated to reflux for 12 h. Sodium hydroxide (72 g) in water (300 ml) was then added and the mixture heated to reflux under nitrogen for a further 3 h. Hydrated sodium sulfide (50 g) was then added to the reaction mixture and the solvent evaporated under vacuum until crystals began to appear. The mixture was cooled in ice, covered with ether (300 ml) and neutralized to p*H* 3 with 20% sulfuric acid. The organic layer was diluted with ether and the resulting solution washed with water saturated with sodium chloride and dried over anhydrous sodium sulfate. The ether was evaporated *in vacuo* and the remaining oil distilled under reduced pressure, to give 73% (60 g) of mercaptopivalic acid; b.p. 120°/15 mm. The i.r.: 3000, 2580, and 1700 cm^{-1}; n.m.r. (DMSO-d_6): δ 1.18 (s, 6H); 2.14 (s, 2H).

*Methyl Mercaptopivalate (**8**)*

A solution of mercaptopivalic acid (60 g, 448 mmol) in anhydrous methanol was saturated with anhydrous hydrogen chloride and then stirred at room temperature for 6 h. The solvent was evaporated to dryness and the residue taken up in ether, and washed twice with a 5% sodium bicarbonate solution. After drying over anhydrous sodium sulfate the ether was evaporated under vacuum and the remaining oil distilled under reduced pressure, yielding 62% (40 g) of methyl mercaptopivalate (**8**), b.p. 40°/0.05 mm. The i.r.: 2580 and 1730 cm^{-1}; n.m.r.: δ 1.26 (s, 6H); 1.45 (t, 1H); 2.69 (d, 2H); 3.69 (s, 3H).

Anal. Calcd. for $C_6H_{12}O_2S$: C, 48.65; H, 8.15. Found: C, 49.05; H, 8.43.

*Methyl N-Formyl S-(2-Carbomethoxy-2-methyl propyl)-cysteinate (**10a**)*

Methyl α-formamidoacrylate (**9**) (1.04 g, 8.07 mmol) was added to a solution of methyl mercaptopivalate (**8**) (1.19 g, 8.07 mmol) in methanol (25 ml). Three drops of triethylamine were then added and the mixture stirred at room temperature for 4 h. The solvent was evaporated to dryness and the residue chromatographed on silica gel using ether as eluent. The diester **10*a*** was obtained as an oil (1.85 g, 83%) which was used for the next step without further purification. The i.r. (CH_2Cl_2): 3430, 1735 and 1690 cm^{-1}; n.m.r.: δ 1.25 (s, 6H); 2.78 (s, 2H); 3.03 (d, 2H); 3.71 (s, 3H); 3.79 (s, 3H); 4.90 (m, 1H); 6.85 (m, 1H); 8.27 (s, 1H).

*Methyl S-(2-Carbomethoxy-2-methyl propyl)cysteinate (**10b**)*

Diester **10*a*** (100 mg, 3.61 mmol) was dissolved in methanol (10 ml) and the resulting solution saturated with dry hydrogen chloride and stirred at room temperature for 1 h. The solvent was then evaporated to dryness and the remaining oil taken up in ether. The organic layer was washed with a 5% sodium carbonate solution. After drying over anhydrous sodium sulfate, the ether was evaporated and compound **10*b*** (0.087 g, 95%) was obtained as a yellow oil which was used without further purification. The i.r. (CH_2Cl_2): 3400, 1730, 1380 and 1360 cm^{-1}; n.m.r.: δ 1.26 (s, 6H); 2.82 (s, 2H); 3.0 (m, 2H); 3.71 (s, 3H); 3.75 (m, 1H); 3.78 (s, 3H).

*S-(2-Carbomethoxy-2-methyl propyl)cysteine Hydrochloride (**10c**)*

Amino-diester **10*b*** (4.0 g, 16.1 mmol) was added to a 10% sodium carbonate solution (150 ml) and the resulting mixture stirred at room temperature for 1 h, after which it was acidified to p*H* 0 by careful addition of 6 *N* hydrochloric acid. The aqueous solution was then concentrated to 75 ml by evaporation under vacuum. The precipitate formed was filtered and recrystallized from 6 *N* HCl, to yield 95% (4.2 g) of the amino-diacid monoester hydrochloride **10*c***, m.p. 245° (dec.), which was used without further purification. The i.r. (Nujol): 3000, 2800, 1720 and 1700 cm^{-1}; n.m.r. (D_2O): δ 1.65 (s, 6H); 3.30 (s, 2H); 3.58 (d, 2H); 4.13 (s, 3H); 4.70 (t, 1H); 5.22 (HDO).

*3-Carboxy-6,6-dimethyl-5-oxoperhydro-1,4-thiazepine (**11**)*

A mixture of acid-ester hydrochloride **10*c*** (3.0 g, 11.1 mmol) and redistilled hydrazine hydrate (20 ml) was heated to reflux for 2 h. The excess hydrazine hydrate was evaporated to dryness; the residue was taken up in *n*-butanol (5 ml) and the solvent once again evaporated *in vacuo*. The residue was dissolved in methanol and the remaining crystals of hydrazine hydrochloride filtered. The methanolic filtrate was evaporated to dryness to yield 56% (1.45 g) of the required hydrazide as a gum.

The crude hydrazide (1.45 g, 6.18 mmol) was dissolved in 2 *N* hydrochloric acid (62 ml) at 0° and sodium nitrite (0.428 g, 6.18 mmol) added. The mixture was stirred at 0° for 15 min, and then poured into ice-cold water (3.6 l). The solution was neutralized by the addition of sodium bicarbonate (7.8 g) and kept at 4° for 40 h in the refrigerator. The mixture was then acidified to p*H* 4 with 2 *N* hydrochloric acid (about 50 ml) and the water evaporated under vacuum to a final volume of 175 ml. Crystals which appeared during the evaporation were filtered under vacuum. Recrystallization from ethanol–ether yielded 40% (495 mg) of 3-carboxy-6,6-dimethyl-5-oxoperhydro-1,4-thiazepine (**11**) m.p. 218–220°. The i.r. (Nujol);

3340, 1720 and 1555 cm^{-1}; n.m.r. (DMSO-d_6): δ 1.15 (s, 3H); 1.20 (s, 3H); 2.3–3.2 (m, 4H); 4.55 (m, 1H); 6.53 (d, 1H).

Anal. Calcd. for $C_8H_{13}NO_3S$: C, 47.27; H, 6.44. Found: C, 47.12; H, 6.87.

*3-Carbomethoxy-6,6-dimethyl-5-oxoperhydro-1,4-thiazepine (**12**)*

A solution of thiazepine **11** (1.0 g, 4.93 mmol) in methanol (10 ml) was treated with a solution of diazomethane in ether until the evolution of nitrogen ceased and the reaction mixture took on a faint yellow color. The solvent was evaporated to dryness and the residue recrystallized from ether, to yield 80% (0.85 g) of 3-carbomethoxy-6,6-dimethyl-5-oxo-perhydro-1,4-thiazepine (**12**), m.p. 89–89.5°. The i.r. (Nujol): 3450, 1735 and 1630 cm^{-1}; n.m.r.: δ 1.20 (s, 3H); 1.25 (s, 3H); 2.2–3.2 (m, 4H); 3.74 (s, 3H); 4.50 (m, 1H); 6.40 (m, 1H).

Anal. Calcd. for $C_9H_{15}NO_3S$: C, 49.85; H, 6.97. Found: C, 49.92; H, 7.04.

Reaction of 3-Carbomethoxy-5-oxoperhydro-1,4-thiazepine (7) with Chlorine

A solution of the thiazepine **7** (18.9 g, 100 mmol) in anhydrous dichloromethane (500 ml) was cooled in a mixture of Dry Ice and acetone and slowly treated (dropwise) with 1 equiv of chlorine in carbon tetrachloride (182 ml, 0.55 *M*). The resulting mixture was stirred for 2 h at −65° and, after removal of the cooling bath, allowed to warm up to room temperature, at which point evolution of hydrogen chloride could be observed. After a 2 h reflux, the solution was concentrated *in vacuo*, the oily residue dissolved in a minimum amount of chloroform and chromatographed on silica gel.

Three products were obtained by eluting successively with ether (first product) and methanol–ether (1:20) (second and third products):

(*i*) 3-Carbomethoxy-5-oxo-4,5,6,7-tetrahydro-1,4-thiazepine (**14**) (3.5 g, 19%), m.p. 88–89° (ether); u.v.: 298 mμ (ε 1700).

Anal. Calcd. for $C_7H_9NO_3S$: C, 44.91; H, 4.84; N, 7.48. Found: C, 44.71; H, 5.03; N, 7.48.

(*ii*) 3-Carbomethoxy-2-methoxy-5-oxoperhydro-1,4-thiazepine (**16**) (0.60 g, ~1%), m.p. 148–149°.

Anal. Calcd. for $C_8H_{13}NO_4S$: C, 43.82; H, 5.98; N, 6.39. Found: C, 44.15; H, 6.05; N, 6.42.

(*iii*) 3-Carbomethoxy-5-oxo-2,3,4,5-tetrahydro-1,4-thiazepine (**13**) (6.9 g, 37%), m.p. 131–132° (methanol–ether); u.v.: 227 (ε 4900) and 279 mμ (ε 7700).

Anal. Calcd. for $C_7H_9NO_3S$: C, 44.91; H, 4.84; N, 7.48. Found: C, 45.14; H, 5.02; N, 7.48.

*6,7-Dibromo-3-carbomethoxy-5-oxoperhydro-1,4-thiazepine (**18**)*

A solution of thiazepine **13** (0.935 g, 5 mmol) in anhydrous dichloromethane (100 ml) was treated (dropwise) with a solution of bromine in carbon tetrachloride (5.5 ml, 0.92 *M*). The solvent was then evaporated *in vacuo*, and the residue chromatographed on a silica gel column, eluting with dichloromethane. Recrystallization from chloroform–ether yielded 78% of dibromothiazepine **18**, m.p. 133–134°. The i.r. (CH_2Cl_2): 3380, 1750 and 1675 cm^{-1}; n.m.r.: δ 3.25 (m, 2H); 3.92 (s, 3H); 5.05 (d + m, 2H); 5.30 (d, 1H); 6.85 (m, 1H).

Anal. Calcd. for $C_7H_9Br_2NO_3S$: C, 24.22; H, 2.62. Found: C, 24.27; H, 2.52.

*Reaction of 3-Carbomethoxy-5-oxo-2,3,4,5-tetrahydro-1,4-thiazepine (**13**) with Chlorine*

A stirred solution of thiazepine **13** (1.87 g, 10 mmol) in nitromethane was slowly treated (dropwise) with chlorine in carbon tetrachloride (11 mmol; 20 ml, 0.54 *M*). Evaporation of the solvent *in vacuo* and chromatography of the residue on silica gel, eluting with dichloromethane, gave a first product in a 60% yield: 3-carbomethoxy-6,7-dichloro-5-oxoperhydro-1,4-thiazepine (**19**) (1.54 g), m.p. 158–160° (chloroform–ether).

Anal. Calcd. for $C_7H_9Cl_2NO_3S$: C, 32.57; H, 3.51. Found: C, 32.48; H, 3.63.

Further elution with dichloromethane gave 3% (340 mg) of an unseparable mixture of two products: probably a dichloro thiazepine (isomer of **19**) and the corresponding unsaturated chlorothiazepine u.v. (C_2H_5OH): 290 mμ.

*Reaction of the Dichlorothiazepine **19** with Zinc*

A mixture of the dichlorothiazepine **19** (10 mg) and zinc powder (50 mg) in methanol (10 ml) is heated to reflux for 30 min. After filtration and evaporation of the solvent, t.l.c. on silica gel using ether or methanol–ether 1:20 as eluent showed a complete transformation into 3-carbomethoxy-5-oxo-2,3,4,5-tetrahydro-1,4-thiazepine (**13**).

*Reaction of the Dibromothiazepine **18** with Zinc*

The above procedure applied to the dibromothiazepine **18** gave quantitatively the same results.

*3-Carbomethoxy-7-chloro-6,6-dimethyl-5-oxoperhydro-1,4-thiazepine (**2**)*

A solution of thiazepine **12** (1.926 g, 8.88 mmol) in methylene chloride (150 ml) was cooled to −65° in a Dry Ice – acetone bath, and treated dropwise with a solution of chlorine in carbon tetrachloride (8.8 mmol; 27 ml, 0.34 *M*). The mixture was stirred at −65° for 1 h and then heated to reflux for 20 h. The solvent was evaporated under vacuum and the residue recrystallized from carbon tetrachloride, to yield 67% (1.40 g) of chloro derivative **2**, m.p. 148.5°. The i.r. (CCl_4): 3380, 1750 and 1665 cm^{-1}; n.m.r.: δ 1.53 (s, 6H); 2.8–3.6 (m, 2H); 3.92 (s, 3H); 4.7 (m, 1H); 4.90 (s, 1H); 6.80 (m, 1H).

Anal. Calcd. for $C_9H_{14}ClNO_3S$: C, 42.94; H, 5.61. Found: C, 43.20; H, 5.69.

*3-Carbomethoxy-6-chloro-7-methoxy-5-oxoperhydro-1,4-thiazepine (**22**)*

A solution of 3-carbomethoxy-6,7-dichloro-5-oxoperhydro-1,4-thiazepine (**19**) (100 mg, 0.4 mmol) and pyridine (63 mg, 0.8 mmol) in methanol (10 ml) was stirred at room temperature for 24 h. The t.l.c. (silica gel, ether) showed the presence of two products, the dimethoxy thiazepine **20** at R_f 0.1 and the chloro-methoxy thiazepine **22** at R_f 0.5. Evaporation of the solvent and chromatography on silica gel (10 g) eluting with dichloromethane yielded 77% (75 mg) of 3-carbomethoxy-6-chloro-7-methoxy-5-oxoperhydro-1,4-thiazepine (**22**), m.p. 151–152° (chloroform–ether). The i.r.: 3375, 1745 and 1675 cm^{-1}; n.m.r.: δ 3.00 (m, 2H); 3.52 (s, 3H); 3.88 (s, 3H); 4.55 (d, 1H); 4.85 (d, 1H); 4.90 (m, 1H); 6.80 (m, 1H).

*3-Carbomethoxy-6,7-dimethoxy-5-oxoperhydro-1,4-thiazepine (**20**)*

Method A

A mixture of 3-carbomethoxy-6,7-dibromo-5-oxoperhydro-1,4-thiazepine (**18**) (160 mg, 0.43 mmol) and pyridine (68 mg, 0.86 mmol) in methanol (20 ml) was stirred at room temperature for 12 h. After evaporation of the solvent under vacuum, the reaction product was dissolved in a small amount of dichloromethane and chromatographed on silica gel (20 g) using ether–dichloromethane (1:20) as eluent to yield 98% (113 mg) of 3-carbomethoxy-6,7-dimethoxy-5-oxoperhydro-1,4-thiazepine (**20**), m.p. 154–155°. The i.r.: 3410, 1750 and 1670 cm^{-1}; n.m.r.: δ 2.7–3.3 (m, 2H); 3.48 (s, 3H); 3.50 (s, 3H); 3.72 (d, 1H); 3.82 (s, 3H); 4.42 (m, 1H); 4.88 (d, 1H); 6.80 (m, 1H).

Anal. Calcd. for $C_9H_{15}NO_5S$: C, 43.36; H, 6.06. Found: C, 43.49; H, 6.14.

Method B

A mixture of the dibromo thiazepine **18** (36 mg, 0.10 mmol) and silver carbonate (100 mg, 0.40 mmol) in methanol (10 ml) was stirred at room temperature for 2 h. Filtration of the solution on Celite and evaporation of the solvent under vacuum gave, after recrystallization from chloroform–ether, a nearly quantitative yield of the dimethoxy thiazepine **20**, identical in all respects to the product obtained in method A.

The same result is obtained if silver oxide is used instead of silver carbonate.

*6-Bromo-3-carbomethoxy-7-methoxy-5-oxoperhydro-1,4-thiazepine (**21**)*

A mixture of 6,7-dibromo-3-carbomethoxy-5-oxoperhydro-1,4-thiazepine (**18**) (500 mg, 1.35 mmol) and silver carbonate (1.35 g, 5.4 mmol) in methanol (50 ml) was stirred at room temperature for 20 min. The t.l.c. then showed disappearance of the starting material and the presence of two reaction products. The mixture was filtered on Celite, the solvent evaporated under vacuum and the residue chromatographed on a silica gel column (50 g) using ether as eluent. Evaporation of the first fractions yielded 23% (100 mg) of 6-bromo-3-carbomethoxy-7-methoxy-5-oxoperhydro-1,4-thiazepine (**21**) melting, after recrystallization from chloroform–ether, at 108–110°; *m/e* 296.9651; calcd. 296.9671.

The second spot observed on t.l.c. corresponds to the 6,7-dimethoxy compound **20**.

*Reaction of Thiazepine **2** with Silver Oxide and Methanol*

A mixture of 3-carboxy-7-chloro-6,6-dimethyl-5-oxoperhydro-1,4-thiazepine (**2**) (100 mg, 0.40 mmol) and silver oxide (250 mg, 1.1 mmol) in methanol (15 ml) was heated to reflux for 1 h. The mixture was then filtered on Celite, the solvent evaporated *in vacuo* and the residue chromatographed on a silica gel column (10 g) using dichloromethane as eluent. The enamide **23** (90 mg) was obtained as an oil with a 92% yield. The i.r. (CH_2Cl_2): 3330, 1720 and 1675 cm^{-1}; n.m.r.: δ 1.24 (s, 6H); 3.60 (s, 6H); 3.89 (s, 3H); 4.23 (s, 1H); 5.90 (d, 1H); 6.66 (s, 1H); 9.33 (m, 1H); *m/e*: 245.

*Reaction of Enamide **23** with Methanolic Hydrogen Chloride*

The enamide **23** (90 mg, 0.368 mmol) was dissolved in anhydrous methanol (10 ml) saturated with hydrogen chloride, and the resulting solution stirred at 25° for 3 h. The hydrogen chloride was then neutralized by careful addition of solid sodium bicarbonate, the solvent evaporated to dryness and the residue taken up in ether. The inorganic salts were filtered and the reaction products separated by preparative t.l.c. using ether as eluent, to yield 50% (50 mg) of the oily amide **24**. The i.r. (CH_2Cl_2): 3380, 1745, and 1680 cm^{-1}; n.m.r.: δ 1.16 (s, 6H); 1.70 (s, 3H); 3.24 (s, 3H); 3.55 (s, 6H); 3.83 (s, 3H); 3.18 (s, 1H); 7.60 (m, 1H).

The authors are grateful to the National Research Council of Canada for generous support of this research through grants A-2034 and A-71 to D.G. and C.B., and also through fellowships for P.B. and R.G.

On the Chemistry of the Isomeric Dichlorodiphenylacetaldehydes Related to DDT. Stereoelectronic Effects in the Hydrolysis of their Cyclic Acetals

J. D. McKinney, R. E. Hawk,[1] E. L. Boozer,[1] and J. E. Suggs[1]

National Institute of Environmental Health Sciences, National Institutes of Health, Public Health Service and Department of Health, Education and Welfare, Research Triangle Park, North Carolina 27709

Received July 7, 1970[2]

The chemistry of the isomeric dichlorodiphenylacetaldehydes related to DDT was investigated to aid in delineating their possible role in the metabolism of this pesticide. In the case of the *p,p'*-isomer, the most important system under consideration, several literature syntheses were shown to be incorrect. The failure of at least one of these methods was attributed to the preferred oxidative involvement of the benzhydryl carbon via rearrangement of a β-hydroxy enol ether which normally led to the isolation of the *p,p'*-dichlorobenzophenone instead of the desired aldehyde. The *o,p'*-isomer exhibited chemistry similar to that of the *p,p'*-isomer although the steric effect of the ortho-substituted chlorine on the benzhydryl proton was notable. The *o,o'*-isomer was normal in that it did not undergo reactions involving the benzhydryl carbon. Some possible mechanistic and biological implications of the work are discussed.

La chimie des dichlorodiphénylacétaldéhydes isomères, apparentés au DDT, a été étudiée afin de délimiter leurs rôles possibles dans le métabolisme de ce pesticide. Dans le cas de l'isomère-*p,p'*, le système considéré comme le plus important, plusieurs synthèses données dans la littérature sont incorrectes. L'échec d'au moins une de ces méthodes est attribuée à l'entrée en jeu de l'oxydation préférentielle du carbone benzhydryle via une transposition d'un éther énolique β-hydroxylé qui normalement conduit au *p,p'*-dichlorobenzophénone au lieu de conduire à l'aldéhyde désiré. L'isomère-*o,p'* montre un comportement analogue à celui de l'isomère-*p,p'*, bien que l'effet stérique des substituants ortho sur le proton benzhydryle soit notable. L'isomère-*o,o'* a un comportement normal en ce sen qu'il ne subit aucune réaction impliquant le carbone benzhydryle. Certains mécanismes possibles et certaines implications biologiques de ce travail sont discutés.

Canadian Journal of Chemistry, **49**, 3877 (1971)

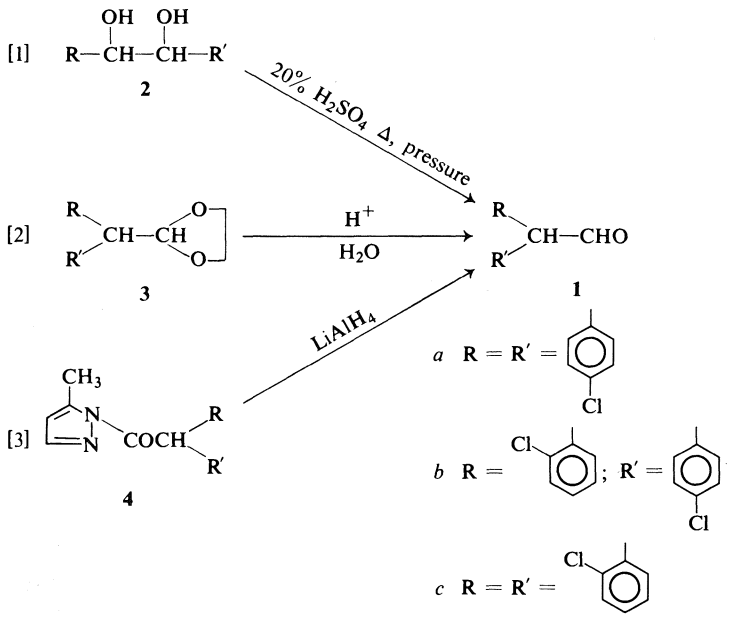
Today DDT is of immense biological importance, with vast quantities now distributed in the worldwide environment. However, surprisingly little work has been done toward gaining a firm theoretical understanding of its chemistry. The synthesis of the isomeric dichlorodiphenylacetaldehydes related to DDT and a study of some of their reactions were undertaken to help correct this deficiency. Investigation of their role in DDT metabolism (1) seemed essential since they are the logical intermediates in the formation of the dichlorodiphenylacetic acids which are major metabolites. Although several syntheses have been reported for these aldehydes, our attempts to reproduce some of them led to contradictory results which are theoretically interesting and may be of biological consequence.

The several syntheses reported for *bis*(*p*-chlorophenyl)acetaldehyde (**1***a*) include the rearrangement of 1,2-*bis*(*p*-chlorophenyl)ethylene glycol (**2***a*) in a sealed tube under vigorous conditions to effect a phenyl migration (2) (eq. 1); the hydrolysis of the cyclic acetal (3), 2-(*p,p'*-dichlorobenzhydryl)-1,3-dioxolane (**3***a*) (eq. 2); the reductive cleavage of the pyrazolene **4***a* (4) (eq. 3). In all three cases the aldehyde was reported as a crystalline compound varying in m.p. from 135 to 149 °C.

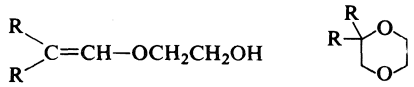
The synthesis of **1***a* by the hydrolysis of **3***a* appeared straightforward and was especially attractive since the starting material for synthesis of **3***a* was 2,2-dichloro-1,1-*bis*(*p*-chlorophenyl)-ethane (DDD) which is readily available. Our attempts (5) to reproduce this method afforded crystalline **3***a* whose structure confirmation conveniently eliminated structures **5***a* and **6** which are conceivable products of this reaction proposed by Riemschneider and co-workers. However, the results of our hydrolyses of **3***a* confirm that the previous workers (3) had isolated 4,4'-dichlorobenzophenone (**7**) instead of the desired aldehyde (**1***a*). The aldehyde was obtained as an oil which could not be crystallized. The crystalline material isolated by the previous workers (2–4) is characteristic of **7** in varying degrees of purity. It was later found that other workers (6) had arrived at the same conclusion since their

[1]Chamblee Toxicology Laboratory, Environmental Protection Agency, Chamblee, Georgia 30341.

[2]Revision received August 31, 1971.

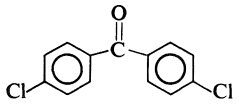


Darzens synthesis of the aldehyde had afforded an oily product. Investigation of this chemistry was undertaken since the chemistry encompassing the formation of the dichlorobenzophenone might have a bearing on its occurrence in DDT metabolism.



5*a*

6



7

Based on these findings, it seemed plausible but mechanistically obscure that **1***a* might be intermediate in the formation of **7** during the hydrolysis of the acetal **3***a* under the heterogeneous conditions. However, the aldehyde was recovered in good yield when it was subjected to the conditions of hydrolysis with no appreciable conversion to dichlorobenzophenone (**7**). When the hydrolysis was carried out using mixtures of *p*-dioxane and 20% aqueous HCl (1:1 v/v), **7** was formed as the major characterizable product (30–60% yields) in 3–5 h at reflux temperature. There was no t.l.c. evidence for the intermediate formation of **1***a*. This result was supported by following the hydrolysis of **3***a* by n.m.r. under similar conditions.[3] Since the purity and structure of **3***a* have been rigorously established, an alternative route by which dichlorobenzophenone **7** can be formed from acid hydrolysis of acetal **3***a* without invoking the intermediacy of aldehyde **1***a* apparently exists. The experiments outlined in Scheme 1 were carried out with the objective of trapping or stablizing intermediates which might be responsible for the formation of **7** from acetal **3***a*.

Solvolysis of **3***a* in acetic acid in the presence of concentrated sulfuric acid at 100 °C for 1 h gave a mixture of the dichlorobenzophenone **7**, aldehyde **1***a*, and the acetoxyethanol **9***b*. These products were isolated by preparative t.l.c.[4] and

[3]The hydrolysis was carried out at 75° in *p*-dioxane-d_8 with 20% DCl. The n.m.r. scans were made at 5-min intervals for 1 h. The acetal apparently underwent immediate hydrolysis; however, there were no resonances indicating the formation of **1***a*. A control experiment had indicated that **1***a* was stable under these conditions.

[4]The acetoxyethanol **9***b* decomposed on t.l.c. to two materials; one remaining at the origin and the other near the solvent front. The latter material characteristically fluoresced light blue under short wave u.v. light. The exact nature of these products will be discussed later; however, n.m.r. studies of product mixtures of **9***b* in the presence of the n.m.r. shift reagent (7), $Eu(DPM)_3$, confirmed that the acetate group (three proton, singlet) was associated with the benzhydryl carbon and a hydroxyl group was associated with the methylene group (two proton, singlet) since the latter group experienced the largest paramagnetic shift with the reagent while the aromatic signals experienced relatively little shift.

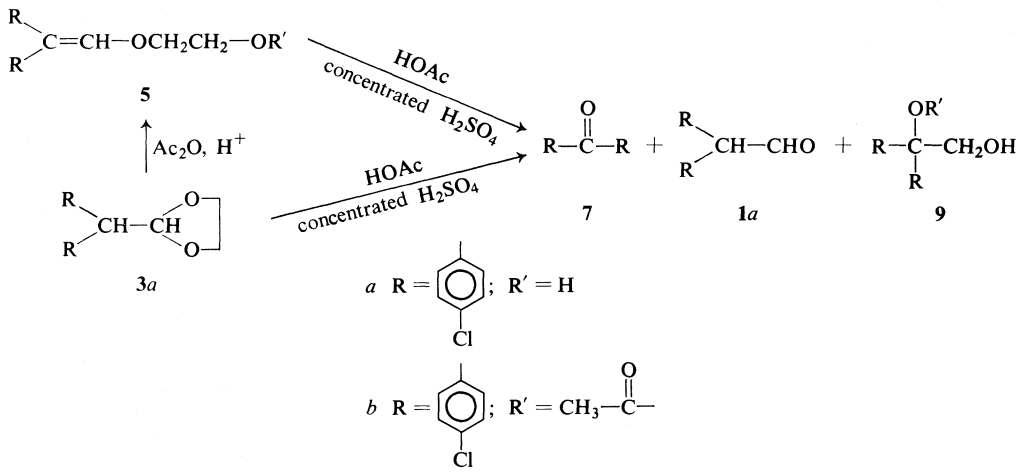
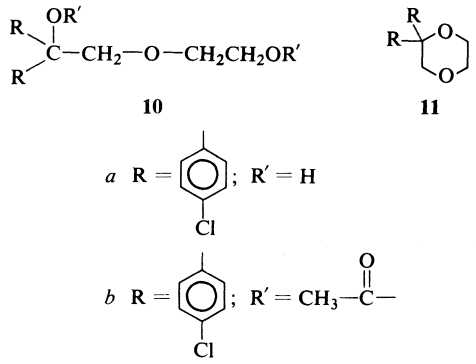


SCHEME 1

identified by their spectral properties. The benzophenone **7** constituted about 10–15% of the total along with major amounts of the aldehyde and acetoxyethanol. Solvolysis of the enol ether acetate **5***b*, which was obtained from **3***a* in good yield by treatment with acetic anhydride containing concentrated sulfuric acid, gave qualitatively but not quantitatively the same product mixture; the benzophenone **7** was formed in about 40% yield with appreciable amounts of the acetoxyethanol **9***b* and trace amounts of aldehyde **1***a*. It was also shown that neither **1***a* nor **9***b* were intermediate in the formation of **7** under the solvolysis conditions.

Since the enol acetate **5***b* affords **7** as a major product and the acetoxyethanol **9***b* is not intermediate in this conversion, the benzophenone **7** must have resulted from rearrangement of **5***b* itself or from some other yet undetected intermediate. Protonation of the enol ether acetate at the ether oxygen should activate the molecule to attack by acetate ion at the benzhydryl carbon or intramolecular attack by its own acetate group via a *quasi*-six-membered ring. The former possibility should have resulted in the diacetate **10***b*. However, this compound was not found among the products and suggested that **10***b*, if formed, possibly undergoes further cleavage at the ether oxygen to form the acetoxyethanol **9***b*, a major product of the acetic acid solvolysis reaction. Nevertheless, 2,2-*bis*-(*p*-chlorophenyl)-diethylene glycol (**10***a*) was synthesized according to the reported method (8), and its hydrolysis properties were investigated. The diethylene glycol could dehydrate in a cyclic fashion (9) to



form dichlorobenzophenone **7** or dehydrate to 2,2-*bis*(*p*-chlorophenyl)-*p*-dioxane (**11**) which could possibly undergo pyrolysis to **7**. Hydrolysis experiments with **10***a* repeatedly gave mixtures as determined by t.l.c. and gas chromatography (g.c.). The mixtures consisted primarily of two materials whose chromatographic properties were reminiscent of the decomposition products[4] of the acetoxyethanol **9***b*; one material was highly polar and polymeric in nature while the other material was relatively non-polar and fluoresced light blue under u.v. light. The latter material was purified by preparative t.l.c. and identified as the symmetrical *p*-dioxane **12**. The n.m.r. spectrum of **12** revealed the non-equivalency of the methylene protons, and Drieding models show that because of the steric requirements of the bulky phenyl groups the molecule prefers a twist-boat conformation in which the methylene protons experience different environments. The mass spectrum of the compound contained a parent ion greater than 500 (*m/e*)

12

and was otherwise indicative of structure **12**. The dioxane **12** and polymeric products were also shown to be spontaneous decomposition products of the diethylene glycol **10***a* with or without solvent. The most plausible explanation for formation of such products would be that intramolecular hydrogen bonding may facilitate decomposition of the diethylene glycol **10***a* to the ethylene glycol **9***a* which in turn can undergo dimerization to **12** or polymerization. The dichlorobenzophenone **7** was only a minor decomposition product (<10%) of **10***a* and was detected by electron capture g.c. A small amount of dioxane **11** was also detectable among the products. Therefore, the intermediacy of **10***b* in the solvolysis of the enol ether acetate **5***b* seems likely since it would explain the presence of the acetoxyethanol **9***b* and polymeric material among the products. The formation of dichlorobenzophenone **7** from rearrangement of **5***b* is now credible and is shown in Scheme 2.[5] Invoking the intermediacy of an α-hydroxy aldehyde (**13***b*) in the formation of the dichlorobenzophenone **7** was attractive since such an intermediate would be expected to be both chemically and thermally labile and is a conceivable product in the other erroneous syntheses reported for aldehyde **1***a* by other workers. Although there is no chemical evidence to support the intermediacy of **13***a*, gas chromatography – mass spectrometry (g.c.–m.s.) confirmed its presence among the decomposition products of the enol ether acetate **5***b*. Gas chromatography on a 3% diethylene glycol succinate/2% orthophosphoric acid column at 170 °C gave eight peaks for pure enol ether acetate **5***b*, six of which were identified by their mass spectra. The first peak was the expected dichlorobenzophenone **7** in comparatively good yield having a base peak of *m/e* 139 $(R—C\equiv O)^+$ in its mass spectrum. The second peak was identified as the α-hydroxy aldehyde (**13***b*) whose mass spectrum also has a base peak of *m/e* 139 along with M (*m/e* 281), M-1 and M-HCHO (*m/e* 251) of intensities approximately 0.3% that of the base peak. The third peak was the expected aldehyde **1***a* in less than 10% yield of that of the ketone **7**. The fourth peak was a major component and was identified as the α-acetoxy aldehyde (**13***a*) although the parent molecular ion (*m/e* 313) was not discernible. However, there are prominent fragments corresponding to the loss of both HCHO (*m/e* 293) and HOAc (*m/e* 264) as well as the base peak of *m/e* 139. The presence of these fragments in the spectrum implies that both the aldehyde and acetate moieties must have been present in the original molecule. The detection of the parent ion of the α-hydroxy aldehyde (**13***b*) is probably a reflection of increased stability of this ion via hydrogen bonding. Both peaks five and seven were too weak to identify conclusively. Peaks six and eight were identified as the enol ether alcohol (**5***a*) and the enol ether acetate (**5***b*) respectively. The acidic column conditions favored decomposition since g.c. on a 3% SE-30 column at 212 °C gave smaller relative amounts of the major decomposition products. In fact, the α-acetoxy aldehyde (**13***a*) was not detectable under these conditions; however, this may also be a reflection of the poorer stability of acetate **13***a* under these conditions since the α-hydroxy aldehyde was detected. In addition, the introduction of the enol ether acetate **5***b* into the mass spectrometer by the direct probe inlet produced spectra indicating that extensive rearrangement had occurred.

In light of these data, it was suspected that similar intermediates could occur in the hydrolysis of **3***a* under aqueous acidic conditions affording dichlorobenzophenone **7**. Hydrolysis of the substituted dioxane **12** and the enol ether acetate **5***b* in *p*-dioxane and 20% HCl (1:1 v/v) gave the aldehyde **1***a* as the major product. These results are not entirely surprising since dioxane **12** might be expected to undergo cleavage and rearrangement to the aldehyde on heating with a mineral acid and, in the case of **5***b* cleavage at the ether oxygen would be expected

[5]The nature of the products from this reaction seems to clearly indicate that the normal oxonium ion resonance contribution of enol ethers, $R_2\overset{\ominus}{C}CH=\overset{\oplus}{O}—R'$, is of little importance in **5***b*. Rearrangement of **5***b* can be considered analogous to the thermal rearrangements of enolic ethers in general and allyl aryl ethers (Claisen rearrangement) producing in the case of **5***b* somewhat unexpected products because of the anomalous electronic distribution. Such thermally influenced rearrangements of this type for the most part are known (10) to proceed via first-order kinetics as depicted for **5***b* although it was not ascertained.

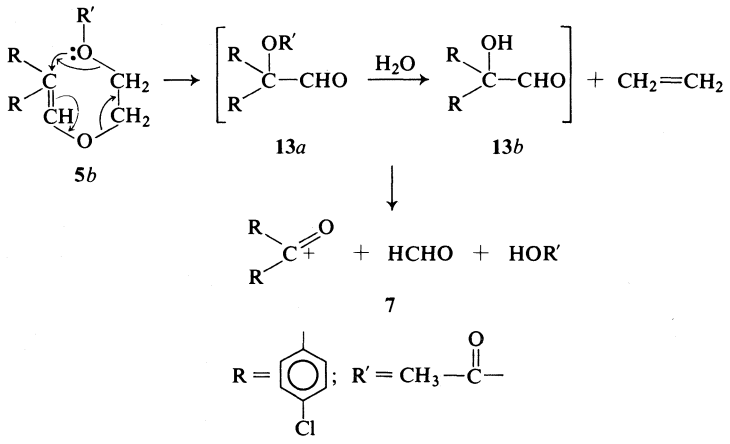

SCHEME 2

to occur more rapidly than hydrolysis of the acetate group such that an appreciable amount of the suspected "real" intermediate, the enol ether alcohol (**5***a*) is never available for rearrangement leading to dichlorobenzophenone **7**. In considering the transition state for rearranging **5***b* to **7**, the comparatively large acetate group in the vicinity of the reacting center restricts the number of configurations which may be assumed by the atoms involved, resulting in further reduction in entropy which is rate-retarding. Therefore, one would expect the enol ether alcohol (**5***a*) to rearrange as shown in Scheme 2 with a more positive entropy which would be comparatively rate-enhancing. The fact that the enol ether alcohol could not be isolated is consistent with this argument.

Variations[6] in the hydrolysis conditions of acetal **3***a* gave qualitatively but not quantitatively the same products, acetaldehyde **1***a* and dichlorobenzophenone **7**. Hydrolysis in 95% ethanol with 20% aqueous sulfuric acid (2:1 v/v) produced approximately equal quantities of **7** and **1***a*. Hydrolysis in 95% ethanol or 1,4-dioxane with concentrated sulfuric (10:1 v/v) afforded aldehyde **1***a* in good yields. Totally aqueous acidic conditions gave either no reaction or the dichlorobenzophenone **7** as the major product. These results imply that more aqueous conditions and hence more heterogeneous conditions favor production of **7**. Under more heterogeneous conditions solvolysis reactions would be minimized and intramolecular vapor phase reactions, which would be thermally influenced, become more important. This is consistent with a cyclic decomposition of **5***b* to **7** as delineated in Scheme 2. The intermediates formed in the hydrolysis of acetal **3***a* which are most tenable with our results are given in Scheme 3.

Preequilibrium protonation of **3** followed by decomposition to a resonance-stabilized carbonium ion would be expected (11). The enol ether alcohol (**5***a*) could be formed by deprotonation of this carbonium ion, and once formed, can undergo several reactions (paths *a–c*). Normal hydrolysis as in path *b* would lead to aldehyde **7**. Protonation of the enol ether oxygen followed by hydration of the double bond (path *a*) would lead to diethylene glycol **10***a* which in turn could decompose to ethylene glycol **9***a* ultimately leading to dimers and polymers. Protonation of the ether oxygen followed by intramolecular attack on the double bond and rearrangement would lead to the α-hydroxy aldehyde **13***b* which would decompose[7] to the dichlorobenzophenone **7**.

[6]Several classical methods for preparing aldehydes (Rosenmund and metal hydride reductions of the acid chloride, chromium oxide oxidation of the alcohol, etc.) were unsuccessful for **1***a*; in most cases the major isolable product was the dichlorobenzophenone **7**. The mechanistic implications of these results are not completely understood.

[7]The expected by-products of these disproportionation reactions are formaldehyde and ethylene. One would expect formaldehyde to polymerize under the reaction conditions, and attempts to trap it with various carbonyl derivatizing agents were unsuccessful. Likewise, ethylene could not be trapped as its dibromide; however, an n.m.r. hydrolysis study of **3***a* with aqueous D_2SO_4 in d_6-dimethylsulfoxide, which indicated the presence of **7** as well as trace amounts of **1***a*, showed a singlet of weak intensity at a chemical shift (τ 4.55) identical to that of authentic ethylene.

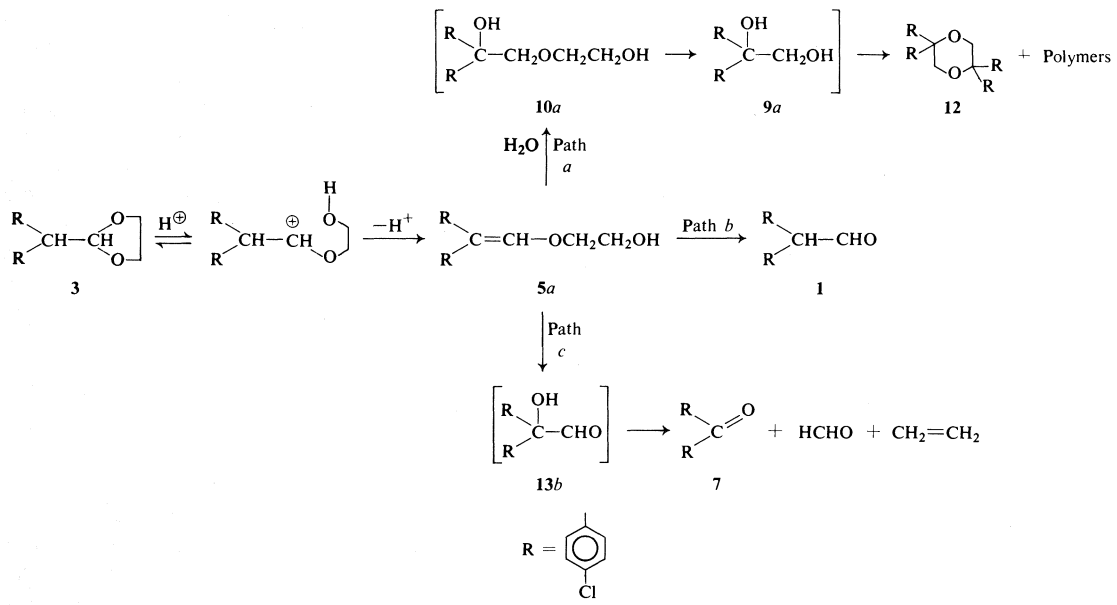
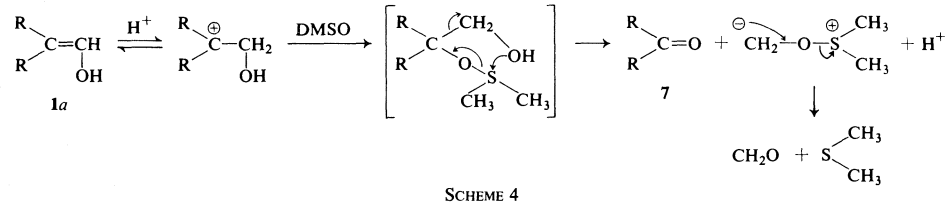


SCHEME 3



SCHEME 4

Our investigations were extended to include the *o,p'*-dioxolane **3***b* since commercial preparations of DDT contain the *o,p'*-isomer as a major component whose metabolism is qualitatively similar although quantitatively different (12). Dioxolanes **3***a* and *b* are electronically analogous and would be expected to undergo similar reactions. Under the hydrolysis conditions of **3***a* that afford only minor amounts of the expected aldehyde **1***a*, **3***b* affords quantitative yields of aldehyde **1***b*.

The anomalous hydrolysis of **3***a* seems to be manifested in the facility by which the benzhydryl carbon of this system can undergo oxidation. This reflects greater charge stabilization associated with the bis(*p*-chlorophenyl) system than with the *o,p'*-system which must be explained on the basis of steric arguments. CPK-Models[8] indicate that there are two sterically derived factors which would hinder or prevent oxidation of the benzhydryl carbon in the *o,p'*-system (**3***b*). There is steric hindrance to removal of the benzhydryl proton imposed by the *o*-chlorine,[9] and there is steric inhibition of resonance which would impair charge stabilization once the proton has been removed. Aldehyde **1***b* would be the expected hydrolysis product of **3***b* regardless of which of the two steric effects is more important in determining the course of the reaction.

Previous investigators (6) observed steric dependence in attempting to prepare the isomeric iodides from the corresponding tosylates of the

[8]Corey–Pauling–Koltun atomic models.

[9]A measure of this effect is evident from a comparison of the chemical shift of the benzhydryl proton in *p,p'*-DDT (τ 5.00) with that in *o,p'*-DDT (τ 4.25) and *o,p'*-DDD (τ 4.28); an ortho chlorine within the aromatic ring deshields the benzhydryl proton more than a para-substituted chlorine. See Keith *et al.* (13) for a discussion of the n.m.r. spectra of DDT-related compounds.

[4] 
14

dichlorodiphenylethanols (eq. 4). The elimination product **14** was the sole product in the case of *p,p'*-isomer whereas the *o,p'*-isomer gave a mixture of the two products. On the other hand, the *o,o'*-isomer gave the iodide as the sole product. Steric factors are known (14) to play an important role in bimolecular elimination reactions. Steric hindrance to resonance stabilization of the product might also influence the reaction course in this case.

A steric dependence of this system was further demonstrated in our laboratory by observing the n.m.r. spectra of the aldehydes in dimethylsulfoxide (d_6-DMSO). In DMSO, **1***a*, is converted to its enol form almost quantitatively upon solution as evidenced by a decrease in the n.m.r. proton signal of the benzhydryl carbon. In most instances this enolization was accompanied by a small (<10%) conversion to the dichlorobenzophenone **7**. Crystalline material isolated from the DMSO solutions had properties identical to those of authentic **7**. The *o,p'*-isomer undergoes a slower rate of enolization as measured by n.m.r.; however, there was no evidence to indicate reactions with DMSO. It was shown using the *o,p'*-isomer that the enolization rate in DMSO could be catalyzed by the addition of either acid or base. Shaking the protio-aldehyde in chloroform-*d* with D_2O in the presence of sodium carbonate resulted in the exchange of the benzhydryl proton for deuterium while the aldehyde proton remained unchanged. The *o,o'*-isomer[10] **1***c*, however, failed to undergo enolization in DMSO at temperatures ranging from 26 to 75 °C. In comparison, diphenylacetaldehyde enolizes in DMSO to a lesser extent than did the bis(*p*-chlorophenyl)acetaldehyde. From this result one infers that the electronic effects of the chlorine substituents as well as steric factors play a role in the enolization processes. In the case of the *p,p'*-isomer, the electronic effects must also influence subsequent reactions since the dichlorobenzophenone **7** was detected in its DMSO solutions. Since enolization of **1***a* appears to be very rapid in DMSO, it is probable that formation of **7** involves the enol. Steric hindrance to removal of the benzhydryl proton would be manifested if enolization were required to form a reactive species. Although there is no compelling evidence, the following pathway is proposed (Scheme 4).[11] Preequilibrium protonation of the enol could generate the bis(*p*-chlorophenyl) carbonium ion system which is susceptible to attack by oxygen of DMSO. The resulting labile alkoxysulfonium salt could undergo intramolecular attack at sulfur to afford **7**.

This work has shown that the bis(*p*-chlorophenyl) system in conjunction with a vicinal electron deficient carbon, such as is contained in the aldehyde moiety and possibly in a trichloromethyl group,[12] can undergo rather facile reactions involving the benzhydryl carbon usually resulting in an overall oxidation at this position which may be concomitant with the loss of the adjacent group. In comparing the oxidative propensities of the *p,p'*- and *o,p'*-systems, it is evident that the requisite removal of the benzhydryl proton is subject to the stereoelectronic requirements imposed by the chlorophenyl groups. The *o*-chlorophenyl compounds have much less tendency toward oxidation and double bond formation at their benzhydryl carbons. In light of this work, the possible intermediacy of the α-hydroxy aldehyde **13***b* in the formation of dichlorobenzophenone **7** during DDT metabolism is plausible. The ease of enolization of the *p,p'*-aldehyde **1***a* could facilitate its interactions in biological systems subsequently leading to redox products such as α-hydroxy aldehyde **13***b*. Our results also lend some credence to the corollary that, if such an aldehyde were formed *in vivo*, conjugates[13] involving the hydroxy group could activate the

[10]The aldehyde **1***c*, which was obtained from Aldrich Chemical Co., Milwaukee, Wisc., exhibited no unusual reaction properties.

[11]The use of polarizing agents to promote DMSO oxidations of alcohols has been reported (15) to produce alkoxysulfonium salts which undergo base-catalyzed decomposition to carbonyl compounds. The hydroxymethylalkoxysulfonium ion which could be formed from **1***a* may constitute a special case of this in which the hydroxymethyl group acts as an internal base to effect the stepwise decomposition to two carbonyl compounds.

[12]The compound 1,1-bis(*p*-chlorophenyl)-2,2,2-trichloroethanol has been shown (16) to pyrolyze to **7** and chloroform.

[13]Previous workers (17) have shown that DDT metabolite conjugates are formed, although their exact nature is not known. However, they do not appear to be conjugated with glucuronic or sulfuric acids.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

molecule as an alkylating agent.[14] Nevertheless, the occurrence of such an aldehyde would implicate a host of new and interesting metabolites which will be described elsewhere. Although, it is not surprising that the aldehyde **1***a* has not been detected in DDT metabolism, earlier work (18) has shown that 2,2-bis(*p*-chlorophenyl)-ethanol (DDOH), a known DDT metabolite (1), is a substrate of crystalline liver alcohol dehydrogenase which oxidizes DDOH to **1***a*.

Experimental

Melting points were taken on a Fisher–Johns melting point apparatus and are corrected. The i.r. spectra were obtained with Perkin–Elmer 337 and 521 spectrophotometers. The n.m.r. studies were made with a Varian T-60 and an HA-100 spectrometer equipped with a variable temperature probe using tetramethylsilane (TMS) or sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as internal references. Routine gas chromatograms were obtained with a Varian Aerograph model 1868-40 chromatograph equipped with a tritium detector. The low-resolution mass spectra were obtained with an LKB 9000 gas chromatograph-mass spectrometer. Thin-layer chromatograms were run on Uniplate, Silica Gel GF plates 250 and 500 μ in thickness and were developed in methylene chloride. The bands were detected with u.v. light.

Formation of 2,2-Bis(p-chlorophenyl)acetaldehyde (1a)

(a) From Darzens Condensation

To a solution of 7.5 ml (0.077 mol) of ethyl chloroacetate and 10 g (0.04 mol) of 4,4′-dichlorobenzophenone (Eastman Organic Chemicals) in 25 ml of anhydrous benzene under nitrogen was added 6.0 g (0.12 mol) of sodium hydride (50% dispersion) with stirring over a 2 h period. The reaction mixture was stirred for 16 h at room temperature and poured into 50 ml of ice-cold 25% HCl solution. The resulting suspension was extracted with two 50-ml portions of benzene. The combined extracts were dried over anhydrous sodium sulfate and evaporated to dryness. The partially solidified residue was recrystallized from methanol, affording 9.5 g of ethyl β,β-bis(*p*-chlorophenyl)glycidate melting at 98–105°. Without further purification this material was dissolved in 40 ml of ethanol and the resulting solution was refluxed for 6 h with 15 ml of 35% aqueous potassium hydroxide solution. The ethanol was removed by rotary evaporation and the remaining mixture was diluted with 25 ml of distilled water and extracted with two 30-ml portions of ether. The aqueous phase was acidified (p*H* 4–5) with 20% hydrochloric acid, forming a milky solid suspension. The suspension was extracted with two 50-ml portions of ether and the combined extracts were washed with distilled water, dried over anhydrous sodium sulfate, and evaporated to an oily residue. Decarboxylation of the crude material was accomplished by heating in an oil bath at 140–160° under reduced pressure (water aspiration) for 30 min. The crude product **1***a* weighed 4.5 g (60%). The aldehyde was purified by dissolving in 10 ml of methanol and adding the resulting solution dropwise with stirring to 25 ml of saturated sodium bisulfite solution. The mixture was stirred at room temperature for 5 h and the solid suspension was removed by filtration. The cake was washed with water, 2-propanol, and then ether before drying under vacuum. The aldehyde was regenerated prior to use by heating portions of the bisulfite addition product with 10% sodium carbonate solution at 75° until an oil separated (15–30 min). The pure aldehyde was obtained by extraction into ether and had the following spectral properties: i.r., λ (neat) 5.80 (C=O), 3.49 (CH), 13.2 (C—Cl); n.m.r., τ (chloroform-*d*) 0.10 (doublet, J = 2.4 Hz, 1H, CHO), 3.00 (multiplet, 8H, aromatics), 5.08 (doublet, J = 2.4 Hz, 1H, benzhydryl).

The *p*-nitrophenylhydrazine derivative prepared according to the method of Shine (19) contained one molecule of methanol of crystallization and melted at 85–88°. When this material was recrystallized from ether – petroleum ether, the methanol was removed to give a crystalline compound melting at 135–138 °C: i.r., λ (Nujol) 3.03 (NH), 6.26 (C=N), 7.58, 7.72 (NO_2); n.m.r., τ (dimethylsulfoxide-d_6) 1.84, 2.95 (pair of doublets, J = 9 Hz, for *p*-nitrophenyl aromatics); 2.10, 4.82 (pair of doublets, J = 6 Hz, for azomethinyl and benzhydryl protons); 2.57 (multiplet for bis(*p*-chlorophenyl) aromatics).

The *p*-nitrophenyl hydrazone of the dichlorobenzophenone **7** was prepared according to the same procedure and melted at 213–215°: i.r., λ (Nujol) 3.02 (NH), 6.30 (C=N), 7.55, 7.90 (NO_2); n.m.r., τ (dimethylsulfoxide-d_6) 1.97 (doublet, J = 9 Hz, 2H of *p*-nitrophenyl aromatics); 2.64 (multiplet, 2H of *p*-nitrophenyl aromatics, 8H of bis(*p*-chlorophenyl) aromatics).

(b) From Hydrolysis of 2-(4,4′-Dichlorobenzhydryl)-1,3-dioxolane (3a)

To a solution of 85 mg (0.28 mmol) of dioxolane in 5 ml of 95% aqueous 1,4-dioxane was added 0.4 ml of concentrated H_2SO_4. The resulting solution was magnetically stirred and refluxed for 3 h. The 1,4-dioxane was removed by rotary evaporation and the aqueous phase doubled in volume with distilled water to 3 ml. The aqueous solution was then extracted with two 3-ml portions of anhydrous ether and the combined extracts were dried over anhydrous Na_2SO_4 containing solid Na_2CO_3. Evaporation of the ether extracts under a nitrogen stream followed by pumping *in vacuo* gave 79 mg of a mixture composed of the 2,2-bis(*p*-chlorophenyl) acetaldehyde **1***a* and starting material. The aldehyde which was purified by preparative t.l.c. (40 mg, 55% yield) was identical in every respect to aldehyde obtained via the Darzens synthesis. Longer reflux times (6–8 h) gave increasingly higher yields of aldehyde under these conditions.

Solvolysis of 2-(4,4′-Dichlorobenzhydryl)-1,3-dioxolane (3a) in Acetic Acid

To a solution of 8 ml of glacial acetic acid and 0.05 ml of concentrated H_2SO_4 was added 155 mg (0.5 mmol) of

[14]The formation of the symmetrical dioxane **12** previously discussed can be considered a head-to-tail alkylation of two molecules of the acetoxyethanol **9***b* via displacement of the acetate groups. This reaction appears to be facile since it occurs directly on a silica gel t.l.c. plate during development. This compound was also found as a reaction product of unsuccessful attempts to form amino acid Schiff bases of aldehyde **1***a*.

dioxolane **3***a*. The resulting solution was heated at 100 °C for 1 h. The acetic acid was removed by lyophilization and the residue pumped *in vacuo* over P_2O_5. The residual oil was dissolved in chloroform-*d* and examined by n.m.r. spectroscopy. The spectrum indicated a mixture of products of which the three major components were tentatively identified as 2,2-bis (*p*-chlorophenyl)acetaldehyde (**1***a*), 4,4′-dichlorobenzophenone (**7**), and 1,1-bis(*p*-chlorophenyl)-1-acetoxyethanol (**9***b*) in an approximate ratio of 3:1:3. Preparative t.l.c. of the mixture gave 45 mg of aldehyde **1***a* and 15 mg of dichlorobenzophenone **7** along with 27 mg of dimer **12** and 20 mg of polymeric material (dark brown material remaining at the origin) both of the latter materials being decomposition products of the acetoxyethanol **9***b*. A small amount (10 mg) of pure dimer **12** was obtained by repeated preparative t.l.c. and had the following properties: i.r., λ ($CHCl_3$ film) (aromatic) 6.70, 12.2; (C—O—C) 8.88, 9.18, 9.85; n.m.r., τ (chloroform-*d*) 2.99 (multiplet, aromatics), 4.65, 5.89 (doublets, J = 2.0, Hz, methylene protons); τ (benzene-d_6) 3.10 (multiplet, aromatics), 5.19, 6.17 (doublets, J = 2.0, Hz, methylene protons).

Anal. Calcd. for $C_{28}H_{20}O_2Cl_4$: C, 63.42; H, 3.77. Found: C, 63.19, H, 4.38.

1,1-Bis(p-chlorophenyl)-3-oxa-1-pentenyl-5-acetate (Enol Ether Acetate (5b))

To a solution of 20 ml of acetic anhydride and 2 ml of concentrated H_2SO_4 was added 2.0 g (65 mmol) of the dioxolane **3***a*. The resulting solution was heated at 100 °C with stirring for 0.5 h. On cooling, the reaction mixture was poured into ice water (approximately 30 ml) and extracted with two 50-ml portions of anhydrous ether. The combined extracts were washed with saturated Na_2CO_3 solution, water, and then dried over anhydrous Na_2SO_4 followed by evaporation. The residue remaining (approximately 3.2 g) was chromatographed on a column of Silcar CC-7 (40 g) using a mixture of hexane:chloroform:methanol (3:2:1) as the eluting solvent. The fractions were analyzed with t.l.c. and combined accordingly. The residue remaining on evaporation of the solvent weighed 1.87 g (91%). A portion of this material was crystallized twice from *n*-hexane affording a crystalline hygroscopic solid melting at 73–75 °C: i.r., λ (neat) (C═O) 5.75, (O—C═C) 6.20; n.m.r., τ (chloroform-*d*) 2.76 (multiplet, aromatics); 3.54 (singlet, enolic proton); 5.80 (multiplet, methylene protons); 7.97 (singlet, acetate CH_3).

Anal. Calcd. for $C_{18}H_{16}O_3Cl_2$: C, 61.56; H, 4.56; O, 13.77; Cl, 20.22. Found: C, 61.22; H, 4.74; O, 13.58; Cl, 20.04.

Formation of 4,4′-Dichlorobenzophenone (7)

(a) From Hydrolysis of 2-(4,4′-Dichlorobenzhydryl)-1,3-dioxolane (3a)

To a mixture of 10 ml of 1,4-dioxane and 10 ml of 20% aqueous HCl was added 1.0 g (3.2 mmol) of dioxolane **3***a*, and the resulting mixture was refluxed for 3.5 h. The solution after cooling to room temperature was diluted with additional water to 50 ml and extracted with two 30-ml portions of anhydrous ether. Combined ethers were washed with water, dried over anhydrous Na_2SO_4, and then evaporated. The residue was dissolved in 10 ml of methanol and gave on prolonged cooling 0.21 g (30%) crystalline material identical in every respect to authentic 4,4′-dichlorobenzophenone **7**. The mother liquor was evaporated and examined by n.m.r. spectroscopy. The remaining material (0.52 g) consisted of a mixture of dioxolane **3***a*, dichlorobenzophenone **7**, and aldehyde **1***a* (1:1:2). The total yield of **7** was approximately 57%.

(b) From Solvolysis of Enol Ether Acetate (5b)

A solution of 3 ml of glacial acetic acid and 0.1 ml of concentrated H_2SO_4 containing 83 mg (0.24 mmol) of enol ether acetate was heated at 100 °C for 1 h. The acetic acid was removed by lyophilization and pumping *in vacuo* over P_2O_5. The residual oil was examined by n.m.r. spectroscopy and consisted primarily of 4,4′-dichlorobenzophenone (**7**) and 1,1-bis(*p*-chlorophenyl)-1-acetoxyethanol (**9***b*). The oil was transferred to preparative t.l.c. plates by streaking, and the plates were developed in methylene chloride. Three major bands were detected and the middle band was removed (24 mg, 40%) and found to be identical in every respect to 4,4′-dichlorobenzophenone (**7**). The other two bands were indicative of the dimer and polymeric decomposition products of the acetoxyethanol **9***b* and were not isolated; a band was found at the origin and one near solvent front which had light blue fluorescence under short wave u.v. light.

2-(o,p′-Dichlorobenzhydryl)-1,3-dioxolane (3b)

To a solution of 6.9 g (0.028 mol) of 1-(*o*-chlorophenyl)-1-(*p*-chlorophenyl)-2,2-dichloroethane in 25 ml of ethylene glycol was added 7.05 g (0.051 mol) of powdered anhydrous potassium carbonate. The mixture was refluxed at 190–200° for 16 h and poured into ice water. The aqueous suspension was extracted with two 25-ml portions of ether, and the combined extracts were dried over anhydrous sodium sulfate and taken to dryness. The crude residue (6.2 g) afforded 4.0 g (59%) of crystalline material melting at 73–76° when crystallized from methanol: n.m.r., τ (chloroform-*d*) 2.80 (8H multiplet for aromatics); 4.54, 5.30 (2H pair of doublets, J = 4 Hz, benzhydryl proton and methinyl proton of dioxolane ring); 6.26 (4H multiplet, dioxolane ring).

2-(o-Chlorophenyl)-2-(p-chlorophenyl)acetaldehyde (1b)

A solution of 9.4 g (0.034 mol) of **3***b* in 25 ml of *p*-dioxane and 50 ml of 25% aqueous sulfuric acid was refluxed with stirring for 5 h. The reaction mixture on cooling was extracted with two 50-ml portions of ether. The combined ether extracts were extracted twice with dilute sodium bicarbonate solution and washed twice with distilled water. The ether phase was dried over anhydrous sodium sulfate and evaporated to a liquid residue weighing 9.2 g. The liquid was purified by formation of the bisulfite addition product as described for **1***a* except the stirring time was increased to 24 h. A 7.0 g portion of the addition product when decomposed with dilute sodium carbonate solution gave 5.0 g (81%) of pure aldehyde **1***b* with the following spectral properties: i.r., λ (neat) 5.75 (C═O), 6.65 (aromatic), 13.3 (C—Cl); n.m.r., τ (chloroform-*d*) 0.16 (singlet, 1H, CHO), 2.80 (multiplet, 8H, aromatics), 4.67 (singlet, 1H, benzhydryl).

NOTES

Special Catalytic Power of Enzymes: Some Evidence from Model Systems

KEITH BOWDEN[1] AND A. M. LAST
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received April 28, 1971

Evidence from model systems for enzyme catalysis is discussed. These models involve neighboring group participation by carbonyl or carbon-acid groups, and indicate the important roles of proximity, strain, and orientation as potential sources of the special catalytic power of enzymes.

Nous discutons de preuves pour la catalyse enzymatique à partir de systèmes modèles. Ces modèles impliquent la participation de groupes voisins au moyen de groupes carbonyle ou carbone-acide et indiquent les rôles importants que tiennent la proximité, la contrainte et l'orientation comme sources possibles du pouvoir catalytique spécial des enzymes.

Canadian Journal of Chemistry, 49, 3887 (1971)

Several workers have discussed a number of potential sources of the special catalytic power of enzymes (1–3). Proposals indicating important roles for proximity (1, 2), strain (2), and "orbital steering" (3)[2] have been made. Our recent studies (5–8) of model systems for enzyme catalysis have enabled us to further evaluate certain of these factors.

The first model concerns the effect of a proximate formyl group on alkaline ester hydrolysis (6–8). These hydrolyses occur by initial attack of hydroxide anion on the formyl group, accompanied by intramolecular nucleophilic catalysis, in a similar way to a number of related hydrolyses (5, 9). The rate-determining step for these formyl esters appears to be either a concerted process with attack by the hydroxide anion at the formyl-carbon, synchronized with intramolecular attack at the ester carbonyl-carbon, or an intramolecular attack at the ester carbonyl-carbon, preceded by addition of the hydroxide anion to the formyl group (6–8). The rate coefficients for alkaline hydrolysis of these esters are shown in Table 1, together with the observed and "expected" rate ratios compared to their parent unsubstituted esters. These "expected" values for the formyl esters are estimated from closely related model substrates, using the known steric and polar effects of the formyl and other substituents, to give the rate ratio expected for hydrolysis by the normal direct route (6–8). Study of molecular models ("Catalin") of the three formyl esters show that both the proximity of the formyl to the ester group and internal strain increase in passing along the series, benzoate, naphthoate, and phenanthroate (Table 1). The very large rate enhancements, shown in Table 1, are a consequence of the ability of the formyl esters to employ the intramolecular catalytic route. This results from two sources. These are, firstly, the proximity of the "internal" nucleophile once formed and, secondly, internal strain. The latter, already present in the naphthoate and phenanthroate, is either increased or induced by the "primary" addition process; but is relieved as the "secondary" intramolecular attack proceeds. This process results in the formation of a cyclic intermediate. Other studies (10) of ring–chain tautomerization in both formyl- and closely related keto-carboxylic acids have shown that the formation of the ring (cyclic) tautomer is favored when internal strain caused by steric bulk interactions increase. Thus the reaction is facilitated by the induction of strain derived from the binding between substrate and the hydroxide anion. The modest rate decreases observed in passing from the benzoate to phenanthroate esters in Table 1 (attack at formyl group) are in great contrast to those expected from a comparison with the hydrolysis of 2-substituted benzoates, 8-substituted 1-naphthoates, and 5-substituted 4-phenanthroates (6, 8,

[1]Present address: Department of Chemistry, University of Essex, Cochester, Essex, England.

[2]Recently this concept has been discussed by Bruice and coworkers (4), who have presented an alternative interpretation.

TABLE 1. Rates of alkaline hydrolysis in 70% v/v aqueous dioxan at 20 °C

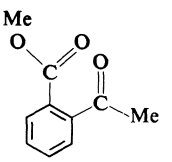
Methyl ester	k (l mol^{-1} s^{-1})	k/k_0 Observed	k/k_0 "Expected"
2-Formylbenzoate	271	31 900	5.0
8-Formyl-1-naphthoate	35.5	10 700	0.02
5-Formyl-4-phenanthroate	7.47	110 000	<0.01

TABLE 2. Rates of reaction with hydroxide anion in 70% v/v aqueous dioxan at 20 °C

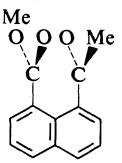
Methyl ester	k (l mol^{-1} s^{-1})	k/k_0 Observed	k/k_0 "Expected"
2-Acetylbenzoate	6.45	760	1.0
8-Acetyl-1-naphthoate	0.533	160	0.005

11). The action, in part, of a number of esterases and allied enzymes can be related to this study. The model system described employs the addition of hydroxide anion to the formyl group to simulate the nucleophilic activity of the hydroxyl group in the unique serine residues in such enzymes.

The second model concerns the effect of a proximate acetyl group on alkaline ester hydrolysis. Methyl 2-acetylbenzoate rapidly undergoes alkaline hydrolysis, employing neighboring group participation by the carbonyl group, by the pathway described above (6). However, methyl 8-acetyl-1-naphthoate reacts by attack on the ester group by the carbanion, generated by rate-determining proton-abstraction from the acetyl group by the hydroxide anion (7). The latter cyclization process is also very rapid (Table 2). The dichotomy displayed by these two esters clearly indicates the specific control of reaction afforded by the orientation and environment of the assisting group. Study of molecular models ("Catalin") and i.r. spectroscopic investigations (8) of these two esters indicates that methyl 2-acetylbenzoate has the almost fully coplanar conformation shown (**1**) and methyl 8-acetyl-1-naphthoate has the conformation (**2**) in which the planes of the acetyl and ester groups are parallel to one another, while being perpendicular to that of naphthalene itself. The 8-acetyl-1-naphthoate reacts with intramolecular catalysis from the carbon acid. The carbanion is generated with highly favorable orientation for substitution and is closely proximate to the reaction site, the ester carbonyl-carbon. However, catalysis by the carbonyl group has distinct spatial requirements, unlike the carbon-acid process, as reaction



1



2

proceeds by a comparatively "crowded" transition state involving tetrahedral configurations at both acetyl and ester groups. The latter "crowding" is very severe in the 8-acetyl-1-naphthoate, compared to the 2-acetylbenzoate. Further the 2-acetylbenzoate has not the favorable orientation and close proximity of the methyl group for the carbon-acid path to be favored. The carbon-acid catalytic model simulates the carbon–carbon bond formation in aldolases and related enzymes.

Clearly, while an exact separation of the causes of the catalytic power of enzymes is not yet possible (12), proximity, strain, and orientation can be demonstrated in physical organic model systems to produce rate enhancements comparable to those produced by enzymes themselves.

The authors thank Dr. T. C. Bruice for a prior communication of his recent study (4).

Per-deuteration of *t*-Butanol in Mildly Acidic Deuterium Oxide

MARTIN B. HOCKING
Research Department, Dow Chemical of Canada, Limited,[1] *Sarnia, Ontario*

Received June 25, 1971

Heating a solution of *t*-butanol in acidified deuterium oxide under slight pressure has yielded 85% per-deuterated *t*-butanol. At atmospheric pressure normal isobutylene was produced. Isobutylene could not be hydrated in good yield by this method. A number of related alcohols were resistant to exchange by this method, but one of them, 1-methylcyclohexanol, gave nearly complete dehydration without deuterium incorporation.

En chauffant sous une légère pression une solution de *t*-butanol dans de l'oxyde de deutérium acidifié, le *t*-butanol perdeutéré est obtenu avec un rendement de 85%. Sous pression atmosphérique, l'isobutylène est obtenu. L'isobutylène, par cette méthode, ne peut pas être hydraté selon un bon rendement. Par cette méthode, un certain nombre d'alcools apparentés résistent à l'échange; cependant, l'un deux, le méthyl-1 cyclohexanol, se déshydrate presque complètement sans incorporation de deutérium.

Canadian Journal of Chemistry, **49**, 3889 (1971)

Introduction

Hydroxyl hydrogen–deuterium exchange in *t*-butanol has been shown to occur catalytically in the presence of deuterium gas at a rate of about 2% per minute at 79 °C (1) and is too fast to measure in deuterium oxide at 25° (2). Deuterium exchange of hydrogen bonded to carbon, in alcohols, has been shown to occur only to a very small extent with methanol and ethanol and not at all with isopropanol or *t*-butanol (1). Exchange of deuterium for hydrogen bonded to carbon has been achieved with the tertiary alcohol l-methylcyclohexanol in cold deuterium-enriched phosphoric acid (3), and phenolate anion has been rapidly per-deuterated in potassium deuterioamide/deuterio-ammonia (4).

We have recently discovered that *t*-butanol can be rapidly per-deuterated in mildly acidic deuterium oxide (5). The only previously reported per-deuterio-*t*-butanol synthesis was an alkylation of per-deuterio-acetone (6) and not via an exchange reaction. Hence the experimental determination of some of the parameters of this exchange, it is hoped, will be of value for future syntheses of "heavy" *t*-butanol.

Results and Discussion

Small Scale Experiments

The preliminary qualitative exchange experiments were carried out in sealed n.m.r. tubes. The progress was followed by noting the changes in the proton integrals for the respective proton groups.

A very low concentration (about 0.2 *M*) of sulfuric acid in deuterium oxide was ineffective for the alkyl hydrogen exchange of *t*-butanol at

Per-deuteration of *t*-Butanol in Mildly Acidic Deuterium Oxide

MARTIN B. HOCKING
Research Department, Dow Chemical of Canada, Limited,[1] *Sarnia, Ontario*

Received June 25, 1971

Heating a solution of *t*-butanol in acidified deuterium oxide under slight pressure has yielded 85% per-deuterated *t*-butanol. At atmospheric pressure normal isobutylene was produced. Isobutylene could not be hydrated in good yield by this method. A number of related alcohols were resistant to exchange by this method, but one of them, 1-methylcyclohexanol, gave nearly complete dehydration without deuterium incorporation.

En chauffant sous une légère pression une solution de *t*-butanol dans de l'oxyde de deutérium acidifié, le *t*-butanol perdeutéré est obtenu avec un rendement de 85%. Sous pression atmosphérique, l'isobutylène est obtenu. L'isobutylène, par cette méthode, ne peut pas être hydraté selon un bon rendement. Par cette méthode, un certain nombre d'alcools apparentés résistent à l'échange; cependant, l'un deux, le méthyl-1 cyclohexanol, se déshydrate presque complètement sans incorporation de deutérium.

Canadian Journal of Chemistry, **49**, 3889 (1971)

Introduction

Hydroxyl hydrogen–deuterium exchange in *t*-butanol has been shown to occur catalytically in the presence of deuterium gas at a rate of about 2% per minute at 79 °C (1) and is too fast to measure in deuterium oxide at 25° (2). Deuterium exchange of hydrogen bonded to carbon, in alcohols, has been shown to occur only to a very small extent with methanol and ethanol and not at all with isopropanol or *t*-butanol (1). Exchange of deuterium for hydrogen bonded to carbon has been achieved with the tertiary alcohol l-methylcyclohexanol in cold deuterium-enriched phosphoric acid (3), and phenolate anion has been rapidly per-deuterated in potassium deuterioamide/deuterio-ammonia (4).

We have recently discovered that *t*-butanol can be rapidly per-deuterated in mildly acidic deuterium oxide (5). The only previously reported per-deuterio-*t*-butanol synthesis was an alkylation of per-deuterio-acetone (6) and not via an exchange reaction. Hence the experimental determination of some of the parameters of this exchange, it is hoped, will be of value for future syntheses of "heavy" *t*-butanol.

Results and Discussion

Small Scale Experiments

The preliminary qualitative exchange experiments were carried out in sealed n.m.r. tubes. The progress was followed by noting the changes in the proton integrals for the respective proton groups.

A very low concentration (about 0.2 *M*) of sulfuric acid in deuterium oxide was ineffective for the alkyl hydrogen exchange of *t*-butanol at

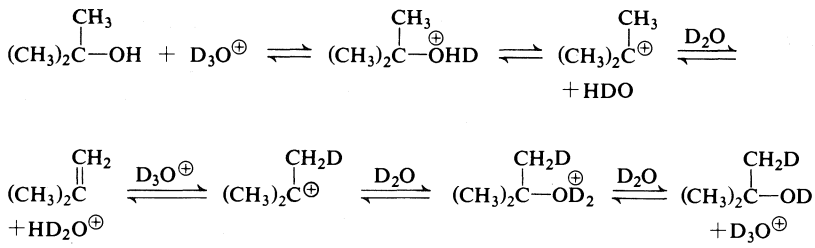

SCHEME 1

room temperature. But at 100°, 2 h were sufficient to promote exchange of 87% of the carbon-bound hydrogens and a further 2 h heating caused a further slight improvement to 93%.

Exchange was probably occurring via a succession of dehydration–hydration sequences (see Scheme 1), each sequence bringing about the exchange of one carbon-bound hydrogen for deuterium.

Preparative Scale Experiments

Attempts to carry out preparative scale exchange reactions with *t*-butanol at atmospheric pressure confirmed the intermediate formation of isobutylene. Examination of the evolved isobutylene by n.m.r. showed that no deuterium exchange had taken place, as found by Purlee and Taft (7) for the hydration of 2-methyl-2-butene in acidified deuterium oxide. Hence, the sequence of reactions leading to isobutylene must be fast relative to rate of protonation of isobutylene, the first step in its re-hydration, since the solubility limit of isobutylene in water is so readily exceeded. Additional confirmation of the slow rate of protonation of isobutylene was obtained on isolation of the residual *t*-butanol from an atmospheric pressure exchange experiment, in which it was found that only hydroxyl hydrogen–deuterium exchange had occurred. Virtually none of the isobutylene formed was retained in solution by protonation. Purlee and Taft (7) have also shown that the steps following initial protonation of 2-methyl-2-butene are extremely fast relative to the rate of protonation, and thus that any protonated isobutylene should appear as *C*-deuterated *t*-butanol.

Preparative scale deuterium exchange under pressure with a ratio of deuterium oxide:*t*-butanol of 15:1, larger than in the small scale experiments, gave 64% exchange of the methyl hydrogens. Decreasing this ratio to 10:1 decreased the extent of exchange to only 20%. If these experiments had yielded a statistical hydrogen–deuterium distribution, exchanges of 75 and 67% respectively, should have been observed. Since the small scale experiments demonstrated that 4 h was sufficient at those reagent ratios for the exchange to reach equilibrium, these too, were probably near equilibrium. However, isotope effects on the many relative rates in the steps outlined previously together with the reduced isobutylene solubility at the lower *t*-butanol/deuterium oxide ratios, could explain the discrepancies shown between the statistical and the observed deuterium distributions.

When the same preparative exchange experiments were tried with initial isobutylene, using deuterium oxide:isobutylene of 15:1, only about 3% of the theoretical hydration was achieved and this *t*-butanol was only 28% exchanged on carbon. This lack of success was possibly a consequence of the very low miscibility of the reactants. The unreacted isobutylene was not examined for its isotopic content.

Exchange Reactions with Related Alcohols

Isopropanol gave no deuterium exchange or dehydration at 25 or 100°. Anderson and Kemball (8) found that both isopropanol and *t*-butanol were resistant to catalytic vapor phase exchange of hydrogen with deuterium gas, yet ethanol and methanol were found to exchange to a very small extent.

2-Phenylisopropanol, and 1-phenylcyclohexanol were also resistant to deuterium exchange or dehydration at 25 or 100°, in agreement with that found for the former compound by Stephens and Leitch (9). In these exchange reactions methanol again was unaffected but not surprisingly (10, 11), 25% of the acetone exchanged in 3 days at room temperature, about 75% after a further hour at 100°.

Experimental

Deuterium oxide (99.8%) was purchased from Atomic Energy of Canada, Ltd. *t*-Butanol was dried ($MgSO_4$) and distilled immediately prior to use. Vinylacetic acid was used with the carboxyl hydrogen already exchanged for deuterium and dried (5). Other reagent alcohols were standard grades used as purchased from Aldrich Chemical Co. Solvent methanol was hydroxyl deuterated by

exchange with several portions of deuterium oxide, dried ($MgSO_4$), and distilled prior to use.

Determination of Isotopic Purity of Exchanged t-Butanol

Preliminary small scale experiments were carried out in sealed n.m.r. tubes. Progress of the exchange was followed by relating the initial to the subsequent integrals in the n.m.r. spectra of the peaks at 85 Hz (*t*-butyl methyls) and at about 300 Hz (H_2O). The maximum variation in the total integral for all protons present in the sealed tube was found to be ± 3% of the mean. Integrals for each proton group were normalized by a factor, when necessary, to bring the sum of the component integrals to the same value as the initial total integral.

Preparative Scale Experiments

Dry exchanged *t*-butanol contained about 4% methylene chloride on recovery. An integrated n.m.r. spectrum was obtained for this material, neat. Immediately after, using the same instrument settings, integrated spectra of pure normal *t*-butanol and pure methylene chloride were obtained, using the same washed and dried sample tube as initially. Taking the integrals observed for methyl and hydroxyl hydrogens of deuterated *t*-butanol and dividing these by the appropriately reduced (to account for CH_2Cl_2 present in deuterated sample) integrals obtained for normal *t*-butanol, gave the fractions of hydrogen still present in respective parts of the deuterated alcohol.

Small Scale Deuterium Exchanges with t-Butanol

The details of the initial experimental results with *t*-butanol and deuterium oxide under mildly alkaline conditions, and in the presence of a weak acid in sealed tubes have been reported separately (5).

Sulfuric Acid Conditions

Vinylacetic acid (130 mg), *t*-butanol (10 μl), deuterium oxide (500 μl), and concentrated sulfuric acid (8.0 mg), left 10 days at room temperature caused no change in the *t*-butyl methyl proton integral. Heating the solution for 2 h at 100°, and a further 2 h, caused reductions to 1/8 and 1/16 of the original value.

A further experiment without vinylacetic acid and using 50 l of *t*-butanol, gave 75% exchange of the *t*-butyl methyl protons after 4 h heating at 100°.

Preparative Scale Deuterium Exchange with t-Butanol

Atmospheric Pressure Attempt

Deuterium oxide (40 ml), *t*-butanol (7.4 g), and concentrated sulfuric acid (8 drops) were boiled together under reflux with protection from atmospheric moisture for 6 h, during which time isobutylene was evolved (by odor). Aliquots were removed at 4 and 6 h. Recovery of the remaining *t*-butanol (1.2 g) was accomplished by azeotropic distillation and methylene chloride extraction. Examination of this material by n.m.r. showed that no methyl proton deuterium exchange had taken place, and that the OH was 70% exchanged.

A second similar experiment was run on twice the scale through which the evolved isobutylene (7.6 g; 70%) was trapped during 6 h boiling in a U-tube cooled in Dry Ice/CCl_4/$CHCl_3$. The evolved material had a g.c. retention time at 0° and an n.m.r. spectrum identical to that of a sample of authentic isobutylene.

Pressure Deuterium Exchange

Deuterium oxide (30 ml; 1.5 mol), *t*-butanol (7.4 g; 0.1 mol), and concentrated sulfuric acid (6 drops) were placed in a 110 ml glass-lined stainless steel pressure vessel and heated in a boiling water bath for 5 h. The contents were neutralized with solid sodium carbonate and worked-up by the previous method, yielding 2.6 g of 64% carbon-deuterated (5.5 deuteriums/*t*-butyl) *t*-butanol.

The above experiment was repeated using deuterium oxide (60 ml; 3 mol), *t*-butanol (23.2 g; 0.3 mol), and concentrated sulfuric acid (16 drops). The contents were neutralized with $NaOD/D_2O$, saturated with sodium chloride, and extracted with pentane (4 × 30 ml). The combined pentane extracts yielded 15.3 g of deuterated *t*-butanol (20% carbon-deuterated; 1.8 deuteriums/*t*-butyl) after drying and distillation. Re-exchange of this partially deuterated *t*-butanol with fresh heavy water (60 ml) and concentrated sulfuric acid (12 drops) gave 10 g of 45% carbon-deuterated (4 deuteriums/*t*-butyl) *t*-butanol.

Isobutylene Hydration

Deuterium oxide (60 ml) and concentrated sulfuric acid (12 drops) were placed in the same pressure vessel and the contents cooled to 0°. Then isobutylene (11.2 g; 0.2 mol) was added. The vessel was heated at 100° for 6 h with vigorous agitation every 20 min, then cooled to −5°. The contents were neutralized with solid sodium carbonate and worked-up by the first method yielding 0.4 g of 28% carbon-deuterated *t*-butanol (2.5 deuteriums/*t*-butyl). Further extraction and examination by n.m.r. of the aqueous phase showed that no further *t*-butanol was present.

Qualitative Deuterium Exchange with Other Alcohols

Isopropanol (20 μl), 2-phenylisopropanol (20 μl), and 1-phenylcyclohexanol (53 mg; made homogeneous with 0.95 ml of hydroxyl-deuterated methanol), sealed into n.m.r. tubes with deuterium oxide (0.5, 0.5, and 0.6 ml respectively) and concentrated sulfuric acid (5.5, 8, 8 mg respectively) gave no exchange after 5 days at 25°, nor after heating at 100° for 4 h.

1-Methylcyclohexanol (40 μl, made homogeneous with 0.21 ml acetone), deuterium oxide (0.5 ml), and concentrated sulfuric acid (18 mg), when sealed into an n.m.r. tube, gave no alcohol C—H exchange during 3 days at 25°, but 25% of the acetone hydrogens had exchanged. One hour at 100° increased the extent of acetone exchange to 75% of the total and caused a colorless upper immiscible phase to appear. The b.p. of this phase was about 96° (Siwoloboff method; lit. (12) for 1-methylcyclohexene, 110°) and i.r. and n.m.r. data were consistent with a predominance of 1-methylcyclohexene together with traces of acetone and 1-methylcyclohexanol.

The author thanks H.D. Mak for the n.m.r. spectra required for this work, and for suggesting the isotopic analytical method used. He also thanks a referee for bringing his attention to ref. 9.

Olefin Formation in the Radiolysis of *n*-Hexadecane[1]

W. E. FALCONER, W. A. SUNDER, AND L. G. WALKER[2]
Bell Telephone Laboratories, Incorporated, Murray Hill, N.J. 07974

Received June 21, 1971

Olefin production in *n*-hexadecane, irradiated both in liquid and solid states, was estimated by gas chromatography and coulometric titration. Yields of congruent olefin extrapolated to zero dose were $G = 1.6$ and 2.8 in the solid and liquid, respectively. Total olefin yields at low doses are 2.2 and 4.2 in the solid and liquid. Scission olefin yields are 0.5 and 1.0. Evidence was found for *cis* as well as *trans* hexadecene isomers. *cis*-Olefins can be lost preferentially by exposure to air.

La formation d'oléfine à partir du *n*-hexadécane, irradié à l'état liquide et solide a été estimée par c.p.g. et titrage coulométrique. Les rendements en oléfine, extrapolés à une dose de zéro, sont respectivement de $G = 1.6$ et 2.8 pour le solide et le liquide. Les rendements totaux en oléfine sont, pour de faibles doses, respectivement de 2.2 et 4.2 pour le solide et le liquide. Les rendements de scission oléfinique sont de 0.5 et 1.0. Des preuves sont apportées sur la présence des isomères *cis* et *trans* de l'hexadécène. Les oléfines *cis* se dégradent préférentiellement au contact de l'air.

Canadian Journal of Chemistry, **49**, 3892 (1971)

Introduction

In the radiolysis of paraffinic hydrocarbons, one finds two types of mono-olefin products: isomeric congruent olefins formed by the elimination of hydrogen without disruption of the hydrocarbon skeleton, and scission olefins, the result of carbon–carbon rupture. The mechanism of formation of either type may be ionic, molecular, radical, or any combination of these. In small hydrocarbons, both *cis*- and *trans*-isomers of the congruent olefin are observed, the proportions being a function of state and other variables (1, 2). By contrast, only *trans*-vinylene unsaturation is reported for polyethylene, apart from terminal vinyl groups (3, 4) and polyenes (5, 6). Unsaturation in polyethylene is usually studied by i.r. absorption at 964 cm^{-1} and 700 and 1657 cm^{-1} for *trans*- and *cis*-vinylene, respectively. Smaller extinction coefficients or spectral interference might mask small amounts of *cis*-vinylene. Alternatively, *cis*-unsaturation, if formed, could be preferentially destroyed prior to taking the spectrum.

Irradiated *n*-hexadecane has been studied as a polyethylene prototype, both in the liquid and solid phases near the melting point (7, 8). This paper discusses the formation of olefinic products of *n*-hexadecane radiolysis with the object in part of clarifying the difference between lower paraffins on the one hand and polyethylene on the other.

Experimental

Materials

Two types of *n*-hexadecane were used in this study. The first was a combination of API standard samples, 99.91% pure, which were scrubbed with sulfuric acid, washed with distilled water, dried over calcium oxide, and distilled at 157–158 °C at 15 Torr in a grease free system. The second was Humphrey Chemical Company petroleum derived olefin free grade, stated purity >99%. This

[2]Present address: Ryerson Polytechnical Institute, Toronto, Ontario.

sample was treated with acid as above, then purified by urea clathrate formation (7).

Radiolysis

Samples were degassed and sealed under vacuum in thin-walled Pyrex tubes prior to irradiation. They were irradiated either in an ice bath or at ~30 °C with Co^{60} γ-rays at a dose rate of $\sim 3 \times 10^{19}$ eV g^{-1} h^{-1}. Fricke dosimetry was used (9).

Analysis

Scission olefins with 6 to 14 carbon atoms were separated from each other and from the corresponding *n*-alkanes on a 40 ft by 0.125 in. o.d. stainless steel column packed with 5% Carbowax 20M on 70–80 mesh Chromosorb G, AW-DMCS. Temperature programming was used in the separation. Concentrations were monitored with a flame ionization detector.

Linear hexadecene isomers were separated isothermally on a terephthalic acid treated Carbowax 20M column, as described elsewhere (10). Although individual hexadecene isomers could be isolated only for *cis*- and *trans*-hexadecene-2, separation from the large excess of parent *n*-hexadecane was adequate to obtain analytical precision of ±5% and an accuracy of ±10% for the congruent olefin products as a group.

Total olefin yields were also determined by coulometric titration to an amperometric end point. Low solubilities of these larger hydrocarbons precluded using well-established aqueous systems for the titrations. Bromination of the olefins proved too slow to give a satisfactory end-point. Therefore a chlorination technique in dichloroacetic acid solvent was developed. To prevent loss of Cl_2 to the atmosphere, the cell shown in cutaway in Fig. 1 was designed to minimize dead volume during the titration. To determine total olefin content, 0.5 ml aliquots of irradiated *n*-hexadecane were dissolved in 30 ml of prechlorinated, redistilled dichloroacetic acid. To this, 1 ml of 30% aqueous LiCl was added, and the cell base adjusted to submerge the electrodes and minimize dead space. Chlorine was generated electrolytically using a current of 0.4 mA. Its concentration was monitored using a Heathkit Potentiostat in a three electrode configuration and a detector potential of +0.25 V.

The reliability of the technique was assessed by analysis of synthetic samples. Approximately 10^{-7} mol of olefin in a sample could be estimated to about a factor of two. The accuracy of analysis of samples containing >1 μmol of olefin was ±5%.

Results and Discussion

Yields of congruent olefin determined by gas chromatographic analysis are plotted as a function of dose in Fig. 2. The decrease in *G*(congruent olefin) with increasing dose is consistent with a mechanism in which formation of congruent olefin is linear with dose and its radiation induced removal is first order in olefin concentration. Similar behavior for *trans*-vinylene unsaturation in studies of polyethylene radiolysis has been observed by Dole *et al.* (11). The effect of state on the yield of congruent olefin is pronounced, solid

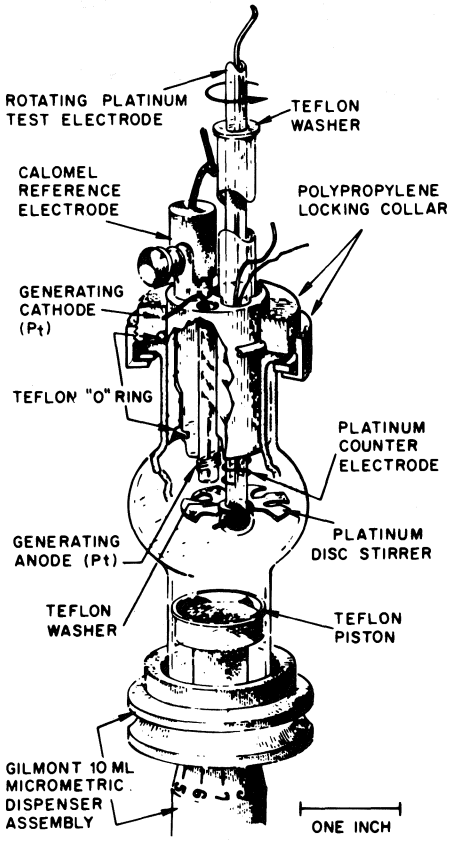

FIG. 1. Cell for coulometric titration.

state yields being about one-half those for the liquid. The incremental olefin yield in the liquid phase may result in part from the disproportionation of hexadecyl radicals with lower molecular weight scission radicals which are less abundant in the solid. The reduction in *G*(congruent olefin) with state is larger however than the change in yield of scission products. Removal of trapped hexadecyl radicals by reaction with H atoms has been suggested (7) as another factor in reducing congruent olefin yields in the solid phase. Disproportionation–combination ratios for H atoms with alkyl radicals are smaller than those between alkyl radical pairs, at least in the gas phase (12), and hence these interactions would not favor formation of olefin.

cis- and *trans*-Hexadecene-2 were examined individually. At a dose of 2×10^{19} eV g^{-1}, yields of *cis*-hexadecene-2 were $G = 0.07$ and 0.17 in the solid and liquid state, respectively, and for *trans*-hexadecene-2, $G = 0.23$ and 0.30. Dose dependence for these isomers paralleled that of the total

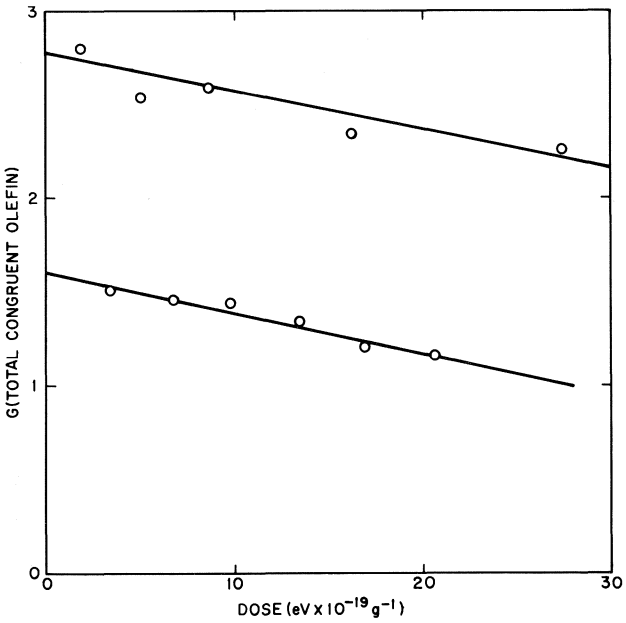

FIG. 2. Dose dependence of total yield of congruent olefin. Upper trace, liquid phase radiolysis; lower trace, solid state radiolysis.

congruent olefin shown in Fig. 2. If these *cis–trans* ratios are representative of positions other than 2, then ~25 and 35% of the congruent mono-olefin is *cis* in the solid and liquid respectively, comparable to what has been found for lower paraffins (1, 2). This finding is suggestive that one should find significant amounts of *cis*-vinylene unsaturation in irradiated polyethylene crystals or melts, which is not observed (11, 13–15). However, it was observed that *cis*-hexadecene-2 rapidly disappeared when the sample was open to air. In ~12 h its concentration fell below the limit of chromatographic detection, and the total yield of congruent olefin similarly decreased to a plateau value some 25–35% below that of a freshly opened sample. The concentration of *trans*-olefin did not appear to be affected, even on exposure to air for 2 or 3 weeks. Apparently the *cis*-isomers are preferentially air-oxidized with lower activation energies than the *trans*-olefins. A similar occurrence in polyethylene prior to i.r. examination might cause initially formed *cis*-vinylene unsaturation to escape notice, since i.r. observations were on thin polyethylene films and frequently in air (11, 13, 15). However, no evidence was found for carbonyl bands characteristic of oxidation and at least one author worked with a helium filled absorption cell (14).

The yield of *cis*- and *trans*-hexadecene-3 plus hexadecene-1, the three isomers being unresolved from each other chromatographically but separate from all other isomers, is approximately equal to that of *trans*-hexadecene-2. This places a limit on the yield of terminal olefin, which cannot be abnormally large.

In previous studies of *n*-hexadecene radiolysis (8), olefins and paraffins with the same number of carbon atoms, resulting from main chain scission were analyzed together. Total scission fraction yields were $G = 0.50$ and 1.00 for solid and liquid irradiation, respectively. Analysis of the scission olefins showed their yields to be only 20–25% of the total, *i.e.* G(scission olefin) is ~0.12 and 0.25 for solid and liquid. Comparison of product retention times with those of various olefinic standards indicates these scission olefins are all linear and probably terminal. Within the accuracy of the present analysis, the yield of each scission olefin is the same.

The total radiation induced unsaturation was determined by the coulometric titration technique, with G-values being 2.2 and 4.2 for solid and liquid respectively at doses of $\sim 10^{20}$ eV g^{-1}. This analysis indicates additional unsaturation beyond what can be accounted for in the congruent olefins and scission olefins of 0.7 and 1.3 G-units in the solid and liquid states, a difference considerably greater than the experimental un-

For personal use only.

certainty. These differences may be associated with polyenes or with higher molecular weight unsaturated products of the radiolysis. Kang *et al.* (16) have found dienes play a significant role in the material balance of irradiated polyethylene.

In principle, a hydrogen material balance can be made by the equality

$$G(H_2) = G(\text{dimer}) + G(\text{congruent olefin}) + 2G(\text{diene}) + 3G(\text{triene}) + \ldots.$$
$$= G(\text{dimer}) + G(\text{total unsaturation}) - G(\text{scission olefin})$$

Best available values for G(dimer) at $\sim 10^{20}$ eV g^{-1} are 1.45 and 1.0 for the liquid and solid, respectively (7). For liquid phase radiolysis at this dose, $G(H_2)$ from this relationship is 5.4 compared with an observed value of 5.0 (7). For the solid the calculated $G(H_2)$ is only 3.1 compared with a measured value of 4.0. Agreement is satisfactory for the liquid, but the difference of 0.9 G-units in the solid state radiolysis suggests an unidentified source of molecular hydrogen, *i.e.* products deficient in hydrogen other than olefins and radical dimers.

Sulfur Dioxide Formation in the Photo-oxidation of Methanethiol

D. M. GRAHAM AND BILLY K. T. SIE

Department of Chemistry, University of Western Ontario, London, Ontario

Received June 24, 1971

Photolysis of methanethiol in the presence of oxygen has been investigated at 228.8 and 254–265 nm. The major products detected were 2,3-dithiabutane and a liquid, tentatively identified as hydrogen peroxide. The quantum yield of sulfur dioxide was found to be small (3×10^{-5}) at 25 °C, increasing only by an order of magnitude at 125 °C. It has therefore been concluded that the reaction between CH_3S and oxygen is very slow if it occurs at all.

La photolyse du méthanethiol en présence d'oxygène a été étudiée à 228.8 nm et 254–265 nm. Les produits majoritaires détectés sont le dithia-2,3 butane et un liquide, identifié comme étant probablement du peroxyde d'hydrogène. Le rendement quantique en dioxyde de soufre est petit (3×10^{-5}) à 25 °C et n'augmente que d'un ordre de grandeur à 125 °C. Il en a été conclu que la réaction entre CH_3S et l'oxygène est une réaction très lente si elle a lieu.

*+826 Torr CF_4.

position. In order to obtain relative reactivities, it is necessary to assume that no appreciable reaction occurs between thiyl radicals and oxygen. Some qualitative observations on the photo-oxidation of methanethiol had seemed to indicate that this was the case. However in a recent flash photolysis investigation of this reaction, strong absorptions due to SO and SO_2 were detected (5). Further, a transient absorption band at 218.5 nm, which is observed in the flash photolysis of CH_3S-containing species, disappears in the presence of oxygen. It was therefore suggested that the sulfur oxides result from oxidation of the thiyl radical. Because of the apparent disagreement between these results and our earlier work, a more careful investigation of the photo-oxidation of methanethiol was imperative.

Experimental

Methanethiol and hydrogen sulfide were purified by trap to trap distillations, using the appropriate slush baths, until the impurity level was below 0.1% as determined by g.l.c. Irradiation was carried out in quartz cells with a 100 W high pressure Hanovia SH616A lamp filtered by 1 cm of a 10% solution of 2,7-dimethyl-3,6-diazocyclohepta-1,6-diene iodide (6). This combination has maximum output intensities at 254 and 265 nm. For the short wavelength experiments, a Phillips 25 W cadmium lamp was used with no filter. Since methanethiol does not absorb at 326 nm, the effective photolysis wavelength was 228.8 nm. Analysis was performed using a mass spectrometer calibrated for each gas.

Results

The rates of formation of sulfur dioxide are given in Table 1. The absorbed light intensity was determined from the rate of hydrogen production in the photolysis of methanethiol in the absence of oxygen, assuming the quantum yield of hydrogen to be unity. This appears to be the case at 254–265 nm where the rate of hydrogen production has been shown to be equal to one-half the rate of CH_3S production, determined separately using butadiene-1,3 as a scavenger of the thiyl radical (3). Measurements, using an acetone actinometer, also indicate a hydrogen quantum yield of unity (7). At shorter wavelengths however, carbon–sulfur bond scission may become an important reaction channel (5), in which case hydrogen measurements would underestimate the absorbed light intensity.

The very low sulfur dioxide quantum yields determined are consistent with the large amounts of 2,3-dithiabutane observed. It proved impossible to determine this compound quantitatively due to its low vapor pressure and extremely strong absorption on the mass spectrometer inlet system. However it was always observed to be present in much larger quantities than sulfur dioxide. Sulfur dioxide is formed exclusively in a photolytic process, since in the absence of radiation, no reaction was observed after 10 h at 125 °C. During reaction a mist

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

formed on the cell walls; on warming, an explosion occurred, the only product of which appeared to be water. The mist therefore is probably hydrogen peroxide formed from the hydrogen atoms produced in the primary process. Secondary reactions involving this peroxide are likely responsible for the small increase in $\Phi(SO_2)$ as the irradiation time is increased; this effect is seen to be larger at the higher temperature.

Since the flash photolysis work was carried out in the presence of a high pressure of inert gas, two experiments were done in the presence of 826 Torr of tetrafluoromethane in order to determine if collisional stabilization is important. As is seen from the results in Table 1, addition of the inert gas had no effect. The quantum yield is also independent of thiol pressure. There is a small but significant increase in quantum yield at the shorter wavelength, and a tenfold increase in going from 25 to 125 °C.

The possibility that the low quantum yields are due to reactive disappearance of sulfur dioxide was eliminated by irradiating a mixture of methanethiol and sulfur dioxide with the mercury lamp for 10 h. No product other than 2,3-dithiabutane was detected and no change in the sulfur dioxide pressure occurred.

Since the yield of HS from carbon sulfur bond scission in the primary step is very small at 254–265 nm, and becomes appreciable at the wavelength used in the flash experiments (185–205 nm), it appeared possible that sulfur dioxide was formed from oxidation of this species. Some results obtained from irradiation of hydrogen sulfide/oxygen mixtures are given at the bottom of Table 1. The quantum yields were calculated assuming that the same amount of light is absorbed by H_2S and CH_3SH; this is reasonable since both have very high extinction coefficients at this wavelength. Only the last result approximates an initial quantum yield; in the first two the amount of photodecomposition was 40–60%. The initial sulfur dioxide quantum yield is about the same as that found for methanethiol, and it may be concluded that HS does not oxidize to any extent. This is consistent with flash photolysis observations that no sulfur dioxide is formed in the photoinitiated combustion of H_2S in the presence of high pressures of inert gas (8, 9), although it does become an important product at higher temperatures achieved under adiabatic flash conditions (8–10).

Although a definitive mechanism for the formation of sulfur dioxide cannot be ascertained from the results given here, it may be concluded that the reaction of CH_3S and HS with oxygen is extremely slow, even at 125 °C. At present it does not appear feasible to reconcile this conclusion with the flash photolysis results. The possibility exists that, even though the flash experiments were carried out in the presence of 100–200 Torr nitrogen as a temperature moderator, strictly isothermal conditions did not exist and oxidation occurred by a process analogous to the adiabatic flash combustion of H_2S (8–10).

Another possible explanation is suggested by some recent work on the partitioning of energy in the photodissociation of H_2S and CH_3SH (11). At wavelengths longer than 213.8 nm most of the available photolysis energy was observed to appear as kinetic energy of the hydrogen atom, and very little goes into internal excitation of the radical fragment. At 184.9 nm however, hydrogen atoms are produced with smaller kinetic energies than at 213.8 nm, and at the same time a large fraction of the available energy appears as internal excitation of HS and CH_3S. As the authors have suggested, this indicates a change in the primary process due either to Franck–Condon excitation to different regions of the RSH potential energy surface, or due to excitation to a different electronic state of RSH, either of which leading to dissociation into vibrationally and/or rotationally excited RS. Since the photolysis wavelength range for the flash experiments was 185–205 nm it is possible that internally excited CH_3S could have been produced, and that this internal excitation could greatly increase the rate of radical oxidation, which as we have shown does have a small activation energy. Interpretation of results obtained in the short wavelength region may also be complicated by excitation of the Schumann–Runge bands of O_2 (175–195 nm), and formation of SO_2 and SO could arise from reactions of O_2 ($^3\Sigma_u^-$) and $O(^3P)$ with CH_3S.

Electron Spin Resonance Studies of Radiation Damage. Part. V. γ-Radiolysis and Photolysis of Aqueous Alkaline Glasses Containing Acetonitrile. The Photo Conversion of an Imino Radical to an Alkyl Radical at 77 °K[1, 2]

F. P. SARGENT AND M. G. BAILEY

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba

Received June 7, 1971

The reactions of γ and photochemically produced electrons with acetonitrile in 8 *M* sodium hydroxide glasses at 77 °K have been re-investigated. The results differed from those previously reported and a novel photo-conversion of an imino radical to an alkyl radical was found. These results lead to a unified interpretation of (seemingly discrepant) observations on polar and nonpolar glasses.

Les réactions des électrons, produits par rayons gamma ou par effet photochimique, avec l'acétonitrile sur des verres d'hydroxyde de sodium 8 *M* à 77 °K ont été à nouveau étudiées. Les résultats diffèrent de ceux précédemment rapportés et une nouvelle photo-conversion d'un radical imino en un radical alkyl a été trouvée. Ces résultats permettent une interprétation unifiée des observations apparemment divergentes sur les verres polaires et non-polaires.

Canadian Journal of Chemistry, 49, 3898 (1971)

The reactions of acetonitrile with both radiation and photochemically produced electrons have received considerable attention in recent years. The radiolysis of solid acetonitrile has been extensively studied by Williams and co-workers (1)[3] and, largely due to their efforts, is reasonably well understood. The use of acetonitrile as an electron scavenger in various polar and non-polar solvents has been reported but the results seem to be in conflict with the recent work of Neta and Fessenden (2). Ayscough *et al.* (3) report that electrons produced by the γ radiolysis of aqueous 8 *M* sodium hydroxide glasses containing acetonitrile react by dissociative electron capture to produce methyl radicals. Williams and co-workers (4) have shown that electrons produced from the photolysis of tetramethylphenylenediamine (TMPD) at 366 nm in 2-methyltetrahydrofuran (MTHF) glasses also react with acetonitrile to produce methyl radicals. However, Neta and Fessenden (2) report that in their e.s.r. *in situ* irradiation experiments with aqueous solutions of acetonitrile at various p*H* values, the product was an imino radical $CH_3CHN\cdot$ characterized by an 80 G doublet. Methyl radicals were not observed. These workers performed separate experiments to determine if cyanide ion was formed. Their *G* values were in the range of 0.3 to 0.2 suggesting only about 10% of the electrons give methyl radicals by dissociative electron capture, and the majority reacted by electron capture followed by protonation to give an imino radical. We found the differences between the results in aqueous solutions and those found in glasses intriguing. We have re-examined the reactions of acetonitrile with electrons produced both photolytically and

Their *G* values were in the range of 0.3 to 0.2 suggesting only about 10% of the electrons give methyl radicals by dissociative electron capture, and the majority reacted by electron capture followed by protonation to give an imino radical. We found the differences between the results in aqueous solutions and those found in glasses intriguing. We have re-examined the reactions of acetonitrile with electrons produced both photolytically and

[1]AECL No. 3937.

[3]See also refs. 4 to 8 in this reference.

radiolytically in aqueous and other polar glasses at 77 °K; however, for brevity only the results found in aqueous 8 *M* sodium hydroxide are reported here.

We repeated the experiment of Ayscough *et al.* by γ irradiating aqueous 8 *M* sodium hydroxide glasses containing acetonitrile. Instead of the expected methyl radical the spectrum in Fig. 1(*a*) was observed. This consists of a broad trapped electron singlet flanked by two peaks separated by about 80 G. Photobleaching the trapped electrons with light of wavelength longer than 400 nm led to an increase in intensity of the doublet species. After complete removal of the singlet the spectrum in Fig. 1(*b*) was observed. We interpret this spectrum as indicated in the figure, namely, the usual methyl radical quartet together with the imino radical $CH_3CHN\cdot$, the latter being characterized by an 80 G doublet. The nitrogen $M_I \pm 1$ lines although broad, were detected at the appropriate magnetic field values (2, 5). The relative yields of the imino and methyl radicals were computed from their respective linewidths of 7.5 and 3.4 G assuming similar line shapes, binomial intensity distribution for methyl and six lines of equal area for the imino radical. This led to a relative concentration of about 10:1 *i.e.* only about 10% methyl radical. Therefore our results are in substantial agreement with those found by Neta and Fessenden.

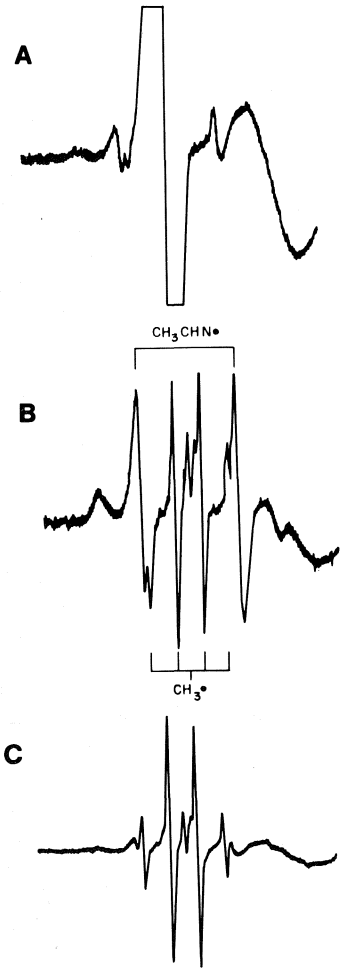

FIG. 1. Electron spin resonance spectra observed in γ irradiated aqueous 8 *M* sodium hydroxide glasses containing acetonitrile at 77 °K (*a*) examined in the dark immediately after radiolysis, gain setting 800 (*b*) followed by photobleaching λ > 400 nm, gain setting 800 (*c*) followed by photolysis at 254 nm, gain setting 250. Magnetic field increasing to left. Broad low field line is due to O^-

When the sample of Fig. 1(*b*) was further exposed to 254 nm light from a low pressure mercury resonance lamp the imino radicals were converted to methyl radicals as shown in Fig. 1(*c*). In additional experiments we were able to follow the decrease in imino radicals and the accompanying increase in methyl.

Photolysis at 254 nm of aqueous 8 *M* sodium hydroxide glasses containing acetonitrile and ferrocyanide produced spectra similar to that in Fig. 2(*a*). However, at short periods of photolysis or at reduced 254 nm light intensity spectra similar to that in Fig. 2(*b*) were obtained. This shows the presence of both methyl and imino radicals. The relative linewidths of the radicals indicate that the imino radical is present in ten-fold excess over methyl. In the absence of ferrocyanide there was a negligible amount of methyl radicals formed by photolysis.

