Reactions of Alkyl Halides in Fused Salt Media[1]

R. A. BAILEY AND S. F. PREST

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York 12181

Received July 13, 1970

Passage of C_1 to C_5 haloalkanes through $SnCl_2$–KCl melts results in halide exchange reactions, alkene formation, and rearrangement (including cyclization) reactions of the organic molecules. Relative reactivities, product distributions and melt composition effects are consistent with a carbonium ion mechanism in which the melt functions as a halide ion acceptor. Some control of product distribution by choice of Lewis acid character of the melt seems possible.

Canadian Journal of Chemistry, **49**, 1 (1971)

While the physical properties of fused salts have been the subject of extensive investigations, reaction chemistry in such media has been studied much less systematically. However, a variety of reactions have been reported, including a number involving substitution, elimination, and other reactions of organic molecules; many of the known examples have been reviewed by Sundermeyer (1). These include halide and pseudohalide exchange, halogenation, and elimination reactions. For the most part they involve small aliphatic or aromatic systems. While some work has involved simple ionic salts such as the alkali halides, most reactions of this type have used low melting systems composed of salts employed as catalysts in more classical reactions, *e.g.* $AlCl_3$–alkali chloride melts and similar systems below 200 °C. These have established the catalytic action of such melts, although the behavior of the molten salt in other systems is not so evident. Generally, little has been done to establish the role of the molten salt in the overall mechanism, or the effect of varying reaction parameters (temperature, melt composition, etc.).

This report considers the reactions of several alkyl halides (C_1 to C_5) in molten KCl–$SnCl_2$ mixtures. Substitution, elimination, and rearrangement reactions were observed, and some beginnings can be made to understand the basic mechanism of the reactions.

Experimental

The reaction system consisted of a vertical cylindrical tube 30 mm in diameter with a fritted Pyrex disc (normally fine porosity) some distance from the lower end. This was enclosed in a cylindrical furnace and the temperature maintained at the desired value by means of an electronic controller. Fisher $SnCl_2.2H_2O$ was dehydrated with acetic anhydride (2), mixed with dry Baker Analyzed KCl, and placed above the frit in the reaction tube. Final purification was effected by passing HCl gas through the salt as the temperature was raised to the desired value. This was followed by a lengthy flush with dry N_2. The organic reactant was added to a flask attached to the lower end of the reaction system, and distilled through the melt aided by a slightly reduced pressure at the exit side. When a constant flow rate had been attained, samples were collected at the exit in liquid nitrogen traps and analyzed by gas chromatography. Care was taken to preheat the reactant vapors to the melt temperature, and to heat the exist system before the traps to prevent product condensation. Proton magnetic resonance and infrared spectroscopy were used when necessary to aid in product identification.

In comparing results, a number of factors must be considered. The melt height was fixed by weight of salt and tube diameter, and was 4.4 cm for the results reported here. The average size of the bubbles passing through the melt was reasonably reproducible for a frit of given porosity, but varied with flow rate. Photographs permitted the average bubble diameter to be estimated as a function of flow rate, and from this and the flow rate the number of collisions of a gas molecule with the melt could be estimated. This was greater at low flow rates, but was of the order of 10^4. It varied somewhat with the reactants, as did the height of froth above the melt during a reaction

in which a significant amount of the overall process could occur. Therefore, the significance of the following data lies in the relative values and trends rather than in the absolute yield values. While a few reactions approached 100% under these conditions, in general we attempted to operate so as to have only partial reaction so that effects could be detected. Results by no means imply the maximum yield of any product. While a few compounds showed gross decomposition in the melt as evidenced by charring, most recoveries were close to 100%.

The data given in the accompanying Figures and Tables are averaged; variation of the moderate or high yields of ±5% from the results given are typical for runs made under apparently identical conditions. This reflects primarily variation in bubble size. Certain systems showing apparent surface activity of the reactant as indicated by considerable frothing are more erratic.

Results and Discussion

As discussed above, contact times and hence the extent of reaction depend upon flow rate, such that reactivities usually increase with decreasing flow rate. There are occasional exceptions to this, when the yield of one product decreases as a consequence of competition from another; overall reactivities invariably increase as expected. An indication of the magnitude of the flow rate effect is included in the following tables of data.

TABLE 2. Product yields of bromomethanes in 62 mole% $SnCl_2$–KCl, at 280 °C; flow rate, 2 × 10^{-2} mM s^{-1}

Reactant	Products			
$CHBr_3$	$CHBr_2Cl$ 5%	$CHBrCl_2$ 17%	$CHCl_3$ 50%	Overall 72%
CH_2Br_2	CH_2BrCl 10%	CH_2Cl_2 70%	—	80%
CH_2BrCl	CH_2Cl_2 72%			

Substitution and Reactivity Patterns

The relative reactivities of the various compounds studied can be observed from Tables 1–3. Studies on benzyl and allyl bromides were not fully successful due to considerable decomposition and quantitative data are not given, but results indicated the reactivity in the 62 mole% $SnCl_2$–KCl eutectic to be benzyl > allyl > alkyl > aryl (bromobenzene gave essentially no reaction). Within the bromobutanes, the reaction order is tertiary > secondary > iso > primary. These reaction patterns are generally observed with carbonium ion or S_N1 mechanisms (3, 4). The formation of 1-chloroalkanes from the bromo compounds is in the order ethyl > propyl >

butyl > pentyl. This is similar to the order of reactivity in the substitution of thiocyanate and cyanate for chloride in methyl, ethyl, and 1-propyl chloride using melts reported by Packham and Rackley (5), although this may be a very different situation as is indicated by the level of reactivity of benzyl bromide. At a flow rate of 2×10^{-2} mM/s, the ratios of chloride compound formation are 1.9 : 1.1 : 1.0 : 0.5 for bromoethane, 1-bromopropane, 1-bromobutane, and 1-bromopentane, respectively. As a comparison to reactions in more classical media, solvolysis rates in dioxane at 40 °C for the same compounds (6) are in the rather similar ratios 2.2 : 1.2 : 1.0 : 0.9.

The overall reactions of the halopropanes and -butanes follow the order I > Br > Cl. In both the propanes and butanes, product ratios for the substitution, elimination, and rearrangement products were similar for the bromo- and iodo compounds of each series, implying the possibility of a common intermediate. Considerably less rearranged product is formed from the 1-chloro compounds here than in the 1-bromo or 1-iodo systems. This may be explained, since both 2-chlorobutane and 2-chloropropane are more reactive than the 1-chloro compounds, resulting in their being reacted as formed from the latter. As they are less reactive than the parent bromides and iodides, however, they form in proportionately greater yields in these cases.

The completely chlorinated methanes are seen to be the predominant products from the reactions of di- and tri-bromomethane at all flow rates studied (Table 2). The order of reactivity of the individual compounds is $CHBrCl_2$ > $CHBr_2Cl$ > $CHBr_3$. In addition, bromochloromethane is somewhat more reactive than dibromomethane, although an apparent surface active behavior of the latter in the melt makes comparison difficult. Hine and co-workers found that the intermediates of a number of S_N1 solvolysis reactions of halomethanes were stabilized more by chloride than bromide substituents, and thus the reactions were enhanced as observed here (3, 7, 8). All of the above reaction patterns are consistent with a carbonium ion intermediate in the melt or at the melt–vapor interface.

Rearrangement Products

Most primary halides considered here gave some rearranged products (Tables 1 and 3); indeed, 1-bromo-2-methylpropane gave 5–10 times as much rearrangement product, 2-chloro-2-methylpropane, as the expected 1-chloro compound. Rearrangement of secondary halides to primary was slight. Such observations may be explained by the known stabilities of carbonium ions, which are tertiary > secondary > primary. This is indicated both from kinetic data and mass spectrometric formation energies (9). Hence, there would be a net loss in energy for a rearrangement such as

$$CH_3CH_2CH_2^+ \rightarrow (CH_3)_2CH^+$$

This would be even greater in the 1-bromo-2-methylpropane example. Thus, the observed rearrangements would not be surprising if the cation has a sufficient life-time in the melt.

Melt Effects

Variation of melt composition has an appreciable effect on reaction as shown in Table 4, particularly when melts rich in $SnCl_2$ are used. This is understandable on the basis of Lewis acid behavior of the $SnCl_2$, and may be comparable to the behavior of silver and mercuric halides which are used to favor carbonium ion formation in solvolysis reactions of alkyl halides (3, 8). Pure stannous chloride appears readily to accept a halide ion; the pure melt has been shown to be slightly polymeric through chloride bridges (10) and on addition of KCl this structure may be broken down through formation of $SnCl_3^-$ or $SnCl_4^{2-}$ ions in the melt. Conceivably, the melt functions by abstracting a chloride (or bromide)

ion from the organic molecule to produce the complex anion and a carbonium cation. The tendency for this to happen is reduced as the $SnCl_2$ is satisfied by free Cl^- from the KCl, although it is not markedly effected until appreciable KCl has been added. It may be noted that products not detected in 62 mole% $SnCl_2$ may appear with higher $SnCl_2$ concentration, also implying that the carbonium ion has a longer lifetime for reaction in the latter media.

Data in Table 5 show that increasing temperature results in increased reaction. However, changes in melt properties with temperature (*e.g.* viscosity) and their resulting influence on contact times may be equally significant. At temperatures above 330 °C yields decreased, probably because of the change in flow properties of the melt.