Our results show that in aqueous 8 *N* sodium hydroxide glasses the imino radicals may be photochemically decomposed by 254 nm light to give alkyl radicals. We have found this to hold for other nitriles in polar solvents, but not in a non-polar matrix such as adamantane. Imino radicals were produced from amines in adamantane by the method of Wood *et al.* (5), but when they were photolyzed at 254 nm and 77 °K little or no conversion to alkyl radicals occurred. Therefore we suggest that the photodecomposition of imino radicals produces an alkyl radical and HCN. If the latter cannot be removed via production of cyanide ion then the reverse reaction will take place leading to no net de-

Magnetic field increasing to left.

composition. The results presented here may be rationalized in terms of the following reaction scheme

$$[1] \quad CH_3CN + e \rightarrow (CH_3CN)^-$$

$$[2] \quad e + CH_3CN \rightarrow CH_3 + CN^-$$

$$[3] \quad (CH_3CN)^- \xrightarrow{h\nu} CH_3 + CN^-$$

$$[4] \quad (CH_3CN)^- + H_2O \rightarrow CH_3CHN\cdot + OH^-$$

$$[5] \quad CH_3CHN \xrightarrow{254\,nm} CH_3 + HCN$$

where reactions 2 and 3 only account for 10% of the radicals produced. In non-polar glasses such as MTHF the photolysis of TMPD at 366 nm is usually employed as the source of electrons. We have found that the photolysis of imino radicals is very slow at this wavelength so if imino radicals were formed they would be easily detected. Williams and co-workers report only the presence of methyl radicals (4), therefore the intermediate initially formed is probably $(CH_3CN)^-$, but in the non-polar glasses there is no source of protons to form the imino radical. The acetonitrile anion is very sensitive to light (1) and would subsequently dissociate to give methyl radicals. Although it is not possible to distinguish between methyl radicals produced by reactions 2 or 3, our results indicate that the dissociative electron capture reaction of acetonitrile in aqueous glasses is by no means as efficient as previously supposed. This conclusion is further supported by the thermodynamic data, namely the reaction 2 is endothermic in the gas phase by 0.7 ± 0.2 eV.[4]

We wish to thank R. S. Dixon for drawing our attention to the quoted thermodynamic data.

On the Existence of Free OH Groups in Liquid Water

J.-J. PÉRON,[1] C. BOURDÉRON, AND C. SANDORFY
Département de Chimie, Université de Montréal, Montréal, Québec

Received July 19, 1971

It is shown that despite the complexity of the related parts of the spectrum, vibrational overtones give evidence of the presence of free OH groups in liquid water.

Malgré la complexité du spectre on montre que l'examen des harmoniques apporte des arguments en faveur de la présence de OH libre dans l'eau liquide.

The presence of free OH groups in liquid water is a much debated subject. Extensive infrared and Raman work has been done including studies of vibrational overtones (1–10). Evidence for the presence of free OH groups using the fundamental was given by Walrafen (11–14), Senior and Verrall (15), and Yellin and Courchene (16). A related, and also somewhat controversial problem is whether we can apply to liquid water the so-called continuum model (4, 6, 7) or if we have to distinguish variously associated "species" in it. There has been a recent exchange of views in this respect between Schiffer (17) and Walrafen (18) which makes interesting reading.

In the present note we intend to make two points: (*a*) it is advantageous to place the problem of liquid water into the broader context of the problem of hydrogen bonded liquids and (*b*) in spite of the complexity of the overtone region it can still be used as a source of information on liquid water.

It is important in this respect to recognize the fact that the OH-stretching overtones of hydrogen bonded polymers are unusually weak compared to those of the corresponding free OH groups. This has been observed in various cases by Luck and Ditter (19), Burneau and Corset (20), and ourselves (21, 22). This weakness is likely to be due to decreased electric anharmonicity (21) and it makes it possible to observe free and oligomer vibrations, which do not show up in the fundamental region. The contribution of the free and oligomer species to the observed intensity of the overtones increases rapidly with the order of the overtones (22).

We have shown in the case of sterically hindered alcohols that such free species and oligomers can exist even at liquid nitrogen temperature in glassy matrices (21), and that in the case of liquid methanol at room temperature we also have some free and oligomeric molecules (22).

Falk and Ford (23) have cautioned against the use of overtones when dealing with the water problem. They rightly pointed out that the observed bands are likely to receive contributions from a number of other combination tones. This complexity is due to the triatomic character of the water vibrator but it is not so serious for HDO.

Worley and Klotz (24) measured the first overtone of HDO and found a band which could be assigned to a free OH group. It is followed by broader bands due to associated OH groups. This result was recently confirmed by Luck and Ditter (25) who measured the spectrum of HDO under various conditions including the critical region. When temperature is raised the intensity of the free band increases considerably. Significantly, the strongest band in this part of the spectrum is the $\nu_{OH} + \nu_{OD}$ combination band (25).

We have measured the second overtone of HDO[2] with a Cary-17 instrument using a 10 cm cell with 3× scale expansion. At room temperature we find a band at 10 400 cm^{-1} which, because of its frequency, must be the second overtone of a free OH band. It is broadened at its low frequency side. The intensity of the band increases when temperature is increased also indicating that it must belong to free or oligomer species. This implies that the polymer bands are too weak to be observed. (This conclusion is less surprising if we have examined the overtones of liquid methanol (22).) A confirmation of this assignment comes from the anharmonicity constants. For a free OH band in alcohols its value

is $\omega_e x_e \approx 80\ cm^{-1}$ (26). For the ν_3 band of H_2O it is only 40 cm^{-1}. Siebrand and Williams (27) have actually shown that for a single OH group this should be about double what is observed for two coupled OH groups, so in HDO we expect about 80 cm^{-1}. This is what Burneau and Corset (20) found for HDO in CCl_4 solution and this is what we find using the frequencies of the first and second overtones of the free bands as assigned above.

Turning our attention now to liquid H_2O we measured the first, second, and third overtones at temperatures varying from 20 to 80 °C (Figs. 1, 2, and 3). At 20 °C the maximum is gradually moving to higher frequencies within the respective region of absorption as we go from the first to the second and then to the third overtone. In the region of the first overtone the changes with increasing temperature are clearly due to relative intensity changes in at least two overlapping bands. The high frequency band (at 80 °C) is at 7030 cm^{-1}, the low frequency band (at 20 °C) at 6870 cm^{-1}. This region of absorption must receive contributions from both free and associated OH groups of the $2\nu_1$, $2\nu_3$, $\nu_1 + \nu_3$, $\nu_1 + 2\nu_2$, and $\nu_3 + 2\nu_2$ band of each species and possibly others (23) whose frequencies could be affected by Fermi-resonance. There is no real reason, however, why the high frequency side of the observed broad band should become more intense when temperature is raised if there is no change in the proportion of free and associated molecules. We are not going to take this for granted, since there are multiple coincidences and Fermi-resonance is possible between more than two levels. Even if we consider these pairwise, there is no insurance that the unperturbed intensity of

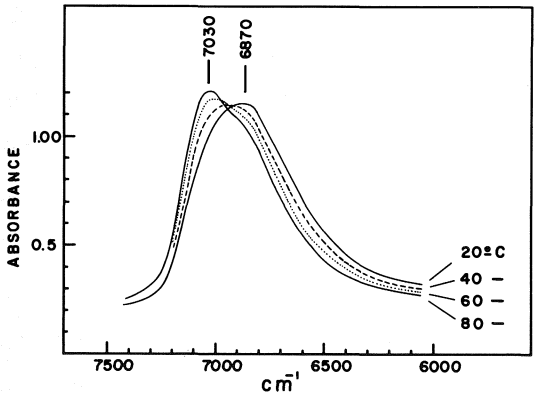

FIG. 1. The first overtone of H_2O at various temperatures (cell length 0.75 mm).

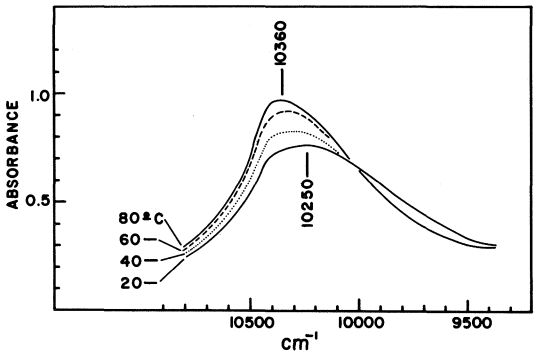

FIG. 2. The second overtone of H_2O at various temperatures (cell length 2 cm).

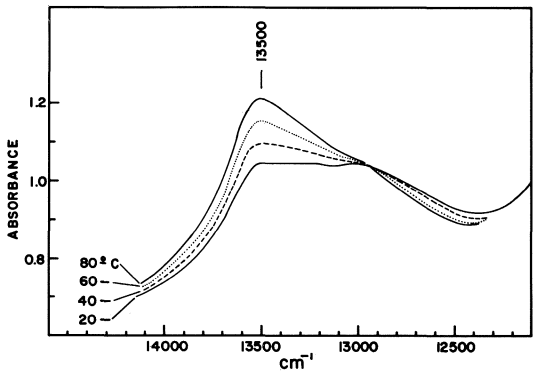

FIG. 3. The third overtone of H_2O at various temperatures (cell length 10 cm and 5 × scale expansion).

one of the interacting vibrations is negligible compared to the other, two conditions underlying the usual qualitative arguments on cases of Fermi-resonance. Under these circumstances an attempt to extract the unperturbed frequencies from the observed ones would not be justified.

The case of HDO is much clearer, however, since there is only one combination $\nu_1 + 3\nu_2$ which could have a frequency close enough to $2\nu_3$ for causing anharmonic resonance (23). Now using reasonable anharmonicity constants we can predict a difference of about 150–200 cm^{-1} between $2\nu_3$ and $\nu_1 + 3\nu_2$, a mediocre coincidence. Even more important is the fact that by far the largest perturbing term which could bring about this interaction (disregarding any possible symmetry requirement), $\langle 0,0,2|\ k_{122233} q_1 q_2^3 q_3^2 |\ 1,3,0\rangle$, would have to be a sextic term in the potential making the interaction entirely negligible. Thus we can conclude that the 7090 cm^{-1} band of HDO is a free band and not an associated band whose apparent frequency is heightened by anhar-

monic resonance. Furthermore, if the association in HDO would entirely conform to continuum theory there should be only one broad band at the level of $2\nu_3$ at all the temperatures, since no other vibration exists having similar frequencies and a non-negligible intensity. This, as we have stated, is not the case. Therefore even if the fundamental had a perfectly Gaussian or Lorentzian shape, this would be no sufficient proof for the total inexistence of "species". We also have to look at the overtones.

Now, there is a band at almost the same frequency (7030 cm^{-1}) in the spectrum of H_2O. In view of the analogy of associations in HDO and H_2O, their similar behavior when temperature is raised and the analogy between HDO and methanol (which has only one OH bond), we assign this band to molecules in which (at least) one OH group is approximately free. Then the 6870 cm^{-1} band must be due to vibrations of associated OH groups receiving intensity from both oligomers and polymers.

If these assignments are correct we have to expect that the "free" part of the higher stretching overtones becomes stronger in going from 2ν to 3ν and 4ν... This is actually what we observe. It is very significant that the effect of temperature is less and less in this order, showing that more and more of the absorbed intensity is due to the free species even at room temperature. Indeed the effect of decreased electric anharmonicity should become greater and greater in this order. The anharmonicity constant computed from the "free" overtones according to these assignments (at 80 °C) is about 75 cm^{-1}. This corresponds well to what is expected for an approximately free and uncoupled OH band. The other OH should be hydrogen bonded then so that the free OH is a part of an oligomer or polymer. If we compute the frequency of the fundamental with the above anharmonicity constant we obtain about 3600 cm^{-1} which is the free OH value obtained by Walrafen (3) in the Raman spectrum.

These observations yield a coherent picture covering the cases of alcohols, HDO, and H_2O in spite of the complexity of the water spectra. We believe that these facts add weight to the assumption that free OH groups do exist in liquid water at least at room temperature and higher temperatures. Finding "species" in liquid water is not so surprising if we have studied liquid or dissolved alcohols (21, 22) and amines (28) at low temperatures, where their bands appear clearly often even at the fundamental level. The proportion of free and oligomer species must be low, however, at least at room temperature, otherwise they would show up more strongly in the fundamental region.

Shock-Tube Study of Cr* Chemiluminescence During the Induction Period of the C_2H_2–O_2 Reaction

DAVID GUTMAN
Department of Chemistry, Illinois Institute of Technology, Chicago, Illinois 60616
AND
SHIMPEI MATSUDA
Department of Chemistry, Harvard University, Cambridge, Massachusetts 02138

Received April 14, 1971

The Cr* (a^7S–y^7P) chemiluminescence at 360 nm during the induction period of the C_2H_2–O_2 reaction was studied behind reflected shock waves. When the reaction gas mixture containing 10 p.p.m. $Cr(CO)_6$, 0.5% C_2H_2, 1.0% O_2, and 98.5% Ar was shock heated to 1650 °K, the emission intensity of Cr* grew exponentially with a growth constant equal to the chain branching constant. This observation indicates that reaction(s) leading to Cr* chemiluminescence involve only one chain carrier during the induction period of the C_2H_2–O_2 reaction. The mechanism of the chemical excitation of Cr is discussed.

La chimioluminescence de Cr*(a^7S–y^7P) à 360 nm, pendant la période d'induction de la réaction C_2H_2–O_2, a été étudiée derrière les ondes de choc réfléchies. Lorsque le mélange qazeux réactionnel, contenant 10 p.p.m. de $Cr(CO)_6$, 0.5% de C_2H_2, 1.0% de O_2 et 98.5% de Ar, est chauffé à 1650 °K, l'intensité de l'émission en Cr* croît d'une façon exponentielle et la constante de croissance est égale à la constante de fixation de chaîne. Cette observation montre que les réactions conduisant à la chimioluminescence de Cr*, impliquent uniquement un seul véhiculeur de chaîne pendant la période d'induction de la réaction C_2H_2–O_2. Le mécanisme de l'excitation chimique de Cr est discuté.

Canadian Journal of Chemistry, 49, 3904 (1971)

Introduction

It has long been observed that flames, especially the C_2H_2–O_2 and C_2H_2–air flames, containing certain additives emit intense atomic lines (1, 2). It has been shown that the excitation process is chemical rather than thermal in origin, and although the process of chemical excitation of atoms in flames has been the subject of many studies, it is not well established (1–3). This report describes the results of a kinetic study of the formation of the y^7P level of Cr as measured by the resonance emissions from 357.9 to 360.5 nm (hereafter denoted by Cr*) during the induction period of the C_2H_2–O_2 reaction in reflected shock waves.

The early part of the C_2H_2–O_2 reaction has been shown to be a highly branched chain reaction (4, 5). During the induction period of a chain branching reaction all the main chain carriers grow exponentially with the same growth constant (4, 6). If a side reaction, for example chemiluminescence and chemi-ionization in the C_2H_2–O_2 reaction, occurs between two chain carriers, products from this reaction grow according to $\exp(2\alpha t)$, where α is the chain branching constant. In general, the exponential growth constant, α^*, of a particular phenomenon is related to the chain branching constant, α, by

$$\alpha^* = n\alpha \quad [1]$$

where n is the number of chain carriers involved in the reaction leading to the phenomenon (4, 5). Since the knowledge of n in eq. 1 gives information to identify the process leading to atom excitation in flames, the exponential growth constant of Cr* emission was compared with that of the emission at 308 nm during the induction period of the C_2H_2–O_2 reaction. The emission at 308 nm has been shown to grow exponentially with a growth constant equal to the chain branching constant (7, 8).

Experimental

The 4 in. i.d. shock tube and end-on detection apparatus used in this study have been described previously (7). Two detectors (Amperex 150 UVP) were used simultaneously; one monitoring an emission at various wavelength through a monochromator (full band pass 15 nm) and the other the emission at 308 nm through an interference filter (half band pass 3 nm). Argon gas was passed through a packed column of $Cr(CO)_6$ and saturated with $Cr(CO)_6$ vapor (9).[1] The reaction gas mixture was prepared by adding the $Cr(CO)_6$ saturated Ar to C_2H_2/O_2/Ar gas mixtures. For Cr* emission

[1]For the vapor pressure of $Cr(CO)_6$, see refs. 10 and 11.

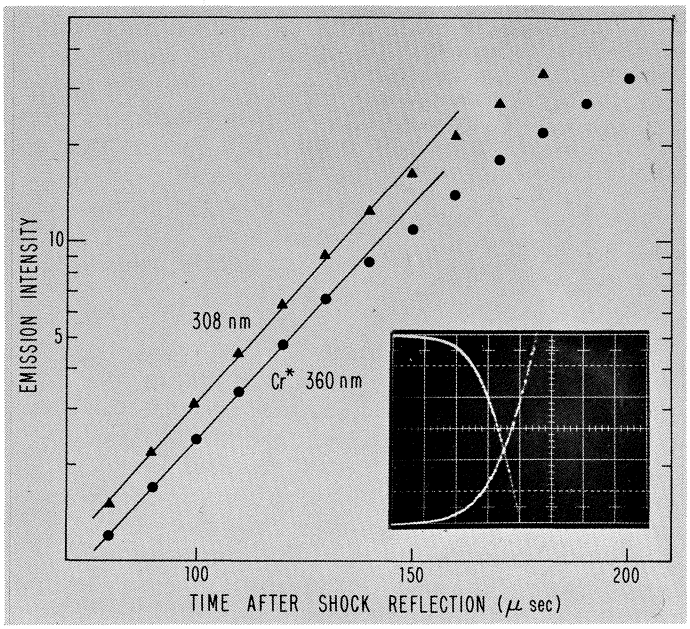

FIG. 1. Plot of emission intensity *vs.* time after shock wave reflection and oscillogram obtained in this experiment. Upper trace of the oscillogram: emission at 308 nm, 500 mV/div, lower trace: emission at 360 nm, 200 mV/div, sweep time is 50 μs/div for both traces.

measurements the gas mixture containing 10 p.p.m. $Cr(CO)_6$, 0.5% C_2H_2, 1.0% O_2, and 98.5% Ar was mainly used throughout this study. The experiment was performed at about 1650 °K and at a total concentration of 1.5×10^{-3} mol/l.

Results

It is known that there exists a continuum in the range 300–600 nm produced by the C_2H_2–O_2 reaction (1, 7, 8). Therefore, in a series of experiments the emission intensity distribution around Cr*(360 nm) was investigated in order to assure that the Cr* lines were isolated from the background continuum emission. Table 1 shows the emission intensity distribution around 360 nm for the mixture ($C_2H_2/O_2/Ar$ = 5/10/985) containing 10 p.p.m. $Cr(CO)_6$ and for the same mixture without $Cr(CO)_6$ using the emission at 308 nm as a reference. It is seen that an intense Cr* emission lies at 360 nm which is as strong as the CH*($C^2\Sigma^+$–$X^2\pi$) emission at 314 nm. It should be noted here that the CH* emission at 314 nm is much stronger in the shock heated C_2H_2–O_2 reaction than in C_2H_2–O_2 flames (7). From Table 1 it is known that the emission intensity observed at 360 nm is about 95% due to Cr* and 5% due to a background continuum.

TABLE 1. Emission intensity distribution around 360 nm (normalized at 314 nm)*

λ (nm)	I_λ/I_{308nm}	
	10 p.p.m. $Cr(CO)_6$	No $Cr(CO)_6$
370	0.05	0.05
360	0.96 (Cr*)	0.05
350	0.05	0.05
314	1.00 (CH*)	1.00 (CH*)

*Reaction gas mixture; $C_2H_2/O_2/Ar$ = 5/10/985.

The emission intensity of Cr* and the reference emission from a typical experiment is plotted against the reaction time in Fig. 1. It can be seen that both Cr* and the second emission grow exponentially with nearly the same growth constant. The exponential growth constants of Cr* and CH*(314 nm) were compared indirectly in separate experiments and found to be equal under the same experimental conditions.

Since both CH* and the reference emission grow with the same growth constant as the chain carriers (7, 8) (see Table 2), the above observations suggest that the reaction leading to Cr* excitation also involves only one chain carrier (n = 1 in eq. 1) during the induction period of the C_2H_2–O_2 reaction. When the reaction gas mixtures con-

TABLE 2. Order of reaction in chain carriers of various phenomena observed in the C_2H_2–O_2 reaction

Process	Order of reaction	Reference
CH ($A^2\Delta$–$X^2\pi$) 432 nm	1	5
($B^2\Sigma^-$–$X^2\pi$) 390 nm	1	7
($C^2\Sigma^+$–$X^2\pi$) 314 nm	1	7
Continuum 300–600 nm	1	7, 8
Cr* 360 nm	1	This study
C_2($A^3\pi_g$–$X^3\pi_u$) 515 nm	2	7
CO ($A^1\pi$–$X^1\Sigma^+$)	2	8
Chemi-ionization	2	4, 8

taining more than 25 p.p.m. $Cr(CO)_6$ were shock heated, reaction occurred extremely fast[2] and the exponential growth of the emission was no longer observed. In this case it was observed that I(Cr*)/I(308 nm) and I(314 nm)/I(308 nm) were nearly constant during the early part of the reaction. This observation also supports the result that Cr* is produced in a reaction first order in chain carriers.

Discussion

The order of reaction in chain carriers leading to the various phenomena observed in the C_2H_2–O_2 reaction is summarized in Table 2. From this table it is immediately concluded that $C_2(A^3\pi_g)$, $CO(A^1\pi)$, and chemi-ions can not be precursors of Cr* emission, because they are all formed in reactions second order in chain carriers. Several mechanisms have been proposed for metal excitation in flames.

[2] $CH + O + M \rightarrow CHO + M^*$ (ref. 3)

[3] $CH + O + M \rightarrow CO + H + M^*$ (ref. 12)

[4] $CH + OH + M \rightarrow CO + H_2 + M^*$ (ref. 13)

[5] $\begin{cases} CH(X^2\pi) + O \rightarrow CO^*(a^3\pi) + H \\ CO^* + M \rightarrow CO(X^1\Sigma^+) + M^* \end{cases}$ (ref. 1)

[6] $C + MO \rightarrow CO + M^*$ (ref. 14)

(M is a metallic element)

Reactions 2–5 involve two chain carriers, *i.e.* they are second order process in chain carriers. Consequently in the case that M is Cr, they are not consistent with the present experimental findings. In the shock tube study of $Cr(CO)_6$–O_2 and $Cr(CO)_6$–CO–O_2 reactions the formation of CrO, CrO_2, and CrO_3 has been observed by a time-of-flight mass spectrometer coupled to a shock tube (16). In the present reaction system $Cr(CO)_6$ is probably oxidized (at least partially) to CrO, CrO_2, and CrO_3. Reaction 6 is exothermic by about 150 kcal/mol in case of CrO and is able to excite Cr in the y^7P state. Thus, if there is a first order reaction or a sequence of first order reactions in chain carriers to produce carbon atoms during the induction period of the C_2H_2–O_2 reaction, reaction 6 is not inconsistent with the present experimental results.

It has been found that metal emissions are more closely related to the CH* than C_2* emission in flames (14). This observation is in agreement with the present experimental results, because both CH* and Cr* are formed in first order reactions in chain carriers while C_2* is formed in a second order process (see Table 2). Since the orders of reaction leading to Cr* and C_2* formation are different, the kinetic behaviors of Cr* and C_2* will be greatly different in flames.

In the present study it was found that Cr* together with CH* and the continuum were produced by a mechanism *first* order in chain carriers. Thus, the following processes for the Cr* emission during the induction period of the C_2H_2–O_2 reaction are suggested.

[7] $C_2H + O_2 + Cr \rightarrow Cr^* + 2CO + H$

[8] $CH + O_2 + Cr \rightarrow Cr^* + CO + OH$

Reactions 7 and 8 are exothermic by 115 and 159 kcal/mol (without Cr excitation), respectively (15). It should be pointed out that reactions 7 and 8 are kinetically indistinguishable from the two pairs of reactions,

[7*a*] $C_2H + O_2 \rightarrow CH(C^2\Sigma^+) + CO_2$

[7*b*] $CH(C^2\Sigma^+) + Cr \rightarrow CH + Cr^*$

and

[8*a*] $CH + O_2 \rightarrow OH(A^2\Sigma^+) + CO$

[8*b*] $OH(A^2\Sigma^+) + Cr \rightarrow OH + Cr^*$

Thus Cr may in fact be excited by electronic energy transfer in this system.

Since some species are excited by more than 160 kcal/mol in flames (1, 2), there arises a fundamental question over whether the excitation process is the same for all kinds of metal elements. In order to answer this question it is necessary to investigate the kinetic behaviors of various atomic emissions. Further studies related to this problem are being undertaken.

[2]The catalytic effect of $Cr(CO)_6$ on the C_2H_2–O_2 reaction will be discussed elsewhere.

Studies of the Carbonatobis(R-propylenediamine)cobalt(III) Ion

ROLAND A. HAINES AND ANTHONY A. SMITH
Department of Chemistry, University of Western Ontario, London 72, Ontario

Received July 2, 1971

The complex carbonatobis(R-propylenediamine)cobalt(III) perchlorate, $[Co(R\text{-}pn)_2CO_3]ClO_4$ has been prepared both as a mixture of isomers and as one pure optical isomer. The nature of the products is discussed and structures are assigned on the basis of c.d. and n.m.r. data.

Le complexe, perchlorate de carbonatobis (R-propylènediamine)cobalt(III), $[Co(R\text{-}pn)_2CO_3]ClO_4$, a été préparé à la fois sous forme d'un mélange d'isomères et sous forme d'un seul isomère optique. La nature des produits est discutée et les structures sont attribuées en se fondant sur les données r.m.n. et d.c.

Canadian Journal of Chemistry, 49, 3907 (1971)

There have been previous reports in the literature concerning the preparation of the carbonatobis(R-propylenediamine)cobalt(III) complex ion (1, 2). There, evidence was presented for stereoselectivity in the preparation of these complexes and the latter workers reported the isolation of a pure optically active form on the basis of o.r.d. data. However, little has been reported concerning the actual structure of the product obtained in these studies, and this is unfortunate since the synthesis could produce three possible geometric isomers, each of which has a diastereomeric mirror image. Recently it has been necessary for us to examine this system in detail while carrying out some related studies on stereoselectivity and in this paper we wish to report the results of our findings.

The traditional preparation of carbonato complexes of the type $[Co(diamine)_2CO_3]^+$ involves reaction of the corresponding *trans*-$[Co(diamine)_2Cl_2]^+$ ion with a carbonate salt. If the diamine is not itself optically active, preparation of the complex in this manner should yield equal amounts of the Λ and Δ optical isomers (3). However, the use of an optically active ligand such as R-(−)propylenediamine (R-pn) usually imposes an asymmetric bias on the synthesis and the isomers are not prepared in equal amounts. This stereoselectivity is applicable both to the formation of a particular geometric isomer and its particular optical isomer. Thus examination of the c.d. or o.r.d. spectrum of the reaction product of such a synthesis is often not too informative since such a curve would be a

resultant of contributions from all the species present.

In our work the reaction mixture for the synthesis of $[Co(R\text{-}pn)_2CO_3]^+$ yielded a c.d. curve with a predominant negative peak (530 nm) in the vicinity of the first absorption band, with a smaller positive peak at lower wavelength (470 nm). A study of the proton n.m.r. spectrum for this product, however, revealed that a mixture of species was present. The region corresponding to the resonances of the methyl groups of propylenediamine showed two doublets of unequal intensities. The predominant doublet had peaks at 1.36 and 1.31 p.p.m. downfield from sodium DSS while the other had peaks at 1.34 and 1.28 p.p.m. In addition, a minor peak occurred at 1.26 p.p.m., which was attributed to the presence of a small amount of one other isomer. A typical spectrum is shown in Fig. 1. Thus one species is predominant and will influence the resultant observed c.d. curve the most. The question remained as to the nature of this species, however, and the other major component in solution.

In order to gain further information, it was necessary to have a pure sample of one of the components and this was accomplished by making use of a variation of the stereospecific synthesis reported by Dwyer and MacDermott (2). In this way, a sample of $[Co(R\text{-}pn)_2CO_3]ClO_4$ was obtained which had a large negative c.d. peak in the region of the first absorption band (see Fig. 2) and whose proton n.m.r. spectrum showed only a single doublet with peaks at 1.37 and 1.31 p.p.m. Thus this sample corresponded to one pure optical isomer and on the basis of the sign of the predominant c.d. band (4), the Δ absolute configuration could be assigned.

A decision needed to be made, however, as to which geometric isomer was present. The n.m.r. spectrum indicated that the methyl groups of the two propylenediamine ligands were equivalent, since only one doublet was observed. Of the three possible geometric isomers, only the two shown in Fig. 3 possess a C_2 axis and hence would be consistent with the n.m.r. spectrum. It is difficult to choose between these two possibilities but the latter could be somewhat favored when one considers the structure found for the Δ isomer of $[Co(R\text{-}pn)_3]^{3+}$ from X-ray analysis (5). There the *fac*-configuration was found and the structure shown in Fig. 3(*b*) could more readily attain an

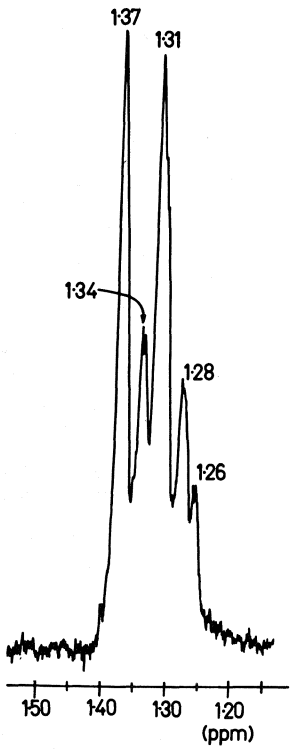

FIG. 1. Methyl region of 100 MHz n.m.r. spectrum of $[Co(R\text{-}pn)_2CO_3]ClO_4$ reaction product in D_2O.

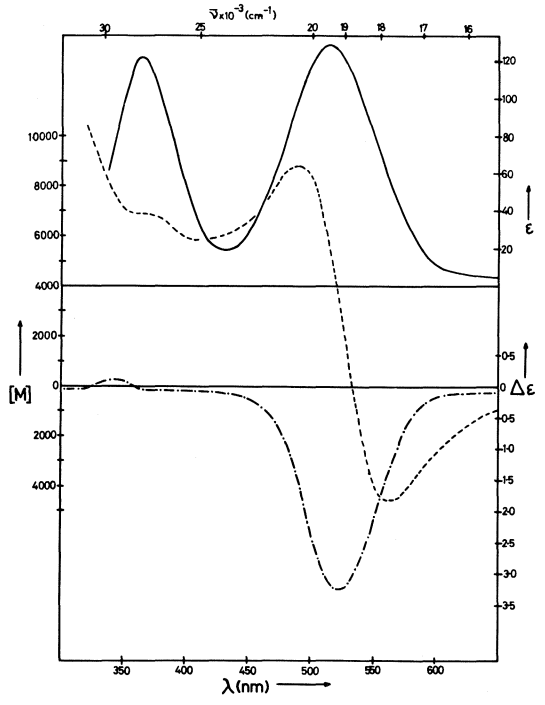

FIG. 2. Absorption (—), c.d. (·····), and o.r.d. (---) spectra of Δ-$[Co(R\text{-}pn)_2CO_3]ClO_4$.

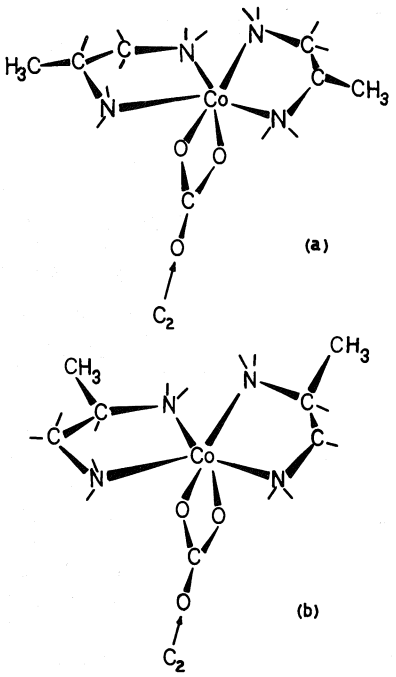

FIG. 3. Two possible geometric isomers of Δ-[Co(R-pn)$_2$CO$_3$]ClO$_4$.

intermediate leading to that configuration upon substituting CO_3^{2-} by an R-propylenediamine ligand. As illustrated, the λ conformation of each chelate ring would be expected to be found since coordination of R-pn with this conformation allows the methyl group to be equatorial and hence the complex has added stability (6).

Thus the predominant component of the original reaction mixture may be assigned to the Δ configuration of one particular geometric isomer as shown in Fig. 3(*b*). The other principal component is most likely its diastereomeric mirror image, *i.e.*, the Λ optical isomer. A comparison of the c.d. spectra of the reaction product and the pure Δ compound indicates that it is unlikely that this component corresponds to a different geometric isomer of the Δ configuration. All of the geometric isomers would be predicted to favor the Δ absolute configuration on the basis of stability arguments (6) and hence all geometric isomers would show a predominant negative c.d. band. Hence the c.d. band of the reaction product would not be expected to be too different in intensity from that of the pure Δ compound. However, such is not the case and the c.d. maximum of the Δ isomer is much more intense than that of the reaction product. These results are consistent with a cancellation effect of two isomers of opposite configurations.

Further support was provided from observations of the mother liquor obtained following filtration of the pure Δ isomer. Nuclear magnetic resonance spectra indicated that the relative proportions of the two major components had not changed significantly from that of the reaction mixture, even though a large amount of the one component had been removed. Further crops of the pure Δ isomer could be obtained from the mother liquor without changing the relative proportions. Thus the minor component must continually be converting to the pure Δ isomer to maintain an equilibrium in solution. Such a conversion is likely to occur by an intramolecular mechanism (see, for example, ref. 7) and from the n.m.r. results would be consistent with an inversion reaction without isomerization. This is due to the fact that most of the proposed intramolecular rearrangements would produce the isomer containing nonequivalent methyl groups on the pn rings. No evidence for such an isomer was observed.

Experimental

Preparation of trans-Dichlorobis(R-propylenediamine)-cobalt(III) Perchlorate, [Co(R-pn)$_2$Cl$_2$]ClO$_4$

This complex was prepared using a modification of the method of Martinette *et al.* (8), using R-propylenediamine dihydrochloride obtained from Frinton Laboratories, Vineland, N.J. The solid (12.9 g) was dissolved in ~50 ml of water and neutralized with a solution of sodium hydroxide (7.3 g) in the minimum amount of water. To this mixture was added 9.52 g of $CoCl_2.6H_2O$ in an ice bath and approximately 20 ml of 30% H_2O_2 was added slowly with stirring. After the reaction had subsided, the beaker was removed from the ice and 50 ml of concentrated hydrochloric acid was added. The dull grey solution was then concentrated to 25 ml by blowing air over the surface, keeping the temperature below 80 °C. The dark green crystals were filtered off, washed with ether and dried under a heat lamp where they crumbled to a dull green powder. This chloride salt was converted to the perchlorate salt by dissolution of the product in water followed by the addition of a slight excess of sodium perchlorate. The solid readily precipitated and was filtered off and washed on the filter with ice water until the filtrate became green. Finally, the precipitate was washed with ethanol and ether and dried under a heat lamp.

Further product could be obtained by evaporating the filtrate on a steam bath. This product was contaminated with large amounts of sodium perchlorate but could be purified by dissolving the product in acetone, filtering and reprecipitating the complex with a large excess of ether. Total yield ~6 g.

Preparation of Carbonatobis(R-propylenediamine)-cobalt(III) Perchlorate, [Co(R-pn)$_2$CO$_3$]ClO$_4$

A solution of *trans*-[Co(R-pn)$_2$Cl$_2$]ClO$_4$ (3 g) in water

(50 ml) was heated to 50 °C and an excess of solid silver carbonate (5 g) was added. The solution was stirred for 10 min, keeping the temperature at 50–55 °C. The dark red solution was allowed to cool, the silver salts were filtered off, and the filtrate was evaporated to dryness on a steam bath. The residue was dissolved in the minimum amount of boiling water, the solution was filtered and the filtrate was cooled in an ice bath to precipitate the solid.

Preparation of Δ-carbonatobis(R-propylenediamine)-cobalt(III) Perchlorate

This complex was prepared using a stereoselective method similar to that reported for the corresponding iodide salt. A quantity of the mixed complex prepared above was dissolved in a small amount of water and acetone was added until the solution turned cloudy. The flask was then stoppered and allowed to stand for a week. At the end of that time, the needle-shaped crystals were filtered, washed with acetone, and dried under a heat lamp.

^{35}Cl Nuclear Quadrupole Resonance of Some Phosphorus–Chlorine Compounds

J. K. B. Bishop, W. R. Cullen, and M. C. L. Gerry
Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received June 2, 1971

Chlorine nuclear quadrupole resonance spectra have been observed for several compounds containing phosphorus–chlorine bonds. The compounds included some complexes of phosphorus trichloride with transition metals as well as some alkyl derivatives of thiophosphoryl chloride and phosphorus trichloride.

Les spectres de résonance quadrupolaire nucléaire du chlore ont été observés pour plusieurs composés contenant des liaisons phosphore–chlore. Ces composés incluent certains complexes du trichlorure de phosphore avec des métaux de transition ainsi que certains dérivés alkylés du chlorure de thiophosphoryle et du trichlorure de phosphore.

Canadian Journal of Chemistry, **49**, 3910 (1971)

There have been several previous reports of nuclear quadrupole resonance (n.q.r.) spectra of phosphorus–chlorine derivatives (1–9). Yet, though trivalent phosphorus halides form many complexes with transition metals there have been no previous reports of their chlorine n.q.r. spectra. We have begun a study of these, and report here the measurement of the resonances of two, namely tetrakis(trichlorophosphine)nickel, $Ni(PCl_3)_4$, and *fac*-tris(trichlorophosphine)tricarbonylmolybdenum, $Mo(CO)_3(PCl_3)_3$. We report also some further measurements of the n.q.r. spectra of compounds having general formulae $RPCl_2$ and $RPSCl_2$.

Experimental Methods

Nuclear quadrupole resonance spectra were observed using an externally quenched superregenerative spectrometer constructed in this Department. Its circuit was similar to that of Smith and Tong (10). Provision was made to permit independent variation of both pulse

(50 ml) was heated to 50 °C and an excess of solid silver carbonate (5 g) was added. The solution was stirred for 10 min, keeping the temperature at 50–55 °C. length and quench frequency, the latter in the range 13–40 kHz. The carrier frequency could be swept electronically, in which case resonances were displayed on an oscilloscope, or mechanically, allowing chart presentation of resonances; in the latter case square wave Zeeman modulation at 34 Hz was used. Rough measurement of a resonance frequency (to about 50 kHz) was made by counting the oscillator, unquenched, with a Hewlett–Packard 5246L frequency counter. When resonances were strong enough to be observed on the oscilloscope accurate measurements (to between 0.5 and 5 kHz, depending on the resonance line width) were made by beating the signal from the superregenerative oscillator with that of a General Radio 1211-C oscillator, superimposing the zero beat on the resonance line, and measuring the frequency of the 1211-C oscillator with the frequency counter. Samples were cooled to a particular low temperature by immersing sample and sample coil in an appropriate bath.

Tetrakis(trichlorophosphine)nickel was prepared by the reaction of nickel carbonyl with phosphorus trichloride and was recrystallized from petroleum ether (11); its purity was checked using its Raman spectrum (12). *fac*-Tris(trichlorophosphine)tricarbonylmolybdenum was prepared by reacting h^5-cycloheptatrienetricarbonylmolybdenum, $Mo(C_7H_8)(CO)_3$, with phosphorus trichloride. The product was recrystallized from petroleum ether (13) and its purity was established from its infrared spectrum (14). Methylphosphonous dichloride, ethylphosphonous dichloride, methylphosphonothioic dichloride, and ethylphosphonothioic dichloride were all obtained from the Ethyl Corporation and used without further purification; their n.m.r. spectra were used to check their purity. The spectra of all compounds studied were obtained at 77 °K; for these measurements approximately 5 g of sample were sealed under vacuum in a glass vial. The spectrum of tetrakis(trichlorophosphine)nickel was also observed at room temperature. However, since this complex tends to decompose rather rapidly under vacuum at this temperature, the sample was sealed in the vial under nitrogen at atmospheric pressure.

Results and Discussion

In Table 1 are given the ^{35}Cl resonance frequencies measured in the present investigation, together with those of some related compounds. The frequencies for both transition metal complexes are very similar and are about 2 MHz higher than that of phosphorus trichloride but somewhat lower than those of phosphoryl chloride and thiophosphoryl chloride. Both complexes show a complicated group of lines; the magnitudes of the line separations ($\sim$0.1 MHz) suggest that the groups are due to chlorine atoms in different environments in the crystal, rather than to chemically inequivalent chlorine atoms. The resonance frequency of tetrakis(trichlorophosphine)nickel decreases by 0.5 MHz between 77 °K and room temperature, giving an approximate temperature coefficient of − 2.33 kHz/deg.

The measured molecular quadrupole coupling constants can be approximately related to that of the chlorine atom by the following relationship (15)

$$[1] \qquad eQq(\text{mol}) = (1 - s + d - I - \pi)\, eQq(\text{atom})$$

Here s and d are the degree of s- and d-hybridization of chlorine; I and π are the ionic character and pi character of the P—Cl bond. Also eQq(mol) = $-2 \times$ resonance frequency and eQq(atom) = -109.7 MHz. The internuclear parameters of tetrakis(trichlorophosphine)nickel and *fac*-tris(trichlorophosphine)tricarbonylmolybdenum have not been determined. Those of phosphorus trichloride, phosphoryl chloride, and thiophosphoryl chloride are all known (16), however, to have similar PCl_3 lengths and angles, with the P—Cl length very near the sum of the single bond radii. There is little reason to believe that the PCl_3 moieties in the complex would have a different structure. Thus s and d are expected to be essentially constant for all five compounds and π is probably very small, so that differences in the coupling constants, and hence the resonance frequencies, would be expected to reflect chiefly differences in ionic character of the PCl bond. Now, both complexes, as well as $OPCl_3$ and $SPCl_3$, have higher resonance frequencies than PCl_3, implying that their PCl bonds have evidently lower ionic character. This can be rationalized by noting that in formal terms the lone pair of electrons originally on phosphorus in PCl_3 is withdrawn toward the metal (or O or S) to form a dative bond. This in turn is reflected by withdrawal of σ-electron density from chlorine, and hence the decrease in ionic character.

The newly determined resonance frequencies of some organophosphorus compounds are also given in Table 1. Our values for methylphosphonous dichloride, CH_3PCl_2, are in good agreement with the earlier ones, whereas for ethylphosphonous dichloride, $C_2H_5PCl_2$, the agreement is poorer. The central line of the latter compound is actually a strong doublet, somewhat in disagreement with earlier work; however the spectrum showed a weak line at 25.93 MHz and probably a fourth at 25.75 MHz, in agreement with previous observations. For methylphosphonothioic dichloride, CH_3PSCl_2, the previously observed broad signal at 27.6 MHz was not found, but was replaced by a single strong line 27.859

TABLE 1. ^{35}Cl nuclear quadrupole resonance frequencies of some phosphorus–chlorine derivatives

Compound	Temperature (°K)	Resonance frequency (MHz) Present work	Earlier work (8)

*Frequency given is the mean of a complex band of width 0.25 MHz.
†Frequency given is the mean of a complex band of width 0.40 MHz.

MHz; evidently the crystals studied in the present work were somewhat better formed, with the chlorine atoms all in one lattice site. The magnitude of the splitting of the doublet spectrum of ethylphosphonothioic dichloride, $C_2H_5PSCl_2$, suggests that the chlorine atoms occupy two different lattice sites.

Our data confirm the report (8) that linear relationships exist between the frequencies of the alkyl derivatives of thiophosphonyl chloride, but not those of phosphorus trichloride. The relationships are

$$[2] \quad \nu(RPSCl_2) = (1/2)[\nu(R_2PSCl) + \nu(PSCl_3)]$$

$$[3] \quad \nu(RR'PSCl) = \nu(PSCl_3) - \Delta\nu(R) - \Delta\nu(R')$$

Thus from eq. 2 the frequency of the dichloroalkyl derivative is the mean of those of the trichloro and dialkylmonochloro derivative. Combination of our data with those previously published improves the validity of the relationship to the extent that it holds to within 50 kHz for both alkyl groups studied here. Equation 3 implies further that substitution of a particular alkyl group will always cause the same frequency change. Our data, combined with the earlier results, yield improved values of $\Delta\nu(CH_3) = 1.80$ MHz and $\Delta\nu(C_2H_5) = 2.14$ MHz. Table 1 shows that the frequencies of all possible methyl and ethyl derivatives can now be predicted to within 150 kHz, well within the variations expected from crystal lattice effects.

We are indebted to Mr. J. Sallos and Mr. M. Hatton for invaluable assistance and advice in the construction of the nuclear quadrupole resonance spectrometer.

We acknowledge gratefully the support of the National Research Council of Canada in the form of research grants.

OH···π Bond Enthalpy for the Phenol–Benzene Complex

DONALD BLOSER, JOSEPH MURPHY, AND J. N. SPENCER[1]
Department of Chemistry, Lebanon Valley College, Annville, Pennsylvania 17003

The OH···π hydrogen bond enthalpy for the phenol–benzene complex has been determined spectrophotometrically. Equilibrium constants for the hydrogen bonded complex are reported. The OH···π bond enthalpy was found to be -4.1 ± 0.5 kcal mol^{-1} and the entropy change -17 cal deg^{-1} mol^{-1}.

L'enthalpie de la liaison hydrogène OH···π a été déterminée par spectrophotométrie pour le complexe phénol-benzène. Les constantes d'équilibre du complexe sont rapportées. L'enthalpie de la liaison OH···π est de -4.1 ± 0.5 kcal mol^{-1} et le changement entropique de -17 cal deg^{-1} mol^{-1}.

Canadian Journal of Chemistry, **49**, 3913 (1971)

There are few spectral determinations of the magnitude of the intermolecular OH···π bond enthalpy reported in the literature. Szczepaniak and Falk (1) have determined the enthalpy difference between OH···CH_n and OH···π interactions for 2,6-diisopropyl-phenol and phenol in various solvents containing π electrons. For 2,6-diisopropyl-phenol in a 50% CCl_4–benzene mixture, the enthalpy difference between OH···CH and OH···π interactions was found to be -1.2 kcal mol^{-1}. These authors did not take into account the changes of integrated absorptivities with temperature. Powell and West (2) utilizing spectral measurements found ΔH^0 to be -1.56 kcal mol^{-1} for the OH···π bond between benzene and phenol in carbon tetrachloride solution. They further report $\Delta G_{298}{}^0$ to be 0.76 kcal mol^{-1} and ΔS^0 to be -7.8 cal deg^{-1} mol^{-1}. Murakami and Fujishiro (3) have determined OH···π enthalpies by calorimetric means and find for the system benzylalcohol–ethylbenzene–cyclohexane ΔH for the OH···π bond is -1.5 kcal mol^{-1}. For the *m*-cresol–*m*-xylene–cyclohexane system they find ΔH for the OH···π bond to be -3.1 kcal mol^{-1}. Rao, Murthy, and Bhat (4) using CNDO/2 calculations, find a theoretical OH···π enthalpy of -0.5 kcal mol^{-1}. If the equation found by Drago and Epley (5) relating OH···O and OH···N enthalpy changes and frequency shifts can be applied to OH···π systems, ΔH for the phenol–benzene adduct may be calculated to be -3.54 kcal mol^{-1} corresponding to the frequency shift for the adduct of 46 cm^{-1}. Oda, Yoshida, and Osawa (6) have reported spectrally determined free energy changes for the phenol–benzene system at 20 °C in CCl_4. However, these workers did not determine the free energy as a function of temperature and no enthalpy value could be found. The free energy change for unit concentration standard states found by these workers is 0.6 kcal mol^{-1} at 20 °C. These workers also report that a ΔH of -1.7 kcal mol^{-1} for the phenol–benzene complex was determined by Shimanouchi and Ikeda.

Experimental

Thiophene free reagent grade benzene was washed with sulfuric acid, followed by washings with water and dilute sodium hydroxide solution. After drying, benzene was

refluxed over LiAlH and fractionally distilled onto activated molecular sieves. The final distillation of benzene was carried out under a dry nitrogen atmosphere. The refractive index and boiling point were used as purity criteria.

Reagent grade carbon tetrachloride was refluxed over sodium hydroxide pellets and fractionally distilled onto P_2O_5, and after drying was fractionally distilled under dry nitrogen atmosphere. A chromatogram taken before and after purification showed the procedure eliminated major impurities. Refractive index and boiling point were used as criteria for purity.

Reagent grade phenol was fractionally distilled in a three foot spinning band column under reduced pressure. The middle cut of the distillate was taken. All reagents were stored in a dry atmosphere.

All spectra were recorded on the Beckmann DK-2A recording spectrophotometer using 1 cm Teflon stoppered cells. The fundamental hydroxyl stretching frequency, 3610 cm^{-1} was used for all measurements. The solvent was carbon tetrachloride and a mixture of benzene and carbon tetrachloride served as reference. The phenol concentrations ranged from 0.003 to 0.005 M and that of benzene was 2 M in all cases. The temperature of the system was controlled to within ±1 °C with the Beckmann temperature regulator. Corrections for the change in concentrations with temperature were made by determining the density of 2 M benzene – carbon tetrachloride mixtures over the temperature range of this work. A pycnometer was used for density determinations. The densities found were 1.4876, 1.4686, 1.4495, 1.4303, and 1.4112 g ml^{-1} at 20, 30, 40, 50, and 60 °C, respectively. It was found that at the benzene concentrations used in this study, the spectral slit opened appreciably over the wavelength range of interest. Thus the extinction coefficients determined for phenol in carbon tetrachloride could not be used as a measure of the free phenol present in the ternary solution when using the absorbance mode of the DK-2A. The opening of the slit causes the peak to broaden and hence the peak absorptivity decreases. Spectra of mixtures of phenol in 2 M cyclohexane – carbon tetrachloride showed considerably different peak absorbancies from phenol spectra in CCl_4. Cyclohexane was used because its transmission in this spectral region is similar to that of benzene yet cyclohexane does not bond to phenol. Thus the DK-2A was run as a single beam instrument operated on the energy mode using manual slits. When the energy mode was used, phenol–cyclohexane – carbon tetrachloride solutions were found to have the same molar absorptivities as solutions of phenol in CCl_4.

The equilibrium constants reported are the average of a maximum of 11 determinations at 20 °C and a minimum of six determinations at 60 °C. The concentration of free phenol in the equilibrium mixture was found by using Beer's law and the temperature dependent molar absorptivities reported previously (7). The concentration of the complex was found by subtracting the free phenol concentration from the analytical concentration of phenol.

Results

The pertinent thermodynamic information and the molar absorptivity for the hydroxyl stretch of phenol is given in Table 1 and the plot log K_c *vs.* $1/T$ is shown in Fig. 1.

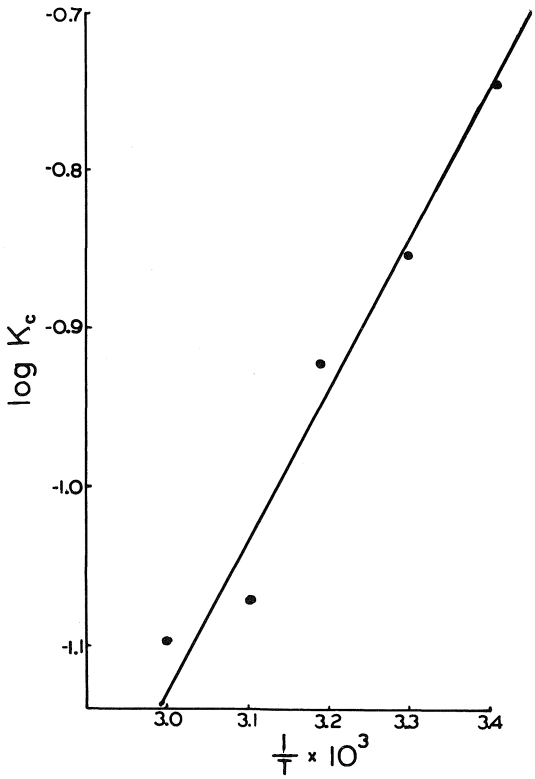

FIG. 1. Plot of log K_c *vs.* $1/T$.

The enthalpy change for the formation of the phenol–benzene OH···π bond of −4.1 kcal is larger than that previously reported (2, 6) and larger in general than the OH···π enthalpies reported for other systems. For the spectrophotometrically determined enthalpy, the discrepancy could arise from improper accounting of the effect of the temperature dependence of the molar absorptivity or neglect of the effect of changing slit width. Neglect of either of these factors could lead to apparently high free energy changes and low enthalpy changes.

The results of this work suggest that benzene is not a weak base for hydrogen bonding. Recent studies have shown that benzene is a sufficiently strong base to cause disruption of the intramolecular hydrogen bond in catechol, guaiacol, and sym-trichlorophenol (7).

Master Equation for the Dissociation of a Dilute Diatomic Gas. V. Effect of Energy-level Spacing

D. L. S. McElwain and H. O. Pritchard
Centre for Research in Experimental Space Science, York University, Downsview, Ontario

Received June 7, 1971

Our previous vibration–dissociation coupling calculations for H_2 have been repeated for D_2. Closer spacing of the vibrational energy levels in D_2 leads to increased translation–vibration transition probabilities, and the effect of this is to increase the rate of recombination by the vibrational mechanism at all temperatures. These numerical experiments also clarify two other issues: (*i*) that the position of the bottleneck does not necessarily occur at that level above which *direct* collisional dissociation can take place rapidly, and (*ii*) that there is no simple correspondence between the position of the bottleneck and the Arrhenius temperature coefficient for dissociation.

Nos calculs antérieurs de couplage vibration–dissociation pour H_2 ont été répétés pour D_2. L'espacement plus rapproché des niveaux d'énergie vibrationnelle dans D_2 conduit à un accroissement des probabilités de transition translation–vibration. Ceci a pour effet d'accroître la vitesse de recombinaison par le mécanisme vibrationnel à toutes les températures. Ces expériences numériques clarifient également deux autres issues (*i*) que la position du "bottleneck" n'arrive pas nécessairement à ce niveau au-dessus duquel la dissociation par collision *directe* peut avoir lieu rapidement et (*ii*) qu'il n'y a pas de correspondance simple entre la position du "bottleneck" et le coefficient de température d'Arrhénius pour la dissociation.

Canadian Journal of Chemistry, **49**, 3915 (1971)

In part III of this series (1),[1] the vibration–dissociation coupling relaxation equations were solved for H_2 at a series of temperatures, using a set of T–V transition probabilities given by eq. III (1). This equation gives an approximate prescription for the behavior of these transition probabilities as a function of the temperature and the energy gap between the levels; mass effects, except in-so-far as they enter through the diatomic vibrational characteristics, are ignored. A major drawback in our previous work, using H_2 as a model for the description of the dissociation of the general diatomic molecule, is that the vibrational energy level distribution is too sparse;

[1]Reference should be made to this and earlier papers for a full description of the details of these calculations.

Ceci a pour effet d'accroître la vitesse de recombinaison par le mécanisme vibrationnel à toutes les températures. Ces expériences numériques clarifient également deux autres issues (*i*) que la position du "bottleneck" n'arrive pas nécessairement à ce niveau au-dessus duquel la dissociation par collision *directe* peut avoir lieu rapidement et (*ii*) qu'il n'y a pas de correspondance simple entre la position du "bottleneck" et le coefficient de température d'Arrhénius pour la dissociation.

Canadian Journal of Chemistry, **49**, 3915 (1971)

In part III of this series (1),[1] the vibration–dissociation coupling relaxation equations were solved for H_2 at a series of temperatures, using a set of T–V transition probabilities given by eq. III (1). This equation gives an approximate prescription for the behavior of these transition probabilities as a function of the temperature and the energy gap between the levels; mass effects, except in-so-far as they enter through the diatomic vibrational characteristics, are ignored. A major drawback in our previous work, using H_2 as a model for the description of the dissociation of the general diatomic molecule, is that the vibrational energy level distribution is too sparse;

[1]Reference should be made to this and earlier papers for a full description of the details of these calculations.

molecules of interest have many more vibrational levels, and in this calculation we try to explore the likely effect of reducing the vibrational spacing[2] by repeating these calculations for D_2 which has 22 bound vibrational levels in the ground state (2) instead of the 15 in H_2.

The general pattern of behavior for D_2 at 2000 °K was very similar to that already described for H_2 at 2000 °K: an initial transient period lasting of the order of τ_{01}, the vibrational relaxation time, followed by a pseudo-steady period in which the states $v = 0$–11 were overpopulated and $v = 12$–21 were underpopulated; further, that the phenomenological rate constant and the smallest non-zero eigenvalue were related by the equation

$$d_{n-1} = -[\mathrm{M}]k_{\mathrm{d,M}}$$

as before (1). The changeover from over- to under-population occurring at $v = 11$ in D_2 is about 10 200 cm^{-1} below the dissociation limit, in contrast to the changeover at $v = 9$ in H_2, only 7000 cm^{-1} below the limit; thus it seems that, to the extent that this changeover is an indication of the presence of a bottleneck (1), the bottleneck is lower down in D_2 than in H_2. Consequently, we investigated the position of the bottleneck using our criterion (1, 3) of finding the nearest-neighbor transition to which the dissociation rate is the most sensitive. This is illustrated in Table 1, placing the bottleneck at the transition $v = 15 \leftrightarrow 16$, about 5400 cm^{-1} below the dissociation limit. In H_2, the bottleneck appeared (1, 3) to be at the transition $v = 11 \leftrightarrow 12$, about 3200 cm^{-1} below the dissociation limit, and Bauer observed (4) that this could have been due to the fact that the specific rates for direct dissociation were only significant for levels $v = 12$, 13, and 14. Since the transition probabilities used in the present calculation have the same dependence on the energy separation, the D_2 results show that the position of the bottleneck is not determined solely by whether or not there is a rapid direct dissociation channel from the levels concerned; the position of the bottleneck is determined co-operatively by much more complex factors, as we have already described (3).

[2]The wider issue of the interleaving of these vibrational states by rotational substates presents a much more severe computational problem, and work on the general rotation vibration–dissociation problem is in progress; however, at shock-tube temperatures, it is generally held that only vibration–dissociation coupling need be considered.

TABLE 1. Characterization of the bottleneck by perturbation of nearest neighbor transition probabilities. Data refer to D_2 at 2000 °K, where the standard set of transition probabilities gives $-100\,d_{n-1} = 5.757$; in this table, each transition in turn is decreased by a factor of 100

Perturbed transition	$-100\,d_{n-1}$
$7 \leftrightarrow 8$	5.737
$8 \leftrightarrow 9$	5.698
$9 \leftrightarrow 10$	5.605
$10 \leftrightarrow 11$	5.413
$11 \leftrightarrow 12$	5.087
$12 \leftrightarrow 13$	4.646
$13 \leftrightarrow 14$	4.190
$14 \leftrightarrow 15$	3.862
$15 \leftrightarrow 16$	3.804
$16 \leftrightarrow 17$	4.170
$17 \leftrightarrow 18$	4.950
$18 \leftrightarrow 19$	5.540
$19 \leftrightarrow 20$	5.717
$20 \leftrightarrow 21$	5.753

The rate of dissociation or recombination was determined as before (1) for three temperatures, 300, 1500, and 2000 °K, and the results are presented in Table 2. The following conclusions emerge.

(*i*) That at high temperatures, D_2 dissociates faster than does H_2, despite the fact that it has a slightly greater ΔE for dissociation (105.1 kcal/mol as opposed to 103.2 kcal/mol). This arises because the T–V transition probabilities fall off with increasing energy separation between the levels, and it is easier to make rapid progress in a lot of small jumps than in a few big ones; thus, as the spacings between the levels become infinitesimally small, the dissociation rate constant will approach a limit (5) of the order of a collision rate times the Boltzmann factor $\exp(-\Delta E/RT)$. Relatively few studies (6, 7) have been made on the rate of dissociation of D_2, and only in one case (7) have H_2 and D_2 been studied in the same shock tube: this was the work of Sutton, which covered the temperature range 2800–4500 °K. A relatively short extrapolation of his data to 2000 °K gives recombination rate constants for D_2 and H_2, respectively, as 4.0×10^{14} and 3.2×10^{14} mol^{-2} cm^6 s^{-1}, *i.e.* $k_r^{D_2}/k_r^{H_2} \approx 1.25$, with argon as third body. Thus, on the basis of the relatively scant evidence that exists, our conclusion that both the dissociation and recombination rates are faster for D_2 than for H_2 seems reasonable.

(*ii*) In contrast, our results for 300 °K are in direct conflict with a very substantial body of

TABLE 2. Comparison of dissociation and recombination rate constants for D_2 and H_2*

Parameter	Value at 300 °K	Value at 1500 °K	Value at 2000 °K	Unit
$K_c^{H_2}$	4.292×10^{-52}	1.630×10^{9}	9.610×10^{12}	molecules cm^{-3}
$K_c^{D_2}$	3.093×10^{-53}	1.140×10^{9}	8.173×10^{12}	molecules cm^{-3}
$K_c^{D_2}/K_c^{H_2}$	0.072	0.700	0.850	
$k_d^{H_2}$	(2.27×10^{-85})	2.516×10^{-25}	1.248×10^{-21}	molecule^{-1} cm^3 s^{-1}
$k_d^{D_2}$	(2.31×10^{-86})	2.918×10^{-25}	1.645×10^{-21}	molecule^{-1} cm^3 s^{-1}
$k_d^{D_2}/k_d^{H_2}$	0.10	1.16	1.32	
$k_r^{H_2}$	5.301×10^{-34}	1.544×10^{-34}	1.299×10^{-34}	molecule^{-2} cm^6 s^{-1}
$k_r^{D_2}$	7.469×10^{-34}	2.559×10^{-34}	2.013×10^{-34}	molecule^{-2} cm^6 s^{-1}
$k_r^{D_2}/k_r^{H_2}$	1.41	1.66	1.55	

*Values in parentheses are estimated values.

data (8–10) which shows unambiguously that H_2 recombines faster than does D_2 at 300 °K. It is believed (11, 12) that at these temperatures, recombination takes place by a rotational rather than a vibrational mechanism, and we hope to throw some light on this supposition in future work;[2] more instructive, however, would be a series of experiments between 300 and 2800 °K to detect the changeover in the ratio of $k_r^{D_2}/k_r^{H_2}$ from less-than to greater-than unity.

(*iii*) Comparison of the dissociation rates at 1500 and 2000 °K shows that the Arrhenius temperature coefficients for dissociation are D_2: 103.0 kcal/mol; H_2: 101.4 kcal/mol; *i.e.* in both cases approximately 2 kcal/mol below the spectroscopic dissociation energy. The idea that the observed Arrhenius temperature coefficient should give an indication of the position of the rate-determining step in the dissociation process has some supporters (1), but based on a visual criterion, the bottlenecks are placed at 76.0 and 83.3 kcal, respectively; alternatively, based on our criterion, such as is illustrated in Table 1, the bottlenecks are placed at 93.3 and 98.1 kcal, respectively. Clearly there is no correspondence between the Arrhenius temperature coefficient and the position of the bottleneck.

A Complex Ion Model for Molten Halides

A. D. PELTON[1]

Department of Metallurgy and Materials Science, University of Toronto, Toronto 181, Ontario

Received May 28, 1971

The formation of complex anions in molten halide systems is treated semi-quantitatively by a discrete complex anion model. The treatment is a more general application and extension of an approach reported previously by the author. By assuming the existence of discrete MY_4^{2-} tetrahalo complex anions, the model gives good agreement to experimental enthalpies and entropies of mixing and electrical conductivities in a large number of different halide systems of the general formula MY_2–AY, where M is a divalent metal, and A is an alkali. Very few adjustable parameters are required. The parameters provide semi-quantitative basicity (or acidity) scales by which molten salts and slags may be classified. The relationships of these basicity scales to ionic radii, ligand field stabilization energies, etc. are shown. General thermodynamic and mathematical aspects of the problem of complexing are discussed, particularly as regards the proper method of calculating the degree of dissociation of the complexes.

Nous avons traité de la formation d'anions complexes dans les systèmes d'halogénures fondus de façon semi-quantitative en utilisant un modèle discontinu d'anion complexe. Le traitement est une application plus générale et une extension d'une approche rapportée précédemment par l'auteur. En supposant l'existence d'anions complexes tétrahalo discontinus MY_4^{2-}, le modèle est en accord avec les enthalpies et les entropies de mélange expérimentales et les conductivités électriques pour un grand nombre de différents systèmes d'halogénures de formule générale MY_2–AY, où M est un métal divalent et A est un alcalin. Très peu de paramètres ajustables sont requis. Les paramètres fournissent des échelles semi-quantitatives de basicité (ou d'acidité) au moyen desquelles les sels fondus et les scories peuvent être classifiés. On montre les relations entre le rayon ionique, les énergies de stabilisation du champ de ligand, etc. et ces échelles de basicité. On discute aussi de la thermodynamique générale et des aspects mathématiques du problème de la formation de complexe, particulièrement en ce qui concerne la méthode appropriée pour calculer le degré de dissociation des complexes.

Canadian Journal of Chemistry, **49**, 3919 (1971)

Introduction

The concept of complex ion formation in molten salts and slags has been the subject of much recent interest. The halides, MY_2, of many divalent metals, for instance, appear to form tetrahedral anionic complexes, MY_4^{2-}, when dissolved in alkali halides. From phase diagram calculations, Lumsden (1) has shown that solutions of up to about 30 mol% of MCl_2 (where M = Mn, Mg, Fe, Zn) in KCl can be treated as ideal Temkin solutions of K^+ cations, Cl^- anions, and the complex anions MCl_4^{2-}; and similarly, solutions of up to about 20 mol% MF_2 (where M = Mn, Fe, Co, Ni, Zn, Mg, Be) in NaF can be treated as containing only Na^+, F^-, and MF_4^{2-} ions. This evidence of MY_4^{2-} anions from phase diagram calculations was first noted by Flood and Urnes (2) for the $MgCl_2$ – alkali chloride systems.

Kleppa and McCarty (3) measured enthalpies of mixing in the $MgCl_2$–ACl (where A = alkali) systems. Østvold (4) made e.m.f. measurements in these systems using glass membrane cells. By combining these data with the enthalpy data, he calculated entropies of mixing. These authors showed that their data gave evidence of tetrahedral $MgCl_4^{2-}$ complex anions. They also showed that as the alkali cation A^+ is changed

TABLE 1. Moles of ionic species per overall mole of solution

Ion	Complete complexing		Partial dissociation
	$X_{MY_2} \leqslant 1/3$	$X_{MY_2} \geqslant 1/3$	
M^{2+}	0	$X_{MY_2} - (2X_{MY_2} + X_{AY})/4$	$X_{MY_2}(1 - \alpha/2)$
A^+	X_{AY}	X_{AY}	X_{AY}
MY_4^{2-}	X_{MY_2}	$(2X_{MY_2} + X_{AY})/4$	$\alpha X_{MY_2}/2$
Y^-	$(X_{AY} - 2X_{MY_2})$	0	$X_{AY} + 2X_{MY_2}(1 - \alpha)$ $= (1 + X_{MY_2} - 2\alpha X_{MY_2})$
Total positive ions	X_{AY}	$(3 - X_{MY_2})/4$	$(1 - \alpha X_{MY_2}/2)$
Total negative ions	$(X_{AY} - X_{MY_2})$	$(2X_{MY_2} + X_{AY})/4$	$(1 + X_{MY_2} - 3\alpha X_{MY_2}/2)$

up the periodic table from Cs^+ to Li^+, there is apparently an increasing tendency for the complexes to dissociate into Mg^{2+} and Cl^- ions.

Pelton and Thompson (5) proposed a "discrete complex anion model", based upon the assumption of MY_4^{2-} complex anions, to account semi-quantitatively for the data in the $MgCl_2$–ACl systems. Recently, a great amount of new experimental data on halide systems of the general formulae MY_2–AY (where M = Mn, Fe, Ni, etc., and A = alkali) has become available. In the present publication, these new data will be discussed, and the applicability of the discrete complex anion model will be examined with regard to all presently available data. The basic premises of the model will also be discussed in more detail than previously (5).

A minimum of adjustable parameters is used in the model. It will be shown that these parameters provide semi-quantitative "basicity scales" for a variety of molten salts and slags. The relationship of these basicity scales to ionic radii, ligand field energies, etc. will be discussed.

Discrete Complex Anion Model, Complete Complexing

The limiting case of "complete complexing", in which dissociation of the complexes is not considered, will be discussed first. The assumption of complete complexing is, of course, thermodynamically incorrect since, as will become clear later, this assumption is inconsistent with the minimization of the free energy of the system. Partial dissociation of the complexes must occur to some greater or lesser degree. An initial examination of the simple limiting case of complete complexing will, however, make the basic physical ideas of the model much clearer than if a discussion of the complete model with partial dissociation were begun immediately.

For a molten system MY_2–AY, let X_{MY_2} and X_{AY} be the overall mole fractions of the two components. It is assumed that the only complex ions formed are the tetrahedral anions MY_4^{2-}. For $X_{MY_2} \leqslant 1/3$, and assuming complete complexing, all the M is complexed, and only the three ionic species A^+, Y^-, and MY_4^{2-} exist. The amounts of the various species in solution in this case are given in column 2 of Table 1. At $X_{MY_2} = 1/3$, only the two species A^+ and MY_4^{2-} exist, and this composition corresponds to the liquid "compound" A_2MY_4. For $X_{MY_2} \geqslant 1/3$, every M can be "complexed" only if the MY_4 tetrahedra share corners or edges through "Y-bridges". In the discrete complex anion model it is assumed that this does not happen. Discrete MY_4^{2-} anions form until all Y species are used up. The remaining M species are not preferentially bonded to any fixed number of Y's, and, for the purposes of statistical calculations, exist as independent M^{2+} cations. This assumption of two environments for an M species is taken to hold true for all compositions up to and including pure MY_2. One mole of pure MY_2, for the case of complete complexing, is considered to contain one half mole of M^{2+} cations and one half mole of MY_4^{2-} anions. This assumption will be examined later in the discussion on polymeric liquids.

The amounts of the various ionic species in solution for $X_{MY_2} \geqslant 1/3$ are given in column 3 of Table 1.

The solutions are assumed to be ideal Temkin (6) solutions of the cations A^+ and M^{2+} and of the anions Y^- and MY_4^{2-}. Of course, for the case of complete complexing, no more than three types of ions exist simultaneously.

Enthalpies

Consider the formation of a complex according to

[1] $$M^{2+} + 4Y^- \rightarrow MY_4^{2-}$$

Let the molar energy change for this process be b_1, and assume for the moment that b_1 is independent of concentration. An enthalpy of mixing term of the following form will then result due to the increase in the number of complexes which occurs when the pure components are mixed. (X_{MY_2} moles of pure MY_2 contain $X_{MY_2}/2$ moles of complexes.)

$$[2] \quad \Delta H = X_{MY_2} b_1 - \frac{X_{MY_2}}{2} b_1 = \frac{X_{MY_2}}{2} b_1 \qquad [X_{MY_2} \leqslant 1/3]$$

$$[3] \quad \Delta H = \left(\frac{2X_{MY_2} + X_{AY}}{4}\right) b_1 - \frac{X_{MY_2}}{2} b_1 = \frac{X_{AY}}{4} b_1 \qquad [X_{MY_2} \geqslant 1/3]$$

where ΔH is the molar enthalpy of mixing of X_{MY_2} moles of MY_2 and X_{AY} moles of AY. The resulting plot of ΔH *vs.* composition is shown as the upper curve in Fig. 1*a*, and is the form of a sharp peak, peaking at $X_{MY_2} = 1/3$, which is the "compound composition". This is, of course, the typical sort of curve expected for a system showing "compound formation".

The "interaction parameter" λ, defined as $\lambda = \Delta H / X_{MY_2} X_{AY}$, will have the general shape shown in Fig. 1*b*, with a pronounced "dip" at $X_{MY_2} = 1/3$ (taking b_1 to be negative).

In Figs. 2–7, the heavy lines are plots of λ for various chloride systems of the formulae MCl_2–ACl, (where A = alkali, and M = Co, Fe, Ni, Mn, Mg, Cd, Pb), as obtained calorimetrically by Papatheodorou and Kleppa (7–9), and McCarty and Kleppa (3, 10). These authors qualitatively explain the prominent dip at $X_{MCl_2} = 1/3$ in these systems along lines similar to that just discussed.

In any one of Figs. 2–7 it can be seen that for any set of systems MCl_2–ACl, λ becomes progressively less negative as A is changed up the periodic table from Cs to Li, and at the same time the dip at $X_{MY_2} = 1/3$ becomes progressively less prominent. This suggests, as discussed by McCarty and Kleppa (3, 10) and by Papatheodorou and Kleppa (7, 8), firstly that the complexes become weaker as A is changed from Cs to Li, and secondly that dissociation occurs in the less strongly complexed systems.

In the present model, the energy of formation of a complex may be taken to depend upon the environment in which it is formed. For the formation of complexes which are totally surrounded by M^{2+} cations (as in pure MY_2), let the molar energy of reaction 1 be Δe_1. For the formation of complexes which are totally surrounded by A^+ cations (as at infinite dilution in AY), let the molar energy change of reaction 1 be Δe_2. In the MCl_2–ACl systems, if A^+ is a large cation like Cs^+ with a low field strength and, therefore, good ligand donor properties, it would be expected that $\Delta e_2 < \Delta e_1$. If A^+ is a small cation like Li^+ with a high field strength, then Δe_2 would be much less negative, and could be approximately equal to or greater than Δe_1. For the general case, the energy of formation, Δe, of a mole of complex ions according to reaction 1 is taken to vary between Δe_1 and Δe_2 depending upon the cationic fractions, $N_{M^{2+}}$ and N_{A^+}, of the two cations in its first coordination shell. As a first approximation, a linear variation is assumed. That is

$$[4] \qquad \Delta e = (N_{M^{2+}} \Delta e_1 + N_{A^+} \Delta e_2)$$

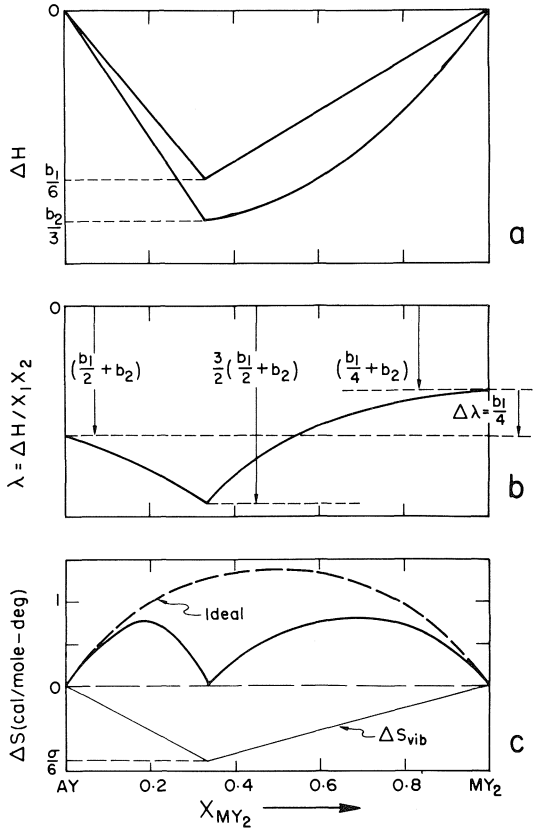

FIG. 1 (*a*) Enthalpies of mixing for complete complexing (eqs. 7 and 8). (*b*) Interaction parameter for discrete complex anion model for complete complexing. (*c*) Entropies of mixing for models.

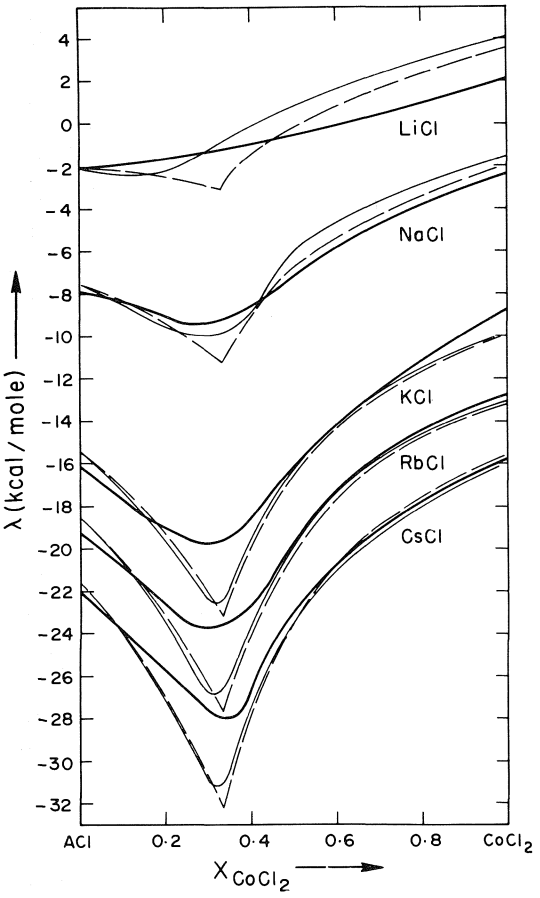

FIG. 2. Interaction parameters in $CoCl_2$–ACl systems ——— Experimental (8). - - - From model for complete complexing. ——— From model for partial dissociation.

Since the pressure–volume work of mixing is negligible, the molar enthalpy of mixing, ΔH, may be taken to be equal to the change in internal energy on mixing. Still under the assumption of complete complexing, that part of the enthalpy of mixing resulting from complex formation is now given by

$$[5]\quad \Delta H = X_{MY_2}\Delta e - \frac{X_{MY_2}}{2}\Delta e_1 \qquad [X_{MY_2} \leqslant 1/3]$$

$$[6]\quad \Delta H = \left(\frac{2X_{MY_2} + X_{AY}}{4}\right)\Delta e - \frac{X_{MY_2}}{2}\Delta e_1 \qquad [X_{MY_2} \geqslant 1/3]$$

where Δe is given by eq. 4. For $X_{MY_2} \leqslant 1/3$, $N_{A^+} = 1$, and $N_{M^{2+}} = 0$. For $X_{MY_2} \geqslant 1/3$, N_{A^+}

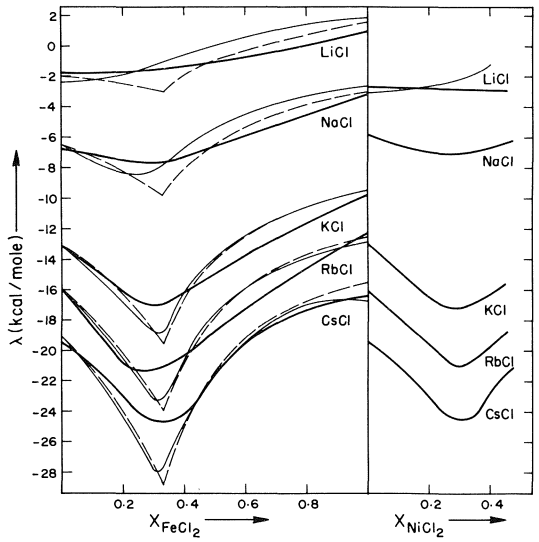

FIG. 3. Interaction parameters in $FeCl_2$–ACl and $NiCl_2$–ACl systems. ——— Experimental (7, 8). - - - From model for complete complexing. ——— From model for partial dissociation.

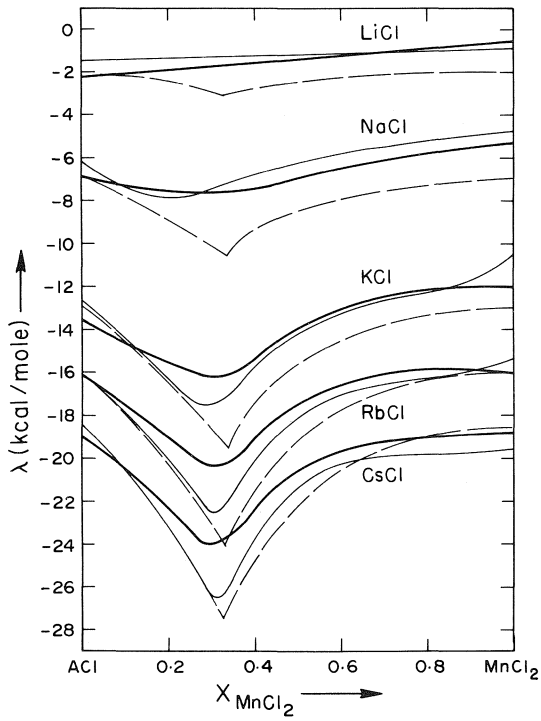

FIG. 4. Interaction parameters in $MnCl_2$–ACl systems. ——— Experimental (8). - - - From model for complete complexing. ——— From model for partial dissociation.

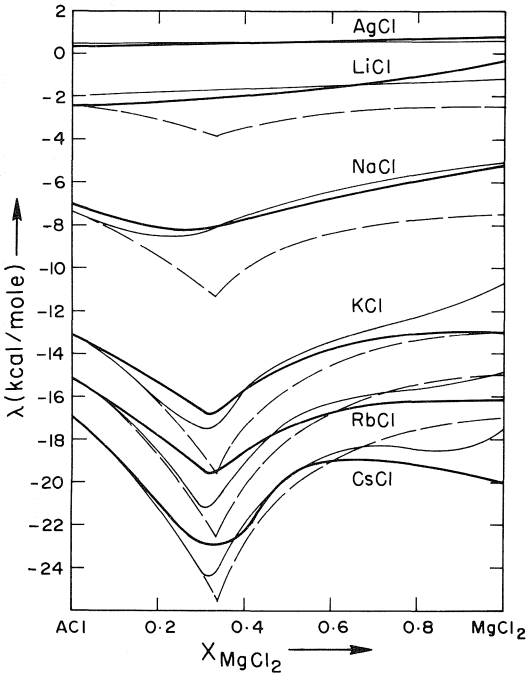

FIG. 5. Interaction parameters in $MgCl_2$–ACl systems. ——— Experimental (3). - - - From model for complete complexing. ——— From model for partial dissociation.

$= 4X_{AY}/(3 - X_{MY_2})$, and $N_{M^{2+}} = (1 - N_{A^+})$ (see Table 1). Making the substitutions in eqs. 5 and 6 and simplifying, the following equations for the case of complete complexing result

$$[7] \quad \Delta H = \frac{X_{MY_2}}{2} b_1 + X_{MY_2} b_2 \qquad [X_{MY_2} \leqslant 1/3]$$

$$[8] \quad \Delta H = \frac{X_{AY}}{4} b_1 + \frac{X_{AY}(1 + X_{MY_2})}{(3 - X_{MY_2})} b_2 \qquad [X_{MY_2} \geqslant 1/3]$$

where b_1 and b_2 are defined as

$$[9] \quad b_1 = \Delta e_1$$

$$[10] \quad b_2 = (\Delta e_2 - \Delta e_1)$$

The parameter b_1 is independent of concentration, and is a property only of the salt MY_2. It is independent of the particular MY_2–AY system. The parameter b_2 has one concentration-independent value for each MY_2–AY system. The first terms in eqs. 7 and 8 are the same as eqs. 2 and 3. The final terms in eqs. 7 and 8 give the strengthening (or weakening) effect of the A^+ ions on the complexes, and these terms are shown as the lower curve in Fig. 1*a* (b_2 is taken to be negative in Fig. 1*a*).

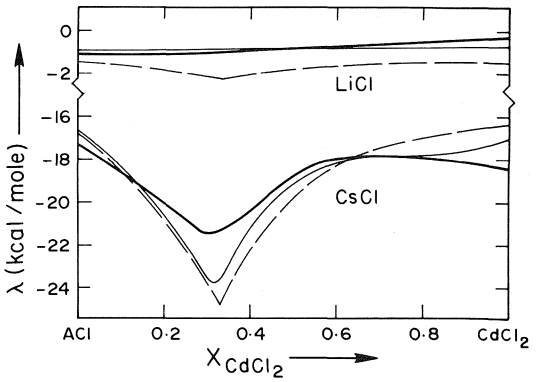

FIG. 6. Interaction parameters in $CdCl_2$–ACl systems. ——— Experimental (9). - - - From model for complete complexing. ——— From model for partial dissociation.

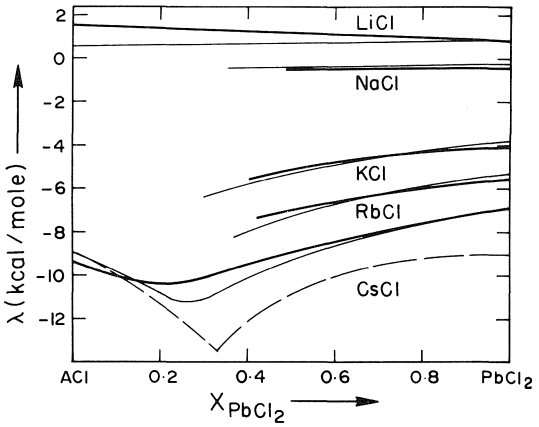

FIG. 7. Interaction parameters in $PbCl_2$–ACl systems. ——— Experimental (10). - - - From model for complete complexing. ——— From model for partial dissociation.

The overall interaction parameter which results from the combination of both enthalpy terms is shown in Fig. 1*b*. Let $\lambda_{X=1}$ and $\lambda_{X=0}$ be the values of λ when $X_{MY_2} = 1$ and $X_{MY_2} = 0$, respectively, and let $\Delta\lambda = (\lambda_{X=0} - \lambda_{X=1})$. From Fig. 1*b* it can be seen that $\Delta\lambda = b_1/4$. $\Delta\lambda$ should thus depend only on the salt MY_2, and should be constant within a group of MY_2–AY systems for a given salt MY_2. Furthermore, from the experimental value of $\Delta\lambda$, b_1 can be numerically estimated. The greater is the tendency of a salt MY_2 to form complexes, the more negative should be $\Delta\lambda$.

*$\Delta e_2 = b_1 + b_2$ (as in eqs. 9 and 10).

For the $CoCl_2$–ACl (8) systems in Fig. 2, $\Delta\lambda$ averages about −5.5 kcal for all the systems. The value of b_1 for $CoCl_2$ was thus taken to be −22 kcal. A value of b_2 for each individual system was then chosen to give the best fits (determined "by eye") to the data. Values of b_2 are listed in Table 2, and the fits obtained for the case of complete complexing (using eqs. 7 and 8) are shown as the dashed lines in Fig. 2. The fits appear to be quite good in all but the system with LiCl. The calculated "dip" at $X_{CoCl_2} = 1/3$ is, however, somewhat too sharp in all cases.

For the $FeCl_2$–ACl (8) systems in Fig. 3, $\Delta\lambda$ averages about −3.5 kcal for all systems. The value of b_1 for $FeCl_2$ was thus taken to be −14 kcal. The b_2 values which were chosen to give the best fits are listed in Table 2. These fits are shown in Fig. 3 as the dashed lines. The agreement is reasonable, but in the systems with LiCl and NaCl there is strong evidence for dissociation. For the $NiCl_2$–ACl systems in Fig. 3, measurements have been made (7) only over to $X_{NiCl_2} = 0.5$. The values of λ, however, are almost exactly the same at all concentrations as the values for the corresponding $FeCl_2$ systems, and so the same values of b_1 and b_2 were chosen for the $NiCl_2$ systems as for the $FeCl_2$ systems, except for the systems with LiCl, in which slightly different b_2 values were chosen in the two cases.

For the $MnCl_2$–ACl (8), $MgCl_2$–ACl (3), and $CdCl_2$–ACl (9) systems in Figs. 4–6, $\Delta\lambda$ is approximately zero for all the systems with KCl, RbCl, and CsCl (except for the $MgCl_2$–CsCl system in which $\Delta\lambda$ is actually quite positive). For the sys-

For personal use only.

tems with NaCl and LiCl, $\Delta\lambda$ is somewhat negative, but, as shown later, this is thought to result from dissociation of the complexes. A value of $b_1 = 0.0$ was chosen for all these systems. As shown in Figs. 4–6, this results in reasonable agreement with the experimental data. The values of b_2 used are listed in Table 2.

In these less strongly complexed systems ($b_1 = 0$), the evidence for dissociation of the complexes is very strong in the systems with LiCl and NaCl, and is evident in the systems with KCl also.

For the $MgCl_2$ systems, enthalpies for the system $MgCl_2$–AgCl are available (3), and are shown in Fig. 5. This system is best fitted with $b_2 = +1.5$ kcal. The positive value may result from the fact that Ag has a tendency to form covalent bonds with chlorine and thus has a strong tendency to weaken and break up the complexes.

In the previous publication (5), a value of $b_1 = -3.0$ kcal was chosen to fit the $MgCl_2$ systems. The difference between this and the present value of 0.0 is small enough to make very little difference in the calculated curves.

For the $PbCl_2$–ACl systems (10) in Fig. 7, a value of $b_1 = 0.0$ and values of b_2 as listed in Table 2 were used. These parameters do not give good fits for the case of complete complexing, as can be seen from the dashed line for the $PbCl_2$–CsCl system in Fig. 7. However, as will be discussed later, these values do appear to give good fits when dissociation is taken into account. In the $PbCl_2$ systems there is evidence for dissociation even in the system with CsCl.

In Fig. 8*a* are plotted, as the heavy solid lines, ΔH curves for the BeF_2–LiF and BeF_2–KF systems as obtained calorimetrically by Holm and Kleppa (11). For the BeF_2–LiF system, ΔH is negative for small X_{BeF_2} and positive for large X_{BeF_2}. A plot of λ for this system is shown in Fig. 8*b*, and is of the general shape predicted by the present model. A value of $b_1 = -50$ kcal for BeF_2 gives a good fit to $\Delta\lambda$ for this system. This means that BeF_2 has a very strong tendency to form tetrahedral complexes. With a value of $b_2 = +20$ kcal for the BeF_2–LiF system, the curves calculated for complete complexing are shown as the dashed lines in Figs. 8*a*, *b*. Quite good agreement is obtained. For the BeF_2–KF system, a value of $b_2 = 0.0$ was chosen.

By comparing the fits to ΔH in Fig. 8*a* with the same fits to λ in Fig. 8*b*, it can be appreciated how small discrepancies in agreement between experimental and calculated values of ΔH are greatly magnified in the "interaction parameter" plots. This effect is particularly pronounced near the ends of the curves, as is readily seen in the curves for the BeF_2–KF system. A discrepancy between experimental and calculated values of 1.0 kcal at $X_{MY_2} = 0.9$, say, is magnified to a discrepancy of about 11.0 kcal in the plots of λ. For the chloride systems discussed previously, the interaction parameter plots of Figs. 2–7 similarly magnify discrepancies. The agreement between experiment and model in absolute values of ΔH would be more readily apparent in plots of ΔH than in the plots of λ. However, the important shape factors (the extent of the "dip" at $X_{MY_2} = 1/3$, the value of "$\Delta\lambda$", etc.) can only be seen in plots of λ.

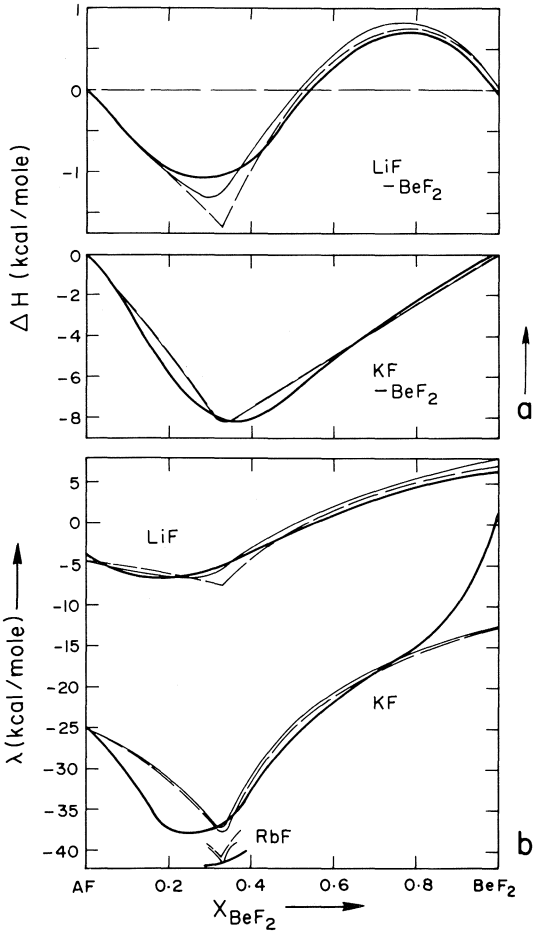

FIG. 8. Enthalpies and interaction parameters in BeF_2–AF systems. ——— Experimental (11). - - - From model for complete complexing. ——— From model for partial dissociation.

Of course, because of evidence of viscosities, electrical conductivities, etc., molten BeF_2 is generally accepted as being polymeric in nature, with BeF_4 tetrahedra sharing corners, and the assumption of discrete BeF_4^{2-} anions and Be^{2+} cations in pure BeF_2 as required by the present model is undoubtedly incorrect. This matter will be discussed at somewhat greater length later. Nevertheless, the very simple model just discussed can give surprisingly good agreement to the enthalpy of mixing data. In particular, for the BeF_2–LiF system, the existence of positive ΔH values in the BeF_2-rich concentration range, and negative values in the LiF-rich range is quite simply treated.

Entropies

The configurational entropy of mixing under the assumption of complete complexing is calculated as follows. For $X_{MY_2} \leqslant 1/3$, there is only one type of cation, A^+. The configurational entropy is then calculated by assuming a random mixture of the MY_4^{2-} and Y^- anions over $(X_{AY} - X_{MY_2})$ anion sites. For $X_{MY_2} \geqslant 1/3$, only one type of anion, MY_4^{2-}, exists, and a random mixture of the A^+ and M^{2+} cations over the $(3 - X_{MY_2})/4$ cation sites is assumed. At $X_{MY_2} = 1/3$, only A^+ cations and MY_4^{2-} anions exist and the configurational entropy is zero. Pure MY_2 contains only M^{2+} cations and MY_4^{2-} anions, and so has zero configurational entropy.

The molar configurational entropy of mixing, ΔS, is shown in Fig. 1*c* as the curve with two "humps". This is the typical sort of curve expected if the "compound" A_2MY_4 is formed, as has been discussed by Østvold (4) and by Østvold and Kleppa (12). The ideal (Raoultian) entropy of mixing is also shown in Fig. 1*c*.

Experimental partial molar entropies of mixing, $\Delta\bar{S}_{ACl}$, of ACl in the $MgCl_2$–ACl systems are shown in Fig. 9. These curves were obtained by Østvold (4), who measured the e.m.f. of concentration cells with glass membranes and combined his data with the partial enthalpies calculated from the calorimetric data (3). The ideal partial entropies, $-R \ln X_{ACl}$, are also shown in Fig. 9. The experimental curves show positive deviations from ideality for solutions concentrated in ACl, and then, near $X_{MgCl_2} = 1/3$, there is a rapid change to negative deviations. From the integral entropy of mixing curve in Fig. 1*c* it can be appreciated that this is qualitatively the predicted

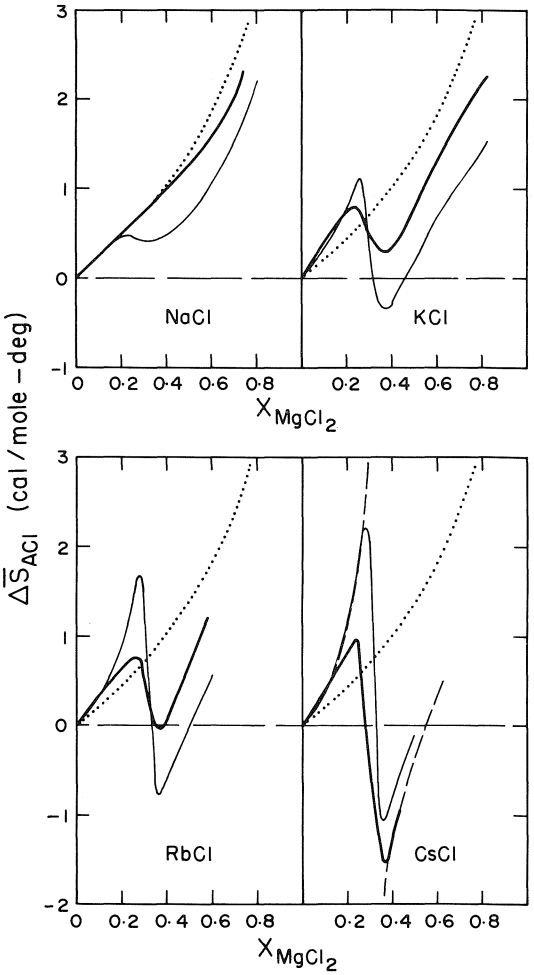

FIG. 9. Partial molar entropies of mixing of alkali chloride in $MgCl_2$–ACl systems. ——— Experimental (4). - - - From model for complete complexing. ———— From model for partial dissociation. ···· Ideal (Raoultian).

behavior of the partial entropy. In Fig. 9, in the graph for the system with CsCl, the dashed line is $\Delta\bar{S}_{ACl}$ as calculated for complete complexing. The predicted effect at $X_{MgCl_2} = 1/3$ is, of course, too drastic. As the A^+ cations become smaller, the experimentally observed effect at $X_{MgCl_2} = 1/3$ becomes less and less pronounced, again suggesting, as discussed by Østvold (4), that dissociation of the complexes occurs.

In Fig. 10 are partial excess entropies of mixing of $MnCl_2$, $\Delta\bar{S}^E_{MnCl_2}$, in $MnCl_2$–ACl systems, as calculated by Kucharski and Flengas (13) from the temperature dependences of the e.m.f.s of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

formation cells, The dashed line in the graph for the system with CsCl is the curve predicted from the model for complete complexing. Positive values of $\Delta\bar{S}^{E}_{MnCl_2}$ are predicted for $X_{MnCl_2} > 1/3$, with a sudden change to negative values for $X_{MnCl_2} < 1/3$. This is in quite good agreement with the experimental curve for the $MnCl_2$–CsCl system. For smaller alkali cations, the experimentally observed effect at $X_{MnCl_2} = 1/3$ becomes less and less pronounced, again suggesting that dissociation of the complexes occurs.

Kucharski and Flengas (13) discussed the results in Fig. 10 using a similar model which was based upon the assumption of $MnCl_4^{2-}$ complexes, and which assumed complete complexing. They also included an additional term to account for vibrational entropy effects.

Discrete Complex Anion Model, Partial Dissociation

A complete discussion of the treatment of partial dissociation in the discrete complex anion model has been given previously (5).

Reaction 1 is not displaced completely to the right as was assumed in the case of complete complexing, and instead, an equilibrium is set up, with a fraction ($\alpha/2$) of the total M existing in MY_4^{2-} anionic complexes, and a fraction ($1 - \alpha/2$) existing, for the purposes of statistical calculations, as free M^{2+} cations. The amounts of the various ionic species in a mole of solution are given as functions of α in column 4 of Table 1.

Let α_{max} be the maximum permissible value of α. For $X_{MY_2} \leqslant 1/3$, $\alpha_{max} = 2$, and is that value of α for which all M is complexed. For $\alpha = 2$, column 4 of Table 1 reduces to column 2. For $X_{MY_2} \geqslant 1/3$, $\alpha_{max} = (1 + X_{MY_2})/2X_{MY_2}$, and is that value of α (see ref. 5) for which all the Y is complexed. With $\alpha = (1 + X_{MY_2})/2X_{MY_2}$, column 4 of Table 1 reduces to column 3. For $X_{MY_2} = 1$, for instance, $\alpha_{max} = 1$, and one half of the M is complexed when complete complexing occurs in pure MY_2.

The molar configurational entropy, S, of the solution at any composition is written by assuming a Temkin solution of M^{2+} and A^{+} cations and of Y^{-} and MY_4^{2-} anions. This gives S as a function of α and of composition, $S(\alpha,X)$.

Self-association of pure MY_2 must also be considered. The fact that no such model for complexing in molten salts can be thermodynamically consistent without the consideration of self-association of the pure components was first pointed out by Braunstein (14). If α^0 is the value of α in pure MY_2, then $S^0_{MY_2}$, the molar configurational entropy of pure MY_2, may be written as a function of α^0, $S^0_{MY_2}(\alpha^0)$, assuming a Temkin solution of the three ionic species M^{2+}, MY_4^{2-}, and Y^{-}. For $\alpha^0 = \alpha^0_{max} = 1$, for instance, complete complexing occurs. In this case there are only M^{2+} and MY_4^{2-} species in pure MY_2, and $S^0_{MY_2} = 0$ as discussed earlier.

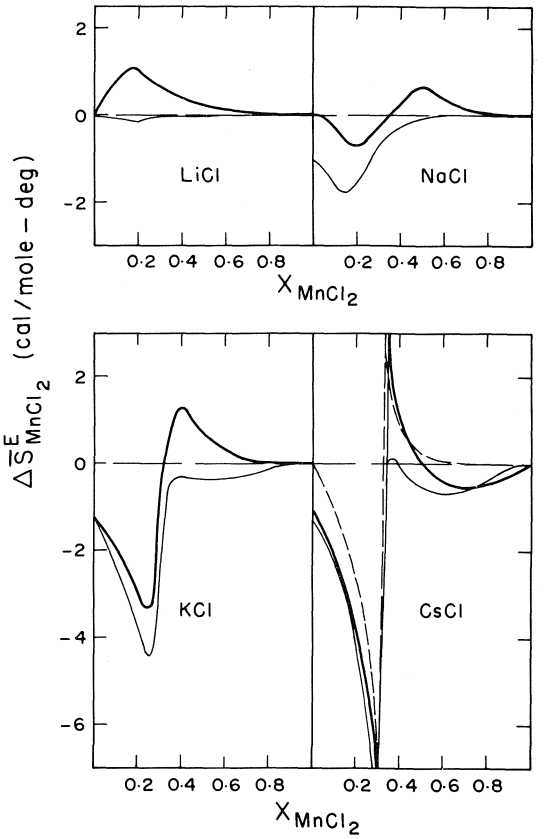

FIG. 10. Partial molar excess entropies of mixing of $MnCl_2$ in $MnCl_2$–ACl systems. ——— Experimental (13). - - - From model for complete complexing. ——— From model for partial dissociation.

The configurational entropy, S^0_{AY}, of pure AY is zero, and so the molar configurational entropy of mixing, ΔS, is given as a function of α, α^0, and composition

$$[11] \quad \Delta S(\alpha,\alpha^0,X) = S(\alpha,X) - X_{MY_2}S^0_{MY_2}(\alpha^0)$$

The explicit function has been given previously (5). For complete complexing, with $\alpha = \alpha_{max}$ and $\alpha^0 = 1$, the equation for ΔS reduces to the curve

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in Fig. 1*c* for complete complexing. For $\alpha = 0$ and $\alpha^0 = 0$, the equation for ΔS reduces to the ideal (Raoultian) entropy of mixing expression.

The calculation of the enthalpy of mixing is similar to the calculation for the case of complete complexing. Δe_1 and Δe_2 are defined as before. A linear variation of Δe with the cationic fractions N_{A^+} and $N_{M^{2+}}$ as in eq. 4 is again assumed. There are $\alpha X_{MY_2}/2$ moles of complexes in solution and $\alpha^0/2$ moles in one mole of pure MY_2. That part of the enthalpy of mixing resulting from complex formation is thus given as

$$[12] \quad \Delta H = \frac{\alpha X_{MY_2}}{2}(N_{M^{2+}}\Delta e_1 + N_{A^+}\Delta e_2) - \frac{\alpha^0 X_{MY_2}}{2}\Delta e_1$$

which may be simplified to give

$$[13] \quad \Delta H = (\alpha - \alpha^0)\frac{X_{MY_2}b_1}{2} + \frac{\alpha X_{MY_2}N_{A^+}}{2}b_2$$

where b_1 and b_2 are defined as in eqs. 9 and 10. From Table 1, $N_{A^+} = X_{AY}/(1 - \alpha X_{MY_2}/2)$. Equation 13 gives an expression for ΔH as a function of α, α^0, b_1, b_2, and composition, $\Delta H(\alpha,\alpha^0,b_1, b_2,X)$. When $\alpha = \alpha_{max}$, and $\alpha^0 = 1$, the two terms of eq. 13 reduce to the two terms of eq. 7 or eq. 8 for complete complexing.

The variables α and α^0 are not independently adjustable parameters, but are uniquely determined by the values of b_1 and b_2. The values of α and α^0 actually assumed by the system are those which minimize the free energy. That is, by solving the equations $\partial(\Delta G)/\partial\alpha = 0$ and $\partial(\Delta G)/\partial\alpha^0 = 0$, where $\Delta G = \Delta H(\alpha,\alpha^0,b_1,b_2,X) - T\Delta S(\alpha,\alpha^0,X)$, α may be found as a function of b_1, b_2, and composition, $\alpha(b_1,b_2,X)$, and α^0 may be found as a function of b_1, $\alpha^0(b_1)$. Full details and explicit functions have been given previously (5). Once values of b_1 and b_2 have been chosen, values of α and α^0 at any composition may be calculated. These values may then be substituted back into the expressions for ΔS and ΔH to give unique simultaneous solutions for these properties at any composition.

Although the problem of partial dissociation could also be approached by writing an "equilibrium constant" for reaction 1, the present approach of defining α and then minimizing ΔG by setting $\partial(\Delta G)/\partial\alpha = 0$ overcomes problems of defining ionic activities and standard states, and would seem to be conceptually simpler and less subject to error. Furthermore, the fact that an equilibrium constant cannot be introduced as a third adjustable parameter, but is uniquely determined by b_1 and b_2, is emphasized by the present technique.

Since all four ionic species are simultaneously present in solution, a correction for non-random mixing must be introduced. For example, if b_2 is negative, then A^+ and MY_4^{2-} ions are favored as nearest neighbors. So the number of A^+–MY_4^{2-} and M^{2+}–Y^- nearest neighbors is increased and the number of A^+–Y^- and M^{2+}–MY_4^{2-} nearest neighbors is decreased from that predicted on the basis of random mixing. This correction has been fully discussed previously (5). The quasichemical method, as discussed by Førland (15), was used. An anion coordination number, z, must be assumed for these calculations. The value of z must lie between about 4 and 8, and it has been shown (5) that the results are quite insensitive to the value of z chosen. A value of $z = 6$ was used in the present calculations. In most systems, the correction for non-randomness is negligibly small anyway. If b_2 is small, then there is not enough driving force for non-randomization to occur to any extent. If, on the other hand, b_2 is negative enough, then the degree of complexing will be high, and α will be close to its maximum possible value. In this case, only three ionic species will exist to any extent in solution at one time (as in columns 2 and 3 of Table 1), and this type of non-randomness due to nearest neighbor "pair-exchange" cannot, of course, occur. For the systems discussed previously, the effect of non-randomness has been found to be negligible in all the systems with $CoCl_2$, $FeCl_2$, $NiCl_2$, and BeF_2. In the $MnCl_2$, $MgCl_2$, and $CdCl_2$ systems, only the systems with KCl, RbCl, and CsCl are affected, and then only in the MCl_2-rich concentration range (see ref. 5). The $PbCl_2$–CsCl system is slightly affected in the $PbCl_2$-rich concentration range. In all cases where non-randomness makes any difference, its effect is to improve the fits with the experimental data.

Comparison with Experimental Data

Using the values of b_1 and b_2 in Table 2, enthalpies and entropies of mixing were calculated for all the systems by the method just described. The calculated interaction parameters are shown in Figs. 2–8 as the light solid lines. Generally, the fits are improved over those for the complete

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

complexing case in all systems. In all the systems with CsCl, there is little difference between the calculated curves for complete and partial complexing, except for the weakly-complexed $PbCl_2$–CsCl system (Fig. 7) in which the consideration of partial dissociation improves the fit. For the systems with KCl, a significant difference and improvement in fit results when partial dissociation is considered in the $MnCl_2$–KCl and $MgCl_2$–KCl systems (Figs. 4 and 5). In the $CoCl_2$–KCl and $FeCl_2$–KCl systems (Figs. 2 and 3), however, b_1 is more negative than for $MnCl_2$ or $MgCl_2$, and in these systems there is little difference in λ between the cases of complete and partial complexing. In all the systems with NaCl and LiCl, however, marked dissociation can be seen to occur, except in the strongly-complexed BeF_2–LiF system (Fig. 8).

In Fig. 9 are plots of $\Delta\bar{S}_{ACl}$ for the $MgCl_2$ systems, calculated using the same b_1 and b_2 values from Table 2 which were used to fit the enthalpies. Agreement with the experimental data is reasonable, and the increasing degree of dissociation which occurs as the size of the alkali cation decreases is clearly seen. In Fig. 10 are curves of $\Delta\bar{S}^E_{MnCl_2}$ calculated from the values of b_1 and b_2 in Table 2. Agreement with experiment is reasonable, and progressive dissociation is clearly seen. Calculated values are generally somewhat too negative.

Papatheodorou and Kleppa (8) calculated partial entropies of mixing of $FeCl_2$ and $CoCl_2$ in the systems with NaCl and KCl by combining their enthalpy data with free energies calculated from vapor pressure, phase diagram, and e.m.f. data from the literature. Partial entropy curves were similar to those in Fig. 10 for the $MnCl_2$ systems, with the deviations from ideality increasing in the order Mn < Fe < Co as expected from the present model.

The effect of dissociation of the complexes upon the entropies (Figs. 9 and 10) is apparently more drastic than upon the enthalpies (Figs. 2–8). Even when dissociation is taken into account, the "dips" at $X_{MY_2} = 1/3$ in Figs. 2–8 are still generally overestimated, as is the effect at $X_{MgCl_2} = 1/3$ in Fig. 9 for the entropies. This suggests that dissociation may actually occur to a somewhat greater extent than predicted by the present treatment. Of course, the fact that only one discrete complex, MY_4^{2-}, is considered in the model would be expected to result in too "sharp" a predicted effect at $X_{MY_2} = 1/3$, since the existence of other complexes or "polymerization" would be expected to cause a "rounding off" here.