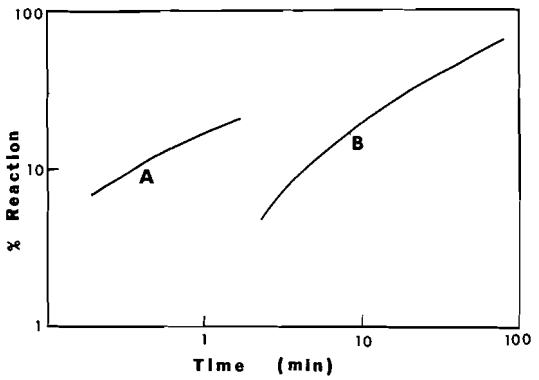

FIG. 1. Comparison of gas phase and molten salt (62 mole% $SnCl_2$–KCl; 317 °C) reaction of 1-bromopropane to give propene. *A*, melt reaction; *B*, gas phase reaction.

Elimination Reactions

Most systems produced unsaturated products corresponding to loss of hydrogen halide from the original molecule, as shown in Tables 1 and 3. That these results are due to melt reactions and not purely thermal decomposition is shown by Fig. 1, which compares the conversion of 1-bromopropane to propene in a gas phase reaction studied by Aguis and Maccoll (11), with our results in the melt. Time refers to the total time in the heated region of our apparatus, which in these experiments was usually much longer than the melt contact time alone. Such results show that the elimination reaction observed in this case is

essentially wholly due to reaction with the melt at any reasonable flow rate.

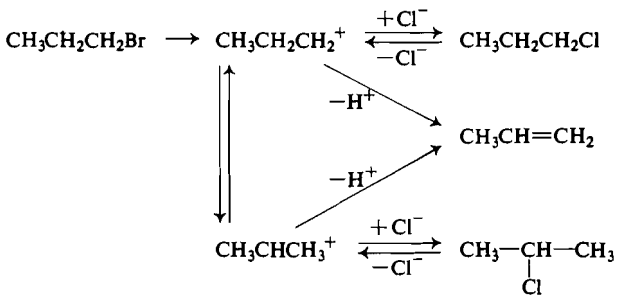
Six chloro-compounds were studied to evaluate the amount of β-elimination of hydrogen in the absence of substitution reactions (Tables 1 and 3). 2-Chloropropane and 2-chlorobutane both give more alkene than the 1-chloro compounds. Also, 2-chlorobutane yields more alkene than does 2-chloro-2-methylpropane, although the overall reactivity of the bromides is in the reverse order. The differences are accountable in terms of the ease of formation of the carbonium ion, since it is well established for S_N1 mechanisms that a secondary carbonium ion is not as stable as a tertiary. Stabilization of the secondary may require a greater shift of electron density from the β-hydrogens, and the stability may then be dependent on the number of such hydrogens available; for example, nine on 2-chloro-2-methylpropane, but five with 2-chlorobutane. If the electron delocalization is greater per hydrogen in the latter, these hydrogens become more acidic and hence more readily available to the bases in the solvent; *i.e.* Cl^-, $SnCl_3^-$ or $SnCl_4^{2-}$.

It is also noted that 1- and 2-butene are formed more readily than propene while ethylene is the most difficult to obtain. This reflects the known values of heats of formation in the series ethylene < propene ~ 1-butene < 2-butene, which has been discussed in equivalent terms by Hughes, Ingold, and Shiner (12). While elimination reactions seem to be understandable on the basis of carbonium ion formation, more data would be required to elucidate all of the details of the reactivities observed.

Reaction Mechanism

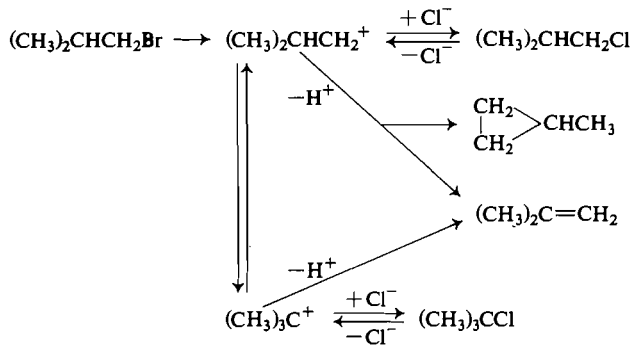
We have accounted for the various observations above by means of carbonium ion formation in the melt, or at the melt–vapor interface. Free radical formation should also be considered, particularly in view of the elevated temperatures. Other molten salt reactions in the literature, such as the formation of ethane from methanol and dimethylether (13), may arise through some type of free radical mechanism. A number of compounds investigated in this study, notably α-bromotoluene, tetrabromomethane, and tribromomethane, gave considerable carbonaceous decomposition material in the melt, and produced Sn(IV) compounds which volatilized and were collected with the products. (Sn(IV) was not produced in detectable amounts in the other reactions.) These examples may be cases where homolytic dissociation is a competitive or even favored mode of reaction, but the majority of the reactions reported here are better described by the ionic mechanism.