Trends in the Chloride Systems

Tetrahedral field stabilization energies (TFSE) for $MgCl_2$, $MnCl_2$, $FeCl_2$, $CoCl_2$, $NiCl_2$, and $CdCl_2$ from ref. 16 are plotted in Fig. 11. Mg, Mn, and Cd have d^0, d^5, and d^{10} configurations, respectively, and thus have zero values of the TFSE (Mg and Cd are shown in brackets in Fig. 11 to indicate that they are from different periods in the periodic table than the other elements.) In Table 2 are the values of Δe_2 used for the various systems, where Δe_2 has been defined as the energy of formation of the complexes when they are completely surrounded by A^+ cations. From eq. 10, $\Delta e_2 = b_1 + b_2$. Plots of Δe_2 for the systems of MCl_2 with various alkali chlorides are shown in Fig. 11. It can be seen that, to a first approximation, the function (Δe_2 − TFSE) is independent of the salt MCl_2, and depends mainly upon the alkali chloride alone. That is, the energy of formation of complexes when surrounded completely by alkali cations appears to be approximately equal to the TFSE plus a factor which depends only upon the cation A^+. Plots of (Δe_2 − TFSE) *vs.* r_+, the Goldschmidt radius of the alkali cation, are shown in Fig. 12 for the $CoCl_2$, $FeCl_2$, $NiCl_2$, and $MnCl_2$ systems. The curves are all quite linear, and the slopes are all nearly the same. The lines for the different MCl_2 systems still differ somewhat from each other. However, with a maximum error of only 3–4 kcal, (Δe_2 − TFSE) for all the chloride systems could be fitted by one single linear curve.

Also in Fig. 11 are plotted values of b_1 for the

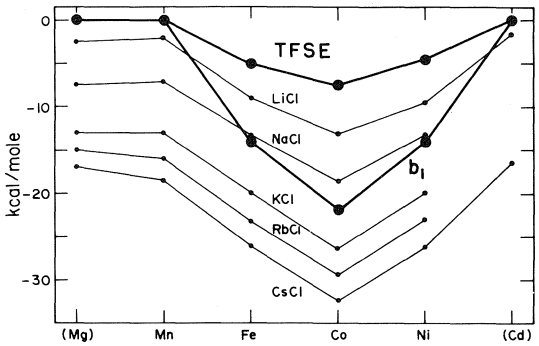

FIG. 11. Tetrahedral field stabilization energies (TFSE) and values of b_1 and Δe_2 for chloride systems from Table 2.

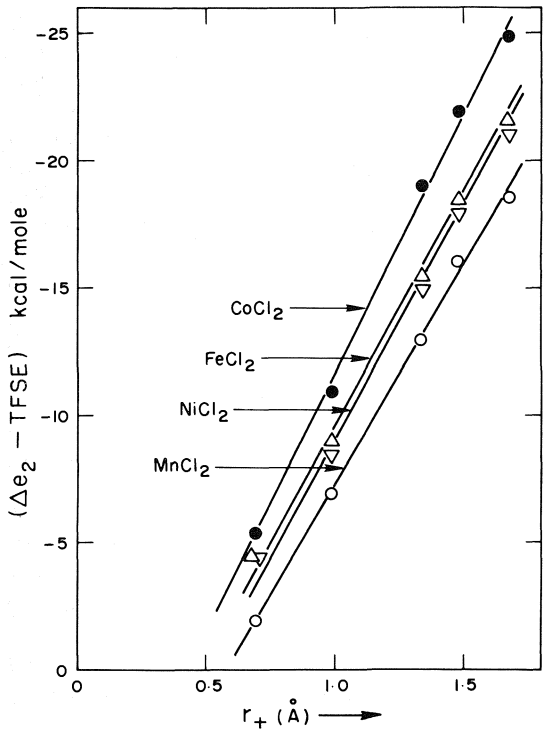

FIG. 12. (Δe_2 – TFSE) *vs.* alkali cation radius for MCl_2–ACl systems.

various systems. b_1 appears to vary approximately directly as the TFSE. (This is also the case for the $PbCl_2$ systems where TFSE = 0 and $b_1 = 0$.) No particular correlation between b_1 for the MCl_2 systems and the radius of M^{2+} is evident.

For the systems in Fig. 11, (Δe_2 – TFSE) appears to be relatively independent of the radius of M^{2+} as has just been discussed. For the $PbCl_2$ systems, however, values of Δe_2 are quite significantly less negative than for the other systems. Thus, it seems that for large enough M^{2+} ions, the strength of the complexes does begin to depend upon the M^{2+} radius.

Cantor (17) has measured freezing point depressions for additions of alkaline earth fluorides to NaF. For BeF_2 and MgF_2 additions, the liquidi are as predicted for the formation of MF_4^{2-} complexes. For CaF_2 additions, however, there are significant deviations, and for SrF_2 and BaF_2 additions, nearly ideal Raoultian liquidi are observed, thus indicating large dissociation of any complexes. This again shows that for large enough M^{2+} ions, the strength of the complexes decreases as the radius increases.

Other Experimental Data

Kucharski and Flengas (13) measured electrical conductivities and molar volumes in the $MnCl_2$–ACl systems. Experimental excess molar conductivities, Λ^E, are plotted in Fig. 13*b*, where Λ^E is defined as

$$[14] \quad \Lambda^E = \Lambda - (X_{MY_2}\Lambda_{MY_2} + X_{AY}\Lambda_{AY})$$

where Λ, Λ_{MY_2}, and Λ_{AY} are the molar conductivities of the solution and of the pure components. Note that all experimental values of Λ^E in Fig. 13*b* are negative.

Non-zero excess conductivities result from changes in number and mobility of charge carriers upon mixing. The present model permits a pre-

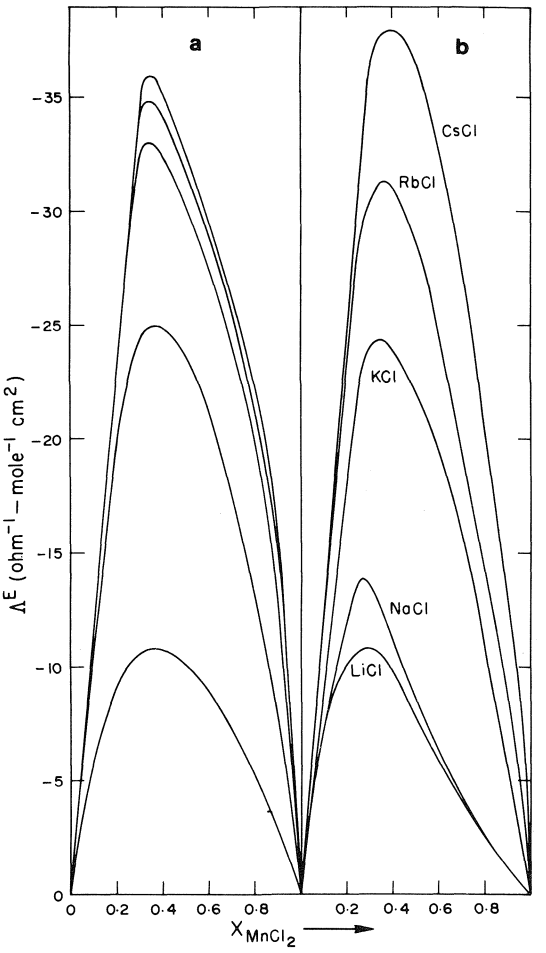

FIG. 13. (*a*) Excess molar conductivities calculated from model for $MnCl_2$–ACl systems. (*b*) Experimental (18) excess molar conductivities for $MnCl_2$–ACl systems at 800 °C.

diction of the change in the number of charge carriers which occurs when the pure components are mixed. Upon mixing, reaction 1 occurs to a certain extent, removing the relatively mobile Mn^{2+} and Cl^- ions from solution, and replacing them with the large, relatively immobile $MnCl_4^{2-}$ complexes. Let us assume that this effect is much more important than any effect due to simultaneous changes in individual ion mobilities. Since there are $\alpha X_{MnCl_2}/2$ moles of complexes in a mole of solution and $\alpha^0 X_{MnCl_2}/2$ moles in X_{MnCl_2} moles of pure $MnCl_2$, then Λ^E should, to a first approximation, be given by

$$[15] \quad \Lambda^E = \left(\frac{\alpha - \alpha^0}{2}\right) X_{MnCl_2}(2\mu_{MnCl_4^{2-}} - 2\mu_{Mn^{2+}} - 4\mu_{Cl^-})$$

where the μ_i are the individual ion mobilities, assumed independent of concentration, and the factors 2 before $\mu_{MnCl_4^{2-}}$ and $\mu_{Mn^{2+}}$ are there because these ions are doubly charged. Let us also assume that the mobilities μ_i in eq. 15 are independent not only of concentration within a given system, but are also independent of the particular $MnCl_2$–ACl system in question. (Note that μ_{A^+} does not appear in eq. 15.) Then

$$[16] \quad \Lambda^E = \left(\frac{\alpha - \alpha^0}{2}\right) X_{MnCl_2}\gamma$$

where γ is a single constant for all the $MnCl_2$ systems.

With values of α and α^0 calculated using the b_1 and b_2 parameters for the $MnCl_2$–ACl systems as in Table 2, and with $\gamma = -164$ ohm^{-1} mol^{-1} cm^2, the curves in Fig. 13*a* were calculated. The curves agree in shape quite well with the experimental curves. The peak heights for the systems with CsCl and LiCl are in good agreement with experiment, but for the other systems, the calculated values of Λ^E are rather too negative.

In Fig. 13*b*, the experimental Λ^E curves approach zero approximately linearly along nearly coincident paths as X_{MnCl_2} approaches zero. From Fig. 13*a* it can be seen that this behavior is as predicted. For the case of complete complexing, with $\alpha = \alpha_{max}$ and $\alpha^0 = 1$, eq. 16 reduces to

$$[17] \quad \Lambda^E = X_{MnCl_2}\gamma/2 \qquad [X_{MnCl_2} \leqslant 1/3]$$

$$[18] \quad \Lambda^E = X_{ACl}\gamma/4 \qquad [X_{MnCl_2} \geqslant 1/3]$$

A sharp negative peak at $X_{MnCl_2} = 1/3$ is thus predicted (as in the upper ΔH curve in Fig. 1*a*). This, of course, qualitatively explains the shape of the curves in Fig. 13. As $X_{MnCl_2} \to 0$, the model predicts that complete complexing is approached (since the equlibrium in reaction 1 is shifted to the right as the concentration of Cl^- ions increases, see ref. 5), and this explains the limiting behavior of the curves in Fig. 13 as $X_{MnCl_2} \to 0$.

In view of the simplicity of the present model and the use of only one adjustable parameter, γ, for all systems, the agreement obtained in Fig. 13 is thought to be satisfactory. Kucharski (18) discussed his measurements of Λ^E by a model assuming $MnCl_4^{2-}$ complexes and assuming complete complexing. He obtained equations for Λ^E similar to eqs. 17 and 18, thus predicting sharp peaks at $X_{MnCl_2} = 1/3$ as just discussed. A different value of γ was needed for each individual system, of course. In this case then too, all the calculated curves did not have the same limiting slope as $X_{MnCl_2} \to 0$.

Similar Λ^E curves in the $MgCl_2$–NaCl and $MgCl_2$–KCl systems have been discussed by Grjotheim, Nikolic, and Øye (19).

It has been argued that "complexes" are only a formalism for treating non-randomness in molten salts, and that complexes should not be regarded as "particles". The success of the present model in explaining the electrical conductivity, a transport property, however, supports the concept of complexes as distinct particles. Also, recent studies by Lamb (20) of transference cells containing molybdenum chloride in LiCl–KCl eutectic showed that molybdenum was transported to the anode compartment, and thus moved as a negatively charged particle, presumably an $MoCl_6^{3-}$ complex.

Excess molar volumes of mixing, ΔV^E, of the $MnCl_2$–ACl systems have been measured by Kucharski and Flengas (13), and were found to be positive. The curves are very similar in shape to the Λ^E curves of Fig. 13, with peaks at $X_{MnCl_2} = 1/3$. The peaks decrease in height from the CsCl to the LiCl system. This gives good qualitative evidence for the formation of $MnCl_4^{2-}$ complexes, and this has been discussed by the authors (13). The formation of the large complex anions appears to cause an increase in the molar volume of the solutions.

There is also, of course, a large and rapidly growing body of spectral data on molten salts

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

which gives strong qualitative evidence for complex anions. These data have been extensively reviewed (16, 21).

Discussion

BeF_2 and SiO_2 Systems

It was shown in Fig. 8 that the discrete complex anion model gives reasonably good fits to enthalpies in BeF_2–AF systems. For solutions rich in alkali fluoride, phase diagram calculations in the BeF_2–NaF (17) and BeF_2–LiF (22) systems support the contention that discrete BeF_4^{2-} anions are the predominant complexes.

For solutions richer in BeF_2, however, it is generally accepted that these melts are "polymeric", with the BeF_4 tetrahedra sharing corners through "fluorine bridges" in a structure similar to that of crystoballite. Molten SiO_2 is thought to have a similar structure.

For BeF_2–AF systems which are rich in BeF_2, and also for SiO_2-rich solutions of SiO_2 with basic oxides, models exist (23, 24) which attempt to explain the thermodynamic data by considering the solutions as mixtures of polymeric species such as dimers, trimers, etc. Although the ultimate explanation of the properties of these systems will undoubtedly require the consideration of such polymeric species, the success of the discrete complex anion model suggests that such an approach, in which only simple structural units are considered, can be of value and can provide insight into the melt structure.

For pure BeF_2, the discrete complex anion model is, of course, unrealistic, since even for complete complexing it assumes that only half the beryllium in pure BeF_2 is complexed. In reality, nearly all the beryllium is complexed through the sharing of fluorines. Although enthalpies are well-fitted by the simple model, entropies of mixing in solutions rich in BeF_2 are not. Experimental partial excess entropies of mixing of BeF_2 in the BeF_2-rich composition region of the BeF_2–LiF system (11) have large positive values which cannot be explained by the model, even with complete complexing. These "polymerized" melts thus appear to have a greater multiplicity than that calculated from the discrete complex anion model. Experimental $\Delta\bar{S}^E_{MnCl_2}$ values in Fig. 10 are somewhat more positive than those calculated previously, possibly giving some evidence that polymerization occurs to some extent in these systems. (Although for complete complexing, the discrete complex anion model does fit the data for the system with CsCl quite well.) McCarty and Kleppa (10) also found slight positive values of $\Delta\bar{S}^E_{PbCl_2}$ in the $PbCl_2$-rich concentration range in the $PbCl_2$–ACl systems.

Some qualitative applicability of the present model might also be expected for molten SiO_2–BO systems, where B is a divalent metal, at least in the basic melts. In the SiO_2–PbO system, for example, activities calculated from the e.m.f. data of Charette and Flengas (25) indicate that SiO_4^{4-} anions are the main complex species in the PbO-rich composition region. Østvold and Kleppa (12) measured enthalpies of mixing in this system from $X_{SiO_2} = 0$ to 0.5, and found a curve for λ similar to that in Fig. 1*b*. Curves of $\Delta\bar{S}_{PbO}$ as calculated by Østvold and Kleppa by combining their enthalpy data with activity data from the literature were qualitatively similar to those in Fig. 9.

As has been shown for the BeF_2–LiF system, a negative value of b_1 and a positive value of b_2 in an MY_2–AY system can result in positive values of ΔH for solutions rich in MY_2, and negative values for solutions rich in AY. Such an effect, if great enough, could give rise to a liquid–liquid immiscibility gap in the MY_2-rich concentration region. Such immiscibility gaps are found in many SiO_2–BO systems. (The systems where B = Mg, Ca, Sr, and Mn are examples.) Such positive b_2 values in polymeric SiO_2–BO melts could be associated with the tendency of the B^{2+} cations to polarize and distort the highly directional Si—O bonds, thus greatly weakening the network structure of the melts. As the radius of the B^{2+} cations increases, their polarizing power decreases, and less positive b_2 values occur. The large positive b_2 value in the BeF_2–LiF system can be similarly explained. The present model may thus give some qualitative insight into the reason for the existence of the immiscibility gaps in SiO_2–BO systems in the acidic region.

Vibrational Entropy

Vibrational entropy contributions have been neglected in the present treatment. Let σ be the molar vibrational entropy change associated with the formation of one mole of complexes as in reaction 1, and assume that σ is independent of composition. Then, in the discrete complex anion model, a vibrational entropy of mixing contribution, ΔS_{vib}, as shown in Fig. 1*c* should result for the case of complete complexing. This curve is similar to the upper ("b_1") curve for ΔH in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Fig. 1*a*. Such a function for ΔS_{vib} was used by Kucharski (18) in his treatment of complexing.

For partial complexing, a ΔS_{vib} term of the form:

$$[19] \qquad \Delta S_{vib} = \frac{(\alpha - \alpha^0) X_{MY_2}}{2} \sigma$$

(*cf.*: the first term in eq. 13) would result. (Again, it has been assumed that σ is independent of concentration.) If the effect of different A^+ cations is to be considered, then "σ_1" and "σ_2" parameters (analogous to the b_1 and b_2 parameters) could be defined.

If Fig. 1*c*, σ is shown as negative. However, for polymeric materials such as those containing SiO_2 or BeF_2, the formation of discrete complexes upon mixing would result in the breakdown of the ordered three-dimensional network, and positive values of σ might be expected.

Undoubtedly, vibrational entropy contributions are important in these systems. However, since the general features of the experimental data can be reasonably well-fitted by considering only the configurational entropy, and since the inclusion of the vibrational entropy terms introduces more adjustable parameters into the model, no attempt to numerically include the vibrational terms will be made at the present time.

Additional Parameters

Additional enthalpy terms could also be added to include changes in coulombic and polarization interactions upon mixing which are not accounted for in the terms in eq. 13. This has been discussed previously (5) in some detail. Extra terms to try to account for other effects such as variations in coordination number with composition could also be added. Such additional terms necessitate further adjustable parameters, however, and the justification for neglecting these terms is that the data are quite well-fitted without them.

The addition of one more adjustable parameter per system would nearly double the number of such parameters being used, and so would yield a great improvement in the agreement between experiment and theory, whether or not there were any basis whatsoever in physical fact for the reasoning which gave rise to the additional parameters.

Conclusions

For a large number of molten systems of the general formula MY_2–AY, the discrete complex anion model appears to explain quite a wide range of experimental data quite well, on the assumption of the existence of discrete MY_4^{n-} complex anions as the only complex species present.

The model can be applied to strongly complexed systems such as the $CoCl_2$ systems, and can also be applied to weakly-complexed systems such as the PbY_2 system. In the limit of zero complexing, the model reduces to the ideal Temkin model. At the other extreme, the treatment can explain some of the data for systems with strong polymerized complexes, such as systems with BeF_2 or SiO_2, although a basic limitation of the approach is that polymerization is neglected.

Molten salts such as LiCl or CsCl may be called strong bases since they are completely dissociated into A^+ and Cl^- ions. MY_2 salts in which free Y^- ions are removed from solution by an equilibrium as in reaction 1 may be called weak bases. The b_1 parameter introduced in the present treatment provides a possible quantitative basicity (or acidity) scale for molten salts and slags. Thus, $CoCl_2$, for which $b_1 = -22$ kcal, is a weaker base than $FeCl_2$ for which $b_1 = -14$; and $FeCl_2$ is a weaker base than $MnCl_2$ for which $b_1 = 0$.

For each weak base MY_2, a second basicity scale, the "b_2 scale" is also necessary for each solution of that salt with a strong base, AY, in order to account for the effect of the A^+ ions on the energy of the complexes. The situation is more complicated than the case of dilute solutions of weak protonic acids in water for which one single acidity scale suffices since there is only one solvent and only solutions in the Henrian concentration range are considered.

The relationship of the b_1 and b_2 basicity scales to such things as ionic radii and ligand field stabilization energies has been discussed.

For fused salt systems other than those discussed here, there is also strong evidence for the existence of complex ions. Spectroscopic data (16, 21) appear to indicate that tetrahedral MY_4^{n-} and octahedral MY_6^{n-} complexes may be the most common complex anions in molten halides. Many salts which are molecular liquids when pure, such as $TiCl_4$ and Al_2F_6, nevertheless form complex anions ($TiCl_6^{2-}$, AlF_4^-) when dissolved in the strongly basic alkali halides. Preferred grouping of particles to form the statistical entities called complex ions may be of prime importance in a wide variety of molten salts.

The discrete complex anion model is an attempt to classify a quite wide variety of molten salt and slag systems of the form MY_2–AY by simple quantitative "basicity scales". Undoubtedly the treatment is highly oversimplified, but the strength of the treatment lies in this simplicity and in the use of an absolute minimum of adjustable parameters. It is hoped that this type of treatment may also prove useful in classifying and understanding other more complicated complex-forming salt and slag systems.

The author wishes to thank Dr. W. T. Thompson, Dr. A. S. Kucharski, and Professor S. N. Flengas for many helpful discussions. Financial assistance from the National Research Council of Canada is also gratefully acknowledged.

Chaleur de dilution de solutions aqueuses d'acide polyacrylique, de son sel de sodium et de l'acide propionique

JEAN-PIERRE CARTIER[1] ET HUBERT DAOUST
Département de chimie, Université de Montréal, Montréal, Québec

Reçu le 12 juillet 1971

Des mesures de chaleur de dilution de solutions aqueuses d'acide polyacrylique et de son sel de sodium, ainsi que de l'acide propionique, ont été réalisées à l'aide d'un microcalorimètre du type Tian–Calvet à 25 °C. Les mêmes mesures ont été répétées (sauf pour le sel de sodium) en utilisant une solution aqueuse de HCl 0.2 *N* comme solvant. Les résultats obtenus pour l'acide polyacrylique sont en accord avec ceux de Silberberg, Eliassaf et Katchalsky. Les différences dans les résultats pour cet acide et son monomère "libre", l'acide propionique, sont interprétées en termes de changements de structure de l'eau induits par la longueur de la chaîne de polymère, en d'autres termes, par l'effet de chaîne. L'endothermicité de la dilution de solutions modérément concentrées du polyacrylate de sodium dans l'eau peut être expliquée à la lumière de la théorie d'Eigen et Wicke sur les solutions concentrées d'électrolytes forts.

With a Tian–Calvet microcalorimeter, heats of dilution at 25 °C have been measured for aqueous and acid (0.2 *N* HCl) solutions of polyacrylic acid and of propionic acid, and for aqueous solutions of the sodium salts of polyacrylic acid. The results are interpreted in terms of the change in structure of water resulting from the lengthening of the solute molecule. The heat of dilution of moderately concentrated solutions of sodium polyacrylate can be explained by the theory of Eigen and Wicke.

Canadian Journal of Chemistry, **49**, 3935 (1971)

Introduction

Plusieurs propriétés des polymères vinyliques solubles dans l'eau peuvent s'expliquer par la formation de liens hydrophobes entre sites ou groupements sur la chaîne (1). Ainsi, on tente d'expliquer plusieurs différences dans les propriétés physico-chimiques en solution aqueuse de l'acide poly-méthyl-méthacrylique (APMM) et de l'acide polyacrylique (APA) par le fait que ce dernier ne possède pas de groupement latéral hydrophobe. Il est bien connu que les groupements hydrophobes permettent la formation d'icebergs autour des chaînes d'hydrocarbures et favorisent ainsi une structure plus ordonnée de l'eau à l'état liquide (2, 3).

Des mesures de diffusion de la lumière par des solutions diluées d'APA et d'APMM dans HCl 0.2 *N* à différentes températures ont montré que les chaleurs de dilution sont endothermiques dans le premier cas et exothermiques dans le second (4). Par ailleurs, des travaux ont montré que le volume molal apparent du motif de base de différentes fractions d'APA dans l'eau diminue avec l'augmentation de la masse moléculaire du polymère (5).

Les résultats présentés dans le présent article confirment les résultats de Silberberg et coll. et permettent de proposer une explication pour les résultats obtenus par densimétrie (5).

Partie expérimentale

L'acide propionique et les produits utilisés dans la préparation des polymères étaient tous des réactifs de pureté analytique. L'eau utilisée comme solvant avait une conductivité spécifique de l'ordre de 10^{-6} mho^{-1} cm^{-1}. Deux échantillons d'APA furent utilisés dans ce travail. Le premier (APA-1) fut obtenu par la polymérisation de l'acide acrylique en s'inspirant de travaux antérieurs (6). Le sel de sodium (NaPA) fut obtenu par la neutralisation d'un échantillon d'APA-2 par de l'hydroxyde de sodium (7), l'APA-2 étant aussi préparé selon la méthode mentionnée plus haut. Chaque échantillon de polymère fut dialysé pendant au moins vingt-quatre heures puis séché par liophylisation pendant une semaine. Les masses molaires moyennes des deux échantillons d'APA furent déterminées par viscosimétrie en utilisant HCl 0.2 *N* comme solvant (4); leur valeur respective sont 270 000 et 300 000. Des titrages potentiométriques de solutions préparées gravimétriquement à partir d'échantillons séchés d'APA ont indiqué un degré de pureté de l'ordre de 92% dans les deux cas; une analyse par infrarouge de la poudre de polymère dans le nujol d'une part et en solution dans du dioxanne d'autre part, a montré que l'eau retenue par le polymère après séchage est la seule impureté détectable.

Les mesures de chaleurs de dilution furent réalisées à l'aide d'un microcalorimètre différentiel du type Tian–Calvet (8) à mille thermocouples par élément calorimétrique. Le courant produit par l'effet thermoélectrique est amplifié par un amplificateur de courant continu

Leeds and Northrup modèle 9835B et enregistré à l'aide d'un enregistreur Phillips modèle RR 3216A/00. Le microcalorimètre utilisé est basculant ce qui simplifie grandement le déclanchement de la dilution et l'agitation à l'intérieur des cellules. Deux types de cellules furent utilisées pour la dilution, soit en téflon supportée par une gaine extérieure en laiton, soit en verre Pyrex, mais leur description est essentiellement la même. Elles consistent en deux tubes cylindriques concentriques fermés par le bas. Le tube extérieur a un diamètre d'environ 25 mm et une hauteur totale de 100 mm; le tube intérieur a un diamètre de 13 mm et une hauteur de 88 mm. Le tout est fermé à l'aide d'un bouchon en téflon. Un volume de 7 ml de solvant est versé dans le tube central et 21 ml de solution dans le tube extérieur. Les vapeurs des deux liquides sont séparées avant la dilution en déposant une faible quantité d'huile de paraffine légère, soit 0.2 à 0.4 ml. Cette quantité d'huile doit être maintenue la plus faible possible car le mouillage de l'huile lors de l'agitation peut produire un effet endothermique appréciable. L'agitation à l'intérieur de la cellule est assurée par l'addition de deux cent billes de verre de 1 mm de diamètre. L'étalonnage du microcalorimètre a été fait par effet Joule et vérifié par des mesures de chaleur de neutralisation de HCl par NaOH. En aucun cas l'écart entre les valeurs données pour cette réaction (9) et les valeurs calculées ne dépasse 3%.

Résultats et discussion

Les résultats obtenus sont donnés dans les Tableaux 1 à 3. Les concentrations exprimées en grammes de soluté par 100 g de solvant apparaissant dans la première colonne sont celles des solutions initiales. Dans la deuxième colonne, les masses du soluté dans les solutions sont données, tandis que dans la troisième apparaissent les nombres de moles (de motif de base dans le cas des polymères). La quantité Δm_1 est la masse de solvant ajouté lors de la dilution et $\bar{n}_1$ est le nombre moyen de moles d'eau pour une mole de soluté; φ_2 et φ_2' sont les fractions volumiques du soluté avant et après dilution. Finalement, ΔH_d est l'enthalpie de dilution telle

que calculée à partir des données expérimentales; ici, on peut négliger la différence entre l'enthalpie de dilution et l'énergie de dilution étant donné que les changements de volume lors de la dilution sont négligeables ou nuls (5).

Les chaleurs de dilution de l'APA dans l'eau sont endothermiques de même que dans HCl 0.2 *N* en accord avec les résultats de Silberberg et coll. Pour fins de comparaison, il est utile de définir un paramètre enthalpique apparent d'après la relation (11)

$$[1] \qquad \kappa_a = \Delta H_d / RTn_2(\varphi_2 - \varphi_2') \qquad \text{Ce paramètre est une mesure des interactions entre un soluté et un solvant; les valeurs de } \kappa_a \text{ sont données dans la dernière colonne du Tableau 1. Il y a une nette diminution de la valeur moyenne de } \kappa_a \text{ lorsque l'eau est remplacée par HCl 0.2 } N \text{ comme solvant soit de 0.48 à 0.12 et cette derniére valeur se compare assez bien avec celle donnée par la littérature (5), soit 0.0647. Lorsque les chaleurs de dilution de l'APA dans l'eau et dans HCl 0.2 } N \text{ (Fig. 1) sont comparées à celles obtenues pour l'acide propionique}$$

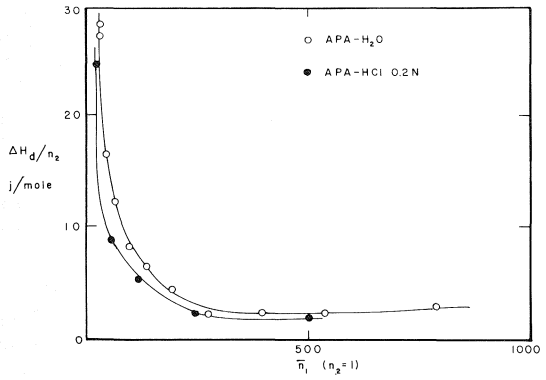

FIG. 1. Variation de l'enthalpie de dilution par mole de motif de base d'APA en fonction du nombre moyen de moles d'eau à 25 °C.

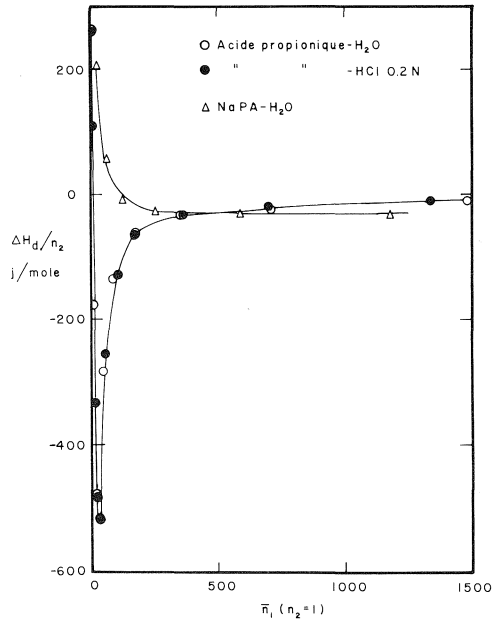

FIG. 2. Variation de l'enthalpie de dilution par mole (ou mole de motif de base) de soluté en fonction du nombre moyen de moles d'eau à 25 °C.

dans les mêmes solvants (Fig. 2), le comportement de l'APA apparait totalement différent de celui de son monomère "libre". Ces résultats peuvent être expliqués en examinant ce qui se passe à l'échelle moléculaire lors de la dilution. Les chaleurs de dilution calculées à partir des résultats de la littérature (12), montrent que la dilution d'une solution aqueuse d'acide acétique, propionique ou butyrique normal est fortement endothermique pour des solutions très concentrées pour devenir rapidement exothermique lorsque la dilution progresse et la courbe donnée dans la Fig. 2 pour l'acide propionique peut être considérée comme typique pour ces trois acides. En solution fortement concentrée, la dilution amène la rupture des ponts hydrogène persistants entre les molécules d'acide (13). La rupture des ponts hydrogène est un phénomène endothermique (2) et il est alors plus important que la solvatation des groupements COOH par intéraction dipôle–dipôle avec les molécules d'eau, phénomène qui serait exothermique d'après l'allure des résultats obtenus. Lorsque la dilution se continue, il peut y avoir formation d'icebergs autour des radicaux hydrophobes (3) et ceci pourrait expliquer le passage d'une très forte endothermicité à une très forte exothermicité

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

pour une augmentation relativement petite du nombre moyen de moles d'eau. Lorsque les molécules d'acide sont finalement dispersées uniformément dans la solution, pratiquement seule l'ionisation de l'acide contribue à la chaleur de dilution et globalement le phénomène d'ionisation en solution aqueuse est essentiellement endothermique (14). L'utilisation de HCl 0.2 *N* comme solvant de l'acide propionique ne modifie en rien les résultats obtenus pour les chaleurs de dilution dans l'eau pure comme le montre également la Fig. 2. Le changement de structure de l'eau que pourrait apporter l'addition de HCl n'influence donc nullement le mécanisme de dilution de l'acide propionique.

Avant de tenter d'expliquer les résultats obtenus dans le cas de l'APA, il faut savoir que: (*1*) les groupements COOH du polymère ne sont pas ionisés dans le domaine de concentration étudié ici (15); (*2*) les groupements COOH sont libres dans l'eau, *i.e.*, ils ne participent aucunement à la formation de ponts hydrogène de quelque nature que se soit d'après une étude spectroscopique récente (16). De plus, il faut accepter l'hypothèse que les effets combinés des ions H^+ (ou H_3O^+) et Cl^- sur la structure de l'eau est de briser d'importants agrégats moléculaires par solvatation des espèces ioniques pour des solutions 0.05 *m* et plus (17). A la lumière de ce qui a été écrit plus haut et des explications données à l'allure des résultats obtenus pour l'acide propionique, il faut croire que l'endothermicité de la dilution de l'APA dans l'eau ne s'explique que par un changement important dans la structure de l'eau. Les groupements COOH le long de la chaîne favorisent la dissolution de ce polymère dans l'eau par intéraction dipôle–dipôle mais afin de loger une longue chaîne dans le réseau "semi-cristallin" de l'eau, il faut briser un certain nombre d'agrégats moléculaires de dimension importante en agrégats plus petits ou en molécules libres; c'est ce qu'on peut appeler l'effet de chaîne. La rupture ou la formation de ces agrégats étant un phénomène coopératif (18), *i.e.*, que lorsqu'un lien se brise, l'agrégat tout entier se désagrège, les changements dans la structure de l'eau peuvent devenir très importants lors de la dissolution de l'APA dans l'eau ou lors de la dilution d'une solution aqueuse de cet acide. La "fusion" des agrégats peut donc expliquer la valeur positive pour l'enthalpie de dilution Lorsque HCl 0.2 *N* est employé comme solvant, il y a une nette diminution dans la valeur de cette enthalpie et ceci peut s'expliquer par le fait que les changements de structure de l'eau sont moins considérables, le nombre de gros agrégats étant moindre que dans l'eau pure.

Ce changement dans la structure de l'eau dû à l'effet de chaîne peut expliquer les résultats obtenus en densimétrie (5, 10). On remarque que la valeur de $\bar{v}_2$ pour l'APA dans l'eau est notablement plus faible que dans HCl 0.2 *N* (voir Tableau 1). En supposant que cela est entièrement dû à la différence de structure de l'eau dans les deux cas et non à celle du polymère, et sachant que la fusion des agrégats entraîne une diminution du volume spécifique de l'eau, cette diminution est plus considérable dans le cas de l'eau pure et il s'ensuit que $\bar{v}_2$ apparait plus faible dans l'eau que dans HCl 0.2 *N*. D'autre part, la diminution de φ_u^0 (= volume molaire apparent d'un motif de base d'APA non-dissocié) avec l'augmentation de la masse moléculaire du polymère peut s'expliquer par le fait qu'une longue chaîne de polymère est plus difficilement logée dans le réseau semi-cristallin du solvant qu'une courte chaîne; la transition agrégats → molécules d'eau libres devient alors plus importante dans le cas de la dissolution de longues chaînes d'APA dans l'eau d'où la valeur plus faible pour φ_u^0.

Les résultats obtenus pour les chaleurs de dilution de NaPA dans l'eau montrent que dans le cas de solutions modérément concentrées la dilution est endothermique et devient exothermique lorsque la dilution progresse (Fig. 2). En négligeant le phénomène d'hydrolyse qui existe dans ce cas, l'allure des résultats est tout à fait analogue à ceux obtenus lors de la dilution d'une solution modérément concentrée d'un électrolyte fort tel un halogénure de sodium ou de potassium. Afin d'expliquer l'endothermicité de la dilution d'une telle solution, Eigen et Wicke (19) font intervenir la dissociation qui est un phénomène typiquement endothermique. Tenant compte de ce nouvel apport d'énergie, la chaleur de dilution mesurée par mole de soluté devient la somme de deux contributions:

$$[2] \quad \Delta H_d(c) = \alpha(c)\Delta H_d^*(c) + [1 - \alpha(c)]\Delta H_\infty$$

où α est le degré de dissociation, ΔH_d^*, l'enthalpie de dilution pour l'électrolyte entièrement dissocié et ΔH_∞, l'enthalpie de dissociation complète d'une mole de soluté.

Pour les polyélectrolytes forts, comme pour les électrolytes forts ordinaires, on admet que les forces de nature électrostatique constituent la principale contribution à l'énergie libre d'interaction entre le polyion et ses ions antagonistes (20). Alors, en utilisant les bases de la théorie de Eigen et Wicke, Hosono et Ise (21) prévoient que ΔH_d^* sera exothermique en solution légèrement concentrée pour devenir endothermique en solution très diluée. Parmi les résultats rapportés dans la littérature (22–24) aucun ne donne une chaleur de dilution exothermique à haute dilution; afin de vérifier les prédictions théoriques d'Hosono et Ise, il faudrait travailler à des dilutions qui pour le moment ne sont pas accessibles aux méthodes expérimentales utilisées jusqu'ici. Une étude plus détaillée des polyélectrolytes forts fait l'objet d'une autre communication (24).

Nous tenons à remercier le Conseil National de Recherche du Canada pour l'aide financière apportée à ce projet. Nous remercions également le Service de réadaptation des handicapés physiques du Ministère de l'éducation de la Province de Québec (J.-P. C.).

Hydrogen Gas Solubility in the Dimethyl Sulfoxide – Water System: A Further Clue to Solvent Structure in These Media[1]

E. A. SYMONS[2]

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba

Received July 21, 1971

The solubility of hydrogen gas in the dimethyl sulfoxide (DMSO) – water system has been measured as a function of temperature from 25 to 80 °C. A distinct minimum occurs in the solubility, as expressed on the molar scale, in the region 25–35 mol% DMSO at 25 °C. As the temperature is raised towards 80 °C the minimum becomes less pronounced. The maximum deviation from calculated "ideal" behavior is found at 32 ± 5, 35 ± 5, and 32 ± 5 mol% DMSO for 25, 50, and 80 °C, respectively.

A maximum is observed for both the partial molal entropy and heat of solution of hydrogen in the same solvent composition region. These results are discussed in terms of a changing entropy and energy of hole formation in the solvent with composition, which in turn is related to DMSO–water interaction in solution.

A temperature-dependent equilibrium between $DMSO.2H_2O$ and $DMSO.3H_2O$ complexes in solution is proposed in an attempt to correlate the considerable data which have been reported in the literature for the DMSO–water system. The second complex is thought to be present in significant quantity only at temperatures well below 25 °C.

On a mesuré la solubilité de l'hydrogène gazeux dans le système diméthyl sulfoxyde (DMSO) – eau en fonction de la température, de 25 à 80 °C. Un minimum distinct de solubilité se produit dans la région de 25 à 35 mol% de DMSO à 25 °C, tel qu'exprimé sur l'échelle molaire. Lorsqu'on élève la température aux environs de 80 °C, le minimum devient moins prononcé. On trouve la déviation maximale au comportement "idéal" calculé à des compositions de 32 ± 5, 35 ± 5 et 32 ± 5 mol% de DMSO à 25, 50 et 80 °C, respectivement.

On observe un maximum, à la fois pour l'entropie molaire partielle et pour la chaleur de dissolution de l'hydrogène dans la même région de composition de solvant. On discute de ces résultats en termes de changement d'entropie et d'énergie de formation de trous dans le solvant avec la composition, ce qui est relié à l'interaction de l'eau et du DMSO dans la solution.

On propose un équilibre dépendant de la température entre les complexes en solution $DMSO.2H_2O$ et $DMSO.3H_2O$ dans le but de faire la corrélation entre les différents résultats qui ont été rapportés en nombre considérable dans la littérature pour le système DMSO–eau. On croit que le second complexe est présent en quantité appréciable à des températures bien au-dessous de 25 °C.

Canadian Journal of Chemistry, **49**, 3940 (1971)

Introduction

The structure of dimethyl sulfoxide (DMSO) – water mixtures has been under investigation for some time (1–11). The general conclusion drawn from density, viscosity, dielectric, and thermodynamic data is that 2:1 water:DMSO association occurs to a considerable extent. However, there is evidence from phase diagram (5) and deuteron relaxation (7) studies that 3:1 association may also take place. Hydrogen bonding between DMSO and water molecules has recently been detected (6), in contrast to previous evidence to the contrary (4).

It is known that the solubility of an inert gas in a liquid can be employed as a means of examining the structure of the liquid (12–14). Since a solute gas such as hydrogen is non-polar and non-ionic, solute–solvent interaction will be small, and the effect of a changing solvent composition on its solubility should reflect mainly the relative ease of hole formation in the medium (15). This ease will depend upon the change in solvent interaction with composition.

In the present work the solubility of hydrogen gas has been measured in several DMSO–water mixtures ranging from 20.2 to 100 mol% DMSO. The temperature dependence of the solubility was determined at most compositions over the range 25.0–80.0 °C, allowing calculation of the partial molal entropies and heats of solution. These data have been combined with the results

of Gubbins and co-workers (16) for pure water to provide complete coverage for this solvent system.

Experimental

Reagents

DMSO (Fisher Certified Reagent) was dried at least 48 h over Linde type 4A molecular sieves, then vacuum distilled with nitrogen bleed through a 16 in. Vigreux column. The central fraction, 38–40 °C at *ca.* 1 mm Hg, was retained for use under a nitrogen atmosphere at ambient temperature.

Deionized distilled water was used throughout.

Hydrogen gas was taken directly from a lecture bottle (Matheson, extra dry).

Tetramethylammonium hydroxide (25% aqueous solution, Matheson, Coleman, and Bell) was employed as received, the polyethylene bottle being fitted with a rubber serum cap to facilitate solution withdrawal by syringe. Samples were titrated frequently against standard sulfuric acid.

Solution Preparation

Solutions were made up in a modified 100 ml round bottom flask; the vessel is shown in Fig. 1. The side arms permitted connection of the flask to a vacuum pump and, by means of the rubber serum cap and syringe needle, to a manometer and hydrogen gas cylinder. Appropriate volumes of water and DMSO were transferred under nitrogen to the flask by pipet; where required, base solution was added by syringe.[3] The solvent composition was calculated from the number of moles of each component introduced.

The solution was cooled to minimize vaporization of the solvent, and the flask was evacuated for several minutes to remove any dissolved gas. After the vessel had been submerged in a constant temperature bath (controlled to better than ± 0.05 °C), hydrogen was introduced to a pressure equal to 1 atm plus the estimated vapor pressure of the solvent at the particular temperature. The latter pressure was obtained by extrapolation of the data of Kenttämaa and Lindberg measured at 70 °C (17). It was assumed that the shape of the vapor pressure – composition curve joining known pressures for pure water (18) and DMSO (19) at 25, 35, 50, 65, and 80 °C would be similar to that observed at 70 °C. Effects of the dissolved base on this vapor pressure were neglected.

In order to achieve equilibration of the hydrogen between the liquid and vapor phases, the solution was stirred for 5 min by means of a magnet attached to the shaft of a variable speed motor. Further stirring did not yield significant changes in measured solubility. It is apparent from the literature (see ref. 12 and references therein) that great effort is often made to ensure both complete degassing and gas equilibration, thereby allowing precision as high as 0.1%. However, the large increase necessary in analysis time to improve from 99% of the gas dissolved (typically several minutes equilibration time) to 100% (several hours) was not considered justifiable in the present case. The main reasons for this decision were the uncertainty in the solution vapor pressures and the method of analysis employed (see below).

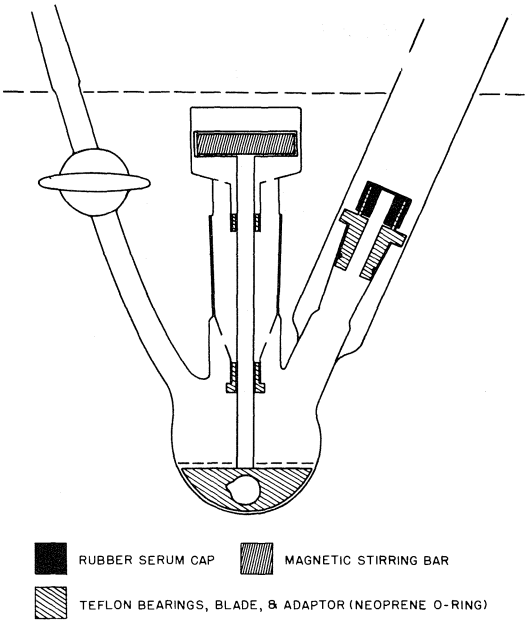

FIG. 1. Gas–liquid equilibration cell. Stiff springs hold the upper and lower sections together. The openings into the upper chamber of the stirrer unit allow free circulation of the gas.

Approximately 1 ml of solution was discarded before each main 5.0 ml sample was removed by a calibrated 5 ml syringe. It was necessary to withdraw the samples slowly in order to prevent some gas from being drawn out of solution in the syringe. Between samples, the slight pressure drop in the flask was corrected and the solution given further agitation. A total of three or four samples was normally taken per solution.

Gas Solubility Measurements

A gas chromatographic method of analysis, adapted from Gubbins and co-workers (16, 20), was utilized, wherein the dissolved gas was stripped from a solution sample by the carrier gas. The solution compartment of the gas stripping cell, shown in Fig. 2, had a capacity of 6 ml. The chromatograph, a Varian Aerograph model 1520, was operated with the thermal conductivity detector at 65 °C and the injector and column (10 ft, 1/4 in. stainless steel, 40–60 mesh 13X molecular sieve) at ambient temperature. The carrier gas was nitrogen at a flow rate of 34 ml per min. A recorder and Infotronics Corporation digital integration system were used to monitor the detector output.

Each 5.0 ml solution sample was introduced by syringe into the stripping cell at a rate which stopped the carrier gas flow until all of the sample had been added. The hydrogen was then stripped out over a period of 1–2 min. Chromatograph response was calibrated, usually

[3]The base concentrations corresponded to those employed for a reaction currently under investigation in these media, the base-catalyzed exchange of deuterium gas.

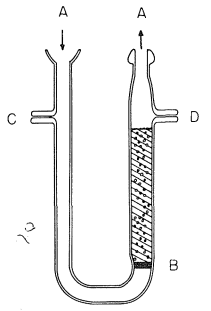

FIG. 2. Gas stripping cell for solubility analysis; overall size 5 in. × 2½ in. Points *A*, to a 4-way stopcock; *B*, medium porosity glass frit; *C*, calibration gas sample inlet; *D*, solution sample inlet. Attached at *C* and *D* were Beckman teflon ¼ in. unions whose outer ends were fitted with silicone rubber septums. The lines connecting the stopcock to the chromatograph were 1/8 in. nylon; inserted at the return side of the stopcock was a coil of 10 ft of translucent ¼ in. nylon tubing packed with 10–20 mesh indicating drierite to remove water and DMSO vapor from the gas flow.

once per solution sample, by injecting 100 μl samples of hydrogen with a 250 μl gas-tight syringe.

The complete analysis procedure was tested by determining the solubility of hydrogen in pure water and DMSO at 25.0 °C. The results, presented in Table 1, are in good agreement with literature data obtained by a method analogous to the present case (16) and by a method involving observation of the pressure drop upon equilibration of gas and liquid (21). Accuracy in the latter case was believed to be within 1%.

Results

Solubilities

The hydrogen solubilities, expressed on the molar scale, are presented in Table 2 as a function of both medium composition and temperature. They were determined by comparing the stripped gas and calibration gas integrated areas, which allowed calculation of the number of moles of gas dissolved in each 5 ml solution sample. This means of presentation was used because solubilities expressed as moles per litre were required elsewhere (see footnote 3). The corresponding mole fraction data were not included in Table 2, in order to maintain clarity.[4]

TABLE 1. A comparison of the measured and literature values for hydrogen gas solubility in DMSO and water at 25.0 °C

	H_2 solubility, $\times 10^{-5}$ mole fraction*	
Solvent	This work†	Lit. value (ref.)
Water	1.45 1.45	1.43 (16)
DMSO	7.5 7.7	7.61 (21)

*Hydrogen partial pressure of 1 atm.
†Each entry is the mean of three separate values measured for one stock solution; estimated error is ± 2%.

The solubility data are considered to be accurate to ±2%, since standard deviations for the triplicate or quadruplicate measurements leading to each entry in Table 2 varied between 0.1 and 4%, with most falling well below 2%. Within this 2% precision, smooth curves could be drawn through the data for each of the five temperatures as a function of solvent composition, as is shown in Fig. 3. The data for pure water were taken from Gubbins and co-workers (16).

The salting-out effect of added base on hydrogen solubility has been shown to be considerable for water at 25–100 °C (16). Some of the mixed media in the present study contained tetramethylammonium hydroxide in order to duplicate conditions for a related deuterium exchange study (see footnote 3). Therefore these media were examined at 65 °C to determine if a similar effect was operating in the DMSO–water mix-

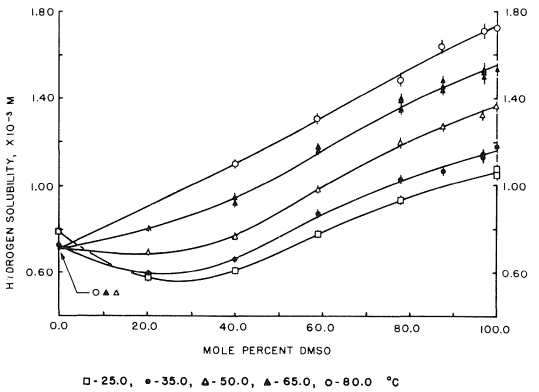

FIG. 3. Hydrogen gas solubility as a function of medium composition at the indicated temperatures. Error bars are ±2%. Data for pure water are from Gubbins and co-workers (16).

[4]The mole fraction data can be obtained by conversion of the molar values in the following manner, utilizing the density–temperature results of Cowie and Toporowski (2) for the DMSO–water system. For a chosen "moles of hydrogen per litre of solution", the litre of solution is reduced to the number of moles of DMSO plus water. The number of moles of hydrogen is negligible in comparison and can be neglected. The appropriate density yields the weight of the litre of solution, and since the relation between weight and mol% DMSO can be calculated, the individual weights of DMSO and water can be determined. Hence the number of moles of each is known, and therefore the total "moles of solvent" corresponding to the litre of mixed solvent.

TABLE 2. Solubility* of hydrogen in DMSO – water – tetramethylammonium hydroxide media† as a function of temperature

Temperature (°C)	Mole percent DMSO (base concentration, *M*)						
	100 (0)	96.9 (0.022)	87.5 (0.096)	77.9 (0.13)	59.0 (0.42)	40.1 (0.36)	20.2 (0)
25.0	1.05 1.08	—	—	0.93	0.78	0.61	0.58
35.0	1.18	1.13 1.15	1.07	1.03	0.87	0.66	0.60
50.0	1.37	1.33	1.27	1.20	0.98	0.77	0.69
65.0	1.54	1.50 1.52 1.53	1.44 1.45 1.48	1.35 1.39 1.40	1.16 1.17	0.92 0.95	0.80
80.0	1.73	1.71	1.64	1.49	1.31	1.10	—

* $\times 10^{-3}$ mol/l at 1 atm partial pressure for each temperature. Each entry is the mean of three or four separate values for one stock solution. The estimated error is ± 2%.
†See comments in text concerning the negligible effect of base concentration at this level on gas solubility. The base was not completely soluble for some solutions at 25 °C.

tures. It was found that, for 96.9, 87.5, 77.9 mol% DMSO at approximately one half and two times the listed base concentration (Table 2), and for 59.0 and 40.1% at one half the concentration, the measured solubility values were within experimental error of the mean for each set. Thus the presence of hydroxide ion in these solutions has little effect on the solubility data, and the values in Table 2 can all be considered as applying to the neutral solutions. The additional data obtained at 65 °C are included in Fig. 3 and Table 2.

Temperature Dependence

The partial molal heats of solution of hydrogen in the media were determined from the slopes of least squares plots of log (mole fraction solubility) *vs.* reciprocal absolute temperature (12). Similarly, partial molal entropies of solution were obtained from log (mole fraction solubility) *vs.* log (absolute temperature) graphs (12). In both sets of plots the least squares lines fell within 2% of all data points except two; correlation coefficients ranged from 0.997–0.999, except 0.994 at 77.9 mol% DMSO. The solubility data at 25 °C for 40.1 and 20.2 mol% DMSO were not included in these calculations, since definite upward curvature in the plots began to appear by this temperature. The results are shown in Fig. 4.

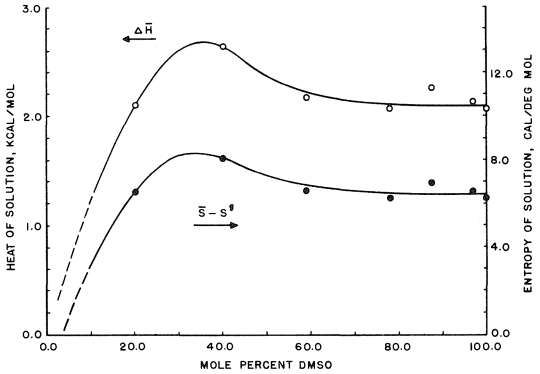

FIG. 4. Partial molal entropy (solid circles) and heat of solution (open circles) of hydrogen as a function of medium composition for 35–80 °C. The standard state for entropy is 1 atm partial pressure.

Discussion

Interpretation of Hydrogen Solubility Data

The data of Fig. 3 show a gradual disappearance of the minimum in the molar solubility – composition curve with increasing temperature. Such behavior is analogous to that for the viscosity of this solvent system (2), where the maximum in viscosity at 30–35 mol% DMSO becomes less pronounced as the temperature is raised. This viscosity effect has been ascribed to a gradual breakdown in the specific DMSO–water association (2, 6). More recently Schichman and Amey (11) have extended the viscosity measurements to lower temperatures, down to −60 °C in the region of 30 mol% DMSO. The viscosity maximum becomes even more clearly defined at the low temperatures. In Fig. 3 the position of minimum gas solubility changes with temperature from *ca.* 30 mol% DMSO at 25 °C to *ca.* 20 mol% at 50 °C.

The maximum in the partial molal entropy and heat of solution plots, Fig. 4, occurs in the same

25–35 mol% DMSO range. Hydrogen solubility in water is practically independent of temperature from about 35 to 70 °C (16), and the curves in Fig. 4 are projected towards zero for the heat of solution in water and slightly negative for the entropy.[5]

Fairly strong dipolar and/or ionic association in pure DMSO (6) must be overcome in the formation of cavities of proper size to accept the hydrogen molecules, and this is reflected in the positive heat of solution in DMSO. From 100 to *ca.* 50 mol% DMSO this function exhibits little change (Fig. 4), in agreement with the suggestion of Lindberg and Kenttämaa (1) that solvent structure remains essentially constant in this region. At the other extreme, water at lower temperatures is characterized by a relatively open structure (22–24 and references therein) which readily accepts small gas molecules; an enhanced ordering of the solvent molecules about the solute results. However, as DMSO is added to water the open structure is disrupted (6) and gradually replaced by the stronger DMSO–water complexes. The ease of accommodating the hydrogen molecules thus decreases, which leads to the observed increase in heat of solution from the value in water. Maximum energy is required in the region 25–35 mol% DMSO because intersolvent bonding is greatest at this point.

Further support for this argument comes from the energy–volume coefficient data of Macdonald and Hyne (10) for DMSO–water mixtures; their data are shown in Fig. 5. This function, the energy required per unit volume to enlarge a cavity in the solvent, is related directly to the strength of the solvent–solvent interaction. The shape of the plot in Fig. 5 resembles closely the present entropy and heat of solution curves in Fig. 4. Thus it becomes evident that the major factor controlling the solubility of hydrogen in these media lies in the structure of the mixed solvent itself.

The partial molal entropy of solution function in Fig. 4 can be interpreted in the following manner. Hildebrand and Scott consider (25) that, except for cases of specific gas–solvent interaction, the entropy of solution is comprized of two factors: (*1*) dilution of the solute on dissolution,

[5]The values for 50 °C, estimated from the data provided by Himmelblau (22), are 0.0 kcal/mol and −2.0 cal/deg mol, respectively; both become more positive with increasing temperature.

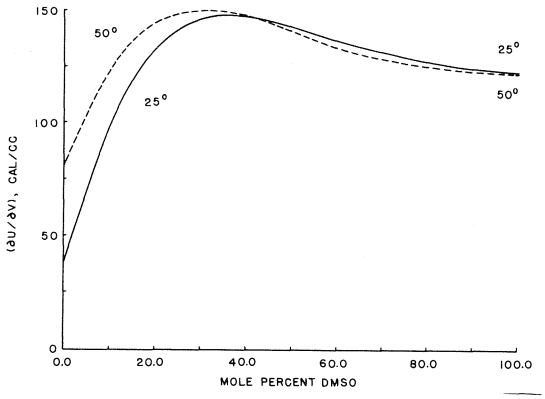

FIG. 5. Energy–volume coefficient data for the DMSO–water system at 25 and 50 °C, derived from the data of Macdonald and Hyne (10).

and (*2*) expansion of the solvent cavities in reaction to the gas molecules. Since the dilution term can be calculated directly from eq. 1, which gives the entropy change

$$[1] \qquad S_b - S_a = n \cdot R \cdot \ln (V_b/V_a)$$

for isothermal expansion of an ideal gas (26), the cavity expansion term can be obtained by difference. In eq. 1 V_a and V_b are the volumes occupied by 1 mol of gas ($n = 1$) in the vapor space and in solution, respectively; the latter value is the reciprocal of the molar gas solubility.

The results of this procedure are presented in Fig. 6 for 25, 50, and 80 °C. The figures for pure water were estimated from entropy of solution data reported by Himmelblau (22), while the gas solubilities were taken from the smooth curves of Fig. 3. Points for 40.1 and 20.2 mol% DMSO at 25 °C were not included in Fig. 6 since, due to curvature of the log (mole fraction solubility) *vs.* log (T) plots at this temperature, reliable estimates of the entropy of solution could not be made for these solvent compositions.[6] However, it appears that the maximum is not very pronounced at 25 °C.

It is apparent from a comparison of Figs. 4 and 6 that the cavity reaction term is the major contributor to the observed entropy of solution curve over the composition range from 0 to *ca.* 50 mol% DMSO. However, from 50–100 mol%

[6]The observed curvature arises from the transition in this solvent composition region from one type of temperature dependence of the solubility to another. In pure water the solubility *increases* when the temperature is *lowered* from 50 to 25 °C, whereas for solutions containing more than *ca.* 50 mol% DMSO the solubility *decreases* for the same temperature change.

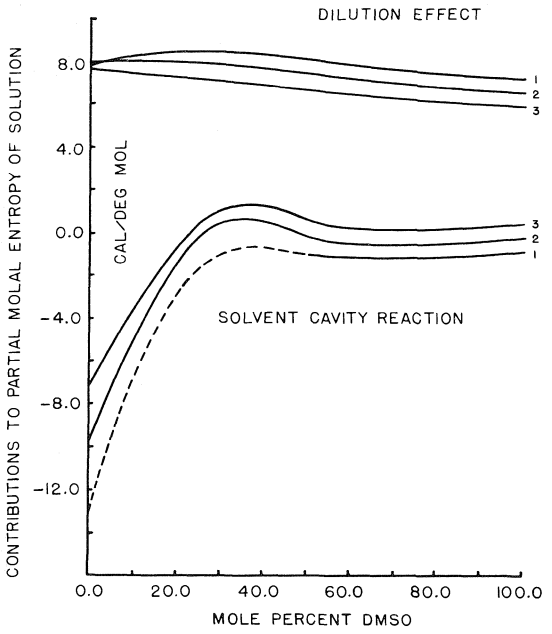

FIG. 6. A breakdown of the partial molal entropy of solution of hydrogen into contributions from dilution of the gas upon dissolution and from solvent cavity reaction to the gas molecules. Curves *1*, 25.0 °C; curves *2*, 50.0 °C; curves *3*, 80.0 °C. The standard state is 1 atm partial pressure.

DMSO, the dilution term becomes dominant, since the expansion term is now approximately zero (Fig. 6). The maximum in the net entropy near 35 mol% DMSO arises from the maximum in the expansion entropy at this point.[7] Such a result is not surprising since this region of greatest DMSO–water association is expected to be the most sensitive to perturbations such as a change of temperature (10) or introduction of an inert solute.

Similar observations to those in Fig. 4 have been made by Ben-Naim and co-workers during their investigation of the solubility of argon in several aqueous–organic systems (13, 14); their work was undertaken with a view to explaining what they considered to be the anomalously large negative heats and entropies of solution of inert gases in water. It was found in the water–methanol case (14), for example, that on changing from water to methanol the molar heat of solution of argon increased rapidly and then passed through a slight maximum before levelling off. The behavior was similar for the entropy, although no maximum was evident, in contrast to the present case. This dependence on medium composition was thought (14) to arise from a breakdown of large, hydrogen-bonded clusters of water molecules as the organic component is added. The major contribution to each function was believed to be liquid–liquid, and not gas–liquid interaction (14, 25).

DMSO–Water Complexes

Glasel (7) has discussed in some detail the experimental evidence pointing both to DMSO.$2H_2O$ and to DMSO.$3H_2O$ complexes. The excess relaxation times from his deuteron magnetic relaxation studies of DMSO–water solutions at 31 °C pass through a broad maximum at 25–30 mol% DMSO. The excess dielectric constant data of Doucet *et al.* (27) and Tommila and Pajunen (28) exhibit a similar behavior, and are interpreted by Glasel as an indication of 3:1 association. He concludes that both complexes are present in solution, and that the excess value functions for all the appropriate literature data are too flat and asymmetric to resolve a mixture of the two.

Glasel points out (7) that if the rotational reorientation time of the D_2O molecules in the 2:1 complex were considerably shorter than that for the 3:1 form, then the former complex might not be detected in a 50:50 mixture of the two. If this were the case, then even, for example, in a mixture which contains 95% of the 2:1 form the latter would probably not be observed in its true proportion, as determined from the maximum in the excess function curves arising from magnetic relaxation and dielectric constant measurements. The maximum in such curves would be strongly biased towards the 3:1 complex.

The following interpretation of complex formation in this system is put forward as a satisfactory explanation of the literature data to date. At least in the region 25–40 mol% DMSO, it is suggested that equilibria 2 and 3 are present in solution. It is clear from the DMSO–water phase

[2] $$DMSO.2H_2O = DMSO + 2H_2O$$

[3] $$DMSO.3H_2O = DMSO.2H_2O + H_2O$$

diagram (5) that at −65 °C the 3:1 form is dominant. However, at 25 °C equilibrium 3 must

[7]It should be noted that, although this maximum is believed to be real, the experimental error in the determination of the cavity entropy function is considerable, since it is obtained as the difference between two larger numbers of comparable size.

lie well to the right, since in general the various excess value functions have their maxima centered in the range 30–35 mol% DMSO (1, 2, 29). Also, the energy and entropy of activation for viscous flow for DMSO–water mixtures pass through a maximum near 30 mol% DMSO (11*a*). Since it has been demonstrated (2, 6) that the "2:1" complex is thermolabile, the proposal of the temperature-dependent equilibria 2 and 3 should overcome the problem of relating the phase diagram for this system to the various ambient temperature data (7, 11*a*).

Further evidence favoring the 2:1 complex at 25 °C and above comes from the present hydrogen solubility data, specifically from its deviation from "ideality". The "ideal" solubility has been defined for the present case as the sum of the quantities of gas which would have dissolved in the separated solvent components at each composition. These quantities were based on the hydrogen solubility in the pure liquids at each temperature. As can be seen in Fig. 7 for 25 °C, the effect of the real DMSO–water interaction is remarkable. The plots for 50 and 80 °C are similar, and show that this interaction is still fairly strong at 80 °C. The deviation functions at 25, 50, and 80 °C are quite symmetrical at the maximum, which occurs at 32 ± 5, 35 ± 5, and 32 ± 5 mol% DMSO, respectively.

It may be useful to extend the hydrogen solubility measurements to lower temperatures in order to test this two-complex hypothesis. Unfortunately, at such temperatures the DMSO–water mixtures are not in a liquid state over the full composition range (*e.g.* only from 0 to 70 mol% DMSO at 0 °C, and from *ca.* 20 to 45 mol% at −40 °C (5)), so that valuable information concerning deviation from ideality remains inaccessible (11). A shift in the maximum deviation towards 25 mol% would be predicted. However, it is interesting to note that the viscosity data recently obtained at the lower temperatures still show a maximum nearer 30 mol% (11), although the position of maximum deviation from ideality is not known. The latter would also be predicted to lie at or near 25 mol% DMSO.

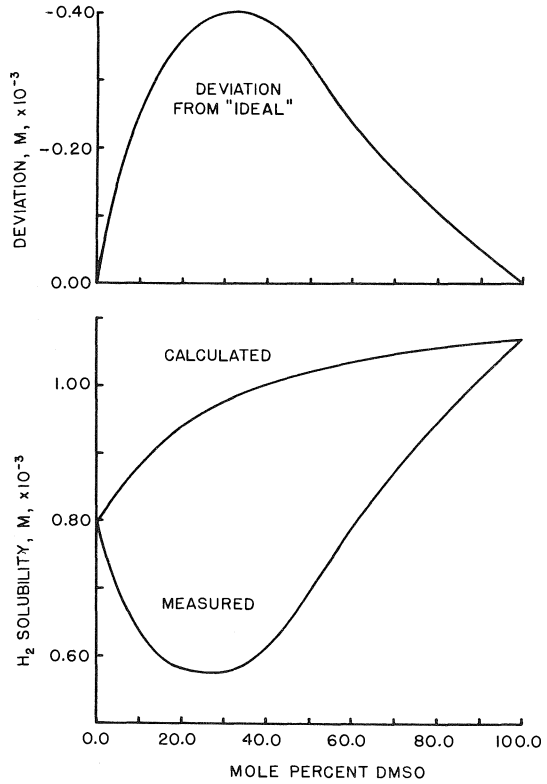

FIG. 7. The deviation from the calculated "ideal" hydrogen solubility as a function of medium composition.

The author wishes to thank Atomic Energy of Canada Limited for a fellowship, which was administered by the National Research Council of Canada, and for a very rewarding two year stay at WNRE. Valuable discussions with Dr. D. D. Macdonald, and provision of a preprint of some of their data by Dr. Macdonald and Dr. J. B. Hyne are gratefully acknowledged. The helpful comments of Drs. E. Buncel, D. A. Head, G. G. Strathdee, and N. H. Sagert on the manuscript were also appreciated.

Proton Magnetic Resonance Studies of Ionic Solvation in Ion-exchange Resins. Part III. Multivalent Counterions

H. D. SHARMA[1] AND N. SUBRAMANIAN[2]

Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received June 9, 1971

The p.m.r. spectra of Dowex AG 50W, X8, resins containing multivalent counterions have been measured. The ionic molal shifts in the exchanger phase are compared with those reported in homogeneous aqueous solutions. The spectral results are consistent with the concentrated electrolyte model of ion-exchange resins. Concentration and temperature dependence of proton chemical shifts in multivalent ionic forms of the resin suggests that ion association at high crosslinkages is more pronounced for counterions with high charge densities. The shapes of the shift-molality plots are explained by postulating that, at high crosslinkages, Mg^{2+} ion and the fixed $—SO_3^-$ group form "contact-ion pair" while the formation of "solvent-separated ion pair" is important in Be^{2+} and Al^{3+} forms of the resin. The anomalous trend in the hydration number values for magnesium and aluminum resinates can be understood as due to the long-range ordering of water structure in the presence of structure-forming ions. The p.m.r. spectra of resin–methanol system have been recorded at room temperature and at -65 °C. Failure to observe the resonance signal due to the cationic solvation shell at low temperature is attributed to the high degree of ion association under the conditions prevailing in the resin medium.

On a mesuré le spectre r.p.m. de la Dowex AG 50W, X8, résine contenant des contre-ions multivalents. On a comparé les déplacements molals ioniques dans la phase échangeuse avec ceux rapportés dans le le cas de solutions homogènes aqueuses. Les résultats spectraux sont consistants avec le modèle d'électrolyte concentré des résines échangeuses d'ions. Le fait que les déplacements chimiques des protons dépendent de la concentration et de la température dans les formes ioniques multivalentes de la résine suggère que l'association ionique à des degrés de pontage élevés est plus prononcée dans le cas de contre-ions à densité de charge élevée. On explique les formes des graphes des déplacements de molalité en postulant que, à des degrés de pontage élevés, l'ion Mg^{2+} et le groupe fixé $—SO_3^-$ forment une "paire d'ions en contact", alors que la formation de "paires d'ions séparées du solvant" est importante dans les cas où la résine a la forme Be^{2+} et Al^{3+}. On peut comprendre la tendance anormale des valeurs de nombre d'hydratation pour les résinates d'aluminium et de magnésium, connaissant l'ordre à longue portée de la structure de l'eau en présence d'ions formant la structure. On a enrégistré le spectre r.p.m. du système résine-méthanol à la température de la pièce et à -65 °C. On attribue l'insuccès à observer le signal de résonance dû à la couche de solvatation cationique à basse température, au degré élevé d'association ionique sous les conditions prévalant dans le milieu de la résine.

Canadian Journal of Chemistry, **49**, 3948 (1971)

Introduction

The n.m.r. technique is becoming increasingly useful as a means of observing directly the several phenomena connected with ion-exchange resin (1–17). Following the preliminary investigations of Gordon (1, 2) and Dinius and co-workers (3), n.m.r. has been applied to the study of a variety of problems such as electrolyte invasion (4), characterization of resin samples (6, 11), determination of rate of exchange of water protons between the internal and external phases (10), kinetics of ion exchange (12), and solvent selectivity in resin-binary aqueous solvent systems (14, 15). A report on the n.m.r. spectra of macroreticular resins has appeared very recently (17).

The main aim of the several other studies (5, 7–9, 13, 16) was to examine the structural properties of the sorbed liquid and the environments of the ionic species within the exchanger phase which are of importance in understanding the ion-exchange behavior. A systematic study of the effects of chemical structure, crosslinking, nature of counterion, inner molality and temperature on the p.m.r. spectra of several cation- and anion-exchange resins carrying monovalent counterions was reported by us earlier (8, 16). Our results as well as those from similar such studies (5, 7, 9, 13) are consistent with the model of the ion exchanger as a concentrated electrolyte

solution. They also serve to indicate that ion–water interactions in the resin phase and in the homogeneous aqueous solution are closely similar, although there is increased ion association in the resin medium, especially in highly crosslinked resins. We have extended the p.m.r. spectral studies to cation-exchange resins loaded with multivalent counterions in order to obtain additional information about ionic solvation in the resin phase. The p.m.r. spectra of the exchanger suspended in a non-aqueous solvent are also reported.

Experimental

Dowex AG 50W (200–400 mesh) resins with varying nominal divinylbenzene (DVB) contents were procured from Bio-Rad Laboratories in the H^+ form. (In the case of 1% DVB resin only 50–100 mesh beads were available.) They were converted to the required ionic forms according to the recommended procedures (18). The moisture contents of the swollen resin beads were determined by the Karl Fischer titration method (19).

The capacities of the resin in the Mg^{2+} and Al^{3+} forms were estimated by the following procedure. A weighed amount of the air-dried resin in the H^+ form was placed in a column. A known volume of a standard solution of $MgSO_4$ or $Al(NO_3)_3$ followed by several bed volumes of distilled water were passed through the column. The quantities of Mg^{2+} or Al^{3+} ions used were in liberal excess of the total capacity of the resin bed to ensure complete conversion. The effluent was collected in each case and made up to a known volume. Convenient aliquot parts of the solution were titrated against standard EDTA solution using Eriochrome Black T as indicator (20). From the difference in the metal-ion concentration between the original standard solution and the effluent, the capacity of the resin for Mg^{2+} or Al^{3+} ion was calculated. The overall error in the values of the resin molalities (m) reported is expected not to exceed $\pm 4\%$.

The p.m.r. spectral measurements were made with a J.E.O.L. C-60 spectrometer. The temperature of the sample was controlled by a JES VT2 unit. A copper–constantan thermocouple placed adjacent to the sample and a Hewlett–Packard 3420A DC differential voltmeter were used to measure the temperature. The temperature of the samples could be maintained within ± 1 °C of the desired temperature. All the spectral data reported in this work are the average results of at least three separate measurements. The chemical shifts could be determined to an accuracy of ± 1 c.p.s.

Preparation of sample for the resin–methanol system was as follows. The water-swollen Dowex AG 50W resin in the particular ionic form was first air-dried and then kept at 80 °C under 1 mm pressure for 12 h. This procedure was adopted to keep the fracturing of the beads during drying to a minimum. Fisher "spectranalyzed" methanol was used without further purification. Direct titration with Karl Fischer reagent gave an upper limit of 0.05% (w/w) for water present in methanol. The anhydrous exchanger was allowed to swell in methanol for a sufficiently long time and the suspension transferred to a n.m.r. sample tube. During the preparation of the sample, care was taken to ensure minimal contact of the materials with the atmosphere.

Results

The p.m.r. spectrum of a well-settled suspension of ion-exchange resin beads in water usually shows two distinct signals attributable to the water protons inside and outside the resin particle (1–3, 8). If the interior and exterior water peaks overlap considerably, they were resolved by the use of a computer routine developed by the Computing Center, University of Waterloo (21). The shift $\Delta\nu$ c.p.s. or δ_{soln} p.p.m. represents the chemical shifts of the interior water signal with respect to the exterior water signal, a negative value signifying that the internal water peak is downfield of the external water peak.

The p.m.r. spectra of aqueous suspensions of Dowex AG 50W (X8) in the Be^{2+}, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Zn^{2+}, Al^{3+}, La^{3+}, and Th^{4+} forms were recorded at a temperature of 23 ± 1 °C. The ionic molalities and the respective chemical shifts are listed in Table 1.

The effect of crosslinking on the internal water proton chemical shift was studied in Be^{2+}, Mg^{2+}, Ba^{2+}, and Al^{3+} forms of the exchanger. The δ_{soln}–m plots are shown in Fig. 1.

The influence of temperature on the p.m.r. spectrum was examined in several cases of the

Discussion

Influence of Ionic Form

It is known from p.m.r. studies of the exchanger in univalent ionic forms that the anomalous shielding effects of the aromatic rings of the resin matrix do not contribute significantly to the experimentally observed chemical shift (8, 16). Also, for the case of the spherical resin beads in contact with the solvent, corrections due to bulk susceptibility effects can be neglected (22, 23). Since the measured shifts are free from matrix and susceptibility effects, one could attribute δ_{soln} almost entirely to salt effects, *i.e.*, interactions between the sorbed water molecules and the ionic species present within the resin particle. It is then possible to divide δ_{soln} into individual ionic contributions by making an arbitrary assumption, *viz.*, $\delta_{NH_4^+}^0 = 0$ (24) ($\delta^0 = \delta/m$ as $m \to 0$). Based on this scale, a value of $\delta_{SO_3^-}^0 =$ 0.021 p.p.m./mol was obtained by us from measurements on the ammonium form of the sulfonated cation exchange resins (8). Using this value, the ionic molal shifts characteristic of the multivalent counterions studied, δ_+, were calculated. The values are compared with those obtained in homogeneous aqueous solutions in Table 1.

In both the resin and the aqueous media, the algebraic values of the molal chemical shift increase in the same order:

$$Al^{3+} \ll Be^{2+} \ll La^{3+} < Zn^{2+} < Mg^{2+} < Ca^{2+} < Sr^{2+} < Ba^{2+}$$

In a recent independent study, Howery and Kittay (7) determined the ionic molal shifts of a few divalent counterions (see Table 1). However,

For personal use only.

their measurements were carried out at a probe temperature of 40–42 °C. It has been shown that the frequency separation between the interior and exterior water proton resonance is a function of temperature (8, 9, 16). This would explain the difference between their values and those reported in our work. The slight difference between the resin phase δ_+ values observed by us and those obtained in aqueous solutions (25) are partly due to a difference of 5 °C in the temperature of spectral measurements. Also, the aqueous solution values for Zn^{2+}, Al^{3+}, and La^{3+} are from the work of Shoolery and Alder (26) and are uncorrected for susceptibility effects. Considering these factors and the limits of experimental error involved in the measurement of molal chemical shifts, the similarity in the sign and magnitude of δ_+ values in the two systems is indeed striking. It is significant that the cation inside the resin particle exerts its "structure-making" or "structure-breaking" property to almost the same extent as in an aqueous electrolyte solution (24). This result is consistent with the earlier observations on the ion-exchange resins with univalent counterions (8, 16).

Effect of Crosslinking

Compared to the univalent ionic forms of the resin, the internal water line broadening at higher crosslinkings is generally more pronounced with multivalent counterions. For instance, the width at half-height ($W_{1/2}$) has values of 72 and 90 c.p.s., respectively, for Be^{2+} and Al^{3+} forms of 16% crosslinked resin. There is evidence for ion association at higher resin crosslinkages even among univalent counterions. Under the circumstances, one would expect the small, multiply-charged counterions like Be^{2+} and Al^{3+} to exhibit considerably greater tendencies to form ion pairs. The relatively immobile multivalent cations closely adjacent to the organic matrix hold on to the water molecules in the primary hydration sheath very tightly. This would result in large differences in the relaxation times of "free" and "bound" water. Also, the exchange between the two kinds of internal water might be expected to be relatively slow.

It can be seen from Fig. 1 that the (negative) deviation from linearity of δ_{soln}–m plots is more pronounced than in the case of monovalent counterions and occurs at lower ionic concentrations (8, 16). With increase in crosslinkage (and, therefore, molality), the interactions between counterion and resin ion are obviously enhanced to a greater extent in resins carrying multiply charged counterions. Recent p.m.r. studies in aqueous electrolyte solutions have led Vogrin and co-workers (27) to conclude that ion pairing becomes important above 2 m for bi–uni salts ($Mg(ClO_4)_2$, $CaCl_2$, $Ca(NO_3)_2$) whereas for alkali metal salts it is significant only above 5 m. It is conceivable that small multivalent ions having relatively high charge densities possess residual electrostatic free energy beyond their primary hydration sphere and therefore can interact with anions in solution. Such interactions can be expected to become more important as the dielectric constant of the medium is lowered.

It can be further observed from Fig. 1 that the δ_{soln}–m plot for Mg^{2+} resin has a maximum and that at $m = 3.52$ (corresponding to X16) δ_{soln} is actually zero. The fact that the interior and exterior water lines are buried under each other is confirmed by varying the temperature of the sample. Since the temperature coefficients of proton chemical shift are normally different for pure water and the solution, increase in temperature causes the single peak to first undergo unsymmetrical broadening and then split into two separate peaks (Fig. 3). In the case of the other three ions, δ_{soln} continues to increase up to X16, although the rate of increase is noticeably diminished at higher concentrations. Further, whereas the interior water line is considerably broadened in Be^{2+} and Al^{3+} forms of the resin, especially at X16, the line is comparatively much narrower in Mg^{2+} resin. It would seem that at crosslinking above X8, the interaction between Mg^{2+} and the fixed ionic group is enhanced to such an extent that the $—SO_3^-$ ion displaces at least one water molecule from the primary hydration shell of the cation ("contact ion pair" formation). The proportion of bulk water would correspondingly increase thereby leading to an apparent decrease in the overall effect of this cation on the structure of water. The existence of $(M—NO_3)^+$ complex in highly concentrated aqueous solutions of divalent metal nitrates has been inferred from vibrational spectral studies (28–30). Mg^{2+} is believed to exhibit contact ion pairing with NO_3^- in aqueous solutions with water to salt ratio below 6:1 (31).

On the other hand, Be^{2+} and Al^{3+} ions, by virtue of their high charge densities, tend to retain their primary hydration sphere intact and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

probably bind the sulfonate anion in their second coordination shell ("solvent-separated ion pair"). Thus, with increase in concentration, these ions would have a lesser effect on the structure of water in the secondary layer while they continue to polarize the nearest-neighbor water molecules. Raman (31), infrared and n.m.r. (32) spectral evidences indicate the absence of Al^{3+}–NO_3^- contact in aqueous $Al(NO_3)_3$ solutions with concentrations comparable to those prevailing in Al^{3+} resins.

Effect of Temperature

The observed effect of temperature on $\Delta\nu$ is quite similar to that encountered in univalent ionic forms of the exchanger, *viz.*, in the case of structure-forming counterions, *e.g.*, Be^{2+}, Mg^{2+}, Zn^{2+}, Al^{3+}, La^{3+}, for which $\Delta\nu$ is negative, increase of temperature moves the peaks farther apart (*cf.* H^+, F^-); on the other hand, in the case of structure-breaking counterions, *e.g.*, Ba^{2+}, Sr^{2+}, for which $\Delta\nu$ is positive, increase of temperature decreases the separation between the two peaks (*cf.* Na^+, K^+).

Change in temperature has very little effect on the shape of the internal water line in the case of monovalent counterions (9). But for multivalent counterions, increase in temperature results in a significant sharpening of the resin phase water proton resonance (Figs. 2–4). The effect was also observed with Zn^{2+} and La^{3+} forms of the exchanger. Creekmore and Reilley (9) noted the same effect in their study of the Mg^{2+} resin. The narrowing of the internal water resonance with increase in temperature can be explained in terms of the two effects invoked above in connection with line broadening at higher resin crosslinkages, *viz.*, (*i*) the large difference in the relaxation exhibited by free and hydration water (9) and (*ii*) the lower rate of exchange between free and bound water molecules in the resin phase. Thus the observed effects of crosslinking and temperature on the internal water linewidth supplement each other.

Shoolery and Alder (26) found that the proton linewidths for aqueous electrolyte solutions were not noticeably broader than the pure water line except for Al^{3+}, Be^{2+}, and the most concentrated $ZnCl_2$ solutions. In the latter cases, lowering the temperature to slow down the proton exchange resulted only in a broadening of the line rather than a splitting of the line. It is interesting to note a similar behavior for the internal water linewidths in the resin system. It is found that $W_{1/2}$ varies within narrow limits for most ionic forms studied and has a value close to that for the H^+ form of the resin. Change in temperature has very little effect on $W_{1/2}$. But, in the case of Be^{2+} and Al^{3+} ions, lowering of temperature does result in considerable broadening of the interior water line. The observed effects within the resin phase are thus analogous to those produced by electrolytes in the homogeneous aqueous phase. This again lends support to the concept of the ion-exchange resin as a concentrated electrolyte solution.

Malinowski and co-workers (33) have developed a relationship between the "effective" hydration number of the electrolyte, h, and the temperature coefficients of proton resonance in pure water and in aqueous electrolyte solution

$$[1] \quad h = \frac{55.55}{m}\left(\frac{d\delta_{H_2O}{}^{ethane}/dt - d\delta_{soln}{}^{ethane}/dt}{d\delta_{H_2O}{}^{ethane}/dt}\right)$$

From what has been said above, it is clear that changes in temperature affect the average proton chemical shift of the interior and exterior water to different extents. The effect is identical to that observed in homogeneous electrolyte solutions. It should therefore be possible to apply eq. 1 to determine the "effective" hydration numbers of the resin salts. This has already been done in several cases involving monovalent counterions (8, 9, 16). Creekmore and Reilley (9) have estimated the h value for magnesium resinate in Dowex 50, X8, resin. We have used the $d\delta_{soln}{}^{ethane}/dt$ value listed in Table 2 to calculate the hydration numbers of Mg^{2+} and Al^{3+} forms of Dowex AG 50W. The results are included in Table 2.

Firstly, the h values for magnesium and aluminum resinates are found to be lower than those of $MgCl_2$ (34) and $Al(NO_3)_3$ (35), respectively, in aqueous solutions of comparable concentrations. Creekmore and Reilley (9) explained the lower hydration number of the magnesium resinate (X8) as due to the difference between Cl^- hydration (h = 0.6–1.0) and the resinate hydration (assumed ~0). The assumption that the hydration of the fixed sulfonate group is ~0 is not borne out by our experiments on the ammonium form of the cation exchanger (16). We attribute the observed lowering of h in the resin phase to enhanced cation–anion association

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

aided by the very low dielectric constant of the exchanger medium.

Secondly, the hydration numbers increase with increase in crosslinkage (or, concentration). It may be recalled here that a similar trend is also observable in the case of H^+ and F^- counterions (16). Such behavior is quite contrary to the expected effect of concentration on h. It is significant that ions exhibiting this anomalous behavior all possess the common ability to promote the structure of liquid water. In the derivation of eq. 1 it has been tacitly assumed that the ion does not perturb the secondary layer of water molecules around it. While this assumption may perhaps be reasonable for moderately large monovalent ions (*e.g.*, Na^+), it is certainly not valid for ions with high charge densities. It is therefore not surprising that for ions of the latter type, the hydration numbers determined by Malinowski's technique are rather anomalous. By taking into account the long-range ordering of water molecules in a solution containing structure-making ions, it is in fact possible to explain the observed trend in h values as a function of concentration (36).

Resin–Methanol System

Spectra at 23 °C

The p.m.r. spectrum of a suspension of the cation-exchange resin in methanol consists of two broad, unsymmetrical bands due to the methyl and the hydroxyl protons. Spinning side bands are invariably present in these spectra (2). It was observed that the spectral characteristics do not change significantly with bead size (50–100 to 200–400 mesh), resin crosslinkage (X1 to X8), or ionic form (Na^+, Be^{2+}, Mg^{2+}, and Al^{3+}). The methyl and hydroxyl proton resonances were separated by ~93 c.p.s. For all the cases studied, $W_{1/2}$ of both the peaks were ~25 c.p.s. When the solvent external to the beads was removed and the spectrum of the resin phase alone was recorded, two broad peaks ($W_{1/2} = 35$ c.p.s.) with diminished intensities and separated by 96 c.p.s. were seen in the spectrum. This shows that the interior solvent resonance is masked under the exterior solvent peaks.

According to Gordon (2), the diamagnetic anisotropy of the polystyrene matrix in cation-exchange resins can be expected to shift the carbon-bound proton resonance of the interior liquid by +14–18 c.p.s. Similar upfield shift of the methyl resonance can be expected also for the resin–methanol system. However, the interior and exterior methyl resonances are unresolved in the spectrum owing to the large peakwidth of the external solvent in this case. The broadening of the exterior liquid line increases with increasing difference in the diamagnetic susceptibility of the liquid and the solid ($\Delta\chi$) (2). Since this difference is relatively large when methanol is the solvent ($\Delta\chi = 0.221 \times 10^{-6}$ c.p.s. units), the exterior resonance is considerably broadened.

From their studies of methanolic solutions of electrolytes, Butler and Symons (37) have assigned values of −0.458 and −0.30 p.p.m. at 40 and −69 °C, respectively, for the molal shifts in the hydroxyl resonance due to Mg^{2+} ion. Based on these values, one would expect a difference of at least 30 and 70 c.p.s. between the chemical shifts of the interior and exterior hydroxyl resonances in the 1 and 8% crosslinked resins, respectively. Even greater values for this shift can be expected for the Be^{2+} and Al^{3+} forms of the exchanger. But the actually observed value has an upper limit of only 25 c.p.s. in all the cases. This could be attributed to ion pairing in the resin phase. When water is replaced by an organic solvent such as methanol, the dielectric constant of the resin medium is further lowered, thereby favoring enhanced ion association.

Spectra at Low Temperature

The spectra of the resin samples in methanol were recorded at low temperatures in an attempt to observe the resonance due to the cationic solvation shell. However, unlike in homogeneous electrolyte solutions (38), no separate signal attributable to primary shell solvent molecules appeared in the spectrum up to −70 °C. When the temperature was lowered beyond −70 °C, the sample became too viscous for any signal to be observed.

Failure to observe the cation solvation shell in the p.m.r. spectra at low temperature can be considered as evidence for the high degree of ion pairing in these resins. As mentioned earlier, strong interactions between counterions of high charge density and the fixed resin group may be expected at the low dielectric constant of the resin medium in the presence of an organic solvent. It is likely that as a consequence, the solvent molecules firmly bound in the primary shell of these cations will lose their rotational degree of freedom. Due to the resulting large

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

increase in the correlation time, τ_c, their resonance may be broadened beyond detection. It is interesting to note that Gordon (2) failed to observe any signal due to the counterion in the presence of anhydrous non-aqueous solvents. He considered this to reflect the very low fluidity of the resin in contact with these liquids and the consequent loss of rotational freedom of the ions. The disappearance of the ^{23}Na signal at higher resin crosslinkages has also been attributed to an increase in τ_c (9).

Ion pairing has been postulated in mixed aqueous and non-aqueous solutions of electrolytes to account for the decrease in the measured hydration number at the concentrations similar to those prevailing in the resin phase (39, 40). In contrast to the resin phase, however, cations and anions are both mobile in these systems; furthermore, the diffusion coefficients of the ionic species are also higher due to the relatively lower viscosity of the homogeneous phase. Thus, while the cationic solvation shell can be observed for these solutions in the p.m.r. spectrum at low temperatures, such is not the case for the more viscous exchanger medium, in which the anionic species is immobile. The slow rate of exchange of ions observed in 85% methanol solution can also be attributed to the immobility of ions in the resin phase (41).

The authors thank the National Research Council of Canada for providing financial support for this work and for the award of a Post-Graduate scholarship to N. Subramanian. We are grateful to Mr. W. Gilchrist for the technical assistance rendered during the spectral measurements.

The Isothermal Compressibility of Organic Liquids by Ultracentrifugation. Correlation with Surface Tension

ALFRED J. RICHARD

Department of Chemistry and Pharmaceutical Chemistry, Medical College of Virginia, Health Sciences Division of Virginia Commonwealth University, Richmond, Virginia 23219

AND

KENNETH S. ROGERS

Department of Biochemistry, Medical College of Virginia, Health Sciences Division of Virginia Commonwealth University, Richmond, Virginia 23219

Received July 22, 1971

Isothermal compressibilities of seven organic liquids have been determined by analytical ultracentrifuge techniques, in good agreement with literature values obtained by other methods.

A least squares regression equation was derived that correlated the logarithmic values of isothermal compressibilities of 7 organic liquids, determined experimentally, with the liquids' surface tensions. This equation was shown to be valid for 11 other organic liquids (values obtained from literature) over a temperature range of 0° through 50°, and a surface tension range of 13 to 44 dyn per cm.

Nous avons déterminé la compressibilité isothermique pour 7 liquides organiques, avec l'ultracentrifugeuse analytique. Nos valeurs sont toujours semblables a celles déterminés par d'autres méthodes.

Une équation des moindres carrés a été déconverte entre le logarithme des valeurs des compressibilités isothermiques des 7 liquides, et de leurs tensions superficielles. Cette équation est valide pour 11 autres liquides organiques (valeurs des compressibilités obtenue dans la littérature) ayant des tensions superficielles de 13 a 44 dyn/cm et entre les températures de 0 a 50 °C.

Canadian Journal of Chemistry, **49**, 3956 (1971)

Introduction

The isothermal compressibilities (1, 2) and the isothermal piezooptic coefficients (2, 3) of liquids have been measured by ultracentrifugation. During the course of our continuing studies on the determination of isothermal compressibilities of liquids by ultracentrifugation, it was found necessary to make modifications on the schlieren optical system of the ultracentrifuge. These modifications are reported here for the Beckman Instruments Spinco E analytical ultracentrifuge.

In addition, an empirical relationship has been found between the isothermal compressibility at 1 atm and the surface tension of several liquids.

Experimental

The procedure of Dayantis (1) was followed in this work. If the refractive index (n) of a liquid at 5461 Å, and its density (ρ_0) at the temperature of choice were known, then the isothermal compressibility (β) was given by the relation:

$$\beta = \frac{(y)6n \tan\theta}{(Lam_1m_2)(n^2+2)(n^2-1)\rho_0 w^2 r_0}$$

where y was the height of the schlieren line above a baseline obtained with the same cell at a low speed, 2000–3000 r.p.m., both measured from the counter balance references, θ the schlieren bar angle, 70° for all these experiments, L the optical lever, a the cell thickness, (m_1m_2) the vertical magnification of the optical system, w the angular velocity, and r_0 the distance of the meniscus from the center of rotation. The temperature was measured before each picture was taken and was always found to be 20 ± 0.02 °C (4). The filter above the light-source was taped in place to prevent it from moving as the chamber was lowered or raised. Of great importance was the lateral position of the schlieren bar. Correct values of compressibilities were obtained only when the bar was placed relative to the slit image such that the bar image, as seen on the viewing screen, did not rise or fall as the bar angle approached 0°. Rather, the image, without tilting, should smear out symmetrically at 0°, about its position at all other angles. The bar was positioned with the chamber closed and evacuated. It was difficult to set the lateral position of the bar accurately with the counter-locking set screw arrangement on the bar holder; therefore, these screws were removed, and a micrometer was attached to the bar holder such that the micrometer abutted against the camera lens holder, thereby fixing the lateral position of the bar, see Fig. 1. Contact was maintained by spring tension. To test the effect on compressibility of the lateral position of the bar, the bar was moved 25 μ to either side of the true position at the end of a benzene determination, and a picture taken for each setting. For the displacement of the bar toward the front of the centrifuge, the compressibility was increased by 0.5% and similarly, the compressibility was decreased by 0.5% when the bar was moved toward the back of the centrifuge.

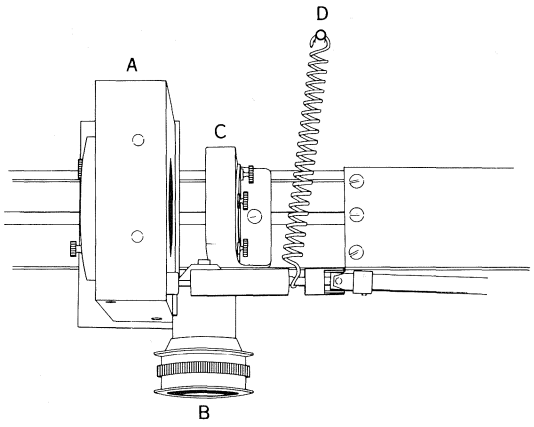

FIG. 1. View of the schlieren optical track of the ultracentrifuge, with protective cover removed. Visible components are: *A*, schlieren bar assembly; *B*, micrometer, attached to the bar assembly; *C*, camera lens mount; *D*, spring. The spring was attached to the bar assembly and to one of the support posts of the protective cover.

The cell used for these experiments had a 12 mm, 2° sector, aluminum centerpiece. Sapphire windows were necessary, but to minimize bending of even these windows, the window holders were of the older design with openings just slightly greater than the size of the sector. The clear gaskets between the windows and the window holders dissolved readily in some of the liquids used in this study, and were replaced therefore by red polyethylene gaskets normally used for the centerpiece. As a precaution, the red centerpiece gaskets were always presoaked for 2 h with the liquid under study. Cyclohexane caused some expansion of the gaskets, but the other liquids in the study did not seem to affect them. Excess grease was carefully removed from the threads and keyway of the cell body to prevent leaching.

As a check on the bar angle setting, it was found useful to place on the optical track, directly in front of the bar, an aluminum plate with the top cut to 70° to the vertical. A white card placed behind the bar, and appropriate lighting, made it possible to sight along the bar over the top of the aluminum plate. Perpendicular scribe marks on the front of the aluminum plate were also used simultaneously to check the vertical setting of the slit image. The lightsource slit width was reduced to 0.15 mm by feeler gauge, with care for the parallel alignment of the slit edges.

Each run was carried out as follows: The centrifuge was accelerated to 33 450 r.p.m. and allowed to spin there for at least 5 min. The speed was then reduced to 2095 r.p.m. and maintained there for at least 15 min at 20 °C. A picture was taken to provide the base line. The few minutes overspeed at the start of each run eliminated base line shifts that otherwise frequently occurred during centrifugation, apparently due to slight rearrangements of cell components. The final picture was taken at 23 150 r.p.m. after a minimum of 15 min at speed and at 20 °C. With benzene and cyclohexane, patterns taken 3 h after reaching speed were identical with those taken at 15 min.

All liquids studied in this work were purchased of C.P. or spectroanalyzed grade and were used with no further purification other than drying overnight with pellet KOH or $CaSO_4$ (drierite), followed by vacuum distillation to eliminate gases. The still was brought to 1 atm by the injection of He through a rubber septum on the collecting vessel; and samples, taken by syringe, were transferred quickly to the centrifuge cell that was also filled with He.

Results and Discussion

The isothermal compressibilities of seven liquids are listed in Table 1 along with available literature values.

Agreement was quite good in most cases. The values of Holder and Whalley (5) were extrapolated to 20 °C from their data at higher tem-

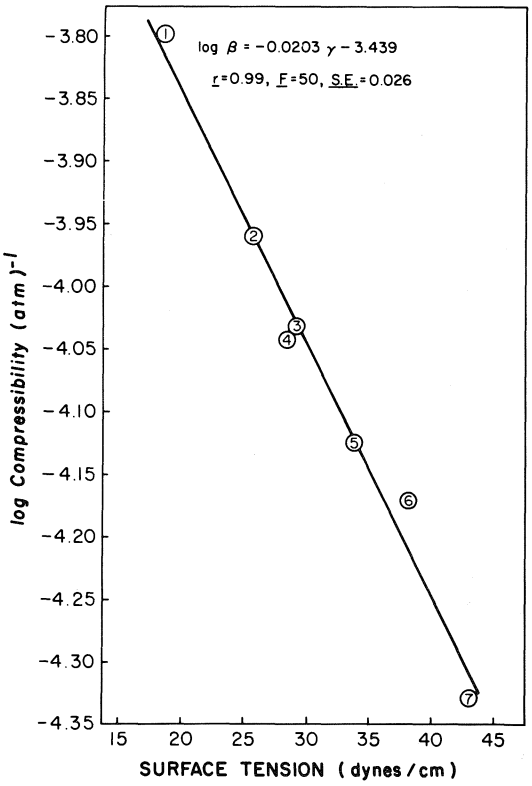

FIG. 2. Plot of the logarithm of the isothermal compressibilities (β) against the surface tensions (γ) of seven organic liquids. Values of β at 20° were determined by ultracentrifugation, values of γ also at 20° were taken from ref. 6. The liquids were: *1*, hexane; *2*, cyclohexane; *3*, benzene; *4*, toluene; *5*, chlorobenzene; *6*, pyridine; and *7*, aniline. The regression coefficient (*r*) is for the fit of experimental points to the equation given in the figure, the significance of the equation in describing the data is given by the *F*-test coefficient (*F*), and *s.e.* represents the standard error of the estimate (log β) calculated from the equation.

peratures. The value of 100×10^{-6} atm^{-1} for benzene at 20°, quoted in ref. 6, is incorrect because of an erroneous unit conversion in the transcription from the original paper (7). Dayantis (1) showed agreement with this latter value. However, there is no indication of the quality of benzene used by Dayantis, nor is it reported that the benzene was dried and degassed prior to centrifugation.

An empirical relationship was noted between β and the surface tension (γ) of the liquids in this study. As liquids became more compressible (gas-like), the surface tension decreased. A least squares equation was derived that correlated the experimental β values with literature values of γ, Fig. 2. The regression coefficient (r) for the fit of experimental points to the line was 0.99. A value of 1.00 for r would indicate a perfect fit.

A comparison of measured β values with β values calculated from the equation in Fig. 2 is presented in Table 2. All data in Table 2 were taken from literature sources, thus the equation deduced from ultracentrifugal evaluation of β

was satisfactory to represent β values obtained by other means, *e.g.*, measurement of the speed of sound through a liquid (8) or piezometry (9). Although the least square equation was obtained for data at 20 °C, the same equation was used to represent the relation between β and γ for liquids in the temperature ranges from 0–50 °C. Thus the log β and γ seem to vary in the same way with temperature.

Sinanoglu (10) has related bulk surface tension of liquids to the energy requirement for the formation of a cavity in a liquid by the displacement of the liquid's own molecules. Then solute interactions with the pre-formed cavity in the liquid were related to the interactions of various molecules of biological interest, *e.g.*, solvent denaturation of DNA, actinomyocin dimerization, and benzoquinone-hydroquinone associations in various solvents.

Surface tension values have also been related to cohesive energies of liquids (latent heat of vaporization) and as such, have been used to calculate Hildebrand and Scott solubility parameters (11). The solubility parameters have generally been useful only for regular solutions, however. For instance, the solution of aniline in water would be non-regular because of hydrogen bond interactions.

Since the energy required to form a hole, or fixed space, in a liquid was proportional to γ of that liquid (10, 12), then it was reasonable that the compressibility of the liquid was determined, at least in part, by the existence of pre-formed cavities. Thus, hydrogen bonding liquids, with considerable fixed space would be incompressible relative to ideal liquids containing little or no fixed space.

Further work is in progress to determine whether the amount of fixed space in a liquid can be determined from studying the pressure dependence of the isothermal compressibility in the ultracentrifuge.

Configurational Equilibria in Methyl 3,6-Dideoxy-3-nitro-α-L-hexopyranosides[1]

JAN KOVÁŘ, KAREL ČAPEK,[2] AND HANS H. BAER
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received June 21, 1971

Epimerizations in alkaline medium, by which the methyl 3,6-dideoxy-3-nitrohexopyranosides having the α-L-*gluco* (**1**), α-L-*galacto* (**2**), α-L-*manno* (**3**), and α-L-*talo* (**4**) configurations are mutually interconverted, were investigated quantitatively by n.m.r. spectroscopy and by preparative separation of products. The epimeric equilibrium compositions obtained depend on whether an equimolar or a catalytic amount of alkali is supplied. In the first case they are governed by the thermodynamic stabilities of the nitronate anions (**4***a* > **3***a* > **2***a* ≃ **1***a*), and in the second case, by those of the free nitro glycosides (**1** > **2** ≃ **3** > **4**). The results are discussed in terms of conformational analysis, and a value of 2 kcal/mol is found for the contribution of the $A^{(1,3)}$ interaction to the conformational free energy in the nitronates. The $A^{(1,3)}$ effect strongly influences not only the product composition at the nitronate equilibrium but also the pathway of epimerization.

L'épimérisation en milieu alcalin, par laquelle les didéoxy-3,6 nitro-3 hexopyranosides de méthyle ayant les configurations α-L-*gluco* (**1**), α-L-*galacto* (**2**), α-L-*manno* (**3**), et α-L-*talo* (**4**), s'interconvertissent mutuellement, est étudiée quantitativement par r.m.n. et par séparation préparative des produits. Les compositions des équilibres épimériques obtenus dépendent des quantités de base ajoutées (équimolaire ou catalytique). Dans le cas d'une quantité équimolaire, les équilibres sont gouvernés par les stabilités thermodynamiques des anions nitronates (**4***a* > **3***a* > **2***a* ≃ **1***a*) et dans le cas d'une quantité catalytique, ils sont gouvernés par les stabilités thermodynamiques des nitro glycosides libres (**1** > **2** ≃ **3** > **4**). Les résultats sont discutés en terme d'analyse conformationnelle et une valeur de 2 kcal/mol est obtenue pour la contribution de l'interaction $A^{(1,3)}$ à l'énergie libre conformationnelle des nitronates. L'effet $A^{(1,3)}$ influence fortement non seulement la composition des produits à l'équilibre des nitronates mais également le processus de l'épimérisation.

Canadian Journal of Chemistry, **49**, 3960 (1971)

Introduction

Certain nitro glycosides and nitro cyclitols are known to undergo spontaneous epimerizations in alkaline medium (1). Two preceding investigations in this series have dealt specifically with structural, conformational, and mechanistic aspects of such reactions in methyl 3-deoxy-3-nitropentopyranosides (2) and methyl 4,6-*O*-benzylidene-3-deoxy-3-nitrohexopyranosides (3). It has been realized in those studies that the $A^{(1,3)}$ effect (4), the nonbonded interaction between a group attached by a double bond to the ring (here, $=NO_2^-$) and a vicinal, equatorial substituent (here, —OH), has a profound influence upon conformational preferences and configurational interconversions (2, 3). On the basis of free energy calculations (2) one may predict the behavior of other groups of nitro glycosides in alkaline solution, and it is the purpose of the present article to elaborate this concept by disclosing results obtained with the four available methyl 3,6-dideoxy-3-nitro-α-L-hexopyranosides.

Results

The compounds used were crystalline methyl 3,6-dideoxy-3-nitro-α-L-glucopyranoside (**1**) (5, 6) and its isomers (6) having the α-L-*galacto* (**2**), α-L-*manno* (**3**), and α-L-*talo* (**4**) configurations. In aqueous solution containing one or more equivalents of sodium hydroxide, these glycosides incur changes in optical rotation as exemplified in Fig. 1. The compounds exist, in media of sufficient alkalinity, as nitronate salts showing high intensity u.v. absorption (ε 9000–11000 in 0.01 *N* NaOH) at 248–250 nm. It was possible to distinguish the individual isomers by n.m.r. spectroscopy by virtue of differing chemical shifts in their respective *O*-CH_3 and *C*-CH_3 signals (Table 1), and to determine isomer ratios, in mixtures, by integration of these signals.

Each of the four nitro glycosides gave a spectrum corresponding to a practically uniform nitronate within the first 10 min after the addition

of alkali; with progressing time, epimerizations became evident by the appearance, in each case, of the signals corresponding to the other isomers (Fig. 2). The most interesting feature was that **1** and **2** gave the same initial nitronate and showed the same time-dependent changes in the resulting isomer ratios, an unexpected phenomenon that

will be explained in the Discussion. The nitronate initially produced from **3** was different, but in the course of 3.5 h the composition of the mixture became nearly the same as that observed starting from **1** and **2**. The spectroscopic results thus parallel the optical rotation curves which indicated a closely similar reaction course for **1** and **2**, and attainment of a mobile equilibrium of nitronates departing from **1**, **2**, and **3**. It was found that the nitronate initially engendered from both **1** and **2** is that having the α-L-*xylo* configuration (**2***a*), *i.e.*, the nitronate corresponding to the α-L-*galacto* parent glycoside **2**. The remarkable fact that **1** did not form the α-L-*ribo* nitronate **1***a* at an early stage of the reaction was first suggested by a comparison of the *C*-CH_3 chemical shifts of the nitronates (Table 1) with those of the free nitro compounds in neutral solution (Table 2), the corresponding signals being affected very little when a given nitro glycoside is converted into its configurationally related nitronate. Def-

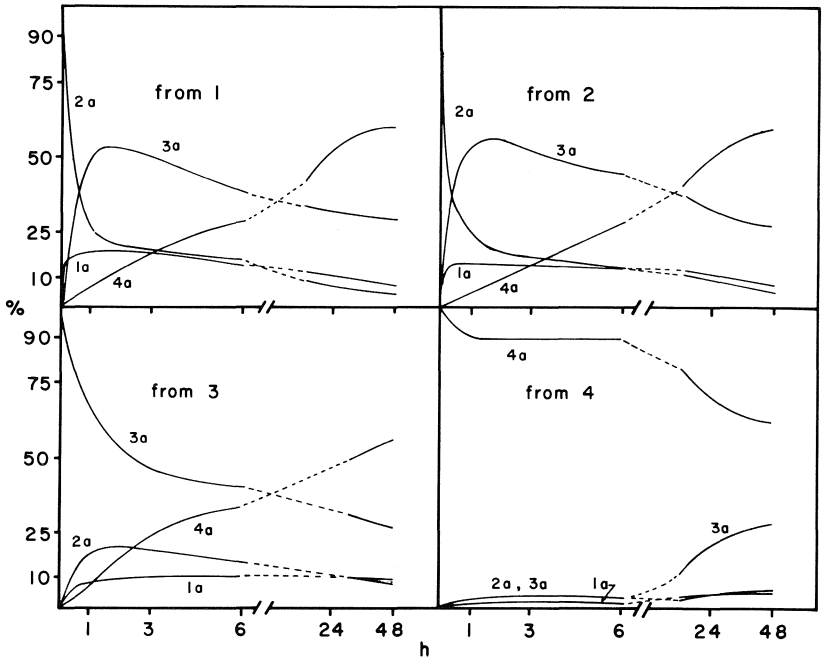

FIG. 2. Change in composition of glycoside mixtures during epimerization in the presence of excess base.

inite confirmation was provided by the preparative isolation, in 60% yield, of **2** from **1** after treatment with alkali for 1 min followed by acidification. The nitronate **1***a* did, however, constitute a component of the epimeric mixtures eventually produced from all the four nitro glycosides. The nitronate initially given by the mannoside **3** undoubtedly was the expected α-L-*arabino* salt **3***a* as was deduced from the n.m.r. data (Tables 1 and 2) and proved by the recovery of **3** in good yield upon acidification. The nitronate that initially arose from the α-L-*talo* isomer **4** had the α-L-*lyxo* configuration (**4***a*). It underwent epimerization relatively slowly so that, after the period of time when the other nitronates had reached a quasi-equilibrium among themselves (3–4 h), changes were insignificant (Figs. 1 and 2). However, after 2–3 days the reaction mixture contained **4***a* and the three isomers in the ratio of 60:40. Whereas the mixtures of nitronates obtained from **1**, **2**, and **3** contained about 20% of **4***a* at their quasi-equilibrium, they eventually assumed the same final composition, with **4***a* being the main component. From this second equilibrium we have calculated standard free energy differences for **1***a*, **2***a*, and **3***a* with respect to the thermodynamically most stable isomer, **4***a* (Table 3). It is seen that the α-L-*arabino* salt **3***a* ranks second in stability, and that the α-L-*ribo* (**1***a*) and α-L-*xylo* (**2***a*) compounds are significantly less stable and quite similar to each other. Since the equilibrium concentrations of **1***a* and **2***a* were rather small and their spectroscopic determination was, therefore, subject to a relatively large error, we also calculated the standard free energy differences for these compounds with respect to **3***a* at the quasi-equilibrium, where larger concentrations prevailed (Table 3). The latter data show the stability of **2***a* to be somewhat greater than that of **1***a*, but it is open to question whether equilibration between **1***a*, **2***a*, and **3***a* had in fact been complete at that point.

In a different series of experiments we have studied in the same way the epimerization of the nitro glycosides in the presence of a catalytic amount of base (0.05–0.1 molar equiv of NaOD) rather than in the presence of 1 molar equiv or more. Again, **1**, **2**, and **3** each underwent epimeric equilibration, and the mixtures obtained after 2 days were identical in composition within an experimental error estimated at 10% of values found (Fig. 3). As was to be expected (see Discussion), the ratio of the free nitro sugars **1**–**4** so attained was different from that of their salts

*Used for calculating *K*.

1*a*–**4***a* observed in the previous series of experiments. It is seen (Fig. 3) that the α-L-*gluco* isomer (**1**) was the preponderant component and the α-L-*galacto* (**2**) and α-L-*manno* (**3**) isomers were present as minor components in about equal proportions, the ratio being about 3:1:1. The α-L-*talo* isomer was not detected (although it is spectroscopically distinguishable from the others), but its nitronate, the α-L-*lyxo* salt **4***a*, was present to the extent of the amount of base that had been added.[3] Table 4 gives the equilibrium concentrations and standard free energy differences derived therefrom, for **2** and **3** relative to **1**.

Addition of a limited amount of base to the *talo* compound **4** also caused epimerizations (Fig. 3), but these were so slow that the approach of an epimeric equilibrium was obscured by the occurrence of side reactions which were not elucidated.

[3]This is understandable in view of the considerable differences in nitromethylene acidities. Compound **4** was found to have the lowest pK_a value (8.25) as determined potentiometrically by half-titration in water solution. The values for **1**, **2**, and **3** were 10.60, 10.45, and 9.90 respectively. (Since **1***a* is rapidly epimerized as outlined above, the value found for **1** does not represent the simple equilibrium **1** ⇌ **1***a* but a more complex equilibrium involving also **2** ⇌ **2***a*; compare a similar situation observed (2) with methyl 3-deoxy-3-nitro-β-D-xylopyranoside (2).)

TABLE 4. Configurational equilibration of nitro glycosides in the presence of a catalytic amount of NaOD at 35°

$K_{1/3} = 3.53$		$= 0.76$		

The spectroscopic studies recorded above were complemented by experiments on a preparative scale. The nitro glycosides **1**–**4** were allowed to epimerize in the presence of 1 equiv of sodium hydroxide, and samples were deionized after given periods of time. The mixtures produced were then separated by column chromatography and the epimers were isolated in crystalline form. The results are summarized in Table 5. Comparison of the ratios of glycosides isolated with the ratios of products encountered in spectroscopic experiments (Figs. 2 and 3) shows reasonable agreement, although there are some apparent discrepancies that will be discussed later on. Based on these studies, conditions have been worked out which render the *galacto* and

talo isomers **2** and **4** readily accessible. These isomers had previously been obtained only as minor components in the nitromethane cyclization that had afforded mainly **1** and **3** (6).

Discussion

The epimerizations occurring in the presence of an excess of base show that the order of thermodynamic stability of the nitronates is $4a >$ $3a > 2a \simeq 1a$. On the other hand, the order of stability of the free nitro glycosides as revealed by the epimerization equilibria obtained in the presence of a catalytic amount of base is $1 > 3 \simeq 2 > 4$. This is in accord with expectations based on conformational analysis as will now be outlined.

It was reasonable to assume that the free nitro glycosides **1**–**4** in aqueous solution prefer the

†Plus energy of two *gauche* NO_2–OH interactions.

C_1^4 conformation, with axial anomeric methoxyl and equatorial C-3 nitro and C-5 methyl groups.[4] This assumption was confirmed by the n.m.r. spectra of **1**–**4** (Table 2). Calculation of conformational free energies using Angyal's procedure and parameters (8) and following the example of our previous work (2) gave data (Table 6) which indicated, for the C_1^4 conformers, the same order of stabilities as was found experimentally.[5]

As far as the nitronates **1***a*–**4***a* are concerned, n.m.r. spectroscopy afforded only limited information about their preferred conformations. Thus, the α-L-*xylo* salt **2***a* exhibited small coupling constants $J_{1,2}$ and $J_{4,5}$, but this feature does not permit a distinction between the C_1^4 and C_4^1 chairs in this instance. The α-L-*arabino* salt **3***a* showed a large splitting $J_{4,5}$, which agrees with the C_1^4 form and rules out the C_4^1 form. Unfortunately, the splitting of the H-1 and -2 signals, which would have confirmed this, could not be measured. In the α-L-*lyxo* salt **4***a* the splitting of H-4 and -5 was observed to be small, but this was to be expected for both chair forms. The coupling pattern of H-1 and -2 should have been able to provide a decision, but these signals were insufficiently separated to allow determination of $J_{1,2}$. However, the close spacing of the peaks tended to suggest a small rather than a large splitting, thus supporting the C_1^4 conformation. Finally, the α-L-*ribo* salt **1***a* could not be analyzed owing to its rapid epimerization; in epimeric mixtures, its presence was indicated by the OCH_3 and C—CH_3 signals, but the ring protons could not be differentiated.

Even though the n.m.r. spectral data assisted little in making conformational assignments, one may confidently assume that compounds **2***a*, **3***a*, and **4***a* prefer the C_1^4 conformation (OCH_3 axial, C—CH_3 equatorial). This follows from a comparison of the conformational free energies calculated for both chair conformations (Table 6). For computing these energies, a term (*A*) must be added for the non-bonded interaction between the nitronate grouping and an adjacent, equatorial hydroxyl group ($A^{(1,3)}$-effect) whenever this condition occurs (2). However, for **2***a* and **3***a* a numerical value of *A* is not needed for calculating the free energy differences of the chair conformers, since there is one $A^{(1,3)}$ interaction in each. The value of 1.95 kcal/mol for the calculated energy difference in the conformers of **2***a* (Table 6) corresponds to 96% of the C_1^4 form in conformational equilibrium. Similarly, for **3***a* that figure is 91.5%. In the isomer **4***a*, the C_1^4 form would be favored only moderately (by 0.35 kcal/mol) if the two $A^{(1,3)}$ interactions in the alternate, C_4^1 form were negligible. However, it is known (2) that the $A^{(1,3)}$ effect is associated with such a large energy that **4***a* will exist practically exclusively (to more than 99%) in the C_1^4 form which avoids this interaction. The fact that **4***a* in its preferred conformation is free from this strain while **2***a* and **3***a* are subject to it in either chair form accounts for the predominance of **4***a* in epimeric equilibrium. From the equilibrium ratio (2.1) of **4***a* to **3***a* it follows that the latter is higher in energy by 0.44 kcal/mol. Hence, if the conformational free energy of **4***a* is taken as 2.40 kcal/mol, that of **3***a* becomes 2.84 kcal/mol. The energy of the pure, preferred conformer of **3***a* is therefrom calculated to be 3.04 kcal/mol, accounting for the entropy change associated with conformer mixing. From this value, the *A* term in **3***a* is derived as 1.7 kcal/mol. Similar

[4]The inverse, C_4^1 form is strongly disfavored due to the anomeric effect and, particularly, due to the 3,5-diaxial interaction between the nitro and *C*-methyl groups. For the conformational symbolism see ref. 7.

[5]From the calculated, conformational free energy differences one may derive a theoretical equilibrium ratio of 2:1.5:1 for **1**, **3**, and **2**, whereas we found the ratio of 3:1:1. In view of the uncertainties inherent in both the method of determining the concentrations and the parameters used for calculating the non-bonded interactions, we consider this to be a satisfactory result. A possible source of error could be the arbitrary equating of all the *gauche* NO_2–OH interactions.

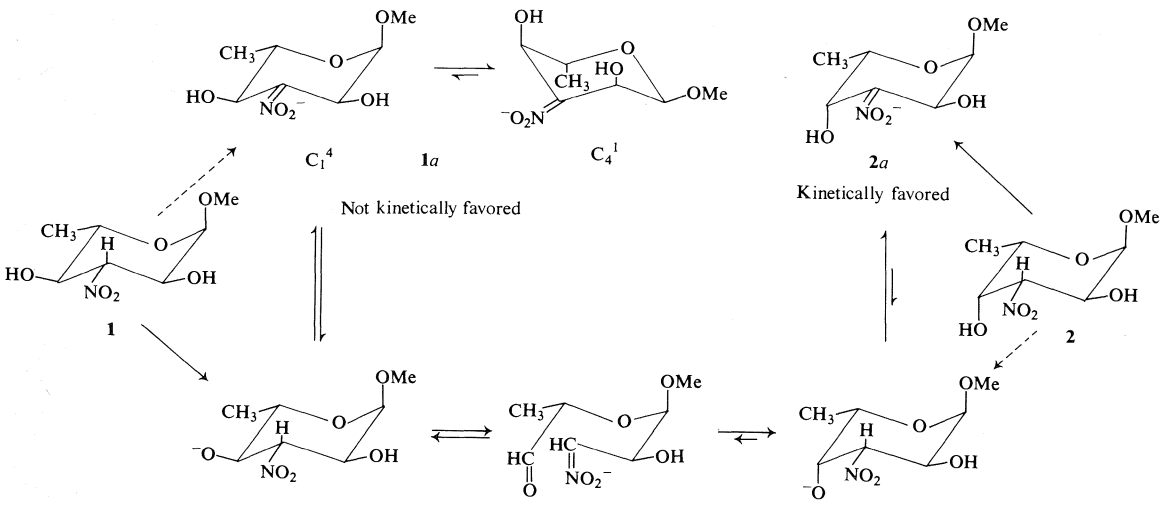
calculation using the equilibrium ratio (9.35) of **4***a* to **2***a* gave an *A* value of 2.0 kcal/mol. The latter may contain a larger error owing to the small concentration of **2***a* which probably rendered the determination of the equilibrium ratio less accurate. As far as the α-L-*ribo* isomer **1***a* is concerned, calculation shows that any *A* value exceeding 1.5 kcal/mol will make the inverted chair (C_4^1, with axial OH and C—CH_3 groups but free from $A^{(1,3)}$ strain) more stable than the normal C_1^4 chair, and from the above results one can therefore safely assume that the former preponderates considerably. This allows one to take 4.25 kcal/mol as the approximate conformational free energy of **1***a*, and it thus becomes clear why that compound is the least stable of the four epimeric salts. From our own measurements of the equilibrium compositions it follows that **1***a* exceeds **3***a* in energy by about 0.8 kcal/mol. (The value derived from the quasi-equilibrium is 0.77, and that from the final equilibrium is 0.85 kcal/mol.) These results lead to an *A* term of 2.0–2.1 kcal/mol. Analogous calculations based on the ratios of **2***a* to **1***a* found in the quasi-equilibrium (1.35) and in the final equlibrium (1.0) gave *A* values of 2.1 and 2.3 kcal/mol, respectively. Note that the calculations involving **1***a* and those involving **4***a* originated from independent measurements. The data are in excellent agreement with one another ($A = 2.0 \pm 0.3$ kcal/mol), and they are also in remarkably good harmony with the results obtained in the pentoside series (2). There, we had come to the conclusion that *A* is at least as high as 2 kcal/mol.[6] The present work thus reaffirms the magnitude of the $A^{(1,3)}$ effect and its directive power in the stereochemistry of nitro sugars where it may override such factors as the anomeric effect and the *syn*-diaxial hydroxyl group interaction. The results provide a theoretical understanding also of the epimerizations, occurring in methyl 3-deoxy-3-nitro-α-D-hexopyranosides, that had been discovered and utilized in earlier, synthetic work (9). The previous findings, which were already in good qualitative agreement with the present concept, have recently been supplemented by more reliable, quantitative data (10) revealing the configurational equilibrium of the hexoside nitronates to be fairly similar to that of their 6-deoxy analogs reported here.

Now the question must be posed as to why the nitronate which is observed immediately upon alkali addition to **1** is in fact **2***a* rather than **1***a*. Evidently a very fast epimerization takes place, at C-4, leaving behind no spectroscopically observable amount of **1** or its salt at the time of first scanning. Since the equilibrium studies have shown that **1***a* and **2***a* differ little in thermodynamic stability, it seems inconceivable that **1***a* should be formed as the first product, to be transformed completely into **2***a*, and then to be slowly regenerated as the equilibrium position demands. However, the reaction may be explained by assuming that proton abstraction from **1** involves the C-4 hydroxyl function, in significant competition with the nitromethylene group, producing an intermediate alkoxide ion through which the ensuing, rapid epimerization proceeds. This epimerization would take place by reversible ring opening between C-3 and -4, with the epimerized alkoxide being trapped, by proton transfer, to give the nitronate ion **2***a* as the kinetically favored product. Conversely, in the isomer **2** proton abstraction is more facile at the nitromethylene group so that **2***a* is readily formed and, because of paucity of the corresponding alkoxide ions in equilibrium, epimerization in the opposition direction is slow (Scheme 1). In effect, the observed reaction pattern can be attributed to differential nitromethylene acidities in **1** and **2**. Firstly, the difference in free energy between **2** and **2***a* is calculated to be smaller than that between **1** and **1***a*. Moreover, proton abstraction from C-3 in the stable C_1^4 chair of **1** would give the C_1^4 chair of **1***a* which is calculated to be the less stable conformation due to its two $A^{(1,3)}$ interactions. Therefore, in passing from **1** to the more stable C_4^1 chair of **1***a*, an energy barrier must be overcome which has no counterpart in the reaction **2** → **2***a*.

It should be recalled at this point that similar observations were made, and explanations offered, in the work on nitro pentosides (2) where the β-D-xylopyranoside underwent, in part, rapid

[6]From measurements of equilibrium constants and calculations based on chair conformations, values of 1.7 and 2.0 kcal/mol were derived. Since we found at least one of the pentoside nitronates to exist in a conformation other than the chair, we postulated that the $A^{(1,3)}$ strain that would be present in the latter contributes somewhat more energy than the figures indicated, causing the molecules to deviate from the chair form.



SCHEME 1

C-4 epimerization without intermediacy of its nitronate. The question as to why in that case as well as in the present one the site of preferential epimerization is C-4 rather than C-2 remains open; as a possible explanation one may invoke a lesser facility of bond cleavage between C-2 and -3 owing to an inductive, electron-pulling effect of the anomeric center.

Finally, we have to consider some of the results of the preparative epimerization experiments. While the ratios of isolated amounts of isomers starting from the α-L-*manno* and α-L-*talo* glycosides (**3** and **4**) corresponded well enough with the nitronate composition determined by spectroscopy prior to acidification, there appeared certain inconsistencies in the experiments with the α-L-*gluco* and α-L-*galacto* compounds (**1** and **2**). Starting with **1** and **2**, the ratios of isolated nitro sugars did not conform with expectations based on the distribution of nitronates in the mixtures (Table 5). Two factors may have been operative: incomplete nitronate formation owing to insufficient alkalinity of the medium from the beginning;[7] and secondly, performance of the deionization with cation exchange resin which, being a comparatively slow operation, may have caused a temporary condition of diminished alkalinity. We have demonstrated that under conditions of weak alkalinity (catalytic amount of base) the equilibrium is determined by the stabilities of the free nitro glycosides and not by those of their salts. Hence, in experiments of this kind one may obtain product compositions arising from fortuitous combinations of processes governed by both types of equilibria.

In the light of the present results the course of the nitromethane cyclization leading to **1**–**4** is readily understandable. The cyclization, as performed in alcoholic solution with sodium methoxide and an excess of nitromethane (5, 6), takes place in a medium of moderate alkalinity due to the buffer action of nitromethane. It afforded (6) mainly the glucoside **1** and the mannoside **3**. Establishment of epimeric equilibrium was not awaited, nor was completion of the cyclization ascertained, but extrapolation of the yield ratios of runs interrupted after 20 and 40 min allow the conclusion that **3** is kinetically favored and that **1** gains preponderance by virtue of epimerization that progresses concurrently with the cyclization.

Experimental

Instrumental Techniques

For all experiments, chromatographically pure, crystalline samples of the compounds **1**–**4** (6) were used. The n.m.r. spectra in the epimerization studies were obtained on a Varian T-60 instrument, using acetone as internal standard. Integration of C—CH_3 and (or) OCH_3 peaks was performed at 50 Hz sweep width, with appropriate

[7]In contrast to the spectroscopic experiments, in which an excess of base (1.2–1.5 equiv) and a higher concentration in sugar was employed, only 1 equiv was used here, and it is probably significant that aberrations occurred with the weak acids **1** and **2** and not with the stronger acids **3** and **4** (*cf.* footnote 3).

sweep offset. The chemical shifts and coupling constants listed in Tables 1 and 2 were confirmed by measurements on a Varian HA-100 instrument.

Assignments of the ring proton signals were by first-order analysis and, for the free nitro glycosides, were supported by changes in the splitting patterns observed upon deuterium exchange at C-3. All n.m.r. spectra were taken from approximately 0.17–0.25 *M* solutions (20 mg of glycoside in 0.4–0.6 ml of solution). Optical rotations were measured in a Perkin–Elmer 141 automatic polarimeter.

Preparative Epimerizations

The results assembled in Table 5 were obtained as follows. A given pure glycoside (200 mg, 0.97 mmol) was dissolved in carbon dioxide – free water (19 ml), and *N* sodium hydroxide solution (1 ml) was added. The reaction mixture was kept in a stoppered flask at 21° for the time specified (Table 5). It was then deionized by stirring with 3 ml of Rexyn 101 (H^+) cation exchange resin. After filtration the resin was washed well with water, and the combined filtrates were evaporated (bath temperature, 35°) to give a yellowish to brown syrup from which several portions of added benzene were evaporated. The syrup was then subjected to column chromatography, and the fractions eluted were examined by t.l.c., using the method previously employed for the separation of **1**–**4** (6). In the present series of experiments, the columns (2 cm in diameter) were packed with 20 g of silicic acid (Mallinckrodt analytical grade, 100 mesh), and 50-ml fractions were collected. Better separations than previously were achieved owing to the smaller amount of glycoside mixture applied. Sequential elution was performed with benzene–ethanol (99.5%) mixtures of the following compositions (v/v): *a*, 200:1; *b*, 100:1; *c*, 100:1.2; *d*, 100:1.5. Eluent *a* first produced a few milligrams of a brown oil that was inhomogeneous according to t.l.c. but did not contain any of the known glycosides. This forerun was followed by syrupy **4** containing an unknown contaminant; from later fractions, **4** crystallized spontaneously. The material was recrystallized once from ether – petroleum ether (b.p. 30–60°), if necessary with the use of a small amount of decolorizing carbon. Continuation of the chromatography with eluent *b* gave blank fractions only. Eluent *c* then gave fractions containing predominantly **3** which was accompanied by some **1**. Crystallization of these fractions from ethyl acetate – petroleum ether, with addition of a small drop of water and seeding with **3**-hydrate (6), furnished crystalline **3**. Later fractions of eluent *c* contained mainly **1** which was accompanied by residual **3**. Crystallization from chloroform – petroleum ether and seeding with **1** gave the pure compound. The mother liquors from the crystallizations of **3** and **1** were pooled and evaporated, and the residue was treated with some activated charcoal in water and then recovered. Such mixed fractions (which usually were small) showed a single spot on t.l.c., and the ratio of **1** and **3** was determined polarimetrically (6). Finally, eluent *d* produced **2** which was recrystallized from ethyl acetate – petroleum ether. A further increase in the ethanol proportion of the eluent did not give any additional amount of nitro glycoside. With few exceptions (where yields were about 5 mg or less), the data in Table 5 refer to recrystallized materials. In all cases, identity and satisfactory purity of the products were checked by t.l.c., optical rotation, and melting point. The volumes of eluents required for the chromatography depended on the composition of the glycoside mixture and varied from one separation to another.

Preparation of Methyl 3,6-Dideoxy-3-nitro-α-L-galactopyranoside (2) from 1

A solution of the glucoside **1** (100 mg) in water (2 ml) was introduced, with a syringe, into 0.75 ml of *N* sodium hydroxide solution (1.5 molar equiv). The solution was kept at 24° for 60 s and then poured into 0.05 *N* acetic acid (20 ml). The mixture was then passed sequentially through small columns of Dowex 1 × 8 (acetate form) (0.5 ml) and Rexyn 101(H^+) (5 ml), and the filtrate was evaporated to give a syrup (109 mg). Crystallization from ethyl acetate gave a first crop of **2** (23 mg, m.p. 151–153°), and recrystallization of the mother liquor material from the same solvent and some petroleum ether gave a second crop (36 mg, m.p. 147–148°); $[\alpha]_D$ −218 and −206°, respectively (*c*, 0.2 in water); reported (6): m.p. 155–158° $[\alpha]_D$ −216°. The product was identified as essentially pure **2** also by its n.m.r. spectrum. The mother liquor from the second crop (dry weight, 40 mg) was revealed by its n.m.r. spectrum to contain approximately 18 mg of **1**, 5 mg of **2**, 12 mg of **3**, and 5 mg of another component (presumably **4**).

Preparation of Methyl 3,6-Dideoxy-3-nitro-α-L-talopyranoside (4) from 1

Epimerization of **1** (200 mg) as described in a preceding section was allowed to proceed for 6 days. Elution of the chromatographic column with benzene–ethanol (200:1) gave, in fractions no. 11–14, 78 mg of crystalline **4**. Recrystallization from ether – petroleum ether afforded 60 mg (30%) of nearly pure **4**, $[\alpha]_D$ −88.1° (*c*, 1.2 in water); reported (6): −89.8°.

It also proved feasible to utilize, for preparing **4**, mother liquors that remained after the isolation of crystalline **1** in the nitromethane cyclization of L′-methoxy-L-methyldiglycolic aldehyde (5, 6). Such mother liquors had been shown (6) to contain only a small proportion of **4**. However, the proportion was increased, for example, by allowing a syrupy mixture (1.9 g) to undergo partial epimerization in an equivalent amount (9.2 ml) of aqueous *N* sodium hydroxide (22 h at room temperature). Deionization with Rexyn 101(H^+), filtration with activated charcoal, and evaporation gave a syrup that was dissolved in 5–7 ml of ether. Addition of petroleum ether to incipient turbidity and inoculation with **4** furnished crude **4** (235 mg) that was recrystallized twice in the same manner. The yield was 113 mg of pure **4**, m.p. 104–107°, $[\alpha]_D$ −89.6° (*c*, 0.8 in water). Another 240 mg of **4** (m.p. 103–107°, $[\alpha]_D$ −89.1°) was obtained from this experiment by column chromatography.

Theory of Enthalpy of Mixing in Reactive Charge Asymmetrical Molten Salt Systems. Part I. Binary Solutions

S. N. Flengas and A. S. Kucharski

Department of Metallurgy and Materials Science, University of Toronto, Toronto 181, Ontario

Received June 15, 1971

The enthalpies of mixing for the charge asymmetrical molten salt systems; $MnCl_2$–ACl, $FeCl_2$–ACl, $CoCl_2$–ACl, $NiCl_2$–ACl, $MgCl_2$–ACl, and $CdCl_2$–ACl (where A represents Li, Na, K, Rb, and Cs) have been calculated by separating the mixing process into two parts. One part of enthalpy of mixing results from the "reaction" to form a tetrahedral complex, MCl_4^{2-}, and another part of the enthalpy of mixing arises from the "mixing" of the complexed species with the remaining free components. The "complex" species are treated as orderly configurations defined by shorter anion to cation distances within which the central metal cation interacts with the surrounding other metal cations through bridging chloride ions. The model takes into account the difference in the coordination number of the mono- and divalent components. The interaction parameters are shown to depend upon the radii of the alkali metal cations.

Les enthalpies de mélange pour des systèmes de sel fondu assymétrique tels que $MnCl_2$–ACl, $FeCl_2$–ACl, $CoCl_2$–ACl, $NiCl_2$–ACl, $MgCl_2$–ACl et $CdCl_2$–ACl (dans lesquels A représente Li, Na, K, Rb et Cs) ont été calculées en séparant le procédé de mélange en deux parties. Une partie de l'enthalpie de mélange est le résultat de la "réaction" pour former un complexe tetrahédrique, MCl_4^{2-} et une autre partie de l'enthalpie de mélange provient du "mélange" des espèces complexées avec les composants libres restants. Les espèces "complexées" sont traitées comme les configurations ordonnées définies par les plus courtes distances anion–cation à l'intérieur desquelles le cation métallique central interagit avec les autres cations métalliques environnants à travers les ions chlore pontés. Le modèle tient compte de la différence dans le nombre de coordination des composés mono- et divalents. On montre que les paramètres d'interaction dépendent des rayons des cations des métaux alcalins.

Canadian Journal of Chemistry, 49, 3971 (1971)

Introduction

Recent calorimetric measurements mainly by Kleppa and co-workers (1–3) have made available accurate determinations of the enthalpies of mixing of binary charge asymmetrical molten salt mixtures containing divalent metal chlorides and alkali chlorides. These measurements include the systems $MnCl_2$–ACl (1), $FeCl_2$–ACl (1), $CoCl_2$–ACl (1), $CdCl_2$–ACl (2), $NiCl_2$–ACl (3), and $MgCl_2$–ACl (4), where A represents alkali metal cations from Li^+ to Cs^+.

In addition the partial molar properties of the $MgCl_2$–ACl (5), the $NiCl_2$–ACl (6) and $CoCl_2$–ACl (7) systems are available from equilibrium e.m.f. studies.

Heats of mixing in these charge asymmetrical systems show pronounced deviations from regular behavior and are characterized by relatively high exothermic heat effects. In addition, the activities of the MCl_2 component indicate pronounced negative deviations from ideality.

Flood and Urnes (8) interpreted cryoscopic activities of $MgCl_2$ in the $MgCl_2$–ACl binary systems, where A = Na, K, Rb, by assuming the formation of the complex $MgCl_4^{2-}$ ions. The calculation, however, was entirely based on configurational entropies and disregarded the now known pronounced heats of mixing.

The concentration dependence of the regular solution interaction parameter defined as $\Delta H_M/X_1X_2$, where X_1 and X_2 are the mole fractions of the two components calculated from the calorimetric measurements by Papatheodorou and Kleppa (1–3) for the systems MCl_2–ACl, where, M is Mn, Fe, Co, Cd and Ni, indicates a minimum at a composition of about 33 mol% MCl_2. This behavior was interpreted as indicating that a tetrahedrally coordinated complex ionic species was present in these melts.

According to Papatheodorou and Kleppa (3) the exothermic heats of mixing in these charge asymmetrical systems is thought to originate from an enthalpy contribution assigned to the formation of the tetrahedral MCl_4^{2-} complex and by dispersion type interactions during the formation of the mixture. The treatment appears to be qualitative and the various interaction parameters are given arbitrary values to provide agreement with the experimental results. The complex ions appear to be more stable in the presence of large alkali cations like K^+ or Cs^+. Pronounced stabilization is not evident in the presence of Li^+.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Recently, Davis (9) has proposed a modified conformal solution theory for the heats of mixing in charge asymmetrical fused salt systems based on a model for an ionic melt by Reiss *et al.* (10).

If it is assumed that the interaction between the ions in the component salts and in the mixture is purely ionic, then the enthalpies of mixing may be approximated by the equation

$$[1]\quad \Delta H_M = A(X, T, \delta_{12}) - X_1[[1 + X_2(Z-1)]\, B_{12}(T, X, \delta_{12}) - B(T, \delta_{12})]\delta_{12}$$

where A, B_{12}, and B are complicated integral functions of the composition X, the coordination number Z, and the parameter $\delta_{12} = (d_1 - d_2)/d_1 \cdot d_2$, where d_1, d_2 are the sums of ionic radii in the two melts.

The Davis (9) theory for charge asymmetrical mixtures is not readily amenable to verification because of the complexity of the terms and the difficulty in making quantitative predictions regarding energetic asymmetry. In addition, in a binary mixture containing mono- and divalent cations, the coordination number cannot be expected to remain constant throughout all compositions.

Recently, Pelton and Thompson (11) calculated the concentration dependence of the heats and of the entropies of mixing in the $MgCl_2$–ACl binary systems for about 60% of the composition range using a dissociating complex ion model based on the existence of $MgCl_4^{2-}$ species. In this model, the complex anions are taken to be present even in pure liquid $MgCl_2$ and the degree of dissociation at each point is calculated by minimizing the free energy of the solution. Although the method is mathematically correct some of the physical assumptions may be considered as questionable. For example, the entropy of mixing is taken as being entirely configurational although the formation of a strong complex anion is postulated. Also, the coordination number is considered to remain constant for all compositions, and the pure salt $MgCl_2$ is calculated to consist largely of complex anions. The calculation, however, has the advantage of requiring only two adjustable parameters for each binary system, one of which is common for all five MCl_2–ACl systems.

Also, recently, Ostvold (12) has used a similar method to calculate the heats of mixing in the $MgCl_2$–ACl systems. However, in this treatment the heat of mixing was accounted for by a method outlined by Førland (13) for the mixing of mono- and divalent ions. The agreement between the theory and calculated concentration dependence of the interaction parameter is only qualitative.

In the present study the concentration dependence of the heats of mixing in binary charge asymmetrical reactive systems are calculated on the basis of a simple complex anion model. In this model, the heats of mixing are taken to originate from two sources. In the first part, the component salts react stoichiometrically to form completely a tetrahedrally coordinated anionic complex with a pronounced exothermic heat effect. The second part of the heat arises from mixing the reaction products with the unused components to form a regular type solution in which nearest or next nearest Coulombic interactions are considered to be significant. For the treatment the effects due to charge asymmetry are accounted for in terms of a variable coordination number.

The mathematical relationships derived in this manner have been applied with success to the binary mixtures of $FeCl_2$, $MgCl_2$, $MnCl_2$, $CoCl_2$, $NiCl_2$, and $CdCl_2$ with the various alkali chlorides for which experimental data are available (1–3). The theory is particularly applicable to systems which approximate the tetrahedral coordination and in which the complex anions do not dissociate to any appreciable extent. The treatment could also be adapted to take into account either linearly or octahedrally coordinated complexes.

Concept of Complex Ions in Molten Salts

The concept of complex ions in molten salts should be entirely different from that generally accepted in aqueous solutions. In dilute aqueous solutions because of the high dielectric constant of water, complex ionic species having a discrete structure may be considered to exist as well defined separate entities and the properties of the solutions may be interpreted by considering the behavior of point electrical changes in a dielectric medium.

In molten salts, the medium is totally ionic and because of the existence of strong short range electrostatic forces the requirement of local electrical neutrality is satisfied through the concept of interlocking anionic and cationic quasi-lattices.

In this sense the liquid structure is continuous and the existence of discrete complex species is conceptually difficult. It is most likely that a "complex anion" in molten salts should be best

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

represented by a configuration of a cation M^{n+} surrounded by anions X^- having a given coordination number within which the bond distances MX, and accordingly their energies, should be different from those expected to represent a non-complexed dissociated ionic state. It is also convenient to take the non-complexed state of the salt MX as that of the pure MX. The "complex" is expected to form only in the presence of a second salt AX which is considered to act as the ligand donor. Thus, the formation of the complex species is assumed to be the result of reactions of the type

$$MX + (n - 1)AX \rightarrow A_{n-1}MX_n$$

and the strength of the complex shall depend upon the magnitude of the competing interactions of the A^+ and M^+ cations for the same ligand anions X^-.

In a melt containing both AX and MX, it is conceivable that two kinds of MX bonds could exist: M—X bonds having the bond distance describing the "complex" state, and M—X bonds describing the "free" MX species. The pure material is expected to have only bonds of the second type.

It is also evident that the continuity of the medium imposes the restriction that the "complex" anions are not discrete isolated species but are part of the ionic liquid structure and therefore their central M cations interact with the surrounding cations through bridging X^- anions. In a melt containing MX and AX components, it is meaningless to postulate a structure based on the MX_n anions occupying single anion lattice sites in addition to other free anions and cations. The structure should still be one represented by arrays of positive and negative ions in a continuous sequence in such a manner that positive ions are always surrounded by negative ones.

Since the only characteristic of a "complex" anion is the bond distance MX, its coordination configuration, MX_n may be treated as a separate statistical entity. When MX is added to AX a "reaction" may be postulated according to the stoichiometry indicating the preferred coordination within the complex anion. For example, for a tetrahedrally coordinated complex between a divalent metal chloride and an alkali metal chloride, the reaction represented by,

$$MCl_2 + 2ACl \rightarrow A_2MCl_4$$

Regarding the preferred coordination of complex ions in fused salts, the accumulated experimental evidence indicates that such coordinations are relatively simple. Thus, mixtures of monovalent cations appear to prefer the 2-ligand configuration representing a linear or angular structure as in $Ag(CN)_2^-$ (14). Mixtures of mono- and divalent cations appear to follow the tetrahedral coordination as in $MgCl_4^{2-}$. Finally, mixtures of mono- and tetravalent cations as in the systems, $ZrCl_4$, $TiCl_4$, $HfCl_4$, with alkali chlorides (15), prefer to form octahedrally coordinated complexes of the type $ZrCl_6^{2-}$, $TiCl_6^{2-}$, and $HfCl_6^{2-}$. In these systems it has been shown that the thermodynamic properties of the solutions can be accounted for on the basis of the MCl_6^{2-} complex ion (16, 17).

From the previous discussion it follows that "complex" species in fused salts are not expected to dissociate in the same manner as their counterparts in aqueous solutions. The formation of the new type of M—Cl bond distances is initiated by the presence of the A^+ cations. Each added A^+ cation is expected to disturb one M—Cl bond and the "complex" should form "stoichiometrically."

Accordingly, the difference between the effects of various kinds of ACl ligand donors upon the same MCl_2 salt, shall be manifested as a heat effect, and the introduction of a dissociation constant is not necessary for the mathematical treatment. In a solution containing various proportions of ACl to MCl_2, the changes in the bond energies which may result from the replacement of one kind of neighboring ion by another, should result in changes in the overall heat effect of mixing and may be accounted for by assigning different values to the bond energies representing the various possible ionic combinations. Again the concept of a "dissociating complex" is not necessary.

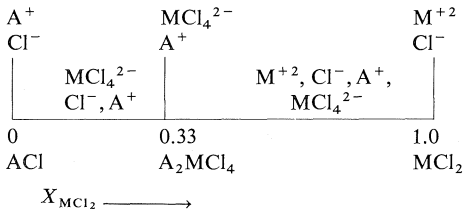
However, if two or more "complex" coordinations are energetically favorable, then the concepts of equilibrium between "complex" species, and of dissociation, become significant.

The present treatment is applicable to salt systems which appear to conform with the concept of a single complex configuration.

Theory of Mixing of Charge Asymmetrical System Forming Complex Anions

Considering the binary mixture MCl_2–ACl over the entire composition range, from pure MCl_2 to pure ACl, the complex A_2MCl_4 is expected to form quantitatively at a composition $X_{MCl_2} = 0.333$.

TABLE 1. Mass balance for the MCl_2–ACl system*



(*a*) $1.0 > X_{MCl_2} > 0.333$

$n_{MCl_2} = X_{MCl_2} - 0.5X_{ACl} = n_1$, $n_{ACl} = 0$, $n_{A_2MCl_4} = 0.5X_{ACl} = n_2$

Ionic composition	Ionic fraction
$n_{M^{2+}} = X_{MCl_2} - 0.5X_{ACl}$	$N_{M^{2+}} = \dfrac{2X_{MCl_2} - X_{ACl}}{1 + X_{MCl_2}}$
$n_{A^+} = X_{ACl}$	$N_{A^+} = \dfrac{2X_{ACl}}{1 + X_{MCl_2}}$
$n_{Cl^-} = 2X_{MCl_2} - X_{ACl}$	$N_{Cl^-} = \dfrac{4X_{MCl_2} - 2X_{ACl}}{4X_{MCl_2} - X_{ACl}}$
$n_{MCl_4^{2-}} = 0.5X_{ACl}$	$N_{MCl_4^{2-}} = \dfrac{X_{ACl}}{4X_{MCl_2} - X_{ACl}}$

(*b*) $0.333 > X_{MCl_2} > 0$

$n_{MCl_2} = 0$, $n_{ACl} = X_{ACl} - 2X_{MCl_2} = n_1$, $n_{A_2MCl_4} = X_{MCl_2} = n_2$

Ionic composition	Ionic fraction
$n_{M^{2+}} = 0$	$N_{M^{2+}} = 0$
$n_{A^+} = X_{ACl}$	$N_{A^+} = 1.0$
$n_{Cl^-} = X_{ACl} - 2X_{MCl_2}$	$N_{Cl^-} = \dfrac{X_{ACl} - 2X_{MCl_2}}{X_{ACl} - X_{MCl_2}}$
$n_{MCl_4^{2-}} = X_{MCl_2}$	$N_{MCl_4^{2-}} = \dfrac{X_{MCl_2}}{X_{ACl} - X_{MCl_2}}$

*X = the original mole fractions in the solution which is prepared by mixing the components ACl and MCl_2; n = the amount of a component in g-mol; N = ionic fractions after the complex forming reaction has taken place.

For compositions rich in ACl; namely for $0.333 > X_{MCl_2} > 0$, the melt is taken to consist of unreacted ACl and the complex compound A_2MCl_4. For compositions rich in MCl_2, namely for $1.00 > X_{MCl_2} > 0.333$, the melt may be taken to consist of unreacted MCl_2 and the complex compound A_2MCl_4.

The ionic compositions, assuming that the complex only dissociates into A^+ cations and MCl_4^{2-} anions, may be calculated from the original mole fractions by a mass balance calculation, and are given in Table 1.

For the common cation subsystem, ACl–A_2MCl_4, if the ability of the M^{2+} ions for interaction is considered as having been nearly satisfied through the formation of the "complex" anion MCl_4^{2-}, it is reasonable to expect that the species present should be randomly distributed and that only next nearest neighbor type interactions should be significant. The solutions could then be treated as regular. Thus, the bond energies to be considered in the "pure" components ACl and A_2MCl_4 are characterized by the energies of the next nearest neighbor interactions, Cl^-–A^+–Cl^- and MCl_4^{2-}–A^+–MCl_4^{2-}, respectively. The solution, in addition to the above interactions, is also characterized by interactions of the type Cl^-–A^+–MCl_4^{2-}. However, the concept of continuity in the structure of the ionic melt discussed earlier requires that the MCl_4^{2-} species be nonexistent as an isolated entity. The A^+ cations are expected to interact with the M^{2+} central cations in the "complex" species via bridging Cl^- anions. Thus it is more realistic to describe the MCl_4^{2-}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

type interactions in pure A_2MCl_4 and the Cl^-–A^+–MCl_4^{2-} type interactions in the solution, as interactions between a central A^+ cation and two chloride species representing ionic arrays of the type

$$\begin{array}{ccccc} & Cl^* & & Cl^* & \\ Cl^*—M—Cl^*\cdots & A^+ & \cdots Cl^*—M—Cl^* \\ & Cl^* & & Cl^* & \end{array}$$

and

$$\begin{array}{ccc} & & Cl^* \\ Cl^-\cdots A^+\cdots & Cl^*—M—Cl^* \\ & & Cl^* \end{array}$$

where Cl^- and Cl* describe the states of the Cl^- in pure ACl and in the "complex" species, MCl_4^{2-}, respectively.

It should be noted that although the number of MCl_4^{2-} configurations in the system is fixed by stoichiometry, the two types of chloride ions in the solution can readily exchange positions so that the probability of finding a chloride species of the Cl* type in any position is taken as the fraction of the anionic positions occupied by the configuration MCl_4^{2-}.

The "significant" next nearest neighbors type interactions for the pure components and for their mixture are therefore best represented by the following energy terms. For pure ACl, the Cl^-–A^+–Cl^- type interaction is described by $E_{Cl—A—Cl}$; for pure A_2MCl_4, the Cl*—A^+—Cl* type interaction is described by $E_{Cl^*—A—Cl^*}$, and in the binary solution ACl–A_2MCl_4, the bond energies are the $E_{Cl—A—Cl}$, $E_{Cl—A—Cl^*}$, and $E_{Cl^*—A—Cl^*}$ where $E_{Cl^*—A—Cl}$ describes the new type of interaction discussed previously.

Since we are only concerned with the chloride ion coordination of the A^+ cations, the nearest neighbor coordination number for the A^+ cations should not be affected by mixing the charge asymmetric system ACl–A_2MCl_4.

In this composition range, for a melt represented by the nominal mole fractions X_{ACl} and X_{MCl_2}, respectively, the "true" composition is given in Table 1.

As the complex anions present in the mixture have originated from the reaction of X_{MCl_2} g-moles of MCl_2, the first part of the heat effect or the "reaction part" is simply proportional to the amount of complex formed, and is given by the equation

$$[2] \qquad \Delta H_1 = X_{MCl_2} b_R$$

The constant b_R represents the heat of formation per g-mol of complex according to

$$MCl_2 + 2ACl \rightarrow A_2MCl_4$$

The second part or the "mixing part" of the total heat originates by the regular solution type mixing of the charge asymmetrical mixture containing n_1 g-mol of ACl and n_2 g-mol of A_2MCl_4 according to the reaction

$$n_1ACl + n_2A_2\,MCl_4 \rightarrow (ACl)_{n_1}\,(A_2MCl_4)_{n_2}$$

This "mixing" part may be calculated by interpreting the energy of mixing as the difference between the internal energy of the solution from that of the pure components, where the previously described interactions are the only ones which are considered as being significant. Pair interactions of the same kind are taken to have the same energy in the pure components as in the solution and cancel out.

The energy change for the mixing reaction is therefore

$$[3] \qquad \Delta E_{mix}{}^{int} = E_{mix} - n_1E_{ACl} - n_2E_{A_2MCl_4}$$

The total number of next nearest neighbors interactions originating from a central A^+ cation is given by $(1/2)N(n_1 + 2n_2)Z_1$ where N is the Avogadro number and Z_1 is the coordination number for ACl. In pure ACl and A_2MCl_4, the total numbers of such interactions are $(1/2)n_1NZ_1$ and n_2NZ_1, respectively. Hence, using the above relationships and taking the probability of finding a bonded chlorine in the complex MCl_4^{2-} as being the same as that of finding the entity MCl_4^{2-}, the following expression is readily obtained according to the method which is followed for regular solutions.

$$[4] \quad \Delta E_M = \tfrac{1}{2}Z_1N(n_1 + 2n_2)\left[\frac{n_1^2}{(n_1 + n_2)^2}E_{Cl—A—Cl} + \frac{n_2^2}{(n_1 + n_2)^2}E_{Cl^*—A—Cl^*} + \frac{2n_1n_2}{(n_1 + n_2)^2}E_{Cl—A—Cl^*}\right] - \tfrac{1}{2}NZ_1n_1E_{Cl—A—Cl} - \tfrac{1}{2}NZ_12n_2E_{Cl^*—A—Cl^*}$$

$$= \frac{n_1n_2}{n_1 + n_2}\left[\frac{n_1}{n_1 + n_2}b_1 + b_2\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Introducing into this equation the expressions for n_1 and n_2, from Table 1, and performing the necessary cancellations of common terms, the following relationship is obtained

$$[4a] \qquad \Delta E_M = \frac{(X_{ACl} - 2X_{MCl_2})X_{MCl_2}}{X_{ACl} - X_{MCl_2}} \cdot \left[\frac{X_{ACl} - 2X_{MCl_2}}{X_{ACl} - X_{MCl_2}} b_1 + b_2\right]$$

where

$$b_1 = \tfrac{1}{2}NZ_1[E_{Cl^*-A-Cl^*} + E_{Cl-A-Cl} - 2E_{Cl^*-A-Cl}]$$

and

$$b_2 = \tfrac{1}{2}NZ_1[4E_{Cl-A-Cl^*} - 3E_{Cl^*-A-Cl^*} - E_{Cl-A-Cl}]$$

are parameters to be determined experimentally. Assuming that pressure–volume work is negligible eq. 4*a* can be used to represent the enthalpy of mixing ($\Delta E_M = \Delta H_M$). Thus the total enthalpy will be given by the sum of eqs. 2 and 4*a*, as shown below

$$[5] \qquad \Delta H_M = X_{MCl_2}b_R + \frac{(X_{ACl} - 2X_{MCl_2})X_{MCl_2}}{X_{ACl} - X_{MCl_2}} \cdot \left[\frac{X_{ACl} - 2X_{MCl_2}}{X_{ACl} - X_{MCl_2}} b_1 + b_2\right]$$

It should be noted that the parameter b_2 is similar to that obtained from regular solution theory for a charge symmetric mixture. The parameter b_1 is the result of charge asymmetry. Hence, the total integral heat of mixing in the reacting system is determined by the heat contribution due to the complex ion forming reaction, by a heat effect due to an exchange reaction between next nearest neighbor anions, and by asymmetry.

Considering the composition range in the subsystem MCl_2–A_2MCl_4 from $1.0 > X_{MCl_2} > 0.333$, the true composition of the solution is given in Table 1. In this range the "reaction" part of the total mixing reaction is given by

$$[6] \qquad \Delta H_1' = 0.5X_{ACl}b_R$$

Once the complex has been formed the second part of the reaction involves mixing of the unreacted MCl_2 with A_2MCl_4 according to

$$n_1MCl_2 + n_2A_2MCl_4 \rightarrow [(MCl_2)_{n_1}(A_2MCl_4)_{n_2}]$$

Again, in this system the following different kinds of chloride ions should be considered: chloride ions which surround "free" M^{2+} or A^+ cations, and chloride ions bonded in the complex ionic configuration $[MCl_4^*]^{2-}$. Also, the cation M^{2+} in the complex $[MCl_4^*]^{2-}$ is bonded to the surrounding M^{2+} or A^+ "free" cations through bridging Cl* ions. Accordingly, the system is a reciprocal salt mixture and the significant interactions in a system where the complex ion configuration is already present are given by the nearest neighbor cation to anion attractions having energy contributions given as: E_{Cl-A}, E_{Cl^*-A}, E_{Cl-M}, E_{Cl^*-M}, where the interactions E_{Cl-A} and E_{Cl-M} are also common in the pure components ACl and MCl_2. It is also expected that if the nearest neighbor coordination number of the "free" M^{2+} cations is Z_1, then the nearest neighbor coordination number of the A^+ cations should be $0.5Z_1$.

In a random system the total number of bonds which emanate from the "free" A^+ and M^{2+} ions may be calculated from the average coordination number of the solution defined as

$$[7] \qquad \bar{Z} = \frac{n_1}{n_1 + 2n_2} Z_1 + \frac{2n_2}{n_1 + 2n_2} 0.5Z_1$$

$$= \frac{n_1 + n_2}{n_1 + 2n_2} Z_1$$

The total number of significant nearest neighbor type bonds in the solution is readily calculated as,

$$\tfrac{1}{2}N(n_1 + 2n_2)\bar{Z} = \tfrac{1}{2}N(n_1 + n_2)Z_1$$

Using the same assumptions as for the ACl rich solutions, the integral energy of mixing is derived as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[8] $$\Delta E_M = \tfrac{1}{2}NZ_1(n_1 + n_2)[N_{A^+} \cdot N_{Cl^-} \cdot E_{A-Cl} + N_{A^+} \cdot N_{MCl_4^*} \cdot E_{A-Cl^*} + N_{M^{2+}} \cdot N_{Cl^-} \cdot E_{M-Cl} + N_{M^{2+}} \cdot N_{MCl_4} \cdot E_{M-Cl^*}] - \tfrac{1}{2}NZ_1 n_1 E_{M-Cl} - \frac{\tfrac{1}{2}NZ_1}{2}(2n_2)E_{A-Cl^*}$$

where the ionic fractions are given in Table 1.

From eq. 8, after performing the necessary cancellations of common terms, the following expression is derived

[9] $$\Delta E_M = \frac{(X_{MCl_2} - 0.5X_{ACl})0.5X_{ACl}}{(2X_{MCl_2} - 0.5X_{ACl})}\left[\frac{X_{MCl_2} - 0.5X_{ACl}}{X_{MCl_2} + 0.5X_{ACl}} b_1' + b_2'\right]$$

where

[9a] $$b_1' = \tfrac{1}{2}NZ_1[2E_{ACl} + 0.5E_{MCl^*} - 2E_{MCl} - 0.5E_{ACl^*}]$$

$$b_2' = \tfrac{1}{2}NZ_1[2E_{ACl} + 0.5E_{MCl^*} - E_{MCl} - 1.5E_{A-Cl^*}]$$

are interaction parameters.

The total integral heat of mixing is given as

[10] $$\Delta H_M = 0.5X_{ACl}b_R + \frac{(X_{MCl_2} - 0.5X_{ACl})0.5X_{ACl}}{(2X_{MCl_2} - 0.5X_{ACl})}\left[\frac{X_{MCl_2} - 0.5X_{ACl}}{X_{MCl_2} + 0.5X_{ACl}} b_1' + b_2'\right]$$

The second part of eq. 10 is of the form

[11] $$\Delta E_M = \frac{n_1 n_2}{2n_1 + n_2}\left[\frac{n_1}{n_1 + 2n_2} b_1' + b_2'\right]$$

and accordingly the parameter b_2' describes the regular behavior of the solution when asymmetry effects are not accounted for. The effect of variable coordination number is accounted for by the asymmetric parameter b_1'.

The above calculations indicate that the concentration dependence of the integral heat of mixing is a complex function of the concentration and that the entire heat of mixing curve may be accounted for by five parameters, b_R, b_1, b_2, b_1', and b_2'.

Determination of Energetic Parameters

The "reaction" parameter b_R can be found from an experimentally measured heat of mixing curve by substituting for $X_{MCl_2} = 0.333$ and solving either eqs. 5 and 10. Thus

[12] $$b_R = 3(\Delta H_M)_{X=0.333}$$

The parameters b_1 and b_2' may be determined from the partial molar heats of mixing.

In the ACl–A_2MCl_4 subsystem at $0.333 > X_{MCl_2} > 0$, the partial molar heats of mixing for ACl and MCl_2 may be represented by the following mixing reactions

[13] $$ACl + [(ACl)_{n_1}(A_2MCl_4)_{n_2} \rightarrow [(ACl)_{n_1+1}(A_2MCl_4)_{n_2+1}]$$

and

[14] $$MCl_2 + [(ACl)_{n_1}(A_2MCl_4)_{n_2}] \rightarrow [(ACl)_{n-2}(A_2MCl_4)_{n_2+1}]$$

The corresponding equations for the partial molar heats of mixing are derived by partial differentiation of eq. 5,

[15] $$\Delta\bar{H}_{MCl_2} = b_R + \frac{(X_{ACl}^3 - 4X_{MCl_2}^3 - 7X_{MCl_2}X_{ACl}^2 + 12X_{ACl}X_{MCl_2}^2)}{(X_{ACl} - X_{MCl_2})^3} b_1 - \frac{2X_{MCl_2}^2 - (X_{ACl} - 2X_{MCl_2})^2}{(X_{ACl} - X_{MCl_2})^2} b_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$$[16] \qquad \Delta\bar{H}_{ACl} = \frac{X_{MCl_2}{}^2}{(X_{ACl} - X_{MCl_2})^2}\left[b_2 + \frac{2(X_{ACl} - 2X_{MCl_2})}{(X_{ACl} - X_{MCl_2})}\,b_1\right]$$

At $X_{ACl} = 2X_{MCl_2}$, or at the composition $X_{MCl_2} = 0.333$ eqs. 15 and 16 yield

$$[17] \qquad b_2 = (\Delta\bar{H}_{ACl})_{\text{at } X_{MCl_2}=0.333}$$

or

$$[18] \qquad b_2 = \frac{b_R - (\Delta\bar{H}_{MCl_2})_{X_{MCl_2}=0.333}}{2}$$

In the MCl_2–A_2MCl_4 subsystem at $1.0 > X_{MCl_2} > 0.333$, the mixing reactions for ACl and MCl_2 are given as

$$[19] \qquad MCl_2 + [(MCl_2)_{n_1}(A_2MCl_4)_{n_2}] \rightarrow [(MCl_2)_{n_1+1}(A_2MCl_4)_{n_2}]$$

and

$$[20] \qquad ACl + [(MCl_2)_{n_1}(A_2MCl_4)_{n_2}] \rightarrow [(MCl_2)_{n_1-0.5}(A_2MCl_4)_{n_2+0.5}$$

The partial molar heats of mixing for ACl and MCl_2 are obtained by partial differentiation of eq. 10, and are given as

$$[21] \quad \Delta\bar{H}_{MCl_2} = \frac{0.0625X_{ACl}{}^4 + 1.25X_{MCl_2}{}^2X_{ACl}{}^2 - 0.75X_{ACl}{}^3X_{MCl_2}}{((2X_{MCl_2} - 0.5X_{ACl})(X_{MCl_2} + 0.5X_{ACl}))^2}\,b_1' + \frac{X_{ACl}{}^2}{4(2X_{MCl_2} - 0.5X_{ACl})^2}\,b_2'$$

$$[22] \quad \Delta\bar{H}_{ACl} = 0.5b_R + \left[\frac{0.5X_{MCl_2}{}^2 - X_{MCl_2}X_{ACl} + 0.375X_{ACl}{}^2}{(2X_{MCl_2} - 0.5X_{ACl})(X_{MCl_2} + 0.5X_{ACl})} - \frac{0.25X_{ACl}(X_{MCl_2} - 0.5X_{ACl})^2(X_{MCl_2} - X_{ACl})}{(2X_{MCl_2} - 0.5X_{ACl})^2(X_{MCl_2} + 0.5X_{ACl})^2}\right]b_1' + \frac{(X_{MCl_2}{}^2 - X_{ACl}X_{MCl_2} - 0.125X_{ACl}{}^2)}{(2X_{MCl_2} - 0.5X_{ACl})^2}\,b_2'$$

From eq. 22, at a composition $X_{MCl_2} = 0.333$

$$[23] \qquad (\Delta\bar{H}_{ACl}) = \frac{b_R - b_2'}{2}$$

and from eq. 21,

$$[24] \qquad (\Delta\bar{H}_{MCl_2}) = b_2'$$

From eqs. 17 and 23, it follows that

$$[25] \qquad b_R = 2b_2 + b_2'$$

Hence, the parameters b_2' and b_2 may be determined directly from the experimentally obtained partial molar heats of mixing of either ACl or MCl_2 at the stoichiometric composition of $X_{MCl_2} = 0.333$,

The parameters b_1 and b_1' are determined from the equations for the integral heats of mixing 5 and 10 written in the following forms:

b_1'	—	—	—	—	—
b_1	+418	0	−210	−470	−340
$CdCl_2$					
b_R	−14070	—	—	—	−630
b_2'	−7290	—	—	—	+95
b_2	−3380	—	—	—	−55
b_1'	−27240	—	—	—	−500
b_1	−206	—	—	—	−332

For the composition range, $0.333 > X_{MCl_2} > 0$

$$[26] \qquad \frac{(\Delta H_M - X_{MCl_2} b_R)(X_{ACl} - X_{MCl_2})}{(X_{ACl} - 2X_{MCl_2})X_{MCl_2}} = \frac{X_{ACl} - 2X_{MCl_2}}{X_{ACl} - X_{MCl_2}} b_1 + b_2$$

which is of the linear form

$$I = Pb_1 + b_2$$

Similarly, from eq. 10,

$$[27] \qquad \frac{(\Delta H_M - 0.5X_{ACl} b_R)(8X_{MCl_2} - 2X_{ACl})}{(2X_{MCl_2} - X_{ACl})X_{ACl}} = \frac{2X_{MCl_2} - X_{ACl}}{2X_{MCl_2} + X_{ACl}} b_1' + b_2'$$

which is of the linear form

$$[28] \qquad I' = Qb_1' + b_2'$$

Because the calculations involve small differences between large numbers, it is best to obtain the parameters b_2 and b_2' from the partial molar heats of mixing, and then use the linear plots predicted by eqs. 24 and 25 to evaluate the slopes b_1 and b_1'. Alternatively, b_1 and b_1' may be calculated by solving eqs. 5 and 10, for various points along the curve where, b_R, b_2, and b_1 are known using the previously described methods.

Results and Discussion

The heats of mixing for the systems $MgCl_2$–ACl, $MnCl_2$–ACl, $FeCl_2$–ACl, $CoCl_2$–ACl, $NiCl_2$–ACl, and $CdCl_2$–ACl, which are available from calorimetric measurements by Papatheodorou and Kleppa (1–3), have been treated using the previously described expressions, and the b parameters $b_1, b_2, b_1', b_2', b_R$ for each system are summarized in Table 2.

For this calculation the parameters b_1 and b_1' were obtained both analytically and graphically.

Using the b-parameters given in Table 2, the integral heats of mixing and the regular solution interaction parameter given as $\Delta H_{mix}{}^{int}/X_{ACl}X_{MCl_2}$ can now be calculated. The plots of these interaction parameters for the MCl_2–ACl systems are shown in Figs. 1 to 6. The calculated integral heats of mixing in the MCl_2–CsCl systems are compared with the experimental values in Figs. 7 to 9. It is seen that small discrepancies between the experimental and calculated values are exaggerated in the plot of the interaction parameters, since a small error of ± 50 cal in the integral heats

of mixing leads to a large error in the value of $\Delta H_M/X_{ACl}\cdot X_{MCl_2}$.

It is significant that the interaction parameters $\Delta H_M/X_{ACl}\cdot X_{MCl_2}$ reach minimum values at a composition corresponding to the stoichiometry MCl_4^{2-}. Similarly, the integral heats of mixing reach maxima at about the same composition.

If the strength of the complex configuration MCl_4^{2-} is considered to be the result of competing interactions between the M^{2+} and the A^+ cations for the same chloride anion, it is evident that small alkali cations like Li^+ or Na^+ which create strong electrostatic fields shall have the tendency to increase the M—Cl bond distance and create weak complexes. Accordingly, the reaction parameter b_R is expected to be a function of the alkali cation radius for each MCl_2–ACl system.

Figure 10 shows the plots of b_R against r_{A^+}, for the various MCl_2–ACl binary systems. It is seen that the relationship is linear and indicates that the alkali chlorides with the largest cation size, like Rb^+ and Cs^+, form the strongest complexes, as expected.

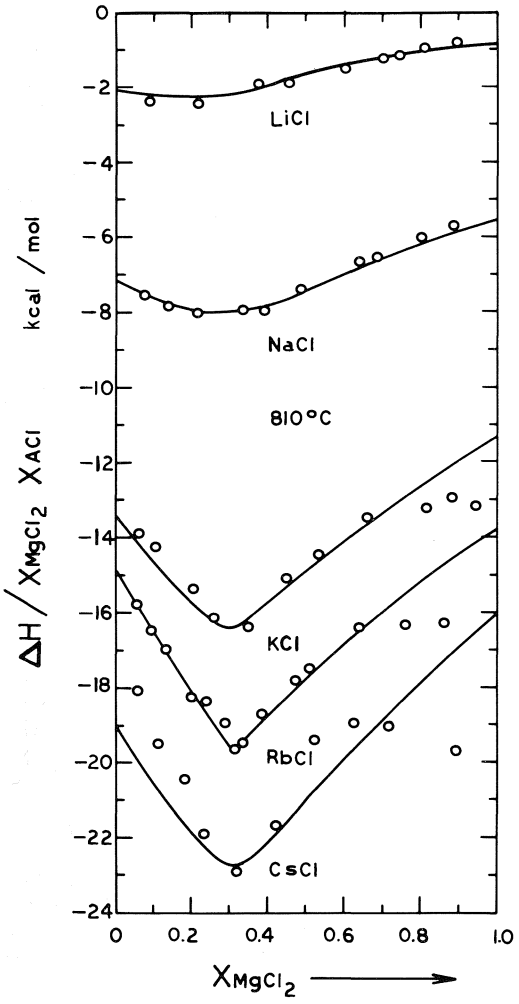

FIG. 5. Plots of $\Delta H_M/X_{ACl}X_{MCl_2}$ *vs.* X_{MCl_2} for the binary systems $MgCl_2$–ACl, where A = Li, Na, K, Rb, Cs. The points represent experimental data (4). The solid lines have been calculated from theory using the *b*-values in Table 2.

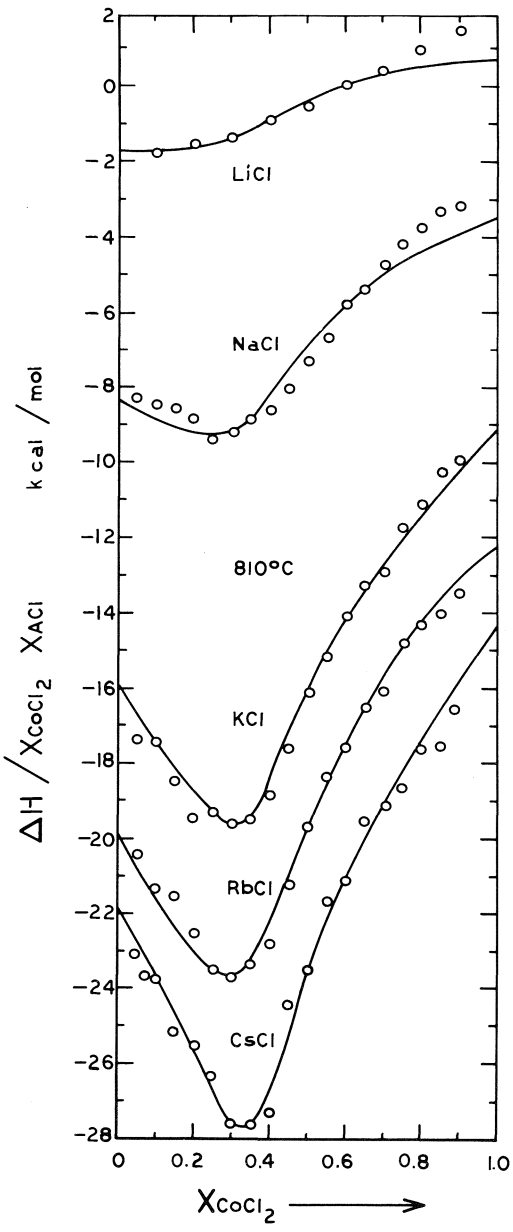

FIG. 6. Plots of $\Delta H_M/X_{ACl}X_{MCl_2}$ *vs.* X_{MCl_2} in the binary systems $CoCl_2$–ACl, where A = Li, Na, K, Rb, Cs. The points represent experimental data (1). The solid lines have been calculated from theory using the *b*-values in Table 2.

The physical significance of the parameters b_1, b_2, and b_1', b_2', is given by eqs. 4*a* and 9*a*. Although each of these parameters represent summations of energy terms which are difficult to interpret, the quantities $b_1 + b_2$ and $b_1' - b_2'$ describe the relatively simple expressions given below

$$[29]\quad b_1 + b_2 = 2(E_{Cl—A—Cl^*} - E_{Cl^*—A—Cl^*})$$

and

$$[30]\quad b_2' - b_1' = E_{M—Cl} - E_{A—Cl^*}$$

The difference in energies, shown in eq. 29, essentially describes the difference in the internal energies between a "free" chloride ion and a chloride ion bonded in a complex configuration.

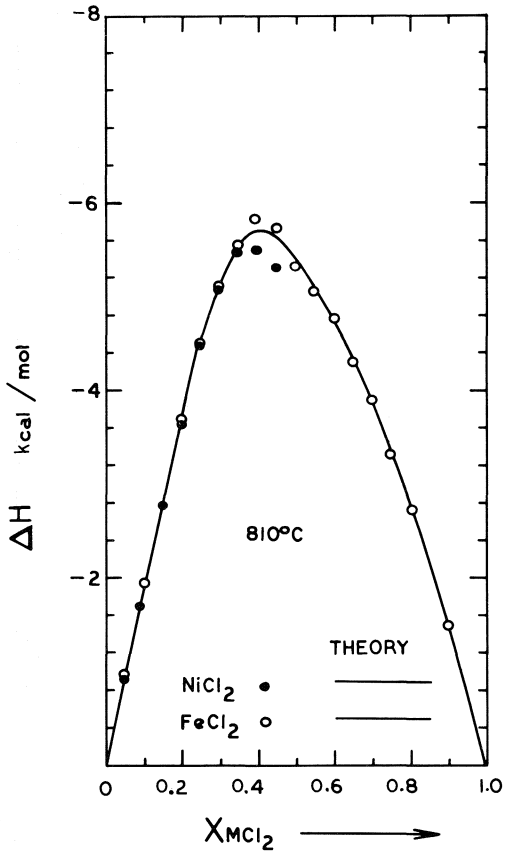

FIG. 7. Plots of the integral heats of mixing in the binary systems $NiCl_2$–CsCl and $FeCl_2$–CsCl as functions of composition. Points are experimental (3). The continuous and dashed lines represent heats calculated from theory using the *b*-parameters in Table 2.

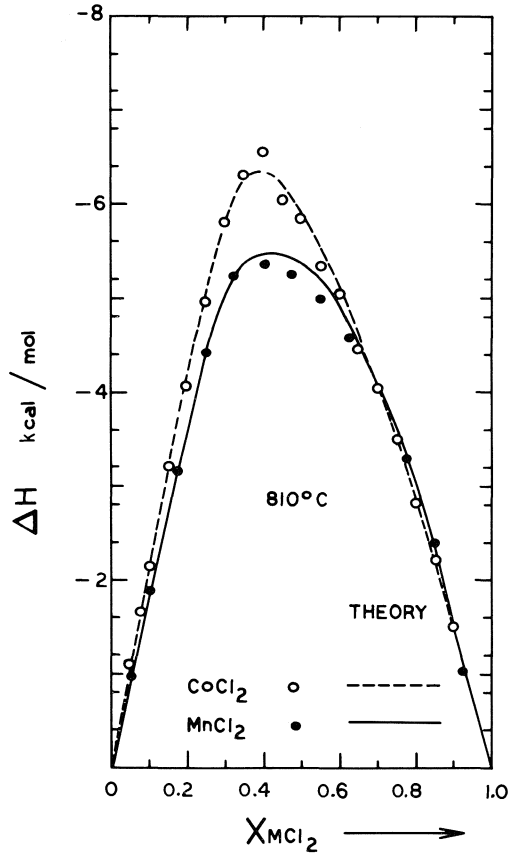

FIG. 8. Plots of the integral heats of mixing in the binary systems $CoCl_2$–CsCl and $MnCl_2$–CsCl as functions of composition. Points are experimental (1). The dashed and continuous lines are calculated from theory using the *b*-parameters in Table 2.

It follows that $b_1 + b_2$ should be proportional to the reaction parameter b_R.

Plots of $b_1 + b_2$ against b_R for the systems investigated are given in Fig. 11. It is seen that there is an almost linear relationship between $b_1 + b_2$ and b_R. Similarly, $b_2' - b_1'$ describes the difference in the interaction energies between "free" MCl and ACl*, where the Cl* refers to a chloride ion bonded in the complex. If the state of Cl* is approximated to that of the "free" chloride ions, then $b_2' - b_1'$ is expected to be proportional to the difference

$$[31] \quad \frac{1}{r_{M^{2+}} + r_{Cl^-}} - \frac{1}{r_{A+} + r_{Cl^-}} = \Delta\left(\frac{1}{d}\right)$$

The plot of $b_2' - b_1'$ against $\Delta(1/d)$ is given in Fig. 12 and indicates a nearly linear relationship within each system.

From the previously presented results it appears that the $CdCl_2$–ACl, $MgCl_2$–ACl, and $MnCl_2$–ACl systems, in which the M^{2+} ion has either no d-electrons or has a filled d^{10} or half-filled d^5 outer electronic structure, form complex species of the same approximate strength. Furthermore, the concentration dependence of the heats of mixing in $MgCl_2$ and $MnCl_2$ for solutions rich in MCl_2 cannot be predicted from the present model as accurately as with the other systems investigated. The greatest deviations are observed with the $MnCl_2$–CsCl and $MgCl_2$–CsCl binary systems, where the model is expected to hold best. It is possible that dissociation effects and the formation of more complicated complex

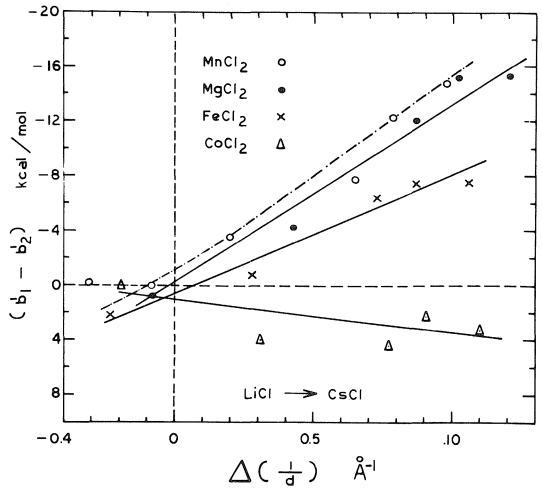

FIG. 12. Plots of the difference $b_1' - b_2'$ *vs.* $\Delta(1/d)$ for the systems MCl_2–ACl. $\Delta(1/d) = 1/(r_{M2+} + r_{Cl-}) - 1/(r_{A+} + r_{Cl-})$.

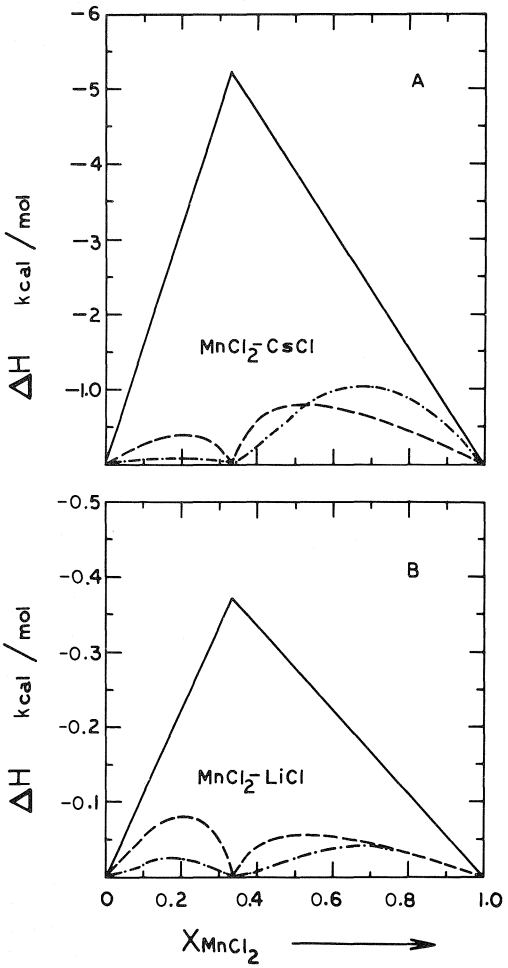

FIG. 13. (*A*) Contribution of the various *b*-parameters to the heats of mixing in the $MnCl_2$–CsCl system. ———, "reaction" part of the heat of mixing; – – –, part of the heat of mixing attributed to the parameter b_2 and b_2'; –·–·–·, part of the heat of mixing attributed to the parameters b_1 and b_1'. (*B*) Same plots for the $MnCl_2$–LiCl system.

species may take place in the metal chloride rich solutions.

It should be emphasized that although the various parameters b_1, b_2, b_1', and b_2' are large negative quantities, their contribution to the heats of mixing is much smaller than that due to the reaction parameter b_R. Figure 13 shows the contribution of the various heat effects to the total heat of mixing, for the system $MnCl_2$–CsCl.

It is evident that the heat of mixing is primarily determined by the reaction parameter b_R. For the weak complexed systems, such as the $MnCl_2$–LiCl, the contribution of the solution parameters b_1, b_2, b_1', and b_2' becomes more significant. Again the distribution of the total heat into the various contributions is shown in Fig. 13*b*.

Actually, such weakly complexed systems could also be treated as a first approximation by a simple regular solution model.

Summary

Charge asymmetrical binary systems which indicate pronounced negative heats of mixing are interpreted in terms of a model which takes into account the reaction and the asymmetry effects. The calculation accounts for the change in coordination number in a solution of mono- and divalent salts. The derived relationships predict well the concentration dependence of the heats of mixing in the systems $MnCl_2$–ACl, $FeCl_2$–ACl, $CoCl_2$–ACl, $MgCl_2$–ACl, and $NiCl_2$–ACl, where A = Li, Na, K, Rb, or Cs.

The method allows the calculation of exact equations for the partial molar heats of mixing. The parameters, b_R, b_1, b_2, b_1', and b_2', are shown to be physically meaningful as they relate to the structural characteristics of the salt components in the melt.

Differential Thermal Analysis Studies on Ag_2CO_3[1]

G. D. NAGY, J. B. VERGETTE,[2] AND J. P. CONNOLLY
Defence Research Establishment Ottawa, Defence Research Board, Ottawa 4, Canada

Received March 1, 1971

The decomposition and phase transitions that occur during the heating and cooling of Ag_2CO_3 were studied by differential thermal analysis at heating rates of 7 to 14° per min. In helium, the Ag_2CO_3 was partially decomposed evolving CO_2 (7–35% depending upon the method of preparation) giving rise to peaks at 190 to 200°; at 350 to 400°, two endothermic peaks were observed at which CO_2 and O_2 were given off simultaneously, leaving silver metal. In CO_2 the initial partial decomposition gave rise to a peak at about 265°. The partially decomposed Ag_2CO_3 ($Ag_2O{\cdot}nCO_2$, where n is less than one) gave the same X-ray diffraction pattern as Ag_2O, which slowly converted to that for Ag_2CO_3 if left exposed to air or CO_2. The $Ag_2O{\cdot}nCO_2$ undergoes two distinct "reversible" phase transitions at 180 and 197° on subsequent reheatings. The $Ag_2O{\cdot}nCO_2$ behaves like a clathrate-type of structure in which CO_2 can be entrapped in the Ag_2O lattice.

La décomposition et les transitions de phase qui ont lieu durant le chauffage et le refroidissement du Ag_2CO_3 ont été étudiées par l'analyse différentielle thermique à une vitesse de chauffage de 7 à 14° par min. Dans l'hélium, le Ag_2CO_3 s'est décomposé partiellement (7–35% selon la manière de préparation) en dégageant du CO_2 et a occasionné des pics à une température de 190 à 200°; de 350 à 400°, deux pics endothermiques ont été observés aux températures où se sont dégagés simultanément du CO_2 et du O_2 en laissant du métal argent. Dans le CO_2, la première étape de la décomposition a occasionné un pic à une température d'environ 265°. Le Ag_2CO_3, partiellement décomposé ($Ag_2O{\cdot}nCO_2$, où n est inférieur à un), a donné le même diagramme de rayons-X que le Ag_2O; ce diagramme s'est transformé lentement en celui du Ag_2CO_3, quand le Ag_2O était exposé à l'air ou au CO_2. Le $Ag_2O{\cdot}nCO_2$ subit deux transitions "réversibles" de phase distinctes aux températures de 180 et de 197° durant des réchauffages ultérieurs. Le $Ag_2O{\cdot}nCO_2$ agit d'un type clathrate dans lequel le CO_2 peut être logé dans le réseau du Ag_2O.

Canadian Journal of Chemistry, **49**, 3986 (1971)

Introduction

The thermal decomposition of Ag_2CO_3 has been studied by other investigators as an example of a reversible chemical change involving a solid reactant giving solid and gaseous products (1–10). These studies are relevant to the development of silver oxide – silver carbonate systems used as regenerable chemisorbers for carbon dioxide (11–13) and also for silver electrodes for the reduction of oxygen (14). Our interest in Ag_2CO_3 results from the use of silver oxide electrodes in silver–zinc or silver–cadmium batteries. The silver oxides in these batteries may be converted to the carbonate by atmospheric carbon dioxide or by potassium carbonate in the potassium hydroxide electrolyte.

There is evidence that Ag_2CO_3 exists in two different forms, called active and inactive (2, 3, 7, 14). The two forms have the same chemical and crystallographic structures and are distinguished by their preparation and thermal decomposition. The active form can be precipitated from dilute aqueous equimolar solutions of silver nitrate and alkali carbonates or bicarbonates (less than 0.005 *M* for the carbonate and 0.015 *M* for the bicarbonate). It decomposes completely to Ag_2O and carbon dioxide below 200° under isothermal conditions. The inactive form can be prepared from concentrated solutions of the same salts as the active form as well as by bubbling carbon dioxide through aqueous silver bicarbonate solutions or solutions containing the silver–ammonia complex. The inactive form has been reported not to decompose at any measurable rate (7) or only to an extent of 10 to 12% below 280° (9). Above this temperature it decomposes directly to metallic silver with simultaneous evolution of carbon dioxide and oxygen. Kadlets and Dubinin (7) suggested that the 10–12% decomposition below 280° was due to the precipitation of some of the active form during the latter stages of the precipitation when the solution becomes dilute.

In previous differential thermal analysis

(DTA) work, either one or two endothermic peaks have been observed in the range 20 to 300° (8, 11, 15, 16). These have been reported to occur in the ranges 185 to 215°, and 227 to 300°. Wydeven (17) using a differential scanning calorimeter and working in a carbon dioxide atmosphere showed that, on reheating, the lower peak split into two endothermic peaks occurring at 185 and 200°. Corresponding exothermic peaks were observed at 115 and 185° on cooling. Repeated heating and cooling had little effect on these thermograms. The exothermic peak at 115° was quite broad, starting at 134° and ending at 105°. The intensity of the corresponding endothermic peak at 185° on reheating was proportional to how far into the range of the exotherm the sample was allowed to cool. Wydeven also showed that these so-called reversible peaks were not due to the reaction

[1] $$Ag_2CO_3 \rightleftarrows Ag_2O + CO_2$$

Experimental

A large proportion of the data presented here will be for commercially available Ag_2CO_3 (Mallinckrodt AR). This was prepared from $AgNO_3$ and Na_2CO_3 and can be expected to contain both forms, but predominantly the inactive form.

Attempts were made to prepare pure active and inactive forms from equimolar aqueous solutions of $AgNO_3$ and Na_2CO_3 varying from saturated solutions down to 7.5×10^{-4} *M*. In order to study the effect of coprecipitation of both forms, two preparations were made at each concentration. In one case the precipitates were filtered immediately after mixing. In the other case there were digestion periods of 24 h before filtration.

Attempts were also made to prepare the active form from dilute solutions of $AgNO_3$ and $NaHCO_3$ (7) and from carbon dioxide saturated solutions of $AgNO_3$ and $KHCO_3$ (2). We restricted our preparations to those which would be common to battery systems.

The DTA apparatus used was an R. L. Stone model with effluent gas detection (E.G.D.). The sample and reference materials were contained in platinum sample cups which rested in a Stone ring-type platinel II differential thermocouple. Helium and carbon dioxide were used as dynamic gases. At a pressure of 25 Torr above atmospheric, chemical and physical changes giving rise to temperature peaks of the order of 0.01° could be detected.

For some experiments the effluent gas was fed into a Varian Aerograph chromatograph fitted with an automatic sampler. This was used to measure the concentrations of the evolved gases in the dynamic stream. Helium was used as the carrier gas. The sensitivity was 50 p.p.m. for O_2 and 100 p.p.m. for CO_2.

X-Ray diffraction studies were done with a Philips Norelco direct-reading diffractometer. The goniometer was equipped with a high temperature stage that could be operated at reduced pressure or in a controlled gas atmosphere.

Results

(A) General Characteristics of the DTA Traces

Figure 1 shows traces of the Ag_2CO_3 and chemically precipitated Ag_2O and AgO at a heating rate of 14 °C per min. (The Ag_2O was commercially available and the AgO was prepared by the silver nitrate – potassium peroxydisulfate method (18).) Helium was used as the carrier gas except for the dashed curve for Ag_2CO_3 where CO_2 was used. The lower trace, for Ag_2O, shows a peak at 458° due to Ag_2O decomposing to silver and oxygen. The upper trace, for AgO, shows the decomposition to Ag_2O and oxygen gives rise to a peak at 210° and this Ag_2O to silver gives rise to a peak at 423°. The important things to note here are the differences in the peaks for the decomposition of normal Ag_2O and the Ag_2O from decomposed AgO. Although they have the same peak area they have different shapes and occur at different temperatures. The middle traces for commercially available Ag_2CO_3 showed three definite peaks in He, the solid curve. Carbon dioxide is evolved after the peak at 197°, in the vicinity of 200 to 220°. In a CO_2 atmosphere, the dashed curve, an additional peak is observed at 263°, at which CO_2 is evolved. Thus the discrepancy in earlier work with regard to the observance of either one or two peaks is

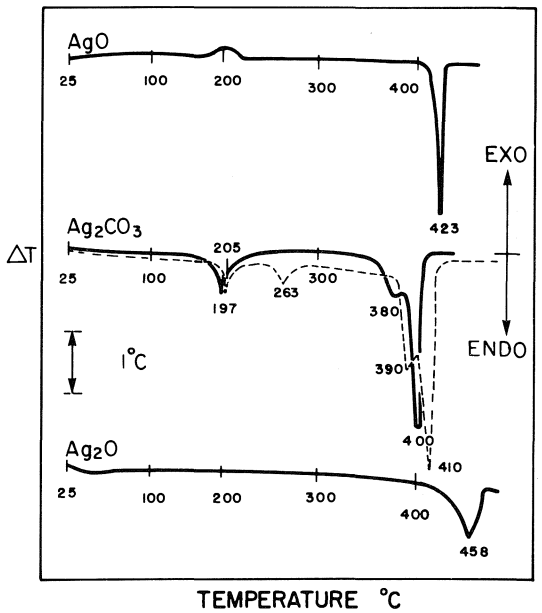

FIG. 1. DTA traces of commercially available Ag_2CO_3 and chemically precipitated AgO and Ag_2O. 14° per min. Solid lines in helium, dashed in CO_2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

due mainly to the ability of the particular apparatus to remove any evolved CO_2 and reaction 1.

The two peaks at 380 and 400° which involve decomposition to silver with the simultaneous evolution of CO_2 and O_2 occur at a considerably lower temperature than for both of the other two forms of Ag_2O shown. Carbon dioxide as the dynamic gas had less effect on these peaks than on that at the lower temperature. Here the increase was only 5 to 10° as compared to close to 70° for the lower temperature peak.

Figure 2 shows DTA traces for precipitates from various concentrations of equimolar $AgNO_3$ and Na_2CO_3 solutions. These curves do not show all of the various concentrations studied, but do show the trends. The concentrations of the solutions were: *A*, saturated with respect to Na_2CO_3; *B*, 0.1 *M*; *C*, 0.0125 *M*; *D*, 0.006 *M*; *E*, 0.0022 *M*, the lowest concentration at which enough precipitate to analyze was obtained.

There are gradual shifts in the peak temperatures as the concentration is decreased. All curves had peaks in the vicinity of 195 to 200°. Curves *A* and *E* have additional peaks at 225 and 210°. On curve *D* a peak at 210° in the form of a slight shoulder can be seen.

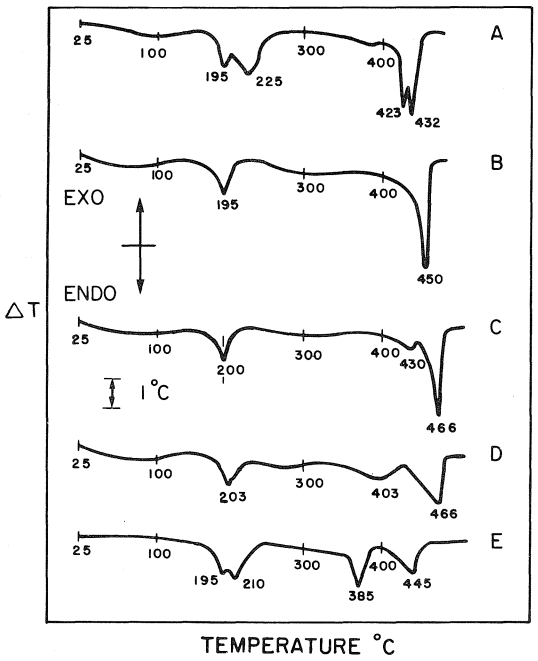

FIG. 2. DTA traces, in helium, of Ag_2CO_3 precipitated from equimolar aqueous $AgNO_3$ and Na_2CO_3 solutions. 14° per min. *A*, saturated with respect to Na_2CO_3; *B*, 0.1 *M*; *C*, 0.0125 *M*; *D*, 0.006 *M*; *E*, 0.0022 *M*.

In the temperature range of 385 to 466° two distinct peaks were observed, with the exception of the precipitates from solutions in the range of 1.0 to 0.1 *M* (see curve *B*). In these latter cases, shoulders were observed. One can see the gradual increase in the temperature of the higher peaks from curve *A* to curve *C*. A second peak begins to develop at 430° on curve *C*. The area of this new peak increases, and the temperature at which it occurs decreases as the concentration of the solutions decreases. At the same time there is a decrease in the area, and to a lesser degree, the temperature of the higher peak.

Carbon dioxide was the only gas evolved between 195 and 230°. In the case of curves *B* and *C* the gas was evolved about 10° after the peaks, but for the curves *A*, *D*, and *E*, only at the higher of the two peaks. The percentage of the total amount of CO_2 present as carbonate in the sample which was evolved below 220° increased from about 7% for curve *B* to 30% for curve *E*. About 35% of the available CO_2 was evolved for curve *A*. Vigorous stirring of the solution during precipitation decreased the amount of CO_2 evolved at these temperatures. The shift to higher peak temperatures as more CO_2 is evolved is probably due to the inhibition of the decomposition by the gaseous product. From the results of X-ray diffraction work described later, we prefer to call this partially decomposed carbonate $Ag_2O{\cdot}nCO_2$ where n is less than one.

At the peaks between 385 and 465°, CO_2 and O_2 were evolved simultaneously at each of the peaks, roughly in proportion to the amount of heat absorbed. This will be shown in more detail later.

Similarities between the precipitates for which DTA traces are shown by curves *A* and *E* were not confined to the DTA traces. The precipitates were a lemon color. The precipitate from the solution which was saturated with respect to Na_2CO_3 (curve *A*) had some medium gray powder as well. The precipitate from the 1.0 *M* solution was medium gray and the color changed through a greenish to a lemon yellow color as the concentration decreased. In all cases the precipitate blackened on exposure to light.

Digestion and aging affected only the higher temperature peaks. Typical curves are shown in

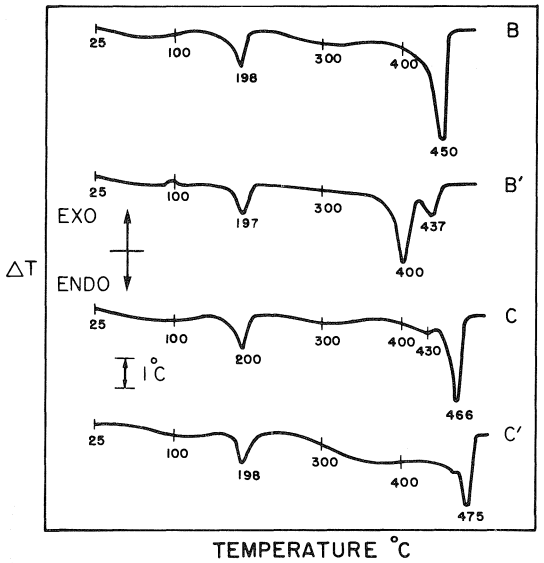

FIG. 3. DTA traces, in helium, of Ag_2CO_3, precipitated from equimolar aqueous $AgNO_3$ and Na_2CO_3 solutions. 14° per min. *B*, 0.1 *M*; *B'*, 0.1 *M*, stored 3½ months dry; *C*, 0.025 *M*, filtered immediately; *C'*, 0.025 *M*, digested 24 h.

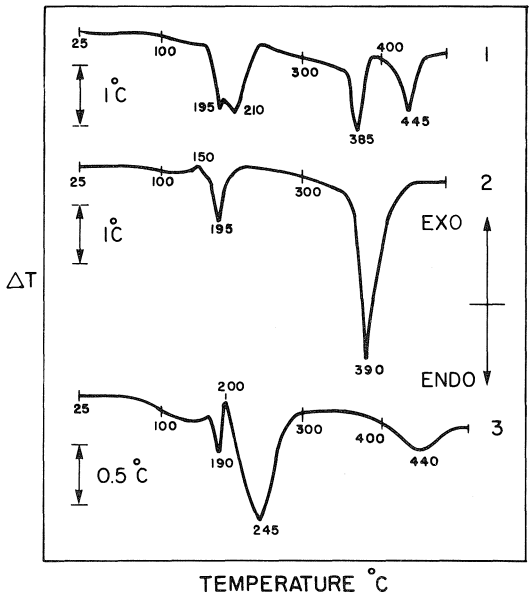

FIG. 4. DTA traces, in helium, of Ag_2CO_3 precipitates. 14° per min. (*1*) equimolar 0.0022 *M*, solutions $AgNO_3$ and $NaCO_3$; (*2*) equimolar, 0.015 *M*, solutions $AgNO_3$ and $NaHCO_3$; (*3*) equimolar 0.015 *M*, solutions $AgNO_3$ and $KHCO_3$ saturated with respect to CO_2 before mixing.

Fig. 3. Digestion increased the peak temperature. All aged material had two peaks which were observed at lower temperatures.

Figure 4 shows DTA traces of some of the precipitates made in an attempt to form the pure active form of Ag_2CO_3. The first curve is the same as curve *E* of Fig. 2. The second curve is that for the precipitate from 0.015 *M* solutions of $AgNO_3$ and $NaHCO_3$. The third curve was obtained from the precipitate resulting from mixing 0.015 *M* solutions of $AgNO_3$ and $KHCO_3$ which had been saturated with CO_2. The temperature scale on this last curve has been expanded to show some of the finer detail. In all cases the concentrations used were the lowest that gave enough precipitate to analyze. It is quite obvious that it is very unlikely that these are the same compound.

For curve *2*, gas was evolved at the exothermic peak at 150°. Carbon dioxide was evolved at the shoulder just after the peak at 195°. The amount of CO_2 was equivalent to about 15% of that available as carbonate. At the 390° peak, CO_2 and O_2 were given off simultaneously. For curve *3*, oxygen was given off at the exothermic peak at 200°. No gas was given off at the 190° peak. At 245°, about 90% of the CO_2 available as carbonate was evolved. At 440°, the gas evolved was almost entirely O_2.

It was mentioned earlier that at the peaks in the vicinity of 350 to 470°, O_2 and CO_2 were evolved simultaneously. Figures 5 and 6 show this.

In Fig. 5, the solid curve shows the average amount of carbon dioxide in the effluent gas

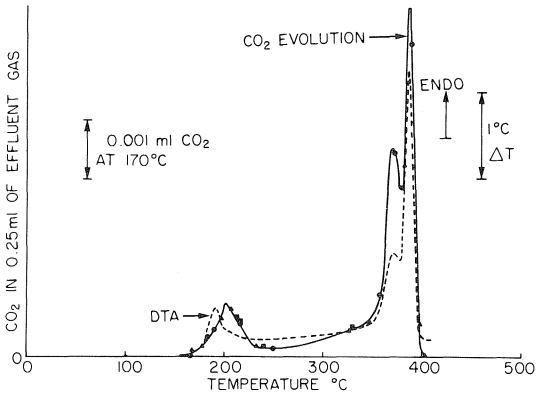

FIG. 5. Amount of CO_2 in a 0.25 ml sample of the effluent gas at 170° *vs.* temperature for commercially available Ag_2CO_3. Solid curve, CO_2 evolution; dashed curve, DTA trace in helium, 7° per min.

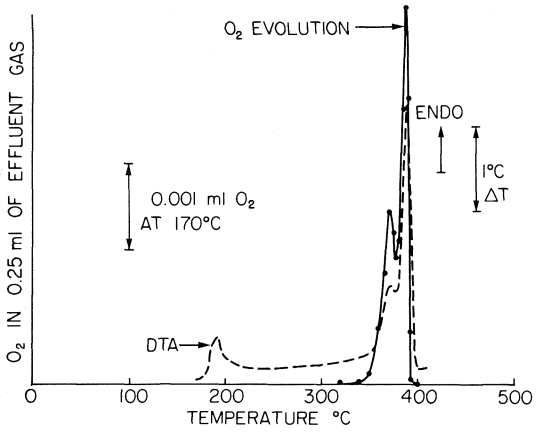

FIG. 6. Amount of O_2 in a 0.25 ml sample of effluent gas at 170° *vs.* temperature for commercially available Ag_2CO_3. Solid curve, O_2 evolution; dashed curve, DTA trace in helium, 7° per min.

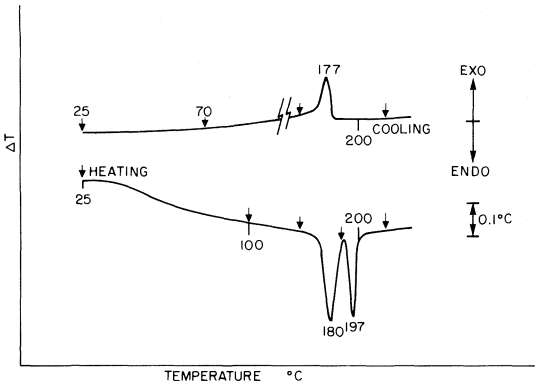

FIG. 7. DTA heating and cooling traces in helium of commercially available Ag_2CO_3 which had been previously heated to 220° and cooled to room temperature in helium. Heating rate 14° per min. Cooling rates, greater than 150°, 25° per min, less than 150°, by natural convection. The arrows refer to points at which X-ray diffraction patterns were taken.

during the course of decomposition of the commercially available Ag_2CO_3 for six runs. One-quarter milliliter samples were taken at the points indicated and about every 7 to 10 min between 230 and 250°. The dashed curve is a superimposed DTA trace.

As can be seen, about 20% of the total available, CO_2 comes off after the peak at about 195° as observed by Wydeven (17). Smaller amounts are evolved between 230 and 350°. Carbon dioxide is evolved at *both* of the peaks near 400° roughly in proportion to the heat absorbed.

Figure 6 shows curves corresponding to Fig. 5 for the case of O_2 evolution. No detectable O_2 is evolved until about 320°. Again as in the case of CO_2 evolution, O_2 is evolved at *both* peaks near 400° and roughly in proportion to the heat absorbed.

(B) Thermal Phenomena Due to Cyclic Heating and Cooling

Figure 7 shows DTA traces in helium exhibiting the so-called reversible thermal phenomena reported by Wydeven (17). The lower curve was obtained by heating $Ag_2O{\cdot}nCO_2$. In CO_2 three peaks were observed. The first two peaks were identical to those shown and the third in the range of 220 to 290° was due to decomposition of the Ag_2CO_3 formed by recombination of the $Ag_2O{\cdot}nCO_2$ and CO_2 during the cooling period.

On cooling we observed only the exotherm at 177° (Fig. 7, upper curve). Below 150°, the curve

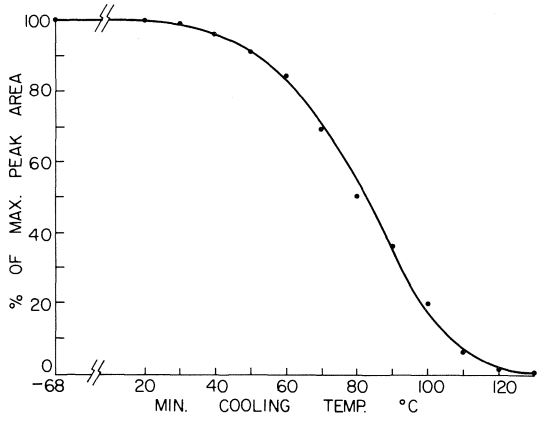

FIG. 8. Area of the 180° peak (see Fig. 7) expressed as the percentage of the maximum area observed for samples cooled to −68° as a function of the temperature to which the sample was cooled.

shown is the compressed trace. In this temperature range, the sample could only be cooled by natural convection at a rate too low to detect the presence of the low temperature transition. However, it was detected by another means as shown on Fig. 8.

In Fig. 8, the area of the 180° peak expressed as the percentage of the maximum area observed for samples which were cooled to −68° is plotted as a function of the temperature to which the sample was cooled. As can be seen the range of the transition was longer and at a lower temperature than the 105 to 134° observed by Wydeven.

For personal use only.

Furthermore, holding the temperature at any of the temperatures in the range of the transition for up to 5 h had little effect on the area of the 180° peak on reheating. The curves were the same for He or CO_2 atmospheres.

Of the various methods used to prepare Ag_2CO_3, all precipitates with the exception of those made with CO_2 saturated solutions, exhibited this reversible phenomenon. In this latter case, where the Ag_2CO_3 is believed to have been almost pure active form, none of the reversible peaks were observed.

The recombination with carbon dioxide of the $Ag_2O{\cdot}nCO_2$ is dependent upon the thermal history and physical state of the sample. A sample which was heated to 290° and rapidly cooled in CO_2 to a temperature above 130° recombined more rapidly with CO_2 than a sample which was allowed to cool into the transition region shown on Fig. 8. In both cases the rate of recombination was much more rapid than that for normal Ag_2O.

(C) X-Ray Diffraction Studies

Ag_2CO_3 that had been heated in He to form $Ag_2O{\cdot}nCO_2$ had an X-ray diffraction pattern that was predominantly Ag_2O at 220°. On cooling to room temperature the pattern persisted. However, on exposure to air for extended periods of time the evolved CO_2 was replaced and the pattern reverted to that of Ag_2CO_3. These observations were based on the strong reflections of the 101, 130, 200, 210, 121, 031, and 150 planes of Ag_2CO_3 and the 111, 200, 220, and 311 planes of Ag_2O. Patterns of normal Ag_2O at 220° showed sharpening of the lines compared to those at room temperature observed by Rao *et al.* (15).

The arrows on Fig. 7 indicate temperatures at which X-ray diffraction patterns were taken on $Ag_2O{\cdot}nCO_2$ during the process of heating and cooling. At 100° the Ag_2O pattern began to appear and the intensity increased slowly with time. At 185°, the pattern was predominantly that of Ag_2O in less than $\frac{1}{2}$ h. At 220° the pattern was immediately predominantly that of Ag_2O. On cooling, the patterns were all that of Ag_2O.

There were six or seven additional lines observed in the Ag_2O pattern for the $Ag_2O{\cdot}nCO_2$. These were not present in the original Ag_2CO_3 pattern and could not be matched to other reported patterns for silver oxides (19–23).

It was estimated that the X-rays could completely penetrate the sample. However, to check whether or not the Ag_2O patterns observed were due to a surface layer of Ag_2O comprizing 15 to 20% of the sample, a sample, immediately after cooling to room temperature and an X-ray pattern taken, was ground, intimately mixed and another pattern taken. The pattern was still predominantly that of Ag_2O.

Discussion

Of the various methods used to form Ag_2CO_3, only the CO_2 saturated solutions gave what could be considered to be pure active form. All other preparations gave mixtures of the two forms. There is evidence that more of the active form is precipitated at high and low concentrations. The resultant mixture after partial decomposition is not a mechanical mixture. If a mechanical mixture was obtained one would expect distinct peaks at fairly distinct temperatures and not the gradual shifts as observed.

Co-precipitation of the active form with the inactive form is more subtle than just dilution of the reacting species as explained by Kadlets and Dubinin (7). If the form of the material precipitated is due to concentration alone, it is difficult to explain some of the results. First, digestion increased the temperature of the 430–460° peaks. Second, for curve *B* of Fig. 2, approximately 7% of the precipitate could be considered to be in the active form. The yield of this active form was found to be 2 mmol/l. However, for curve *E*, taking into account the solubility of Ag_2CO_3 and the concentrations of the solution, only 0.2 mmol/l of Ag_2CO_3 can be formed. Furthermore only $\frac{1}{3}$ or less than 0.1 mmol/l of this latter precipitate can be considered to be in the active form. The effect of stirring suggests that the relative quantities of the active and inactive forms are controlled by mass transfer.

The origin of the two exothermic peaks at 150 and 200° of curves *2* and *3* of Fig. 4 at which oxygen was evolved is unknown. The temperatures suggest the decomposition of AgO, but it is difficult to see how AgO can be formed under the conditions used. Since considerably more CO_2 is evolved at 245° for curve *3* compared to 210° for curve *2*, a shift in the peak temperatures is not unexpected. The high temperature peaks resemble the two different peaks observed earlier for the silver oxides both in shape and relative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

temperatures. Curve *2* corresponds to that for Ag_2O formed by the decomposition of AgO and curve *3* to that for chemically prepared Ag_2O. However, we should not carry this analogy too far, since the material used for curve *2* has enough CO_2 present to be equivalent to approximately 85% carbonate.

The results shown on Figs. 5 and 6 show that the first of the two high temperature peaks observed in this work is not due only to the decomposition of the carbonate to Ag_2O and the second only to the further decomposition of the oxide to silver as might be expected. It is unlikely that the double peaks for gas evolution and DTA are due to retardation of the release of CO_2 from the interior of the sample due to a build-up of Ag_2O on the surface, as proposed by Spencer and Topley (2, 3). If this were the case, one would expect a greater effect than that observed on the peak temperatures in the CO_2 atmosphere and also O_2 evolution at only one peak. The reversible phenomena while they can be repeated on cyclic heating and cooling are not reversible in the thermodynamic sense. They can be compared to the hysteresis observed in adsorption and desorption work.

It now remains to decide how the $Ag_2O{\cdot}nCO_2$ can have the structure of Ag_2O but yet have a stoichiometry of 65–93% Ag_2CO_3. The $Ag_2O{\cdot}nCO_2$ behaves very much like clathrate-type compounds such as β-quinol (24, 25) for which CO_2 is a common enclosed molecule (26, 27). Ag_2O has an open structure. Application of extremely high pressure can convert the cubic structure to one that is hexagonal close packed and has a density 30% greater (20). It has been reported that Ag_2O can entrap O_2 (21). Silver oxide, like β-quinol, consists of two interpenetrating and identical frameworks not cross-connected by any primary bonds (28). There are other similarities between $Ag_2O{\cdot}nCO_2$ and clathrate compounds; the O_2 and entrapped CO_2 are released simultaneously when the Ag_2O cage-like structure is broken down, and the CO_2 is readily available at the time the cavity is closed.

Examination of structure of Ag_2O and also solid CO_2 (29, 30) reveals that cavities do exist in Ag_2O that could accommodate CO_2 molecules of the size in the solid form and in the quantity present in $Ag_2O{\cdot}nCO_2$. Moreover the CO_2 can be in two distinct orientations that could account for the multiple peaks observed. However, this type of structure is purely speculative at this time and any confirmation will have to await a more detailed study of the structure.

Summary

The form of Ag_2CO_3 precipitated from solutions containing $AgNO_3$ and alkali carbonate or bicarbonate is greatly dependent upon the reactant concentrations. In general, high and low concentrations and the absence of stirring tended to produce more of the active form. Only dilute CO_2-saturated bicarbonate solutions gave the relatively pure active compound.

Mixtures of active and inactive forms evolved CO_2 (7–35%) when heated to 200–265°, forming $Ag_2O{\cdot}nCO_2$ where n is less than one. This $Ag_2O{\cdot}nCO_2$ is believed to be a clathrate-type of compound which has the structure of normal Ag_2O and contains occluded CO_2 in cavities in the silver oxide. Recombination of the $Ag_2O{\cdot}nCO_2$ with carbon dioxide is dependent upon the physical state and thermal history and is much more rapid than for normal silver oxide.

The $Ag_2O{\cdot}nCO_2$ will undergo transitions at 180 and 200° on heating, with corresponding transitions, on cooling, in the ranges of 20 to 125° and 175 to 185°. The transitions are not reversible in the thermodynamic sense and none of them is due to the reaction $Ag_2CO_3 \rightleftarrows Ag_2O + CO_2$.

At temperatures above 300° two non-reversible endothermic DTA peaks have been observed. Oxygen and CO_2 are evolved simultaneously at these peaks roughly in proportion to the heat absorbed.

The assistance of Messrs. P. J. Powell and F. K. McLusky in obtaining some of the gas chromatographic results, and the Metallurgical Laboratories of Eldorado Nuclear Limited in obtaining the high-temperature X-ray diffraction patterns is gratefully acknowledged.

Identification of ν(N=N) in Metal Arylazo Complexes: The Infrared and Raman Spectra of some Arylazo Complexes of Rhodium(III)

G. W. Rayner-Canham and D. Sutton[1]

Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received July 8, 1971

The Raman and infrared spectra have been obtained for a series of rhodium-arylazo complexes $RhCl_2(PPh_3)_2(p\text{-}XC_6H_4N_2)$ where X = H, F, Br, CF_3, NO_2, OCH_3, NEt_2. The N=N stretching frequency ν(N=N) has been unambiguously identified from its strong appearance in the Raman spectrum and from isotopic substitution studies using ^{15}N. Trends in the value of ν(N=N) with the *p*-substituent X are discussed, in terms of the apparent degree of metal–ligand π-interaction.

Nous avons obtenu les spectres infrarouge et raman d'une série de complexes arylazo du rhodium, du type $RhCl_2(PPh_3)_2(p\text{-}C_6H_4N_2)$ où X = H, F, Br, CF_3, NO_2, OCH_3, NEt_2. La fréquence d'élongation caractéristique de la liaison N=N, ν(N=N) a été identifiée sans ambiguité à cause de sa forte intensité dans le spectre raman et des études de substitution isotopiques utilisant le ^{15}N. On discute des tendances de ν(N=N) en fonction des substituants en para, en termes de degré apparent d'interaction π métal–ligande.

Canadian Journal of Chemistry, **49**, 3994 (1971)

Introduction

Following Parshall's proposal that arylazo metal complexes may be considered as model systems of nitrogen reductase (1), we have begun a systematic study of these systems (2). Of considerable interest is the position of the N=N stretching frequency ν(N=N), since this provides a simple means of observing the effect which substituents may have on ν(N=N) and presumably on the N=N bond strength. However, to date identification of this vibration has proved difficult due to its weakness in the i.r. spectrum (3–6), an unambiguous assignment requiring the use of ^{15}N substitution (1). We have therefore undertaken to identify ν(N=N) in the Raman spectrum, and to investigate the effect of varying the *p*-substituent on the arylazo ligand. The compounds studied are those of the type originally prepared by Baird and Wilkinson (7), namely $RhCl_2(PPh_3)_2(p\text{-}XC_6H_4N_2).\frac{1}{2}CHCl_3$ (7) with X = H, NO_2, CF_3, F, Br, OCH_3, NEt_2, providing a range of electron withdrawing and donating properties (8).

Experimental

The compounds were prepared by the method of Baird and Wilkinson (7), using both chloroform and dichloromethane as solvents. All complexes were washed with acetone and ether, and vacuum dried. Analytical figures for the complexes are shown in Table 1. Analyses were performed by A. Bernhardt, Germany. ^{15}N substitution at the site adjacent to the metal was achieved (1) by using $[p\text{-}XC_6H_4{}^{14}N{\equiv}{}^{15}N]^+$ synthesized from $p\text{-}XC_6H_4{}^{14}NH_2$ and $Na^{15}NO_2$ (95% ^{15}N) obtained from Isomet Corporation, New York. Raman spectra (150–2000 cm^{-1}) of microcrystalline samples were obtained utilizing a Cary 81 Raman spectrophotometer equipped with a Spectra-Physics model 125 He/Ne laser, and calibrated using rare-gas emission lines. Decomposition of the complexes occurred with the laser power at maximum (~35 mW at sample), but the decomposition could be reduced to a negligible rate by using a defocussed beam (~10 mW at sample), except in the case of the *p*-diethylamino complex. Depolarization measurements on solutions in $CHCl_3$ and CH_2Cl_2 were not possible due to photodecomposition of the samples. Infrared spectra were obtained with a Beckman I.R. 12 spectrophotometer using Nujol and fluorolube as mulling agents.

As there are inconsistencies in reported frequencies of ν(N≡N) in solid aryl diazonium tetrafluoroborates (9, 10), we have remeasured the values of this vibration. The sharpness of the vibration in the Raman spectrum enabled accuracies of ± 1 cm^{-1} to be obtained. As in the case of the *p*-diethylamino complex, the parent diazonium salt decomposed in the laser beam.

Results

The positions of ν(N=N) in the i.r. and Raman spectra of the complexes reported here are included in Table 2. In the Raman spectra, ν(N=N) is normally a quite intense single peak, compared with the extremely weak corresponding band in the i.r. spectra. ^{15}N substitution of the co-ordinated nitrogen atom for the *p*-bromo and *p*-methoxy complexes produced isotopic shifts of ~22 cm^{-1}, only slightly smaller than the shift expected for a simple ν(N=N) vibration based on the change in reduced mass. The *p*-methoxy com-

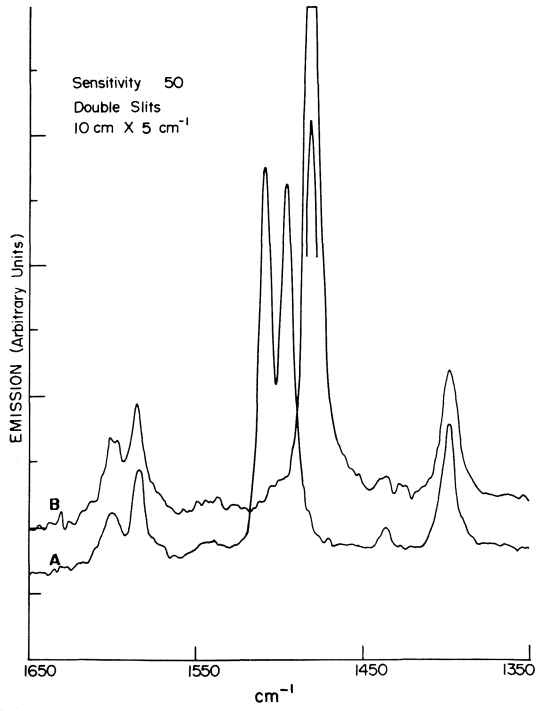

FIG. 1. Raman spectra for the complexes $(MeOC_6H_4\text{-}^{14}N{=}^{14}N)RhCl_2(PPh_3)_2$ (*A*) and $(MeOC_6H_4{}^{14}N{=}^{15}N)\text{-}RhCl_2(PPh_3)_2$ (*B*) in the ν(N=N) region.

plex was unusual in exhibiting two equal intensity peaks at 1509 and 1496 cm^{-1} in the Raman spectrum of the ^{14}N complex, but the usual single peak in the ^{15}N complex (Fig. 1). The splitting in the ^{14}N complex we attribute to Fermi resonance with a weak aromatic mode. Although Raman spectra were not obtained for the *p*-diethylamino complex, a comparison of the i.r. spectra of the ^{14}N and ^{15}N complexes showed that a weak band at 1471 cm^{-1} (^{14}N) was not present in the ^{15}N spectrum. The band is expected to shift in the ^{15}N complex into a position obscured by other absorptions, and no new band was observed.

The only other band which we have observed to shift upon isotopic substitution is the 734 cm^{-1} band in the ^{14}N *p*-bromo complex which shifted to 726 cm^{-1} (^{15}N). This band is tentatively assigned as due to the N=N—C deformation mode (11).

Discussion

The strong Raman activity of ν(N=N) in this series of compounds suggests that Raman spectroscopy is a preferred means of identifying ν(N=N) in metal azo systems, especially in view of the difficulty in distinguishing ν(N=N) from aromatic absorptions in the i.r. The position of

ν(N═N) in the present complexes is in good agreement with Parshall's assignment of bands at 1463 and 1562 cm^{-1} to this vibration in the arylazo platinum and arylazo molybdenum complexes, respectively (1). A polynuclear arylazo molybdenum system has been reported, with a band at 1550 cm^{-1} being assigned as ν(N═N) (12). Derivatives of *trans*-azobenzene (11) have ν(N═N) in the region 1400–1450 cm^{-1}.