The following reaction scheme shows the various steps which we believe take place in the reaction of 1-bromopropane



The steps should be reversible but the small bromide ion concentration in the melt ensures that bromide readdition will not be observed. This mechanism implies that 1-chloropropane should be formed from the 2-chloropropane produced, although this may be in small amount since the latter is energetically favored. It is interesting that while this was not seen in the 62% $SnCl_2$–KCl melts it could be observed in pure $SnCl_2$, where the difficulty in removing the chloride from the melt may produce a longer lived cation with more chance for rearrangement.

A similar mechanism is shown below for the reaction of 1-bromo-2-methylpropane. The formation of methylcyclopropane is interesting. Previous preparations from isobutyl compounds have generally been regarded to involve carbanion intermediates (14–16).



Removal of a proton from $(CH_3)_2CHCH_2^+$ may involve two possible three-centered transition states, leading to methylcyclopropane or 1-butene with the latter being favored.

From the discussion above, it is evident that a number of organic exchange, rearrangement, and elimination reactions can be accounted for by a mechanism involving abstraction of a halide ion from the organic molecule by the melt. To some extent at least, product yields can be controlled by suitable choice of melt and reaction time. Total reaction yields may be high; for most of the reactions discussed here essentially complete utilization of reactant could be achieved by increasing the melt–vapor contact time or introducing more efficient mixing. Yields were reasonably proportional to depth of melt.

Exchange Reactions of the *t*-Butyl Cation[1]

S. BROWNSTEIN AND J. BORNAIS
Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received June 1, 1970

The exchange reaction between *t*-butyl cation and isobutane in sulfur dioxide solution is first order in both species with $E_a = 3.6$ kcal/mole and $\Delta S^{\ddagger}_{298} = -27$ e.u. No reaction is observed, under these conditions, between the *t*-butyl cation and *n*-butane or neopentane. In a similar system the isopropyl chloride – arsenic pentafluoride complex reacts rapidly with *n*-butane to yield propane and the *t*-butyl cation, but does not react with neopentane or cyclopropane. An exchange reaction was also observed between the isopropyl chloride – arsenic pentafluoride complex and propane.

Introduction

Most studies of "stable" carbonium ions in solution have been performed with extremely acidic and reactive solvents such as SbF_5–FSO_3H–SO_2 or HF–SbF_5 (1–3). Intramolecular exchange rates have been measured for some species under these conditions by high resolution proton resonance spectroscopy (3, 4). However, the reactivity of the solvents is such that neutral species of similar structure to the carbonium ions are normally not stable, but react to give carbonium ions themselves.

There have been two studies in which the mechanism and thermodynamic activation parameters have been determined for exchange of a carbonium ion with its halide precursor (5, 6). In the first study (5), relatively stable triphenylmethyl cations were employed and the rate-determining step was found to be the dissociation of the triphenylmethyl halide prior to the actual exchange reaction. In the second study (6), the exchange between acetyl fluoride and acetyl hexafluoroarsenate, the exchange was also found to be an S_N1 process in which the rate-determining step appeared to involve a re-arrangement of the acetyl ion formed by dissociation of acetyl hexafluoroarsenate.

There has been considerable interest in reactions of carbonium ions with hydrocarbons since the pioneering paper of Bartlett *et al.* on hydride ion transfer reactions (7). Considerable information on rates and thermodynamic activation parameters on this reaction has been obtained by studies in strongly acidic systems (8, 9). It seemed worthwhile to see if similar kinetic orders to those observed with carbonium ion – halide exchanges would also be found with hydrocarbons. Since the *t*-butyl cation is the most thermally stable of the simple aliphatic carbonium ions the system *t*-butyl cation – isobutane was chosen for the initial studies. Some qualitative studies have been described in which the exchange of the tertiary proton of isobutane was observed (10). The system was such that the concentration of carbonium ion could not be determined. By choosing appropriate conditions it was possible in the present study to produce known, independently variable, concentrations of carbonium ion and of isobutane.

Experimental

Proton resonance spectra were obtained at 100 MHz on a Varian Associates HA 100 D spectrometer. Probe temperatures were calibrated with a copper–constantan thermocouple in a dummy sample tube. Methylene chloride, purified as previously reported (11), was stored over Linde Molecular Sieve 4A in a container on the vacuum line. Arsenic pentafluoride (Ozark-Mahoning) and anhydrous sulfur dioxide (Matheson) were stored over P_2O_5 in bulbs on the vacuum line. Reagent grade *t*-butyl chloride and *iso*-propyl chloride (Eastman Kodak) were used without further purification. An equal volume mixture of methylene chloride and sulfur dioxide was used as solvent in order to obtain a low freezing point along with adequate solubility. The methylene chloride proton signal was used as an internal reference and lock signal, and the peak positions subsequently corrected and reported relative to tetramethylsilane.

The samples were prepared by standard vacuum line techniques, thawed and mixed in a "Dry Ice" bath and quickly inserted into a pre-cooled n.m.r. probe. Kinetic runs were first measured at the lowest temperature and then at increasing temperatures. At the end of the series of measurements the lowest temperature run was repeated to insure that no sample degradation had occurred. The data were fitted by least square techniques and the listed errors are standard deviations.

Results and Discussion

The proton magnetic resonance spectrum of isobutane in a 50% *v/v* solution of sulfur dioxide and methylene chloride, containing twice the concentration of arsenic pentafluoride utilized in the kinetic experiments, has a sharp doublet (J_{H-H} = 7.3 Hz, δ = 0.98 p.p.m. from tetramethylsilane) at −82 °C. With rising sample temperature the two peaks of the doublet broadened and had almost completely merged to a single peak by −40 °C. The peak position moved 0.07 p.p.m. down field in this temperature interval. Presumably there is some type of exchange reaction occurring with residual impurities in the system. However, as can be seen from Fig. 1, this peak broadening corresponds, at any given temperature, to only a very small amount of the observed rate of exchange when the *t*-butyl cation is also present. Therefore, it is possible to obtain moderately accurate kinetic results for the exchange reaction between the *t*-butyl cation and isobutane despite this interfering reaction.

In the solvent system used for this study the *t*-butyl cation displays a sharp single peak whose chemical shift varies from 4.03 p.p.m. at −82 °C to 4.06 p.p.m. at −40 °C. This may be compared with the previously reported values of 3.95 p.p.m. in the solvent system SbF_5–SO_2 and 4.35 p.p.m. in SbF_5 alone (12). By contrast the chemical shift of the precursor, *t*-butyl chloride, is 1.58 p.p.m. These values leave little doubt that it is the *t*-butyl cation, and not a complex, which is being studied.

Since the change of chemical shift difference between the two exchanging *t*-butyl species is only 3 in 300 Hz over the temperature range of interest, a single average value was used for calculation of theoretical spectra. The theoretical spectra were calculated with the same general matrix technique employed previously (13), but with the inclusion of a convolution integral to include the effects of natural line width (14). The decet from the methine proton of isobutane was not included in the theoretical calculations. When the exchange was rapid the peak of this proton was observed as a relatively sharp spike (due to averaging of the spin-coupling) on the side of the isobutane methyl peak. A comparison of typical theoretical and experimental spectra is displayed in Fig. 1.

In the slow exchange limit where the separation between the resonance peaks is considerably greater than the rate of conversion between the two species, it is possible to separately determine the lifetime of each species. However, in the present studies it is only at the slowest exchange rates that this is possible, and even then only in an approximate manner. Therefore, the theoretical spectra have been calculated for the lifetime of the isobutane molecule. This is related to the lifetime of the *t*-butyl cation by the equation

$$[1] \quad \tau_{\text{isobutane}}/C_{\text{isobutane}} = \tau_{t\text{-butyl}}/C_{t\text{-butyl}}$$

regardless of the mechanism of the exchange reaction. The symbols τ and C denote lifetime and concentration, respectively.

The relationship between the lifetime of a species, as determined by magnetic resonance investigations at equilibrium, and rate of change of concentration, measured in conventional kinetic studies, is given by eq. 2.

$$[2] \quad d[Z]/dt = [Z]/\tau_z$$

A perfectly general equation to describe the kinetics of the exchange reaction between the *t*-butyl cation and isobutane is

$$[3] \quad \frac{d[(CH_3)_3CH]}{dt} = c[(CH_3)_3CH]^x[(CH_3)_3C^+]^y$$

where c is the rate constant for the reaction at some particular temperature. Substituting eq. 2

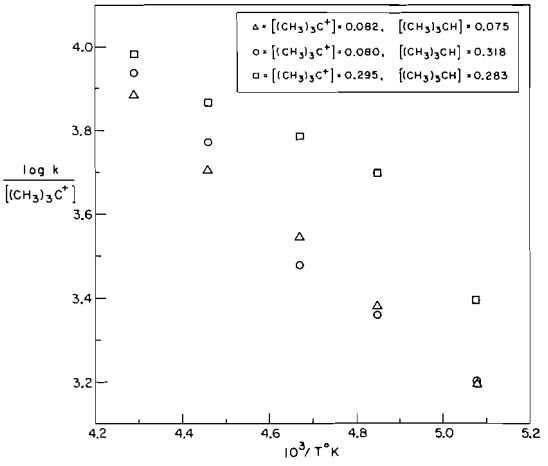

FIG. 2. Temperature dependence of the rate of the exchange reaction between *t*-butyl cation and isobutane.