A comparison of the values reported for the various arylazo complexes of different metals shows that they exhibit a general trend in which ν(N═N) decreases as the d^n configuration of the metal is increased. This is presumably related to a consequent increase in the electron occupancy of the π*(N═N) orbital.

As the observed isotopic shifts are only slightly less than those calculated for a pure ν(N═N) vibration, coupling with other vibrations is evidently small. According to the criteria of Fackler and Coucouvanis (13) the N═N bond order is less than two; this could be brought about by π interactions with either the metal or the aromatic ring. For the arylazo complexes, ν(N═N) decreases as the electron donating capacity of X is increased. There is also a decrease in ν(N≡N) for the corresponding diazonium salt. The near linear relationship between these effects points to the aromatic ring being predominantly responsible for the π interaction in the metal complexes. Thus, if for example, one supposes that the arylazo group withdraws π electrons from the metal, then one would expect electron withdrawing *p*-substituents (*e.g.* NO_2, F, CF_3) to give relatively larger decreases in ν(N═N) for the complexes than the decreases in ν(N≡N) observed for the corresponding diazonium salts, due to the added drain of metal electrons into the N═N function. The near constancy of the ratio ν(N═N)/ν(N≡N) indicates that in these d^6 complexes at least, the results do not appear to support such a postulate. However, for d^8 and d^4 systems, π acceptor (1) and π donor (14) properties, respectively, have been ascribed to the arylazo system.

Added support of this proposal is the observation that the d^6 metal arylazo systems reported to date (7, 15) are all pale yellow in color, irrespective of the ring substituent; whereas both the molybdenum (4) and platinum (3) complexes are intensely colored, especially when the aryl substituent is *p*-NO_2. Evidence was provided in the case of the platinum complexes that the color was due to a visible absorption band of the N═N chromophore (3) and a considerable bathochromic shift of this band relative to organic azo systems has also been observed in silylazo compounds (16). This has been shown to be a result of dπ–pπ interactions. The yellow rhodium complexes we have studied exhibit a steady increase in absorption with increasing frequency. No discrete absorption band is discernible in the visible or near u.v. range, assignable to the N═N chromophore.

The authors are grateful to the National Research Council of Canada for supporting this work through operating grants and to Mr. A. B. Gilchrist for preparation of diazonium salts and for discussions.

Diphenylphosphinato- and Hydroxydiphenylphosphine Complexes of Platinum(II) and Palladium(II)

K. R. Dixon and A. D. Rattray

Department of Chemistry, University of Victoria, Victoria, British Columbia

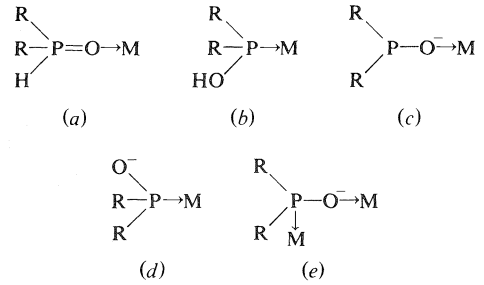
Received July 16, 1971

Preparations and various interconversion reactions are described for the complexes: $[M_2X_2(PPh_2O)_2(PPh_2OH)_2]$, $[MX(PPh_2O)(PPh_2OH)_2]$, $[MX(PPh_2O)(PPh_2OH)(PEt_3)]$, and $[M(PPh_2O)_2]_n$ where M = palladium or platinum, X = chloride or bromide, Ph = phenyl, and Et = ethyl. $[Pt(PPh_2O)_2(PPh_2OH)_2]$ and $[Pt_2(PPh_2O)_4(PPh_2OH)_2]$ are also described and all the complexes are assigned structures on the basis of their infrared spectra.

Les préparations ainsi que plusieurs réactions d'interconversion sont décrites pour les complexes suivants: $[M_2X_2(PPh_2O)_2(PPh_2OH_2]$, $[MX(PPh_2O)(PPh_2OH_2)]$, $[MX(PPh_2O)(PEt_3)]$ et $[M(PPh_2O)_2]_n$ où M = palladium ou platine, X = chlore ou brome, Ph = phényle et Et = éthyle. Les complexes $[Pt(PPh_2O)_2(PPh_2OH)_2]$ et $[Pt_2(PPh_2O)_4(PPh_2)H)_2]$ sont également décrits. A partir de leurs spectres infrarouges, des structures ont été attribuées à tous les complexes.

Canadian Journal of Chemistry, **49**, 3997 (1971)

Dialkyl- or diarylphosphine oxides generally exist in equilibrium with the corresponding hydroxydialkyl- or hydroxydiarylphosphines (alternatively named dialkyl- or diarylphosphinous acids (1) and their interactions with metals are therefore of interest for the several modes of co-ordination, which are possible; namely,



For R = phenyl, equilibrium lies strongly in favor of diphenylphosphine oxide but reactions with platinum complexes appear to proceed via a small equilibrum concentration of hydroxydiphenylphosphine. Using these reactions, and also the hydrolysis of chlorodiphenylphosphine complexes, Chatt and Heaton (2) have prepared platinum complexes containing coordination types *b*, *d*, and *e*. There is also infrared evidence (3) that suggests $Ag[PPh_2O]$ may be an example of type *c* but to our knowledge there are no examples of type *a* where R is alkyl or aryl.

In general this type of ligand has received rather little attention and we now report the results of a study of the reactions of diphenylphosphine oxide with K_2MX_4 complexes, where M = Pd or Pt and X = Cl or Br, together with studies of the structure and reactions of the products. The complexes differ from those reported by Chatt and Heaton in having both hydroxydiphenylphosphine (type *b*) and diphenylphosphinato (type *d*) ligands within the same molecule, a situation which allows very strong intramolecular hydrogen bonding.

Prior to our work, Troitskaya and co-workers (4, 5) had prepared complexes of the types $[Pt\{P(OR)_2O\}_2\{P(OR)_2OH\}_2]$ and $[Pd_2Cl_2\{P(OR)_2\}_2\{P(OR)_2OH\}_2]$ but no structures had been proposed and Pidcock and co-workers (6, 7) have recently studied this type of complex in detail by nuclear magnetic resonance spectroscopy.

Results and Discussion

The principal complexes and reactions studied are shown in Figs. 1 and 2. The structures shown are those considered most probable and they are discussed in detail below after consideration of the preparations and reactions of the complexes. For simplicity the discussion is limited to chloro complexes but their bromo analogues behave similarly.

The reactions of diphenylphosphine oxide are considered to proceed via a small equilibrium concentration of hydroxydiphenylphosphine as previously suggested (2) and the nature of our reactions and products provides further evidence for the correctness of this suggestion.

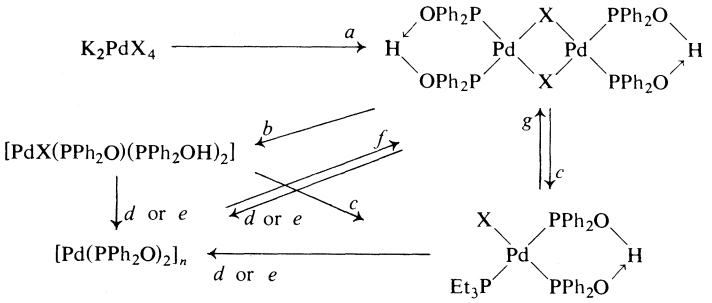


FIG. 1. Reactions of palladium complexes (X = Cl or Br, Ph = phenyl, and Et = ethyl). Reagents: (*a*) Ph_2HPO (2 mol) or Ph_2ClP (2 mol in water–acetone); (*b*) Ph_2HPO (1 mol); (*c*) Et_3P (1 mol); (*d*) NaOH; (*e*) $AgNO_3$; (*g*) HX; (*g*) 160° *in vacuo*.

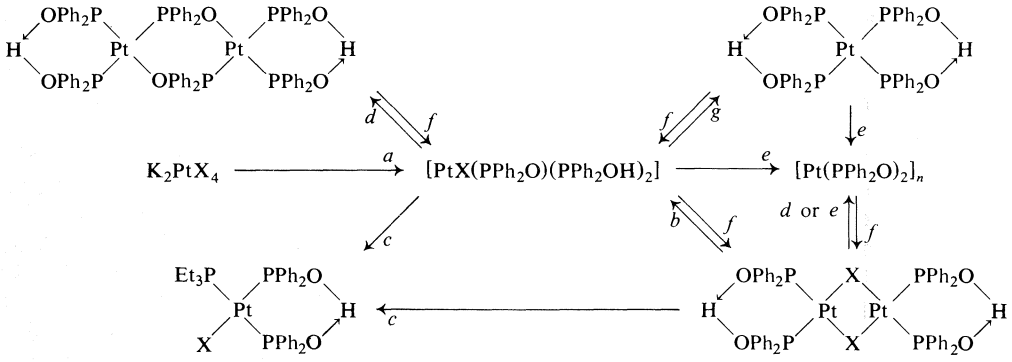

FIG. 2. Reactions of platinum complexes (X = Cl or Br, Ph = phenyl, and Et = ethyl). Reagents: (*a*) Ph_2HPO (3 mol) or Ph_3ClP (3 mol) in water; (*b*) Ph_2HPO (1 mol); (*c*) Et_3P (1 mol); (*d*) NaOH; (*e*) AgNO; (*f*) HX; (*g*) $Ag[PPh_2O]$ (1 mol).

Palladium Complexes

Diphenylphosphine oxide reacts with tetrachloropalladite(II) with elimination of hydrogen chloride according to the equation

$$2PdCl_4^{2-} + 4Ph_2HPO \rightarrow Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2 + 2HCl + 4Cl^-$$

This reaction probably proceeds via an intermediate $[PdCl_2(PPh_2OH)_2]$ complex and the reaction is thus formally similar to the reactions of tetrachloropalladite(II) with diphenylphosphine to give $[Pd_2Cl_2(PPh_2)_2(PPh_2H)_2]$ (8) and of $[PtCl_2(PPh_2OH)(PEt_3)]$ with sodium methoxide to give $[Pt_2Cl_2(PPh_2O)_2(PEt_3)_2]$ (2). However, our product is probably chloride bridged (see below) whereas the others are bridged by diphenylphosphino and diphenylphosphinato groups, respectively.

$[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ is also obtained by reaction of chlorodiphenylphosphine with tetrachloropalladite in aqueous acetone. Hydrolysis of the chlorophosphine to hydroxydiphenylphosphine may occur either before or after coordination to the metal but the reaction is otherwise similar to that of diphenylphosphine oxide.

Elimination of further hydrogen chloride from $[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ is achieved by reaction with sodium hydroxide or silver nitrate. In both cases the product is an insoluble material of empirical composition, $Pd(PPh_2O)_2$, which we believe to be a phosphinato bridged polymer (see below). Preparations of this complex are sometimes contaminated by halide but identical products are obtained from several different starting compounds (see Fig. 1), including both chloro and bromo complexes, and this leaves little doubt that the formulation is correct.

The other typical reaction of $[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$, bridge cleavage by phosphine ligands, is discussed in more detail below.

Platinum Complexes

In contrast to the palladium complexes, tetrachloroplatinite(II) reacts with diphenylphosphine oxide according to the equation

$$PtCl_4^{2-} + 3Ph_2HPO \rightarrow [PtCl(PPh_2O)(PPh_2OH)_2] + HCl + 2Cl^-$$

This is the main reaction even when only 2 mol of diphenylphosphine oxide are added. This difference may be attributed to a greater stability of the chloride bridge system in palladium complexes or to a greater affinity of platinum for phosphorus ligands leading to easier cleavage of the bridges. If the chloride bridge is regarded as a relatively "hard" ligand then both factors are expected to favor the halide bridge system for palladium since this metal has more class (*a*) character (*i.e.* is "harder") (9, 10) than platinum and it is also known, for example, that $[Pd_2Br_4(SMe_2)_2]$ is bridged by bromide whereas a corresponding platinum complex, $[Pt_2Br_4(SEt_2)_2]$ has sulfur bridges (11). Various evidence from our present work supports this view. Thus the reaction

$$[M_2Cl_2(PPh_2O)_2(PPh_2OH)_2] + 2L \rightarrow [MCl(PPh_2O)(PPh_2OH)(L)]$$

proceeds easily in acetone at 25° for L = triethylphosphine or diphenylphosphine oxide for both M = Pd and Pt but for L = triphenylphosphine, reaction only occurs when M = Pt.[1] Moreover the reaction for L = diphenylphosphine oxide and M = Pd is very slow and reverses easily on recrystallization of the product, a difficulty which is responsible for the low figure obtained for the carbon analysis of $[PdCl(PPh_2O)(PPh_2OH)_2]$. Also the reaction for L = triethylphosphine and M = Pd reverses easily *in vacuo* at 160° whereas $[PtCl(PPh_2O)(PPh_2OH)(PEt_3)]$ is stable at this temperature and gives only general decomposition at higher temperatures.

The preference of palladium for a chloride bridge system is further illustrated by the following reaction

$$[Pd_2Cl_4(PEt_3)_2] + 2Ph_2HPO \rightarrow \tfrac{1}{2}[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2] + [PdCl_2(PEt_3)_2] + HCl$$

Chatt and Heaton found that $[Pt_2Cl_4(PEt_3)_2]$ under similar conditions gave only $[PtCl_2(PPh_2OH)(PEt_3)]$ (2).

Since it is known (12) that the strength of the halogens as bridging ligands increases in the order Cl < Br < I we also investigated the reaction of tetraiodoplatinite(II) with diphenylphosphine oxide. However, even in this case, the product is $[PtI(PPh_2O)(PPh_2OH)_2]$ and not the iodide bridged, $[Pt_2I_2(PPh_2O)_2(PPh_2OH)_2]$, although we do find that the former complex reacts easily with HI to give the latter complex in high yield.[2] This is in contrast to the analogous chloro complexes where the conversion is difficult and incomplete.

The other reactions shown in Fig. 2 are similar to those of palladium complexes discussed above or require little further comment except to note that the reactions of $[PtCl(PPh_2O)(PPh_2OH)_2]$ with sodium hydroxide and $Ag[PPh_2O]$ give the new complexes $[Pt_2(PPh_2O)_4(PPh_2OH)_2]$ and $[Pt(PPh_2O)_2(PPh_2OH)_2]$, respectively. We were unable to prepare the palladium analogues since the corresponding reactions give only $[Pd(PPh_2O)_2]_n$. This is in line with the reaction of potassium tetrachloroplatinite(II) with triethylphosphite to give $[Pt\{P(OEt)_2O\}_2\{P(OEt)_2OH\}_2]$ (5) whereas tetrachloropalladite(II) gives $[Pd_2Cl_2\{P(OEt)_2O\}_2\{P(OEt)_2OH\}_2]$ and $[Pd\{P(OEt)_2O\}_2]$ (4). Moreover although Pidcock and Waterhouse (6) obtained $[Pd\{P(OPh)_2O\}_2\{P(OPh)_2OH\}_2]$ on one occasion, they were unable to repeat their preparation.

Structures

The corresponding platinum and palladium complexes have essentially identical infrared spectra and their structures are therefore considered together in the following discussion.

The complexes are characterized by elemental analysis and molecular weight measurements and by the interconversion reactions shown in Figs. 1 and 2. They are non-electrolytes in nitromethane or have small molar conductances (10–20 ohm^{-1}

[1]This reaction required only a few minutes at 25°. The product was not fully characterized but had molecular weight 862 (required for $[PtCl(PPh_2O)(PPh_2OH)(PPh_3)]$ is 896) and ν(P—O) at 1015 cm^{-1}. $[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ did not react with triphenylphosphine in 18 h at 25°.

[2]These iodo complexes were not fully characterized but had infrared spectra identical to those of their bromo analogues.

TABLE 1. Characteristic infrared absorption frequencies (cm^{-1})

Complex	ν(P—O)*	ν(M—Cl)†	Other frequencies‡
$[Pd(PPh_2O)_2]_n$	1020, 1030	—	—
$[Pt(PPh_2O)_2]_n$	990, 1010	—	—

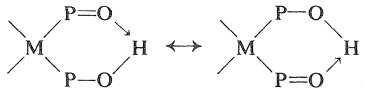
$[PdBr(PPh_2O)(PPh_2OH)(PEt_3)]$	1010	—	1300–1400, 820
$[PtCl(PPh_2O)(PPh_2OH)(PEt_3)]$	1010	280	1300–1400, 800
$[PtBr(PPh_2O)(PPh_2OH)(PEt_3)]$	1010	—	1300–1400, 810

*Except for those designated medium (m) these absorptions were all strong or very strong.
†All very weak absorptions. ν(M—Br) < 250 cm^{-1}.
‡Very broad, ill-defined absorptions, see Discussion.

cm^2) which may be attributed to slight ionization of the POH groups (a typical (13) molar conductance for a 1:1 electrolyte in nitromethane is 97 ohm^{-1} cm^2). Generally the complexes are rather insoluble for nuclear magnetic resonance spectroscopy and this, together with the fact that the resonances are likely to be broadened by exchange (6), accounts for our failure to observe any resonances attributable to the hydroxylic protons.

The infrared spectra of the complexes are all generally similar and show the expected ligand absorptions. Other absorptions are shown in Table 1. The M—Cl stretching modes are assigned by comparison with spectra of the corresponding bromides but they were all very weak bands and, since ligand absorption also occurs in this region, the assignments must be approached with caution. In particular it is not possible to use them to distinguish terminal and bridging chlorines in the dinuclear complexes, since ν(M—Cl) for a chlorine *trans* to a ligand of high *trans* influence often absorbs at as low a frequency as a bridge chlorine and also from our spectra we could not distinguish with certainty between the two bands expected for a bridge system, MCl_2M, and the single band expected for a *trans* arrangement of terminal chlorines. All of the complexes have at least two very intense bands in the P—O stretching region (*ca.* 900–1100 cm^{-1} (2)). One of these, at 1100 cm^{-1}, is almost constant in frequency and corresponds to a less intense band normally observed in the spectra of phenylphosphine complexes. It is therefore assigned to a ligand absorption and the other intense bands in this region are assigned as P—O stretching in Table 1.

The complexes, $[M_2X_2(PPh_2O)_2(PPh_2OH)_2]$, $[MX(PPh_2O)(PPh_2OH)(PEt_3)]$, $[Pt(PPh_2O)_2(PPh_2O)_2]$, and $[Pt_2(PPh_2O)_4(PPh_2OH)_2]$ all show broad absorption in the 1200–1600 cm^{-1} (weak, width at half-height ~250 cm^{-1}) and 700–800 cm^{-1} (medium, width at half-height ~100 cm^{-1}) regions. There are many other absorptions in these regions and those in question, particularly the higher frequency ones, are evident only as a general rise in baseline and loss of resolution. However, the effect is quite unambiguous and is restricted to those complexes where there is a possibility of a *cis* arrangement of one diphenylphosphinato and one hydroxydiphenylphosphine ligand. We therefore consider it to be characteristic of a symmetrical hydrogen bonded system of the type



Evidence for strong hydrogen bonding involving POH groups has been obtained previously from the infrared spectra of organophosphorus acids (14) and a model of our system shows the O—O distance to be only 1.8 Å for a planar ring. Moreover the bond angles are such that the hydrogen atom could lie almost exactly on the O—O axis. Comparison of this distance with the 2.53 Å observed for the hydrogen bonds in orthophosphoric acid (15) shows that the ring is unlikely

For personal use only.

to be planar but it does emphasize the possibility of unusually strong hydrogen bonding. If the system were not symmetrical or the ligands were not *cis* then infrared absorptions would be expected (2) for ν(P—OH) at ~880 cm^{-1}, ν(P=O) at ~1100 cm^{-1}, and ν(PO—H) at ~3200 cm^{-1} whereas the above complexes show only a single P—O stretching absorption in the range 970–1040 cm^{-1}. This is therefore consistent with a ring structure with P—O bonds intermediate between single and double bonds. Double bond character in the P—O bond of a hydrogen bonded POH group has been observed previously (15).

The absence of any infrared absorption assignable to O—H stretching is also consistent with the hydrogen bonded structure since broadening would be expected to make the absorption very difficult to observe. In agreement with this, Pidcock and Waterhouse (6) found no direct infrared evidence for the POH group in their phosphite complexes. The broad bands at 1200–1600 and 700–800 cm^{-1} in our spectra may be associated with the O—H—O system and a ring mode, respectively, but no definite assignments can be made.

On the above basis we therefore propose the structures shown in the Figs. 1 and 2 for these complexes. The $[M_2X_2(PPh_2O)_2(PPh_2OH)_2]$ complexes are consequently halide bridged in contrast to the phosphinato bridged, $[Pt_2X_2(PPh_2O)_2(PEt_3)_2]$ complexes prepared by Chatt and Heaton (2). However, the single line ^{31}P magnetic resonance spectrum of $[Pd_2Cl_2\{P(OPh)_2O\}_2\{P(OPh)_2OH\}_2]$ has been interpreted as implying a chloride bridged structure similar to our complexes (6) and we also consider that the complexes, $[Pd_2Cl_2\{P(OR)_2O\}_2\{P(OR)_2OH\}_2]$ (4), are likely to be chloride bridged and not phosphinato bridged as proposed by Chatt and Heaton (2). If the hydrogen bonded system is symmetrical then no isomers of these structures exist.

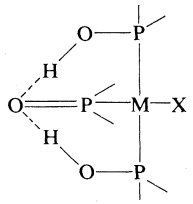
The $[MX(PPh_2O)(PPh_2OH)(PEt_3)]$ complexes have a *cis* arrangement of halide and triethylphosphine groups and again no isomers exist for a symmetrical hydrogen bond although in this case it is likely that the different *trans* influences of halide and triethylphosphine may cause an asymmetry in the hydrogen bond. There is evidence for such an asymmetry in the ^{31}P nuclear magnetic resonance spectrum of $[PtCl\{P(OMe)_2O\}\{P(OMe)_2OH\}(AsEt_3)]$ (6).

Similarly for $[Pt_2(PPh_2O)_4(PPh_2OH)_2]$, asymmetry may be induced by the different *trans* influences of oxygen and phosphorus in the phosphinato bridge. This complex is expected to show two P—O stretches assignable to the bridging and terminal systems. However, we note that ν(P—O) for the diphenylphosphinato bridge is expected at about 970 cm^{-1}. Moreover, in the series $[Pt_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$, $[PtCl(PPh_2O)(PPh_2OH)(PEt_3)]$, $[Pt(PPh_2O)_2(PPh_2OH)_2]$, the ν(P—O) frequencies for the hydrogen bonded system are 1035, 1010, and 990 cm^{-1}, respectively. They therefore fall in order of increasing *trans* influence of the ligands *trans* to the hydrogen bonded system and since the diphenylphosphinato bridge has a very high *trans* influence (2) we may expect ν(P—O) for the hydrogen bonded system in $[Pt_2(PPh_2O)_4(PPh_2OH)_2]$ below 990 cm^{-1} and we consider that it is therefore not resolved from the phosphinato bridge frequency at 970 cm^{-1}.

The above *trans* influence series is also interesting as a measure of electronic effects in these molecules. The *trans* influence of phosphine ligands is due largely to σ effects (16). Thus in an $LPtP(R_2)=O$ system, a ligand, L, of high *trans* influence may be considered as weakening the Pt—P bond by electron repulsion (2) leading to a greater contribution from the structure, $LPt^+---P(R_2)—O^-$, with consequent weakening of the P—O bond.

The $[M(PPh_2O)_2]_n$ complexes have two broad absorptions *ca.* 1000 cm^{-1} which are assigned to P—O stretching modes in a diphenylphosphinato bridged polymer. The two different frequencies may be due to phosphinato groups *trans* to P or O in an irregular polymer and they are similar to the frequencies (992 and 1002 cm^{-1}) observed (2) for the diphenylphosphinato bridges in the isomers of $[Pt_2(OH)_2(PPh_2O)_2(PEt_3)_2]$.

The $[MX(PPh_2O)(PPh_2OH)_2]$ complexes do not show the typical infrared absorptions of the hydrogen bonded ring but a broad band at 2280 cm^{-1} is assigned to a hydrogen bonded OH by a deuteration experiment which shifts the frequency to 1710 cm^{-1}. Also, although there are three P—O stretches in the range 880–970 cm^{-1} which is reasonable for ν(P—O) in hydrogen bonded PO or POH groups, there is no infrared evidence for terminal PO or free POH. These results are consistent with a hydrogen bonded structure of the type



and a model shows the undistorted O—O distance to be 3.2 Å. Fairly small angular distortions could reduce this distance to a value compatible with a hydrogen bond. Although this seems the most likely structure the complexes were not sufficiently soluble for solution infrared and molecular weight studies to exclude the possibility of intermolecular hydrogen bonding.

Experimental

Chlorodiphenylphosphine was used as received from Alfa Inorganics Ltd. Diphenylphosphine oxide (2), $Ag[PPh_2O]$ (3), and $[Pd_2Cl_4(PEt_3)_2]$ (17) were prepared as previously described. Solutions of K_2MX_4 (X = Cl or Br, M = Pt or Pd) were prepared by dissolving $PdCl_2$ or K_2PtCl_4 in water containing a ten-fold excess of NaX.

Data relating to the characterization of the complexes are given in Table 2. Microanalyses were by Schwartzkopf Microanalytical Laboratory, New York. Molecular weights were determined in methylene dibromide solution at 50° using a Hitachi – Perkin Elmer Model 115 Vapor Phase Osmometer. Infrared spectra (Table 1) were recorded from 4000–250 cm^{-1} with accuracy ± 3 cm^{-1} on a Beckman IR 20 Spectrophotometer calibrated against polystyrene film and water vapor. Solid samples were examined as Nujol mulls between caesium iodide plates.

All reactions of phosphines or phosphine oxides were carried out in an atmosphere of dry nitrogen but the product complexes were stable in air. $[M(PPh_2O)_2]_n$, where M = Pt or Pd, $[PtX(PPh_2O)(PPh_2OH)_2]$, where X = Cl or Br, and $[Pt_2(PPh_2O)_4(PPh_2OH)_2]$ were too insoluble in common organic solvents for recrystallization but the other complexes were recrystallized by solution in methylene dichloride followed by addition of ethanol. The methylene dichloride was then allowed to slowly evaporate at 25° until crystals formed. Attempts to recrystallize from hot solvents generally resulted in decomposition or interconversion of complexes.

The preparations of chloro-complexes are described below. In all cases their bromo-analogues were similarly prepared in similar yield.

1. $[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$

Chlorodiphenylphosphine (0.46 ml, 3.0 mmol) was added to a solution of K_2PdCl_4 (0.50 g, 1.5 mmol) in acetone (25 ml) and water (10 ml). After stirring for 5 min at 25°, filtration gave *the complex* (0.80 g, 0.73 mmol) as a yellow powder which was washed with ethanol and water and recrystallized.

A similar procedure using diphenylphosphine oxide (0.58 g, 2.9 mmol), K_2PdCl_4 (0.47 g, 1.4 mmol) in ethanol (25 ml) and water (5 ml) gave *the complex* (0.72 g, 0.66 mmol). Titration of the filtrate with 0.1 *M* NaOH solution indicated that 1.4 mmol of acid was formed during the reaction.

2. $[PdCl(PPh_2O)(PPh_2OH)_2]$

Diphenylphosphine oxide (0.61 g, 3.0 mmol) was added to a suspension of $[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ (1.63 g, 1.5 mmol) in acetone (50 ml). After stirring for 18 h at 25° the mixture was evaporated to 20 ml under reduced pressure and filtration gave *the complex* (2.20 g, 2.95 mmol) as a white powder which was washed with ethanol and recrystallized.

3. $[Pd(PPh_2O)_2]_n$

Sodium hydroxide (10.1 ml of 0.1 *M* aqueous solution, 1.01 mmol) was added to a solution of $[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ (0.55 g, 0.50 mmol) in acetone (200 ml). After stirring for 1 h under reflux, filtration gave *the complex* as a pale yellow powder (0.51 g, 1.0 mmol) which was washed with water. Addition of aqueous silver nitrate solution to the filtrate gave AgCl (0.12 g, 0.84 mmol).

Reaction of sodium hydroxide with $[Pd_2Br_2(PPh_2O)_2(PPh_2OH)_2]$ gave an identical product.

4. $[PdCl(PPh_2O)(PPh_2OH)(PEt_3)]$

Triethylphosphine (0.15 ml, 1.0 mmol) was added to a suspension of $[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ (0.50 g, 0.46 mmol) in acetone (50 ml). After stirring for 30 min at 25° the resulting solution was evaporated under reduced pressure. Diethyl ether was twice added and evaporated with final drying at 50° *in vacuo* to give *the complex* (0.57 g, 0.86 mmol) as white crystals which were washed with diethyl ether and recrystallized.

5. Reaction of $[Pd_2Cl_4(PEt_3)_2]$ with Diphenylphosphine Oxide

A suspension of $[Pd_2Cl_4(PEt_3)_2]$, (0.25 g, 0.42 mmol) in sodium dried benzene (30 ml) was stirred with diphenylphosphine oxide (0.17 g, 0.84 mmol) at 25° for 18 h. Evaporation of the benzene under reduced pressure followed by extraction of the residue with diethyl ether left $[Pd_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ (0.23 g, 0.21 mmol) as a yellow residue. Evaporation of the ether extract gave *trans*-$[PdCl_2(PEt_3)_2]$ (0.17 g, 0.41 mmol) which was identified by infrared spectroscopy (18). In a separate but identical reaction the benzene solution was extracted with water and titration of the extract with 0.1 *M* NaOH solution showed that 0.41 mmol of acid was present.

6. $[PtCl(PPh_2O)(PPh_2OH)_2]$

Chlorodiphenylphosphine (1.15 ml, 7.5 mmol) was added dropwise over a 2 h period to a solution of K_2PtCl_4 (1.05 g, 2.5 mmol) in water (75 ml) and acetone (25 ml). After stirring for a further 18 h at 25° *the complex* (1.86 g, 2.5 mmol) was filtered off and washed with water, ethanol, and methylene dichloride. Some preparations were contaminated by a yellow product which was soluble in methylene dichloride and could be converted to *the complex* by boiling in methylene dichloride containing a few drops of water. This product is still under investigation.

A similar procedure using diphenylphosphine oxide (1.54 g, 7.6 mmol) in ethanol (10 ml) and K_2PtCl_4 (1.05 g, 2.5 mmol) in ethanol (30 ml) and water (20 ml) gave *the complex* (1.90 g, 2.5 mmol) after 18 h at 25°.

7. [$Pt_2Cl_2(PPh_2O)_2(PPh_2OH)_2$]

HCl (3 ml of concentrated aqueous solution) was added dropwise to a suspension of $[Pt(PPh_2O)_2]_n$ (0.23 g, 0.38 mmol) in acetone (25 ml). After stirring at 40° for 3 h, water (25 ml) was added giving *the complex* (0.23 g, 0.18 mmol) as a white precipitate which was washed with water and ethanol and recrystallized.

The mixture of $[Pt(PPh_2O)_2]_n$ with AgCl which resulted from reaction of $[PtCl(PPh_2O)(PPh_2OH)_2]$ with $AgNO_3$ was also suitable for use as starting material in this reaction provided that AgCl was removed by filtration prior to addition of water. Use of this mixture was therefore the best route for preparation of $[Pt_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ from K_2PtCl_4 since the direct conversion of $[PtCl(PPh_2O)(PPh_2OH)_2]$ to $[Pt_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ (see 12(*b*) below) gave poor yields.

8. [$Pt(PPh_2O)_2]_n$

NaOH (3.0 ml of 0.1 *M* aqueous solution, 0.3 mmol) was added to a solution of $[Pt_2Cl_2(PPh_2O)_2(PPh_2OH)_2]$ (0.35 g, 0.28 mmol) in acetone (50 ml). After stirring for 3 h at 50°, filtration gave *the complex* (0.33 g, 0.55 mmol) as a white precipitate which was washed with water and ethanol. Addition of aqueous silver nitrate solution to the filtrate gave AgCl (0.078 g, 0.54 mmol).

An identical product was obtained from reaction of $[Pt_2Br_2(PPh_2O)_2(PPh_2OH)_2]$ with NaOH.

9. [$PtCl(PPh_2O)(PPh_2OH)(PEt_3)$]

Triethylphosphine (0.2 ml, 1.4 mmol) was added to a suspension of $[PtCl(PPh_2O)(PPh_2OH)_2]$ (1.02 g, 1.2 mmol) in acetone (40 ml). After stirring for 2 h at 25° the resulting solution was evaporated *in vacuo*. The residue was washed with ethanol leaving *the complex* (0.74 g, 0.98 mmol) as a white powder which was recrystallized.

10. [$Pt_2(PPh_2O)_4(PPh_2OH)_2$]

NaOH (17.5 ml of 0.1 *M* aqueous solution, 1.75 mmol) was added to a suspension of $[PtCl(PPh_2O)(PPh_2OH)_2]$ (0.90 g, 1.1 mmol) in acetone (100 ml). The resulting solution was basic to litmus and evaporation under reduced pressure to 10 ml gave *the complex* (0.87 g, 0.54 mmol) as a white precipitate. Addition of aqueous $AgNO_3$ solution to the filtrate gave AgCl (0.152 g, 1.06 mmol).

An identical product was obtained from reaction of $[PtBr(PPh_2O)(PPh_2OH)_2]$ with NaOH.

11. [$Pt(PPh_2O)_2(PPh_2OH)_2$]

$Ag[PPh_2O]$ (0.185 g, 0.60 mmol) was added to a suspension of $[PtCl(PPh_2O)(PPh_2OH)_2]$ (0.50 g, 0.60 mmol) in chloroform (100 ml). After stirring for 18 h at 25° in the dark, AgCl and unreacted starting materials were removed by filtration and the resulting solution evaporated to 10 ml under reduced pressure to give *the complex* (0.32 g, 0.32 mmol) as white crystals which were washed with acetone and recrystallized.

An identical product was obtained from reaction of $[PtBr(PPh_2O)(PPh_2OH)_2]$ with $Ag[PPh_2O]$ in methylene dibromide.

12. Other Interconversion Reactions (see Figs. 1 and 2)

With the single exception noted below, the various interconversion reactions proceeded in very high yield (80–90%).

(*a*) Conversions involving $AgNO_3$ were by dropwise addition of a small excess of aqueous $AgNO_3$ solution to a suspension or solution of the reactant complex in acetone. After stirring for 3 h at 25° the product $[M(PPh_2O)_2]_n$ complexes were obtained as precipitates mixed with silver halide. The filtrates were acid to litmus. The reactions with $[PtX(PPh_2O)(PPh_2OH)_2]$ required 20 min under reflux followed by stirring for 3 h.

(*b*) Conversions involving hydrohalic acids were by dropwise addition of excess (*cf.* expt. 7 above) concentrated aqueous acid to a suspension or solution of the reactant complex in acetone. After stirring for 3 h at 25°, addition of water precipitated the products. The reactions with $[PtX(PPh_2O)(PPh_2OH)_2]$ required a large excess of concentrated acid with heating at 50° and reaction was often incomplete making this method unsuitable for the preparation of $[Pt_2X_2(PPh_2O)_2(PPh_2OH)_2]$ complexes.

(*c*) Conversions involving sodium hydroxide were similar to reaction 3 above.

(*d*) Conversions involving triethylphosphine were similar to reactions 4 and 9 above.

(*e*) The reactions of $[PdX(PPh_2O)(PPh_2OH)_2]$ complexes with $Ag[PPh_2O]$ were similar to 12(*a*) above.

Electron Spin Resonance Studies of Reactions of Photo-generated Organic Radicals with Hydrogen Peroxide in Aqueous Solution

C. E. Burchill and P. W. Jones

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2

Received July 30, 1971

The reactions with H_2O_2 of free radicals derived from 2-propanol, methanol, dimethoxymethane, and tetrahydrofuran have been investigated by e.s.r. using in-cavity photolysis with acetone photosensitization to generate the radicals in flowing aqueous solutions. The variation in the concentrations of the radicals derived from a particular solute with addition of H_2O_2 is attributed to the selective oxidation of one radical by H_2O_2, propagating a secondary chain reaction, *e.g.*,

$$(CH_3)_2\dot{C}OH + H_2O_2 \rightarrow (CH_3)_2CO + H_2O + \dot{O}H$$
$$\dot{O}H + (CH_3)_2CHOH \rightarrow H_2O + (CH_3)_2\dot{C}OH$$
$$\dot{O}H + (CH_3)_2CHOH \rightarrow H_2O + \dot{C}H_2(CH_3)CHOH$$
$$\dot{C}H_2(CH_3)CHOH + H_2O_2 \not\rightarrow$$

The rate constant for the oxidation of the acetone ketyl radical ($(CH_3)_2\dot{C}OH$) by H_2O_2 is estimated to be $5 \times 10^5\ M^{-1}\ s^{-1}$.

The results and conclusions of this study are demonstrated to be consistent with the results of previous investigations employing γ-radiation, photolysis, and the reaction of Ti(III) with H_2O_2 for initiation.

Results are also reported for the direct photolysis of aqueous malonic acid in the presence of H_2O_2.

Les réactions en solution aqueuse de l'eau oxygénée sur les radicaux libres dérivés du propanol-2, méthanol, diméthoxyméthane, et du THF ont été étudiées par r.p.e., en utilisant la photolyse "interne" pour produire les radicaux avec l'acétone comme photosensibilisateur.

La variation dans les concentrations des radicaux issus d'un soluté particulier après addition d'eau oxygénée, est attribuée à l'oxydation sélective d'un radical par H_2O_2, donnant ainsi naissance à une réaction en chaîne secondaire, par exemple:

$$(CH_3)_2\dot{C}OH + H_2O_2 \rightarrow CH_3)_2CO + H_2O + \dot{O}H$$
$$\dot{O}H + (CH_3)_2CHOH \rightarrow H_2O + (CH_3)_2\dot{C}OH$$
$$\dot{O}H + (CH_3)_2CHOH \rightarrow H_2O + \dot{C}H_2(CH_3)CHOH$$
$$\dot{C}H_2(CH_3)CHOH + H_2O_2 \not\rightarrow$$

La vitesse d'oxydation par l'eau oxygénée du radical acétone cétyle ($(CH_3)_2\dot{C}OH$) est évaluée à $k = 5 \times 10^5\ M^{-1}\ s^{-1}$.

Les résultats et les conclusions de cette étude sont en accord avec d'autres précédemment obtenus par irradiation γ, photolyse et par réaction du Ti(III) sur H_2O_2 dans l'étape d'initiation.

Les résultats de la photolyse de l'acide malonique en solution aqueuse en présence d'eau oxygénée sont également mentionnés.

Canadian Journal of Chemistry, 49, 4005 (1971)

A number of techniques have been developed for the generation of free radicals directly in the cavity of an e.s.r. spectrometer, and their study under steady state conditions. These techniques include irradiation with high intensity u.v. light or a d.c. beam of high energy electrons, but the most widely employed has been the reaction of a reducing metal ion (particularly Ti(III)) with H_2O_2 to produce secondary radicals from organic substrates via hydrogen abstraction by the resulting OH radicals. All of these methods have been used to generate free radicals from organic substrates in aqueous solutions and the identity and spectral parameters of a large number of such radicals have been established. In most instances the identities of the radicals generated from a particular substrate under oxidizing conditions are independent of the mode of initiation, but the ratios of the concentrations of the radicals (when more than one is formed from a particular substrate) show significant variations.

To cite a particular example of this variability,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the reaction of OH radicals with 2-propanol produces both $(CH_3)_2\dot{C}OH$ (**1**) and $\dot{C}H_2(CH_3)$-CHOH (**2**), and the ratio of their rates of formation has been estimated to be 5.2 (1, 2).[1] Using electron beam irradiation of an aqueous solution of 2-propanol saturated with N_2O, Eiben and Fessenden (3) observed only the spectrum of **1** but indicated that the spectrum of **2**, if present at one-sixth the concentration of **1**, would have been masked by the noise band. Using direct photolysis of H_2O_2 to generate free radicals from 2-propanol Livingston and Zeldes (4) observed only the spectrum of **1** when the solvent was the neat alcohol but, with addition of water, the spectrum of **2** was observed and its concentration increased with increasing water content. In the Ti(III) initiated reaction of 2-propanol with H_2O_2 (5, 6) both **1** and **2** were observed, but the ratio of [**1**] to [**2**] was always less than the value of 5.2 found by Burchill and Thompson (2) for the primary ratio of abstraction by OH from 2-propanol. The ratio of [**1**] to [**2**] was found to increase as the initial concentration of Ti(III) was increased (6), but to decrease as the initial concentration of H_2O_2 was increased (5). Moreover this ratio was a function of the elapsed time between mixing and observation, decreasing with increasing reaction time (6).

It was proposed by Norman and West (5) that, for the Ti(III) initiated reaction, the sensitivity to initial conditions of the relative radical concentrations could be explained by a difference in their reactivity toward H_2O_2 (that radical **1** was selectively oxidized) in propagating a secondary chain reaction. James and Sicilio (6) purported to have refuted this suggestion by a study of the kinetics of the reactions of the radicals with H_2O_2. However both the qualitative arguments of Norman and West (5) and the kinetic analysis by James and Sicilio (6) include the common error of assuming that the radicals observed in the e.s.r. cavity are those generated immediately after mixing and surviving to reach the cavity (*i.e.*, that the reaction of Ti(III) with H_2O_2 is instantaneous on the time scale of the experiments). Burchill (7) has pointed out that this is not a valid assumption and that the observed time dependence of the radicals from 2-propanol could be explained by assuming a secular equilibrium within the cavity, with the ratio of [**1**] to [**2**] modified by a secondary chain reaction involving **1** and H_2O_2. It has been argued that this explanation is impossible (8) but Czapski (9) has independently offered a similar explanation of the results and, in an experimental study (10), has demonstrated that the dependence of the total radical concentrations on the initial concentrations of Ti(III) and H_2O_2 is consistent with the reaction of Ti(III) with H_2O_2 being rate controlling, and the radical concentrations being the steady state values maintained by initiation *within the cavity* and bimolecular termination of the radicals. It has also been demonstrated by Czapski (9) that the ratio of [**1**] to [**2**] could be affected, in the manner observed, by a secondary chain reaction.

The experiments reported in this paper were undertaken in an attempt to examine more directly the reactions with H_2O_2 of the radicals derived from 2-propanol and other organic substrates. It was hoped to find a basis for reconciling a number of seemingly discordant results from previous studies which used a variety of modes and rates of initiation. The method employed for generation of the radicals was high intensity photolysis in the e.s.r. cavity, with photosensitization by acetone in a manner similar to that described by Zeldes and Livingston (11). A somewhat similar study, employing biacetyl and pyruvic acid as photosensitizers, has been reported by Ayscough and Brice (12). Acetone photosensitization has recently been used in flash photolysis studies of amides in aqueous solution (13).

Experimental

The e.s.r. spectrometer used was a conventional X-band instrument (Varian E-3) operating at approximately 9.2 GHz, with 100 kHz field modulation. The resonant cavity was a Varian multi-purpose unit fitted with a slotted end plate to admit light. The light source was a medium pressure mercury arc (the inner envelope from a Westinghouse H33-1-HD 400 W street-lighting lamp). The light was focused on the cavity by a 9-in. hemispherical aluminum mirror and a single quartz condensing lens. The solutions were flowed through a flat silica cell of 0.5 mm internal depth in the light path and approximately 9 mm width. The flow rate was normally 0.5–1.0 ml/min. Control experiments demonstrated that the effects observed were independent of the flow rate over a wide range. All solutions were deoxygenated by purging

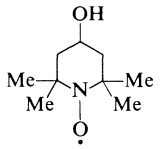
[1]A recently published report of a study of the oxidation of alcohols by Fenton's reagent (29) draws essentially the same quantitative conclusions as refs. 1, 2, and 22 concerning the ratio of α and β abstraction from alcohols by OH and the effects of deuterium substitution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with oxygen-free nitrogen. The temperature of the solutions leaving the cell was approximately 30 °C.

Hydrogen peroxide (30%, unstabilized), acetone, 2-propanol, methanol, dimethoxymethane, tetrahydrofuran, and malonic acid were Fisher Certified Reagent grade and were used as received. In initial experiments the water used in preparing solutions was redistilled once from alkaline permanganate and once from acid dichromate. The results were then compared with those obtained using water redistilled once from a Barnstead still and, as no differences were observed, this latter source was used in all subsequent experiments.

The relative concentrations of alcohol-derived radicals produced simultaneously, and whose spectra were recorded in the same scan, were estimated by graphical double integration of their first-derivative spectra. It was established that, for a particular radical and a given modulation amplitude, there was a constant ratio of derivative peak amplitude to total intensity, and routine calculations of the ratios of radical concentrations were made using peak amplitudes. Absolute concentrations of the radicals were estimated by comparison with the double integral of spectra from aqueous solutions of the stable nitroxide, prepared by the method of Briere *et al.*



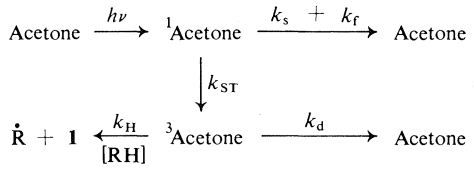
(14), and purified by repeated vacuum sublimation. Aside from the usual difficulties attending attempts at absolute concentration calibrations in e.s.r., we feel that the concentrations estimated for the photo-generated radicals must be regarded as lower limits. The standard was a homogeneous solution, completely filling the reaction cell, whereas the light source probably did not illuminate the cell uniformly. Consequently a particular *number* of spins, characterized by a particular signal intensity, might represent a higher effective *concentration* in the illuminated portion of the cell.

Results and Discussion

(1) Acetone Photosensitized Reactions

When aqueous solutions of acetone (0.68 *M*) and another organic solute (0.4–1.0 *M*) were subjected to u.v. radiation in the cavity, the spectrum of $(CH_3)_2\dot{C}OH$ (**1**) was always observed together with (usually) that of a single radical derived from the second solute.

We have assumed that the radicals are formed by reaction of a triplet excited state of acetone with the second solute. The mechanism has been described schematically by Dalton and Turro (15) (see Scheme 1). The quantum yield for intersystem crossing, ϕ_{ST}, is known to be close to unity for acetone (16), and the triplet lifetime sufficiently



SCHEME 1

long (~10^{-5} s (17)) that the triplet may react with a good hydrogen atom donor by abstraction of H. In the absence of further secondary reactions the radicals will disappear by bimolecular reaction to yield non-radical products.

(a) 2-Propanol

With 2-propanol as substrate only the spectrum of **1** was observed. A spectrum obtained using 0.68 *M* acetone and 0.65 *M* 2-propanol is shown in Fig. 1*a*. A large modulation amplitude (1.0 G) was deliberately used to increase the signal amplitude. Under higher resolution (0.1 G modulation) the splitting due to the —OH proton and the second-order components (11) were observed (see inset Fig. 1*c*). When H_2O_2 was added, the spectrum of $\dot{C}H_2(CH_3)CHOH$ (**2**) (4–6) appeared in addition to that of **1**. As the H_2O_2 concentration was increased from zero to 0.04 *M*, the concentration of **1** decreased while that of **2** increased, but their sum remained essentially constant (see Fig. 2). Figure 1*b* shows the spectrum obtained with 0.017 *M* H_2O_2. The ratio [**2**]/[**1**] continued to increase with increasing [H_2O_2] above 0.04 *M* although the total radical concentration began to decrease. In the absence of acetone, solutions containing 0.65 *M* 2-propanol and H_2O_2 concentrations in this range did not give a useable signal. We therefore conclude that the effects of added H_2O_2 in the presence of acetone are a consequence of secondary reactions of the radicals with H_2O_2 rather than of the direct photolysis of the added H_2O_2.

The effect of varying the H_2O_2 concentration may be rationalized on the basis of the reaction scheme outlined in eqs. 1–8. We assume that, for

[1] $$^3\text{acetone} + \text{2-propanol} \rightarrow \mathbf{1} + \mathbf{1}$$

fixed concentrations of acetone and 2-propanol, the rate of reaction 1 is dependent only on the light intensity, is unaffected by the low concentrations of H_2O_2 added, and may be represented by r_i. The rate of generation of **1** will then be given by $2r_i$. It has been concluded that **1** reacts with H_2O_2 to give an OH radical which may abstract from

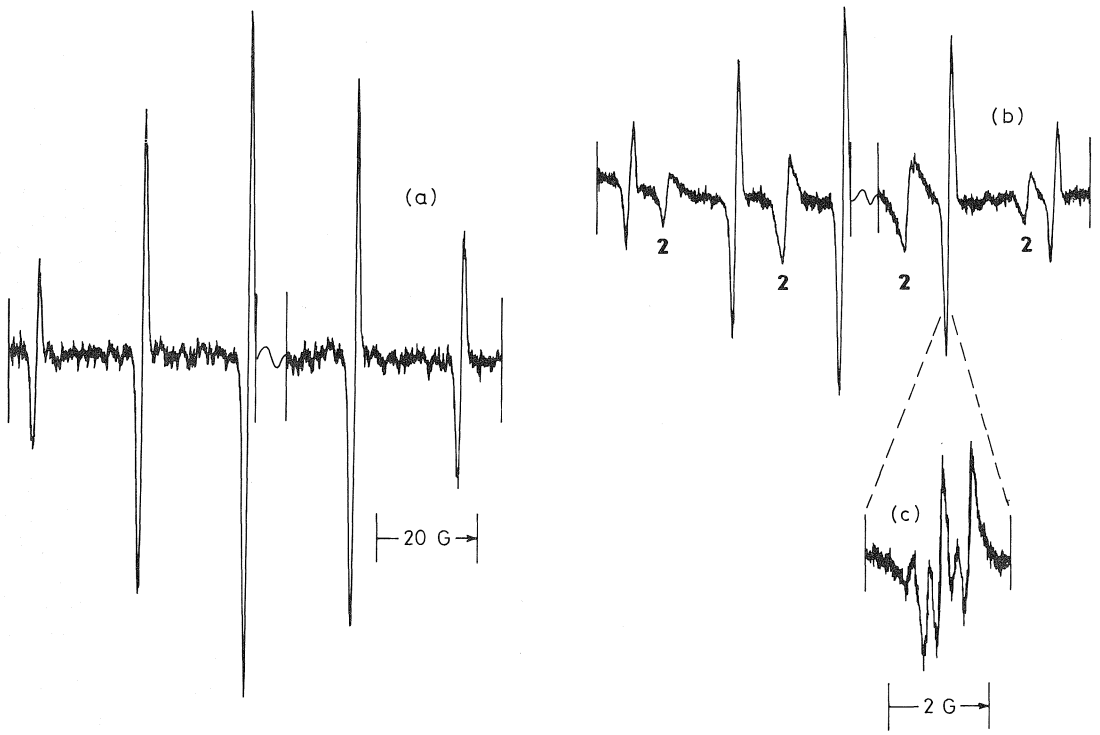

FIG. 1. The e.s.r. spectra during photolysis of aqueous solutions 0.68 *M* in acetone and 0.65 *M* in 2-propanol. The outer pair of lines in the complete spectra have been omitted. The gap in the center of each spectrum represents the region obscured by the photoinduced signal from the standard silica cell. (*a*) No H_2O_2 added. (*b*) 0.017 *M* H_2O_2 added (instrument settings the same as for (*a*)). (*c*) High resolution detail of peak above.

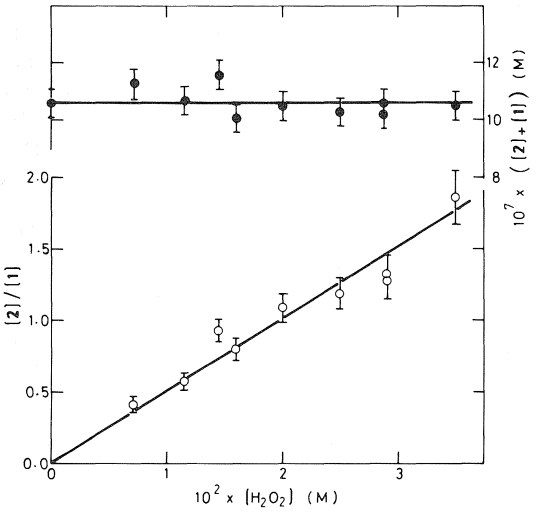

FIG. 2. Effect of added H_2O_2 on the concentrations of $(CH_3)_2\dot{C}OH$ (**1**) and $\dot{C}H_2(CH_3)CHOH$ (**2**) during photolysis of aqueous solutions 0.68 *M* in acetone and 0.65 *M* in 2-propanol.

2-propanol to give *either* **1** or **2** (reactions 2–4)

[2] $\mathbf{1} + H_2O_2 \rightarrow$ acetone $+ H_2O + \dot{O}H$

[3] $\dot{O}H$ + 2-propanol $\rightarrow H_2O + \mathbf{1}$

[4] $\dot{O}H$ + 2-propanol $\rightarrow H_2O + \mathbf{2}$

(1, 2). From the kinetics of the radiation-induced oxidation of 2-propanol by H_2O_2 it has been concluded that **2** does not react with H_2O_2 in a chain propagating reaction (1). As a consequence of the sequence of reactions 2–4 the steady state concentration of **1** would be reduced and that of **2** increased but these would not, of themselves, alter the total radical concentration since no termination is involved. In the steady state radiolysis experiments (1, 2) only one termination process was proposed (the bimolecular reaction of **2**); the assumption being that the chain length was sufficient to make [**2**] $\gg$ [**1**]. In the experiments described here, with their much greater rate of initiation and hence higher radical concentrations, the chain length would be much less. The

observed ratio [2]/[1] was, in some cases, close to unity and at least three termination processes must be considered (reactions 5–7). Reaction 8,

[5] $\mathbf{1} + \mathbf{1} \searrow$

[6] $\mathbf{1} + \mathbf{2} \longrightarrow$ non-radical products

[7] $\mathbf{2} + \mathbf{2} \nearrow$

invoked to explain the alcohol dependence of the yields in the radiation-induced oxidation of 2-propanol by H_2O_2 (1), is included in the scheme but, as demonstrated below, its rate constant is too low for this reaction to be very significant at the alcohol concentrations used in these experiments.

[8] $\mathbf{2}$ + 2-propanol → 2-propanol + $\mathbf{1}$

The rate constant for reaction 5 has been estimated as $2k_5 = 1.4 \times 10^9\ M^{-1}\ s^{-1}$ (18) and the rate constant for reaction 7 is unlikely to be significantly different since the very similar radical from *t*-butyl alcohol also has a bimolecular decay constant $2k = 1.4 \times 10^9\ M^{-1}\ s^{-1}$ (18). We have assumed that the bimolecular terminations (reactions 5-7) can be represented by a single rate constant, k_t, such that $2k_5 = k_6 = 2k_7 = k_t$. (The factor of two is not required for k_6 since this involves dissimilar radicals.) From the mechanism of eqs. 1–8, and the assumption of a steady state, eqs. 9 and 10 may be derived.

Using eq. 9, [1] + [2] = $1.06 \times 10^{-6}\ M$ (from Fig. 2), and assuming $k_t = 1.4 \times 10^9\ M^{-1}\ s^{-1}$, the calculated value of $(2r_ik_t)^{1/2}$ is $1.5 \times 10^3\ s^{-1}$. For [2-propanol] = 0.65 *M* and $k_8 = 51\ M^{-1}\ s^{-1}$ (2), k_8[2-propanol] = $33\ s^{-1}$. Thus the term involving k_8 is not significant for the conditions used and may be eliminated from eq. 10, giving eq. 11.

The proposed mechanism thus predicts that for a constant light intensity, and hence constant rate of initiation, the sum of the organic radical concentrations should be constant as the concentration of H_2O_2 is varied while the ratio of [2] to [1] should be directly proportional to [H_2O_2]. These predictions are experimentally realized as shown in Fig. 2.

[11] $$\frac{[\mathbf{2}]}{[\mathbf{1}]} = \frac{k_4k_2[H_2O_2]}{(k_3 + k_4)(2r_ik_t)^{1/2}}$$

The effect of varying light intensity, and hence r_i, was investigated by inserting a series of calibrated screens between the lamp and the e.s.r. cavity. The results are shown in Fig. 3. Equations 9 and 11 predict that the total radical concentration should vary directly with the square root of the intensity while the ratio [2]/[1] should show an inverse square root dependence.

From eq. 11, the slope of the line in Fig. 2 will be

$$\frac{k_4 \cdot k_2}{(k_3 + k_4)(2r_ik_t)^{1/2}}$$

Using the value of $(2r_ik_t)^{1/2} = 1.5 \times 10^3\ s^{-1}$ estimated above and taking $k_4/(k_3 + k_4) = 0.16$ (2), gives $k_2 = (4.8 \pm 0.3) \times 10^5\ M^{-1}\ s^{-1}$. This value may be a lower limit since, as discussed above, the concentrations estimated are probably lower limits.

The effect of H_2O_2 on solutions 0.68 *M* in acetone and 0.65 *M* in 2-propanol was also investigated in the presence of 0.1 *M* $HClO_4$. No significant difference was observed from the results in neutral solution except for the broadening of the lines for **1** as a result of proton exchange (11). A value of k_2 was estimated from the variation of [2]/[1] with [H_2O_2] and gave $k_2 = (5.1 \pm 0.5) \times 10^5\ M^{-1}\ s^{-1}$, in good agreement with the value for neutral solutions. From this we conclude that none of the rate constants involved is significantly altered in acid solution. This conclusion is also implied by the fact that the radiation-chemical yield for aqueous 2-propanol–H_2O_2 is not affected by the addition of acid (7).

To test the validity of the results and conclusions above we have checked their consequences against the experimental results from the Ti(III) initiated reaction (6) and the radiation-induced reaction (1, 2) of 2-propanol with H_2O_2.

[9] $$[\mathbf{1}] + [\mathbf{2}] = \left(\frac{2r_i}{k_t}\right)^{1/2}$$

[10] $$\frac{[\mathbf{2}]}{[\mathbf{1}]} = \frac{\frac{k_4}{k_3 + k_4} \cdot k_2[H_2O_2] + (2r_ik_t)^{1/2} + k_8[\text{2-propanol}]}{(2r_ik_t)^{1/2} + k_8[\text{2-propanol}]} - 1$$

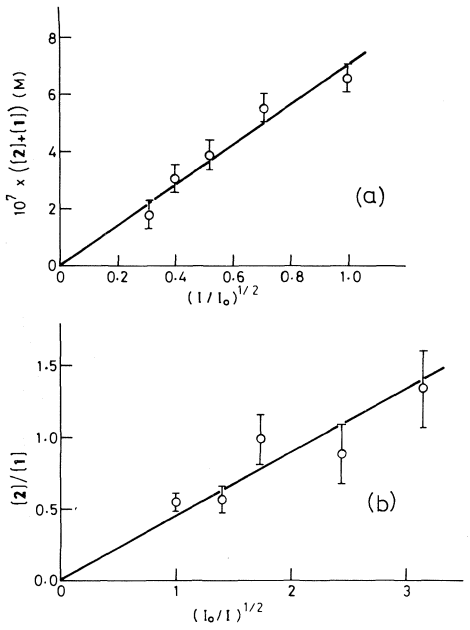

FIG. 3. Effect of varying light intensity (I) on the concentrations of $(CH_3)_2\dot{C}OH$ (**1**) and $\dot{C}H_2(CH_3)CHOH$ (**2**) during photolysis of solutions 0.68 M in acetone, 0.65 M in 2-propanol, and 0.017 M in H_2O_2. I_0 refers to the light intensity with no attenuation.

We have assumed that, in the Ti(III) system, the initiation is rate controlling and that the concentrations of the radicals observed are the steady state values maintained by the instantaneous rate of initiation *in the cavity* and bimolecular combination of the radicals (9, 10). The mechanism assumed is given by eqs. 2–7, 12. Taking k_{12} =

$$[12]\quad \text{Ti(III)} + H_2O_2 \xrightarrow{[H^+]} \text{Ti(IV)} + H_2O + OH$$

590 $M^{-1}\,s^{-1}$ for solutions in sulfuric acid,[2] $k_3/k_4 = 5.2$ (2), $k_3 + k_4 = 1.2 \times 10^9\ M^{-1}\,s^{-1}$ (19), $k_2 = 5 \times 10^5\ M^{-1}\,s^{-1}$ (above), and $k_t = 1.4 \times 10^9\ M^{-1}\,s^{-1}$, numerical integration showed that a *quasi* steady state or secular equilibrium would be reached in about 1 ms after mixing for conditions typical of those used in this type of experiment. Thus, for the mechanism and rate constants proposed, the steady state assumption would be valid for reaction times of 10 ms and greater (typical flow times between the mixer and cavity). The concentrations of the radicals derived from 2-propanol will be given by eqs. 13 and 14,

$$[13]\quad [\mathbf{1}] + [\mathbf{2}] = \left(\frac{k_{12}[\text{Ti (III)}][H_2O_2]}{k_t}\right)^{1/2}$$

$$[14]\quad \frac{[\mathbf{2}]}{[\mathbf{1}]} = \frac{k_4}{k_3}\left[k_2\left(\frac{[H_2O_2]}{k_t k_{12}[\text{Ti (III)}]}\right)^{1/2} + 1\right]$$

where [Ti(III)] and $[H_2O_2]$ refer to the concentrations of these species remaining at the time of observation. Czapski *et al.* (10) have demonstrated that the total radical concentration, observed at a fixed time after mixing, is consistent with eq. 13. We have evaluated, by numerical integration, the individual concentrations of **1** and **2** as a function of time after mixing for a solution (after mixing) 0.05 M in H_2O_2 and 0.005 M in Ti(III). Since reaction 8 was not included in the simplified mechanism the results are independent of the alcohol concentration. (Czapski *et al.* (10) experimentally observed no dependence of the ratio of [**2**] to [**1**] on the alcohol concentration up to 1.5 M.) The results of this calculation are shown in Fig. 4 and may be compared with the experimental results of James and Sicilio (Fig. 3 of ref. 6). For a system such as this, in which $[H_2O_2]_0 \gg [\text{Ti(III)}]_0$, the concentration of H_2O_2 remains roughly constant while that of Ti(III) decreases toward zero with time. As a result, the total radical concentration

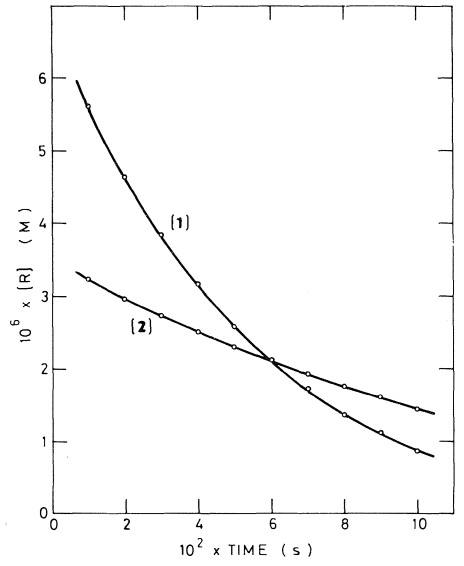

FIG. 4. Calculated time dependence of the concentrations of $(CH_3)_2\dot{C}OH$ (**1**) and $\dot{C}H_2(CH_3)CHOH$ (**2**) in the reaction of Ti(III) (5×10^{-3} M) with H_2O_2 (5×10^{-2} M) based on the mechanism and rate constants described in the text.

decreases with time but the ratio of [**2**] to [**1**] increases, becoming greater than unity at long reaction time. This crossover point would shift to shorter times with an increase in $[H_2O_2]_0$, but to longer times with an increase in $[Ti(III)]_0$, as observed by James and Sicilio (6).

To complete the comparison with the results of James and Sicilio, we have plotted the data of Fig. 4 as log [**R**] *vs.* time after mixing, as shown in Fig. 5. Although the calculated points in Fig. 5 actually define a pair of curves, we have fitted the best straight lines through them. The "first-order rate constants" so obtained were divided by the initial peroxide concentration, giving "second-order rate constants" of 357 M^{-1} s^{-1} for **1** and 189 M^{-1} s^{-1} for **2**. These may be compared with the values of 380 and 190 M^{-1} s^{-1} experimentally obtained by such a treatment of the data (Table 1 of ref. 6). Similar calculations were carried out for a variety of initial conditions and, so long as $[H_2O_2]_0 \geq 3[Ti(III)]_0$, the time dependence of the radical concentrations could be adequately represented by first order plots and the "second-order rate constants", calculated as above, were essentially independent of the absolute values of $[Ti(III)]_0$ and $[H_2O_2]_0$ (*cf.* Table 1 of ref. 6).

The only serious disagreement between the calculated results shown here and the experimental results of James and Sicilio is in the absolute magnitudes of the radical concentrations. The concentrations reported by James and Sicilio are nearly an order of magnitude less than predicted by our mechanism. It is possible that there was a systematic error in the concentration calibration used by these authors since in an earlier study with methanol as substrate (20), in which a similar mechanism should apply, the radical concentrations reported were much greater. It has been suggested (8) that the low radical concentrations are a result of the reaction of OH with Ti(III) but this argument is untenable since the rate constant for this reaction is unlikely to be significantly greater than that for reaction of OH with 2-propanol and the concentration of the alcohol was generally fifty to one hundred times greater than the *initial* [Ti(III)].

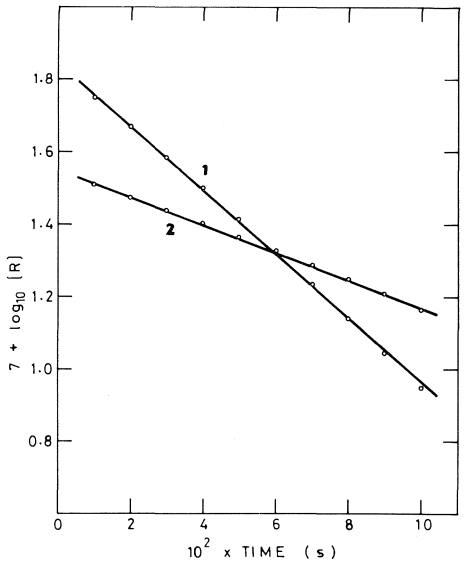

FIG. 5. First order plot of the calculated data of Fig. 4.

In the radiation-induced oxidation of 2-propanol by H_2O_2, reaction 8 was proposed to be of major importance (1). An equation analogous to eq. 10 may be derived for the steady state concentrations of the radicals in the radiation-chemical experiment (eq. 15). G_R is the sum of the primary free-radical yields for the radiolysis of aqueous solutions, and D is the dose rate in units of 6.02×10^{25} eV l^{-1} s^{-1}. For the conditions used by Burchill and Ginns (1), $(G_R.D.k_t)^{1/2} \sim 50$ s^{-1} while k_8[2-propanol] was in the range 5.0–50 s^{-1}. Thus reaction 8 is indeed not negligible at the lower rates of initiation used in the radiation-chemical study. Furthermore, for solutions 0.5 M in 2-propanol, it was found that $G(-H_2O_2)$ was independent of $[H_2O_2]$ in the range 0.05 to <0.01 M (1). This was construed as evidence that the only significant termination was bimolecular reaction of **2** (reaction 7). From eq. 15 it can be calculated that, for [2-propanol] = 0.5 M and $[H_2O_2] = 0.01$ M, [**2**]/[**1**] = 26 for a dose rate of 1.8×10^{19} eV l^{-1} s^{-1} (*i.e.*, only reaction 7 would be a significant terminating process).

In the radiation-induced oxidation of 2-propanol by H_2O_2 the chain yields were found to

$$[15] \qquad \frac{[\mathbf{2}]}{[\mathbf{1}]} = \frac{\frac{k_4}{k_3 + k_4} k_2[H_2O_2] + (G_R.D.k_t)^{1/2} + k_8[\text{2-propanol}]}{\frac{k_3}{k_3 + k_4}(G_R.D.k_t)^{1/2} + k_8[\text{2-propanol}]} - 1$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

decrease at very high alcohol concentrations (1). This phenomenon has also been reported for the photo-induced reaction (21).[3] This reduction of the yields was attributed (1) to a decrease in k_2 with decreasing dielectric constant as the solvent was varied from water to 2-propanol. To examine this proposal we have measured the concentrations of **1** and **2** for solutions containing 0.68 *M* acetone, 0.029 *M* H_2O_2, and varying concentrations of alcohol. The results are shown in Fig. 6. The initial increase in total radical concentration with increasing alcohol may be associated with increased scavenging of the acetone triplets. The decrease in [**2**]/[**1**] (from ~1.4 at low alcohol concentration to 0.13 at 0.5 mole fraction alcohol) is much too great to be accounted for by the inclusion of reaction 8 (as in eq. 10) although it would make some contribution. The most probable reason for this decrease is a decrease in k_2. In the photo-initiated reaction of H_2O_2 in pure 2-propanol (4) only the spectrum of **1** was observed, but with addition of water the spectrum of **2** became increasingly prominent. This could be accounted for by a combination of an increase in k_2 with increasing water content, thus increasing [**2**]/[**1**], and a decreasing contribution from reaction 8, which would have a similar effect.

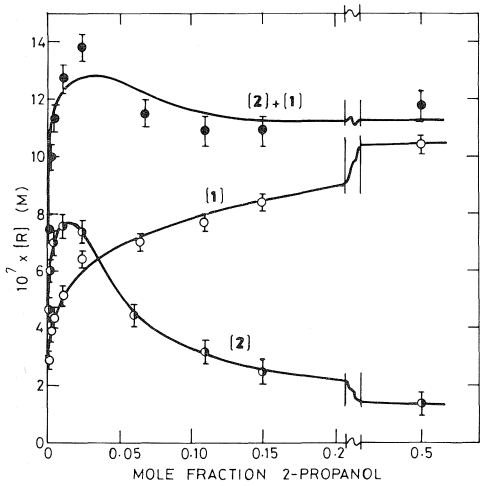

FIG. 6. Effect of varying 2-propanol concentration on the concentrations of $(CH_3)_2\dot{C}OH$ (**1**) and $\dot{C}H_2(CH_3)CHOH$ (**2**) during photolysis of solutions 0.68 *M* in acetone and 0.029 *M* in H_2O_2.

[3]Unpublished results of a re-examination of this system by C. E. Burchill and P. G. Huminicki show that the observed effects may be interpreted by a mechanism entirely analogous to that proposed for radiation initiation.

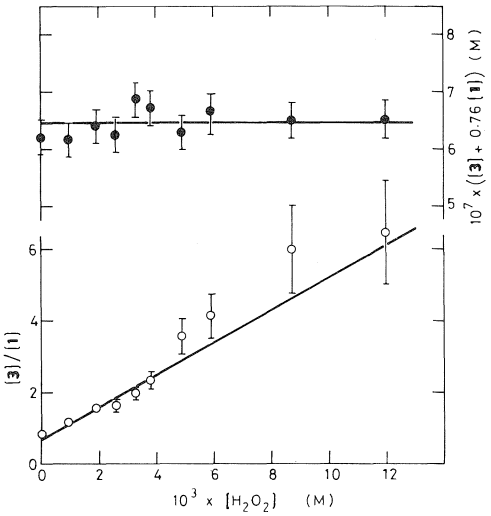

FIG. 7. Effect of H_2O_2 on the concentrations of $(CH_3)_2\dot{C}OH$ (**1**) and $\dot{C}H_2OH$ (**3**) during photolysis of solutions 0.68 *M* in acetone and 0.8 *M* in methanol.

The results and conclusions of this study are thus consistent with the mechanism proposed for the radiation-induced oxidation of 2-propanol by H_2O_2 (1, 2), and with the experimental observations from the photo-induced reaction, and e.s.r. studies using electron beam irradiation (3), photo-initiation (4, 11), and Ti(III) initiation (6, 10).

(b) Methanol

When a solution containing methanol (0.8 *M*) and acetone (0.68 *M*) was irradiated, the spectra of **1** and $\dot{C}H_2OH$ (**3**) were obtained (11). With addition of H_2O_2 the concentration of **3** increased while that of **1** decreased until, at 0.03 *M* H_2O_2, its spectrum could not be observed. The total radical concentration was essentially independent of H_2O_2 concentration while the ratio [**3**]/[**1**] increased linearly with [H_2O_2], as shown in Fig. 7. The mechanism to account for these results is outlined by eqs. 2, 5, and 16–20. Reaction 18 has been included in the mechanism since it has been shown to lead to a chain reduction of H_2O_2 (2, 22) but, as a result of the high rate constant for

[16] ^{3}acetone + $CH_3OH \rightarrow$ **1** + **3**

[2] **1** + $H_2O_2 \rightarrow$ acetone + H_2O + $\dot{O}H$

[17] $\dot{O}H$ + $CH_3OH \rightarrow H_2O$ + **3**

[18] **3** + $H_2O_2 \rightarrow H_2CO + H_2O + \dot{O}H$

[5] **1** + **1** $\rightarrow$

[19] **1** + **3** $\rightarrow$ non-radical products

[20] **3** + **3** $\rightarrow$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reaction 17 ($5 \times 10^8\ M^{-1}\ s^{-1}$ (19)), the steady state concentration of OH will be less than $10^{-8}\ M$ and the concentration of **3** will not be significantly affected by this sequence.

We have assumed that the rates of the termination processes are diffusion controlled and that the three may be represented by a composite rate constant,

$$k_t = 2k_{20} = k_{19}\left(\frac{k_{20}}{k_5}\right)^{1/2} = 2k_5\frac{k_{20}}{k_5}$$

The steady state concentrations of the organic radicals would then be given by eqs. 21 and 22, where r_i represents the rate of reaction 16.

$$[21] \qquad \left(\frac{k_5}{k_{20}}\right)^{1/2}[\mathbf{1}] + [\mathbf{3}] = \left(\frac{2r_i}{k_t}\right)^{1/2}$$

$$[22] \qquad \frac{[\mathbf{3}]}{[\mathbf{1}]} = \left(\frac{k_5}{k_{20}}\right)^{1/2} + \left(\frac{2}{r_i k_t}\right)^{1/2} k_2[H_2O_2]$$

Taking k_5/k_{20} as 1.4/2.4 (16) the observed value of [**3**]/[**1**] in the absence of H_2O_2 (0.85 ± 0.07) is in fair agreement with the predicted value of 0.76. From the peroxide dependence of [**3**]/[**1**] and a value of $k_t = 2.4 \times 10^9\ M^{-1}\ s^{-1}$ a value of $k_2 = (3.5 \pm 0.4) \times 10^5\ M^{-1}\ s^{-1}$ may be calculated, in fair agreement with that previously determined.

(c) Dimethoxymethane (Methylal)

Irradiation of an aqueous solution 0.68 *M* in acetone and 0.55 *M* in methylal gave the spectra of three radicals: **1**, $\dot{C}H(OCH_3)_2$ (**4**), and $\dot{C}H_2OCH_2OCH_3$ (**5**). The spectra of the latter radicals were identical to those obtained by Lewis and Sicilio (23). With no H_2O_2 present the concentration of **4** was significantly greater than that of **5**. With addition of H_2O_2 the intensity of the spectrum of **1** decreased toward zero, that of **4** decreased, and that of **5** increased (see Fig. 8). A quantitative treatment of this system was not attempted but the observed effects may be qualitatively understood in terms of a mechanism similar to that for 2-propanol (eqs. 2, 23–27).

[23] ^{3}acetone + methylal → **1** + **4**

[24] ^{3}acetone + methylal → **1** + **5**

[2] **1** + H_2O_2 → acetone + H_2O + $\dot{O}H$

[25] $\dot{O}H$ + methylal → H_2O + **4**

[26] $\dot{O}H$ + methylal → H_2O + **5**

As H_2O_2 is added, reaction of **1** with H_2O_2 will, via reactions 25 and 26, replace **1** with **4** and **5**.

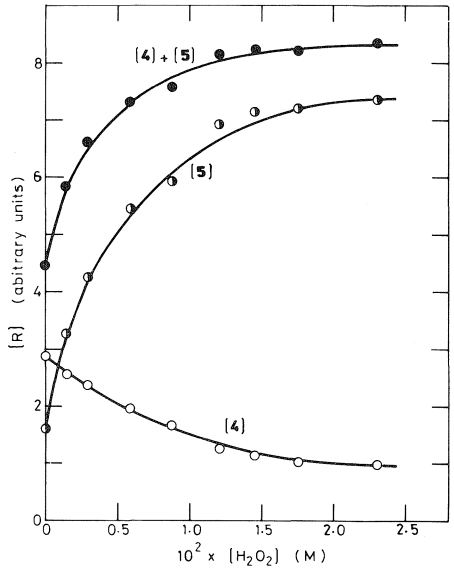

FIG. 8. Effect of H_2O_2 on the concentrations of $\dot{C}H(OCH_3)_2$ (**4**) and $\dot{C}H_2OCH_2OCH_3$ (**5**) during photolysis of solutions 0.68 *M* in acetone and 0.55 *M* in dimethoxymethane.

Thus the total concentration of radicals derived from methylal should increase as **1** decreases. The increase in [**5**] relative to [**4**] as H_2O_2 is added probably originates from a preferential oxidation of **4** by H_2O_2 to give an induced chain reaction (eq. 27). The sequence of reactions 27, 25, 26

[27] **4** + H_2O_2 → oxidized product + $\dot{O}H$ (possibly methyl formate + methanol)

could lead to an inversion of the concentrations of **4** and **5** with increased H_2O_2 in the manner observed.

This interpretation of the inversion of the concentrations of the radicals in the presence of H_2O_2 by a secondary chain reaction is consistent with the data of Lewis and Sicilio (23) for the Ti(III) initiated reaction of methylal with H_2O_2. In that study the concentrations of **4** and **5** showed a difference in time dependence, with the "rate constant" for **4** being greater than that for **5**. The rate constants themselves probably have no physical significance (as noted in a later study (6), "A plausible mechanism for a three-halves order decay is difficult to develop") since it is likely that the time dependence of the total radical concentration simply reflects the rate of initiation while the ratio of [**4**] to [**5**] decreases with decreasing rate of initiation as a result of a secondary chain reaction in a manner similar to that of 2-propanol.

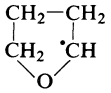
To demonstrate that a free-radical chain reduction of H_2O_2 by methylal may occur we have γ-irradiated deaerated aqueous solutions of methylal and H_2O_2. For solutions 0.2 *M* in methylal and 0.01 *M* in H_2O_2, at a dose rate of 1.2×10^{19} eV l^{-1} s^{-1}, $G(-H_2O_2)$ was 22. The yield was independent of methylal concentration between 0.1 and 1.0 *M* and varied from 15 to 35 as $[H_2O_2]$ was increased from 0.005 to 0.05 *M*. These results imply a chain mechanism.

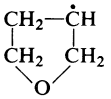
(d) Tetrahydrofuran (THF)

Irradiation of an aqueous solution 0.68 *M* in acetone and 0.55 *M* in THF gave spectra corresponding to two radicals which were identified as **1** and **6**. The latter spectrum consisted of six



6

multiplets of relative intensity 1:1:2:2:1:1 with $a_{\dot{C}H} = 12.4$ and $a_{CH_2} = 28.3$ *G*, in agreement with previous work (24). In the presence of H_2O_2 an additional spectrum of six multiplets was observed. Two splittings of approximately 33 and 20 *G* were assigned to this spectrum and, as previously suggested (24), it is proposed that it represents radical **7**.



7

At low concentrations of H_2O_2 the spectrum of **1** disappeared and there was an increase in the concentration of **6** as well as the appearance of **7**. With further addition of H_2O_2 the concentration of **6** decreased while that of **7** continued to increase (see Fig. 9). It is suggested that a mechanism similar to that for methylal applies and that the initial increase in THF radicals with added H_2O_2 represents the replacement of **1** by **6** and **7**, and the inversion of the concentrations of **6** and **7** at high peroxide concentrations is a consequence of the preferential oxidation of **6** by H_2O_2 in a chain propagating reaction. The very high concentration of H_2O_2 required to bring about this inversion suggests that the rate constant for oxidation of **6** by H_2O_2 is much less than that for **1** or **4**.

When a deaerated aqueous solution 0.2 *M* in THF and 0.01 *M* in H_2O_2 was γ-irradiated at a dose rate of 1.2×10^{19} eV l^{-1} s^{-1} the $G(-H_2O_2)$ value was 29, demonstrating that an induced chain reduction of H_2O_2 by THF may indeed occur.

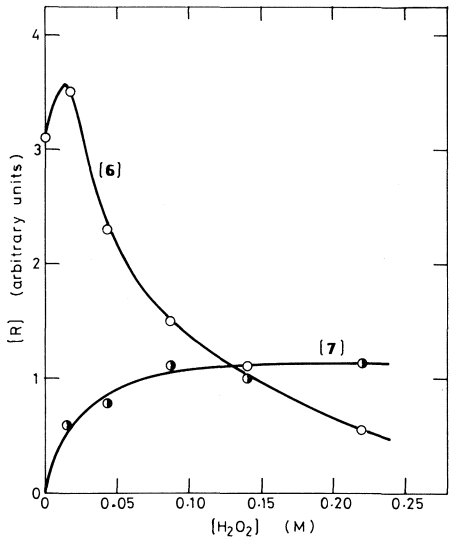


FIG. 9. Effect of H_2O_2 on the concentrations of radicals derived from tetrahydrofuran during photolysis of solutions 0.68 *M* in acetone and 0.55 *M* in THF.

6 = **7** =

(2) Direct Photolysis of Malonic Acid

Eiben and Fessenden (3) have noted that reaction of OH with malonic acid gives only the product of abstraction, $\dot{C}H(CO_2H)_2$ (**8**), whereas Dixon *et al.* (25) found only the fragment radical, $\dot{C}H_2CO_2H$ (**9**), in the Ti(III) initiated reaction with H_2O_2. In pulse radiolysis studies Simic *et al.* (26) identified the major radical species as **8** but noted a short lived transient which might have been **9**. It was thought that the qualitative differences between the results reported in refs. 3 and 25 might be traced to some reaction of the radicals with H_2O_2 which is necessarily present in the Ti(III) studies.

Malonic acid itself absorbs light in the mid u.v. and irradiation of a 1.0 *M* aqueous solution of the acid with no other additives produced a strong spectrum of **9** and a less intense spectrum of **8** (25, 3). Radical **9** is presumably formed by dissociation of an excited (possibly triplet) state of malonic acid, as has been suggested for tartaric acid (27). As in the case of tartaric acid, no

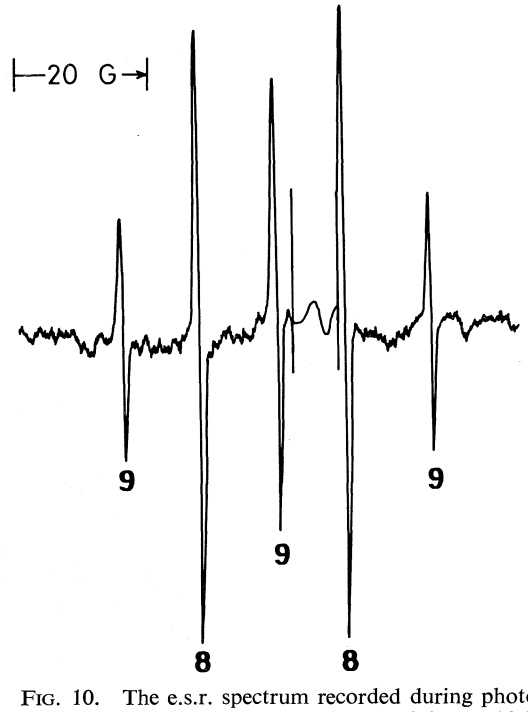

FIG. 10. The e.s.r. spectrum recorded during photolysis of aqueous 1.0 *M* malonic acid containing 0.029 *M* H_2O_2. The lines are attributed to $\dot{C}H(CO_2H)_2$ (**8**) and $\dot{C}H_2CO_2H$ (**9**).

spectrum which could be attributed to $\dot{C}O_2H$ was observed but, unlike tartaric acid, all spectra were found in absorption, nor were any intensity anomalies observed (see Fig. 10).

The origin of **8** in this system is less clear. It is possible that it is formed by abstraction of a methylene hydrogen from malonic acid by a triplet excited state of the acid, but no spectrum of the product of such a hydrogen atom addition was observed.

With the addition of H_2O_2 the spectrum of **8** increased in intensity while that of **9** remained (relatively) constant, as shown in Fig. 11. Although its spectrum was not observed, we suggest that this effect is a consequence of the reaction of $\dot{C}O_2H$ with H_2O_2. $\dot{C}O_2H$ is known to induce decomposition of H_2O_2, as in reaction 28 (28), and reaction of OH with malonic acid has

[28] $$\dot{C}O_2H + H_2O_2 \rightarrow CO_2 + H_2O_2 + \dot{O}H$$

been suggested to give only **8** (3). If the principal photo-decomposition of malonic acid is reaction 29, the subsequent reaction of $\dot{C}O_2H$ with H_2O_2 would result in the formation of **8** via reaction 30.

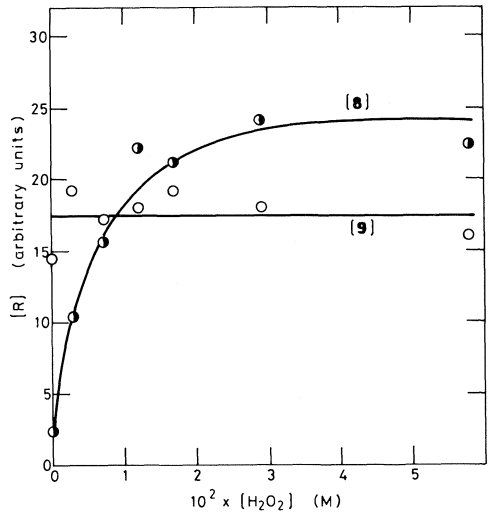

FIG. 11. Effect of H_2O_2 on the concentrations of $\dot{C}H(CO_2H)_2$ (**8**) and $\dot{C}H_2CO_2H$ (**9**) during photolysis of 1.0 *M* malonic acid.

[29] $$CH_2(CO_2H)_2 \xrightarrow{h\nu} \mathbf{9} + \dot{C}O_2H$$

[30] $$\dot{O}H + CH_2(CO_2H)_2 \rightarrow H_2O + \mathbf{8}$$

From these experiments it is clear that the presence of H_2O_2 in the Ti(III) studies is not the factor responsible for the formation of **9** from malonic acid. The explanation of this phenomenon has yet to be found.

Conclusion

This work has demonstrated that, when free radicals are generated from an organic substrate in aqueous solution, the presence of H_2O_2 may have a profound effect on the ratio of the concentrations of the radicals as a consequence of selective oxidation by H_2O_2 and induced secondary chain reactions. It has previously been shown (7, 9, 10) that, in e.s.r. studies of free radicals generated by the reaction of reducing metal ions with H_2O_2, a number of erroneous conclusions have been drawn because of the failure to recognize that the radicals observed in the flowing system are those generated *within the detector* by the rate controlling initiating step. There is therefore a need for a critical re-evaluation of all kinetic and mechanistic conclusions drawn from such studies.

The Condensation of Cyclohexanone with Furan and Pyrrole[1]

W. H. BROWN,[2] B. J. HUTCHINSON,[3] AND M. H. MACKINNON[4]
Department of Chemistry, University of Guelph, Guelph, Ontario

Received April 8, 1970[5]

Several compounds formed by the acid-catalyzed condensation of cyclohexanone with furan and pyrrole have been isolated and identified. A previously-reported structure for one of the products of the condensation of cyclohexanone with pyrrole has been shown to be incorrect.

Plusieurs composés, obtenus par la condensation acido-catalysée de la cyclohexanone avec le furanne et le pyrrole, ont été isolés et identifiés. La structure, précédemment rapportée, d'un des produits de condensation de la cyclohexanone avec le pyrrole est incorrecte.

Canadian Journal of Chemistry, **49**, 4017 (1971)

Introduction

A study of the acid-catalyzed condensation of furan with a number of acyclic carbonyl compounds has been reported in a series of papers by Brown and co-workers (1–4). In general, when ketones, such as acetone, are condensed with furan under the appropriate conditions (furan present in excess), a set of compounds **1**, **2**, **3**, and **4** whose structures are shown in Fig. 1, is obtained. However, when acetone is present in excess, only **4** is obtained. The mechanism of this set of reactions has been studied in our laboratories and will be the subject of a forthcoming communication.

Similar results have been obtained in the acid-catalyzed reaction of pyrrole with carbonyl compounds. Thus Baeyer (5) discovered the first condensation leading to such a cyclic compound; *viz.*, the condensation of pyrrole with acetone in the presence of hydrochloric acid to yield compound **5**, Fig. 1.

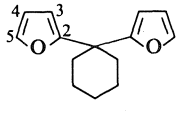
Investigation of this type of reaction was also undertaken by Dennstedt and Zimmerman (6) and by Chelintzev and Tronov (7). Chelintzev *et al.* (8) proposed structure **6** for the product obtained from the reaction of pyrrole with cyclohexanone. However our results indicate that this compound has a tetrazaquaterene structure **13**.

We report the products obtained from the acid-catalyzed condensation of cyclohexanone with furan and have investigated in more detail the structure of the two products formed in the condensation of cyclohexanone with pyrrole. Structures for these compounds are shown in Fig. 1. Since the structures are rather large and their names somewhat lengthy, we have used abbreviated symbols as indicated in Fig. 1. Table 1 lists the names of the compounds and their assigned numbers. These assigned numbers will be used throughout.

Results and Discussion

The Condensation of Cyclohexanone with Furan

When cyclohexanone is treated with furan in a mole ratio of 1:2 in the presence of hydrochloric acid, compounds **7** and **8** of proposed structure as shown in Fig. 1 are obtained. These products were expected on the basis of previous results (1) but no cyclic compound analogous to compound **4** was isolated from the reaction mixture. The 100 MHz proton n.m.r. spectrum of compound **7**, run neat with TMS as an internal standard, showed resonance at δ 1.42 and 2.18, relative intensity 5, which are assignable to the cyclohexyl methylene groups. The furan proton resonance occurred at δ 5.93, 6.13, and 7.13 with the following parameters: $J_{34} = 3.3$; $J_{35} = 0.8$; $J_{45} = 1.8$ Hz.



7

This is an AMX spectrum and the resulting coupling constants are in agreement with a 2-substituted furan (9).

FIG. 1 Abbreviated structures for compounds referred to in text.

By analogy, the structure for **8** follows. The 60 MHz p.m.r spectrum, chemical analysis, and molecular weight are in agreement with the proposed structure.

Treatment of cyclohexanone with furan in a mole ratio of 2:1 in the presence of hydrochloric acid did not yield the expected tetroxaquaterene compound **10**. Instead a compound, corresponding to the empirical formula $C_{26}H_{32}O_2$, was isolated from the reaction mixture. Since the compound exists in good-sized, well-defined crystals it was hoped that the structure could be determined by X-ray diffraction. However, preliminary Weissenberg photographs of the orthorhombic crystals indicated the presence of excessive internal thermal motion or disorder, which ruled out further X-ray studies. A proposed structure, **9**, for the compound fits the empirical formula. If this structure is correct then **7** and **9** should react in the presence of hydrochloric acid to form **10**, as shown in eq. 1.

When this reaction was tried in dioxane satu-

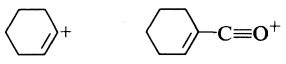
7 9 10



A B

rated with dry hydrogen chloride, the expected compound **10** was formed within 15 min, in 30% yield.

The 100 MHz spectrum of **9** in benzene-d_6 solution shows resonances at δ 6.37, relative intensity 1; 6.00, relative intensity 2; 2.15 and 1.49, relative intensity 13, assignable to the alkene, furan, and methylene protons respectively in the proposed structure for **9**. The resonance, assigned to the furan rings, appears as a singlet and not a multiplet as would be expected from the unsymmetrical substitution in the 2,5-positions of the furan rings in **9**. This ambiguity is fully resolved when the spectrum is run in carbon tetrachloride solution. The alkene resonance now occurs at δ 6.13 and the furan protons appear as a clear AB multiplet centered at δ 5.88, with J_{AB} = 3.2 Hz and $\nu_0\delta$ = 8.5 Hz. This confirms the unsymmetrical substitution of the furan rings in **9**.

The mass spectrum of **9** shows that the parent ion (*m/e* 376) fragments to give ions *m/e* 81 and 109. These correspond to structures **A** and **B**, which explain the alkene resonance observed in the 100 MHz n.m.r. spectrum.

The structure postulated for **10** is supported not only by its synthesis from **7** plus **9**, but also by its formation by treating **7** with cyclohexanone.

The Condensation of Cyclohexanone with Pyrrole

The product obtained from the reaction of equimolar quantities of pyrrole and cyclohexanone in the presence of hydrochloric acid has the same melting point (272–273°) as the compound reported by Chelintzev *et al.* (8). We have found this high-melting solid to have a tetrazaquaterene structure **13** rather than structure **6** previously proposed by these investigators.

The 100 MHz proton spectrum of **13** in dioxane solution shows resonances at δ 7.45, broad singlet, relative intensity 1, 5.85, doublet, relative intensity 2, J = 4.0 Hz, and multiplets at 1.93 and 1.41, total intensity 10, assignable to the pyrrole N—H, the pyrrole β-protons, and the cyclohexane protons in **13** respectively. Addition of D_2O to the solution of **13** in dioxane causes the disappearance of the resonance at δ 7.45, confirming its assignment as the pyrrole N—H and removes the doublet splitting in the resonance at δ 5.85. Since this coupling is from the N—H, the single resonance for the β-protons, which does not split to a multiplet on changing solvent, necessitates symmetrical substitution on the pyrrole rings in the 2,5-positions. Thus, together with the relative ratios of the resonances, the assignment of the structure for **13** is unambiguous. Furthermore, when **14** is treated with cyclohexanone in the mole ratio of 1:5 in the presence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

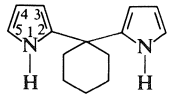
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of hydrochloric acid, **13** is readily formed in excellent yield. The molecular weight of **13** by Rast method is 584.

When pyrrole and cyclohexanone, in a mole ratio of 4:1, are treated with hydrochloric acid, a compound, to which structure **14** is assigned, is formed. The 100 MHz proton n.m.r. spectrum of compound **14** in benzene-d_6 showed multiplets at high field (δ 2.02 and 1.50) and at low field (δ 6.82, 6.18, and 6.06) at relative ratios of 5:3. These are assignable to the cyclohexane methylenes and the pyrrole protons respectively. The low-field multiplets of the pyrrole and its deutero analog could be completely interpreted as an AMNX spectra giving the following parameters: $J_{13} = 2.69$; $J_{14} = 2.56$; $J_{15} = 2.66$; $J_{34} = 3.41$; $J_{35} = 1.38$; $J_{45} = 2.41$ Hz.



14

The values of these coupling constants require substitution of pyrrole in the 2-position as reported by Abraham and Bernstein (10) and Gronowitz *et al.* (11). Hence this interpretation makes unambiguous the assignment of structure of **14**. The n.m.r. data on substituted pyrroles have been summarized by Katritzky (12).

Experimental

Instruments used were Varian A-60-A and HA-100 n.m.r. spectrometers, a Beckman IR 5A, a Meltemp m.p. apparatus using capillary tubes (corrected thermometer), and a Varian-Mat CH-7 mass spectrometer for molecular weights. The reagents, furan, cyclohexanone, and pyrrole were reagent grade and were used without further purification.

Condensation of Cyclohexanone with Furan (Mole Ratio 1:2) to Form 7 and 8

In a three-necked 500 ml flask, fitted with a reflux condenser and stirrer, were placed 49 g (0.5 mol) of cyclohexanone, 68 g (1.0 mol) of furan, and 40 ml of absolute ethanol. To the stirred mixture was added dropwise 30 ml of 37% aqueous hydrochloric acid solution. The reaction mixture was stirred at room temperature for 24 h. When stirring was discontinued the mixture separated into two phases. The upper purple aqueous layer was separated from the lower reddish-orange organic layer. The organic phase was washed with 5% aqueous sodium bicarbonate solution until neutral, dried over anhydrous magnesium sulfate, and fractionally distilled at diminished pressure. The first fraction distilled at 94–95° (1–2 Torr) and weighed 9.23 g (8.5%). It is an oil and has $\eta_D^{25°}$ 1.5221 and $d_4^{20°}$ 1.018. Cooling to −15° for 24 h yielded crystals which melt at 13–17°.

The i.r. data λ_{max} (μ): 3.2, 3.41, 6.65, 6.89, 8.62, 9.87, 10.6, 11.28, 12.49, 13.73; n.m.r. data (δ): 7.2 (2H), 6.15 (2H), 5.90 (2H), 2.18 (4H), and 1.42 (6H).

Anal. Calcd. for $C_{14}H_{16}O_2$ (**7**) (mol. wt. 216): C, 77.76; H, 7.40. Found (216): C, 77.83; H, 7.46.

A second fraction boiled at 200–205° (1–2 Torr) and weighed 17.55 g (9.6%). The product from the distillation was a light-yellow oil which formed crystals on standing at room temperature for 12 h. The crystals were collected on a Büchner funnel and washed with cold diethyl ether to give 10.2 g of white crystals melting at 83.4–85.8°. Crystallization of the sample from hexane (8 ml/g) gave white crystals, m.p. 86.8–87.6°.

The i.r. data λ_{max} (μ): 3.2, 3.41, 6.65, 6.90, 8.21, 8.59, 9.68, 9.94, 10.32, 10.58, 12.55, 12.72, 13.55, 13.70; n.m.r. data (δ): 7.24 (2H), 6.20 (2H), 5.85 (4H), 2.14 (8H), 1.48 (12H).

Anal. Calcd. for $C_{24}H_{28}O_3$ (**8**) (mol. wt. 364): C, 79.12; H, 7.69. Found (364): C, 79.19; H, 7.60.

Condensation of Cyclohexanone with Furan (Mole Ratio 2:1) to Form 9

To a three-necked 500 ml flask, fitted with a stirrer and a reflux condenser, were added 12.8 g (0.188 mol) of furan, 37 g (0.377 mol) of cyclohexanone, and 15 ml of absolute ethanol. The solution was stirred at room temperature while 12 ml of 37% aqueous hydrochloric acid solution was added dropwise over a period of 4 min. The resulting mixture was stirred for 12 h at which time the stirrer was stopped by a sticky solid in the flask. After standing for another 12 h, the product was washed twice with 50 ml of cold water. After washing twice with 15 ml of cold hexane, a yield of 20 g (21%) of white crystals was obtained. The product was crystallized from hexane and yielded 11.5 g of white crystals. The crystals were washed twice with cold 5% aqueous sodium bicarbonate solution and once with cold water to remove any residual acid. Crystallization from absolute ethanol (40 ml/g) gave 10 g of white needles, m.p. 113.5–114.8°. An additional crystallization from the same solvent yielded white needles, m.p. 114.3–115.3°.

The i.r. data λ_{max} (μ): 3.3, 3.41, 6.55, 6.90, 8.28, 9.82, 10.86, 12.50 (shoulder), 12.85 (broad); n.m.r. data (δ): 6.18 (4H), 5.92 (6H), 2.17 (12H), 1.58 (18H). Mass spectrum: M^+ 376: *m/e* 333, M^+-C_3H_7; 320, M^+-C_4H_8; 307, M^+-C_5H_9; 295, M^+-C_6H_9; 267, M^+-O=C—C_6H_9.

Anal. Calcd. for $C_{26}H_{32}O_2$ (mol. wt. 376): C, 82.93; H, 8.57. Found (376): C, 82.48; H, 8.34.

Condensation of 9 with 7 to Form 10

Dry hydrogen chloride gas was bubbled into 10 ml of dioxane until saturated at room temperature. To this solution were added 1.5 g (0.0068 mol) of **7** and 0.85 g (0.023 mol) of **9**, while stirring. After 15 min a fine solid precipitated. After standing for an additional 15 min the solid was removed by filtration and washed on the filter with cold dioxane. The crude product had m.p. 256–262°. Crystallization from dioxane gave 0.39 g (30%) of fine white crystals, m.p. 263–264°. A mixture melting point with compound **10**, prepared by condensing **7** with cyclohexanone (see below) was not depressed.

Condensation of Cyclohexanone with 3 to Form 12

In a two-necked 200 ml flask, fitted with a reflux condenser guarded by a calcium chloride tube, were placed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

3.92 g (0.01 mol) of **3**, 0.98 g (0.01 mol) of cyclohexanone, and 10 ml of absolute ethanol. Dry hydrogen chloride gas was bubbled into the mixture for 25 min by which time separation into two distinct layers had occurred. A magnetic stir bar was introduced and the mixture stirred at room temperature for 5 h. The sticky product was collected on a Büchner funnel and washed with 10 ml of absolute ethanol. The product is a white solid. Crystallization from benzene and then from ethanol–benzene gave 0.98 g (21%) of white crystals, m.p. 182.3–183.3°.

The i.r. data λ_{max} (μ): 3.38, 6.41, 7.90, 8.24, 8.62, 8.98, 9.78, 10.45, 12.88; n.m.r. data (δ): 5.82 (8H), 2.0 (4H), 1.48 (24H).

Anal. Calcd. for $C_{31}H_{36}O_4$ (mol. wt. 472): C, 78.81; H, 7.63. Found (472): C, 79.08; H, 7.69.

Condensation of Acetone with 7 to Form 11

To a 50 ml flask, fitted with a reflux condenser and stirrer, were added 1.43 g (0.007 mol) of compound **7**, 3.92 g (0.135 mol) of acetone, 10 ml of absolute ethanol, and 3 ml of 37% aqueous hydrochloric acid solution. The mixture was stirred at room temperature for 17 h. The product, a sticky solid, was removed by filtration and washed with cold hexane. A yield of 0.54 g (16%) of white crystals, m.p. 198.0–203.0° was obtained. Two crystallizations from hexane (50 ml/g) gave 0.26 g of white crystals m.p. 208.2–209.2°.

The i.r. data λ_{max} (μ): 3.38, 6.41, 6.88, 8.22, 8.95, 9.73, 10.30, 12.83, 12.93, 13.98; n.m.r. data (δ): 5.81 (8H), 2.0 (8H), 1.47 (24H).

Anal. Calcd. for $C_{34}H_{40}O_4$ (mol. wt. 512): C, 79.69; H, 7.81. Found (512): C, 79.91; H, 7.68.

Condensation of Cyclohexanone with 7 to Form 10

In a 200 ml two-necked flask were placed 4.0 g (0.018 mol) of **7**, 1.82 g (0.0185 mol) of cyclohexanone, and 20 ml of absolute ethanol. Dry hydrogen chloride gas was bubbled into the mixture for 10 min. A magnetic stir bar was placed in the flask and the mixture was stirred for 48 h. The sticky product was removed by filtration on a Hirsch funnel and then was triturated in hexane. The fine white crystals were removed by filtration and weighed 0.10 g (0.91%). Crystallization from hexane yielded 0.04 g of white amorphous substance, m.p. 267–268°. When the sample was crystallized from hexane the melting point was raised to 268–269°.

The i.r. data λ_{max} (μ): 3.41, 6.42, 6.90, 8.23, 8.86, 9.81, 10.30, 12.99; n.m.r. data (δ): 5.87 (8H), 2.0 (16H), 1.4 (24H).

Anal. Calcd. for $C_{40}H_{48}O_4$ (mol. wt. 592): C, 81.08; H, 8.11. Found (592): C, 81.09; H, 8.44.

Condensation of Cyclohexanone with Pyrrole to Form 13

A solution of 16.2 g (0.242 mol) of pyrrole and 20 ml of absolute ethanol was placed in a three-necked 500 ml flask. The flask, fitted with a stirrer and reflux condenser, was placed in an ice-bath. To the stirred solution was added dropwise 1 ml of 37% aqueous hydrochloric acid solution, followed by 23.7 g (0.242 mol) of cyclohexanone over a period of 20 min. The stirrer was stopped by the solid formed in the flask when the addition of cyclohexanone was complete. After standing at room temperature for 1 h, the product was washed with 50 ml of cold water. The solid was removed from the flask by partial dissolution in ether. The total yield of crude was 12.86 g (9.0%). Several crystallizations of the product from benzene and then from hexane gave white crystals, m.p. 272.0–272.5°. The melting point reported by Chelintzev *et al.* (8) is 272.0°.

The i.r. data λ_{max} (μ): 3.42, 6.35, 6.90, 7.05, 8.43, 9.55, 13.7 (broad), 14.15; n.m.r. data (δ): 7.45 (broad), 5.87 and 5.83 (8H), 1.93 (16H), 1.41 (24H). After deuteration (solvent, dioxane) the doublet at 5.87 and 5.83 was replaced by a singlet at 5.85.

Anal. Calcd. for $C_{40}H_{52}N_4$ (mol. wt. 588): C, 81.58; H, 8.92; N, 9.52. Found (588): C, 81.67; H, 9.00; N, 9.37.

Condensation of Cyclohexanone with Pyrrole to Form 14

A solution of 26.8 g (0.400 mol) of pyrrole and 20 ml of absolute ethanol in a three-necked 500 ml flask, fitted with a magnetic stirrer and reflux condenser, was placed in an ice-bath. While stirring, 1 ml of 37% aqueous hydrochloric acid solution was added, followed by 9.8 g (0.10 mol) of cyclohexanone, the latter being added dropwise over a period of 5 min. The solution passed through color changes from reddish-brown to dark green and finally dark brown over a period of 24 h. Two phases separated when stirring was discontinued. About 25 ml of ether was added, followed by sufficient 5% aqueous sodium bicarbonate solution to neutralize the acid. The ether layer was separated and evaporated in a current of air, leaving 19.5 g of a dark-brown thick oil. On standing for 4 days the oil partially crystallized. Purification by fractional crystallization of the mixture from dilute ethanol was tedious and wasteful. Accordingly the product was fractionally distilled, yielding 6.5 g (30%) of a pale-yellow oil, boiling at 178–185° (1 Torr). The oil crystallized to a solid, m.p. 93–100°. Crystallization from 70% aqueous ethanol yielded colorless fine needles, m.p. 105–106°. The compound deteriorates rapidly on exposure to air, heat and light.

The i.r. data λ_{max} (μ): 2.91, 3.24, 3.43, 3.50, 6.50, 6.91, 9.16, 9.70, 13.65 (broad); n.m.r. data (δ): 7.06–7.50 (broad, 2H), 6.28–6.45 (multiplet, 2H), 5.95–6.10 (triplet, 4H), 1.80–2.15 (broad, 5H), 1.33–1.70 (broad, 5H).

Anal. Calcd. for $C_{14}H_{18}N_2$ (mol. wt. 214): C, 78.45; H, 8.47; N, 13.08. Found (214): C, 78.40; H, 8.44; N, 13.12.

Condensation of Cyclohexanone with 14 to Form 13

Compound **14** (0.002 mol) was treated with 0.98 g (0.10 mol) of cyclohexanone at 0° using concentrated aqueous hydrochloric acid as catalyst. A yield of 83% of purple crystals resulted. Crystallization of the crude product from hexane and then from acetone–water gave white crystals, m.p. 272°. A mixture melting point with **13**, obtained as described above by the condensation of cyclohexanone with pyrrole, showed no depression.

B.J.H. is grateful to the National Research Council of Canada for financial assistance.

We are indebted to Dr. D. B. MacLean, Department of Chemistry, McMaster University, Hamilton, Ontario, for the determination of some mass spectra, to Dr. C. A. Fyfe for assistance with the 100 MHz proton resonance spectra, and to Mr. T. W. Hall for technical assistance in preparing some of the compounds.

Most of the microanalyses were carried out by Uniroyal Limited Research Laboratories, Guelph, Ontario.

The Pyrolysis of Cumene, *p*-Cymene, and α-Methylstyrene at 800 °C

RAY F. SEVERSON, WALTER H. SCHULLER, AND RAY V. LAWRENCE
Naval Stores Laboratory,[1] *Olustee, Florida 32072*

Received July 9, 1971

Cumene, *p*-cymene, and α-methylstyrene were pyrolyzed at 800 °C on Vycor glass. The products were separated by preparative g.l.p.c. and those identified were benzene, toluene, *p*-xylene, styrene, α-methylstyrene, *p*-methylstyrene, indene, *p*,α-dimethylstyrene, naphthalene, 1- and 2-methylnaphthalene, diphenyl, 2-vinylnaphthalene, acenaphthalene, fluorene, and phenanthrene. Possible mechanisms for the formation of these compounds are discussed.

Le cumène, le *p*-cymène et l'α-méthylstyrène ont été pyrolysés à 800 °C sur du verre Vycor. Les produits obtenus ont été séparés par c.p.g.l. et identifiés comme étant le benzène, le toluène, le *p*-xylène, le styrène, l'α-méthylstyrène, le *p*-méthylstyrène, l'indène, le *p*,α-diméthylstyrène, le naphtalène, le méthyl-1 et -2 naphtalène, le diphényle, le vinyl-2 naphtalène, l'acénaphtalène, le fluorène, et le phénanthrène. Les mécanismes possibles de formation de ces produits sont discutés.

Canadian Journal of Chemistry, **49**, 4023 (1971)

In the course of our study of the thermal behavior of resin acids, we discovered that very little was known about the pyrolytic behavior of the terpene-isopropyl group at high temperature. The behavior of the isopropyl moiety in the 300–700° range on catalytic surfaces has been widely studied (1–3); however, its behavior at 800° on inert Vycor glass had not been reported. It was of interest, in connection with the pyrolysis of resin acids, to determine which of the four possible primary pyrolytic reaction pathways as illustrated in Scheme 1 is the most highly favored at 800°.

Because of the thermal stability of the phenyl nucleus, two simple aromatic terpenes, cumene and *p*-cymene, and their unsaturated analog, α-methylstyrene, were chosen for this study. If a methyl rearrangement to the ring with subsequent loss of ethylene or acetylene was important, cumene and α-methylstyrene (**2**, R = H) should fragment to give a large yield of toluene (**3**) while *p*-cymene would yield *p*- or *m*-xylene depending on whether transfer to either the α- or β-carbon of the ring was important. The elimination of methane (or $CH_3\cdot + H\cdot$) from cumene and *p*-cymene would yield known styrenes (**1**) and dehydrogenation would give α-methylstyrenes (**2**), while the direct loss of the isopropyl moiety (or fragmentation of initial dehydrogenation) would produce benzene or toluene (**4**). The loss of the equivalent of methane from 2-methylstyrenes would yield phenylacetylenes (**5**).

Experimental

Cumene, *p*-cymene, and α-methylstyrene were obtained from commercial sources and were passed through alumina to remove autooxidized material just before use.[2] Toluene, *m*-xylene, cumene, indene, and 1-methylnaphthalene for use as g.l.c. standards were purified by preparative g.l.p.c. Naphthalene, diphenyl, 1,5-dimethylnaphthalene, dibenzyl, phenanthrene, 1-methylphenanthrene, and *m*- and *p*-terphenyl for g.l.c. standards were recrystallized from 95% EtOH. Tetradecane (99%) was used as purchased.