into eq. 3 with $k = 1/\tau$ yields

$$[4] \quad k_{\text{isobutane}} = c[(CH_3)_3CH]^{x-1}\,[(CH_3)_3C^+]^y$$

A plot of log $k/[(CH_3)_3C^+]$ for three of the samples is shown in Fig. 2. From a least squares fit of such a plot for the data from all the samples studied, the Arrhenius energy of activation, E_a, was calculated to be 3.6 ± 0.2 kcal/mole and $\Delta S^{\ddagger}_{298}$ was found to be approximately -27 e.u.

Although there is a large scatter in the rates shown in Fig. 2, the slope for each of the samples is very similar. The concentration of isobutane was varied from 0.075 to 0.318 *m* and of *t*-butyl cation from 0.071 to 0.295 *m*. Over this concentration range, $x - 1 = 0$ and therefore $x = 1$, and the exchange reaction is unimolecular in isobutane. The reaction was also found to be first order in *t*-butyl cation although the limited concentration range experimentally available does not completely exclude the possibility of the reaction being 3/2 order. Some of the scatter in the data of Fig. 2 might be due to the fact that the concentration dependence of the rate is not exactly first order in *t*-butyl cation, but it is primarily due to the difficulties of completely excluding reactive impurities from this very sensitive system (6). Such impurities are likely to reduce the *t*-butyl cation concentration below that calculated and this effect will be most serious at the lower concentrations.

Solutions containing the *t*-butyl cation and *n*-butane showed no evidence of exchange reactions in the temperature region from -82 to -40 °C. The observed spectrum was the sum of those for the individual components. Similarly with neopentane there was no reaction. When *s*-butyl chloride was used as the carbonium ion precursor the *t*-butyl cation was produced and the same results were obtained as with *t*-butyl chloride as a precursor. These results are consistent with previous studies of the rate of *sec*-butyl *t*-butyl cation conversion (15).

The use of isopropyl chloride rather than *t*-butyl chloride gave a solution with a sharp doublet at 2.19 p.p.m. and a septet at 6.10 p.p.m. with a coupling constant of approximately 6.3 Hz between the methyl and methine protons. It is quite unlikely that the isopropyl cation is present since the chemical shifts of the methyl and methine protons are different than those previously reported (16, 17). It seems likely that an isopropyl chloride – arsenic pentafluoride complex is being observed, although the possibility of a rapidly equilibrating system containing a low concentration of carbonium ion cannot be excluded.

This complex was found to exchange rapidly with propane in a system analogous to the system *t*-butyl cation – isobutane. However, it was found that after warming samples containing the isopropyl chloride – arsenic pentafluoride complex, identical spectra were not obtained upon recooling to -76 °C. Some representative results are shown in Fig. 3. Since some decomposition must be occurring upon warming it is not possible to do a kinetic study of this system.

From the results of proton resonance spectroscopy it was observed that the isopropyl chloride – arsenic pentafluoride complex reacts rapidly and completely with *n*-butane to yield the *t*-butyl cation and propane. However, it does not react with neopentane nor cyclopropane at the low temperatures (*ca.* -80 °C) where it is thermally stable.

Total Synthesis of (±)-α-Cubebene and (±)-β-Cubebene

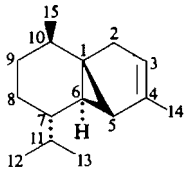
EDWARD PIERS,[1] RONALD W. BRITTON, AND WILLIAM DE WAAL
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received August 10, 1970

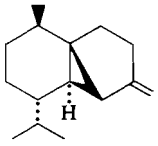
An efficient total synthesis of the racemic forms of the novel tricyclic sesquiterpenes α-cubebene (**1**) and β-cubebene (**2**) is described. The key step of this synthesis involved the cupric sulfate catalyzed intramolecular cyclization of the olefinic diazoketone **3**, which produced, in high yield, (±)-β-cubebene norketone (**24**) and (±)-1,6-epi-β-cubebene norketone (**25**), in a ratio of approximately 3:5, respectively.

Canadian Journal of Chemistry, 49, 12 (1971)

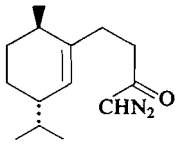
On the basis of spectral data, chemical degradation and correlation with known cadinane derivatives, Hirose *et al.* (1–3) have proposed that **1** and **2** correctly represent the structure and absolute stereochemistry of α-cubebene[2] and β-cubebene, respectively, two sesquiterpenes isolated from the commercial oil of cubeb (*Piper cubeba* L.). Structurally, these two natural products contain the bicyclo[3.1.0]hexane moiety and thus represent a novel and interesting variant of the more normal structures found within the cadinane class of sesquiterpenoids. We report in this paper the total synthesis of the cubebenes via a route which fully supports the structural and stereochemical assignments.[3]



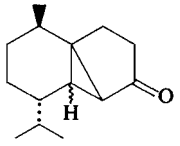
1



2



3



4

The key step of our envisaged synthesis involved the cupric sulfate catalyzed intramolecular cyclization of an appropriately substituted olefinic diazoketone.[4] In particular, it was proposed to prepare and attempt the cyclization of the olefinic diazoketone **3**. Obviously, success of the cyclization would lead to a synthetic intermediate **4** with functionality appropriate for further elaboration to α- (**1**) and β-cubebene (**2**).

Condensation of the commercially available mixture of (±)-menthone and (±)-isomenthone (**5**)[5] (see Scheme 1) with ethyl formate in the presence of sodium methoxide in benzene afforded, in 88% yield, the corresponding hydroxymethylene derivatives **6**. Treatment of the latter under the usual conditions (14) with *n*-butanethiol gave in 89% yield the corresponding *n*-butylthiomethylene derivatives **7**, which, upon reduction with a basic solution of methanolic sodium borohydride provided a quantitative yield of the crude β-hydroxythioenol ether **8**. This material was not purified further, but was immediately subjected to hydrolysis with 1% hydrochloric acid in aqueous acetone. Distillation of the resulting mixture of products produced two major fractions. The first fraction (40%, b.p. 66–68° at 0.35 mm) consisted of the desired α,β-unsaturated aldehydes **10**, while the second fraction (50%, b.p. 120–126° at 0.35 mm) was shown to be the thioenol ether **9**. Normally, the hydrolysis of β-hydroxythioenol ethers of structure similar to compound **8** affords, in good yield, the corresponding α,β-unsaturated aldehyde (15, 16). However, in the present case, although a variety of conditions were used, including the addition of mercuric salts, the isolated yield of the aldehydes **10** did not exceed 40%. Furthermore, various

[1]Fellow of the Alfred P. Sloan Foundation, 1970–1972.

[2]The numbering scheme shown in structure **1** is that normally used for cadinane-type sesquiterpenoids.

[3]For a preliminary report regarding this work, see ref. 4. For another report concerning the synthesis of the cubebenes see ref. 5.

[4]For some previous applications of this type of reaction to terpenoid synthesis, see refs. 6–13, inclusive.

[5]Compounds **5**, **6**, **7**, and **10** represent racemic diastereomeric pairs. Analytical and spectral data of these mixtures were, in each case, in full accord with the structural assignments.

attempts to hydrolyze the thioenol ether **9** to the aldehydes **10** were also unsuccessful.

Reduction of the aldehydes **10** with sodium borohydride afforded, in 91% yield, the corresponding mixture of the alcohols **11** and **12**. To this stage in the synthesis, no attempt had been made to separate the diastereomeric pairs, since all of the intermediates which would have been amenable to separation contained an epimerizable isopropyl group. However, once the aldehyde functionality of **10** had been reduced with sodium borohydride, the possibility for epimerization had been removed. Therefore, attempts were made to separate the mixture of alcohols **11** and **12**.

Gas–liquid chromatographic analysis of this mixture on many different columns at various column temperatures and carrier-gas flow rates failed to reveal any appreciable separation of the two alcohols **11** and **12**. The corresponding acetate derivatives also proved to be extremely difficult to separate. However, the corresponding trimethylsilyl ether derivatives **13** and **14**, which were easily formed in virtually quantitative yield from the alcohols **11** and **12**, were found to separate reasonably well on a preparative Zonyl E-7 column.[6] Preparative g.l.c. thus provided a convenient method for obtaining a sufficient quantity of the pure trimethylsilyl ethers **13** and **14**.

It was important at this stage to ascertain the stereochemistry of the two trimethylsilyl ethers **13** and **14**. Since the ratio of the two compounds in the originally obtained mixture was approximately 1:1, it was impossible to assign the configurations in terms of conformational arguments. Therefore, a chemical proof regarding this point was sought, and the fact that the silyl ether of shorter g.l.c. retention time was indeed the desired *trans* compound **14** was shown as follows.

Hydrolysis of **14** in hot 2% aqueous ethanol gave in, 98% yield, the pure *trans* alcohol **12**, which, upon treatment with phosphorus tribromide in benzene–pyridine at 0° (17), afforded the allylic bromide **15**, in 77% yield. Lithium aluminum hydride reduction of **15** gave a virtually quantitative yield of racemic *trans*-2-methyl-*p*-mentha-2-ene (**16***a*). The spectral properties of this hydrocarbon were in complete accord with the assigned structure.