Apparatus

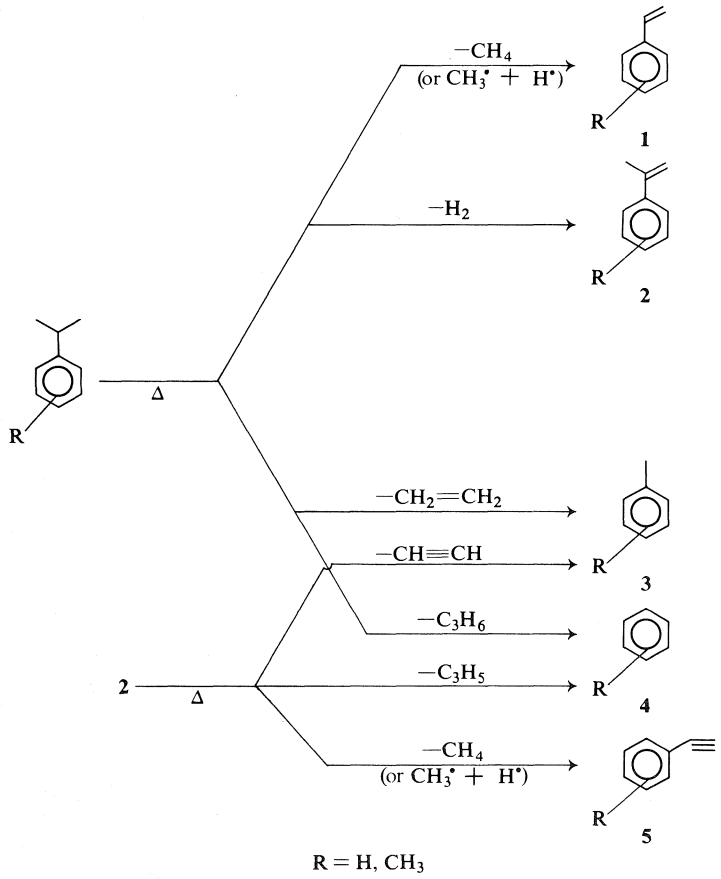
The pyrolysis apparatus consisted of a vertically mounted Cenco Hevi-Duty type 70T electric combustion furnace with a 12 in. heating chamber containing a Vycor glass combustion tube (30 mm o.d. × 32 cm long with a tapered end having a 3-4 mm opening and 24/40 glass joints sealed at the top and bottom) packed with an 1/8 in. diameter Vycor rod. This tube was connected to an air condenser, an ice trap, a Dry Ice trap, a gas dispersion trap (containing 15 ml of acetone), and a final Dry Ice trap. The extensive trapping system was required to trap the aerosol which formed upon cooling of the pyrolytic gases. A Temco portable indicating pyrometer was used to measure the pyrolysis tube temperature and the temperature controller was used to maintain the temperature at 800°.

Typical Pyrolysis Run

A side arm addition funnel was placed on top of the pyrolysis tube and the desired amount of N_2 (400 ml/min), as measured by a flow meter, was allowed to pass through

[1]One of the laboratories of the Southern Marketing and Nutrition Research Division, Agricultural Research Service, U. S. Department of Agriculture.

[2]We have found this procedure to be very effective in removing autooxidation products, *i.e.*, peroxides, hydroperoxides, etc., from organic materials.



SCHEME 1

the system. When the pyrolysis temperature had stabilized, 10 g of the compound to be pyrolyzed was placed in the addition funnel and added dropwise into the pyrolysis tube. When the run was complete, the trapped material was quantitatively removed from the four traps with acetone and the samples were subjected to g.l.p.c. analysis. The last trap generally contained only acetone which had been carried over from the preceding gas dispersion trap.

Analysis of Products and Calculation of % Yield

Analytical g.l.p.c. data was obtained on an F&M 500 using a 12 ft × 1/4 in. copper column packed with 10% OV-17 on 60/70 mesh NAW Chromosorb W with a temperature program of 80–275° at 2.9°/min and He flow rate of 120 ml/min. Tetradecane was used as an internal standard and internal marker. The response factor for each product was estimated from a standard curve obtained by plotting the integration area/mg *vs.* relative retention of a standard solution of 14 representative aromatic hydrocarbons described above and tetradecane in benzene. The plot was essentially linear with a negative slope.

Identification of Products

The products identified were collected from the OV-17 column under the conditions given above. The i.r. spectra were run on a Perkin–Elmer 21, as specified. All u.v. data were obtained on a Spectronic 505 in 95% EtOH.

Benzene, 0.10 (relative retention time, tetradecane = 1.00); toluene, 0.16; *p*-xylene, 0.27; styrene, 0.33; cumene, 0.38; α-methylstyrene, 0.50; *p*-cymene, 0.52; indene, 0.64; naphthalene, 0.93; 2-methylnaphthalene, 1.13; 1-methylnaphthalene, 1.18; diphenyl, 1.31; 2-vinylnaphthalene, 1.40; acenaphthalene, 1.48; fluorene, 1.67; and phenanthrene, 2.02; all had retention times, i.r. and u.v. identical to the authentic samples.

p-Methylstyrene:[3] 0.52; i.r. and u.v. identical with literature (4).

p,α-Dimethylstyrene: 0.67; i.r. ν_{max} (CS_2) 888 (vinylidene), and 822 cm^{-1} (two adjacent ArH); u.v. λ_{max} 250 and 282–293 mμ.

Results and Discussion

Cumene, *p*-cymene, and α-methylstyrene were pyrolyzed neat at 800 °C on Vycor rod to yield

[3] *p*-Cymene and *p*-methylstyrene were not separated on OV-17 column. A 15 ft × 1/4 in. copper column packed with 10% SE-30 on 60/80 mesh NAW Chromosorb W was used to separate and identify these two components.

SCHEME 2

a large number of g.l.p.c. analyzable products. Considerable gaseous and carbonaceous products were produced which were not collected or analyzed. The comparison of the yields of the 18 major products identified from this study is given in Table 1.

As shown, a fair yield of toluene and xylene was obtained. However, the amount is not substantial enough to support a methyl rearrangement mechanism. The magnitude of the yields of toluene and *p*-xylene observed in this work is generally found in the high-temperature pyrolysis of most organic materials (6–8).

However, inspection of Table 1 does give considerable information about the pyrolytic behavior of the arylisopropyl moiety at 800°. The elimination of methane[4] to yield styrenes (**1**) is greatly favored over dehydrogenation to give α-methylstyrenes (**2**) and the direct loss (or fragmentation of initial dehydrogenation) of the isopropyl group (**4**) is highly favored. The failure to isolate phenylacetylenes (**5**) would indicate that loss of methane (or its equivalent) from α-methylstyrenes is not favored or the resulting acetylene is not stable under these conditions. These observations are consistent with the relatively low yield of isopropylphenanthrenes and isopropylnaphthalenes observed in the thermal cracking of the resin acid molecule at 800° (10).

TABLE 1. Major pyrolysis products at 800 °C, contact time ≃ 3.9 s*

Compound	% Yield†		
	p-Cymene	Cumene	α-Methylstyrene

*Calculated according to method of Balandin and Tolstopyatov (5).
†Based on % g.l.p.c. volatile material in pyrolysate.
‡At least 90% the para isomer.
§Percent based on initial amount of compound pyrolyzed.

The relative yield of indene produced here is substantially greater than the amount observed when propylbenzene or other arylalkyl compounds are pyrolyzed (11). One possible rationale for increased indene formation is given in Scheme 2.

The dehydrogenated compound **2** would undergo methyl rearrangement to produce either the *o*-methylstyrene (**6**) or β-methyl compound **8**. Hydrogen abstraction from the arylmethyl **6** or vinyl methyl **8** would be expected to readily occur to yield intermediates **7** and **9**, which would be expected to undergo cyclization with the loss of hydrogen to give the indene **10**.

The above mechanism predicts that a substantial amount of 6-methylindene should be found during the pyrolysis of *p*-cymene. After a careful search through the pyrolysis products from *p*-cymene, the presence of the known 6-methylindene (12) could not be established. However, since the thermal stability of 6-methylindene under these conditions is not known, it would not

[4]The elimination of methane is most likely a two-step process, the first step being a loss of a methyl radical followed by the elimination or abstraction of a hydrogen atom (9).

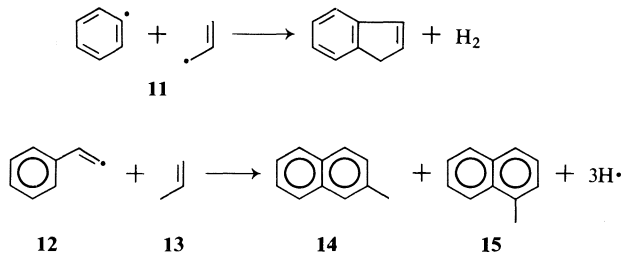

SCHEME 3

be safe to conclude that a mechanism such as Scheme 2 could not be the primary pathway for indene formation.

Another possible mode of indene formation is the attack of a C_3 unit, such as **11**, on a phenyl radical, followed by cyclization and dehydrogenation (Scheme 3). This mechanism has been previously proposed by Badger *et al.* (13) for the formation of indene during the pyrolysis of isoprene.

The high yield of naphthalene can be explained by the attack on styrene by a vinyl radical followed by cyclodehydrogenation. An analogous reaction, as shown in Scheme 3, between a styryl radical **12** and propylene **13** can be used to explain the equal yields of 2-methyl- (**14**) and 1-methylnaphthalene (**15**) obtained during the pyrolysis of α-methylstyrene and cumene. This observation of a 1:1 2-methyl- to 1-methylnaphthalene ratio, also, indicates that the main pathway for methylnaphthalene formation is via styryl propylene condensation, since it has been reported that hot tube reactions between methyl radicals and naphthalene generally greatly favor the formation of the 1-methyl compound (14).

The higher yield of 2-methyl- relative to 1-methylnaphthalene in pyrolysis products from *p*-cymene can be readily explained by the condensation of *p*-methyl styrene with a vinyl radical.

The other products in Table 1 which have not been discussed are most likely formed by coupling of pyrolysis fragments as discussed by Badger *et al.* (13) and Cohen (15).

This research was conducted while author Ray F. Severson was a National Research Council Resident Postdoctorate Research Associate, 1970. Mention of a company or product does not imply endorsement by the U.S. Department of Agriculture to the exclusion of others which may be equally suitable.

The Thermal Behavior of Methyl Dehydroabietate at 600–800 °C

RAY F. SEVERSON, WALTER H. SCHULLER, AND RAY V. LAWRENCE
Naval Stores Laboratory,[1] *Olustee, Florida 32072*

Received July 9, 1971

Methyl dehydroabietate was pyrolyzed on Vycor rod at 600, 700, and 800 °C with varying contact times. Some 40–60 products were observed upon g.l.p.c. analysis, with the number of products decreasing with increasing temperature and increasing contact time at 800 °C. Considerable carbon formation was found to occur at 800 °C and long contact times. The 24 major products which could readily be separated by preparative g.l.p.c. methods were collected and identified. The high yield of naphthalene-related compounds obtained is explained by the thermal rupture of the A-ring which is initiated by elimination of the carbomethoxy moiety.

Le dihydroabiétate de méthyle a été pyrolysé sur du Vycor en tige à 600, 700, et 800 °C en faisant varier le temps de contact. Environ 40 à 60 produits ont été mis en évidence par analyse en c.p.g.l., et il a été constaté que le nombre de produits diminue lorsque la température augmente, et lorsque le temps de contact à 800 °C augmente. Des quantités de carbone importantes se forment à 800 °C lorsque le temps de contact est important. Les 24 produits majeurs qui peuvent être facilement séparés par c.p.g.l. préparative ont été obtenus et identifiés. Le rendement élevé obtenu en produits apparentés au naphtalène est expliqué en invoquant la rupture thermique du cycle-A qui est initiée par l'élimination de la partie carbométhoxy.

Canadian Journal of Chemistry, **49**, 4027 (1971)

For personal use only.

The studies of the thermal behavior of resin acids in the past have been largely confined to relatively low temperatures (below 400 °C). It has been shown that the four conjugated dienoic resin acids and their methyl esters, neoabietic, palustric, abietic, and levopimaric, thermally isomerize, and disproportionation occurs in a slow irreversible step to yield dehydroabietic acid (1). It was thus not surprising that pot distillation decarboxylations of abietic acid and dehydroabietic acid produced the same relative mixture of hydrocarbons which retained the original phenanthrene ring system (2, 3).

In the first reported study of the reactions of resin acids under pyrolytic conditions (4), we found, at 800 °C on Vycor glass, abietic acid, levopimaric acid, dehydroabietic acid, and methyl dehydroabietate; all appeared to fragment in a similar manner to yield the same spectrum of products. In contrast to early findings at low temperature, at 800 °C, and fairly long contact times, the resin acids studied gave naphthalene derivatives as major products. No logical pyrolytic fragmentation mechanisms were deduced from the products formed under these high-temperature conditions (4).

With the assumptions that the C-ring of the dienoic resin acids would readily dehydrogenate to yield dehydroabietic acid and that methyl dehydroabietate would undergo the same pyrolytic fragmentation as the free acid, in this communication methyl dehydroabietate was pyrolyzed on Vycor glass at 600, 700, and 800 °C with varying contact times.[2] The products identified are used to propose a high-temperature pyrolytic fragmentation mechanism for conjugated dienoic resin acids.

Experimental

Methyl dehydroabietate was prepared by the reaction of the free acid with diazomethane and recrystallized from MeOH: $[\alpha]_D^{25}$ +59.8° (*c* 2.0, 95% EtOH). The pyrolysis apparatus used was the same as previously described (5). The percent yield of each product was determined by g.l.p.c. under conditions on OV-17 as reported earlier (5).

Typical Pyrolysis Run

A side-arm addition funnel was placed on top of the pyrolysis tube and the desired flow of nitrogen (400ml/min at STP), as measured by a low meter, was allowed to pass through the system. When the desired pyrolysis temperature had stabilized, 4 g of methyl dehydroabietate was melted by means of a heat lamp and added dropwise into the pyrolysis tube (the nitrogen flow was continued). When the run was complete, the trapped material was quantitatively removed with benzene and the sample was subjected to g.l.p.c. analysis.

Shorter contact times at 800 °C were obtained by

[1]One of the laboratories of the Southern Marketing and Nutrition Research Division, Agricultural Research Service, U. S. Department of Agriculture.

[2]The methyl ester was used since it can be easily pyrolyzed in the absence of solvent.

running the pyrolysis experiments at reduced pressure in the presence of nitrogen (400 ml/min at STP). A pressure regulator and a 33-l surge tank, placed after the trapping system, were used to maintain a constant pressure. The pressure readings were taken at the nitrogen inlet to the pyrolysis system. The 800° runs were run at pressures of 760 (contact time, 2.6 s), 449 (1.5 s), 104 (0.36 s), and 21 Torr (0.07 s).

Equation 1 was used to calculate contact times (τ) with the corresponding corrections being made when atmospheric pressure was not used. In eq. 1: V, free vol-

$$[1] \qquad \tau\ (s) = \frac{(60)\ (273)\ V}{(22\ 410)\ (M/t + a)\ T}$$

ume of tube in the heated area (volume of tube minus volume occupied by packing); M, moles of organic material being pyrolyzed at atmospheric pressure; t, addition time in min; a, velocity of carrier gas ml/min (nitrogen); T, absolute temperature of pyrolysis tube. All calculations were made assuming ideal gas behavior.

Preparative Gas–Liquid Phase Chromatography of Products

The products were collected in four fractions from the OV-17 column (Fraction I, OV-17 relative retention times 0.10 to 0.93; Fraction II, OV-17 relative retention times 1.13 to 1.40; Fraction III, OV-17 relative retention times 1.48 to 1.96; and Fraction IV, OV-17 relative retention times above 1.96). The products were re-collected off a 15 ft × 1/4 in. copper column packed with 10% SE-30 on 60/80 mesh NAW Chromosorb W with a flow rate of 90 ml/min of He under temperature conditions as given below.

Identification of Products

The i.r. spectra were run on a Perkin–Elmer 21 as specified. All u.v. data was obtained on a Spectronic 505 in 95% EtOH.

Mass spectra were obtained on a CEC 21-110B mass spectrometer by the direct inlet technique.

Products from Fraction I, Collected from SE-30 Column Using a Program 80–125° at 2.9°/min

Benzene

OV-17, 0.10;[3] SE-30, 2.7;[4] retention time and u.v. identical to authentic sample.

Toluene

OV-17, 0.16; SE-30, 4.5; retention time, i.r., and u.v. identical to authentic sample.

p-Xylene

OV-17. 0.27; SE-30, 5.4; retention time and u.v. identical to known compound.

Styrene

OV-17, 0.33; SE-30, 9.6; retention time, i.r., and u.v. identical to authentic sample.

α-Methylstyrene

OV-17, 0.50; SE-30, 14.0; retention time and u.v. identical to known compound.

[3]Retention time on OV-17 under conditions previously reported relative to tetradecane (relative retention time, 1.00) (5).

[4]Retention time (min) on SE-30 relative to point of injection.

Indene

OV-17, 0.64; SE-30, 16.1; retention time, i.r., and u.v. identical to authentic sample.

Naphthalene

OV-17, 0.93; SE-30, 23.6; retention time, i.r., and u.v. identical to authentic sample.

Products from Fraction II, Collected from SE-30 Column at 135°

2-Methylnaphthalene

OV-17, 1.13; SE-30, 17.8; retention time, i.r., and u.v. identical to known compound.

1-Methylnaphthalene

OV-17, 1.18; SE-30, 18.0; retention time, i.r., and u.v. identical to authentic sample.

1-Vinylnaphthalene

OV-17, 1.30; SE-30, 29.9; $\nu_{max}(CS_2)$, 983 and 914 (vinyl), 798 (three adjacent ArH), and 773 cm^{-1} (four adjacent ArH); u.v. data identical to literature (6).

2-Vinylnaphthalene

OV-17, 1.40; SE-30, 36.2; retention time, i.r., and u.v. identical to authentic sample.

Products from Fraction III, Collected from SE-30 Column at 160°

Acenaphthalene

OV-17, 1.38; SE-30, 11.8; retention time, i.r., and u.v. identical to authentic sample.

Acenaphthene

OV-17, 1.52; SE-30, 13.5; retention time, i.r., and u.v. identical to known compound.

2-Isopropenylnaphthalene

OV-17, 1.54; SE-30, 15.7; ν_{max} (CS_2), 895 (vinylidene and one ArH), 822 (two adjacent ArH), and 752 cm^{-1} (four adjacent ArH); u.v. data identical to literature (7); mass spectrum m/e, 168, 153 (M-CH_3), 152 (M-CH_4), and 141 (M-CH_2=CH).

1-Methyl-6-vinylnaphthalene

OV-17, 1.57; SE-30, 16.7; i.r. ν_{max} (CS_2), 983 and 895 (vinyl), 875 (one ArH), 827 and 833 (two adjacent ArH), and 810 and 750 cm^{-1} (three adjacent ArH); u.v. λ_{max} 238, 245, 253.5, 276, 285, and 295.5 mμ; mass spectrum m/e, 168, 152 (M-CH_3), and 141 (M-CH_2=CH). General i.r. spectra is consistent with 1,6-disubstituted naphthalene (9, 10). The u.v. spectra has the general characteristics of a 2-vinylnaphthalene (6, 7) with a slight bathochromic shift due to increased alkyl substitution (8).

1-Methyl-2-vinylnaphthalene

OV-17, 1.61; SE-30, 17.7; i.r. ν_{max} (CS_2), 984 and 897 (vinyl), 818 (two adjacent ArH), and 780 and 758 cm^{-1} (four adjacent ArH); u.v. λ_{max} 245.5, 253.5, 267, 277, 287, and 298.5 mμ; mass spectrum m/e, 168, 153 (M-CH_3), and 141 (M-CH_2=CH).

1-Methyl-6-isopropylnaphthalene

OV-17, 1.65; SE-30, 19.5; i.r. ν_{max} (CS_2), 873 (one ArH), 816 (two adjacent ArH), and 772 cm^{-1} (three adjacent ArH); u.v. λ_{max} 210, 227.5, 261–264, 271.5, 289, 293, and 300.5 mμ; mass spectrum m/e, 184, 169 (M-CH_3), 153 (169-CH_4), and 141 (M-C_3H_7).

A Substituted Vinylnaphthalene

OV-17, 1.73; SE-30, 24.0; i.r. ν_{max} (CS_2), 983 and 902 (vinyl), 840, 766, 746, 734, 272, and 683 cm^{-1}; mass

spectrum *m/e*, 184, 182, 180, 178, 169, 167, 165, 157, 155, and 153; u.v. λ_{max} 208.5, 230, 245.5, 277, 287.5, and 299 mμ; data is consistent with a 1- or 2-vinylnaphthalene derivative.

1-Ethyl-6-vinylnaphthalene

OV-17, 1.76, SE-30, 25.5; i.r. ν_{max} (CS_2), 983 and 900 (vinyl), 880 (one ArH), 808 (two adjacent ArH), and 760 cm^{-1} (three adjacent ArH); u.v. λ_{max} 246, 253, 277, 285.5, and 296 mμ; mass spectrum *m/e* 182, 180 ($M-H_2$), 178 ($M-2H_2$), 167 ($M-CH_3$), 165 ($182-CH_3$) 155 ($M-CH{=}CH_2$), 154 ($M-CH_2{=}CH_2$), and 153 ($M-CH_2CH_3$).

2,6-Divinylnaphthalene

OV-17, 1.83; SE-30, 27.5; i.r. ν_{max} (CS_2), 984 and 900 (vinyl), 888 (one ArH), and 810 cm^{-1} (two adjacent ArH); u.v. λ_{max} 232, 240–242, 254.5, 286.5, 297, and 310 mμ; mass spectrum *m/e*, 180, 178 ($M-H_2$), 154 ($M-CH{=}CH$), 153 ($M-CH{=}CH_2$), and 152 ($M-CH_2{=}CH_2$).

4-Vinylacenaphthalene

OV-17, 1.86; SE-30, 29.7; i.r. ν_{max} (CS_2), 982 and 902 (vinyl), 873 (one ArH), 763 (three adjacent ArH), and 728 cm^{-1} (*cis*, $CH{=}CH$); u.v. λ_{max} 211, 232.5, 254.5, 263–264, 323, and 334 mμ; mass spectrum *m/e*, 178, 176 ($M-H_2$), 165 (M-CH), 164 ($M-CH_2$), 163 ($M-CH_3$), 153 ($M-CH{=}C$), 152 ($M-CH{\equiv}CH$), 151 ($M-CH{=}CH_2$), and 150 ($M-CH_2{=}CH_2$).

4-Vinylacenaphthene

OV-17, 1.92; SE-30, 34.5; i.r. ν_{max} (CS_2), 983 and 900 (vinyl), 870 (one ArH), and 764 cm^{-1} (three adjacent ArH); u.v. λ_{max} 247, 256, 284, 294, 306, 330, and 345 mμ; mass spectrum *m/e*, 180, 178 ($M-H_2$), 176 ($M-2H_2$), 167 (M-CH), 166 ($M-CH_2$), 165 ($M-CH_3$), 153 ($M-CH{=}CH_2$), and 152 ($M-CH_2{=}CH_2$).

4-Isopropylacenaphthene

OV-17, 1.96; SE-30, 36.3; i.r. ν_{max} (CS_2) 862 (one ArH) and 762 cm^{-1} (three adjacent ArH); u.v. λ_{max} 231, 249, 290 (282–290 broad, unresolved), and 323 mμ; mass spectrum *m/e*, 196, 183 (M-CH), 182 ($M-CH_2$), 181 ($M-CH_3$), 180 ($M-CH_4$), 168 ($M-CH_2{=}CH_2$), 167 ($M-CH_2CH_3$), 166 ($M-CH_2{=}CH_2$, H_2), 165 ($M-CH_3$, CH_4), 154 (M-isopropenyl), and 153 (M-isopropyl).

Products from Fraction IV, Collected from 10% SE-30 Column Using a Temperature Program 215–275° at 2.9°/min

Phenanthrene

OV-17, 2.02; SE-30, 8.0; retention time, i.r., and u.v. identical to authentic sample.

1-Methylphenanthrene

OV-17, 2.11; SE-30, 10.8; retention time and u.v. identical to known compound.

Results and Discussion

Methyl dehydroabietate was pyrolyzed neat on Vycor rod at 600, 700, and 800 °C with varying contact times. Some 40–60 different products were observed upon g.l.p.c. analysis, with the number of products decreasing with increasing temperature and increasing contact time at 800 °C. Only those compounds which could be readily separated by g.l.p.c. methods and present in approximately a 1% yield were collected and identified. The 24 major products identified and their relative yields are given in Table 1. Considerable carbon formation was observed at 800 °C and long contact times.

The amount of carbonaceous products decreased with decreasing contact time and temperature. Also in the 800°, 2.9 s contact time run, the products were taken up in acetone and a 7% yield of benzene was observed.

Examination of Table 1 shows the following trends: as temperature increases and contact time at 800° increases, the products tend to fragment to the most thermally stable aromatic compounds, *i.e.*, naphthalene, acenaphthylene, and phenanthrenes,[5] and the yield of g.l.p.c. volatile products decreases.

Thus, the compounds found at 800 °C and a long contact time from the pyrolysis of abietic, levopimaric, and dehydroabietic acid (5) have resulted from considerable fragmentation of the initially formed products. However, the products identified at lower temperatures and shorter contact times do give sufficient information to allow for reasonable explanation of the pyrolytic fragmentation pathways of the dienoic resin acids and dehydroabietic acid.

The large yield of naphthalene and naphthalene derivatives must arise from cleavage in the A-ring of the parent molecule. Precedence for rupture of the A-ring is the fact that all compounds studied previously are converted to dehydroabietic acid under relatively mild conditions (1, 4, 11) and the phenyl nucleus is very stable to heat (12). Cleavage of the A-ring is most likely facilitated by the ease with which resin acids undergo decarboxylation (differential thermal analysis and thermogravimetric analysis show that resin acids began to readily decarboxylate at 275 °C (13)) since fragmentation does not appear to readily occur until the carboxylate moiety is lost. In all the high-temperature studies to date only decarboxylated products have been isolated.

The initial fragmentation of methyl dehydro-

[5]We found that at 800 °C, contact time 3.9 s, in benzene solution, 2-vinylnaphthalene yielded toluene, styrene (6%), naphthalene (27%), 2-methylnaphthalene (5%), phenanthrene (3%), and 33% unreacted; 1-methylnaphthalene yielded toluene (2%), naphthalene (17%), 2-methylnaphthalene (2%), and 72% unreacted; acenaphthene yielded naphthalene (8%), acenaphthylene (72%), and 1% unreacted. Naphthalene, acenaphthylene, and phenanthrene were very stable under the pyrolysis conditions.

abietate (**1**) as proposed by Arbuzov and Khiamatullina (2) would be expected to result in the loss of the carbomethoxy group to yield intermediate **2** (Scheme 1). The high resolution mass spectral data on methyl dehydroabietate is also in accord with the initial formation of **2**. Labeling experiments (14) have shown that elimination of carbomethoxy group via the extraction of the 5α-hydrogen to yield the 4,5-dehydro compound **2** is the most highly favored process. Compound **2** would then be expected to thermally equilibrate to yield **3** and **4**.

Hydrocarbon **2** can undergo a retro Diels–Alder (15) reaction losing ethylene to yield **5** (Scheme 2). Aromatization and other fragmentation would yield those products indicated. The A-ring fragmentation of **3** resulting in the loss of a

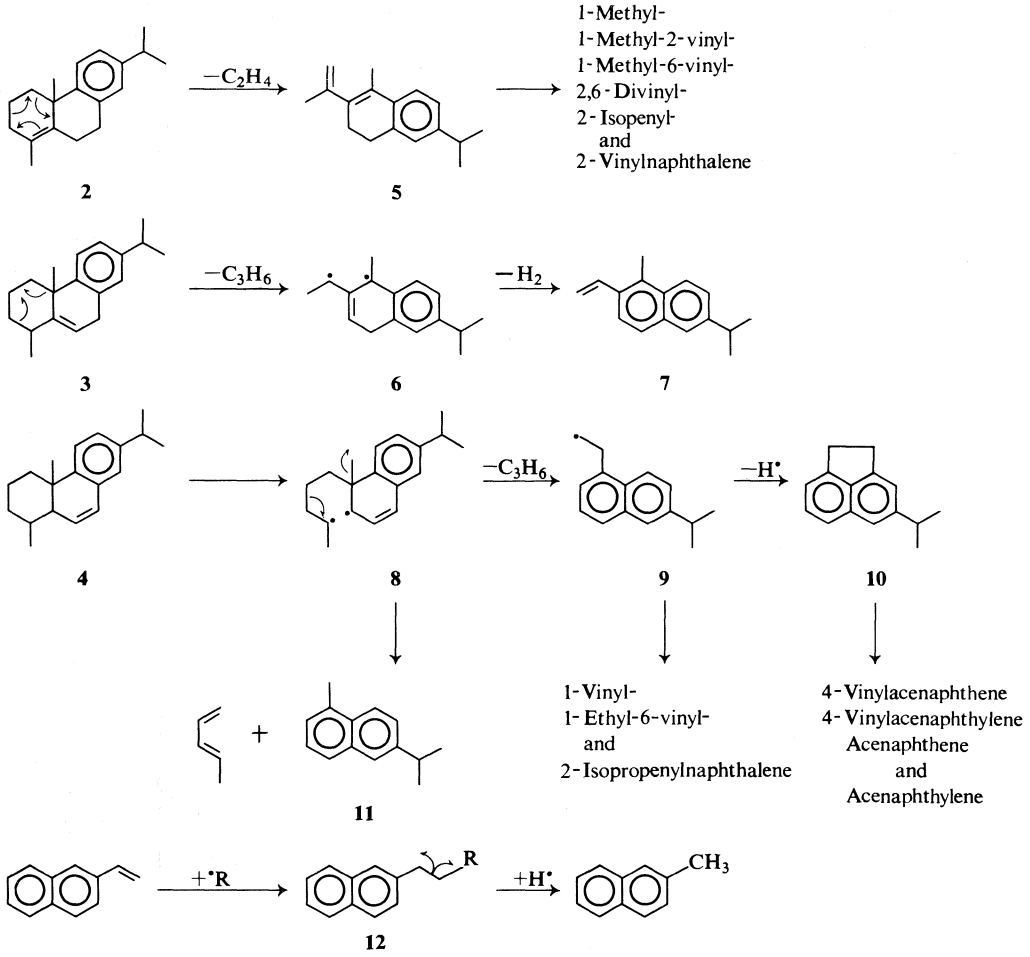

SCHEME 2

C_3H_6 fragment would yield the benzyl-allyl stabilized diradical **6**. Dehydrogenation would yield **7** which could also decompose to yield those products observed from **5**. A homolytic β-cleavage of the C_4—C_5 bond in **4** would result in the formation of the fairly stable diradical **8**. An elimination of the C-17 methyl and the loss of propene would yield 4-isopropylacenaphthene (**10**) which could continue to dehydrogenate and fragment to yield 4-vinylacenaphthene, 4-vinylacenaphthylene, acenaphthene, and acenaphthylene. β-Elimination of a hydrogen atom in **9** would give 1-vinylnaphthalene, while 1-ethyl-6-vinylnaphthalene could result from hydrogen abstraction and fragmentation of isopropyl group. The loss of ethylene from **9** and dehydrogenation of the isopropyl moiety would lead to 2-isopropenylnaphthalene. 1-Methyl-6-isopropylnaphthalene (**11**) could form directly from **8** by the elimination of a C_5 unit which could be expected to disproportionate to yield 1-methylbutadiene.

The higher yield of 2-methyl- relative to 1-methylnaphthalene was an unexpected observation. The cleavage of the A-ring of the resin acid molecule would directly lead to the 1-methyl derivative. Rearrangement of C-19 or -20 methyls to the 5 position or one of the isopropyl methyls to the 12 or 13 position would be required to produce a 2-methylnaphthalene directly from the parent molecule. Rearrangement of the C-19 or -20 methyls was not appealing since upon pyrolysis of 1-methylnaphthalene very little 2-methyl was formed and it has been reported (15) that hot

tube reactions between methyl radicals and naphthalene generally greatly favor the formation of the 1-methyl compound.

A study on the thermal behavior of cumene, *p*-cymene, and α-methylstyrene (5) also indicates that the high yield of 2-methylnaphthalene does not result from a methyl transfer from the isopropyl moiety to the ring system.

It thus appears that a mechanism such as proposed for the formation of toluene during the pyrolysis of styrene (12) is the most probable mode of which 2-methylnaphthalene is formed. The attack of a phenyl naphthyl, or some other radical on 2-vinylnaphthalene would result in the formation of a species such as **12**. β-Fission of the resulting ethylene linkage would be expected to occur readily, and the resulting radical could abstract hydrogen to give 2-methylnaphthalene. This mechanism is supported by the large yield of 2-methylnaphthalene obtained during the pyrolysis of 2-vinylnaphthalene.

Phenanthrene and 1-methylphenanthrene could be formed by complete aromatization of the resin acid molecule with loss of the required alkyl groups. The low yield of 1-methylphenanthrene could indicate that demethylation is a favored process or that the majority of the phenanthrene is formed by the reductive coupling of 2-vinylnaphthalene and styrene (12). The apparent complete lack of retene in the pyrolysate and increasing yield of phenanthrene with increasing temperature and longer contact times would also indicate that the primary route of phenanthrene formation is via 2-vinylnaphthalene.

The other products in Table 1 which have not been discussed are most likely formed by coupling of pyrolysis fragments as discussed by Badger *et al.* (16) and Cohen (12).

This research was conducted while author Ray F. Severson was a National Research Council Resident Postdoctorate Research Associate, 1970. The authors wish to thank Dr. Bernard A. Parkin, Jr., of the Naval Stores Laboratory for many helpful discussions and aid in developing the pyrolysis apparatus, Mr. Gordon S. Fisher of the Naval Stores Laboratory for assistance in interpretation of u.v. and i.r. spectra, and Mr. Verne W. Tripp and Mr. James B. Stanley of the Southern Regional Research Laboratory, SMNRD, for mass spectral analysis.

Photoelectron Spectra and Bonding in Some Halosilanes

D. C. Frost, F. G. Herring, A. Katrib, and R. A. N. McLean
The Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

and

J. E. Drake and N. P. C. Westwood
Department of Chemistry, University of Windsor, Windsor, Ontario

Received June 29, 1971

The photoelectron spectra of some halosilanes, SiH_3X (X = F, Cl, Br), SiH_2X_2 (X = F, Cl), and $SiHCl_3$ have been studied, to obtain information on the bonding, especially (p → d)π back-bonding to silicon. The spectra were assigned on simple orbital overlap grounds, by comparison with the carbon analogues and by use of CNDO/2 calculations. Few discrepancies were found, but in these cases the first method was preferred. There is ample evidence from the individual ionization potentials and by comparison of the spectra with those of the analogous carbon compounds for interaction of the halogen pπ electrons with the silicon d orbitals. This is also indicated by some empirical calculations on the chlorosilanes, which also confirm the assignment of the spectra.

It can also be shown that the ionization potentials are consistent with the silicon–halogen σ bond strength decreasing through the series $H_3SiF > H_3SiCl > H_3SiBr$.

Les spectres photoélectroniques de quelques halosilanes SiH_3X (X = F, Cl, Br), SiH_2X_2 (X = F, Cl), et $SiHCl_3$ ont permis d'étudier le mode de liaison au silicium et plus particulièrement le renforcement de la liaison π(p → d). Les spectres sont attribués en considérant le simple recouvrement des orbitales par comparaison avec les analogues du carbone et en utilisant les calculs CNDO/2. Bien que les résultats soient peu divergents, on préfère dans ces cas, utiliser la première méthode. L'interaction entre les électrons pπ des halogènes et les orbitales d du silicium, est fortement mise en évidence par les potentiels d'ionisation individuels et par comparaison avec les spectres des composés analogues du carbone. Elle est montrée aussi par quelques calculs empiriques qui confirment également l'attribution de spectres.

Il est aussi possible de montrer que les potentiels d'ionisation sont en accord avec la force de la liaison entre le silicium et l'halogène, qui décroît dans la séquence: $H_3SiF > H_3SiCl > H_3SiBr$.

Canadian Journal of Chemistry, **49**, 4033 (1971)

Introduction

Many of the properties of compounds containing silicon bonded to elements with π electrons, either lone pair or bonding have been explained in terms of the interaction of the π orbital with a symmetry related d orbital on silicon to form a (p → d)π bond. A recent review gives an excellent survey of the available evidence (1), but we particularly refer to the physical properties in a series of silicon compounds, which do not conform to what would be expected by simply comparing with the carbon analogues, taking into account the electronegativity difference. Among such properties there are changes in shape and opening of bond angles, anomalously short Si—X bond lengths, bond energies which are greater than expected, low base strengths and dipole moments of silyl species, and higher transition energies in u.v. spectra (see also ref. 2).

Although (p → d)π bonding seems a reasonable explanation for most of these observations (there are some anomalies where it is not, *e.g.* n.m.r. chemical shifts (1)), there is very little real evidence that this is the cause and not any other. For example in one good calculation which shows the presence of (p → d)π bonding in trisilylamine (3), it was recognized that the "lone pair" can interact with an e orbital on the SiH_3 group which may only have a small amount of d character.

We set out therefore to use photoelectron (p.e.) spectroscopy to discover more of the nature of the π or "lone pair" electrons on the atom adjacent to silicon. One would expect on electronegativity grounds that the ionization potential (i.p.) of these π electrons would move to lower energy compared to the carbon analogue, and any deviation from this would indicate that these electrons were involved in bonding with the silicon atoms or groups including the silicon atom. Examination of the other i.p.'s of the molecule could aid with the assignment of the type of interaction involved. If the electrons on the carbon analogue were virtually non-bonding, ionization would produce a species with a very similar

Franck–Condon envelope and hence a fairly sharp band in the p.e. spectrum. Should the electrons on the silicon species be involved in some bonding there would be a change in geometry on ionization and excitation to several vibrational levels could be expected, *i.e.* a broader band would be produced.

Due to our interest in organometallic bases (4*a*), it was decided first to investigate the available methyl silicon compound with atoms of groups **5**, **6**, and **7** attached to the silicon (4*b*). However, it was soon discovered that ionization from orbitals situated mainly on the methyl groups interfered so much to make reasonable deductions difficult. It was then decided to study some simple non-methylated silyl compounds, and the most readily available of these were the halo-silanes, SiH_nX_{4-n}(n = 0–3.) The tetrahalosilanes had already been studied (5–8*a*), although only in the case of SiF_4 was any particular attention paid to the involvement of Si d orbitals (5). (More recently Bassett and Lloyd (8*b*) have also considered d orbital interactions.) In this case CNDO/2 calculations were performed with and without the inclusion of Si d orbitals in the basis set and better agreement with the observed spectrum was obtained with the former.

Two main reasons for choosing the halosilanes were that (*a*) they are the simplest species known with a "lone pair" atom attached to silicon, which should result in obtaining the maximum amount of information from the p.e. spectra and (*b*) many physicochemical studies have been carried out on them and it would be useful to compare the results of these methods with the p.e. spectra. Some of the anomalous properties of the halosilanes which it would be hoped could be rationalized are as follows (1, 2, 9): (*1*) The silicon–halogen bond lengths are less than the sum of the Pauling radii with most disagreement for the lighter halogens, but through the whole series of halosilanes there is very little change in the silicon–hydrogen bond length. (*2*) All SiH_3X species have lower dipole moments and nuclear quadrupole coupling constants than the analogous carbon compounds. (*3*) The Si–X bond energies are higher than estimated on the basis of comparison of the ratio of the energies of the silicon and carbon analogues with that of SiH_4 and CH_4. (*4*) The u.v. absorptions of SiH_3Cl are shifted to shorter wavelengths compared to CH_3Cl (10). (*5*) There is very little change in the average Si—H stretching frequency through the series SiH_3X (X = F, Cl, Br, I). (*6*) Although the proton chemical shifts for most series of halosilanes move to lower field with increasing electronegativity the opposite is true through the series SiH_3F, SiH_2F_2, $SiHF_3$.

Properties *1–4* have all been rationalized in terms of (p → d)π bonding increasing the Si—X bond order (and hence the bond length (1), bond energy (5) and the stability of the electronic ground state (6)) and decreasing the lone pair character on the halogen (and hence the dipole moment and quadrupole coupling constant). If there is as expected very little use of d orbitals in the Si—H bonds then the properties of these bonds would not vary much with the halogen as the most electronegative would have the greatest (p → d)π bonding and thus the charge at the silicon would vary little. Any interaction of the "lone pair" orbitals with Si—H σ orbitals was of course considered negligible. This would then explain properties *1* and *5*. Of course, in the days when n.m.r. chemical shifts were considered purely as a function of electronegativity this would conflict slightly with the first part of property *6*, although even here the difference through a series was not as great as in the analogous series of carbon compounds. The deviation in the fluoro series was rationalized as being due to increased (p → d)π bonding.

As many of the properties of the halosilanes depend on the postulated (p → d)π bonding we set out to use p.e. spectroscopy to try to determine how much influence it has. It was decided that a study of one whole series SiH_3X (X = F, Cl, Br, I) and at least one series SiH_nX_{4-n} (here X = Cl) would be sufficient with comparison with the previously studied carbon analogues to give the information needed. SiH_2F_2 was also studied. The interpretation of the p.e. spectra can be aided by using the results of semi-empirical calculations such as CNDO/2, although care must be exercized (11), so it was decided to perform such calculations on the molecules studied here. It would also be instructive to see the amount of d character obtained for the various molecular orbitals in these calculations.

After completion or our work a note appeared on some of the molecules studied here, *i.e.* the SiH_3X species (12). In this, the breadth of the lowest energy band in the p.e. spectra of X = Cl, Br, I, assigned to ionization of the mainly "lone pair" electrons, and the shift to higher energy compared to the carbon compounds, was cited

For personal use only.

as evidence for (p → d)π bonding. The possibility of p → σ* (SiH_3) bonding was not considered as there was no excitation of any SiH vibration. However, there are a number of cases in which expected vibrations do not appear in the p.e. spectrum and we do not believe that there is sufficient evidence to discount the latter possibility. In fact, our calculations show that this effect is considerable and therefore we believe that some other indications must be looked for in the p.e. spectra of halosilanes to indicate (p → d)π bonding (13).

Experimental

SiH_3Cl and SiH_2Cl_2 were prepared according to the method of Hollandsworth *et al.* (14), by passing SiH_4 (Matheson Co.) over heated silver chloride about ten times, and collecting the products at −126° (methylcyclohexane slush). Pure SiH_3Cl was obtained by passing the products through a −112° trap (*n*-butyl bromide slush). Ninety-five percent pure SiH_2Cl_2 can be obtained by passing the residue in the −112° trap through a −95° trap (toluene slush), the residue in this case being $SiHCl_3$.

SiD_3Cl and SiD_2Cl_2 were prepared as above from SiD_4 and AgCl. SiD_4 was prepared (15) by the action of $LiAlD_4$ on $SiCl_4$ in diglyme *in vacuo*. The products are distilled through a −126° trap to remove $SiCl_4$ and solvent, and pure SiD_4 is collected at −196°.

SiH_3F and SiH_2F_2 were prepared by the reaction (16) of SiH_3Cl and SiH_2Cl_2 respectively with antimony trifluoride and purified by passing through a −126° trap (to remove chloro-silanes). These species especially were kept in the gas phase as short a time as possible.

SiH_3Br and SiH_2Br_2 were prepared by the reaction of a three to one excess of SiH_4 with BBr_3 at 0 °C for 6 h (17). SiH_3Br was obtained by passing the products through a −95° trap. The residue from the −95° trap yielded SiH_2Br_2 by passing through a −78° trap (acetone to solid CO_2). Again these species were always kept at −196°. No spectrum of SiH_2Br_2 was obtained as it seemed to decompose to SiH_4, HBr, and SiH_3Br in our spectrometer.

The purity of all samples was tested by comparing the n.m.r. and i.r. spectra with the literature values for the pure species (18, 19). The samples were stored at −196° until used.

The p.e. spectrometer employed a 180 degree 4 in. radius analyzer, and the 21.22 eV radiation emanated from a 2450 mHz microwave discharge in helium.

The approximate molecular orbital calculations performed in this work were as described by Santry and Segal (20) including in the basis set 3d orbitals for all the second row elements.

The bond lengths employed were obtained for each molecule as follows: H_3SiF (21), H_2SiF_2 (22), H_3SiCl (23), H_2SiCl_2 (24), and $HSiCl_3$ (25). The bond angles were assumed to be tetrahedral.

Results and Discussion

We shall discuss the p.e. spectrum and calculations for each molecule in order, and when a series has been completed *e.g.* SiH_nX_{4-n} we shall describe the trends in the discussion of the last molecule. We have referred to the studies of the halomethanes by Potts *et al.* (26) and Dixon *et al.* (31) to aid our interpretation of the p.e. spectra of the halosilanes.

H_3SiF

The p.e. spectrum of this molecule (see Fig. 1 and Table 1) has three bands of relative intensities 2:3:1 with resolved vibrational structure in the last one, and on the high energy side of the second band. This latter structure and the intensity ratios indicate two ionization processes in the second band. The first band has two components, but as this is assigned to the e(SiH_3) orbital, it is expected to have a Jahn–Teller contour. The vertical i.p.'s for the four processes are 12.80, ≈16.13, ≈16.38 (uncertain, as this only appears as a shoulder), and 19.29 eV.

The CNDO/2 calculations including 3d orbitals on Si predict four ionization potentials below 21.22 eV at 12.3, 15.75, 17.27, and 18.42 eV, corresponding to ionization from 3e(σSiH_3), 7a_1(σF—SiH_3), 2e(*n*F), and 6a_1(Si3s) orbitals respectively (major component in brackets). Considering the approximations involved, the agreement appears reasonable.

The first band, corresponding to ionization from the 3e orbital, has maxima at 12.58 and

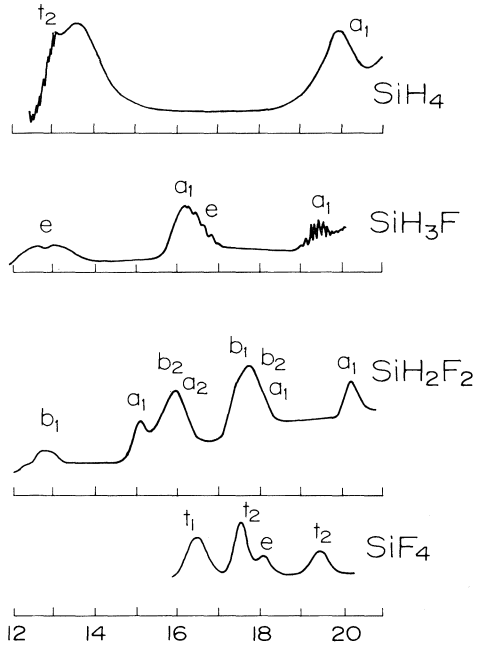

FIG. 1. Photoelectron spectra of fluorosilanes.

13.02 eV, *i.e.* a Jahn–Teller splitting of 0.44 eV which is somewhat less than that in CH_3F (0.5 eV).

The CNDO/2 calculations indicate that there is some Si—F π^* character in this mainly Si—H bonding orbital. This effect is even more obvious in CH_3F (27), and this can be seen by comparing the first i.p.'s of CH_3F and SiH_3F with those of CH_4 and SiH_4. As expected there is quite a large drop from CH_4 (13.97 eV) (27) to SiH_4 (12.60 eV) (28). However the first i.p. in CH_3F (13.04 eV) is very close to that of SiH_3F (12.80 eV); the unexpectedly large reduction in the first i.p. of CH_3F is due to the much larger π^* character compared to the SiH_3F. This in turn, could be caused by better overlap in the orbitals in CH_3F and also by the possibility of F $p\pi \rightarrow$ Si $d\pi$ interaction in SiH_3F which is not available in CH_3F.

As mentioned above, the second band extending from 15.5–16.8 eV has two components with vertical i.p.'s 16.13 and 16.58 eV, and it would appear that these correspond to the $7a_1$ and 2e orbitals predicted by CNDO/2 calculations to be at 15.75 and 17.27 eV respectively. However a Gaussian analysis of the band using the mirror image of the low energy trace to complete the curve for the first ionization process indicates relative intensities 16.13 eV curve : 16.38 eV curve of $\approx$1:1. Normally it has been observed that when two i.p.'s are close together a doubly degenerate one will have a band about twice the area of a non-degenerate one but there is no real indication of this in the present spectrum. It would have been hoped that the structure on the second component of the band would confirm the order predicted by the CNDO/2 calculations. The spacing of the five peaks of the second component are 1470, 1420, 1400, and 1340 cm^{-1}, which is most likely to correspond to a progression in the symmetric SiH_3 stretching vibration considerably reduced from 2206 cm^{-1} in SiH_3F (18). It would have been thought more likely for this mode to be excited by ionization from a_1 (mainly σ SiH_3) orbital, but if as the calculation suggests the higher energy component is the e(*n*F), then there is a considerable bonding interaction between the fluorine "lone pair" orbital and the SiH_3 bonding orbital. In fact it suggests that the 3e and 2e levels can be considered as antibonding and bonding levels respectively produced by the interaction of the fluorine $2p\pi$ and σ (SiH_3) orbitals. Although we should prefer the assignment of the structure on the basis of ionization from an a_1 orbital, it is possible to reconcile either assignment and we follow the order given by the calculation.

The 2e orbital is almost all fluorine lone pair with an almost equal small amount (5%) of Si p and d character, but from the breadth of the p.e. band this seems to be a considerable underestimation. In CH_3F the band appears to be somewhat wider and is at a higher energy ($\sim$17 eV) which is in agreement with our earlier suggestion that there is a greater interaction between the F $p\pi$ orbitals and the CH_3 moiety in CH_3F than in SiH_3F. The fact that the F lone pair electrons are at a higher orbital energy in SiH_3F than in CH_3F probably also means that there is no large stabilization of these electrons by the Si $d\pi$ orbital as is also shown in the CNDO calculations. The $7a_1$ orbital is mainly Si—H and Si—F bonding.

The third band in the spectrum consists of a progression of eight peaks from 19.10–19.81 eV with spacings of $\sim$ 800 cm^{-1}. This band is assigned to ionization from the $6a_1$ orbital in accord with the CNDO/2 calculations. The progression could be in ν_3, Si—F stretch (870 cm^{-1} in SiH_3F) or ν_2, H_3Si wag (990 in SiH_3F). As most of the bonding character in this orbital is Si—F σ bonding, one would expect the former vibration to be excited. However, this would mean a very small decrease in frequency from the molecule to the ion, which would be surprising for a bonding electron. As there is some H—F antibonding character, it is more likely that the H_3Si wag has been excited.

Purely on the evidence presented here we cannot say that there is extensive (p $\rightarrow$ d)π bonding in this molecule. Any stabilization of the F lone pair could be caused by the same type of interaction as in CH_3F.

SiH_2F_2

The p.e. spectrum of SiH_2F_2 below 21.22 eV has five distinct broad bands in the ranges (*a*) 12.3–13.4, (*b*) 14.6–15.54, (*c*) 15.54–16.67, (*d*) 16.92–18.77, and (*e*) 19.83–20.85 eV with no apparent vibrational structure. This pattern is exactly analogous to the spectrum of CH_2F_2, except that in general the bands have moved to lower energy in SiH_2F_2. Eight i.p.'s are predicted below 21.22 eV. The next i.p. is predicted to be as high as 36 eV and therefore we should expect eight

[a]Relative intensity in brackets.

or less i.p.'s. In fact bands *c* and *d* above appear to contain two and three components respectively, as the intensity ratios for the five bands are 3:4:8:12:3 and as these have obvious shoulders. As a result eight vertical i.p.'s can be distinguished and these are listed in Table 2 along with the values obtained from the CNDO/2 calculations and assignments based on these calculations. Of course, as was shown for SiH_3F, the order of observed and calculated i.p.'s are not necessarily the same, but as there is no structure observed on the bands it is not possible to assign the spectrum otherwise.

The assignment of the first two bands to b_1 and a_1 σ(SiH_2) orbitals is essentially correct as (*a*) these orbitals are derived from the t_2 orbital of SiH_4 at ~12.60 eV (see Fig. 1) whereas the lowest energy t_1 orbital of SiF_4 is at 16.46 eV (*b*) the CNDO/2 calculations give fairly good agreement with the observed value, and the slight reduction in energies calculated is probably due to overestimation of the interaction with lower orbitals, and (*c*) the order $b_1 > a_1$ is also the order of the highest energy orbitals in CH_2F_2.

The next two lowest energy i.p.'s are calculated to be from b_2 orbitals, the lower from a F lone pair orbital and the higher a Si—F σ bonding orbital. It is surprising that these two are so close together. The a_2 orbital which is purely F lone pair in CH_2F_2 has been relatively stabilized in SiH_2F_2 and this is due to the effect of the Si 3d orbitals, and the increased distance between the F atoms (see below and ref. 13). The mainly lone pair orbitals a_2, b_1, and a_1 are all shown to be stabilized by (p → d)π bonding, and this may be the reason why they are at lower energy than the b_2 (Si—F) σ bonding orbital. Despite this explanation the position of the a_2 band is questionable as reference to Fig. 1 indicates. The a_2 orbital can only be derived from the t_1 orbital of SiF_4 and it is highly unlikely that it would move to higher energy than the t_1 orbital of SiF_4. We therefore prefer the assignment given in Fig. 1 to the calculated assignment in Table 2. All the i.p.'s of SiH_2F_2 show a slight decrease in energy compared to the analogous carbon compounds as expected, except for the lowest energy b_2 and a_2 i.p.'s. These are the lone pair orbitals which are least influenced by bonding with the σ(SiH_2) framework. If the influence of the F....F distance on the energy of these orbitals were small the relative stabilization compared to CH_2F_2 would be a better indication of (p → d)π bonding than the comparison between CH_3X and SiH_3X as these orbitals have no interaction with the σ(Si—H) system. A comparison of the spectra through the series SiH_4 → SiF_4 (see Fig. 1) should reveal some interesting points about the bonding. The bands at ~13 eV in the fluorosilanes are clearly derived from the t_2 band in SiH_4, but to get a measure of Si—H bonding it seems reasonable to try to consider the average values of all orbitals involved in mainly Si—H bonding. If we make the gross assumption that the orbitals we assign as being mainly Si—H σ bonding are purely due to this, then we can estimate the weighted average σ Si—H i.p. as SiH_4, 12.6; SiH_3F, 13.91, and SiH_2F_2, 14.03 eV. There is obviously some Si—F σ bonding involved in the a_1 orbital of the latter two, and this would cause an increase in the i.p. However as the a_1 σ(Si—F) orbital is fairly close to the lowest σ(Si—F) orbital in SiF_4 (t_2), σ(Si—F) bonding is not going to have an overwhelming effect on the lower orbital. From the figures, therefore, it is surprising that the second F atom has so little effect. The average σ M—H i.p. does not seem to give a very good indication of the bonding properties of the M—H bond, although the correct trend is indicated. For example, the average Si—H stretching frequencies (18) through the series SiH_4, SiH_3F, and SiH_2F_2 are 2189, 2201, and 2247.5 cm^{-1} which could

indicate a progressive increase in Si—H bond order. A simple comparison of the lowest energy σ(Si—H) orbital also gives this expected order *i.e.* SiH_4 (12.6), SiH_3F (12.8), SiH_2F_2 (12.85 eV). Comparison of the whole series of spectra with the analogous carbon series shows almost identical positioning of the bands with respect to one another except for the relative increase in the lower b_1 and a_1 i.p.'s in SiH_2F_2. However, on the whole the bands are better resolved from ones in the silicon series. The chlorosilanes are the only series for which we have all the members $SiH_{4-n}Cl_n$(n = 0, 1, 2, 3, and 4) and the photoelectron spectra of these are shown in Fig. 2. We shall discuss each molecule separately and then compare the whole series.

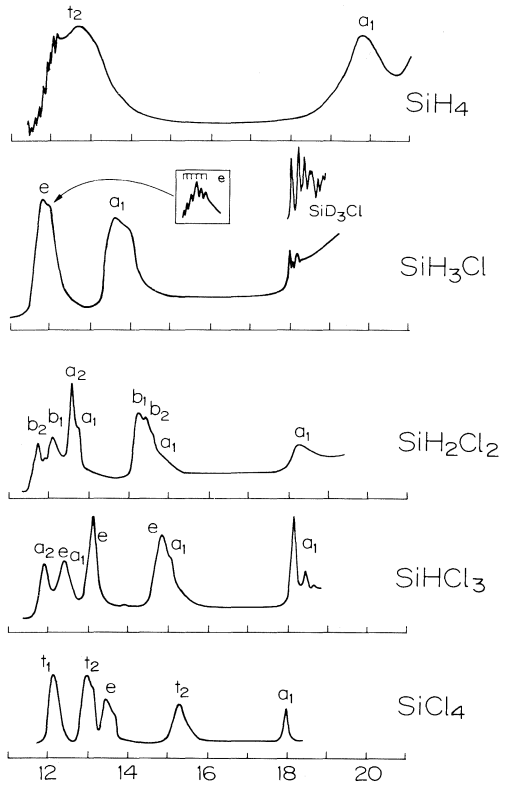

FIG. 2. Photoelectron spectra of chlorosilanes.

SiH_3Cl

SiH_3Cl has three bands below 21.2 eV in its p.e. spectrum (Fig. 2, Table 3) 11.3–12.3, 13.1–14.7, and 17.9–18.9 eV with intensity ratios 6:9:2. One expects to observe four i.p.'s below 21.22 eV corresponding to ionization from e[*n*(Cl)], a_1[σ(Si—Cl)], e[σ(SiH_3)], and a_1[σ-(SiH_3)] orbitals. The observed spectrum seems to correspond to this series if the second and third i.p.'s are together in the second band. The observed maxima for these bands are 11.65, 13.51, 13.99, and 18.23 eV respectively, and these can be compared with values of 11.42, 13.08, 13.66, and 17.16 eV obtained in a CNDO/2 calculation. However it is possible that the assignment of the second and third i.p.'s could be interchanged.

The first band has a barely resolved progression with a separation of 500 cm^{-1} which corresponds to the Si—Cl stretching vibration at 545 cm^{-1} in SiH_3Cl. This would be expected to be excited if the Cl lone pair electrons were involved in extensive bonding to the silicon. As pointed out previously (12) other indications of this influence are obvious from the spectra. Firstly, the band is much broader in SiH_3Cl (band width $w_{1/2}$ = 0.4 eV) than CH_3Cl ($w_{1/2}$ = 0.2 eV) and HCl ($w_{1/2}$ = 0.1 eV), as expected for ionization from an orbital with more bonding character. Also the band has moved to higher i.p. than in CH_3Cl, which is the opposite from what one would expect on electronegativity grounds. The CNDO/2 calculations give fairly good agreement for the energy of this i.p. but indicate that it has a high proportion of σ SiH_3 character with a fairly large π* contribution from the Cl lone pair. The major

For personal use only.

lone pair electron density, however, is calculated to be in the second highest e orbital. This does not appear to be correct as changing the halogen atom has a much greater effect on the lower e orbital than on the upper e orbital (*cf.* SiH_3Cl and SiH_3Br below). The calculation certainly describes the orbitals correctly as the antibonding and bonding combination of Cl lone pair and $\sigma(SiH_3)$ orbitals respectively, but it appears to interchange the centers of electron density. The upper e band is broad but the components caused by Jahn–Teller distortion are not obvious as in SiH_3F and SiH_3Br, probably because of the close proximity of the a_1 band.

The a_1 band at 18.23 eV with adiabatic i.p. 18.13 eV has signs of structure. Two vibrational components separated by 1800 cm^{-1} are clearly observed but in this region the rising background and very poor signal/noise ratio prevent the assignment of further peaks. The p.e. spectrum of SiD_3Cl showed this band much more clearly and six components of separation 1320 cm^{-1} were observed (see Fig. 2). The vibration which is excited is obviously ν_1 at 2201 in SiH_3Cl and 1581 cm^{-1} in SiD_3Cl (18). The reduction in stretching frequency in the ion is as expected for the removal of an electron from a bonding orbital, which in this case is mainly $\sigma(SiH_3)$. In other respects SiD_3Cl has an almost identical spectrum to SiH_3Cl.

SiH_2Cl_2

The spectrum of SiH_2Cl_2 (see Fig. 2 and Table 4) has three distinct bands below 13 eV with maxima at 11.70, 12.09, and 12.53 eV respectively of relative intensity 1:1:2. Obviously there are two processes involved in the last band which has a shoulder at $\approx$12.76 eV. Between 13.8 and 15 eV there is a broad band three and one half times as intense as the first two bands and there is a further weak band at 18.32 eV. Eight i.p.'s are predicted below 21 eV and as a result of this and the intensity pattern three i.p.'s must be present in the broad band. Gaussian analyses revealed these components. As all the bands are structureless, comparison with CH_2Cl_2 and SiH_2F_2 CNDO/2 and empirical calculations must be used to aid assignment.

If one considers that the lone pair orbitals are not involved in bonding one would expect four low energy ionizations from a_1, b_1, a_2, and b_2 orbitals. These correspond to the in plane-out of phase, out of plane-in phase, out of plane-out of phase and in plane-in phase combinations and, as discussed earlier (26) on overlap grounds this should be the order of increasing energy. CH_2Cl_2 was assigned according to these arguments, but later reassigned with a_2 and b_1 interchanged in the basis of the empirical calculations described below. The CNDO/2 calculations do not fit well with this assignment. As can be seen from the table the calculated i.p.'s do not agree with the observed i.p.'s as well as in the other molecules particularly in the first two i.p.'s. Also the four lowest energy i.p.'s are not as clearly separated from the next set of i.p.'s as they should be. This is because the calculations predict considerable bonding character in these orbitals (see column 5 of Table 4). As discussed with SiH_3Cl, these calculations seem to sometimes overestimate the interaction between two symmetry related orbitals. In SiH_2Cl_2, this means that the b_1 and a_1 orbitals could be pushed to higher energy than the observed value and in fact we believe that this has happened in this molecule with b_1 and b_2, and a_1 and a_2 being interchanged. However, the fact that the a_2 comes at lower energy than expected compared to CH_2Cl_2 (12.22 eV) is interesting. This is the only orbital which is completely non-bonding in CH_2Cl_2 but can be stabilized in SiH_2Cl_2 by gaining some Si dπ character. The calculations also indicate that the highest b_2 orbital is mainly lone pair on the chlorine. However the highest b_2 and a_2 orbitals are calculated to have mainly σ(Si—H) character and the next highest b_1 and a_1 orbitals around 14 eV to have considerable lone pair character. This is probably too extreme but it does show that the four lowest orbitals cannot be considered as pure lone pair orbitals. The assignment we prefer for the lowest energy i.p.'s places the almost non-bonding a_2 orbital as the third band as it is the sharpest, consistent with a small change in geometry on ionization.

The other orbitals have the same order as given by purely overlap of lone pair considerations. The preferred order is $b_2 > b_1 > a_2 > a_1$. For the mainly lone pair orbitals (b_2, a_2) the CNDO calculations give the correct order.

The 18.32 eV band is as expected an a_1 orbital being mainly Si(3s) but having (Si—H_2) and ($SiCl_2$) bonding character. The assignment of the other three i.p.'s around 14–15 eV is by no means clear. The calculation gives $b_2 > b_1 > a_1$, but it seems more reasonable for the mainly σ(Si—H) b_1 orbital to be at higher energy than the σ(Si—Cl) b_2 orbital.

$SiHCl_3$

The p.e. spectrum of $SiHCl_3$ has five distinct bands with maxima at 11.96, 12.41, 13.07, 14.75, and 18.14 eV with relative intensities 1.2:3.4:2.1:3.4:1. There is a distinct shoulder at 14.98 eV on the fourth band which is broad enough and of intensity to imply the presence of two components. We expect four low energy i.p.'s from mainly Cl lone pair orbitals, a_2, e, a_1, and e in order of increasing orbital energy. The a_1 and the first e orbital appear to be accidentally degenerate at 12.41 eV, and the intensity ratios are in good agreement with placing the a_2 at 11.94 eV and the other e at 13.07 eV. The assignment of the 11.94 eV band to the a_2 orbital is further confirmed by the narrowness of the band as this is the only pure Cl lone pair orbital, and also by the fact that the a_2 orbital is derived from the t_1 orbital of $SiCl_4$ at 12.03 eV (see Fig. 2). The shift of the a_2 band from 11.48 eV in $CHCl_3$ to 11.94 eV in $SiHCl_3$ indicates the effect of central atom size on this completely non-bonding orbital. The stabilization of this orbital in the $SiHCl_3$ shows that we cannot just consider shifts in otherwise non-bonding orbitals as an indication of (p–d)π bonding. One must consider all the "lone pair" orbitals which can possibly bond with d orbitals on the central atom. The CNDO/2 calculations also confirm the order $a_2 > a_1 > e > e$, although as for SiH_2Cl_2 the calculated i.p.'s are rather bad at lowest energy (see Table 5). The a_1 orbital is calculated to have a considerable amount of Si—H and Si—Cl bonding character as for the lowest a_1 orbital in SiH_3Cl and SiH_2Cl_2. The higher energy e orbital is mainly n(Cl) with some π (Si—Cl) whereas the lower energy e orbital has some σ(Si—Cl) character, though again it is mainly n(Cl).

The maximum at 14.75 eV is assigned as mainly the e σ(Si—Cl) and the shoulder at 14.98 to the

a_1 σ(Si—Cl) on the basis of intensity and the relation to the t_2 σ(Si—Cl) orbital of $SiCl_4$ at 15.13 eV. Although all the previous bands have had no structure, the a_1 σ($SiHCl_3$) band at 18.14 eV has three peaks separated by 2000 cm^{-1}. This progression obviously involves ν(a_1) Si—H stretch, which has a value of 2236 cm^{-1} in the neutral molecule (18). CNDO/2 calculations again indicate that this band is mainly Si(3s).

Comparison with the chloroform ($CHCl_3$) spectrum shows that the orbitals are in the same order for $SiHCl_3$ and $CHCl_3$. Again the first four bands are at lower energy in the carbon species indicating the lower bonding character of the halogen pπ electrons and greater halogen–halogen interactions. If lone pair repulsions were the only factor in determining the energy of the higher orbitals (considering them purely as lone pair orbitals) it would be expected that the range of the first four i.p.'s would be much smaller for $SiHCl_3$. In fact the separation between the first and fourth i.p. is only reduced by 0.24 eV and between first and third reduced by 0.06 eV and between the first and second it is actually increased by 0.04 eV from $CHCl_3$ to $SiHCl_3$. It can be seen that the second through fourth orbitals have been stabilized by some other means *i.e.* (p → d)π bonding compared to the non-bonding a_2 orbital. However the mainly Si—Cl σ bonding orbitals are at a higher energy (e, 14.75; a, 14.98) than the corresponding C—Cl σ bonding orbitals (e, 15.99; a, 16.96), for a weaker σ bonding system in the former case. The weighted average chlorine 'lone pair orbital' energy increases as expected on electronegativity grounds through the series; SiH_3Cl (11.65 eV), SiH_2Cl_2 (12.27 eV), $SiHCl_3$ (12.55 eV), and $SiCl_4$ (12.73 eV). The spectra of the chlorosilanes are again very similar to the corresponding series of carbon compounds, but in contrast to the fluoro compounds the bands are not as well resolved, except for the lower band of SiH_2Cl_2. As the t_2 band in SiH_4 and the lone pair bands in $SiCl_4$ occur in the same energy range (12–13.5 eV), the SiH bonding orbitals are not as well separated as in the series of fluoro compounds. However a study of the trends in Fig. 2 shows that the lowest energy i.p.'s in the chlorosilanes between 12 and 13.5 eV are mostly derived from the lone pair electrons of $SiCl_4$ and that the next set of bands (13.5–15 eV) are mainly due to σ(Si—Cl). The bands around 15 eV in SiH_2Cl_2 and $SiHCl_3$ are all derived from the t_2 band of $SiCl_4$ at 15 eV. If these bands in the halosilanes were totally due to Si—Cl σ bonding then we observe the expected decrease in the σ(Si—Cl) i.p. from $SiCl_4$ to SiH_3Cl. The bands derived from the t_2 band of SiH_4 move to lower orbital energy in the chlorosilanes (see Fig. 2) and coalesce with the bands derived from the t_2 σ(Si—Cl) orbital of $SiCl_4$. The shift to lower energy is expected on substitution of the electron withdrawing halogen atom. For example the Si—H stretching frequencies increase on substitution of a H atom. However, as there are no purely σ(SiH) bonding orbitals it is difficult to put too much stress on these arguments. One interesting point of comparison between the carbon series and silicon series is that in the former the energy separation between the highest "lone pair" i.p. and the lowest of the next set of "σ-bonding" i.p.'s is a constant 3 eV through the whole series whereas for the latter the separation is only 1.5–2 eV. This is caused by both the greater stabilization of the Cl "lone-pair" orbitals by bonding to the silicon atom, reducing the orbital energy of the lowest i.p.'s, and also by the weaker σ bonding system round the silicon atom increasing the orbital energy of the next lowest i.p.'s.

SiH_3Br

In SiH_3Br the same three bands appear as in SiH_3Cl, in this case with intensity ratios approximately 2:3:1, but the two ionization processes in the second band are better resolved (see Fig. 3). Ionization from the e(Br), a_1(SiH_3Br), e(SiH_3), and a_1(SiH_3Br) orbitals occurs at 11.00, 12.96, 13.63, and 18.04 eV respectively where the values for the two e orbitals are the average of two maxima. No CNDO/2 calculations were carried out for this molecule.

The first band of half width 0.5 eV has a spin-

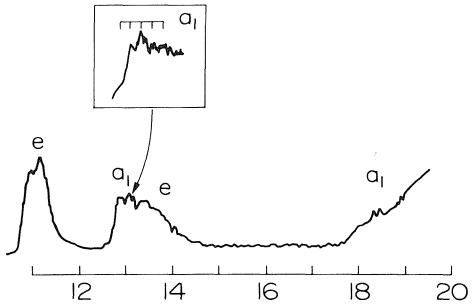

FIG. 3. Photoelectron spectrum of silyl bromide.

orbit splitting of 0.20 eV, which is more reasonable than the 0.14 eV reported previously (12), as HBr and CH_3Br have splittings of $\sim$0.30 eV (30). The half-width of the band is considerably greater than that in CH_3Br and the i.p. is 0.30 eV higher. As discussed previously, all these observations are indicative that the pπ lone pairs on the bromine atom in SiH_3Br have considerably more bonding character than those in CH_3Br. This bonding almost certainly involves the dπ orbitals on the silicon atom. There were some signs of barely resolved structure on the low energy spin-orbit component of the first band. It corresponds to a progression of $\sim$320 cm^{-1}, which seems to be too small to be the Si—Br stretch, which is at 430 cm^{-1} in the parent molecule.

Comparing the mainly lone pair i.p.'s with the carbon analogues through the series SiH_3X (X = F, Cl, Br), we observe a similar though smaller stabilization from CH_3Br (10.70 eV) to SiH_3Br (11.00 eV) as for CH_3Cl (11.30 eV) to SiH_3Cl (11.65 eV). This could be taken as an indication of slightly greater (p $\rightarrow$ d)π bonding in SiH_3Cl. Of course, as discussed earlier the lone pair orbital in SiH_3F (16.13 eV) is destabilized with respect to CH_3F (17.06 eV), as expected on electronegativity grounds, but this is probably due to greater F(pπ) $\rightarrow$ $\sigma^*(CH_3)$ bonding in the latter.

The a_1 component of the second band with maximum at 12.96 eV has three resolvable peaks with a separation of 400 cm^{-1}, corresponding to the Si—Br stretch. This is the first time structure has been observed on the a_1 band of an MH_3X system. It is rather surprising that ν(Si—Br) is excited and not $\nu(SiH_3)$ or $\delta(SiH_3)$ though evidence is possibly lost in the rest of the band, especially as the part of the band where the structure is observed has more complex structure as well as the three obvious peaks. Calculations on SiH_3Cl indicate that this orbital is nevertheless expected to be mainly Si—X σ bonding with only a small amount of Si—H_3 σ bonding, although this is less so for SiH_3F. In agreement with this, a steady decrease in this a_1 i.p. is observed through the series: SiH_3F (16.13), SiH_3Cl (13.51), SiH_3Br (12.96 eV), indicating a weakening of the σ bonding system, especially the Si—X bond, through the series. For the methyl halides a similar trend is observed except of course all of the a_1 i.p.'s are at higher energy, *viz*: CH_3F (17.06 eV), CH_3Cl (14.42 eV), and CH_3Br (13.49 eV). The overall weakening of the Si—X bond through the series can be observed from Table 6 in which we compare the Si—X bond length in SiH_3X compounds with the C—X bond length in the analogous CH_3X species (1). As the i.p.'s indicate, the Si—F bond is considerably stronger than the Si—Cl and Si—Br bonds. Multiple bonding in the Si–halogen bond is indicated by the smaller difference between r(Si—X) and r(C—X) compared to MH_3X where X = CH_3, H.

The second lowest energy e orbital ionizes to produce a band with two maxima at 13.43 and 13.83 eV *i.e.* a Jahn–Teller splitting of 0.4 eV. As can be seen in Fig. 2 this orbital is derived from the t_2 orbital in SiH_4, and ionization from this orbital produces a Jahn–Teller splitting of 0.5 eV. The splitting is not observed in SiH_3Cl as there is an overlap with the a_1 band, but in SiH_3F the splitting is 0.46 eV. These splittings are somewhat less than those observed in the analogous carbon containing compounds (0.5–0.7 eV) as would be expected for species with lower vibrational energies.

It is instructive to compare the position of this band through the series of MH_3X complexes: H_3SiF, 12.8; H_3SiCl, 13.90; H_3SiBr, 13.61; H_3CF, 13.06; H_3CCl, 15.40; H_3CBr, 15.08 eV. As expected the orbital is more stable in the silicon chloride than in the bromide and much less stable in these than in the carbon analogues. All the orbitals discussed so far are at lower energy in SiH_3Cl than in SiH_3Br. This weaker bonding possibly explains the much more ready disproportionation of the latter. The ionization potential of SiH_3F appears to be anomalously low but in this case $\sigma(SiH_3)$ is destabilized by interaction with the other low energy e orbital, the F lone pair which is at higher energy. We have already discussed the relatively lower energy of CH_3F in terms of the π contribution from the F atom. Of all the silyl halides, SiH_3F dispro-

portionates fastest, and the fact that this has the lowest energy σ-bonding electrons indicates the weaker Si—H σ bond may be the driving force behind the disproportionation.

Empirical Calculations on Chlorosilanes

After the completion of the work described in this manuscript, Dixon *et al.* (31) published a paper on the assignment of the "non-bonding" electron i.p.'s for the chloromethanes on the basis of a simple pseudo one-electron Hamiltonian. In the first approximation the matrix elements of the Hamiltonian are proportional to the overlaps between the constituent atomic orbitals and the corrections to the average chlorine "lone-pair" i.p.'s are given in terms of $\beta_\sigma = kS_{\sigma\sigma}$ and $\beta_\pi = kS_{\pi\pi}$. As this model did not give very good predictions of the observed ionization potentials, interaction with the σ bonding orbitals was included and this gave excellent agreement. The interaction was considered as being between the chlorine 2pπ orbitals and an average carbon 2p orbital and the correction to the i.p. obtained by the first model is

$$\Delta I = \frac{-x\beta_\pi^2(\mathrm{CX})}{\Delta E(\mathrm{CX})} \equiv -x_\gamma$$

where x is determined from the orbital overlaps.

Solving the equations of Table 7 without column 5 for the chlorosilanes, *i.e.* exactly analogous to the previous treatment of the chloromethanes, produces the results given in Table 8, calculation *b* (calculation *a* is the calculation including only chlorine–chlorine interaction). In these calculations, the ratio $\beta_\sigma/\beta_\pi = S_\sigma/S_\pi$ was again estimated using best atom single-zeta

Slater orbitals and a value of 7.58 was obtained. The γ_2 and γ_3 values were again obtained by interpolating $1/\gamma$ linearly between γ_1 and γ_4, although we believe this is a rather unsatisfactory procedure. All other operations were carried out as for the halomethanes. Although the agreement between calculations *b* and the observed values is good, the I values obtained are all higher than for the carbon analogues, which is impossible, as silicon is less electronegative than carbon. Also there is a small internal inconsistency in the calculations for carbon compounds, which becomes considerably greater for the silicon compounds. This arises as follows:

Dixon *et al.* calculated a value for $I_4 - I_2$ for relationship A

$$[A] \quad \tfrac{1}{2}[I(E) + I(T_1)](MCl_4) - I(A_2)(MH_2Cl_2) = I_4 - I_2$$

and the values obtained for the carbon and silicon compounds are 0.34 and 0.22 eV respectively. However, they neglected to point out that $I_4 - I_2$ can also be obtained from the relationship B

$$[B] \quad I(T_1)(MCl_4) - \tfrac{1}{2}[3I(B_2) - I(B_1)](MH_2Cl_2) = I_4 - I_2$$

and in this case the corresponding values are 0.29 and 0.56 eV respectively for the silicon series. The small error for the carbon species (0.06 eV) shows what was suspected by Dixon *et al.*, *i.e.* that the β values would not be quite constant in the series $CH_{4-n}X_n$ due to the change in electronic charge. However, we believe that this error is too small (within the error in measurement of i.p.'s) to affect the value of the method for the carbon compounds. However, along with the high I values obtained, the large difference (0.3 eV) for the silicon compounds indicates that another factor has been omitted from the equations used for the i.p.'s. It is reasonable to assume that the variation in β values through the silicon series $SiH_{4-n}X_n$ is not significantly greater than in the corresponding carbon series. The only way to obtain suitable I_n values would be to include a contribution to the i.p.'s for the interaction of the lone pairs with the silicon d orbitals. As can readily be shown, when this contribution is included (see below), relationship B for $I_4 - I_2$ is independent of this effect whereas relationship A is not. Therefore the better value of $I_4 - I_2$ is 0.56 eV.

As mentioned above the obvious improvement for the chlorosilanes would be the inclusion in the calculated i.p.'s of a term indicating d orbital participation. By analogy with the γ interaction

$$\Delta I = +x\beta_\pi{}^2 \frac{[\text{Si (3d)} - \text{Cl (2p)}]}{\Delta E[\text{Si (3d)} - \text{Cl (2p)}]} = +x\delta$$

where again x is determined by orbital overlap. The values of γ obtained are given in column 5 of Table 7. However, the inclusion of δ values presents a major problem. Without them, there were ten parameters to be found, of which three, β_π, γ_2, and γ_3 could be related to other parameters, the last two by rather a dubious process. Now there are 14 parameters and only 12 equations. Therefore more parameters have to be fixed before any predictions can be made, and additional approximations have to be made compared to the halomethanes.

First attempts were made to fix the I values at a constant ratio of the I values for the corresponding carbon species based on electronegativity differences. However it was impossible to get a suitable ratio which would give the correct value of $I_4 - I_3$, fixed at 0.12 eV and $I_4 - I_2$ fixed at 0.56 eV on our assignments. It was thought more suitable then to fix both β_σ and β_π from the carbon values, as these values principally depend on the distance between the chlorine atoms. The β values for silicon were then obtained from the carbon values by assuming k in the equations $\beta = kS$ is the same, and multiplying the carbon β values by the ratios of the appropriate overlap integrals. The calculated values for the silicon compounds were $\beta_\sigma = -0.66$, $\beta_\pi = -0.085$ (for carbon $\beta_\sigma = -1.50$, $\beta_\pi = -0.24$). This then fixes I_4, I_3, and I_2 and γ_4, δ_4, γ_2, and δ_2 can then be calculated using the T_2, $E(SiCl_4)$, A_2 and $B_1(SiH_2Cl_2)$ states respectively. The A_1 state of SiH_2Cl_2 is then predicted at 12.93 eV compared to the observed 12.76 eV. This is reasonable, but it is impossible taking intermediate values of either γ_3 or δ_3 or both, to obtain any sensible values for the i.p.'s of $SiHCl_3$. Therefore other solutions were sought with different values of $\beta_\sigma = 7.58\ \beta_\pi$.

Complete solutions are possible for $SiCl_4$ and SiH_2Cl_2 (as discussed above) and for $SiHCl_3$, by solving for γ_3 and δ_3 between the average of the E states and the A_1 state. Then the only predictions which can be made are the A_1 state of SiH_2Cl_2 and the separation of the E states in $SiHCl_3$. Larger values produced even worse results. How-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ever small values seemed much more reasonable especially as the complete solution of SiH_2Cl_2 (which is possible with four independent equations) gave $\beta_\pi \approx 0$. A satisfactory solution is obtained with $\beta_\pi = 0.05$ eV, and the results are shown in Table 8. The *I* values are now all smaller than the corresponding values for the carbon compounds, as predicted on electronegativity grounds. The δ values indicate, as expected, the dominance of the d orbitals on silicon and the decrease in δ with increasing number of chlorines per silicon reflects the decreasing ratio of available silicon d orbitals to chlorine lone pair orbitals. The γ values would also be expected to show a steady decrease with increasing number of chlorines. However the error on these values is quite large. For example, if we use the $^2A_1$ state of SiH_2Cl_2 rather than the $^2B_1$ to estimate γ_2, we obtain a value of 0.18 eV instead of 0.08 eV.

In general the error on the parameters will be quite large, not only because of the error in the measurement of the p.e. spectra (±0.1 eV) but also because of accidental degeneracy (*i.e.* for ^2E and $^2A_1$ in $SiHCl_3$ and $^2A_2$ and $^2A_1$ in SiH_2Cl_2). However, for all the calculations we have carried out varying the value of β_π from 0–(−0.15) the best and almost only reasonable assignment is that given in Tables 8 and 9 and the *I* and δ values show the same trends as the calculation of Table 9. The only possible alternative assignment which emerged was the $^2A_1$ state of $SiHCl_3$ at 13.07 eV accidentally degenerate with the $^2E_1$ state, and this was only for large values of β. Despite the many gross assumptions we believe this method gives a satisfactory description of the assignment of the p.e. spectra of the halosilanes and an indication of the importance of silicon d orbital participation.

Conclusions

The p.e. spectra of the halosilanes indicate that, compared to the halomethanes, the predominantly halogen "lone pair" orbitals have more bonding character. Among the evidence is the shift to higher energy of the "lone pair" i.p.'s along with the reduction in all other i.p.'s for the halosilanes, and SiH_3Cl and SiH_3Br have broader bands than the corresponding CH_3Cl and CH_3Br. For the di-, tri-, and tetra-halosilanes, the expected convergence of the "lone pair" orbitals due to reduced halogen–halogen (pπ–pπ) interaction is not observed. As a result it is postulated that some of the "lone pairs" are being stabilized more than others by bonding with the rest of the system. Although, in most cases, this can be via other than Si d orbital, in the tetrahalides this cannot be for two of the three "lone pair" orbitals. As the di- and tri-halides show similar trends to the corresponding tetrahalides we inferred that Si d orbitals are as important in the bonding in these species.

Other trends in the bonding in the silyl halides which can be deduced from the p.e. spectra, are (*1*) the strengthening of the Si—X σ bond through the series $SiH_3Br > SiH_3Cl > SiH_3F$ and (*2*) compared to the other orbitals the relatively small effect on the SiH_3 σ bonding orbital with change in the halogen. As mentioned in the introduction, this latter effect is evident in some of the physical properties of the halosilanes. A general weakening in the σ bonding system compared to the halomethanes is also evident from the lower i.p.'s for the halosilanes and, as a result, the physical properties of the halosilanes indicating stronger silicon halogen bonds must be caused by the additional (p → d)π bonding and perhaps p → σ* (SiH) bonding. There is as yet no explanation for the anomalies in the n.m.r. chemical shifts mentioned in the introduction, but as these are caused by second order effects we are not likely to get much information from p.e. spectroscopy.

The empirical one-electron Hamiltonian calculations carried out lend support to the conclusion made above that (p → d)π bonding is an important influence in stabilizing the chlorine "lone pair" orbitals of the chlorosilanes. In fact variations in silicon d orbital participation (δ) appear to have a much greater effect on these

orbitals than variations in the other silicon orbitals (γ) and interactions between the orbitals on the constituent atoms (β).

The confirmation of the assignment by the results of these calculations also evokes some observations regarding the CNDO/2 calculations. In SiH_2Cl_2 the low i.p. values obtained for the non-bonding b_1, b_2 and a_1 orbitals but not the a_2 orbital is almost certainly a consequence of the overestimation of the interaction of the former with other bonding orbitals of the same symmetry. In contrast for $SiHCl_3$ the a_2 orbital is at relatively higher energy than the other "lone pair" orbitals. In this case overestimation of silicon 3d participation has effectively cancelled the former effect. However this effect is evident in the energy separation of the two lowest e orbitals. The CNDO/2 calculations can obviously cause considerable confusion in the assignment of p.e. spectra, (8, 11, 29, 32, 33) if these effects are not taken into account.

We thank the National Research Council of Canada for financial support and Professor C. A. McDowell for his continued interest in the work. One of us (R.A.N.M.) acknowledges receipt of a Killam Fellowship from the University of British Columbia.

Reductions with Sulfurated Borohydrides. VII. Reactions with Epoxides

J. M. Lalancette and A. Frêche
Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke, Québec

Received August 9, 1971

The reaction of $NaBH_2S_3$ with epoxides gives symmetrical bis-(2-hydroxyethyl) disulfides. The stereochemistry of the reaction is similar to the attack of H_2S on the epoxides in basic solution. Substituted epoxides are opened from the less hindered side. The reaction proceeds with good yield and is general. An improved method of preparation of the 1,2-mercaptols is presented.

La réaction de $NaBH_2S_3$ avec les époxydes mène aux bis-(hydroxy-2 éthyl) disulfures symétriques. La stéréochimie de la réaction est semblable à celle de l'action de H_2S sur un époxyde, en milieu basique. L'époxyde est ouvert du côté le moins empêché. La réaction, qui apparaît générale, fonctionne avec de bons rendements. Une méthode améliorée de préparation des 1,2-mercaptols est présentée.

Canadian Journal of Chemistry, **49**, 4047 (1971)

The formation of sulfurated borohydrides of general formula MBH_2S_3 has been reported (1). This new type of hydride has shown distinctive reducing properties with aldehydes (2), ketones (3), oximes (4), nitro compounds, and nitriles (5). This paper completes this study and describes the reaction of different epoxides with $NaBH_2S_3$.

From previous observations of ketones, it is known that $NaBH_2S_3$ can act either as a source of hydride or sulfide ions. With the epoxide group, the reaction products indicate that the sulfide group rather than the hydride ion is involved in the reaction. The nucleophilic reaction can be illustrated by eq. 1. An attack by the hydride ion instead of the sulfide group would have led to the formation of the alcohol rather than the disulfide, as is the case with $NaBH_4$ or $LiAlH_4$.

The reaction has been observed with *cis*-stilbene oxide, *trans*-stilbene oxide, styrene oxide, 3-phenoxy-1-propene oxide, and 1-phenyl-1-methylethylene oxide. In all cases, very good yields of the corresponding disulfides were obtained, in accordance with eq. 1. The usual measurements reported in Table 1 have confirmed the structure of those new compounds. Depending on the structure of the starting epoxides, temperature and reaction time have been adjusted in order to achieve high yields of disulfides.

In order to obtain complementary information on the structure of the disulfides, they were reduced with $LiAlH_4$ to give the corresponding 1,2-mercaptols. Subsequent action of phosgene led to expected 1,3-oxathiolan-2-ones as indicated in eq. 2. The 1,2-mercaptols and their derivatives are described in Table 2. The 1,2-mercaptols obtained from *cis*- and *trans*-stilbene were also treated by Raney nickel giving a mixture of alcohol by simple desulfurization and hydrocarbon by desulfurization and hydrogenolysis.

From the structure of the disulfides, it can be noted that the opening of the epoxide ring gives the most substituted alcohols, indicating that the attack of the sulfide group takes place on the less-substituted end of the epoxide.

The Stereochemistry of the Disulfides

The reaction products of the epoxides of *cis*- and *trans*-stilbenes have been examined more closely in order to establish the stereochemistry of the corresponding disulfides and the stereochemistry of the reaction with $NaBH_2S_3$. Each disulfide having four asymetric carbons, several possible configurations have to be considered.

[2] 
The n.m.r. of the disulfides obtained from these epoxides shows two doublets for each H—C—O and H—C—S structure, these four peaks being centered around 5 and 4 δ; those two doublets have equivalent intensities and very similar J, of the order of 6 Hz. This suggests that each of these disulfides is a mixture of two diastereoisomers in approximately equal proportions.

The n.m.r. of the corresponding 1,2-mercaptols or their 1,3-oxathiolan-2-ones cannot differentiate clearly between *threo* and *erythro* structures. In order to assign the proper configurations to the disulfides and 1,2-mercaptols, the *erythro* isomer was prepared by the action of H_2S in basic solution on the *trans*-stilbene oxide (6), this reaction being known to proceed via a Walden inversion. By comparison with the products obtained by the action of $NaBH_2S_3$ on the stilbene oxides followed by $LiAlH_4$, it was found that *trans*-stilbene oxide gave the *erythro*-1,2-mercaptol, the *threo* isomer being obtained from *cis*-stilbene oxide. It must be noted that the reaction was highly specific, each of those diastereoisomers being obtained in a pure state, after the action of $LiAlH_4$.

The stereochemistry of the reaction of each of the stilbene oxides with $NaBH_2S_3$ is represented in Figs. 1 and 2. Since a *trans* opening mechanism must be accepted, from analogy of the action of HS^- as indicated above, the attack on the (*d,l*)-*trans*-stilbene oxide gives the (*d,l*)-*erythro* isomer and the same reaction on the *meso*-stilbene oxide gives the (*d,l*)-*threo* isomer. Since the reduction of the disulfide by $LiAlH_4$ does not affect the C—S bond (7) and since only one diastereoisomer is produced by the reduction of each of the disulfides, it can be said that each disulfide contains only one type of structure, *erythro* for the disul-

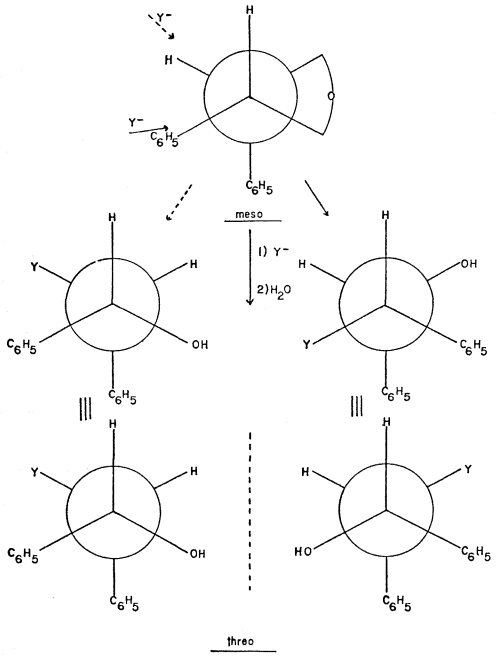

FIG. 1. Stereochemistry of the opening of *cis*-stilbene oxide.

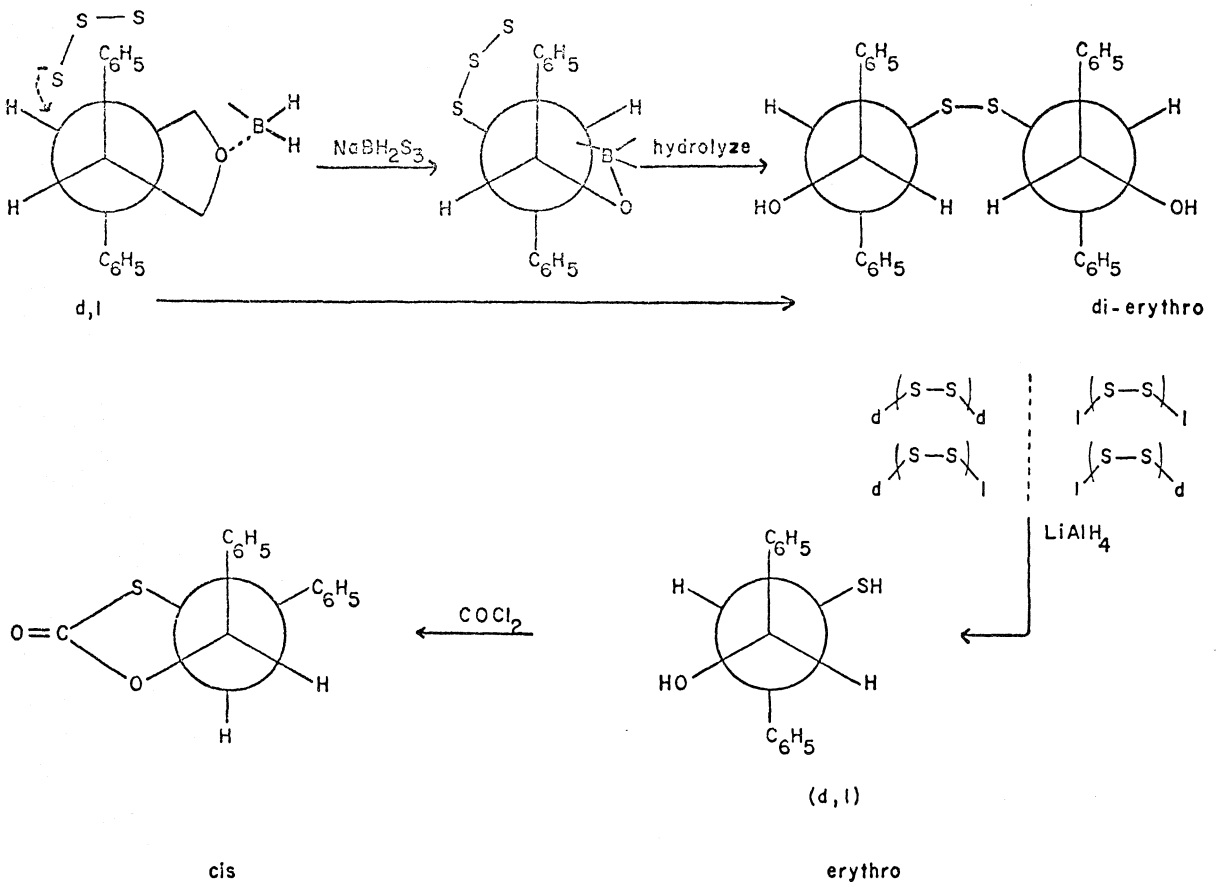

FIG. 3. Stereochemistry of the derivatives of *trans*-stilbene oxide. For sake of clarity, the staggered rather than the more probable eclipsed geometry is presented.

fide originating from the reaction of *trans*-stilbene oxide and *threo* for the disulfide originating from the reaction of the *cis*-stilbene oxide. These conclusions are in accordance with the n.m.r. measurements of the disulfides suggesting the existence of a pair of diastereoisomers in the reaction products. When the *trans* epoxide is opened by $NaBH_2S_3$ an *erythro* racemic mixture is formed and the association of two (*d,l*)-*erythro* structures in the disulfide is responsible for the formation of two pairs of stereoisomers from the four enantiomers present. This situation is illustrated in Figs. 3 and 4.

In the course of the preparation of the 1,2-mercaptols, we found that by reducing the reaction mixture obtained by the action of H_2S on an epoxide, the yields of 1,2-mercaptols were increased from the moderate values reported in the literature (8) of 25–35% to an almost quantitative value. The action of $LiAlH_4$ renders the method much more interesting since all the undesirable polysulfides are reduced to the expected 1,2-mercaptol.

The reaction of $NaBH_2S_3$ on epoxides gives a new class of compounds, the bis-(2-hydroxyethyl) disulfides and the stereochemical study of those disulfides offers clear evidence concerning the *trans* opening of the epoxide ring by the attack of $NaBH_2S_3$. How the two mercaptol fragments unite to give the disulfide remains an open question at the present time. The facile transformation of the disulfide into the 1,2-mercaptol by the action of $LiAlH_4$ offers an interesting alternate route to this class of compounds (6, 9).

Experimental

The n.m.r. measurements were made with a Varian, A60 apparatus. The i.r. measurements were made with a

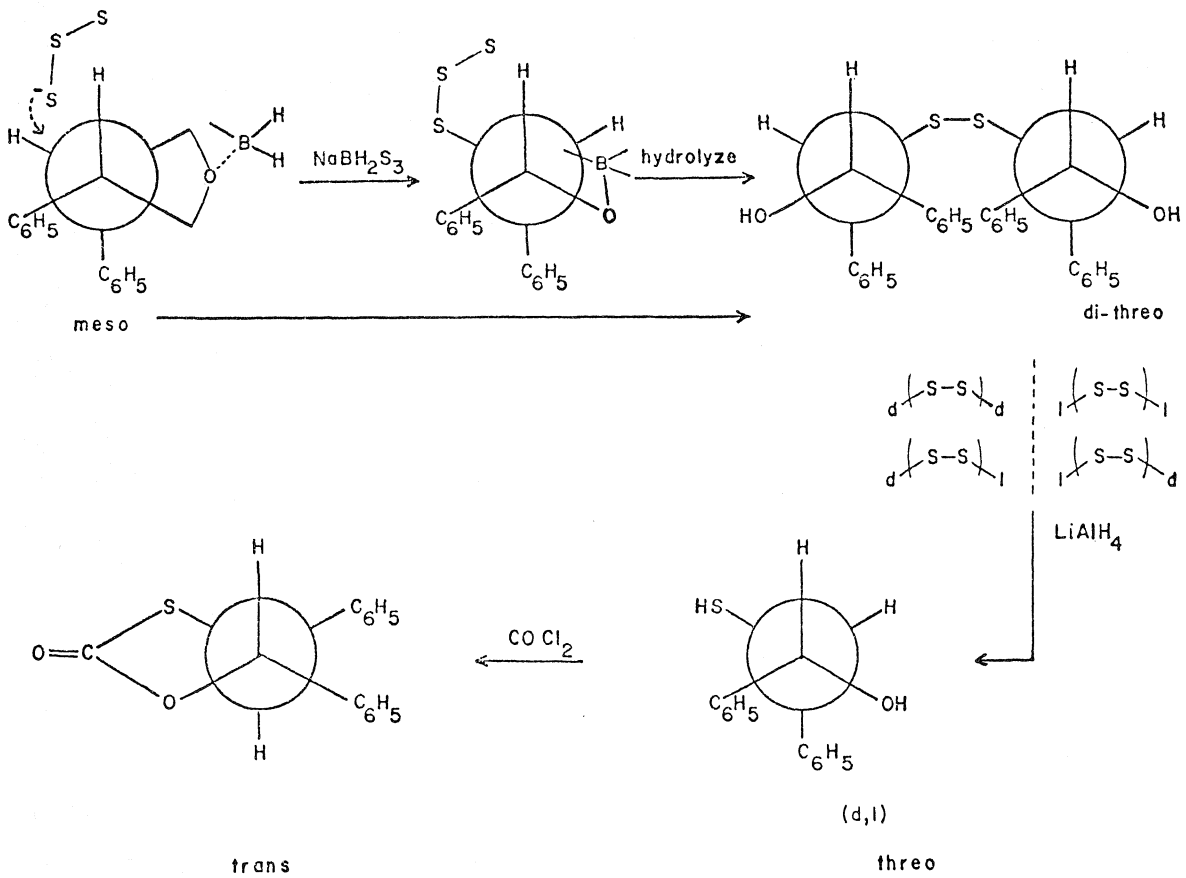

FIG. 4. Stereochemistry of the derivatives of *cis*-stilbene oxide. For sake of clarity, the staggered rather than the more probable eclipsed geometry is presented.

Perkin–Elmer, model 137 spectrophotometer. The v.p.c. measurements were made with a Microteck, model G.C.2000R apparatus, using an Se30, 4 ft column. Mass spectrometry measurements were performed on a Hitachi Perkin–Elmer instrument, model RMU-6.

(1) Reaction of $NaBH_2S_3$ with trans-Stilbene Oxides

The sulfurated borohydride was prepared as described (1) by treating a mixture of 0.050 mol (1.90 g) of $NaBH_4$ and 0.150 mol (4.8 g) of sulfur with 40 ml of anhydrous tetrahydrofuran (THF), the flask being kept cool (25–30°) with a water bath and under anhydrous conditions by circulation of nitrogen in the system. After 15 min, the initial hydrogen evolution had stopped and the sulfurated hydride was used *in situ* by addition of 4.9 g (0.025 mol) of *trans*-stilbene oxide. After a reflux of 34 h under nitrogen, the reaction mixture was cooled and hydrolyzed by 50 ml of a 10% sodium hydroxide solution. By extractions with chloroform, 5.4 g of the disulfide was obtained, the solid being recrystallized in cyclohexane. A similar procedure was used with other epoxides, the variations of experimental conditions and yields being reported in Table 1.

The n.m.r. (δ) of the various disulfides are the following (ref. Table 2): disulfide **1**: singlet at 2.40 (2H); doublet at 5.03 (1H, J = 5.5 Hz); doublet at 4.97 (1H, J = 60 Hz); doublet at 3.64 (1H, J = 5.5 Hz); doublet at 3.68 (1H, J = 6.0 Hz); multiplet at 7.1 (10H). Disulfide **2**: multiplet at 2.0 (2H); doublet at 3.93 (1H, J = 7.25 Hz); doublet at 4.01 (1H, J = 7.5 Hz); doublet at 4.93 (1H, J = 7.5 Hz); doublet at 5.02 (1H, J = 7.25); multiplet at 7.2 (10H). Disulfide **3**: multiplet at 3.0 (4H); multiplet at 4.05 (4H); multiplet at 4.30 (2H); singlet at 5.35 (2H); multiplet at 7.1 (10H). Disulfide **4**: singlet at 1.5 (6H); singlet at 2.80 (2H); multiplet between 3.08 and 3.13 (4H); multiplet around 7.15 (10H). Disulfide **5**: doublet at 2.79 (4H, J = 6 Hz); singlet at 3.80 (2H); triplet at 4.67 (2H, J = 6 Hz); multiplet at 7.1 (10H).

(2) Reduction of the Disulfides by $LiAlH_4$

The disulfide obtained from *trans*-stilbene oxide (2.3 g, 0.005 mol) was treated by an excess (0.75 g, 0.020 mol) of $LiAlH_4$ in 30 ml of anhydrous ether. After a reflux of 3 h, the reaction mixture was hydrolyzed by 1.5 g of water, filtered, and diluted by 50 ml of chloroform. After drying and evaporation of the solvents the expected 1,2-mercaptol (2.1 g, 91%) was obtained and recrystallized in CCl_4. A similar technique was used for the reduction of the other disulfides, the results being reported in Table 2.

The n.m.r. (δ) of the 1,2-mercaptols are the following:

mercaptol **4**: doublet at 4.83 (1H, J_{AM} = 7.8 Hz); double doublet at 4.17 (1H, J_{AM} = 7.8, J_{MX} = 5.1 Hz); doublet at 1.70 (1H, J_{AX} = 5.1 Hz); broad singlet at 2.60 (1H); singlet at 7.27 (10H). Mercaptol **7**: doublet at 4.76 (1H, J_{MX} = 7.5 Hz); double doublet at 4.11 (1H, J_{MX} = 7.5, J_{AM} = 5.7 Hz); doublet at 2.17 (1H, J_{AM} = 5.7 Hz); broad singlet at 3.20 (1H); singlet at 7.07 (10H). Mercaptol **8**: complex multiplet centered at 4.04 (3H); complex multiplet between 2.67 and 3.10 (2H); double doublet centered at 1.60 (1H); singlet at 3.20 (1H); multiplet at 7.0 δ (5H). Mercaptol **9**: singlet at 1.47 (3H); singlet at 3.10 (1H); double doublet at 1.03 (1H, J_{AX} = 10, J_{BX} = 7.5 Hz); two double doublets at 2.63 (2H, J_{AX} = 10, J_{BX} = 7.5 Hz) and 2.91 (J_{AB} = 13.5 Hz). Mercaptol **10**: triplet at 4.44 (1H); singlet at 3.50 (1H); multiplet between 2.70 and 2.45 (2H); double doublet at 1.25 (1H, J_1 = 8.0, J_2 = 8.5 Hz); singlet at 7.1 (5H).

(3) Reaction of the 1,2-Mercaptols with Phosgene

A 30 ml portion of a benzene solution of phosgene (obtained by bubbling $COCl_2$ through the solvent for 15 min) was mixed with a solution of 0.300 g of the 1,2-mercaptol **6** in 50 ml of the same solvent. After adding 0.5 ml of dry pyridine to the reaction mixture, the system was stirred at room temperature for 15 min. After the evaporation of the solvent, the reaction product was recrystallized in the mixture chloroform – ethyl acetate. The characteristics of the 1,3-oxathiolan-2-ones are reported in Table 2. In the n.m.r., the derivative from the *trans*-stilbene (**11**) gave a doublet at 6.14 (1H, J = 6.0 Hz) and a doublet at 5.28 δ (J = 6.0 Hz). With the derivative of the *cis*-stilbene (**12**) the n.m.r. was showing a doublet at 5.46 (1H, J = 9.0 Hz); and a doublet at 4.96 δ (1H, J = 9.0 Hz). The protons of the mercaptan, of the alcohol and of the aromatic system were also present in those spectra.

(4) Desulfurization of the 1,2-Mercaptols with Raney Nickel

A sample of 0.300 g (0.0007 mol) of the 1,2-mercaptol **6** was treated by 6 g of freshly prepared Raney nickel during 24 h at room temperature. After filtration and evaporation of the solvent, 250 mg of a yellow liquid was obtained. From n.m.r. analysis, this liquid was a mixture of 1,2-diphenylethanol (60%) and 1,2-diphenylethane (40%).

The n.m.r. of the 1,2-diphenylethanol: triplet at 4.70 (1H, J = 7 Hz); doublet at 2.88 δ (2H, J = 7 Hz). The n.m.r. of the 1,2-diphenylethane: singlet at 2.89 δ (4H). A similar method was used to characterize the 1,2-mercaptol **7**.

(5) Opening of the Epoxide of trans-Stilbene by H_2S in Basic Solution

A solution of 0.6 g (0.015 mol) of NaOH in 10 ml of CH_3OH was saturated by a stream of H_2S at 0 °C for 1 h. To this solution, 1.0 g (0.005 mol) of epoxide was added slowly, the bubbling of H_2S being maintained in the course of the addition. After a contact of 18 h, the reaction mixture was diluted with 15 ml of water, and acidified at 0° to pH 2 by H_2SO_4. The organic phase was extracted with CH_2Cl_2, washed with a solution of sodium bicarbonate, dried, and distilled. This crude product represented about 25% of the expected 1,2-mercaptol and various polysulfides. The reduction, as described in section 2, was then applied to this mixture and a yield of 94% of the 1,2-mercaptol was thus obtained. The physical properties of this *erythro*-1,2-mercaptol were identical as those observed with **6**.

Thiazoloisoquinolines. IV. The Synthesis and Spectra of Thiazolo[4,5-*h*]- and Thiazolo[5,4-*f*]isoquinolines. The Ultraviolet and Proton Magnetic Resonance Spectra of Some Substituted Isoquinolines[1,2]

ALFRED TAURINS AND RICHARD KANG-CHUAN HSIA[3]

Department of Chemistry, McGill University, Montreal, Quebec

Received July 21, 1971

Thiazolo[4,5-*h*]isoquinoline was synthesized from 7-aminoisoquinoline in four steps: by the reaction with potassium thiocyanate and bromine to give 7-amino-8-thiocyanoisoquinoline; cyclization of the latter with hydrochloric acid to produce 2-aminothiazolo[4,5-*h*]isoquinoline, followed by the Sandmeyer reaction to yield a 2-chloro derivative, and finally, reduction with hydriodic acid and phosphorus. Thiazolo[5,4-*f*]isoquinoline was prepared from 6-aminoisoquinoline via 6-amino-5-thiocyanoisoquinoline. The synthesis of 2,5-diaminothiazolo[5,4-*h*]isoquinoline was achieved by cyclization of 5-acetamido-8-aminoisoquinoline which was obtained from 5-aminoisoquinoline. In 5-amino-8-thiocyano- and 8-amino-5-thiocyanoisoquinolines, the thiocyano group was hydrolyzed to the thiol group with 8 *N* hydrochloric acid and ethanol (1:1).

The u.v. and p.m.r. spectra of the intermediate isoquinolines, and the i.r., u.v., and n.m.r. spectra of thiazoloisoquinolines were studied.

On a synthétisé le thiazolo[4,5-*h*]isoquinoline à partir de la 7-aminoisoquinoline en quatre étapes: par la réaction avec le thiocyanate de potassium et le brome, on obtient le 7-amino-8-thiocyanoisoquinoline; la cyclisation de ce produit avec l'acide chlorhydrique amène au 2-aminothiazolo[4,5-*h*]isoquinoline, suivi par la réaction de Sandmeyer, ce qui donne le dérivé 2-chloro dont on fait la réduction avec l'acide iodhydrique et le phosphore. On a préparé le thiazolo[5,4-*f*]isoquinoline à partir du 6-aminoisoquinoline en passant par le 6-amino-5-thiocyanoisoquinoline. On a réussi la synthèse du 2,5-diaminothiazolo-[5,4-*h*]isoquinoline qui fut obtenu à partir du 5-aminoisoquinoline. Pour les 5-amino-8-thiocyano- et le 8-amino-5-thiocyanoisoquinolines, le groupe thiocyano a été hydrolysé en thiol avec l'acide chlorhydrique 8 *N* et l'éthanol (1:1).

On a étudié les spectres ultraviolet et de r.m.p. des isoquinolines intermédiaires, de même que les spectres i.r., u.v., et r.m.n. des thiazoloisoquinolines.

Canadian Journal of Chemistry, 49, 4054 (1971)

Discussion

The program aimed at the synthesis of eight isomeric thiazoloisoquinolines was continued. Two representatives of this series, thiazolo[4,5-*c*]- and thiazolo[5,4-*c*]isoquinolines have been described in the previous papers (1–3). In this work, we report studies in the series of thiazolo[4,5-*h*]- (**1**), -[5,4-*f*]- (**2**), and -[5,4-*h*]isoquinoline (**3**). The general method for the preparation of the amino derivatives of **1**, **2**, and **3**, was the thiocyanation of the appropriate aminoisoquinolines, followed by the cyclization of the *o*-aminothiocyano derivatives.

The starting material for the preparation of thiazolo[4,5-*h*]isoquinoline (Scheme 1) was 7-aminoisoquinoline (**5**) which was thiocyanated in the 8-position with potassium thiocyanate and bromine in 95% acetic acid to give 7-amino-8-thiocyanoisoquinoline (**6**).

Treatment of **6** with alcoholic hydrochloric acid

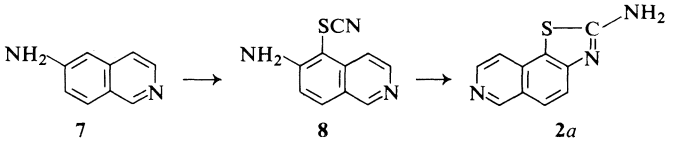
SCHEME 1



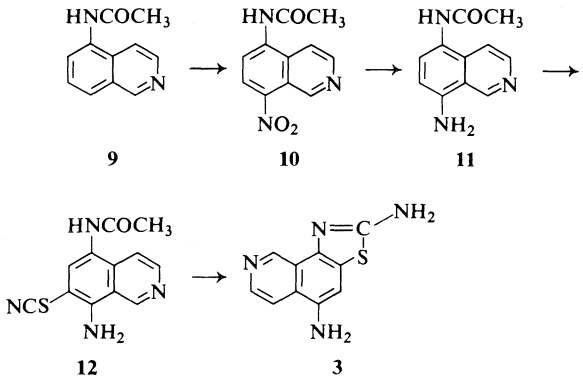
7 8 2*a*

SCHEME 2

at reflux temperature gave 2-aminothiazolo-[4,5-*h*]isoquinoline (**1***a*) in the form of a yellow crystalline substance. Diazatization of 2-amino-thiazolo[4,5-*h*]isoquinoline (**1***a*) with sodium nitrite in 70% nitric and 85% orthophosphoric acid mixture (1:4), followed by the treatment of the diazonium salt with cuprous chloride gave 2-chlorothiazolo[4,5-*h*]isoquinoline (**1***b*), which on reduction with hydriodic acid and red phosphorus gave thiazolo[4,5-*h*]isoquinoline (**1***c*). This forms colorless needles, m.p. 138–139° (*n*-hexane) and has a very low solubility in organic solvents.

In the synthesis of thiazolo[5,4-*f*]isoquinoline (**2***c*), thiocyanation of 6-aminoisoquinoline (**7**) produced the key intermediate 6-amino-5-thiocyanoisoquinoline (**8**) which was cyclized with hydrochloric acid to obtain 2-aminothiazolo-[5,4-*f*]isoquinoline (**2***a*). The further steps leading to the chloro-derivative **2***b* and the parent compound 2*c* were similar to those outlined for the [4,5-*h*] series (Scheme 2). Thiazolo[5,4-*f*]isoquinoline (**2***c*) was obtained in pure state by sublimation and recrystallization from *n*-hexane. This forms colorless needles, m.p. 170° (dec.), and has a very low solubility in organic solvents.

The preparation of 2,5-diaminothiazolo[5,4-*h*]-isoquinoline (**3***a*) is outlined in Scheme 3. To achieve the [5,4-*h*]-fusion of the thiazole and isoquinoline rings, it would be necessary to have amino and thiocyano groups in the 8- and 7-positions, respectively. To prevent the thiocyanation of the 5-position in 8-aminoisoquinoline, that position was blocked by the acetamido group. The starting material, 5-acetamidoisoquinoline (**9**), was nitrated in concentrated sulfuric acid with potassium nitrate to give 5-



9 10 11 12 3

SCHEME 3

acetamido-8-nitroisoquinoline (**10**). Catalytic hydrogenation of **10** with hydrogen and 5% palladium-on-charcoal catalyst produced 5-acetamido-8-aminoisoquinoline (**11**), which on thiocyanation yielded 5-acetamido-8-amino-7-thiocyanoisoquinoline (**12**). The compound **12** was successfully cyclized with hydrochloric acid to give 2,5-diaminothiazolo[5,4-*h*]isoquinoline (**3**), a yellow crystalline compound. Diazatization of **3**, followed by Sandmeyer reaction, failed to produce the desired 2,5-dichloro[5,4-*h*]isoquinoline.

In order to synthesize thiazolo[4,5-*f*]isoquinoline (**4**) by the same type of cyclization reactions as mentioned previously, it was desirable to obtain 5-amino-6-thiocyanoisoquinoline from 5-amino-isoquinoline. However, the only product of the thiocyanation of 5-aminoisoquinoline was 5-amino-8-thiocyanoisoquinoline (**13**). The structure of 5-amino-8-thiocyanoisoquinoline (**13**) was obvious from its inability to cyclize with 4 *N* hydrochloric acid and ethanol (1:1) under reflux (the starting material was recovered). However,

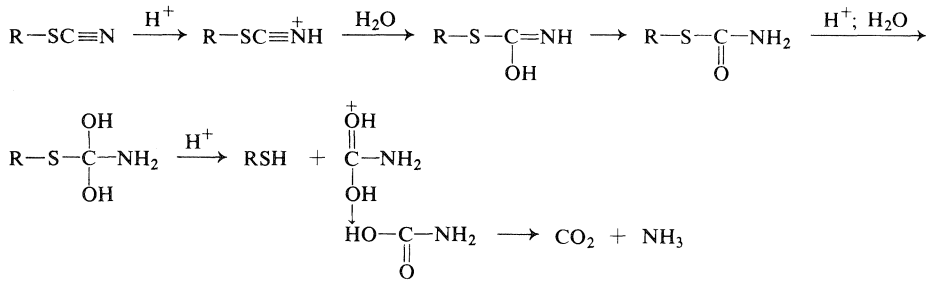

SCHEME 4

8 *N* hydrochloric acid and ethanol (1:1) hydrolyzed **13** to give 5-amino-8-mercaptoisoquinoline (**14**).

Thiocyanation of 8-aminoisoquinoline gave only a para-substituted product, 8-amino-5-thiocyanoisoquinoline (**15**). Since no ortho-substitution occurred, 8-aminoisoquinoline could not serve as the key intermediate for the preparation of thiazolo[5,4-*h*]isoquinoline.

8-Amino-5-thiocyanoisoquinoline (**15**) was also hydrolyzed with 8 *N* hydrochloric acid and ethanol (1:1) to give 8-amino-5-mercaptoisoquinoline (**16**), a kind of reaction not reported for thiocyanates. Conversion of thiocyanates to mercaptans has been usually achieved by reduction, for example, with zinc and hydrochloric acid, lithium aluminum hydride, or sulfides (4). Riemschneider (5) found that thiocyanates are transformed into thiocarbamates by treatment with sulfuric acid at 0 to 5°, but no further change was observed.

It is believed that the acidic hydrolysis of the thiocyano group proceeds through a thiocarbamate intermediate which is hydrolyzed further to give the thiol as shown in Scheme 4.

Spectra

Ultraviolet Spectra

The u.v. absorption data of thiazolo[4,5-*h*]- and -[5,4-*f*]isoquinoline and their derivatives are presented in Tables 1 and 2. The pattern of the spectra of these compounds is characteristic of the angularly fused three-ring aromatic and hetero-aromatic systems which usually display three main types of bands arising from $\pi \rightarrow \pi^*$ transitions. (In most cases, linearly fused three-ring systems show only two bands, due to the coalescing of bands.) These bands are designated as α-, p-, and β-bands by Clar (6), or as L_b, L_a, and $B_a + B_b$ bands by Platt (7). The u.v. spectra of the angular unsubstituted thiazoloisoquinolines **1***c* and **2***c*, and also of thiazolo[4,5-*c*]- and -[5,4-*c*]-

isoquinoline (1, 2) are similar to those of phenanthridine (8) and benzo[*h*]isoquinoline (9).

The u.v. absorption maxima and their corresponding log ε values of the mono- and disubstituted isoquinolines, measured in ethanol, are summarized in Tables 3 and 4. The spectral data for isoquinoline (10) have been added for reference. Osburn *et al.* (11) have recorded the u.v. spectra of 2-, 3-, 4-, 5-, 6-, 7- and 8-aminoisoquinolines in neutral and strongly acidic water solutions, and determined their pK_a values. Comparison of these data with those in Table 3 shows that only 5-aminoisoquinoline has the same spectrum in water and ethanol solution, and that 6-, 7-, and 8-aminoisoquinolines in ethanol display a red shift of α- and p-bands in the order of 10 to 12 nm compared with the values obtained in water. Amino and hydroxyl groups in the 6-position produce a red shift of the β-band, as shown by the 6-amino-, 6-hydroxy-, and 6-amino-5-thio-

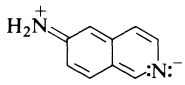
cyanoisoquinoline. It is believed that this shift is due to the resonance effect which involves the 6-amino-, or 6-hydroxy group, and the ring nitrogen; for example,



The 6-amino group in isoquinolines causes also a strong red shift of the p-band. In the majority of 5,8-disubstituted isoquinolines, the p-band shows a blue shift, and a considerable red shift of the α-band, compared with the p-band of unsubstituted isoquinoline. All 5,8-disubstituted isoquinolines have the β-band very close to 216 nm, the position of the β-band in unsubstituted isoquinoline.

Nuclear Magnetic Resonance Spectra

A survey of the literature reveals that in addition to the n.m.r. spectrum of isoquinoline (12, 13) only a few spectra of substituted isoquinolines have been studied (14–16).

In this work, we recorded the n.m.r. spectra of a number of isoquinolines with one (Table 5) or two substituents (Table 6) on the benzenoid ring. When it was possible, first-order interpretation of spectra was applied and the coupling constants were measured with an accuracy of 0.2 Hz. In 5-, 6-, 7-, and 8-aminoisoquinolines, the two doublets for H-3 and -4, are well separated from other bands, but in the rest of the compounds, with the exception of 6-hydroxyisoquinoline, the H-4 is overlapping with bands from the benzenoid ring. 5-Nitroisoquinoline represents a very special case by showing a complex multiplet including also the H-3 band.

In 5-aminoisoquinoline, the protons H-6, -7, and -8 represent an ABX system, however, the spectrum of these protons is "deceptively simple", as in a quasi A_2B system, consisting of a triplet and a doublet.

6-Aminoisoquinoline displays a spectrum of the benzenoid protons from which it is possible to measure the coupling constants $J_{5,7}$ and $J_{7,8}$. However, the coupling constant $J_{5,8}$ seems to be very small, because there is no corresponding splitting between H-5 and -8. Most of the disubstituted isoquinolines (Table 6) investigated were of the 5,8-type, and the bands for H-6 and -7 showed up as two doublets, with the exception of 5-acetamido-8-nitro- and 5-bromo-8-nitroisoquinoline where H-6 and -7 formed a singlet with the intensity of two protons.

In the n.m.r. spectrum of thiazolo[4,5-*h*]isoquinoline, the two doublets at 7.78 and 8.62 δ are assigned to H-6 and -7, and the two singlets at 9.14 and 9.40 δ to H-2 and -9, respectively (Table 7). Such an assignment to H-2 and -9 is in agreement with the n.m.r. spectra of 2-substituted thiazolo-[4,5-*h*]isoquinolines in which the band at 9.14 δ is not present. The band at 9.40 δ shows also a slight coupling with both H-6 and -7. The two remaining benzenoid ring protons H-4 and -5 also display a typical AX pattern of two doublets centered at 7.82 and 8.33 δ ($J_{4,5}$ = 9.0 Hz). However, the assignment for both H-4 and -5 is not

possible from the first-order interpretation of the spectrum. The n.m.r. spectrum of thiazolo-[5,4-*f*]isoquinoline (Table 8) is analogous to that of thiazolo[4,5-*h*]isoquinoline.

Infrared Spectra

The i.r. spectra of thiazoloisoquinolines in the region 1700–400 cm^{-1} are presented in Table 9.

The strong bands starting from 1615–1602 to 1350 cm^{-1} are attributed to the aromatic and heteroaromatic double bond stretching vibrations. The bands in the region 1350–950 cm^{-1} are mostly moderate or weak, and they are assigned to C—H in-plane-deformation vibrations. Strong bands due to C—H out-of-plane bending motions occur in the region 950–650 cm^{-1}. All compounds in this series have strong bands between 835–810 cm^{-1}. In the far i.r. region, 650–400 cm^{-1} (ring deformation vibrations) (17) the band pattern is very sensitive to the nature of substituents.

The 2-aminothiazoloisoquinolines **1***a* and **2***a* are characterized by the bands 1650, 1660 and 1542, 1545 cm^{-1}, respectively (NH_2 group). The 2-hydroxythiazoloisoquinolines **1***d* and **2***d* exist actually in the lactam forms, as indicated by the strong carbonyl absorption bands at 1690 and 1680 cm^{-1}, respectively.

Experimental

Melting points were determined on a Gallenkamp melting point apparatus and are corrected. The u.v. spectra were recorded on a Unicam spectrophotometer model 800. Absolute ethanol was used as the solvent. The n.m.r. spectra were taken on a Varian n.m.r. spectrometer model A-60. Solvents used were acetic acid-d_4, carbon tetrachloride, deuteriochloroform, dimethylsulfoxide-d_6, and deuterium oxide. Tetramethylsilane was used as an internal standard. The i.r. spectra were recorded on a Perkin–Elmer model 521 and model 337 spectrophotometers (on KBr pellets). Elemental analyses were carried out by C. Daessle, Montreal and A. Bernhardt, Germany. The n.m.r. spectra were recorded by Mr. Victor Yu.

2-Aminothiazolo[4,5-h]isoquinoline (1a)

7-Aminoisoquinoline (**5**) (2.88 g, 0.02 mol) and potassium thiocyanate (8 g, 0.063 mol) were dissolved in 80 ml of 95% acetic acid in a 250 ml three-neck flask equipped with a mechanical stirrer, a thermometer, and a dropping funnel. Methanol (8 ml) was also added to the solution, which was cooled to 0–5°. Bromine (1.2 ml, 0.02 mol) in 10 ml of 95% acetic acid was added dropwise with stirring over a period of 20 min. The reaction mixture was poured into 100 ml of water after being stirred for an additional hour. The acid solution was neutralized with saturated sodium carbonate solution. The orange precipitate of 7-amino-8-thiocyanoisoquinoline (**6**) was collected and dried (yield 78%): i.r. (KBr): 2144 (SCN); 3445, 3365, 3230 cm^{-1} (NH_2).

A solution of 3.2 g of crude 7-amino-8-thiocyanoisoquinoline (**6**) in 150 ml of 4 *N* hydrochloric acid and 150 ml of ethanol was refluxed for 2 h. The hot solution was filtered and left to stand overnight. A yellow crystalline compound, 2-aminothiazolo[4,5-*h*]isoquinoline hydrochloride, precipitated. The salt was dissolved in water and neutralized with dilute sodium carbonate solution. The free base, 2-aminothiazolo[4,5-*h*]isoquinoline (**1***a*), precipitated (yield 90%); pale yellow needles, m.p. 303.5–305.5° (ethanol–water).

Anal. Calcd. for $C_{10}H_7N_3S$: C, 59.68; H, 3.51; N, 20.88; S, 15.92. Found: C, 59.60; H, 3.67; N, 20.74; S, 16.01.

2-Chlorothiazolo[4,5-h]isoquinoline (1b)

Cuprous chloride was prepared from 3 g of copper sulfate pentahydrate, 0.66 g of sodium chloride, 0.54 g of sodium hydrogen sulfite, and 0.36 g of sodium hydroxide, and dissolved in 10 ml of concentrated hydrochloric acid. The solution was cooled while the diazotation of the amino compound **1***a* was being carried out.

2-Aminothiazolo[4,5-*h*]isoquinoline (**1***a*) (1.2 g, 6.0 mmol) was added to 40 ml of 85% phosphoric acid with mechanical stirring. It was then cooled and maintained at 5–10° and 10 ml of 70% nitric acid was added. The resulting solution was cooled to 0–5° and sodium nitrite (0.44 g, 6.5 mmol) in 4 ml of water was added, with constant stirring, over a period of 15 min. The reaction mixture was stirred for another 15 min at this temperature, and was then added over a period of 20 min to the stirred solution of cuprous chloride in concentrated hydrochloric acid at 0–5°. The reaction mixture was stirred for another hour at room temperature. It was made basic with 20% sodium hydroxide solution. The basic mixture was extracted with three 250 ml portions of diethyl ether. The ether extract was washed with water, dried over magnesium sulfate, and filtered. The ether solution was evaporated to dryness leaving a pale yellow solid. The crude 2-chlorothiazolo[4,5-*h*]isoquinoline (**1***b*) was sublimed at 2 mm (bath temperature 98°). The sublimate (0.52 g) was recrystallized from *n*-hexane to give 0.45 g of the pure colorless chloro compound, m.p. 130–131°.

Anal. Calcd. for $C_{10}H_5N_2SCl$: C, 54.42; H, 2.28; N, 12.70; S, 14.53. Found: C, 54.33; H, 2.32; N, 12.85; S, 14.57.

Thiazolo[4,5-h]isoquinoline (1c)

2-Chlorothiazolo[4,5-*h*]isoquinoline (**1***b*) (0.5 g, 2.3 mmol) was dissolved in a mixture of 8 ml of 47% hydriodic acid, 4 ml of 95% acetic acid, and 4 ml of water, and 0.28 g of red phosphorus was added. The resulting mixture was refluxed for 3 h and filtered while hot. The volume was reduced to 6 ml and allowed to cool. The orange–red crystalline precipitate was collected, dissolved in water and neutralized with dilute sodium carbonate solution. The resulting precipitate was filtered off, washed with water, and dried. Recrystallization from *n*-hexane gave colorless needles of thiazolo[4,5-*h*]isoquinoline (**1***c*) in 58% yield, m.p. 138–139°.

Anal. Calcd. for $C_{10}H_6N_2S$: C, 64.49; H, 3.25; N, 15.05; S, 17.21. Found: C, 64.34; H, 3.32; N, 14.93; S, 17.08.

2-Acetamidothiazolo[4,5-h]isoquinoline

2-Aminothiazolo[4,5-*h*]isoquinoline (**1***a*) (0.5 g, 2.5

mmol) was refluxed with a mixture of 8 ml of acetic anhydride and 4 ml of pyridine for 2 h. Filtration of the cooled reaction mixture gave 0.55 g of 2-acetamidothiazolo[4,5-*h*]isoquinoline (91% yield). Colorless crystals, m.p. > 350° (absolute ethanol).

Anal. Calcd. for $C_{12}H_9N_3OS$: C, 59.24; H, 3.73; N, 17.27; S, 13.08. Found: C, 59.46; H, 3.37; N, 17.29; S, 13.29.

2-Hydroxythiazolo[4,5-h]isoquinoline

2-Chlorothiazolo[4,5-*h*]isoquinoline (**1***b*) (0.3 g, 1.48 mmol) was refluxed in 30 ml of 0.5 *N* sodium hydroxide solution for 3 h. The solution was cooled and acidified with dilute acetic acid to p*H* 6. The resulting precipitate was filtered off, washed with water and dried to give a 65% yield of 2-hydroxythiazolo[4,5-*h*]isoquinoline. Pale yellow needles, m.p. 296–297.5° (ethanol).

Anal. Calcd. for $C_{10}H_6N_2OS$: C, 59.38; H, 2.99; N, 13.85. Found: C, 59.62; H, 2.81; N, 13.96.

*6-Amino-5-thiocyanoisoquinoline (**8**)*

6-Aminoisoquinoline (**7**) (2.88 g, 0.02 mol) and potassium thiocyanate (8.0 g, 0.063 mol) were dissolved in 100 ml of 95% acetic acid. The solution was cooled to 0–5° and bromine (1.2 ml, 0.02 mol) in 10 ml of glacial acetic acid was added dropwise. The reaction mixture was poured into 100 ml of water, and neutralized with sodium carbonate solution. The orange precipitate was collected and dried (85% yield). Recrystallization from a large volume of benzene gave yellow needles of **8**, m.p. 159.5–161°.

Anal. Calcd. for $C_{10}H_7N_3S$: C, 59.68; H, 3.51; N, 20.88; S, 15.92. Found: C, 59.59; H, 3.52; N, 20.99; S, 15.76. The i.r. (KBr): 2148 (SCN); 3382, 3316, 3162 cm^{-1} (NH_2).

*2-Aminothiazolo[5,4-f]isoquinoline (**2a**)*

A solution of 6-amino-5-thiocyanoisoquinoline (**8**) (2.0 g, 0.01 mol) in 120 ml of 4 *N* hydrochloric acid and 120 ml of ethanol was refluxed for 2 h. The acid solution was evaporated in order to remove the ethanol and was neutralized with sodium carbonate solution. The yellow precipitate was collected, washed with water, and dried to give 1.82 g (91% yield) of **2a**. Recrystallization from aqueous alcoholic solution gave yellow needles, m.p. 251–253°.

Anal. Calcd. for $C_{10}H_7N_3S$: C, 59.68; H, 3.51; N, 20.88; S, 15.92. Found: C, 59.66; H, 3.61; N, 20.73; S, 15.80.

The i.r. (KBr): 3305, 3110 (broad) cm^{-1} (NH_2).

*2-Chlorothiazolo[5,4-f]isoquinoline (**2b**)*

2-Aminothiazolo[5,4-*f*]isoquinoline (1.2 g, 6 mmol) was transformed into 2-chlorothiazolo[5,4-*f*]isoquinoline (**2b**) by a procedure similar to that used for the preparation of **1b**. The crude 2-chlorothiazolo[5,4-*f*]isoquinoline (**2b**) was sublimed at 2 mm (bath temperature 110°). The sublimate (0.52 g, 38% yield) was recrystallized twice from *n*-hexane giving 0.45 g of colorless needles of the chloro compound, m.p. 170° (dec.).

Anal. Calcd. for $C_{10}H_5N_2SCl$: C, 54.42; H, 2.28; N, 12.70; Cl, 16.07. Found: C, 54.03; H, 2.70; N, 12.81; Cl, 16.10.

*Thiazolo[5,4-f]isoquinoline (**2c**)*

This compound was prepared from 2-chlorothiazolo-[5,4-*f*]isoquinoline (0.5 g, 2.3 mmol) by a method analogous to that applied for the preparation of **1c**. Colorless needles (55% yield) m.p. 174–175.5° (*n*-hexane).

Anal. Calcd. for $C_{10}H_6N_2S$: C, 64.49; H, 3.25; N, 15.05; S, 17.21. Found: C, 64.76; H, 3.29; N, 14.92; S, 17.08.

2-Acetamidothiazolo[5,4-f]isoquinoline

Colorless needles (ethanol), m.p. > 350°.

Anal. Calcd. for $C_{12}H_9N_3OS$: C, 59.24; H, 3.73; N, 17.27; S, 13.08. Found: C, 59.64; H, 3.31; N, 17.32; S, 13.33.

2-Hydroxythiazolo[5,4-f]isoquinoline

2-Chlorothiazolo[5,4-*f*]isoquinoline (**2b**) was hydrolyzed with 0.5 *N* sodium hydroxide solution and the hydroxy derivative was obtained in the form of fine yellow needles, m.p. > 350° (aqueous ethanol).

Anal. Calcd. for $C_{10}H_6N_2OS$: C, 59.38; H, 2.99; N, 13.85. Found: C, 59.41; H, 3.37; N, 13.73.

*5-Acetamido-8-aminoisoquinoline (**11**)*

5-Acetamido-8-nitroisoquinoline (**10**) (4.6 g, 0.02 mol) was reduced with hydrogen and 5% palladium-on-charcoal in absolute ethanol for 2 h. The catalyst was filtered off and the filtrate was evaporated to dryness. The resulting substance was crystallized from ethanol to give 2.4 g (85% yield) of 5-acetamido-8-aminoisoquinoline (**11**) as yellow needles, m.p. 270.5–272.5°.

Anal. Calcd. for $C_{11}H_{11}N_3O$: C, 65.67; H, 5.51; N, 20.74. Found: C, 65.77; H, 5.75; N, 20.70.

*2,5-Diaminothiazolo[5,4-h]isoquinoline (**3**)*

5-Acetamido-8-aminoisoquinoline (**11**) (3.02 g, 0.015 mol) and potassium thiocyanate (6.0 g, 0.047 mol) were dissolved in 120 ml of 95% acetic acid, and 10 ml of methanol. The resulting solution was cooled to 0–5° and bromine (0.9 ml, 0.015 mol) in 15 ml of glacial acetic acid was added dropwise over a period of 20 min. The reaction mixture was poured into 100 ml of water. The acid solution was neutralized with sodium carbonate solution. The crude orange product, 5-acetamido-8-amino-7-thiocyanoisoquinoline (**12**), weighed 3.2 g. A solution of 3 g of **12** in 150 ml of ethanol and 150 ml of 4 *N* hydrochloric acid was refluxed for 3 h. The acid solution was filtered, and the volume of the filtrate was reduced to 50 ml. The acid solution was poured onto ice and neutralized with sodium carbonate solution. The dark green precipitate was collected and recrystallized from aqueous alcoholic solution to give pale yellow needles, m.p. 274–276°. The total yield of 2,5-diaminothiazolo[5,4-*h*]isoquinoline (**3**) was 60%.

Anal. Calcd. for $C_{10}H_8N_4S$: C, 55.54; H, 3.73; N, 25.91. Found: C, 55.68; H, 3.77; N, 25.74.

The u.v. (ethanol): λ_{max} 227, 270, 382 nm; log ε 4.36, 4.27, 3.78; i.r. (KBr): 1652 m, 1550 vs, 1484 m, 1442 s, 1426 s, 1380 vs, 1202 m, 885 s, 847 s, 830 s, 802 m, 670 w, 580 m, 497 w, 460 w, 435 m, 420 m cm^{-1}.

2,5-Diacetamidothiazolo[5,4-h]isoquinoline

This compound was prepared from **3** using the procedure reported above for the acetamido derivative of **1c**. Fine colorless needles (dimethylformamide), m.p. > 350° (dec.).

Anal. Calcd. for $C_{14}H_{12}N_4O_2S$: C, 55.98; H, 4.03; N, 18.64; S, 10.68. Found: C, 55.79; H, 4.10; N, 18.78; S, 10.61.

*5-Amino-8-thiocyanoisoquinoline (**13**)*

This compound was obtained from 5-aminoisoquinoline (2.88 g, 0.02 mol) and potassium thiocyanate (8.0 g, 0.063 mol) using the procedure reported above for the preparation of **8**. The crude product (80% yield) was crystallized from a large volume of benzene to give yellow needles of **13**, m.p. 181–183°.

Anal. Calcd. for $C_{10}H_7N_3S$: C, 59.57; H, 3.51; N, 20.88; S, 15.94. Found: C, 59.6; H, 3.6; N, 20.9; S, 15.9.

*5-Amino-8-mercaptoisoquinoline (**14**)*

A solution of 2.0 g (0.01 mol) of 5-amino-8-thiocyanoisoquinoline (**13**) in 120 ml of 8 *N* hydrochloric acid and 120 ml of ethanol was refluxed for 4 h. The acid solution was evaporated to dryness on a water bath leaving a yellow solid, which was dissolved in 50 ml of water. Neutralization of the solution with sodium carbonate solution produced a precipitate which was filtered and

dried. Recrystallization from ethanol gave 1.5 g of **14** (87% yield), m.p. 260–262°.

Anal. Calcd. for $C_9H_8N_2S$: C, 61.36; H, 4.54; N, 15.91; S, 18.19. Found: C, 61.60; H, 4.48; N, 15.71; S, 18.11.

*8-Amino-5-thiocyanoisoquinoline (**15**)*

8-Aminoisoquinoline (3.35 g, 0.015 mol) and potassium thiocyanate (6.0 g, 0.047 mol) were dissolved in 90 ml of 95% acetic acid, and 6 ml of methanol. Bromine (0.9 ml, 0.015 mol) in 10 ml of 95% acetic acid was added dropwise, at 0–5°, followed by steps similar to the preparation of **8**. 8-Amino-5-thiocyanoisoquinoline (**15**) was obtained in a 79% yield (2.4 g). Recrystallization from benzene yielded yellow needles, m.p. 209–211°.

Anal. Calcd. for $C_{10}H_7N_3S$: C, 59.57; H, 3.51; N, 20.88. Found: C, 59.27; H, 3.83; N, 20.66.

*8-Amino-5-mercaptoisoquinoline (**16**)*

8-Amino-5-thiocyanoisoquinoline (**15**) was transformed into **16** by a method similar to that used for the preparation of **14**. 8-Amino-5-mercaptoisoquinoline (**16**) formed colorless needles, m.p. 244–246° (ethanol).

Anal. Calcd. for $C_9H_8N_2S$: C, 61.36; H, 4.54; N, 15.91; S, 18.19. Found: C, 61.77; H, 4.05; N, 16.09; S, 18.13.

Electrophilic Substitution in Methyl-Substituted Naphthalenes. II. The Hyperconjugative Model of the Methyl Group in PPP- and ω-Technique Calculations

LE-KHAC HUY AND W. FORST
Department of Chemistry, Université Laval, Québec 10, Québec

Received June 25, 1971

A study of the dependence of common reactivity indices in 1,4-dimethylnaphthalene on the values of the parameters for the heteroatom model of the methyl group reveals that this model is not suitable within the Pople–Pariser–Parr formalism. However, if this model is used in conjunction with the ω-technique, two of the indices, superdelocalizability and localization energy, may give the correct order of reactive positions of 1,4-dimethylnaphthalene provided that an appropriate choice of parameter values is made.

L'étude de la variation des indices de réactivité usuels du 1,4-diméthyl naphtalène avec les valeurs des paramètres pour le modèle hétéroatome du groupement méthyle révèle que ce modèle ne convient pas au formalisme de Pople–Pariser–Parr. Cependant, si ce modèle est utilisé avec la technique ω, deux des indices, la superdélocalisabilité et l'énergie de localisation, peuvent donner le bon ordre des positions réactives de 1,4-diméthyl naphtalène advenant un choix approprié des valeurs des paramètres.

Canadian Journal of Chemistry, **49**, 4065 (1971)

Introduction

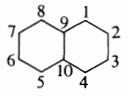
This paper deals with computational aspects of a study of electrophilic substitution reported more fully in Part III (following paper, ref. 17). The justification for a separate presentation is the desire to leave the main argument of Part III uncluttered with details of procedure, some of which is rather involved.

Exploratory calculations have shown that (*a*) it was generally difficult to obtain agreement between theory and experiment whenever substitution took place in a β-position; (*b*) not only the nature of the model for the methyl group but also numerical values of the parameters involved had substantial influence on the calculated result. Therefore before undertaking the study of all the methyl naphthalenes we have investigated first in some detail the model and parameter representation of the methyl group, using 1,4-dimethylnaphthalene as a convenient test case, one where chloromethylation and several other electrophilic substitutions all take place in a β-position; more complete experimental results (1) give the order of reactive positions[1] in this compound as $3 > 5 > 6$ for electrophilic substitution.

Since almost any result can be obtained by appropriate manipulation of parameters in a semi-empirical molecular orbital (m.o.) method, one must choose a consistent set of parameters that can correlate various types of data, *e.g.* spectral properties, reactivity, etc. quantitatively as well as qualitatively. Although we deal in this paper exclusively with the qualitative order of reactive positions in 1,4-dimethylnaphthalene, we show in Part III that parameter values chosen on this basis are in fact consistent in the sense defined above. The reason for testing parameters on reactivity first is due to the fact that the reverse procedure, *i.e.* testing parameters on spectral properties, ionization potentials and the like, before calculating reactivity, is unworkable, as will be pointed out on several occasions.

In a previous note (2), hereafter referred to as Part I, we have investigated the dependence of three representative reactivity indices q_r, S_r and L_r, defined further below, on the value of the parameter h for the *inductive* effect of the methyl group. It turned out that a given reactivity index behaves similarly, whether calculated by the ω-technique or the more expensive (in terms of computer time) Pople–Pariser–Parr (PPP) technique; in particular, only S_r, perhaps accidentally, gave the correct order of reactive positions.

[1]The following numbering is used throughout Parts II and III:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

We now wish to investigate how the three reactivity indices behave as a function of parameters for the *hyperconjugative* effect of the methyl group.

Method of Calculation

The method of calculation by the ω-technique (3) has been described in Part I and will not be repeated here in detail. We only re-write eq. 1 of Part I in the slightly more general form

$$[1] \qquad \alpha_r^{t+1} = \alpha + \omega\beta\,(n_r - q_r^t)$$

where α and β are standard Coulomb and exchange integrals, respectively, q_r is electron density at atom r, n_r is the number of π-electrons made available for conjugation by atom r, and ω is an adjustable parameter. As before, the exchange integral β_{rs} is made dependent on bond length by the relation

$$[2] \qquad \beta_{rs}^{t+1} = \beta \exp[-2.683\,(0.12 - 0.18\,p_{rs}^t)]$$

where p_{rs} is the mobile bond order between atoms r and s. The superscript t in eqs. 1 and 2 represents the number of iterations.

The diagonal and off-diagonal elements in the PPP-technique (4) were also given in Part I. We present them in eqs. 3 and 4 in a slightly more general form,

$$[3] \qquad \alpha_r = (\alpha_r)_{\text{core}} + q_r\gamma_{rr} + \sum_{s \neq r} (q_s - Z_s)\gamma_{rs}$$

$$[4] \qquad \beta_{rs} = (\beta_{rs})_{\text{core}} - \tfrac{1}{2}p_{rs}\gamma_{rs}$$

where $(\alpha_r)_{\text{core}} = -W_r$ is an empirical parameter representing the sum of the π-electron kinetic energy in atomic orbital r and of potential energy due to core r only; γ_{rr} and γ_{rs} are the one- and two-center, two-electron repulsion integrals; $(\beta_{rs})_{\text{core}}$ is the resonance integral between cores r and s; Z_s is the number of electrons contributed by core s to the system.

In both the ω- and PPP-technique, the criterion of self-consistency was a variation of less than 10^{-4} in all wave function coefficients of occupied orbitals. To avoid convergence problems we have used a procedure similar to that of Ettinger (5), which consists of taking the average electron densities and mobile bond orders (eqs. 1 and 2) of two preceding iterations as input for the next iteration.

Values for the various parameters are given in Part I. Calculations were done on IBM 360/60 by means of programs written in Fortran IV.

It has been pointed out recently by Harris (6*a*) that when matrix elements of the total energy operator are dependent on net charges, this charge-dependence should be taken into account. As applied to methods used here, *i.e.* the ω- and PPP-techniques, however, it can be demonstrated (6) that the only changes are the interpretation of parameters appearing in eqs. 1–4, but not the form of the equations; hence no conclusions are affected.

Model for Methyl Group

In contrast with the inductive model, it is assumed in the hyperconjugative model for the methyl group that there is actual mixing of the aromatic ring π-orbitals with the (pseudo) π-orbital of the methyl group, leading to a flow of electrons between the methyl group and the ring, and their redistribution in the ring. Streitwieser and co-workers (3) have discussed the various theoretical representations suitable for describing the hyperconjugative effect; we select the so-called heteroatom model because it requires the least number of parameters. Briefly, the methyl group in this model is treated as a single heteroatom X contributing two electrons to the π-system; thus in eqs. 1 and 3, n_x and $Z_x = 2$ for the heteroatom and n_x, $Z_x = 1$ for all other carbon atoms.

This model has been criticized by Dewar (7) because the methyl group is made to contribute only one π-orbital, while the other antibonding orbital is neglected. In effect, this model gave the wrong prediction for behavior of electrons in the methyl group (8); however it is not likely wrong insofar as properties of electrons *in the ring* are concerned, which is the property of interest in the present study. Furthermore, inclusion of the methyl antibonding π-orbital requires the methyl group to be treated as a modified vinyl group (9), necessitating five parameters. Such large number of adjustable parameters effectively negates whatever superiority this model may have over the heteroatom model.

As applied to the ω-technique, the heteroatom model requires specification of two integrals, the heteroatom Coulomb (α_x) and exchange (β_{c-x}) integrals, which, in turn, are determined in terms of their standard values by means of two parameters, h_x and k_{c-x}:

$$[5] \qquad \alpha_x = \alpha + h_x\,\beta$$

$$[6] \qquad \beta_{c-x} = k_{c-x}\,\beta$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In the PPP-technique, one can always choose W_x and $(\beta_{c-x})_{core}$ so as to make calculations directly comparable with the ω-technique. If we write

$$W_x = W_c - H_x\,\beta \quad [7]$$

$$(\beta_{c-x})_{core} = K_{c-x}\,\beta \quad [8]$$

where $\beta = -2.39$ eV is the standard resonance integral and $W_c = 11.16$ eV is the ionization potential of the carbon atom, then H_x and K_{c-x} are the PPP equivalents of h_x and k_{c-x}. In addition, two subsidiary parameters, the electron affinity E_x and the effective nuclear charge Z_x^{eff} of the heteroatom (to be used in Roothan's formula for calculating repulsion integrals), need to be specified. Electron affinity appears only in the one-center, two-electron repulsion integral γ_{xx}:

$$\gamma_{xx} = W_x - E_x \quad [9]$$

As W_x is allowed to change, one could always compensate for this change by choosing an appropriate value for E_x. Hence the choice of a value for E_x is by no means critical and calculations were done by taking E_x to be equal to E_c, the electron affinity of a carbon atom.

Comparison of the dashed and solid lines in Figs. 5 and 6 shows that whether calculations are done using $Z_x^{eff} = Z_c^{eff} = 2.090$, or using the relation (10)

$$\gamma_{xx} = 5.325\,Z_x^{eff} \quad [10]$$

the general trend is the same. Consequently, the initially four-parameter PPP-problem is reduced to a two-parameter problem, and calculations by the PPP-technique are directly comparable with those using ω-technique.

Reactivity Indices

For convenience, definitions of reactivity indices used in this work (q_r, S_r, and L_r) are summarized here. For completeness, we also include here definitions of two other indices, f_r and π_{rr}, which will be used only in Part III. The definitions apply to a closed-shell molecule and electrophilic substitution. If c_{jr} is the wave function coefficient of atom r in orbital j, then the total π-electron density at atom r is

$$q_r = 2\sum_{j=1}^{m} c_{jr}^2 \quad [11]$$

(sum over occupied orbitals j)

The frontier electron density f_r for an electrophilic substitution is a contribution to q_r arising from the pair of electrons occupying the highest orbital m

$$f_r = 2\,c_{mr}^2 \quad [12]$$

The mobile bond order between atoms r and s is defined as

$$p_{rs} = 2\sum_{j=1}^{m} c_{jr}c_{js} \quad [13]$$

Self-polarizability at atom r is given by

$$\pi_{rr} = 4\sum_{j=1}^{m}\sum_{k=m+1}^{m}\frac{c_{jr}^2 c_{kr}^2}{\varepsilon_j - \varepsilon_k} \quad [14]$$

where the second sum (index k) is over unoccupied orbitals and ε_j is the one-electron energy in orbital j. Superdelocalizability for an electrophilic substitution is defined as

$$S_r = 2\sum_{j=1}^{m} c_{jr}^2/\varepsilon_j \quad [15]$$

As usual, we define localization energy in electrophilic substitution as the difference in π-energy between the original molecule and a "residual molecule" in which two electrons and one carbon atom at position r of attack are taken out of conjugation. However, in contrast to some previous treatments, we have applied iterations to both the original reactant and the "residual molecule", and in the latter have carried all computations to self-consistency at each position r separately. As in Part I, superscripts ω and P are used to distinguish indices calculated by the ω- and PPP-techniques.

Results and Discussion

Since there are two parameters to contend with, cross-comparison between two techniques (ω and PPP) is somewhat complicated. Consequently, for the sake of convenience and clarity we shall discuss separately results based on the two techniques before making the comparison.

(a) ω-Technique

The results of calculations are shown in Figs. 1–3, which represent the dependence of the three reactivity indices q_r^{ω}, S_r^{ω}, and L_r^{ω} on the two hyperconjugative parameters. The effect of one parameter (h_x or k_{c-x}) in the range of its commonly used values is illustrated by keeping the other constant; these constant values were taken more or less arbitrarily[2] as $h_x = 2.5$ and $k_{c-x} = 0.7$.

[2]These values are close to the cross-over-points in Figs. 2 and 3.

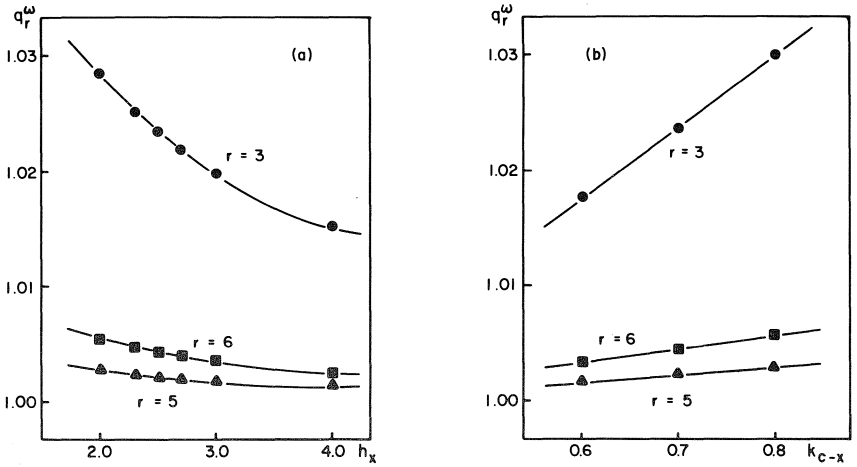


FIG. 1. Electron density of 1,4-dimethylnaphthalene at position r, calculated by the ω-technique (ω = 1.4) and using heteroatom model for representing the methyl groups: (*a*) as a function of parameter h_x (k_{c-x} = constant = 0.7) (*b*) as a function of parameter k_{c-x} (h_x = constant = 2.5).

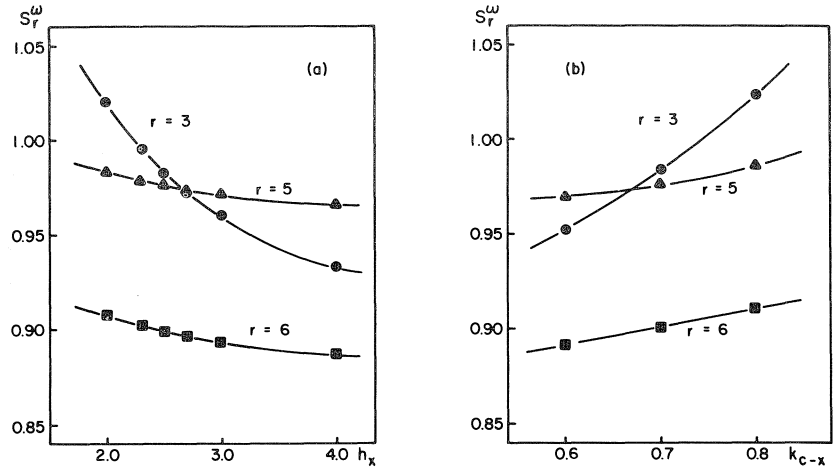

FIG. 2. Superdelocalizability of 1,4-dimethylnaphthalene at position r, calculated by the ω-technique (ω = 1.4) and using heteroatom model for representing the methyl groups: (*a*) as a function of parameter h_x (k_{c-x} = constant = 0.7) (*b*) as a function of parameter k_{c-x} (h_x = constant = 2.5).

The result for electron density q_r^ω (Fig. 1) shows that this index is relatively insensitive to both h_x and k_{c-x}, at least within the chosen range of parameter values. The most reactive position (position 3) is correctly predicted in 1,4-dimethylnaphthalene, but not the following positions. The results are thus quite analogous to those obtained in Part I for the inductive effect of the methyl group so that whatever the model used (inductive or hyperconjugative), electron density does not seem to be a good index of reactivity, a conclusion reached on other grounds by Ridd (11) and Greenwood and McWeeny (12), and corroborated by our own results (13) on other methylnaphthalenes.

The behavior of superdelocalizability S_r^ω (Fig. 2) and of localization energy L_r^ω (Fig. 3) is more interesting. S_r^ω behaves here in the same way as it did on the inductive model: cross-over points are observed in both Figs. 2*a* and *b*, so that depending on the chosen values of h_x and k_{c-x}, S_r^ω may or may not give the correct order of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

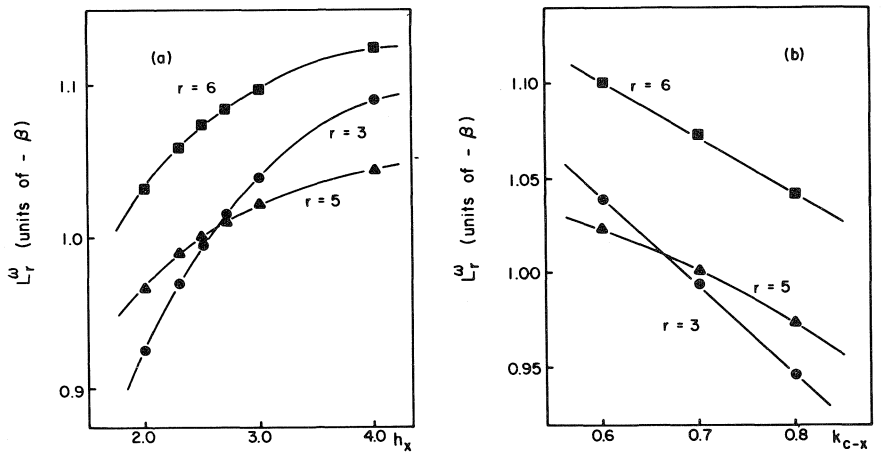

FIG. 3. Localization energy of 1,4-dimethylnaphthalene at position r, calculated by the ω-technique (ω = 1.4) using heteroatom model for representing the methyl groups: (*a*) as a function of parameter h_x(k_{c-x} = constant = 0.7) (*b*) as a function of parameter k_{c-x} (h_x = constant = 2.5).

reactive positions in 1,4-dimethylnaphthalene. The same behavior is now also displayed by L_r^ω (Figs. 3*a* and *b*), which contrasts with the behavior of L_r^ω on the inductive model (Fig. 3, Part I). Interestingly enough, the crossover points occur for both S_r^ω and L_r^ω at nearly the same value of h_x (~2.7) and k_{c-x} (~0.7).

The effect of the parameter ω on q_r^ω and S_r^ω is small, but ω influences considerably the "residual molecule", and hence also L_r^ω. Figure 4 shows the dependence of L_r^ω on ω with h_x and k_{c-x} constant at 2.0 and 0.8, respectively. The dependence on ω is linear, so that order of

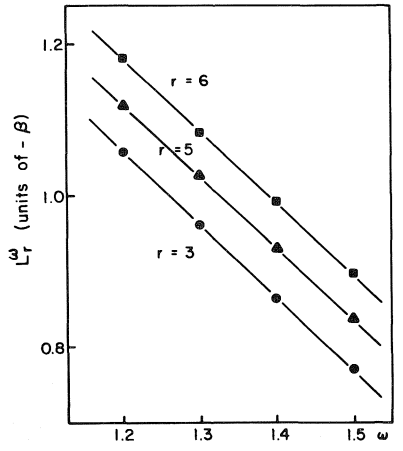

FIG. 4. Localization energy of 1,4-dimethylnaphthalene at position r, calculated using heteroatom model (h_x = 2.0, k_{c-x} = 0.8) for representing the methyl groups as a function of parameter ω

reactive positions is not affected. These findings confirm those of Part I. It is interesting to note that, with the values of h_x and k_{c-x} mentioned, L_r^ω and S_r^ω are in fairly good *quantitative* agreement with experimental results of Dallinga *et al.* (1) on the rate of hydrogen–deuterium exchange in 1,4-dimethylnaphthalene, *i.e.* are proportional to the logarithm of the rate constant (13).

(b) The PPP-Technique

Results of calculations are again given in the form of graphs (Figs. 5 and 6) representing the dependence of the reactivity indices on one parameter (W_x or $(\beta_{c-x})_{core}$) by keeping the other constant. The constant values used (W_x = 16 and $(\beta_{c-x})_{core}$ = −1.4 eV) imply $H_x \sim 2.0$ and $K_{c-x} \sim 0.7$ (*cf.* eqs. 7 and 8), and therefore correspond essentially to h_x and k_{c-x}.

The dependence of q_r^P on both parameters is the same as that of L_r^P, and hence, to conserve space, only the case of the latter will be displayed (Fig. 5). First of all, we can see that L_r^P is relatively insensitive to the values of both parameters. Furthermore, it gives the correct qualitative order of reactive positions of 1,4-dimethylnaphthalene. Quantitatively, however, the predominance of the most reactive position 3 over the other two (see Fig. 5) is somewhat larger than determined by experiment (1). Such behavior is different from that observed previously for L_r^ω in the ω-technique.

In Fig. 6, cross-over points are observed for S_r^P as a function of both parameters. However, the inversion in the order of reactive positions

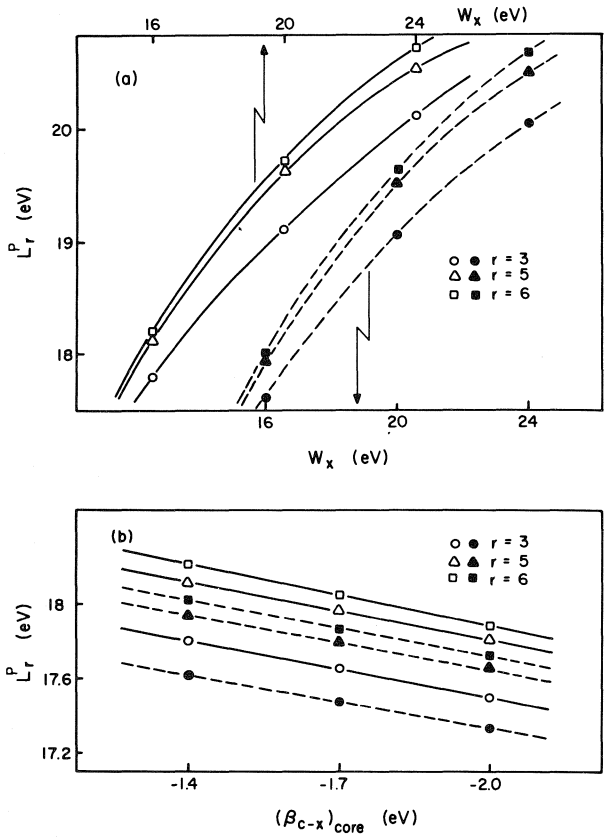

FIG. 5. Localization energy (L_r^P) of 1,4-dimethylnaphthalene at position r, calculated by the PPP-technique and using heteroatom model for representing the methyl group: (*a*) as a function of parameter W_x [$(\beta_{c-x})_{core}$ = constant = −1.4 eV] (*b*) as a function of parameter $(\beta_{c-x})_{core}$ [W_x = constant = 16 eV]. Dashed lines represent calculations where effective nuclear charge (Z_x^{eff}) was made dependent on the W_x by means of eq. 10.

now involves positions 5 and 6 and not positions 3 and 5, as in the case of the ω-technique. Levy and Berthier (14) and Ross (15), in calculations on singlet–singlet transition of propene and methyl-substituted ethylenes, respectively, have determined the parameter values as $W_x \sim 12$ and $(\beta_{c-x})_{core} \sim -1.4$ eV. With reference to Fig. 6, it is seen that these values would lead to a wrong order of reactive positions of 1,4-dimethylnaphthalene. On the other hand, S_r^P predicts, as in the case of q_r^P and L_r^P, too great a predominance of position 3 over the other two (*cf.* Fig. 6) as compared to experimental results (1), irrespective of the values used for hyperconjugative parameters.

As an important aside, we may note that the transfer of charge from the methyl group to the π-system of naphthalene in PPP calculations (~0.7 per methyl group) is very high compared with at most 0.05 per methyl group obtained in the ω-technique calculations. Such a high transfer of charge on the heteroatom model has been noted before by Levy and Berthier (14) who used PPP-technique in calculations on propene. According to recent accurate (all-valence and CNDO) calculations (16), the transfer of π-charge from the methyl group to the π-system of substituted molecule is about 0.03 per methyl group, which compares reasonably well with our ω-technique result, but not with that of the PPP-technique. If the transfer of charge is taken as a measure of perturbation, it may be questioned why the methyl group should lead to such a high perturbation in the PPP result. Thus there is some doubt about the validity of the heteroatom model within the PPP formalism.

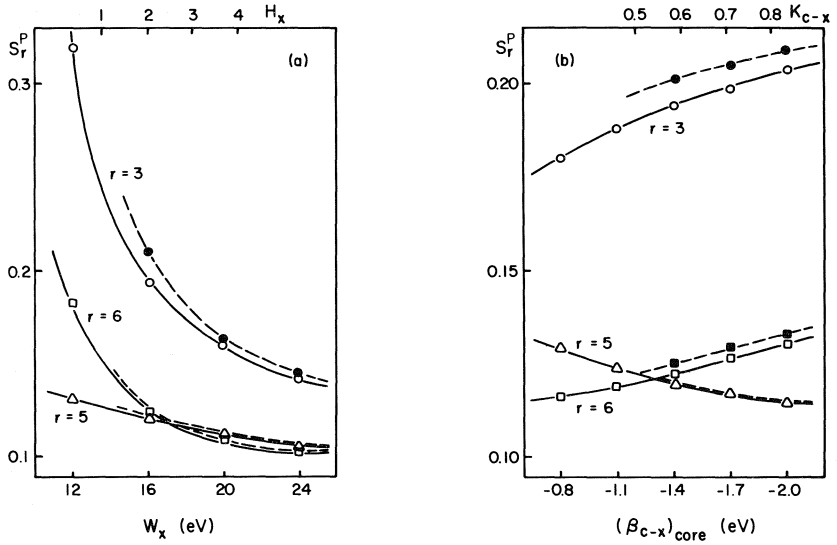

FIG. 6. Superdelocalizability (S_r^P) of 1,4-dimethylnaphthalene at position r, calculated by the PPP-technique and using heteroatom model for representing the methyl group: (*a*) as a function of parameter W_x [$(\beta_{c-x})_{core}$ = constant = -1.4 eV] (*b*) as a function of parameter $(\beta_{c-x})_{core}$ [W_x = constant = 16 eV]. Dashed lines represent calculations where effective nuclear charge (Z_x^{eff}) was made dependent on W_x by means of eq. 10.

Conclusions

Using the inductive model of the methyl group we have pointed out in Part I, where the PPP- and ω-techniques were shown to yield comparable results in reactivity calculations, that the cause of this equivalence was the chosen parametrization and the weak perturbation produced by the methyl group. In the present calculations, involving the heteroatom model for the hyperconjugative effect of the methyl group, the methyl group still produces a weak perturbation in ω-technique calculations, but a large perturbation in the PPP calculations. For this reason it is not too surprising that the ω- and PPP-techniques no longer produce comparable results; in fact, the heteroatom model is clearly unsuitable for PPP calculations.

Insofar as the ω-technique is concerned, the reactivity indices S_r^{ω} and L_r^{ω} are shown to be strongly dependent on the values of the parameters for the hyperconjugative heteroatom model of the methyl group. Both S_r^{ω} and L_r^{ω} may account qualitatively, or even quantitatively, for rates of electrophilic substitution in 1,4-dimethylnaphthalene if $h_x < 2.7$ and $k_{c-x} > 0.7$. Compared with the values $h_x = 3.0$ and $k_{c-x} = 0.7$ advocated by Streitwieser and co-workers (3) for the calculations of ionization potentials (but which would yield the wrong order of reactive positions), our values of h_x and of k_{c-x} suggest a necessity for a stronger hyperconjugative effect in reactivity calculations than in calculations of ionization potentials.

Electrophilic Substitution in Methyl-substituted Naphthalenes III. Correlation between Experimental Results and Molecular Orbital Calculations of Reactivity Indices

P. Canonne, Le-Khac Huy, and W. Forst
Department of Chemistry, Université Laval, Québec 10, Québec

Received June 25, 1971

Common reactivity indices (electron density q_r, self-polarizability π_{rr}, frontier electron density f_r, superdelocalizability S_r, and localization energy L_r) are calculated for electrophilic substitution in 25 methylnaphthalenes. An elementary s.c.f. method in the form of a modified ω-technique is used, using the hyperconjugative-heteroatom model for the methyl groups, with $\omega = 1.4$, $h_x = 2.0$, $k_{c-x} = 0.8$. This choice gives reasonably good ionization potentials and very good correlation for singlet transitions (p-band) in u.v. spectra of α-methylnaphthalenes. Purely static indices q_r, f_r, and π_{rr} are found to be unsuitable for predicting reactive positions for chloromethylation, while S_r and L_r are very satisfactory. On the theory that the polarizing effect of the approaching reagent is important, the index $q_r' = q_r + \pi_{rr}\,\delta\alpha_r$ may be obtained, which is also found to be very satisfactory for $\delta\alpha_r = \beta$. If the interaction is viewed as an interaction between a hard acid (chloromethyl) and soft base (methylnaphthalenes), the index $\Delta E_r = aq_r + bf_r$ is obtained, which is likewise found to be satisfactory with $a = 1$, $b = 0.15$. These results show clearly that it is insufficient to base reactivity considerations in methylnaphthalenes entirely on the properties of the isolated substrate molecule, but that even a very simple description of the substrate–reagent interaction is sufficient since the four indices S_r, L_r, q_r', and ΔE_r all have the same predictive value.

Nous avons entrepris l'étude de la substitution électrophile de 25 méthylnaphtalènes en utilisant une version modifiée de la technique Oméga pour calculer les indices de réactivité usuels (densité électronique q_r, autopolarisabilité π_{rr}, densité des électrons frontaliers f_r, superdélocalisabilité S_r et énergie de localisation L_r). Le modèle hétéroatome a été utilisé pour représenter le groupement méthyle. Notre choix des paramètres ($\omega = 1.4$, $h_x = 2.0$ et $k_{c-x} = 0.8$) nous a permis d'obtenir des valeurs raisonnables des potentiels d'ionisation et une très bonne corrélation entre l'énergie de transition singulet–singulet calculée et observée (bande p) des spectres u.v. Nous avons trouvé que les indices purement statiques q_r, f_r et π_{rr} ne réussissent pas à prédire les positions les plus réactives telles qu'obtenues expérimentalement par la chlorométhylation, tandis que S_r et L_r donnent des résultats satisfaisants. Cependant, en tenant compte de l'effet polarisateur du réactif électrophile, un nouvel indice $q_r' = q_r + \pi_{rr}\,\delta\alpha_r$ peut être défini qui conduit également à des prédictions satisfaisantes si $\delta\alpha = \beta$. D'autre part, si l'interaction substrat-réactif (électrophile) est considérée comme étant celle entre un acide dur (chlorométhyle) et une base molle (méthyl naphtalènes), l'indice ainsi obtenu $\Delta E = aq_r + bf_r$ est aussi un bon indice de réactivité si $a = 1$ et $b = 0.15$. L'ensemble de nos résultats démontre clairement qu'il est insuffisant d'étudier la réactivité chimique en se basant uniquement sur les propriétés de la molécule isolée (molécule du substrat). Cependant, même une très simple description de l'interaction substrat–réactif (électrophile) s'avère déjà suffisante car les quatre bons indices q_r', S_r, L_r, et ΔE conduisent tous à des prédictions identiques.

Canadian Journal of Chemistry, **49**, 4073 (1971)

Introduction

A simple theoretical treatment of the reactivity of conjugated organic compounds seeks a correlation between rate of reaction and some reactivity index derived from the π-molecular orbital (m.o.) representation of the ground state of the substrate molecule (1). A large number of studies have shown that the predictive value of the commonly employed reactivity indices, such as self-polarizability, free valence, reactivity number, superdelocalizability, is about equal for alternant hydrocarbons; the reason is that all ultimately relate to the same basic function (2). The same is not true of non-alternant systems (*e.g.* methylnaphthalenes), and therefore such systems promise to provide a more meaningful test of the reactivity indices. However, theoretical studies on the reactivity of non-alternant hydrocarbons (1*a*, 3, 4) are fragmentary because of the dearth of appropriate experimental results.

Experimental data are now available, mostly from P.C.'s laboratory,[1] giving the yield for chloromethylation (an electrophilic substitution) at various reactive positions of 25 different methyl-substituted naphthalenes (*cf.* Table 2);

[1]See Part IV, to be published.

For personal use only.

there are also rate constants for H–D exchange in six symmetric dimethylnaphthalenes (4). Using this body of data, we propose to examine the problem of electrophilic substitution in methylnaphthalenes from the point of view of m.o. theory in the π-electron approximation. Inasmuch as the amount of calculations is large (an average of four reactive positions are to be calculated per compound for each of six reactivity indices), and since the results of the calculations are then compared against experimental data which give only relative order of reactive positions and not actual rate constants, elaborate s.c.f. calculations are not warranted for reasons of both cost and significance. Furthermore, the problem is considerably circumscribed theoretically in that the attacking reagent is the same in most cases, as are the solvent and reaction conditions in general, so that the only variable is the number of methyl groups in the substrate molecule; hence, to this extent, the calculations provide as much a test of the model for the methyl group as they provide a test of the reactivity indices themselves.

For comparison purposes, Table 3 summarizes experimental results for other types of attacking reagent.

Method of Calculation

We have chosen an elementary s.c.f. method in the form of the so-called "ω-technique" (1*a*), which (unlike the simple Hückel m.o. method) allows for a redistribution of electrons in the aromatic ring, an important point in connection with the hyperconjugative model for the methyl group (*vide infra*), yet requires moderate amounts of computer time. Consequently the superscript ω on reactivity indices (*cf.* Parts I and II) has been dropped as redundant.

This choice was arrived at after comparative investigation of other methods and models for the methyl group, which are described in Part I (5) and Part II (preceding paper, ref. 15) to which the reader is referred for details. On balance, the hyperconjugative-heteroatom model turned out to be the most appropriate for reactivity calculations, and therefore has been used in all calculations reported in this paper.

It is worthwhile to note that the hyperconjugative model, at least insofar as π-electrons are concerned, is supported by recent calculations (6) using more sophisticated methods (CNDO and all-valence *ab initio*) which show that there is a small transfer of charge (*cf.* Part II), accompanied by a polarizing effect (6*c* and *d*), which results in electrons being driven away from the atom to which the methyl group is attached and their redistribution in the π-system of the substrate. On the other hand, it is found by these methods that the methyl group causes *withdrawal* of σ-electrons from the ring (6*b* and *c*), which is an effect opposite to that assumed in the inductive model of the methyl group.

Within the framework of the ω-technique, the heteroatom model for the methyl group requires the specification of three parameters (*cf.* Part II): ω, h_x and k_{c-x}.

It is shown in Parts I and II that the calculated order of reactive positions in 1,4-dimethylnaphthalene, using either model for the methyl group, is independent of the value of ω, so that this choice is not at all critical. We have used throughout Streiwieser's value (1*a*) $\omega = 1.4$.

Insofar as the parameters h_x and k_{c-x} are concerned, results of Part II show that S_r and L_r give the correct order of reactive positions in 1,4-dimethylnaphthalene if $h_x < 2.7$ and $k_{c-x} > 0.7$. The values used throughout this work are $h_x = 2.0$ and $k_{c-x} = 0.8$.

The fact that these values yield the correct *relative* order of reactive positions does not necessarily make them reasonable, and therefore the calculation of the *absolute* value of some property is desirable as a check. Three checks have been made; all satisfactory:

(*1*) As mentioned in Part II, the above choice for h_x and k_{c-x} yields values of L_r that give good semi-quantitative agreement with experimental rate constants (4) for hydrogen–deuterium exchange in 1,4-dimethylnaphthalene.

(*2*) Ionization potentials for 1-methyl- and 2-methylnaphthalene, calculated by the method of Streitwieser (7*a*) with the above values of h_x and k_{c-x}, yield the values of 8.23 eV (1-methyl) and 8.37 eV (2-methyl). This compares reasonably well with the experimental (7*b*) values of 7.96 eV for 1-methyl and 8.10 eV for 2-methyl naphthalene.

(*3*) Table 1 and Fig. 1 show a correlation between the observed energy of the singlet transition in the u.v. spectra of some polymethylnaphthalenes, and $x_{m+1} - x_m$, the energy difference (in units of β) between the lowest unoccupied $(m + 1)$ and the highest occupied (m) orbital. The singlet transition is the $^1L_a \leftarrow {}^1A$ transition, or the

TABLE 1. Experimental data from the u.v. spectra of α-methylnaphthalenes and numerical values for x_m, x_{m+1}, calculated by ω-technique (ω = 1.4, h_x = 2.0, k_{c-x} = 0.8)

Molecule	λ_{max} (p-band)* mμ	eV	x_{m+1}	x_m	$x_{m+1} - x_m$	Solvent	Reference 16 for λ_{max}

*Strictly speaking, the 0—0 band should be used, which is the longest-wavelength peak in the band. It is not always well-resolved, and therefore for consistency the maximum peak of the band is used throughout.

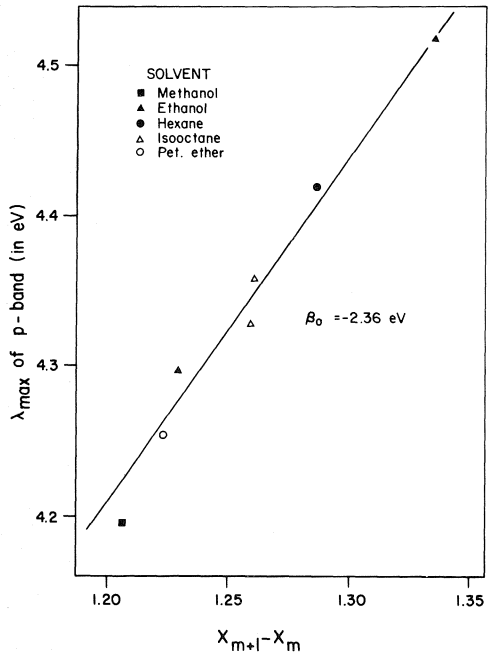

FIG. 1. Correlation between energy of singlet transition in u.v. spectra (λ_{max}) and $x_{m+1} - x_m$ of α-methylnaphthalenes. Standard error on β_0 is $\sigma = \pm 0.15$ eV.

p-band in Clar's notation (8), and it is transversely polarized *i.e.* in the direction perpendicular to the long axis of the molecule, so that methyl substitution in positions 1, 4, 5, or 8 (α-positions) extends conjugation in the transverse direction and produces a bathochromic effect. The correlation is surprisingly good if one considers that configuration interaction is ignored. The least-squares value of β_0 calculated from the slope of the straight line in Fig. 1 is $\beta_0 = -2.36$ eV, in ood agreement with the generally accepted values of −2.4 to −3.0 eV.

It is interesting to note that parameter values recommended by Streitwieser (h_x = 3.0, k_{c-x} = 0.7) (1*a*) give higher ionization potentials for 1- and 2-methylnaphthalene (8.37 and 8.48 eV, respectively), and a much higher β_0 in the correlation of Fig. 1 (−6.54 eV, to be precise).

Experimental

Since we feel that mere specification of the most reactive position is much too crude a criterion that tends to disguise important differences in reactivity, Table 2 summarizes fairly detailed experimental information on chloromethylation. Part *A* lists reactant naphthalenes that in general chloromethylate easily, *i.e.* those that are very reactive, as can be seen from the reaction medium and from reaction conditions. The last three compounds listed in part *A* are somewhat less reactive than the rest, since the reaction conditions are more severe. The chloromethylated compound, once formed, tends to be unstable and some of it ends up as bis-naphthyl methane. On the assumption that all the bis-naphthyl methane found comes from the chloromethylated compound, "yield 2" represents a rough correction for loss to bis-naphthyl methane. Part *B* of Table 2 lists reactant naphthalenes requiring more drastic reaction medium and reaction conditions, *i.e.* methylnaphthalenes significantly less reactive than those of part *A*. The yield of bis-naphthyl methane was generally about 5%, so that yields listed in part *B* should be increased by that amount to correct roughly for loss to bis-naphthyl methane.

Table 3 summarizes available experimental results on other electrophilic substitutions. A critical evaluation of each entry was not feasible, nor was it possible to reconstruct experimental conditions in as much detail as in Table 2, since the pertinent information is mostly lacking, except for the case of hydrogen–deuterium exchange in symmetric dimethylnaphthalenes where experimental data are very complete. With this exception, results listed in Table 3 will be considered as slightly suspect and will not be used to formulate important arguments. It may be noted, however, that with the exception of a few cases of succinoylation (a bulkier substituent than the rest), the most reactive positions for electrophilic substitutions of Table 3 are the same as those for chloromethylation (Table 2).

Results of Calculations

To conserve space, results of the calculations are summarized in several tables of the Discussion, but actual numerical values are not quoted unless it is essential for the argument. A complete listing of numerical results is available (9).

Discussion

It is convenient to consider first a qualitative overview of all the results, and then take a more quantitative look at the more interesting reactivity indices.

(a) Qualitative Correlations

Table 4 gives a comparison between the most reactive position for chloromethylation of methylnaphthalenes as observed experimentally (column 2; *cf.* Table 2) and as predicted by the various reactivity indices (columns 3 to 7). The division into groups *A* and *B* repeats the division made in Table 2. Wrong predictions are put in parentheses.

For methyl naphthalenes of group *A*, all the reactivity indices are equally successful in correctly predicting the most reactive position in all but one case. Note that in all successfully predicted cases of this group substitution takes place at an α-position. For methylnaphthalenes of group *B*, the comparison between theory and experiment is less clear-cut, but if results for

groups *A* and *B* are analyzed together, three types of reactivity indices may be discerned:

(i) Type 1 or α-discriminating. Self-polarizability π_{rr} and frontier electron density f_r belong to this type. These indices invariably predict an α-position as the most reactive, and therefore they may be eliminated from further consideration as unsuitable as such.

(ii) Type 2 or β-discriminating. This is the case of electron density q_r but, unlike type 1, this index does not discriminate absolutely. Actually, with the exception of four cases, q_r correctly predicts the most reactive position for group *B* compounds of Table 4, about half of which substitute in an α-position. Three of the four exceptions are dimethylnaphthalenes, and if these are analyzed more closely by considering the order of reactive positions in a given molecule (Table 5), in four cases out of six the index discriminates in favor of a β-position. Therefore electron density is not a very promising reactivity index, a conclusion also reached in Part II.

(iii) Type 3 or non-discriminating. Indices of this type are superdelocalizability S_r and localization energy L_r which do not appear to discriminate against either α or β positions; in fact these two indices are easily the best of the lot, with wrong predictions in only two out of 25 methylnaphthalenes of Table 4. A more stringent test, such as the prediction of the *order* of reactive positions in a number of dimethylnaphthalenes (Table 5), also shows the superiority of these indices, since the correct order of reactive positions is predicted in every case, except for the 2,7-dimethyl compound where S_r inverts the importance of positions 3 and 4.

The two cases where type 3 indices fail are the 1,3,5,8- and 1,2,3,4-tetramethyl compounds. It is

tempting to explain away the two failures by steric hindrance at positions 4 and 5, respectively. However in the 1,3,6,7-compound, position 4 would be sterically hindered to the same extent as position 5 in the 1,2,3,4-compound, and yet in one case substitution does take place at such a position, and in the other case it does not. Clearly more subtle geometrical considerations, such as non-planarity and bond lengths, seem necessary to put "steric hindrance" on a rational basis. Therefore when geometry is ignored, as in the present work, "steric hindrance" is an undefined concept of no predictive value, and cannot be invoked to explain failures of a reactivity index.

It is interesting to note that when numerical values of S_r and L_r for the most reactive position are examined, a clear gap is found between index values for groups *A* and *B* of Table 4; the more reactive compounds of group *A* all have $S_r > 1.30$, $L_r < -0.60\ \beta_0$, and the less reactive compounds of group *B* all have $S_r < 1.20$, $L_r > -0.65\ \beta_0$ (recall that highest reactivity corresponds to highest S_r but to least L_r).

(b) Quantitative Correlations

After a preliminary screening based on qualitative correlations, we now propose to subject the more promising indices to a limited quantitative correlation using rate constants for hydrogen–deuterium exchange in a number of symmetric dimethylnaphthalenes, obtained by Dallinga *et al.* (4). These studies were all done under the same

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

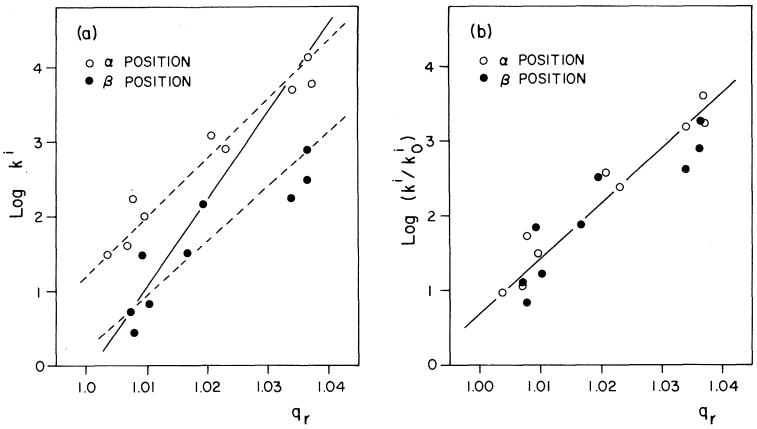

FIG. 2. Correlations between electron density q_r and absolute (*a*) and relative (*b*) rate constant for hydrogen–deuterium exchange in symmetric dimethylnaphthalenes; k^i is in units of $h^{-1} \times 10^3$. Continuous line in (*a*) and (*b*) i the least-squares line for all points (correlation coefficient 0.8 in (*a*), 0.93 in (*b*)), and the dotted lines in (*a*) are least-squares lines for α and β points taken separately (correlation coefficient 0.95 and 0.91, respectively).

experimental conditions; the reagent deuterium is here small enough to make possible steric hindrance quite negligible.

It is important to stress that when the concept of the "most reactive" position is put on a quantitative basis, this implies a correlation with the *absolute* rate constant. By contrast, Dallinga *et al.* have used two reference rate constants, one for substitution in naphthalene at an α-position (k_0^{α}), and the other at β-position (k_0^{β}), and therefore they have two kinds of relative rate constants (k^i/k_0^i, where $i = \alpha$ or β), which is useful for correlating, independently, substitutions at α or β positions, but is inappropriate for our purpose which is to seek a correlation without regard to whether a position is α or β.

(1) Electron Density (Type 2)

Figure 2*b* shows, in agreement with Dallinga *et al.*, that this index correlates with the relative rate constant and not the absolute rate constant (Fig. 2*a*), and therefore is not useful for predicting the most reactive position in a given molecule.

It is now easy to understand why q_r discriminates in favor of β positions. Suppose we have a molecule where the reactivity at an α position slightly exceeds that at β position

$$k^{\alpha} \sim k^{\beta}$$

In naphthalene, however, the two rates are significantly different: $k_0^{\alpha} > k_0^{\beta}$, so that q_r, being proportional to k^i/k_0^i, is nevertheless larger at the β position

$$[1] \qquad k^{\beta}/k_0^{\beta} > k^{\alpha}/k_0^{\alpha}$$

Thus q_r will always give the correct prediction if β is the most reactive position, but will fail to predict a most reactive α position unless $k^{\alpha} - k^{\beta}$ is sufficiently large to reverse the inequality of eq. [1].

(2) Type 3 Indices

Figures 3 and 4 show that S_r and L_r correlate with absolute rate constants, as one would expect for a "good" index, which they both are.

(3) Further Considerations

The fact that S_r and L_r, which are based on a model for the transition state, both emerge as a useful index, while all other reactivity indices derived from the properties of the isolated substrate molecule fail, must be interpreted to mean that successful treatment of reactivity in non-alternant hydrocarbons requires that the effect of the attacking reagent on the electronic structure of the substrate be taken into consideration, at least insofar as the present study is concerned.

A very simple approach along these lines consists of assuming that the field of the approaching reagent (electrophilic or nucleophilic) affects only the Coulomb integral α_r at position r of the substrate molecule. We can then write for the change in ε_{π}, the total π-electron energy

$$[2] \qquad \delta\varepsilon_{\pi} = \frac{\partial\varepsilon_{\pi}}{\partial\alpha_r}\delta\alpha_r + \frac{1}{2}\frac{\partial^2\varepsilon_{\pi}}{\partial\alpha_r^2}\delta\alpha_r^2 + \ldots$$

Since (10): $\partial\varepsilon_{\pi}/\partial\alpha_r = q_r$; $\partial^2\varepsilon_{\pi}/\partial\alpha_r^2 = \pi_{rr}$, then

$$[3] \qquad \delta\varepsilon_{\pi} \approx q_r\delta\alpha_r + (1/2)\pi_{rr}\delta\alpha_r^2$$

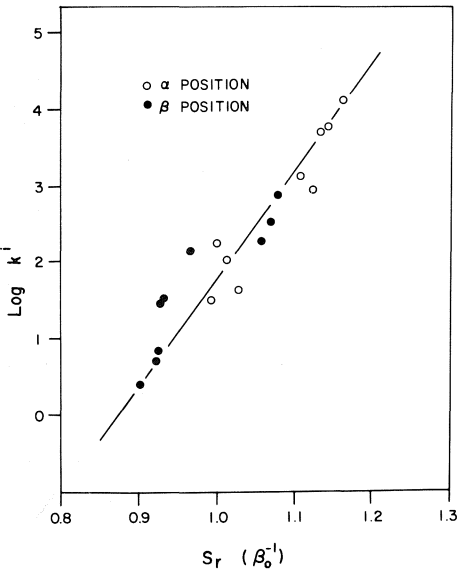

FIG. 3. Correlation between superdelocalizability and absolute rate constant (k^t) for hydrogen–deuterium exchange in symmetric dimethylnaphthalenes; k^t is in units of $h^{-1} \times 10^3$. Correlation coefficient is 0.95.

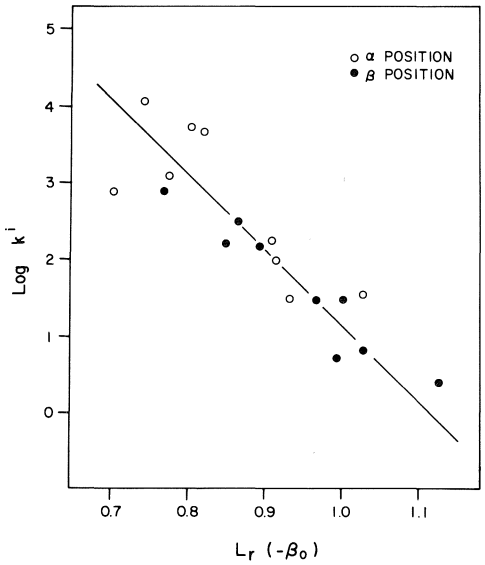

FIG. 4. Correlation between localization energy L_r and absolute rate constant (k^t) for hydrogen–deuterium exchange in symmetric dimethylnaphthalenes; k^t is in units of $h^{-1} \times 10^3$. Correlation coefficient is 0.89.

Equation 3 has been around for a long time, but its two terms are not usually considered together. Thus in alternant hydrocarbons $q_r = 1$ for all r and therefore π_{rr} is taken as the reactivity index, even if the second term of eq. 3 is believed to be much smaller than the first. In non-alternant hydrocarbons q_r is no longer the same for all r, and therefore by the above argument q_r, as part of the leading term in eq. 3, should be the reactivity index.

The failure of q_r noted earlier in the Discussion suggests that the two terms in eq. 9 are actually of comparable magnitude, which in turn implies that $\delta\alpha_r$ is not small, *i.e.* the polarizing effect of the electrophilic reagent produces an appreciable change in the Coulomb integral at position r. For example, Brown (11) has estimated that $\delta\alpha_r \sim 2$ eV at a distance ~ 5 Å, which is of the same magnitude, if not larger, than the effect of the presence of a heteroatom in the molecule (12).

Greenwood and McWeeny (12) have proposed to take the polarization effect into account by defining a new electron density q_r', still given by eq. 11 of Part II (15), but which is calculated by replacing α_r at position r by $\alpha_r + \delta\alpha_r$, and then solving the secular determinant as usual. Table 6 compares q_r and q_r' calculated with $\delta\alpha_r = \beta_0$ for 1-methylnaphthalene, one of the cases where q_r fails (*cf.* Table 4). It can be seen that q_r' tends to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

discriminate less in favor of position 2, a β-position; in fact, the simple Hückel result for q_r' actually correctly predicts position 4 as the most reactive.

It is clear that with appropriate manipulation of the value assigned to $\delta\alpha_r$, q_r' can be made to yield the correct result, but such calculations are very tedious and long, since at every r and for each new value of $\delta\alpha_r$ the secular determinant must be resolved anew. However, we may write approximately

$$[4] \qquad = q_r' \approx q_r + \pi_{rr}\delta\alpha_r$$

where q_r and π_{rr} refer to the unperturbed system, so that q_r' of eq. 4 does not require any new calculations. The last two columns of Table 6 show q_r' obtained from eq. 4 and it is seen that it behaves in the same way as the exact q_r', except that it requires a smaller assigned value of $\delta\alpha_r$; this is not a serious handicap since $\delta\alpha_r$ is adjusted empirically, not for each methylnaphthalene individually but for the methylnaphthalenes as a whole

Table 4, last column but one, gives q_r' of eq. 4, with $\delta\alpha_r = \beta_0$, for all 25 methylnaphthalenes. The index fails only in the same two cases where S_r and L_r have failed. The index q_r' (again with $\delta\alpha_r = \beta_0$) also correctly predicts the order of reactive positions in dimethylnaphthalenes (Table 5, last column but one). Finally Fig. 5 shows that q_r' correlates with the absolute rate constant for H–D exchange, as a "good" index should.

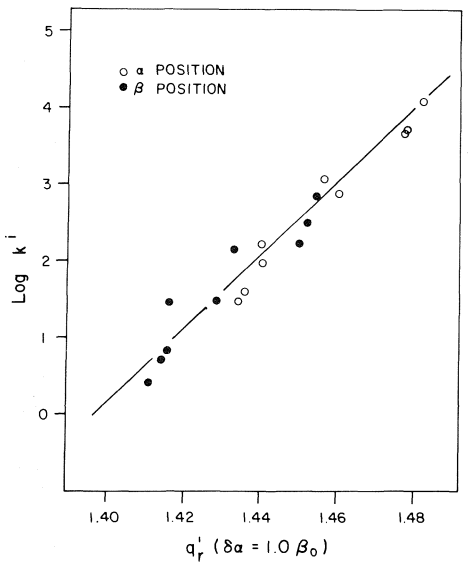

FIG. 5. Correlation between q_r' and absolute rate constant (k^i) for hydrogen–deuterium exchange in symmetric dimethylnaphthalenes; k^i is in units of $h^{-1} \times 10^3$. Correlation coefficient is 0.97.

A treatment of chemical reactivity based on a somewhat different approach is that of Klopman (13). He introduces the concept of soft and hard acids and bases and proceeds to show that reactivity is essentially determined by frontier electron density when the interaction is soft–soft, and by total charges on the two reacting partners when the interaction is hard–hard. If for the moment we confine our attention to reactions involving one and the same electrophilic agent, then relative reactivity of different substrates should be determined by indices calculated for the isolated substrate molecule, *i.e.* f_r for soft–soft interaction, and by q_r for hard–hard interaction. Our results show that neither f_r nor q_r is a good index, so that presumably we are dealing with the intermediate case of a soft–hard interaction. In fact, the two main electrophilic reagents considered here, chloromethyl and particularly deuterium, may be considered as hard acids, while the methylnaphthalenes may be regarded as soft bases.

In such an intermediate case, ΔE, the energy change due to the mutual perturbation of molecular orbitals of both reacting partners, will be given, in the zero-order approximation of Klopman's treatment, by a linear combination of q_r and f_r

$$[5] \qquad \Delta E \approx aq_r + bf_r$$

where a and b are variable parameters that measure the softness of one partner and the hardness of the other. It is noteworthy that in complete analogy with eq. 4, eq. 5 combines a type 1 index (f_r *vs.* π_{rr}) with type 2 index (q_r), although the reasoning that leads to the combination is quite different in each case.

We can therefore expect that with appropriate choice for a and b, the index ΔE should be just as good an index as q_r', or as S_r and L_r. Tables 4 and 5 (last column) and Fig. 6 show that this is indeed the case when $a = 1$, $b = 0.15$. Some degree of correspondence between ΔE and S_r is not too surprising since both are derived from concepts implicating frontier orbitals.

The theory, as presented here, treats $\delta\alpha_r$ and b as adjustable parameters; it is noteworthy, however, that the same value of $\delta\alpha_r$ (or of b) holds essentially for all the methylnaphthalene sub-

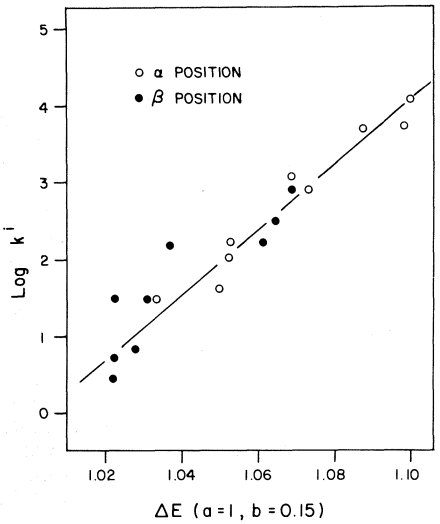

FIG. 6. Correlation between ΔE and absolute rate constant (k^i) for hydrogen–deuterium exchange in symmetric dimethylnaphthalenes; k^i is in units of $h^{-1} \times 10^3$. Correlation coefficient is 0.95.

strates, and for all the electrophilic substitutions (chloromethylation, H–D exchange, and to a less substantiated extent, also nitration and bromination) investigated. Thus $\delta\alpha_r$ and b are relatively insensitive to the details of the substrate–reagent interaction, and therefore promise to be eventually amenable to calculation.

A rather different tack has been taken recently by Daudel, Chalvet, and collaborators (14) whose treatment is somewhat similar to Fukui's but with another twist. They consider the transition state as a structure where delocalization extends from the substrate to include the attacking reagent, so that the latter may be represented by a heteroatom X characterized by the usual parameters k_{c-x}, h_x. Suitable manipulation of h_x, presumably reflecting the nature of the reagent and solvent, can then produce different order of reactive positions; it turns out that manipulation of k_{c-x} merely accentuates the difference of reactivity between different positions. These authors find[2] for electrophilic substitution in 1-methylnaphthalene with acetic anhydride as solvent, that $h_x \sim 0$. But acetic anhydride is precisely the solvent used in the chloromethylation and H–D exchange experiments which served as experimental basis for our treatment. The result $h_x = 0$ at position of attack gives support to our view that in such reactivity calculations in methylnaphthalenes the onus is on the representation for the methyl group to obtain agreement between theory and experiment.

[2]O. Chalvet, personal communication.

Conclusions

The present results show clearly that even if only the crudest correlations are intended, purely static indices q_r, π_{rr}, and f_r are insufficient to account for electrophilic reactivity in methylnaphthalenes. For an index to be successful, the effect of the attacking reagent must be included in some way, as in L_r which measures the energy required to localize two electrons of the delocalized system at site r of the substrate, or as in S_r which is based (14) on a representation where delocalization is assumed to extend to a pseudo orbital involving the attacking reagent and substrate hydrogen at site r.

Looking at the problem slightly differently, we might also say that the reactivity of a methylnaphthalene is basically determined by the reactivity toward the reagent of the parent (naphthalene) substrate, superimposed on which is the effect of the methyl substituents. The electron density q_r is different from unity only in naphthalenes with a methyl substituent, which means that q_r reflects mostly the effect of the substituents; this is also suggested by the fact that q_r is proportional to the *relative* rate constant $k^i/k_0{}^i$, where $i = \alpha$ or β. To become a successful index, q_r must therefore be combined with some quantity that reflects both the properties of the parent hydrocarbon and of the attacking reagent; in one case (q_r', eq. 4) this turns out to be π_{rr}, in the other (ΔE, eq. 5) it is f_r.

Action des organomagnésiens sur les composés β-dicarbonylés V. Synthèses de β-diols bitertiaires à partir de β-hydroxycétones. Induction asymétrique 1-3[1]

JACQUELINE MICHEL[2] ET PERSÉPHONE CANONNE
Département de Chimie, Université Laval, Québec 10, Québec

Reçu le 29 décembre 1970[3]

L'action des organomagnésiens sur des β-hydroxycétones possédant un groupement inducteur en β du carbonyle conduit à des β-diols bitertiaires symétriques. Les proportions des diastéréoisomères *méso* et *thréo* obtenus dépendent surtout de la nature du groupement inducteur.

La détermination de la configuration des β-diols a été menée à bien en utilisant leurs spectres de r.m.n. dont les signaux de méthyles et du méthylène en α des hydroxyles se manifestent à des champs différents. L'étude conformationnelle des β-hydroxycétones et β-diols est réalisée au moyen de leurs spectres i.r.

Nous formulons aussi une hypothèse sur l'attaque préférentielle des organomagnésiens et sur les états de transition de cette réaction.

Addition of organomagnesium compounds to β-hydroxyketones with an asymmetric center gave a diastereoisomeric mixture of symmetric ditertiary β-diols, the ratio of *meso* and *threo* forms depending on the nature of the inductive group.

The configurations of the β-diols were determined using their respective n.m.r. spectra in which the methyl and the methylene protons have different chemical shifts.

The conformations of the β-hydroxyketones and the β-diols were studied by i.r. spectroscopy. Models for a preferred attack of the organomagnesium compounds are proposed and product-determining transition states for the reactions are also suggested.

Canadian Journal of Chemistry, **49**, 4084 (1971)

Ce mémoire expose l'étude de l'action des organomagnésiens sur des β-hydroxycétones de formule $R—C(OH)CH_3—CH_2—COCH_3$ présentant un centre asymétrique en β du groupement carbonyle.

Dans une note préliminaire (1) nous avons rapporté que cette réaction conduit à des β-diols bitertiaires constitués par un mélange de diastéréoisomères *érythro* et *thréo*, et que la proportion de chaque isomère dépend surtout de la nature du substituant *R* inducteur.

Dans le présent travail, nous décrivons les résultats obtenus sur un plus grand nombre de β-hydroxycétones dans le but d'apporter une contribution au domaine de l'induction asymétrique 1-3 auparavant entrepris par Leitereg et Cram (2, 3), Brienne *et al.* (4, 5), et Maffrand et Maroni (6, 7) sur des composés analogues et formulons une hypothèse sur l'attaque préférentielle des organomagnésiens et sur les états de transition probables qui orientent cette réaction.

Pour une approche plus aisée de cette étude, nous classons les hydroxycétones, d'après leurs analogies et propriétés respectives, en trois types (schéma 1).

Les β-hydroxycétones ont été préparées selon la méthode précédemment décrite (8) en faisant réagir 3 mol de réactif de Grignard pour 1 mol de pentadione-2,4.

L'action du réactif de Grignard (RMgX) sur la pentadione-2,4 ou sur la β-hydroxycétone substituée par le même radical R mène à une proportion identique du β-diol diastéréoisomère prépondérant (schéma 2). Ceci démontre que les β-diols bitertiaires résultent de l'addition sur la forme non énolisée de l'acétylacétone avant que celle-ci puisse se tautomériser, et que l'intermédiaire, en l'occurence le cétoalcoolate de magnésien, est le même.

Les rendements de la réaction en β-hydroxycétones figurent à la partie expérimentale. Les trois facteurs influençant cette réaction sont d'après nos expériences:

(*i*) la nature du réactif de Grignard;

(*ii*) la durée du temps d'addition: lorsqu'elle augmente, le rendement baisse car il y a accroissement des composés de clivage formés sous l'influence de l'organomagnésien en excès (9);

(*iii*) la température du mélange réactionnel: l'abaissement défavorise l'élimination de OMgX, donc la formation de produits de déshydratation.

---

Etude conformationnelle des β-hydroxycétones

Etude par i.r.

Les fréquences ν(C=O) sont rapportées à la partie expérimentale (tableau 6). Dans tous les exemples étudiés, nous vérifions l'existence d'une liaison hydrogène intramoléculaire entre l'hydroxyle et le carbonyle (tableau 1). En effet, les fréquences ν(OH) observées se trouvent dans le

SCHÉMA 3

domaine de celles d'hydroxyles engagés dans des associations intramoléculaires 3500–3535 cm^{-1} et les intensités des bandes demeurent inchangées en faisant varier les solutions de 10^{-2} à 10^{-3} *M*. De plus, nous observons pour les β-hydroxycétones de type **II** et la β-hydroxycétone **14** une interaction intramoléculaire entre l'hydroxyle et le noyau aromatique que nous appelons liaison π. Une molécule chélatée pourra rendre compte de ces faits dans des conformations "pseudo chaises".

Les hydroxycétones **12** et **13** présentent un spectre i.r. analogue par ses caractéristiques à celui des hydroxycétones de type **I**, excepté une force moins grande de la liaison hydrogène $\Delta\nu(OH) = 90\ cm^{-1}$. L'absence de liaison π pour **1** à **5** permet de tenir pour acquis qu'il ne peut y avoir de liaison intramoléculaire entre l'hydroxyle et le noyau aromatique lorsque ces deux substituants sont géminés.

Si, à l'exemple de Kuhn (10), nous établissons une relation entre la force des liaisons intramoléculaires et Δν(OH) nous constatons pour les β-hydroxycétones du type **I** une valeur plus élevée donc une liaison hydrogène plus forte que pour celle du type **II**. Ces dernières ont l'hydrogène de l'hydroxyle alternativement lié à l'oxygène du carbonyle et au phényle: les deux conformations répondent à cette exigence (schéma 3).

Etude par r.m.n.

Les résultats donnés par la r.m.n, sont rassemblés dans le tableau 2, les signaux des hydroxyles et des aromatiques n'y sont pas rapportés. Les hydroxyles se manifestent sous la forme d'un singulet vers 3.5 p.p.m. pour les hydroxycétones des types **II** et **III** et vers 4.5 p.p.m. pour celles du type **I**. Les signaux des protons aromatiques ont des déplacements chimiques de l'ordre de 7.0–7.5 p.p.m.

Pour fin de discussion, nous nous référons aux hydroxycétones **12** et **13** car nous supposons que les substituants cyclohexyle et isopropyle influencent moins les autres protons des groupements étudiés que ne peuvent le faire le phényle et le benzyle dans les autres hydroxycétones. L'effet de champ du phényle dans les hydroxycétones de type **I** perturbe l'ensemble des protons dans la molécule et l'on observe la non équivalence magnétique des protons H_A et H_B du méthylène. Les protons méthyléniques des hydroxycétones des types **II** et **III** apparaissent sous la forme d'un singulet.

On note le blindage: 0.26 et 0.16 p.p.m. des signaux des méthyles *D* (voir la structure dans le

tableau 2) des β-cétols **1** et **6**, représentatifs des types **I** et **II**, relativement au signal de celui de **12**. En conséquence, on suppose que le méthyle *D* est situé dans le cône de blindage des phényles. Et pour que cette possibilité existe pour **1**, il faut admettre une prédominance de la conformation **II** de cette hydroxycétone (phényle en position quasi axiale par rapport au cycle "pseudo chaise"). Dans le type **I**, le blindage est moins tangible pour **3**, **4**, **5**: hydroxycétones ayant sur des phényles un substituant chlore ou méthoxyle, mais on peut remarquer que les glissements chimiques de tous les protons de ces hydroxycétones sont déplacés vers les champs faibles; cet effet est imputable au chlore et au groupe méthoxyle.

Les déplacements chimiques des hydroxycétones du type **II** et ceux du type **III** sont d'ordre de grandeur comparable eu égard à l'effet non négligeable du noyau aromatique. On déduit pour les β-cétols du type **II** et **III** une conformation "pseudo chaise" telle que le groupement R soit en position "quasi équatoriale" (conformation **I**).

Préparation des β-diols bitertiaires

Les β-diols bitertiaires symétriques de formule $RC(OH)CH_3—CH_2—C(OH)CH_3R$ sont, soit isolés du milieu réactionnel lors de la synthèse des β-hydroxycétones, soit préparés par action des organomagnésiens (RMgX) sur les hydroxycétones correspondantes.

Le rendement des réactions est fortement influencé par l'encombrement stérique; en effet, il fut impossible d'obtenir les diols correspondants aux groupements *o*-tolyle et naphtylméthyle. Trois moles d'organomagnésiens sont utilisées pour 1 mol d'hydroxycétone et donnent un mélange de deux diastéréoisomères *méso* et *thréo*. L'isomère majoritaire se purifie facilement par cristallisation fractionnée. En général, la séparation des isomères s'effectue par chromatographie sur colonne de gel de silice; leur pureté est controlée par chromatographie en phase gazeuse sur une colonne de Carbowax, par chromatographie sur couche mince et par r.m.n.

Les diols du type **II** (**26**–**31**) et les diols **33**[4] et **34**[4] du type **III** ont des temps de rétention trop voisins pour être séparés. Pour les diols du type **I** (**21**–**25**) et le diol **32** les rapports de leurs temps de rétention $T_{méso}/T_{thréo}$ sont d'environ 1.3–1.5. En considérant l'ordre d'élution d'alcools diastéréoisomères 1–2, Gault et Felkin (12) ont essayé d'élaborer une règle afin de déterminer leur configuration. Par extension, les β-diols suivent la même règle à savoir que généralement le composé *thréo* est élué le premier. La liaison hydrogène intramoléculaire est beaucoup plus forte pour ce diastéréoisomère et il est donc moins susceptible de former des liaisons intermoléculaires avec les groupes polaires de la phase stationnaire. Les temps de rétention relativement voisins pour les couples de diastéréoisomères étudiés à substituants benzyles nous permettent de supposer que les hydroxyles du *méso* et du *thréo* sont engagés également dans des associations intramoléculaires OH...π.

Etude configurationnelle et conformationnelle des β-diols

Dans certains cas (5, 7), l'étude par i.r. des liaisons hydrogène intramoléculaires peut se révéler suffisante pour déterminer à la fois la configuration et la conformation des composés, mais pour nos composés les résultats diffèrent selon les types de diols; nous avons dû avoir recours à la r.m.n. et nous nous sommes basés sur les signaux des méthyles et du méthylène en α des hydroxyles.

Etude par i.r.

Les valeurs des fréquences maximales d'adsorption se rapportant au groupe hydroxyle en solution diluée dans CCl_4 sont groupées dans le tableau 3. Les spectres i.r. des β-diols ont tous en commun une forte absorption entre 3500 et 3530 cm^{-1}, preuve de l'existence d'une conformation cyclique et une bande étroite vers 3610 cm^{-1} correspondant au signal de l'hydroxyle libre. De plus, pour les β-diols *thréo* du type **I** (**21***a*–**26***b*) et les β-diols du type **II** (**26**–**31**), nous observons une bande vers 3570 et 3590 cm^{-1} qui correspond à l'association intramoléculaire entre un hydroxyle et un phényle (liaison π).

Dans les diols du type **I** et le diol **32** les Δν(OH) (différence entre la fréquence de la bande OH libre et celle de la bande OH lié) sont plus élevés dans les isomères *thréo* que dans les isomères *méso*. En outre, le rapport (A'/A) des coefficients d'absorption intégrée des bandes OH lié (A) et OH libre (A'), calculé pour ces diols (13), montre, aux erreurs de mesure de surface près, une très légère prédominance de formes chélatées pour la configuration *méso*. Ce rapport (A'/A) a une

[4]Des essais de séparation par distillation se sont avérés également inefficaces. Des difficultés de cet ordre ont été décrites par Wolf (11).

For personal use only.

Plusieurs conformations cycliques: soit "pseudo chaise" soit "pseudo croisée" peuvent être proposées (schéma 4). Les formes chélatées

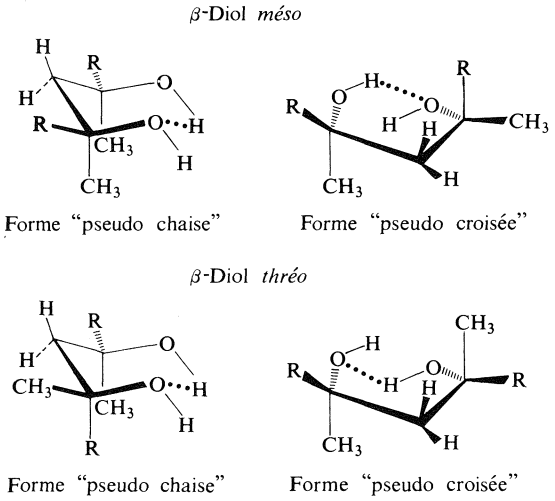

SCHÉMA 4

dans des conformations "pseudo chaises" présentent l'inconvénient pour les diastéréoisomères *thréo* d'avoir de fortes interactions 1-3; un substituant R volumineux se trouve alors en position "quasi axiale", qui est énergétiquement moins favorable que celle "quasi équatoriale" du *méso*.

Par contre une forme "pseudo croisée" peut être vraisemblablement envisagée pour l'isomère *thréo* dans laquelle les interactions 1-3 sont minimisées; les substituants encombrants adoptent une position "quasi équatoriale" plus probable (schéma 4).

Toutefois pour les isomères *thréo* des diols (**21**–**25**), un épaulement vers 3570 cm^{-1} montre l'existence d'une association intramoléculaire entre un des hydroxyles et le noyau benzénique porté par l'autre carbone asymétrique. Cette liaison π ne peut avoir lieu que lorsque le phényle est en position "quasi axiale": seule la conformation "pseudo chaise" répond à cette exigence.

Pour les diols du type **II** (**26**–**31**) et les diols **33** et **34** nous ne sommes pas en mesure de discuter systématiquement des différences entre les deux diastéréoisomères,[5] sauf pour **26***a* et **26***b*. Les trois bandes OH libre, OHπ et OH lié sont présentes pour les deux isomères, et similairement aux β-diols du type **I**, plus intenses pour le *thréo*; mais les Δν(OH) et Δν(OH′), sensiblement plus élevés quand il s'agit du *méso*, signifient selon Kuhn, des liaisons intramoléculaires plus fortes. Dans les cas des diols du type **II** des liaisons ont probablement lieu entre un hydroxyle et un noyau benzénique du groupement benzyle porté par le même carbone. Les deux hydrogènes entrant dans des associations intramoléculaires la bande OH libre est un épaulement et le rapport (A'/A) ne peut être calculé.

Etude par r.m.n.

Nous rassemblons au tableau 4 les déplacements chimiques de signaux des protons méthyliques et méthyléniques afin de déterminer la configuration et conformation des diastéréoisomères *méso* et *thréo* et procéder leur dosage.

Comme il a été déjà constaté précédemment (3 et 7) on remarque que chaque couple de dias-

*Dosage effectué par r.m.n. avec une précision de l'ordre de 10%.
†Pour ces diols, le dosage est très approximatif et les chiffres donnés ne représentent qu'un ordre de grandeur.
‡Impur.

téréoisomères possède des signaux des protons méthyliques et méthyléniques différents.

Les signaux de méthyle se manifestent par un singulet et résonnent à des champs plus faibles pour les isomères *méso* que pour les *thréo*. Cette différence est encore plus importante pour les β-diols du type **I** (**21** à **26**).

Les signaux méthyléniques, en α des hydroxyles, suivent le même ordre et ils sont beaucoup plus déblindés pour les isomères *méso* que *thréo*. De plus on remarque une non équivalence magnétique des protons du méthylène (H_A et H_B) dans le cas des diastéréoisomères *méso* qui se traduit, pour la plupart des β-diols, par un doublet de doublet. Une équivalence magnétique apparente observée dans les cas des composés **23***a*, **24***a*, et **25***a* pour les protons méthyléniques résulterait de l'anisotropie des groupements chlore et méthoxyles substitués sur le noyau benzénique.

Un singulet caractérise les protons méthyléniques des diastéréoisomères *thréo*. De ces constatations on est amené à attribuer la conformation "pseudo chaise" aux diastéréoisomères *méso* et aux *thréo* des diols du type **I**: L'abaissement du signal des méthyles allant jusqu'à 0.38 p.p.m. pour le *thréo* (**25***b*) résulte probablement d'un blindage dû aux groupements phényles dans une conformation cyclique "pseudo chaise". Le déplacement chimique du méthyle donné par le spectre est une valeur moyenne des positions "quasi axiale" et "quasi équatoriale".

Hypothèses conformationnelles

Les données fournies par les études spectroscopiques nous amènent à prévoir une forte population de conformations chélatées cycliques de ces diols à l'image de Maskens *et al.* (14), Wolf (11), et Maffrand et Maroni (7). Nous pouvons conclure à l'existence des conformations "pseudo chaise" et "pseudo croisée" pour les isomères *thréo* et à une conformation majoritaire "pseudo chaise" pour les isomères *méso*.

Cependant, nous ne pouvons négliger la probabilité d'existence des autres conformations et, en particulier, des conformations non cycliques ouvertes. Dans cette éventualité, les groupements portés par les carbones adjacents sont en position décalée. Le schéma 4 présente les conformations cycliques les plus probables des β-diols bitertiaires étudiés dans le présent travail.

Induction asymétrique-1,3

L'examen des résultats rassemblés au tableau 5 nous mène à formuler les remarques suivantes:

(*i*) Les β-hydroxycétones de type **I** (**1–5**) qui possèdent en position 3 du carbonyle un substituant inducteur phényle conduisent à la formation d'un diol majoritaire en *thréo*.

(*ii*) Les β-hydroxycétones de type **II** (**6–11**) dont le groupement en position 3 du carbonyle est un benzyle donnent un diol diastéréoisomère prépondérant *méso*.

(*iii*) Les β-hydroxycétones de type **III** (**13–14**)

SCHÉMA 5

qui ont un groupement cyclohexyle, isopropyle ou allyle montrent une stéréosélectivité moins prononcée et favorisent la formation du diastéréoisomère *méso*.

La stéréosélectivité de cette réaction est en général très affirmée, elle est due à l'importance des volumes effectifs des groupements inducteurs et des réactifs ajoutés. Cette remarque est en accord avec la théorie de Richer fondée sur l'encombrement stérique (15–16); en effet, il a montré que, pour les cétones cycliques, la stéréosélectivité des réactions de réduction dépend de la combinaison des effets stériques du réactif et de la cétone. D'autre part, nous observons une augmentation de la stéréosélectivité lorsque les groupes R sont aromatiques et substitués par des groupements polaires. Cette hypothèse est notamment étayée par l'exemple du groupe para-chlorophényle qui, ajouté à l'hydroxycétone **3** de même groupement inducteur, augmente fortement la stéréosélectivité de la réaction. Par ailleurs, une diminution de la stéréosélectivité est constatée lorsque l'on fait réagir les groupes allyle, isopropyle, et cyclohexyle sur les hydroxycétones correspondantes **12–14**; dans ces cas, seulement, les effets stériques interviennent.

Nous supposons au premier temps la formation de cétoalcoolates de MgX possédant des conformations chélatées analogues au "modèle cyclique" préconisé par Leitereg et Cram (3). Dans chaque conformation "pseudo chaise" possible (**I** et **II**), une des faces est moins encombrée, et selon le volume de l'entité nucléophile (R^-) transférée au carbone du carbonyle se forme l'isomère *thréo* ou *méso* en prédominance (schéma 5). Dans le cas d'effet polaire, Chérest *et al.* (17) supposent que les états de transition sont favorisés dans lesquels la séparation est grande d'entre le réactif nucléophile et un groupe électronégatif.

Partie expérimentale

Les spectres i.r. ont été enregistrés sur les spectrophotomètres Beckman, modèle IR-12, et Perkin–Elmer, modèles 457 et 621, les produits ont été étudiés à l'état dissous dans le tétrachlorure de carbone (Baker), ce solvant ayant été déshydraté par passage sur tamis molécu-

laire (4 Å, 1/16″) (Baker). Les concentrations des solutions varient de 5.10^{-2} à 10^{-3} *M*. Les cellules utilisées sont constituées d'un cylindre de verre, d'une paire de fenêtres en NaCl provenant d'un même lot de polissage, et de montures en acier inoxydable; les épaisseurs des cuves sont de 5, 20, et 50 mm. Les spectres de r.m.n. ont été obtenus avec un spectrographe Varian modèle A60, le tétraméthylsilane servant de référence interne, avec des solutions à 25% dans le chloroforme deutérié. Les déplacements chimiques sont donnés en p.p.m. et les constantes de couplage en Hz. Les points de fusion ont été mesurés sur un appareil Thomas Hoover et sont donnés non corrigés. Les chromatographies sur couche mince analytique ont été effectuées sur gel de silice G (Mackerey-Nagel et Merck-Darmstadt) et ont permis le contrôle de la pureté des produits. Le solvant utilisé était un mélange éther de pétrole – éther en proportions variables suivant les produits à éluer. Les chromatographies sur colonne ont été réalisées à l'aide de gel de silice Davison Chemical grade 923.

Préparation des solutions d'organomagnésiens mixtes

Les chlorures de xylyle et de mésityle ont été préparés au laboratoire par chloration au moyen de chlorure de sulfuryle et par chlorométhylation (8).

L'appareillage comprend un ballon quadricol de 2 l pour la préparation des β-hydroxycétones et de 500 ml en ce qui concerne celle des β-diols, équipés d'un système d'agitation étanche, d'une ampoule à introduction, d'un réfrigérant ascendant avec tube de garde à chlorure de calcium, d'un thermomètre et d'une arrivée d'azote sec.

Les organomagnésiens sont obtenus par la méthode habituelle (8) à partir de tournures de magnésium (BDH) et d'halogénures d'alcoyle et d'aryle fraîchement distillés et séchés sur chlorure de calcium. Les solutions sont préparées sous atmosphère d'azote et sont dosées selon la méthode de Gilman *et al.* (18), donnant des résultats optimistes de 10%.

Synthèse des β-hydroxycétones, type ***II***

Au réactif de Grignard préparé à partir de 1.5 mol d'halogénure d'alcoyle et de 1.61 at/g de Mg (40 g) dans 1100 ml d'éther anhydre ($\simeq 1.2$ *M*) refroidi à $-15°$ par un mélange acétone–carboglace, est ajoutée en 30 min une solution de 0.5 mol d'acétylacétone (50 g) diluée dans 200 ml d'éther anhydre. L'addition terminée, le milieu réactionnel est ramené à température ambiante et laissé sous agitation pendant 18 h. On hydrolyse par une solution glacée de chlorure d'ammonium en contrôlant la température de la réaction à 5°. La phase aqueuse est extraite deux fois par 200 ml d'éther. Cette solution éthérée est jointe à la phase éthérée décantée, l'ensemble est lavé par 100 ml d'eau et séché sur sulfate de magnésium anhydre. L'évaporation de l'éther donne une huile de couleur jaune brun, qui est traitée par le réactif de Girard T, préalablement recristallisé dans un mélange méthanol – éthanol absolu (1:1), ou préparé au laboratoire selon la méthode décrite dans (19). On utilise 100 g dans 200 ml de méthanol absolu auquel on ajoute 2 g de résine cationique acide [Rexyn 102 (H)]. Après un reflux de 2 h, on évapore le méthanol, on hydrolyse le résidu visqueux par 500 ml d'eau et on extrait par 400 ml d'éther de pétrole (p.éb. 30–60°) les produits non cétoniques: hydrocarbures, alcools, et β-diols. Après addition de 50 ml d'une solution aqueuse de formaldéhyde à 36%, on extrait en continu pendant 48 h par l'éther de pétrole, la β-hydroxycétone désirée, accompagnée de cétones α,β-éthyléniques, de cétones de scission. Une distillation sous un vide de 0.1 mm de Hg permet d'obtenir un β-cétol pur (3*e* fraction). Leurs constantes physiques se trouvent rassemblées dans le tableau 6.

Synthèse des β-hydroxycétones, types ***I*** *et* ***III***

Un mode opératoire identique au précédent est suivi, à quelques modifications près. Lors de l'addition de l'acétylacétone à la solution organomagnésienne, on veillera à refrigérer celle-ci à $-25°$ afin d'éviter la formation de cétone α,β-éthylénique, les réactions avec le bromure de phénylmagnésium et surtout avec le chlorure de cyclohexylmagnésium étant plus exothermiques. La préparation est poursuivie de manière analogue mais après distillation la β-hydroxycétone est séparée de la cétone éthylénique par chromatographie. Dix grammes de cétones préalablement distillées sont adsorbés sur une colonne de 800 g de gel de silice, l'éluant est un mélange d'éther de pétrole et d'éther. Nous reportons les constantes physiques de ces hydroxycétones dans le tableau 6, et celles des cétones insaturées correspondantes dans le tableau 7.

Synthèse des β-diols

Mode opératoire ***I****: β-diols* ***21***, ***22***, ***23***, ***24***, ***25***

On ajoute en 10 min 0.02 mol d'hydroxycétone dans 50 ml d'éther anhydre au réactif de Grignard préparé à partir de 0.07 at/g de magnésium (1.68 g) et 0.06 mol d'halogénure d'alcoyle dans 100 ml d'éther anhydre. Lors de l'addition du β-cétol on maintient le mélange réactionnel à une température de 15°, après l'avoir ramené à température ambiante, on l'abandonne sous agitation pendant 18 h. On hydrolyse par 100 ml d'une solution saturée de NH_4Cl le mélange maintenu à 5°, on extrait trois fois à l'éther; après lavage à l'eau, puis séchage sur $MgSO_4$, on évapore l'éther et l'huile obtenue est chromatographiée sur gel de silice. Un mélange d'éther de pétrole (30–60°) et d'éther anhydre en proportions variables est utilisé pour éluer les produits, les conditions opératoires spécifiques seront indiquées pour chaque composé.

*Diphényl-2,4 pentanediol-2,4 (****21****)*

A la solution de Grignard préparée à partir de 9.6 g de bromobenzène, on ajoute 3.5 g de **1**, après traitement de la réaction (mode opératoire **I**), on obtient une huile (6.6 g) laquelle est chromatographiée sur 200 g de gel de silice, on élue aux différents mélanges éther de pétrole (30–60°) – éther suivants: (99:1) le biphényle, (90:10) l'acétophénone et la phényl-4 pentène-3 one-2 **1***i*, (87:13) le β-diol *thréo* (2.7 g), le β-diol *méso* (0.7 g). Après trois recristallisations dans le mélange éther de pétrole – éther (80:20) on recueille 2.5 g d'isomère *thréo* et 0.6 g de *méso*, pour un poids total de 3.1 g.

Anal. calc. pour $C_{17}H_{20}O_2$: C, 79.90; H, 7.80. Trouvé **21***a*: C, 79.51; H, 7.67. **21***b*: C, 79.62; H, 7.80.

*Di-p-tolyl-2,4 pentanediol-2,4 (****22****)*

On introduit 10.3 g de bromotoluène afin de préparer la solution de bromure de *p*-tolylmagnésium, on ajoute 3.8 g de **2**, après traitement de la réaction (mode opératoire **I**) on obtient une huile (7 g), laquelle est chromatographiée sur 700 g de gel de silice, on élue aux mélanges éther de pétrole (30–60°) – éther suivants: (95:5) le bitolyle, (85:15) la *p*-méthylacétophénone, (80:20) la *p*-tolyl-4 pentène-3-one-2 **2***i* (60:40), le β-diol *thréo*

(2.5 g), (50:50) le β-diol *méso* (0.9 g). Après trois recristallisations dans le mélange éther de pétrole – éther (80:20), on recueille 2.3 g d'isomère *thréo* **22***b* et 0.7 g de *méso* **22***a*, pour un poids total de 3 g.

Anal. calc. pour $C_{19}H_{24}O_2$: C, 80.24; H, 8.51. Trouvé **22***a*: C, 80.27; H, 8.60. **22***b*: C, 80.25; H, 8.60.

*Di-p-chlorophényl-2,4 pentanediol-2,4 (**23**)*

On prépare la solution de *p*-chlorophénylmagnésium à partir de 11.5 g de *p*-chlorobromobenzène, à laquelle on ajoute 4.25 g de **3**, après traitement de la réaction, selon le mode opératoire indiqué, on obtient une huile (10 g) que l'on chromatographie sur 800 g de gel de silice, on élue aux mélanges éther de pétrole (30–60°) – éther suivants: (90:10) le dichloro-4,4′-diphényle, (75:25) la *p*-chloroacétophénone, (62:38) le β-diol *thréo* (4.2 g), (40:60) le β-diol *méso* (0.4 g). On recristallise les deux diastéréoisomères séparément; le β-diol *thréo* dans le mélange éther de pétrole – éther (70:30), et le *méso* dans (40:60) et on recueille 3.9 g de *thréo* **23***b* et 0.3 g de *méso* **23***a*, soit un poids total de 4.2 g.

Anal. calc. pour $C_{17}H_{18}O_2$: C, 62.79; H, 5.58. Trouvé **23***a*: C, 61.96; H, 5.36. **23***b*: C, 62.18; H, 5.46.

*Di-m-chlorophényl-2,4 pentanediol-2,4 (**24**)*

A la solution jaune clair du bromure de *m*-chlorophénylmagnésium, préparé à partir de 11.5 g de *m*-bromochlorobenzène et de 2 g de magnésium dans 15 ml d'éther anhydre est ajouté 4.24 g d'hydroxycétone **4** diluée dans 5 ml d'éther anhydre. Un résidu pâteux peu soluble dans l'éther est hydrolysé par 250 ml de chlorure d'ammonium. Après extraction et évaporation, on obtient 7 g d'une pâte brune que l'on dépose sur 500 g de gel de silice. L'isomère *thréo* **24***b* passe à (80:20) d'éther de pétrole – éther (3.0 g) précédé par le dichloro-3,3′ diphényle, une cétone de scission et un peu de cétone α,β-éthylénique. Ce produit blanc très visqueux cristallise difficilement à cause de son bas point de fusion. Au mélange éluant (70:30), on trouve l'autre isomère **24***a* visqueux incristallisable (1.0 g).

Anal. calc. pour $C_{17}H_{18}O_2Cl_2$: C, 62.79; H, 5.58. Trouvé **24***a*: C, 61.76; H, 5.33. **24***b*: C, 61.83; H, 5.35.

*Di-p-méthoxyphényl-2,4 pentanediol-2,4 (**25**)*

p-Chloroanisole (11.22 g) et 2 g de magnésium dans 150 ml d'éther anhydre contribuent à la préparation de la solution organomagnésienne à laquelle est additionnée l'hydroxy cétone **5** selon le mode opératoire **I**. Après hydrolyse par une solution de chlorure d'ammonium et extraction à l'éther, on recueille 8 g de composé brut. Une partie de l'huile est précipitée dans un mélange de solvant éther de pétrole – éther (50:50); 1.5 g de *thréo* est obtenu après recristallisation. On chromatographie la fraction restante (6.5 g) sur une colonne de 500 g de gel de silice. Le composé *thréo* **25***b* est élué à (80:20) d'éther de pétrole – éther (0.5 g) et le *méso* **25***a* (0.5 g) à (70:30) du même mélange.

Anal. calc. pour $C_{19}H_{24}O_4$: C, 72.12; H, 7.65. Trouvé **25***a*: C, 72.40; H, 7.57. **25***b*: C, 71.92; H, 7.59.

*Mode opératoire **II**: β-diols **26–31***

On suit le mode opératoire **I** en ajoutant le β-cétol à température ambiante.

*Diméthyl-2,4 diphényl-1,5 pentanediol-2,4 (**26**)*

On utilise 7.6 g de chlorure de benzyle pour la préparation de la solution de chlorure de benzylmagnésium à laquelle on additionne 3.8 g de β-cétol **4**, la réaction est traitée selon le mode opératoire indiqué précédemment et on obtient 9.0 g d'une huile jaune pâle. La chromatographie est réalisée avec la moitié du liquide soit 4.5 g sur 120 g de gel de silice. L'éluant est un mélange éther de pétrole – éther; sortent à (98:2) le bibenzyle, à (90:10) la phénylacétone, à (82:18) un mélange de diastéréoisomères *thréo* et *méso* (p.f. 94°); le poids total des cristaux ainsi isolés est 1.3 g. L'huile restante se solidifie, on filtre les cristaux, et on recristallise dans le mélange éther de pétrole – éther (70:30). On recueille 1.3 g de composé *méso*, poids total 2.6 g.

Anal. calc. pour $C_{19}H_{24}O_2$: C, 80.29; H, 8.44. Trouvé: C, 80.11; H, 8.38.

*Diméthyl-2,4 di o-tolyl-1,5 pentanediol-2,4 (**27**)*

On utilise 8.4 g de chlorure d'*o*-xylyle pour préparer le réactif de Grignard correspondant auquel on ajoute 4.12 g de β-hydroxycétone **5**, après traitement de la réaction en se référant au mode opératoire **II** on recueille un liquide visqueux jaune clair (10.5 g) lequel est chromatographié sur 1 kg de gel de silice. On élue à différents gradients d'éther de pétrole – éther: à (97:3) le di-*o*-tolyl-1,2 éthane, à (85:15) l'*o*-tolyl acétone, à (80:20) la β-hydroxycétone non réagie, et à (60:40) une huile visqueuse. Une seconde chromatographie effectuée avec 3 g de produit sur 120 g de gel de silice permet de recueillir le diastéréoisomère *méso* **27***a* sous la forme d'une huile cristallisant lentement: 1.8 g après cristallisation de l'hexane–éther, le *thréo* **27***b* restant dans les eaux mères.

Anal. calc. pour $C_{21}H_{28}O_2$: C, 80.73; H, 9.03. Trouvé: C, 80.54; H, 8.99.

*Diméthyl-2,4 di m-tolyl-1,5 pentanediol-2,4 (**28**)*

On opère sur les mêmes quantités employées pour la synthèse de **27**: 8.4 g de chlorure de *m*-xylyle et 4.12 g de β-cétol **6** pour obtenir 10 g d'une huile jaune ocre qui est chromatographiée sur 500 g de gel de silice, l'éluant est un mélange éther de pétrole – éther qui laisse passer à (97:3) le di *m*-tolyl-1,2 éthane, à (80:20) la *m*-tolylacétone, à (70:30) la β-hydroxycétone non réagie et à (50:50) la fraction contenant le diol, celle-ci est rechromatographiée sur 120 g de gel de silice, mais le diol reste sous la forme d'un liquide clair, dont nous recueillons 1.9 g. Le spectre de r.m.n. nous indique la présence des deux diastéréoisomères, le *méso* étant prépondérant.

Anal. calc. pour $C_{21}H_{28}O_2$: C, 80.73; H, 9.03. Trouvé: C, 80.35; H, 8.90.

*Diméthyl-2,4 di p-tolyl-1,5 pentanediol-2,4 (**29**)*

On opère sur les mêmes quantités employées pour la synthèse de **27**. Le chlorure de *p*-xylyle (8.4 g) et 4.12 g de β-cétol **7** pour obtenir 8 g d'un liquide jaune, on le chromatographie sur 500 g de gel de silice et on élue les produits aux mélanges d'éther de pétrole – éther suivants: (97:3) le di *p*-tolyl-1,2 éthane, (85:15) la *p*-tolylacétone et (70:30) le β-diol (mélange des deux diastéréoisomères). Après recristallisation de l'hexane–éther nous isolons le *méso* **29***a* (2.5 g).

Anal. calc. pour $C_{21}H_{28}O_2$: C, 80.73; H, 9.03. Trouvé: C, 80.45; H, 8.98.

*Diméthyl-2,4 di (xylyl-3,4)-1,5 pentanediol-2,4 (**30**)*

On utilise 9.3 g de chlorure de diméthyl-3,4 benzyle pour préparer la solution organomagnésienne correspon-

dante à laquelle on ajoute 4.40 g d'hydroxycétone **8**, la réaction traitée, on recueille 10.5 g d'huile, laquelle est chromatographiée sur 500 g de gel de silice, on élue à des mélanges différents d'éther de pétrole et d'éther: (98:2) le di (xylyl-3,4)-1,2 éthane, (90:10) la xylyl-3,4 acétone, et (80:20) 0.5 g de mélange de diastéréoisomères (p.f. 101°), et 2.0 g de β-diol *méso* **30***a* (p.f. 108°). Après recristallisation de l'hexane–éther, on recueille 1.9 g de β-diol *méso*.

Anal. calc. pour $C_{23}H_{32}O_2$: C, 81.13; H, 9.47. Trouvé: C, 80.60; H, 9.37.

*Diméthyl-2,4 di (xylyl-3,5) pentanediol-2,4 (**31**)*

On peut se référer aux quantités utilisées dans la synthèse de **30** pour le chlorure de diméthyl-3,5 benzyle et l'hydroxycétone **9**, on obtient 11 g d'huile laquelle est chromatographiée sur 500 g de gel de silice. On sépare le di (xylyl-3,5)-1,2 éthane à (99:1) d'éther de pétrole – éther, la xylyl-3,5 acétone à (80:20), et le β-diol à (60:40). On recueille le mélange de diastéréoisomères à prépondérance *méso* et ce dernier est recristallisé, on en obtient 1.8 g.

Anal. calc. pour $C_{23}H_{32}O_2$: C, 81.13; H, 9.47. Trouvé: C, 80.68; H, 9.39.

*Synthèse des β-diols **32–34***

On suit le mode opératoire **I** pour la synthèse de ces diols.

*Dicyclohexyl-2,4 pentanediol-2,4 (**32**)*

On prépare la solution de chlorure de cyclohexylmagnésium en ajoutant 7 g de chlorure de cyclohexyle dilué dans 100 ml d'éther anhydre. (Pour initier la réaction, on chauffe le ballon contenant des tournures de magnésium et quelques millilitres d'éther anhydre, alors que sont introduites quelques gouttes de bromure de cyclohexyle pur.) On additionne l'hydroxy-4 cyclohexyl-4 pentanone-2 **12** (3.7 g) à la solution organomagnésienne refroidie à 15°. La réaction traitée de façon habituelle conduit à 6 g d'une huile jaune clair qui est chromatographiée sur 500 g de gel de silice. On élue au mélange éther de pétrole – éther: en premier, le dicyclohexyle (97:3), l'hydroxycétone non réagie (80:20), le β-diol *thréo* **32***b* (75:25) (0.7 g), et le β-diol *méso* **32***a* (70:30) (1.2 g). Après deux recristallisations dans l'hexane–éther, on recueille 0.6 g de *thréo* et 0.9 g de *méso*.

Anal. calc. pour $C_{17}H_{32}O_2$: C, 76.06; H, 12.02. Trouvé **32***a*: C, 76.08; H, 12.04. **32***b*: C, 76.15; H, 12.08.

*Tétraméthyl-2,3,5,6 heptanediol-3,5 (**33**)*

On additionne la β-hydroxycétone **13** (2.8 g) à la solution magnésienne d'isopropyle (4.7 g de chlorure d'isopropyle et 1.8 g de magnésium dans 100 ml d'éther anhydre). Après traitement de la réaction, on recueille 4 g d'une huile jaune, contenant de l'hydroxycétone non réagie et le mélange des β-diols diastéréoisomères que nous distillons sous 1 mm de Hg. La β-hydroxycétone passe à 40° et le diol entre 76 et 80° (1.8 g). Une tentative de séparation sur colonne de gel de silice (300 g) ne donne aucun résultat.

Anal. calc. pour $C_{11}H_{24}O_2$: C, 70.16; H, 12.85. Trouvé: C, 69.80; H, 12.80.

*Diméthyl-4,6 nonadiène-1,8 diol-4,6 (**34**)*

La β-hydroxycétone **14** (2.8 g) est ajoutée à la solution magnésienne d'allyle (7.26 g de bromure d'allyle et 2 g de magnésium dans 100 ml d'éther anhydre). On traite la réaction selon le mode opératoire **I** et on recueille 3.5 g d'une huile jaune. On distille le mélange sous 1 mm de Hg entre 70 et 75° et nous obtenons 1.8 g d'un liquide incolore **34**. Une tentative de séparation sur colonne de gel de silice donne un léger enrichissement d'isomère *méso*.

Anal. calc. pour $C_{11}H_{20}O_2$: C, 71.69: H, 10.94. Trouvé: C, 71.43; H, 10.85.

Nous remercions Monsieur S. Brownstein de nous avoir conseillés dans l'étude r.m.n. et Monsieur et Madame P. Maroni de nous avoir communiqué les résultats permettant de compléter ces travaux.

Nous exprimons notre reconnaissance au Conseil National de Recherches du Canada et au Conseil des Arts du Canada pour l'aide financière apportée sous forme de subventions.

Ions and Aggregates of Tetra-*n*-Butylammonium Picrate in Nonaqueous Solvents: A Thermodynamic Study

SAUL GOLDMAN AND G. C. B. CAVE
Department of Chemistry, McGill University, Montreal, Quebec

Received December 1, 1970[1]

Values of ΔG^0, ΔH^0, and ΔS^0 at 25 °C were obtained by distribution studies and by calorimetry, for the dimerization and trimerization of tetra-*n*-butylammonium picrate (**1**) in anhydrous benzene, chlorobenzene, and *o*-dichlorobenzene. The standard enthalpy of sublimation of **1** was calculated. The values of ΔG^0 for the ionization, dimerization, and trimerization of **1** were linear functions of the reciprocal of the dielectric constant of the solvent. The intercepts and slopes of these graphs are interpreted; partial desolvation of the ions, and of the monomers on association is invoked. A simple potential function is used with the data, in order to deduce suitable models of the dimer and the trimer of **1**.

Les valeurs de ΔG^0, ΔH^0 et ΔS^0 ont été obtenues à 25 °C, au moyen d'études de distribution et de calorimétrie, pour la dimérisation et la trimérisation du picrate de tétra-*n*-butylammonium (**1**) dans le benzène anhydre, le chlorobenzène et l'*o*-dichlorobenzène. L'enthalpie standard de sublimation de **1** a été calculée. Les valeurs de ΔG^0 pour l'ionisation, la dimérisation et la trimérisation de **1** sont des fonctions linéaires de l'inverse de la constante diélectrique du solvant. Les intersections et les pentes de ces tracés sont interprétées; la désolvatation partielle de ces ions et des monomères pendant l'association est invoquée. Avec ces données, on utilise une fonction potentielle simple de façon à déduire des modèles convenables pour le dimère et le trimère de **1**.

Canadian Journal of Chemistry, **49**, 4096 (1971)

Introduction

In a previous study (1), the values of ΔG^0 at 25 °C were determined for the ionization, dimerization, and trimerization of the tetra-*n*-butylammonium picrate monomer in anhydrous benzene, chlorobenzene, and *o*-dichlorobenzene by using a solvent-extraction method. In the present work, this study has been extended to 35 and 45 °C, in order to be able to evaluate ΔH^0 and ΔS^0 for the above-noted reactions in the same anhydrous solvents. To complement this solvent-extraction study, calorimetric measurements were also made on the nonaqueous systems.

Experimental

Apparatus

Solvent Extraction

The equilibration bottles, the water thermostat, and the apparatus for dielectric-constant measurements have previously been described (1).

Calorimeter

The calorimeter was a conventional 500-ml Dewar flask in the usual tin housing. This flask was capped with a specially constructed hollow glass cover which could be clamped firmly against a rubber gasket on the flask, in order to provide a seal. Inlet and outlet glass tubes in this cover permitted the circulation through it of thermostatted water, thereby preventing condensation of solvent vapor on its under surface. Two glass tubes were also sealed vertically through the cover, to serve as access ports to the flask. The smaller tube accommodated thermistor leads which fitted snugly; the larger tube was for the addition of salt to the solvent in the flask, and it was kept stoppered between additions.

The thermistor was a low-range type, 0 to 90 °C, sensitive to changes of 0.001 °C (Sargent S-81620 Thermometric Element). It was calibrated against a calibrated Beckmann thermometer over the required range of 20 to 50 °C.

Materials

The preparation, purification, and analysis of the tetra-*n*-butylammonium picrate (Bu_4NPi), and the purification and measured densities of the solvents benzene, chlorobenzene, and *o*-dichlorobenzene have been described elsewhere (2). Distilled water was used for the aqueous phase in the solvent-extraction experiments.

Procedures

Solvent Extraction

The preparation of stock standard solutions of Bu_4NPi, the equilibration of the two liquid phases, and the analysis for the equilibrium concentrations of Bu_4NPi in the separated phases have been described elsewhere (1).

Calorimetry

The integral heat of solution of Bu_4NPi was determined in duplicate as a function of its concentration in each of the solvents *o*-dichlorobenzene, chlorobenzene, and the binary mixture (1:1 *v*/*v*) benzene–chlorobenzene, at 25, 35, and 45 °C. Thus a known weight (~ 2 g) of Bu_4NPi

[1]Revision received July 23, 1971.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was added through the cover port to a known weight of the solvent (~ 250 g) in the calorimeter. Prior to this addition, both solute and solvent were separately brought to the same initial, known temperature. Solution of the added Bu_4NPi was effected by hand-swirling the calorimeter. The resulting drop in temperature was found from the observed change in the response of the thermistor immersed in the solution. The entire procedure was executed with the calorimeter immersed up to its cover in a water thermostat held to within 0.2 °C of the contents of the calorimeter. In addition, water from this thermostat was pumped through the hollow cover of the calorimeter. Heat leakage from the calorimeter was found to be negligible over the period of the solution process; the equilibrium temperature remained constant within 0.001 °C for several minutes.

After a constant temperature had been reached following solution of the added Bu_4NPi, the temperature of the water in the thermostat was re-adjusted until it was again within 0.2 °C of the solution's temperature. Additional lots of Bu_4NPi were then added in succession, and the entire procedure was repeated after each addition. In this way, the heats of solution were found over the required concentration range of Bu_4NPi.

Prior to the first addition of Bu_4NPi, the temperature of the pure solvent in the calorimeter was measured with a calibrated thermometer. Thereafter, the temperature of the solution was found prior to each successive addition of Bu_4NPi by subtracting the temperature drop for the preceding run, as found from the thermistor. This method of temperature measurement was necessary because the response curve of the thermistor was temperature sensitive.

The water equivalent of the calorimeter was determined at 25 °C by using KNO_3 and water. This value was assumed to apply also at 35 and 45 °C.

Results, and Treatment of the Data

Solvent Extraction

Distribution experiments at 35.1 and 45.1 °C gave the equilibrium stoichiometric concentrations of Bu_4NPi in the aqueous and in the organic phases. A least-squares fit of these data to a previously derived polynomial (1) permitted evaluation of the formation constants for the various species previously shown (1) to be derived from the Bu_4NPi monomer in the organic phase. The treatment was identical with that reported (1) for the same systems at 25.0 °C. A previous study (2) had also shown Bu_4NPi and its aggregates to be partially hydrated in the present solvents; and the hydration constants and water activities at 25.0, 35.1, and 45.1 °C had at that time been evaluated. By using those hydration constants, the formation constants found from the present distribution studies were corrected as previously described (1), to give corresponding values for the anhydrous species formed from the anhydrous monomer in the organic phase. These molar equilibrium constants for the anhydrous species are entered in Table 1, where

$$p = [Bu_4NPi]_{\text{organic solvent}}/[Bu_4NPi]_{\text{water}}$$

$$Bu_4N^+ + Pi^- \overset{k}{\rightleftharpoons} Bu_4NPi \text{ (water)}$$

$$Bu_4NPi \overset{K}{\rightleftharpoons} Bu_4N^+ + Pi^- \text{ (organic solvent)}$$

$$n\ Bu_4NPi \overset{Kn}{\rightleftharpoons} [Bu_4NPi]_n \text{ (organic solvent)}$$

i.e., p = partition coefficient of the anhydrous monomer Bu_4NPi; K = dissociation constant of the anhydrous monomer in the organic phase; k = formation constant of the monomer in water; K_2, K_3, K_6 = formation constants of the anhydrous dimer (K_2), the anhydrous trimer (K_3), and the anhydrous hexamer (K_6) from the anhydrous monomers, in the organic phase; and D is the dielectric constant of the water-saturated organic solvent.

The values of the equilibrium constants K_2 and K_3 in Table 1 are for anhydrous species in water-saturated solvents. Therefore these values were next corrected to values in anhydrous solvents, that is, the presence of unbound water in the solvents was taken into account. To do so, advantage was taken of the linear relationship found to exist between $1/D$ and each of $\log K_2$ and $\log K_3$. This relationship is illustrated in Fig. 1, by plots of ΔG_2^0 ($= -RT \ln K_2$) and ΔG_3^0 ($= -RT \ln K_3$) *vs.* $1/D$, the data being from Table 1. Then from measured values (1) of the dielectric constant of each water-saturated solvent, and literature values for the corresponding anhydrous solvents, interpolation in Fig. 1 gave the required values for K_2 and K_3 in anhydrous solvents. The corrections proved to be very small. They were not applied to K or K_6 due to the unavailability of plots similar to those in Fig. 1, but the error introduced by applying the values of K and K_6 in Table 1, to the case of anhydrous solvents is doubtless negligibly small.

The values of K, K_2, K_3, and K_6 for the anhydrous solvents were then converted from a molar to a molal basis; previously measured (2) densities were used. From the temperature dependence of these four molal equilibrium constants, the corresponding standard enthalpy changes ΔH^0, ΔH_2^0, ΔH_3^0, and ΔH_6^0 were found by least-squares, and the values are entered in Table

m-Dichlorobenzene	25.0	5.04													11.7	8

*s.d. means standard deviation. For K and pk there were five degrees of freedon, for K_6 there were two; and for K_2 and K_3 the degrees of freedom are entered in the Table.
†$K_f = 1/K$. These values were determined from conductance data.

TABLE 2. Standard enthalpy changes at 25 °C for the dissociation and aggregation of tetra-*n*-butylammonium picrate monomer in three anhydrous solvents

Solvent	ΔH^0 (kcal/mol)		ΔH_2^0 (kcal/mol)		ΔH_3^0 (kcal/mol)		ΔH_6^0 (kcal/mol)	
	Mean	s.d.*	Mean	s.d.*	Mean	s.d.*	Mean	s.d.*
o-Dichlorobenzene	−1.36	0.13	2.91	0.85	−2.5	3.1		
Chlorobenzene			0.3	3.4	−2.6	2.6	−0.5	2.1
Benzene–chlorobenzene (1:1 *v/v*)			−2.3	6.0	−2.8	1.8		

*s.d. is the standard deviation for one degree of freedom. ΔH^0 = standard enthalpy change for the dissociation of the Bu_4NPi monomer; ΔH_2^0, ΔH_3^0, ΔH_6^0 = standard enthalpy changes for the formation of the dimer (ΔH_2^0), the trimer (ΔH_3^0), and the hexamer from the Bu_4NPi monomer.

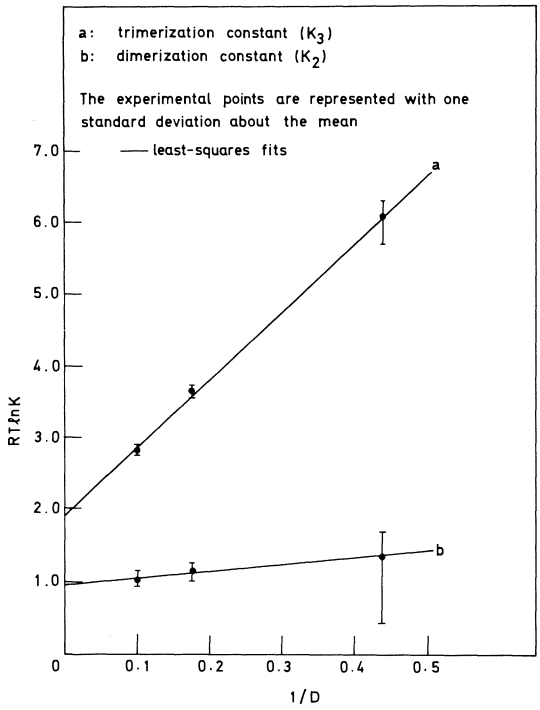

FIG. 1. The relationship between minus the standard free energy of formation of the dimer and the trimer of Bu_4NPi from the monomer, and the reciprocal of the dielectric constant of the solvent, for three solvents at 25 °C.

2. For ΔH^0, namely the standard enthalpy of dissociation of the monomer in the particular solvent, reliable values were obtained only for the *o*-dichlorobenzene system. For the binary solvent system, 1:1 *v/v* benzene–chlorobenzene, the four standard enthalpies were evaluated as follows: Each equilibrium constant K, K_2, K_3, and K_6 was interpolated at each temperature from the linear relationship between $1/D$ and the logarithm of the appropriate equilibrium constant, and the measured value of D for the binary solvent. The standard enthalpy changes were then found from the temperature dependence of the equilibrium constants.

Calorimetry

The heat of solution at each addition of Bu_4NPi to each solvent was calculated in the usual way, by using the heat capacities of the solvents and the measured water equivalent of the calorimeter. However, the heat capacity of the (1:1 *v/v*) benzene–chlorobenzene mixture was interpolated from those of the pure solvents.

The total heat of solution, $\sum\Delta H$, is given in kcal by

$$[1] \quad \sum\Delta H = W_s\left(\Delta H_s^0[m]_T + \sum_{i=1}^{n}\Delta H_i^0[m_i]\right)$$

where W_s = weight in kg of solvent in the calorimeter; ΔH_s^0 = standard enthalpy of solution of Bu_4NPi to give entirely Bu_4NPi monomers, per mole of monomers (kcal/mol); $[m]_T$ = stoichiometric molal concentration of Bu_4NPi in the calorimeter; ΔH_i^0 = standard enthalpy of formation of species X_i from the Bu_4NPi monomer, per mole of X_i (kcal/mol); $[m_i]$ = molal concentration of species X_i in the calorimeter.

The standard state of each species in solution is the conventional, hypothetical ideal one-molal solution. The solutions of the monomer and its aggregates are assumed to obey Henry's law over the concentration ranges studied.

In the present systems, the ΔH_i^0 are ΔH^0, ΔH_2^0, and ΔH_3^0, and also ΔH_6^0 in the case of chlorobenzene. These values were available (Table 2). Their large standard deviations were not unduly detrimental for the present purposes, because the values of $\sum_i\Delta H_i^0[m_i]$ were much smaller than $\Delta H_s^0[m]_T$, at most 10%, even at the highest values of $[m]_T$. The unavailability of

	35	6.36	0.02	11
	45	6.56	0.03	11
Chlorobenzene–benzene (1:1 *v/v*)	25	7.13	0.07	7
	35	7.45	0.03	7
	45	7.75	0.03	7

values of ΔH^0 (enthalpy of dissociation of Bu_4NPi) in the cases of chlorobenzene and the mixture benzene–chlorobenzene was also not detrimental because in the range of Bu_4NPi concentrations studied by calorimetry (0.01–0.1 *m*), the concentration of ions was negligibly small in those two solvents.

The $[m_i]$ in eq. 1 are the concentrations of each individual species in the equilibrium mixture in the calorimeter, namely ions, monomer, dimer, trimer, and also hexamer in the case of chlorobenzene. These values of $[m_i]$ were calculated from the known stoichiometric concentration $[m]_T$ of Bu_4NPi in the calorimeter, by using eq. 2:

$$[2] \quad [m]_T = \frac{K^{1/2}[X_1]}{(\gamma_\pm)_0} + [X_1] + 2K_2[X_1]^2 + 3K_3[X_1]^3 + 6K_6[X_1]^6$$

where $[X_1]$ = molality of the Bu_4NPi monomer (ion pair); $(\gamma_\pm)_0$ = mean ionic activity coefficient of the single ions in the organic phase.

The values of $(\gamma_\pm)_0$ were estimated by using iteratively the conventional Debye–Hückel expression. The values of K, K_2, K_3, K_6 for the anhydrous species in the anhydrous solvents were calculated from the corresponding values in Table 1, by applying the water corrections described above. The value of $[X_1]$ corresponding to a given value of $[m]_T$ was found correct to three significant figures, as follows: A range of values of $[X_1]$ was chosen with very small increments, such that the computer-calculated values of the right-hand side of eq. 2 spanned the entire range of values of $[m]_T$ used in the experiments. From this tabulation, $[X_1]$ was read off for each given $[m]_T$. From each such value of $[X_1]$, the molalities of the ions, dimers, trimers, and hexamers were found from the expressions $K^{1/2}[X_1]^{1/2}(\gamma_\pm)_0^{-1}$, $K_2[X_1]^2$, $K_3[X_1]^3$, and $K_6[X_1]^6$, respectively. Equation 2 was then recast, to give a new linear function ϕ

$$[3] \quad \phi \equiv \sum \Delta H - W_s \sum_{i=1} \Delta H_i^0 [m_i] = \Delta H_s^0 W_s [m]_T$$

A least-squares fit of eq. 3 to the data ϕ *vs.* $W_s[m]_T$ gave the values of ΔH_s^0 entered in Table 3, for each solvent system.

Standard Enthalpy of Sublimation of Bu_4NPi

The standard enthalpy of transfer (ΔH_t^0) of Bu_4NPi monomer from its standard-state solution (1 *m*) to the gas in its standard state (1 atm, 35 °C) was calculated as described below, for each solvent. Each resulting value was added to the standard enthalpy of solution of the Bu_4NPi monomer in the corresponding solvent, obtained from Table 3. Thus, three estimates were obtained, one for each solvent, for the standard enthalpy of sublimation of Bu_4NPi. The results are in Table 5.

In order to calculate ΔH_t^0 for each solvent system, this enthalpy change was considered to consist of a "non-electrostatic" contribution (ΔH_{tne}^0) and an electrostatic one (ΔH_{te}^0). These contributions were estimated separately, as follows.

Non-electrostatic Contribution

By non-electrostatic contribution is meant the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

TABLE 4. The non-electrostatic contribution ΔH_{tne}^0 to the standard enthalpy of transfer of Bu_4NPi monomer from three solvents to the gas, at 35 °C

Solvent	Hildebrand solubility parameters: Solvent δ_2 ($cal^{1/2}/ml^{1/2}$)	Hildebrand solubility parameters: Bu_4NPi δ_1 ($cal^{1/2}/ml^{1/2}$)	Partial molal volume of Bu_4NPi, $\bar{V}_1$ (ml/mol)	ΔH_{tne}^0 (kcal/mol)

Chlorobenzene	9.4	8.5	404	29.6
o-Dichlorobenzene	9.7	8.5	404	29.3

value that the standard enthalpy of transfer would have if there were no charges on the two ions that comprize the monomer. Simple relationships involving Hildebrand solubility parameters (3) were applied to the following two processes, where X_1 denotes the hypothetical Bu_4NPi monomer of zero dipole

$$X_1 \xrightarrow{\Delta H_I^0} X_1 \xrightarrow{\Delta H_{II}^0} X_1$$

solution; standard state 1 *m* | pure liquid; standard state | gas; standard state 1 atm, 35 °C

In general

$$\Delta H_I^0 \simeq \Delta E_I^0 = -\psi_2^2 V_1(\delta_1 - \delta_2)^2$$

and

$$\Delta H_{II}^0 = V_1\delta_1^2 + RT$$

whence

$$[4] \quad \Delta H_{tne}^0 = V_1[\delta_1^2 - \psi_2^2(\delta_1 - \delta_2)^2] + RT$$

where ψ_2 = volume fraction of solvent in the solution at T °K; V_1 = molal volume of Bu_4NPi, supercooled liquid at T °K; δ_1, δ_2 = Hildebrand solubility parameters for the Bu_4NPi monomer and the solvent, respectively; $-\Delta H_I^0$ = partial molal enthalpy of mixing (sometimes designated $\bar{H}_1^M$).

The necessary quantities, and the values calculated for ΔH_{tne}^0 are entered in Table 4. The values of δ_2 were estimated from the internal energy of evaporation of the solvents and their molal volumes. The value for δ_1 was estimated as follows: The value of δ_1 for the discharged Bu_4N^+ ion alone was taken to be similar to that of *n*-butane or *n*-pentane, namely about 7. The value of δ_1 for the discharged picrate ion was taken to be similar to that of benzene or nitrobenzene, namely about 10. Therefore δ_1 for the hypothetical Bu_4NPi monomer of zero dipole was taken to be the average of 7 and 10. The molal volume V_1 of Bu_4NPi (supercooled liquid) was taken as being equal to its partial molal volume ($\bar{V}_1$) in the organic solvents. Values of $\bar{V}_1$ for Bu_4NPi were calculated from measured densities of solutions of Bu_4NPi in the solvents (4). It is recognized that this is an approximation in that the densities were for solutions of Bu_4NPi that had charged ions. In the present case, $\psi_2 = 1$.

The values of ΔH_{tne}^0 in Table 4 must be considered as being rough estimates. Several approximations entered into the calculations. For example, this solubility-parameter approach should strictly be used only with nonpolar solvents. Moreover, the value 8.5 for δ_1 is uncertain.

Electrostatic Contribution

Plots of $RT \ln pk$ *vs.* $(1 - 1/D)$ are shown in Fig. 2; the data are in Table 1. The value of any ordinate in Fig. 2 gives $[\Delta G_{t(s-w)}^0 + RT \ln k]$, where the first term is the standard free energy of transfer of one mole of Bu_4NPi monomers into its standard-state solution (1 *m*) in water, from its standard-state solution (1 *m*) in a solvent of dielectric constant *D*. In the case of the intercept, the solvent is a hypothetical one of unit dielectric constant, and here $\Delta G_{t(s-w)}^0$ is designated as $\Delta G_{t(h-w)}^0$. In this hypothetical solvent the electrostatic interactions between solute and solvent are absent, but the "non-electrostatic" interactions are still present. Thus, the hypothetical solvent is not a vacuum. The almost negligible variation from solvent to solvent, in the values of ΔH_{tne}^0 in Table 4 is relevant to this special case.

Now it is reasonable to write

$$[5] \quad \Delta G_{te(g-s)}^0 = \Delta G_{t(h-s)}^0$$

That is, the electrostatic contribution $\Delta G_{te(g-s)}^0$ to the standard free energy of transfer for the process

Bu_4NPi (gas, s.s.) $\rightarrow$ Bu_4NPi (solution, s.s.)

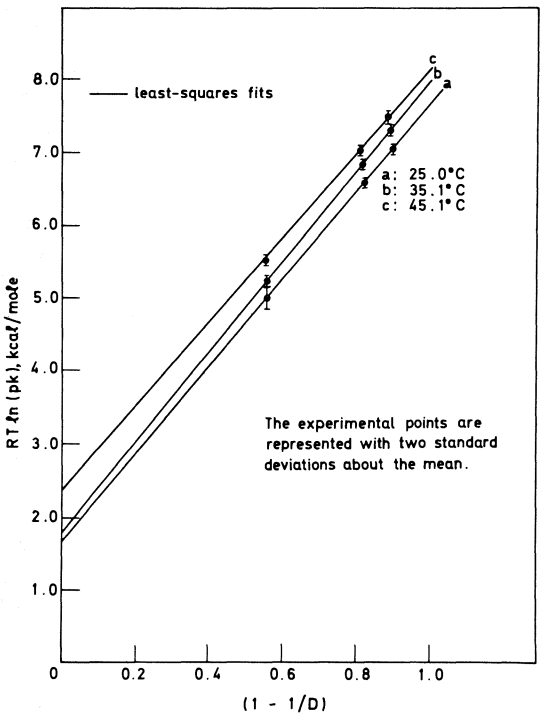

FIG. 2. The relationship between minus the standard free energy change for the transfer Bu_4NPi (water) → Bu_4NPi (org. solvent) of the monomer, and the reciprocal of the dielectric constant (D) of the organic solvent.

equals the total standard free energy of transfer for the following process

$$Bu_4NPi\,(\text{hypothetical solution}, D = 1, \text{s.s.}) \rightarrow Bu_4NPi\,(\text{solution, s.s.})$$

In that case

$$[6] \quad \Delta G_{te(g-s)}^0 = \Delta G_{t(h-w)}^0 - \Delta G_{t(s-w)}^0$$

The right-hand side of eq. 6 is just the intercept (at $D = 1$) minus the ordinate (at D) in Fig. 2.

Equation 6 was used with the data of Fig. 2, to evaluate $\Delta G_{te(g-s)}^0$ for each of the three solvents at each of the three temperatures. The resulting values of $\Delta G_{te(g-s)}^0$ varied linearly with $1/T$ over the range studied. Therefore $\Delta H_{te(g-s)}^0$ was calculated for each solvent, by least-squares. These enthalpy values are entered in Table 5.

The data in Table 5 permitted the calculation of the standard enthalpy of sublimation (ΔH_{subl}^0) of Bu_4NPi from the solid to the monomeric gas at 1 atm and 35 °C. Thus,

$$[6] \quad \Delta H_{subl}^0 = \Delta H_s^0 + \Delta H_{tne(s-g)}^0 + \Delta H_{te(s-g)}^0$$

These values calculated for ΔH_{subl}^0 were not significantly different. This conclusion suggests that the calorimetric data, from which the values of ΔH_s^0 were obtained, are consistent with the distribution data, from which the $\Delta H_{te(s-g)}^0$ data were calculated.

Discussion

The data at 25 °C in Table 1 are plotted in Figs. 1 and 2; $RT \ln K_2$ and $RT \ln K_3$ are plotted against $1/D$, and $RT \ln pk$ is plotted against $(1 - 1/D)$. Figure 3 shows a plot of $RT \ln K_f$ *vs.* $1/D$, where K_f is the formation constant of the Bu_4NPi monomer from its ions. Literature values of K_f obtained from conductance data were used in lieu of the much less precise values of K ($= 1/K_f$) reported in the present work from distribution data.

The observed linearity of all these graphs will now be interpreted.

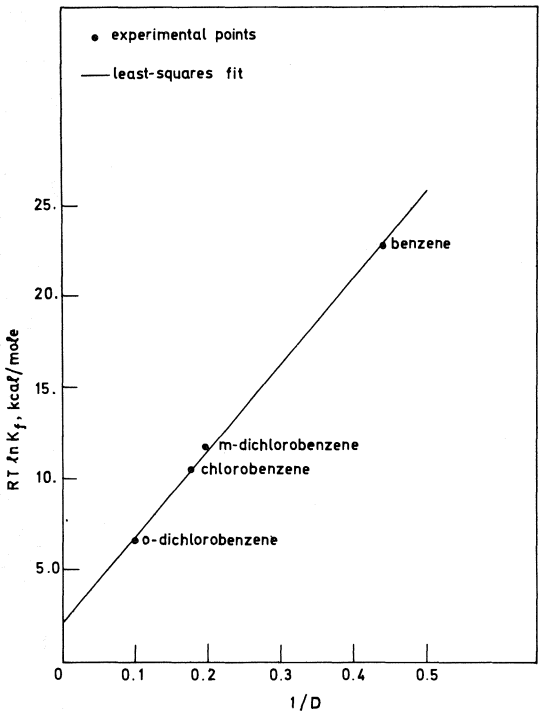

FIG. 3. The relationship between minus the standard free energy of formation of the monomer Bu_4NPi from its simple ions, and the reciprocal of the dielectric constant of the solvent, for four solvents at 25 °C.

Formation Constant K_f

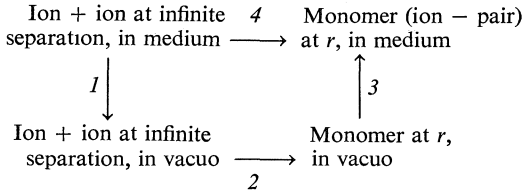
A value for the "internuclear" distance of separation of the two ions in the Bu_4NPi monomer was calculated by using Rittner's formula (5) and published values (6, 7) of his parameters

$$\mu = er - \frac{r^4 e(\alpha_1 + \alpha_2) + 4re\alpha_1\alpha_2}{r^6 - 4\alpha_1\alpha_2}$$

where μ = dipole moment of Bu_4NPi, 16.2×10^{-18} e.s.u. cm (6); $e = 4.803 \times 10^{-10}$ e.s.u.; α_1, α_2 = polarizabilities of the ions: 31.2×10^{-24} ml for Bu_4N^+ (7) and 24.4×10^{-24} ml for Pi^- (7); r = "internuclear" distance of separation of the two ions in Bu_4NPi.

Three real positive roots were obtained for r, namely, 5.74, 4.42, and 1.62 Å. The value 5.74 Å was chosen for use; it agreed best with literature values (8, 9) calculated by applying a Denison–Ramsey model to conductance data for Bu_4NPi in various solvents.

Figure 3 is now interpreted by using a modified Denison–Ramsey approach (9) similar to that used by Pettit and Bruckenstein (10); but our approach avoids their (10) simplifying assumption regarding entropies.



Cycle I

For Cycle I, it is assumed that the non-electrostatic (to use a conventional expression) contributions to ΔH_1 and ΔH_3 are equal and opposite. Then Pettit and Bruckenstein (10) showed that

$$[7] \quad -\Delta G_4^0 = RT \ln K_f = -\Delta V_2/D + T\Delta S_4$$

where ΔV_2 = standard free energy change for step *2* at 0 °K; T = absolute temperature; D = dielectric constant of the medium at T °K; ΔS_4 = entropy change due to translational, rotational, and vibrational changes for step *4*.

Equation 7 was accepted for use in the present treatment; but the further assumption that $\Delta S_2 = \Delta S_4$ made by Pettit and Bruckenstein (10) is unacceptable, and was not used in the present treatment. Instead, eq. 7 was fitted by least-squares to the data $RT \ln K_f$ *vs.* $1/D$, in Table 1; these data are seen in Fig. 3 to give a linear plot. The least-squares value found for the slope in Fig. 3 was $\Delta V_2 = -47.6 \pm 1.2$ kcal/mol; and the value found for the intercept was $\Delta S_4 = 6.7 \pm 1.0$ e.u. Pettit and Bruckenstein (10), by using their assumption that $\Delta S_2 = \Delta S_4$, calculated that $\Delta S_4 = -18.1$ e.u. Thus their value is 24.8 e.u. more negative than ours.

Interpretation of ΔS_4

In order to explain the small but positive entropy change (6.7 e.u.) found for step *4* of Cycle I, partial desolvation of the solvated ions when they combine is postulated. Then step *4* in Cycle I becomes

$$Bu_4N \cdot aS^+ + Pi \cdot bS^- \rightarrow Bu_4NPi \cdot (a + b - x)S + xS$$

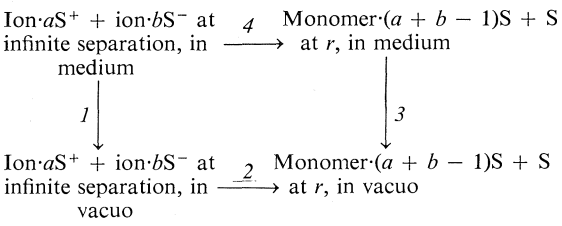
where S is the solvent. Change in translational entropy usually provides the major contribution to the standard entropy change in reactions of this kind. Therefore a value of $x \sim 1$ would account for the small positive value found for ΔS_4^0. Moreover, ion pairing results in some

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

mutual neutralization of oppositely charged particles and fields, which in turn should weaken ion–solvent interaction and thereby promote desolvation. In addition, squeezing out of an intervening, bound solvent molecule would allow closer approach of the ions in the monomer.

Interpretation of ΔV_2

The postulated desolvation with $x \sim 1$ requires that Cycle I be modified as shown in Cycle II, below



Cycle II

Equation 7 then becomes

$$[8] \quad -\Delta G_4^0 = RT \ln K_f = -\Delta V_2/D + T\Delta S_4 - \Delta H_{2,\,\text{desolv}}$$

where $\Delta H_{2,\,\text{desolv}}$ = contribution to the enthalpy change in step *2* of Cycle II at 0 °K and constant pressure, due to the desolvation.

The value of $\Delta H_{2,\,\text{desolv}}$ is considered to be small relative to the other terms. It is also assumed not to vary significantly for the four solvents. However, it is recognized that this is a questionable assumption, supported only tenuously by the fact that the graph in Fig. 3 is linear.

The value found for the intercept in Fig. 3, namely 1.99 kcal/mol, would then be attributed to $(T\Delta S_4 - \Delta H_{2,\,\text{desolv}})$, not solely to $T\Delta S_4$ as was done in the preceding section.

A value will next be calculated for ΔV_2. It proved expedient (4) to use for this purpose a simple ion–ion potential function

$$[9] \quad \Delta V_2 = -\frac{e^2}{r} + \frac{B}{r^{6.9}}$$

where r = equilibrium "internuclear" distance of separation of the two ions in the Bu_4NPi monomer; B = a constant; exponent 6.9 = a value determined empirically by Pettit and Bruckenstein (10), from experimental values of ΔV_2 for the ion pairs of gaseous alkali halides.

By setting $(d\Delta V_2/dr) = 0$ at $r = 5.74$ Å, B was found to be 6.33×10^{-63} e.s.u.^{2} cm$^{5.9}$. Substitution of these values of r and B into eq. 9 then gave $\Delta V_2 = -49.5$ kcal/mol. This calculated value agrees well with the experimental value $\Delta V_2 = -47.6 \pm 1.2$ kcal/mol (1.2 is one standard deviation). Thus, evaluation of r from the measured dipole moment and use of a simple function for the electrostatic potential permitted the calculation of a reasonable value for the slope in Fig. 3.

Partition Coefficient of Bu_4NPi *Monomer*

Figure 2 shows that plots of $RT \ln pk$ *vs.* $(1 - 1/D)$ are linear for each of the three temperatures. Now $RT \ln pk$ is equal to minus the standard free energy of transfer (ΔG_t^0) for the process

$$Bu_4N^+ + Pi^- \rightarrow Bu_4NPi$$
(in water) (in organic solvent)

The least-squares values of the slopes and intercepts of the three lines in Fig. 2 are given in Table 6. In order to interpret these data, it will be supposed that the potential function given by eq. 9, with $B = 6.63 \times 10^{-63}$ e.s.u.^{2} cm$^{5.9}$ is valid for step *3* of Cycle II. Then for the transfer process for the monomer

$$Bu_4NPi \text{ in water, dielectric constant } D_w \xrightarrow{\Delta H_t} Bu_4NPi \text{ in organic solvent, dielectric constant } D$$

it is readily shown that

$$[10] \quad (\Delta H_t)_{0\,°K,\,P} = \left(\frac{e^2}{2a_1} + \frac{e^2}{2a_2} - \frac{e^2}{r} + \frac{6.63 \times 10^{-63}}{r^{6.9}}\right)\left(\frac{1}{D} - \frac{1}{D_w}\right) + \Delta H_{tne}$$

where a_1, a_2 = radii of Bu_4N^+ and Pi^- ions, respectively, at infinite separation; r = defined under eq. 9; ΔH_{tne} = non-electrostatic contribution to the enthalpy of transfer of Bu_4NPi monomer from water to organic solvent, strictly applicable at 0 °K and constant pressure. The

TABLE 6. Least-squares values of slopes and intercepts for the linear plots (Fig. 2) $RT \ln pk$ *vs.* $(1 - 1/D)$ at 25.0, 35.1, and 45.1 °C

Temperature (°C)	Slope (kcal/mol)		Intercept (kcal/mol)	
	Mean	2 × s.d.*	Mean	2 × s.d.*
25.0	6.02	0.18	1.63	0.14
35.1	6.19	0.14	1.77	0.11
45.1	5.78	0.11	2.33	0.08

*s.d. = standard deviation for one degree of freedom. (Twice the s.d. is reported, to conform with bars in Fig. 2.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tacit assumption that ΔH_{tne} is not a function of the dielectric constant introduces an error that is considered to be small compared to the value of the electrostatic term. Abbreviating eq. 10,

$$[11] \quad (\Delta H_t)_{0\,°K,\,P} = Z\left(\frac{1}{D} - \frac{1}{D_w}\right) + \Delta H_{tne}$$

then for a transfer between standard states at T °K, one gets

$$[12] \quad \Delta H_t^0 = (\Delta H_t)_{0\,°K,\,P} + RT^2\left[\frac{\partial \ln Q}{\partial T}\right]_p$$

and

$$[13] \quad \Delta S_t^0 = \Delta S + RT\left[\frac{\partial \ln Q}{\partial T}\right]_p$$

where ΔS includes the translational, rotational, and vibrational entropy changes at T °K that are associated with the transfer; and where Q is the ratio of the partition functions for the "product" and the "reactant".

From eqs. 11, 12, and 13

$$[14] \quad -\Delta G_t^0 = RT\ln p = Z\left(1 - \frac{1}{D}\right) + Z\left(\frac{1}{D_w} - 1\right) + T\Delta S - \Delta H_{tne}$$

whence

$$[15] \quad RT\ln pk = Z\left(1 - \frac{1}{D}\right) + Z\left(\frac{1}{D_w} - 1\right) + T\Delta S - \Delta H_{tne} + RT\ln k$$

On relating eq. 15 to Fig. 2 and the corresponding data in Table 6, it is seen that for these straight lines

$$[16] \quad \text{Slope} = Z = \left(\frac{e^2}{2a_1} + \frac{e^2}{2a_2} - \frac{e^2}{r} + \frac{6.33 \times 10^{-63}}{r^{6.9}}\right)$$

$$[17] \quad \text{Intercept} = Z\left(\frac{1}{D_w} - 1\right) + T\Delta S - \Delta H_{tne} + RT\ln k$$

Interpretation of the Slope

Statistical treatment of the values in columns 2 and 3 of Table 6 showed that the values of the slope do not depend significantly on temperature in the range tested. Inspection of the expression for Z in eq. 16 shows that Z should be essentially independent of temperature.

By assuming for Bu_4NPi spherical ions of equal radii $a = (a_1 + a_2)/2$, then on substituting into eq. 16 the mean value of $Z = 6.00$ kcal/mol from Table 6, and $r = 5.74 \times 10^{-8}$ cm from the dipole moment, $a = 5.98$ Å with a standard deviation of 0.02 Å. This value of a is for the solvated ions at infinite separation. Although the assumptions made are crude, the value 5.98 Å is a reasonable one.

Interpretation of the Intercept

In eq. 17 the term $RT\ln k$ will be neglected. It is not known for Bu_4NPi, but for Et_4NPi it is approximately 1.0 at 25 °C (14). The term ΔH_{tne} will also be considered negligibly small compared to the electrostatic contribution. The grounds for neglecting ΔH_{tne} are presently not very satisfactory, being based only on the large dipole moment (16.2 D) of Bu_4NPi. Unfortunately, the highly structured nature of water makes it impracticable to attempt a solubility-parameter approach to evaluate ΔH_{tne}. Accordingly, the following interpretation of the intercept is provisional.

By neglecting $RT\ln k$ and ΔH_{tne}, and by substituting the observed values for the intercepts and for Z (from Table 6) and the published values for D_w (15), ΔS in eq. 17 was calculated and the values are entered in Table 7.

The value of about 25 e.u. calculated for ΔS is considered to be a reasonable one. Transfer of the Bu_4NPi monomer from water into the organic solvents used would be expected to result in some desolvation, partly because water is known to form cage-like structures around organic solutes, and partly because water molecules are about one-fifth the size of the organic-solvent molecules.

Dimerization (K_2) and Trimerization (K_3) Constants

Figure 1 shows that plots of $RT\ln K_2$ and of $RT\ln K_3$ *vs.* $1/D$ are linear for each of the three temperatures. The data are in Table 1. The large standard deviations in the values of K_2 for benzene were due to the relative paucity of dimers in

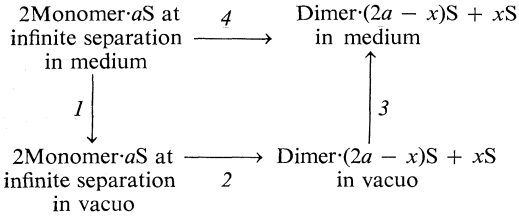
those solutions (always less than 10% of the stoichiometric concentration of the salt).

In order to interpret these data, equations will be derived in a manner analogous to that used above for the formation constant K_f.



Cycle III

For Cycle III it is assumed that the non-electrostatic contributions to ΔH_1 and ΔH_3 are equal and opposite. Then for step *4* of Cycle III

$$[18] \quad -\Delta G_4^0 = RT \ln K_2 = -\frac{\Delta V_2}{D} + T\Delta S_4 + \Delta H_{2,\text{desolv}}$$

where ΔV_2 = standard free energy change for step *2* at 0 °K; $\Delta H_{2,\text{desolv}}$ = contribution to the enthalpy change in step *2* of Cycle III at 0 °K, due to the desolvation; K_2 = equilibrium constant for step *4* of Cycle III.

Similarly, for the reaction

$$\text{3Monomer·}aS \text{ at infinite separation in medium} \xrightarrow{\Delta G_4^0} \text{Trimer·}(3a - y)S + yS \text{ in medium}$$

$$[19] \quad -\Delta G_4^0 = RT \ln K_3 = -\frac{\Delta V_2}{D} + T\Delta S_4 + \Delta H_{2,\text{desolv}}$$

where ΔV_2 and $\Delta H_{2,\text{desolv}}$ now refer to a trimer cycle.

On relating eqs. 18 and 19 to the dimer and trimer plots, respectively, in Fig. 1, and to the corresponding data in Table 1, it is seen that the slopes of these straight lines in Fig. 1 give $-\Delta V_2$, and the intercepts give $(T\Delta S_4 + \Delta H_{2,\text{desolv}})$; the least-squares values of these slopes and intercepts are entered in Table 8.

Interpretation of the Intercepts

By assuming that $\Delta H_{2,\text{desolv}}$ is much smaller than $T\Delta S_4$ in eqs. 18 and 19, values for ΔS_4 were calculated for each plot in Fig. 1 by using the data in Table 8. The results are in Table 9.

These low, positive values for ΔS_4 include all translational, rotational, and vibrational entropy changes associated with step *4* of Cycle III for the dimer, and for the corresponding step for the trimer. In order to explain them, it is necessary to postulate desolvation; and this in turn is based on the presumption that the changes in translational entropy make much the largest contribution to ΔS_4. Provisionally then, it is suggested that the extent of the desolvation is approximately as follows

$$\text{2Monomer·}aS \rightarrow \text{Dimer·}(2a - 1)S + S$$
$$\text{3Monomer·}aS \rightarrow \text{Trimer·}(3a - 2)S + 2S$$

That is, there is no net change in the number of particles in the solutions.

Interpretation of the Slopes of the Dimer Plots

The slope of the straight line in Fig. 1 gives ΔV_2, the standard free energy change for the following reaction at 0 °K

$$\text{2Bu}_4\text{NPi·}aS \text{ at infinite separation in vacuo} \rightarrow \text{Dimer·}(2a - 1)S + S \text{ in vacuo}$$

provided $\Delta H_{2,\text{desolv}}$ is constant for the three solvents, thereby making it part of the intercept.

Two possible models of the solvated dimer are now considered. One is a "rigid-dipole" rectangular model, proposed by Fuoss (16–18) and by Geddes and Kraus (19). In it, the monomers have associated laterally to form the dimer, and the equilibrium internuclear distance of separa-

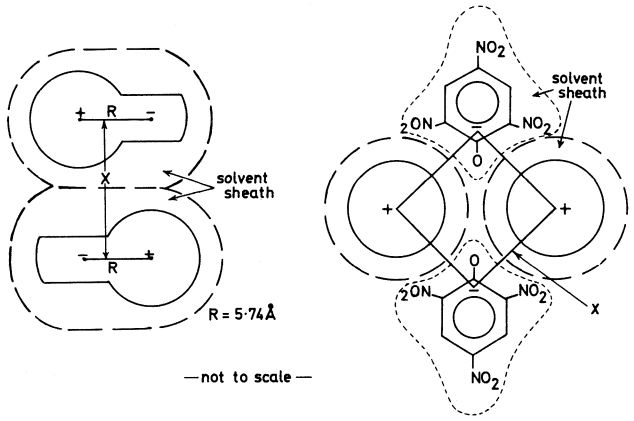

FIG. 4. Sketches of (*a*) rigid-dipole model, and (*b*) square model, for the dimer of Bu_4NPi in a low-dielectric solvent.

TABLE 9. Entropy changes for the dimerization and trimerization of Bu_4NPi monomers at three temperatures

Temperature (°C)	ΔS_4 (e.u.) Dimerization Mean	Dimerization 2 × s.d.*	Trimerization Mean	Trimerization 2 × s.d.*
25.0	3.17	0.25	6.41	0.44
35.1	3.41	0.81	5.45	0.29
45.1	4.53	1.10	5.88	0.22

*s.d. = standard deviation for one degree of freedom (twice the s.d. is reported).

tion of the ions in the monomer is unchanged by dimerization. The second model for the dimer was proposed by O'Konski and Higuchi (20). In it, the dimer is a rhombus. Such a symmetrical planar arrangement gives the most energetically favored configuration that symmetrical ions can assume.

Since the picrate ion is unsymmetrical, and the potential function given by eq. 9 is a simplified one, it is not possible to decide *a priori* which model is better for Bu_4NPi. Therefore both models have been applied to the present data, in order to make a choice.

The two models of the dimer are illustrated in Fig. 4; solvent separation of the constituents of these ionic aggregates has been presumed. Such solvent separation is suggested by at least three facts: (*i*) the "internuclear" distance of separation of the two ions in the monomer was calculated above to be 5.74 Å; (*ii*) the molar absorptivity of the monomer was found to be the same as that of the free picrate ion in the solvents used in the present work, but different from that of picric acid; (*iii*) the distance parameters calculated below for the dimer models.

Electrostatic calculations follow, for the distance parameter X_m of the two models in Fig. 4. For each model, eq. 9 was applied in order to express the potential energy of formation (ΔV_2) of the dimer from the monomers at 0 °K. The value of the exponent in the repulsion term was assumed to be −6.9; but the value of B was expected to differ from the value it had for the case of monomer formation from the two ions. The experimental value used for ΔV_2 was found as follows: statistical treatment showed for the values of the slopes in Table 8 that the variances were homogeneous, and the mean values were not significantly different. Therefore a weighted mean and a weighted standard deviation were calculated from the values at the three temperatures, to give $\Delta V_2 = -0.92$ kcal/mol with a standard deviation of 0.48.

(a) Rigid-dipole Model

Application of eq. 9 to Fig. 4(*a*) gives

$$[20]\quad (\Delta V_2)_{X=X_m} = -\frac{2e^2}{X_m} + \frac{2e^2}{(R^2 + X_m{}^2)^{1/2}} + \frac{B}{X_m{}^{6.9}}$$

whence

$$[21]\quad \left(\frac{\partial \Delta V_2}{\partial X}\right)_{X=X_m} = 0 = \frac{2e^2}{X_m{}^2} - \frac{2e^2 X_m}{(R^2 + X_m{}^2)^{3/2}} - \frac{6.9B}{X_m{}^{7.9}}$$

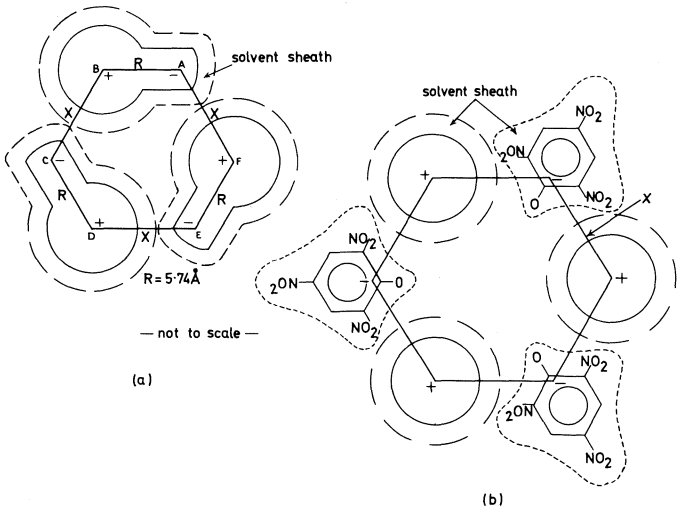

FIG. 5. Sketches of (*a*) rigid-dipole model, and (*b*) regular hexagon model, for the trimer of Bu_4NPi in a low-dielectric solvent.

Solution of eqs. 20 and 21, with $R = 5.74 \times 10^{-8}$ cm, $e = 4.803 \times 10^{-10}$ e.s.u., and $\Delta V_2 = -0.92/14.4 \times 10^{12}$ erg molecule^{-1} gave $X_m =$ 19 Å and $B = 1.70 \times 10^{-60}$ e.s.u.^{2} cm$^{5.9}$. For $\Delta V_2 = -0.92 + 0.48$ and $-0.92 - 0.48$ kcal/mol, respectively, $X_m = 24$ and 16 Å, respectively.

(b) Rhombohedral Model

Exploratory calculations by applying eq. 9 to the rhombohedral model showed that the configuration with minimum energy was a square. On considering only nearest-neighbor repulsion terms, the two simultaneous equations applicable to the square configuration are

$$[22] \quad (\Delta V_2)_{X=X_m} = -\frac{4e^2}{X_m} + \frac{\sqrt{2}e^2}{X_m} + \frac{4B}{X_m^{6.9}} + 2V_p$$

$$[23] \quad \left(\frac{\partial \Delta V_2}{\partial X}\right)_{X=X_m} = 0 = \frac{4e^2}{X_m^2} - \frac{\sqrt{2}e^2}{X_m^2} - \frac{27.6B}{X_m^{7.9}}$$

where V_p = standard free energy change for the reverse of step *2* of Cycle II, calculated above to be 49.5 kcal/mol for an "internuclear" distance of separation of 5.74 Å for the two ions in the monomer.

Solution of eqs. 22 and 23 with $\Delta V_2 = -0.92/14.4 \times 10^{12}$ erg molecule^{-1} gave $X_m = 7.4$ Å and $B = 1.76 \times 10^{-62}$ e.s.u.^{2} cm$^{5.9}$. For $\Delta V_2 = -0.92 + 0.48$ and $-0.92 - 0.48$ kcal/mol, respectively, $X_m = 7.4$, and 7.3 Å, respectively.

Interpretation of the Slopes of the Trimer Plots

The slope of the straight line in Fig. 1 gives ΔV_2, the standard free energy change for the following reaction at 0 °K

$$\underset{\text{at infinite separation in vacuo}}{3Bu_4NPi\cdot aS} \rightarrow \underset{\text{in vacuo}}{\text{Trimer}\cdot(3a-2)S + 2S}$$

provided $\Delta H_{2,\,desolv}$ is constant for the three solvents.

As with the dimer, so too for the solvated trimer two different models can be prescribed. They are illustrated in Fig. 5. One is based on the rigid-dipole approach, and is a non-regular, planar hexagonal ring. The other model is based on the symmetrical-ions approach with the constraint imposed that eq. 9 is used; this model is a regular, planar hexagonal ring.

Electrostatic calculations follow, for the dimensions X and R in Fig. 5(*a*), and X in Fig. 5(*b*). In both cases eq. 9 was used exactly as it was for the dimer calculations. The experimental value used for ΔV_2 was the mean of the three values given in Table 8 for three temperatures. The variance used for this mean was the sample variance around the mean, with two degrees of freedom. Thus $\Delta V_2 = -9.76 \pm 0.25$ kcal/mol.

(a) Rigid-Dipole Model (Non-regular Hexagon)

From Fig. 5*a*, alternate sides (X and R) are equal, and all internal angles are 120°. One

general contact electron-cloud repulsion term is considered for each dipole–dipole interaction. Then the following equations apply

$$[24]\quad (\Delta V_2)_{X=X_m} = -\frac{3e^2}{X_m} - \frac{3e^2}{(R + X_m)} + \frac{6e^2}{(R^2 + X_m{}^2 + RX_m)^{1/2}} + \frac{3B}{X_m{}^{6.9}}$$

$$[25]\quad \left(\frac{\partial \Delta V_2}{\partial X}\right)_{X=X_m} = 0 = \frac{3e^2}{X_m{}^2} + \frac{3e^2}{(R + X_m)^2} - \frac{3e^2(R + 2X_m)}{(R^2 + X_m{}^2 + RX_m)^{3/2}} - \frac{20.7B}{X_m{}^{7.9}}$$

Solution of eqs. 24 and 25, with $R = 5.74 \times 10^{-8}$ cm, and $\Delta V_2 = -9.76/14.39 \times 10^{12}$ erg/molecule gave $X_m = 11.0$ Å and $B = 1.14 \times 10^{-61}$ e.s.u.^{2} cm$^{5.9}$. On repeating the calculation but with $\Delta V_2 = -9.76 + 0.25$, and $-9.76 - 0.25$ kcal/mol, respectively, $X_m = 11.1$ and 10.9 Å, respectively.

(b) Regular Hexagon Model

On considering only nearest-neighbor electron-repulsion terms, application of eq. 9 to Fig. 5*b* gives

$$[26]\quad (\Delta V_2)_{X=X_m} = -\frac{6e^2}{X_m} - \frac{3e^2}{2X_m} + \frac{6}{\sqrt{3}}\frac{e^2}{X_m} + \frac{6B}{X_m{}^{6.9}} + 3V_p$$

$$[27]\quad \left(\frac{\partial \Delta V_2}{\partial X}\right)_{X=X_m} = 0 = \frac{6e^2}{X_m{}^2} + \frac{3e^2}{2X_m{}^2} - \frac{6}{\sqrt{3}}\frac{e^2}{X_m{}^2} - \frac{41.4B}{X_m{}^{7.9}}$$

where V_p has the same meaning as in the dimer case. Solution of eqs. 26 and 27 with $R = 5.74 \times 10^{-8}$ cm and $\Delta V_2 = -9.76/14.39 \times 10^{12}$ erg/molecule gave $X_m = 7.24$ Å and $B = 1.68 \times 10^{-62}$ e.s.u.^{2} cm$^{5.9}$. On repeating the calculation with $\Delta V_2 = -9.76 + 0.25$ and $-9.76 - 0.25$ kcal/mol, respectively, $X_m = 7.25$ and 7.23 Å, respectively.

Choice of a Model

For two reasons, the rigid-dipole models for the dimer and the trimer were considered to be less satisfactory than the regular models, namely a square for the dimer, and a regular hexagon for the trimer. First, the calculations based on rigid-dipole models gave equilibrium separation distances which intuitively seem too large (X_m = 19 Å for the dimer, 11.0 Å for the trimer); similar calculations based on the regular models gave more reasonable values (X_m = 7.4 Å for the dimer, 7.24 Å for the trimer).

Secondly, it was concluded elsewhere (2) that the value of the average hydration number of Bu_4NPi in the organic solvents was not significantly dependent on the extent to which the monomers were associated into the *i*-mers. It was proposed then (2) that the hydration site was the para-nitro group of the picrate ion. Examination of Figs. 4 and 5 reveals that this hydration site is more accessible in the regular models than it is in the rigid-dipole models, which suggests that the regular models are more consistent with this reported behavior of the average hydration number.

We are grateful to the National Research Council of Canada for financial assistance. We also thank Professor W. H. Stockmayer for very helpful suggestions on some of the theoretical aspects.

Observations on the Visible Emission from Electronically Excited CS_2

S. J. Arnold and G. H. Kimbell

Defence Research Establishment Valcartier, P.O. Box 880, Courcelette, Quebec

Received June 7, 1971

A detailed study has been made of the CS_2 afterglow emission observed when either pure CS_2 or a CS_2–Ar mixture is passed through a microwave discharge or when CS_2 is introduced into a stream of discharged argon or active nitrogen. The emission is continuous and extends from 340 to 640 nm with a maximum at 440 nm. The emitting state is thought to be the V state which is responsible for the CS_2 fluorescence.

Nous avons accompli une étude détaillée de l'émission du CS_2 après rayonnement, qu'on peut observer lorsque le CS_2 pur ou un mélange CS_2–Ar passe à travers une décharge de microonde ou lorsque CS_2 est introduit dans un courant d'argon déchargé ou d'azote actif. L'émission est continue et s'étend de 340 à 640 nm, avec un maximum à 440 nm. On croit que l'état émetteur soit l'état V, qui est responsable de la fluorescence de CS_2.

Canadian Journal of Chemistry, **49**, 4110 (1971)

Introduction

Although several reports on the visible absorption and emission spectra of gaseous carbon disulfide have appeared in the literature (1–8), a complete assignment of the various observed features remains to be achieved. Absorption studies (1–3) indicated the existence of two band systems, a relatively strong system in the region 220–150 nm and a weaker system in the region 430–290 nm. Kleman (1) made a rotational analysis of some of the bands at the long wavelength end of the near u.v. system and obtained a value of 74.9 kcal mol^{-1} for the band origin, ν_{000}. Douglas and Milton (2) then positively identified the upper state as the bent $^3A_2$ state. The remaining near u.v. absorption bands (330–290 nm) are frequently referred to as the V system.

Observations of emission spectra attributed to CS_2 were made by Herman *et al.* (5) in pure CS_2 vapor following a condensed discharge and by Westbury and Winkler (6) upon the addition of CS_2 to active nitrogen. In each case a pale blue continuous emission, which extended from 350 to 640 nm with a maximum at 470 nm, was observed; a definite emitting state was not assigned in either case. Recently, Rosenkranz and Wagner (7) and Arnold and Kimbell (8) reported the observation of a similar emission spectrum from shock-heated CS_2/Ar mixtures. Rosenkranz and Wagner attributed the emission to the $^3A_2$ state whereas Arnold and Kimbell assigned it to the previously unobserved $^3\Sigma_u^+$ state whose existence had been postulated by Mulliken (4).

Heicklen (9) and Mills and Zare (10) have observed the fluorescence of CS_2 excited by light of wavelength near 320 nm. Douglas (11) measured the lifetime of this fluorescence to be 15 μs and inferred that the V state was responsible.

In the present study an investigation was made of the afterglow observed when either pure CS_2 or a CS_2/Ar mixture was passed through a microwave discharge and when CS_2 was introduced into discharged argon or active nitrogen. The results of this work, in conjunction with the earlier work just described, suggest that the V state is responsible for the emission observed in both the afterglow and fluorescence experiments. It seems likely that the thermal emission observed in the shock tube experiments may be exclusively from the $^3A_2$ state.

Experimental

The apparatus used for these experiments is shown in Fig. 1. In the first group of experiments either pure CS_2 or a 10% mixture of CS_2 in an inert gas was passed through a 2450 MHz microwave discharge, whereas in the second group of experiments CS_2 was introduced into nitrogen or argon which had previously passed through the discharge. All experiments were conducted at a total

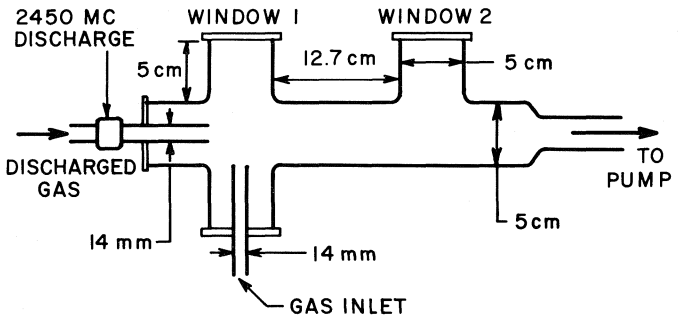

FIG. 1. Schematic of afterglow cell.

pressure of about 3.5 Torr. Emission spectra were obtained either at the inlet jet (window 1) or in the afterglow region (window 2). The detection system consisted of a McPherson Model 235 Monochromator equipped with a 300 L/mm grating having a reciprocal dispersion of 68 A/mm; an EMI 9558 QB photo-multiplier having an "S-20" response was used with an Esterline Angus recorder.

The CS_2 used was Anachemia Reagent Grade which had been dried over "Drierite" and degassed prior to use. The argon and nitrogen were "ultra high purity" grade containing less than 10 p.p.m. of impurities and were supplied by Matheson.

Results and Discussion

The results of the present series of emission measurements are summarized in Table 1. The principal emission feature which could be observed at the second window in all cases (when either pure CS_2 or a CS_2/Ar mixture was passed through a microwave discharge or when CS_2 was introduced in a stream of active nitrogen or discharged argon) was a continuum which extended from 340 to 640 nm with an energy maximum at approximately 440 nm (see Fig. 2). In all cases extensive deposits of carbon and sulfur were observed on the walls of the reaction cell.

Since the afterglow emission is practically identical in all four cases it seems reasonable to suppose that the emitting species (CS_2*) is formed in the same manner in the four systems. A probable mechanism is the three-body recombination reaction

$$[1] \qquad CS + S + M \rightarrow CS_2^* + M \rightarrow CS_2 + h\nu$$

This mechanism is supported by the fact that the afterglow could not be observed at the first window and that extensive dissociation was observed in all cases. The only alternative mechanism for the formation of CS_2* is by direct excitation in the microwave discharge, by energy transfer from metastable argon or a component of active nitrogen. If this is the case, the continuum should be observed at the first window. It is also unlikely that the spectral distribution of the continuum would be virtually identical in all cases; in addition it would be required that in the case of discharged pure CS_2 the emitting species be sufficiently long-lived to emit strongly at a distance of 1 m from the excitation region (system pressure 5 Torr). It would then be impossible to correlate the afterglow with the state responsible for the fluorescence. Consequently, it would appear to be most likely that the emitting species is formed by a recombination mechanism subsequent to dissociation either by a microwave discharge or by highly active components of discharged argon or nitrogen.

The visible emission observed when a CS_2/Ar mixture is shock heated (7, 8) has an energy distribution which is very similar to that of the afterglow continuum. When the emission spectrum shown in ref. 8 is corrected for the relative spectral sensitivity of the photographic plates used, a spectrum extending from 350 nm into the red, with a single maximum at 550 nm, is obtained.

The emission, which occurs at the shock front, is due to thermal excitation of ground state CS_2 and not to recombination. It can be adequately explained by the mechanism

$$[2] \qquad CS_2 + Ar \rightleftarrows CS_2^* + Ar$$

$$[3] \qquad CS_2^* \rightarrow CS_2 + h\nu$$

in which the transition responsible for the emis-

TABLE 1. Results of emission measurements

System	Observations
Pure CS_2 is passed through the discharge	(*a*) A pale blue afterglow which was continuous extended from 340 to 640 nm with a maximum at approximately 440 nm (Fig. 2). The afterglow was visible from the discharge inlet throughout the cell (*b*) Copious deposits of yellow sulfur formed rapidly on the cell walls (*c*) Deposits of carbon formed towards the pump
A 10% mixture of CS_2 in Ar is passed through the discharge	(*a*) An intense blue afterglow which was continuous extended from 340 to 640 nm with a maximum at approximately 440 nm. The afterglow was visible from the discharge inlet throughout the cell (*b*) A weak emission, attributable to $S_2(^3\Sigma-^3\Sigma)$, was superimposed on the continuum (*c*) Sulfur and carbon deposits were again observed on the cell walls
CS_2 is introduced into a stream of discharged argon	(*a*) A brilliant green flame formed on the discharge inlet which changed to a pale blue afterglow midway to the second window. The afterglow was visible to the pump (*b*) Bands, attributable to the $CS(A^1\Pi-X^1\Sigma)$ system, were observed at the first window (*c*) A continuum, extending from 340 to 640 nm with a maximum at approximately 440 nm, was observed at the second window (*d*) Weak emission, attributable to the (0–0) and (0–1) bands of the C_2 "Swan" system, was superimposed on the continuum (*e*) Copious sulfur deposits were observed around the discharge inlet
CS_2 is introduced into a stream of active nitrogen	(*a*) The orange-yellow Lewis–Rayleigh afterglow of active nitrogen changed gradually to a blue-green afterglow which was visible to the pump (*b*) The N_2 first positive $(B^3\Pi-A^3\Sigma)$ and the N_2 second positive $(C^3\Pi-B^3\Pi)$ systems were the only emission observed at the first window (*c*) A continuum, extending from 340 nm to 640 nm with a maximum at approximately 440 nm, was observed at the second window

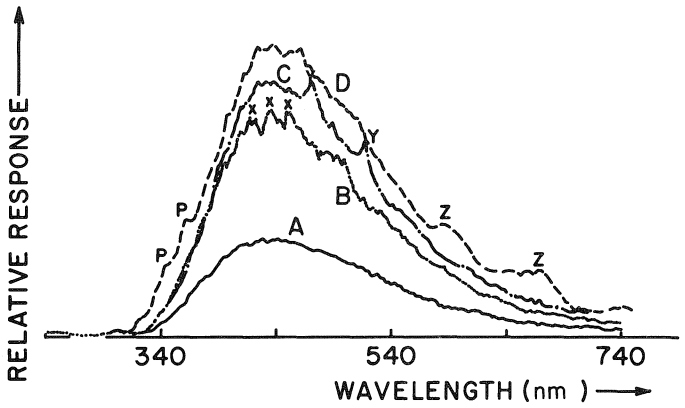

FIG. 2. Relative emission spectrum from electronically excited CS_2. When corrected for photomultiplier response and photon energy the curves broaden with maxima at approximately 440 nm. (*a*) discharged pure CS_2. (*b*) discharged CS_2(10%)–Ar(90%) mixture. *X* indicates the position of $S_2(^3\Sigma-^3\Sigma)$ bands. (*c*) CS_2 introduced into a stream of discharged Ar. *Y* indicates the position of the C_2 "Swan" (0–0) and (0–1) bands. (*d*) CS_2 introduced into a stream of active nitrogen. *Z* indicates the position of N_2 first positive bands and *P*, N_2 second positive bands.

sion is undoubtedly from an excited electronic state to the ground state of the CS_2 molecule.

It is of some interest to speculate on the states responsible for the radiation observed in the fluorescence, afterglow, and shock tube experiments. There appear to be at least two electronic states which could contribute, the $^3A_2$ state and the V state which Douglas (11) has inferred is responsible for the fluorescence. Since the afterglow emission has a spectral distribution essentially identical to the fluorescence, it may, therefore, originate in the same electronic state. Since it is probable that the afterglow emission is formed by a recombination process and since any recombination process is unlikely to involve electronically excited CS or S, it seems reasonable that the state formed on recombination is one which can correlate with ground state $CS(^1\Sigma)$ and $S(^3P)$ at 102 kcal mol^{-1} above ground (12). The $^3A_2$ state, which has a potential minimum at 74.9 kcal mol^{-1} above the ground state, can correlate with $CS(^1\Sigma)$ and $S(^3P)$ (see ref. 13 for a potential energy diagram) whereas the V state which is considered to have singlet character (11) should not. Hence, in order to reconcile these two theses it is necessary to propose (*a*) that the similarity of the fluorescence and the afterglow spectra is coincidental or (*b*) that an interelectronic level mixing process as mentioned by Douglas (11) is operative.

Douglas has suggested that the anomalously long lifetime of the fluorescence is due to interelectronic level mixing. This mixing occurs when a molecule goes back and forth between two excited states spending more of its time in the state with the high density of levels, a state from which it cannot readily radiate because this higher density state is not strongly coupled to the ground state. In the fluorescence case the molecule is thought to be initially excited to the V state which undergoes mixing, possibly with the lower $^3A_2$, accounting for its long fluorescent lifetime. In the afterglow case the molecule is formed by recombination into the $^3A_2$ state and then undergoes mixing with the V state from whence its radiates. That more than one state can be involved in the fluorescence measurements is consistent with recent measurements of Lambert and Kimbell (14) who found that the fluorescence lifetime varied slightly with the wavelength of both the exciting and fluorescing radiation.

Arnold and Kimbell (8) attributed the shock tube emission to the previously unobserved $^3\Sigma_u^+$ state (ν_{000} of 57 kcal mol^{-1}) but Rosenkranz and Wagner (15) have recently pointed out that the temperature dependence of the partition functions must be considered in determining the apparent activation energy. When this is done, the results of Arnold and Kimbell agree with those of Rosenkranz and Wagner who suggested that the emitting state had an activation energy of 74 kcal mol^{-1} and was the $^3A_2$ state previously observed by Kleman in absorption. If this is indeed the case, the question can be raised as to why the same process does not take place as in the case of the afterglow with the resultant emission from the V state. If only the lower vibrational levels of the $^3A_2$ state are populated by shock-heating, mixing with the V state which should lie 86 kcal mol^{-1} above the ground state would be less probable.

Conclusions

When either pure CS_2 or a CS_2–Ar mixture is passed through a microwave discharge, or when CS_2 is introduced into a stream of discharged argon or into active nitrogen, a pale blue afterglow is observed. This afterglow emission, which appears continuous and extends from 340 to 640 nm with a maximum at 440 nm, has a spectral distribution very similar to that observed from the fluorescence of gaseous CS_2. The excited state responsible for both the afterglow emission and the fluorescence is suggested to be the V state. The state from which the shock-heated emission occurs is the $^3A_2$ state. The latter conclusions are speculative only and undoubtedly more experimentation is necessary to unequivocally identify the emitting states.

We wish to acknowledge the assistance of Professor E. F. Greene in the reassessment of the shock tube data.

Comments on the Infrared Spectra of SO_2 Clathrate-hydrate Formed by Vapor Condensation

A. H. HARDIN[1] AND K. B. HARVEY[2]

Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received August 20, 1971

Gaseous mixtures having clathrate-hydrate stoichiometries were condensed at 83 °K into an amorphous phase. Infrared spectra were recorded at a series of temperatures up to 180 °K in order to determine the transformation temperature and the nature of the annealed phase. Bands associated with the H_2O molecules began to shift position at 125 °K while those attributed to guest molecules decreased to null intensity. There was no evidence of a unique clathrate-hydrate H_2O spectrum nor of free or hindered rotation of the guest molecules.

Des mélanges gazeux, ayant une stoichiométrie de clathrate hydraté, ont été condensés à 83 °K en une phase amorphe. Les spectres infrarouges ont été enregistrés à différentes températures jusqu'à 180 °K dans le but de déterminer la température de transformation ainsi que la nature de la phase de recuit. Les bandes associées avec des molécules d'H_2O commencent à se déplacer à 125 °K alors que celles attribuées à des molécules-hôtes diminuent jusqu'à une intensité nulle. Il n'y a aucune preuve quant à la formation d'un spectre unique de clathrate hydraté H_2O ni d'une rotation libre ou empêchée des molécules-hôtes.

Canadian Journal of Chemistry, **49**, 4114 (1971)

Clathrate compounds have provided a means of studying weak intermolecular interactions whereby quantized motions of the trapped guest molecules have been suggested on the basis of infrared (1–5), microwave (6), and nuclear magnetic resonance (7–9) results. Preliminary infrared investigations were made in this laboratory on the type I clathrate-hydrates of Kr, H_2S, and SO_2 (3). Recent work (10) repeated and extended those experiments, but during the process the original results could not be reproduced under suitable experimental conditions. It is concluded that the technique of sample formation did not yield clathrate-hydrate, but an amorphous mixture of ice and guest.

The requirement of maintaining an equilibrium dissociation pressure while forming and observing films sufficiently thin to the infrared is the only difficulty met for clathrate-hydrates. Barrer and Ruzicka (11) formed non-spectroscopic samples by condensing H_2O on a glass surface at 77 °K and by then applying a relatively high pressure of guest vapor. However, guests of interest in the infrared condense at such temperatures and the high pressures needed for non-condensing guest, *i.e.* methane, would lead to a vapor phase spectrum even over a short path length.

Harvey, McCourt, and Shurvell (3) prepared samples by a modification of this method, *i.e.* condensation and annealing of stoichiometric gaseous mixtures. The method was prone to sample fractionation during condensation and/or annealing. Subsequent work attempted to overcome such fractionation by sample formation from the vapor phase in a closed, low volume sample chamber, or as low temperature mulls of crystalline clathrate-hydrates.

In view of the recent infrared results the con-

clusions drawn from the previous work must be revised. The previous samples were not annealed to a temperature sufficiently high to permit the desired phase transformation, even ignoring the problem of sample decomposition. For example, condensates were annealed only to 110 °K for 2–3 min and subsequent spectra had bands at 780, 1640, and 3700 cm^{-1} much as found for amorphous ice (10). More detailed infrared experiments have shown that H_2O molecules only attain sufficient energy to reorient at 125 °K (10). Typical indications of reorientation or annealing were the disappearance of the weak 3700 cm^{-1} peak and the shifting of "lattice" modes to higher wavenumber while the so-called internal modes shifted to lower wavenumber by as much as 30–40 cm^{-1}, *i.e.* as in the amorphous to crystalline ice transformation. The ice phase transformation is also accompanied by a distinct sharpening of the bands, but there is no evidence for this in the clathrate transformation reported by Harvey *et al.* The feature at 2410 cm^{-1} found by Harvey, McCourt, and Shurvell and attributed to the H_2O lattice, did not appear in the subsequent work. They found that this feature was of constant wavenumber for a variety of clathrate-hydrates (Kr, H_2S, SO_2). Upon re-examination of the original background spectra of McCourt (12) and Shurvell (13) a small amount (*ca.* 2%) of uncompensation was found between 2410 and 2240 cm^{-1} due to atmospheric CO_2. Although this was just detectable in the background of the empty cell, after sample deposition and reference beam attenuation the energy difference in this region was proportionally much larger.

These comments have some effect on the conclusions Harvey *et al.* made with respect to the SO_2 guest peaks. The strong $\nu_3(SO_2)$ band observed at 1340 cm^{-1} (78 °K) lies between the $SO_{2\ (g)}$ value (1362 cm^{-1}) and the $SO_{2\ (s)}$ value at 78 °K (1322 cm^{-1}), indicating the presence of relatively large, amorphous SO_2 agglomerates. Further, the shoulders reported on $\nu_3(SO_2)$ for clathrate at 78 °K could have arisen from SO_2 molecules possessing positional or chemical differences in the H_2O support (*e.g.* SO_2 molecular aggregates, SO_2 molecules individually in holes in the H_2O network, or as SO_2 layers between H_2O surfaces). More simply the shoulders could have arisen from changes in the relative intensities of the three features seen in the pure SO_2 solid.

In conclusion the results reported by Harvey, McCourt, and Shurvell appear to be for an amorphous SO_2–H_2O mixture. Thus the $\nu_3(SO_2)$ shoulders cannot be associated with free or hindered SO_2 rotation in a clathrate structure. Finally, the feature at 2410 cm^{-1} which was thought to indicate H_2O in a clathrate-hydrate lattice is an instrumental artifact. Since the work of Harvey *et al.* many data have been published on the various modifications of ice (14) and these indicate that for a clathrate-hydrate with disordered hydrogen bonding the spectra due to the lattice are probably of little difference from those of ice Ih.

Preparation and Structural Elucidation of *cis*- and *trans*-1-Phenyl-2-methylcyclohexanol

K. G. RUTHERFORD, S. WASSENAAR, J. F. BRIEN, AND D. P. C. FUNG
Department of Chemistry, University of Windsor, Windsor, Ontario

Received July 27, 1971

The preparation of *cis*- and *trans*-1-phenyl-2-methylcyclohexanol by hydrolysis of an isomeric mixture of the corresponding hydrogen phthalate esters is described. The elucidation of the structures of the alcohols is also described.

La préparation du *cis*- et *trans*-phényl-1 méthyl-2 cyclohexanol, par hydrolyse d'un mélange isomérique des esters des phthalates d'hydrogène correspondants, est décrite. L'élucidation des structures des alcools est également décrite.

Canadian Journal of Chemistry, **49**, 4116 (1971)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In our studies on the low temperature pyrolysis of sterically hindered hydrogen phthalate esters, it was of interest to investigate the *cis*- and *trans*-1-phenyl-2-methylcyclohexanol system. In the case of our previous investigations (1, 2) on the pyrolysis of the hydrogen phthalate esters of *cis*- and *trans*-1,2-dimethylcyclohexanol, the synthesis of the isomeric alcohols was achieved by the reaction of methyl magnesium iodide with 2-methylcyclohexanone. To our surprise, Cram's rule of "steric control of asymmetric induction" (3) was followed to a greater degree than expected. Thus, from this reaction a crude isomeric mixture of the *trans*- and *cis*-alcohols was obtained in yields of *ca.* 83 and 17% respectively. Purification of the alcohols by spinning band distillation procedure proved acceptable although several large runs were necessary to prepare adequate supplies of the *cis*-alcohol.

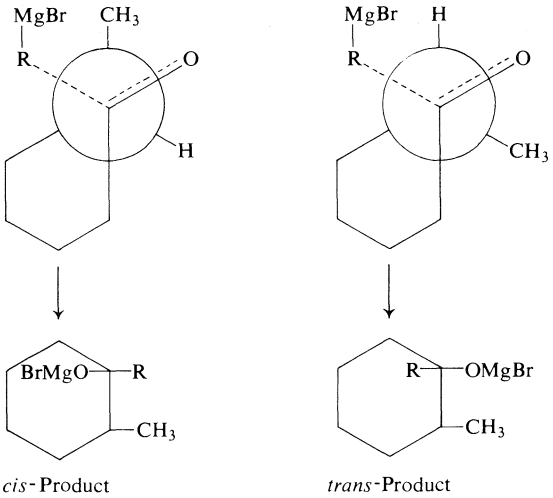
In the case of the Grignard reaction of phenyl magnesium bromide with 2-methylcyclohexanone, an isomeric mixture of alcohols (92 and 8%) was obtained. Intuitively, one would predict the isomer obtained in 8% yield to be the *cis*-alcohol. It was found that if the hydrogen phthalate derivatives of these alcohols were first prepared according to a procedure previously described in this laboratory (4), the mixture of these derivatives could be hydrolyzed easily with sodium hydroxide. Although this procedure results in a yield of 25% olefins, the remaining portion of the reaction mixture contains *ca.* 43% of the *trans*-1-phenyl-2-methylcyclohexanol and 57% of the *cis*-isomer. Undoubtedly, the $B_{AL}1$ mechanism is conveniently operative during basic hydrolysis, thus resulting in the formation of goodly amounts of the *cis*-alcohol.

The structure of the expected *cis*-1-phenyl-2-methylcyclohexanol was elucidated by hydroboration of pure 1-phenyl-2-methylcyclohexene followed by oxidative conversion of the borane intermediate. This procedure was used previously by Brown and Zweifel (5) to prove the structure of *cis*-1,2-dimethylcyclohexanol. It follows then that the alcohol obtained in larger amounts in the Grignard reaction of phenyl magnesium bromide with 2-methylcyclohexanone is the expected *trans*-1-phenyl-2-methylcyclohexanol. Thus Cram's rule is followed to a high degree in the 2-substituted cyclohexanone system. An inspection of Fig. 1, in which are shown Newman projections of proposed transition states leading to products from the reaction of Grignard reagents with 2-methylcyclohexanone, supports the experimental results obtained. Thus, much less steric effect is observed in the transition state leading to *trans*-product than is for that which leads to the *cis*-isomer.

The hydrolytic epimerization technique described in this paper should be applicable to the synthesis of similar isomeric cyclic 1-aryl-2-alkylcyclanols.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Beckman IR-10 spectrophotometer and all solutions were w/w% in the specified solvent. Only the significant absorptions are reported (cm^{-1}). Microanalyses were determined by Midwest Microlab Inc., Indianapolis, Indiana. The n.m.r. spectra were measured



cis-Product *trans*-Product

FIG. 1. Proposed transition states for the reaction of Grignard reagents with 2-methylcyclohexanone.

with a JEOL C-60HL instrument and all solutions were w/v % in the stipulated solvent. The chemical shifts are reported in τ downfield from internal tetramethylsilane (multiplicity: s, singlet; d, doublet; t, triplet; m, multiplet; bm, broad multiplet). All g.l.c. was conducted on a Hewlett Packard (F. and M.) 720 instrument and the peak areas were determined with a disc integrator.

1-Phenyl-2-methylcyclohexene

An isomeric mixture of 1-phenyl-2-methylcyclohexanol (5.0 g, 26.3 mmol) was dehydrated with 15 ml of a 16.5% sulfuric acid – acetic acid solution (v/v) according to the method of Garbisch (6, 7). This yielded a mixture of 1-phenyl-2-methylcyclohexene and 1-phenyl-6-methylcyclohexene (3.2 g, 72.1%) and these olefins were shown to be present in the relative amounts of 87.1 and 12.9%, respectively, by means of g.l.c. analysis (LAC-728, 130°). These olefins were separated by preparative g.l.c. (LAC-728, 140°) and their physical and spectral properties compared favorably with those reported by Garbisch (7).

The 1-phenyl-2-methylcyclohexene was used to prepare *cis*-1-phenyl-2-methylcyclohexanol by the method of Brown and Zweifel (5) involving hydroboration.

cis-1-Phenyl-2-methylcyclohexanol

1-Phenyl-2-methylcyclohexene (0.800 g, 4.64 mmol) was added to a solution of sodium borohydride (0.145 g, 3.83 mmol) and 10 ml of freshly distilled tetrahydrofuran. The reaction was carried out under a nitrogen atmosphere maintaining the temperature at 20–30° with an ice bath during the addition of freshly distilled boron trifluoride etherate (1.09 g, 7.65 mmol). The solution was stirred at 25° for 1 h followed by the cautious addition of 2 ml of water. When reaction ceased, 5.6 ml of 3 *N* sodium hydroxide was added quickly followed by the rapid addition of 5.6 ml of 30% hydrogen peroxide. The solution was stirred for 1 h at 25° after which it was salted out with sodium chloride and extracted with 25 ml of ether. The ethereal layer was washed with five 10 ml portions of ice cold water, dried, and concentrated. The crude product was analyzed by g.l.c. (Carbowax 20M, 180°) and the major component (66.9%) was purified by preparative g.l.c. (Carbowax 20M, 200°). Crystallization from hexane yielded pure *cis*-1-phenyl-2-methylcyclohexanol (0.296 g, 33.4%), m.p. 61–63°. The i.r. spectrum (*ca.* 5% in CCl_4) showed characteristic bands at 3605 (free O—H stretch) and 3480 cm^{-1} (bonded O—H stretch). The n.m.r. spectrum (*ca.* 10% in $(CD_3)_2SO$) showed the following peaks (τ): 2.57 (m, 5, C_6H_5), 5.27 (s, 1, OH), 7.50–8.90 (bm, 9, $(CH_2)_4$ and CH), 9.40 (d, 3, J = 7.0 Hz, CH_3). The singlet at 5.27 disappeared on the addition of deuterium oxide which is indicative of the hydroxyl proton signal.

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.53. Found: C, 82.04; H, 9.56.

1-Phenyl-2-methylcyclohexanol

A solution of phenyl magnesium bromide was prepared from magnesium turnings (7.3 g, 0.30 mol), bromobenzene (42.0 g, 0.27 mol), and 200 ml of anhydrous ether. Reaction of the Grignard reagent with 2-methylcyclohexanone (28.0 g, 0.25 mol) dissolved in 100 ml of anhydrous ether yielded after distillation an isomeric mixture of 1-phenyl-2-methylcyclohexanol (31.1 g, 65.5%) as a colorless oil: b.p. 93–96° (0.38 mm); η_D^{25} 1.5363. Analysis by g.l.c. (LAC-728, 180°) showed two well-defined peaks representing the isomeric alcohols in the amounts of 92.0 and 8.0%, respectively. The isomeric alcohols were converted to the corresponding hydrogen phthalate esters (4). Saponification of the isomeric hydrogen phthalate mixture was carried out in the following manner. To an isomeric mixture of the 1-phenyl-2-methylcyclohexyl hydrogen phthalates (30.0 g, 88.8 mmol), 0.1 *N* sodium hydroxide (932.0 ml, 93.2 mmol) was added. The solution was heated at reflux temperature for 4 h. After cooling to 25°, 100 ml of chloroform was added through the condenser. The organic layer was separated, dried, and concentrated. The yellow oil (15.0 g) was distilled yielding three fractions (13.2 g). The first fraction constituted 25% of the distilled product, b.p. 25–82° (0.5 mm). The i.r. spectrum indicated olefins. The second fraction comprized 43% of the distilled reaction product, b.p. 82–93° (0.45 mm). The i.r. showed the presence of the alcohol group. The third fraction constituted 32% of the product and it solidified partially, b.p. 73–85° (0.05 mm). The i.r. showed the presence of the alcohol group. Fractions two and three were combined and g.l.c. analysis (LAC-728, 180°) indicated that the two alcohols were present in the amounts of 43.4 and 56.6%, respectively. Preparative g.l.c. (Carbowax 20M, 200°) was used to separate the alcohols. The isomer with the shorter retention time (43.4%) was a liquid, η_D^{25} 1.5355. The i.r. spectrum (30% in CS_2) showed characteristic absorption bands at 3610 (free O—H stretch) and 3500 cm^{-1} (bonded O—H stretch). The n.m.r. spectrum ($(CD_3)_2SO$, 18%) showed the following peaks (τ): 2.67 (m, 5, C_6H_5), 5.50 (s, 1, OH), 7.83–8.83 (bm, 9, $(CH_2)_4$ and CH), 9.50 (d, 3, J = 5.5 Hz, CH_3). The peak at 5.50 disappeared on the addition of deuterium oxide. This isomer was assigned the *trans*-structure.

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.53. Found: C, 82.15; H, 9.38.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

After g.l.c. separation, the isomeric alcohol with the longer retention time (56.6%) was recrystallized from hexane, m.p. 62–64°. The n.m.r. and i.r. spectral data were identical to those of *cis*-1-phenyl-2-methylcyclohexanol prepared by the hydroboration procedure previously described. The mixed m.p. was not depressed. This isomer was assigned the *cis*-structure.

The experimental procedure described above proved amenable to much larger scale runs for the preparation of *cis*- and *trans*-alcohols without any appreciable changes. In most runs, the hydrolytic epimerization of the hydrogen phthalate mixture yielded approximately equimolar amounts of *cis*- and *trans*-alcohols.

A single crystal X-ray study of $(Ph_2MeP)_3CuNO_3$ revealed the presence of three different Cu—P distances and a unidentate nitrate group. Steric and electronic factors responsible for the unusual molecular dimensions of the nitrate group and the variation in Cu—P bond lengths and O—Cu—P bond angles are discussed.

Une étude aux rayons-X d'un cristal unique de $(Ph_2MeP)_3CuNO_3$ révèle la présence de trois différentes distances Cu—P et d'un groupe nitrate unidentate. Les facteurs stériques et électroniques responsables des dimensions moléculaires inhabituelles du groupe nitrate et de la variation de la longueur de liaison Cu—P ainsi que des angles des liaisons O—Cu—P sont discutés.

Canadian Journal of Chemistry, **49**, 4119 (1971)

We wish to report the X-ray crystal and molecular structure of nitrato tris(diphenylmethylphosphine)copper(I). This complex has several unprecedented structural features which are of importance to an understanding of the interplay of steric and electronic effects in d^{10} complexes, a subject which has recently attracted considerable attention (1, 2). In addition, the completion of this structure has allowed a direct comparison of accurate molecular parameters for the monodentate nitrate group (in $(Ph_2MeP)_3CuNO_3$) and the bidentate nitrate group (in $(Ph_3P)_2CuNO_3$ (3)) when the metal ion has the *same* oxidation state and coordination number. Only one other instance of such a direct comparison has been reported (4). In that case the metal had a high oxidation state and the results were entirely predictable. Our data for $(Ph_2MeP)_3CuNO_3$ are unexpected in view of current ideas (5) on metal–nitrato bonding.

Colorless crystals of L_3CuNO_3 (L = Ph_2MeP, $PhMe_2P$, $PhEt_2P$, Ph_2EtP) are obtained from the reduction of $Cu(NO_3)_2.3H_2O$ by phosphines (6). The infrared spectra of these complexes indicated that the nitrate coordination differed significantly from that found in $(Ph_3P)_2CuNO_3$ (6). Since no copper(I) complexes with a coordination number greater than four are known, the presence of unidentate nitrate in these compounds seemed likely. Therefore, a single crystal X-ray structural determination of $(Ph_2MeP)_3CuNO_3$ was undertaken.

Crystal Data
$(C_{39}H_{39}P_3CuNO_3)$

Monoclinic crystals, space group $P2_{1/n}$, a = 12.523(3), b = 20.110(6), c = 14.455(5) Å; β = 95.22(2)°; U = 3625.1 Å^3, Dm = 1.322 g/cm^3, Dc = 1.330 g/cm^3, Z = 4.

A total of 5382 independent reflections was measured ($2\theta < 130°$) using the stationary crystal – stationary counter method and $CuK\alpha_1$ (λ = 1.54051 Å) radiation. The 3391 reflections which were considered to be observed were used in the analysis. The structure was solved by the heavy atom method, with the light atoms being located in successive Fourier syntheses. The refinement was by full-matrix least-squares methods using individual isotropic thermal parameters followed by block-diagonal least-squares cycles, with anisotropic thermal parameters to yield a final R, the usual residual, of 0.081.

The stereochemistry around the copper atom together with the atomic numbering are shown

[1]To whom all correspondence to be addressed.

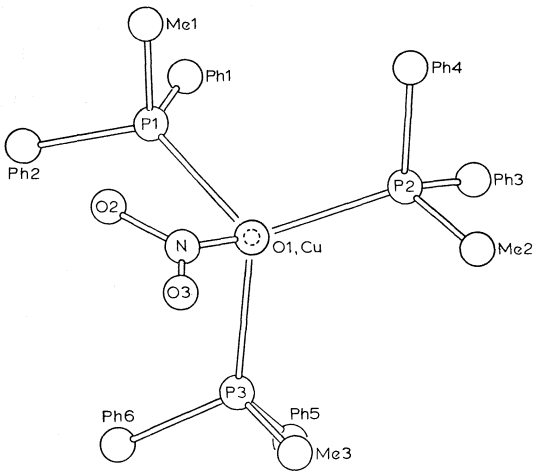

FIG. 1. A view down the O1—Cu bond in nitrato tris(diphenylmethylphosphine)copper(I) illustrating the conformation about the Cu atom and the atomic numbering. Pertinent distances are Cu—P1 of 2.259(2), Cu—P2 of 2.315(2), Cu—P3 of 2.270(2), Cu—O1 of 2.206(6), O1—N of 1.166(8), N—O2 of 1.247(8), and N—O3 of 1.209(8) Å.

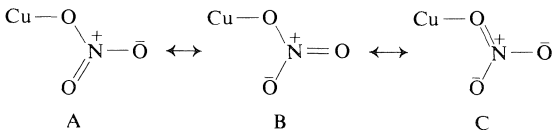
in Fig. 1 which is a view down the Cu—O1 bond. The nitrate is bonded in a unidentate fashion to the Cu atom at a distance of 2.206(6) Å, compared to the non-bonded distances Cu—O(3) of 4.060(5) and Cu—O(2) of 3.249(2) Å. Surprisingly the Cu—O1 distance is not significantly different from the Cu—O distance of 2.22(1) Å found in $(Ph_3P)_2CuNO_3$(3) where the nitrate is bidentate; other studies (4) have found distinctly shorter M—O bonds in unidentate nitrate complexes. Similarly the N—O1 bond length of 1.166(8) Å is *shorter* than the N—O (coordinated) distance in $(Ph_3P)_2CuNO_3$(3) contrary to popular prediction[1] and considerably shorter than the N—O (coordinated) distances in any other complex containing unidentate nitrate.[2]

Furthermore, the N—O distances increase in the order N—O1 < N—O3 < N—O2, the opposite of that found for other unidentate nitrate species and in disagreement with π bonding arguments.[1] We believe that these results are explicable in terms of a larger than normal contribution from a resonance form of type C below to the metal–nitrato bond in order to minimize electronic charge build up on the copper atom. We are currently investigating other low valent metal nitrato complexes containing strong σ donor ligands to see whether this idea is of more general applicability.



A B C

Another significant feature of the structure is the steric effect of the unsymmetrically bonded nitrate group on the P—Cu—P and P—Cu—O1 angles and Cu—P bond lengths. The P1—Cu—P2 angle of 127.8(2)° results from the orientation of the nitrate ion relative to the Cu—P bonds. In $(Ph_2MeP)_3CuCl$ (2) all the P—Cu—P angles are close to 115° in spite of severe steric crowding. Furthermore, the inequality of the P—Cu distances, Cu—P1 is 2.259(2), Cu—P2 is 2.315(2), and Cu—P3 is 2.270(2) Å, appears to be correlated with the corresponding P—Cu—O1 angle. The longest distance Cu—P2 has the smallest P—Cu—O1 angle (87.9(2)°) compared to P3—Cu—O1 (96.3(2)°) and P1—Cu—O1 (107.4(2)°). The relationship between the Cu—P distance and the P—Cu—O angle is a reflection of the s character in the Cu—P bonds which is, in turn, dependent on the angle (or vice versa) the increase in s character for a Cu—P bond corresponding to a shorter bond and larger angle. Making the realistic assumption (11) that the s character in the copper bonding orbitals is concentrated in bonds to the more electropositive (phosphorus) ligands, a weak Cu—O interaction would be predicted, and is indeed found. We have therefore an interesting example of the importance of cooperative steric and electronic effects in a d^{10} complex. This work also lends further credence to the idea that metal–phosphorus bond lengths in d^{10} complexes are sensitive to s electron character in a similar fashion to M—P bonds in complexes of the heavier transition metals (12).

---

[1]Attachment of one oxygen atom to a metal should partially restrict π bonding to the NO_2 fragment of the M—O1—N$\langle^{O2}_{O3}$ unit. Hence the N—O2 and N—O3 bond orders should increase at the expense of N—O1.

[2]Accurate X-ray data have been reported for only 5 complexes containing unidentate nitrate groups. These are: $Ni(NO_3)_2(H_2O)_4$ (7), $Cu(NO_3)_2$ (pyridine-*N*-oxide) (8), $Cu(NO_3)_2$(1,4-diazacycloheptane)$_2\cdot\frac{1}{2}H_2O$ (9), K[Au$(NO_3)_4$] (10), $VO(NO_3)_3CH_3CN$ (4). Unidentate nitrate groups have been identified in other compounds by X-ray methods (see ref. 5) but the data are either incomplete or of low precision.