[6]We are very grateful to Mr. J. Booker, Varian-Aerograph, California, for his help in the selection of a g.l.c. column for this separation.

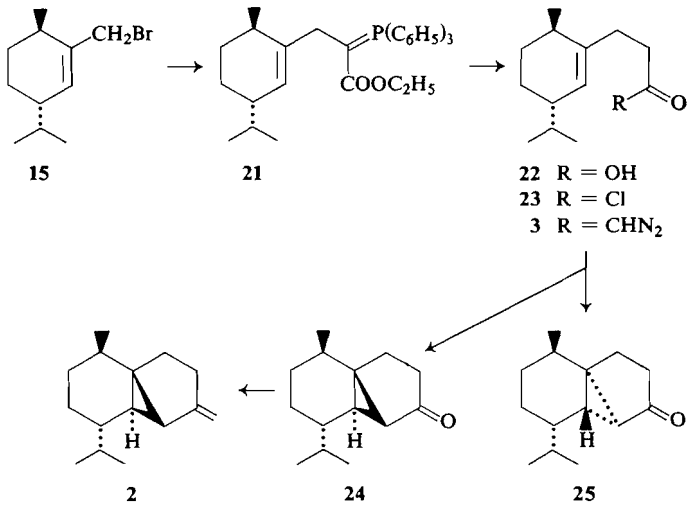
An unambiguous synthesis of (+)-*trans*-2-methyl-*p*-mentha-2-ene (**16***b*) was carried out as follows (see Scheme 1). The bicyclic ketone (−)-*trans*-caran-2-one (**18**) was prepared from (+)-dihydrocarvone (**17**) according to literature procedures (18, 19), and could be conveniently purified by recrystallization from *n*-hexane at −78°. A sample of **18** purified in this manner exhibited $[\alpha]_D^{22}$ − 181° [lit. $[\alpha]_D^{19}$ − 162.9° (19), − 153° (20)] and in the n.m.r. spectrum showed no signals due to olefinic protons.[7] Reaction of ketone **18** with ethereal methyllithium produced, in high yield, only one product, formulated as **19**. The stereochemistry of the latter was assigned on the basis of the reasonable assumption that the methyllithium would approach the carbonyl group of **18** from the less hindered side, opposite to the sterically bulky *gem*-dimethylcyclopropyl moiety (see ref. 21).

Pyrolysis of the tertiary alcohol **19** in the presence of a small amount of pyridine in a sealed tube at 190–200° for 2 h (19) gave approximately 70% of (+)-*trans*-2-methyl-*p*-mentha-2,8-diene (**20**),[8] which was purified by preparative g.l.c. Hydrogenation of the latter in the presence of the homogeneous catalyst tris(triphenylphosphine)-chlororhodium (22, 23) stopped after the uptake of one equivalent of hydrogen. Isolation of the product afforded (+)-*trans*-2-methyl-*p*-mentha-2-ene (**16***b*), which exhibited i.r. and n.m.r. spectra and g.l.c. retention times identical with those obtained from the racemic compound **16***a*, prepared as described previously. This correlation provided unambiguous evidence for the stereochemistry of our synthetic intermediates **12** and **15** and allowed us to continue with the proposed synthesis of the cubebenes.

Treatment of the allylic bromide **15** (see Scheme 2) with two equivalents of carbethoxymethylenetriphenylphosphorane (24) in refluxing ethyl

[7]The n.m.r. spectrum of samples of **18** which had not been purified by recrystallization clearly showed the presence of small amounts of starting material, (+)-dihydrocarvone (**17**). Furthermore, purification of **18** by preparative g.l.c. or by distillation at temperatures greater than 100° was attended by partial isomerization to **17**. Presumably, these observations account for the fact that our specific rotation value for compound **18** was considerably higher than those previously reported.

[8]This material had to be purified and analyzed immediately, as it tended to autoxidize on standing for even short periods of time. This type of observation had been previously noted by Cocker *et al.* (19) in the case of the analogous compound, (+)-*trans*-*p*-mentha-2,8-diene.



SCHEME 2

acetate for 2.5 h (25) gave, in addition to the crystalline carbethoxymethyltriphenylphosphonium bromide, a virtually quantitative yield of the corresponding alkylated phosphorane **21** as a yellow oil. Hydrolysis of this crude material with 10% potassium hydroxide in refluxing aqueous methanol afforded, in 69% yield, the olefinic carboxylic acid **22**. The stage was now set for the rather simple sequence of reactions which would lead to the formation of the synthetically crucial diazoketone **3**. To this end, **22** was converted into its sodium salt, and the latter was reacted with oxalyl chloride in benzene at 0° to afford the crude acid chloride **23**. When this compound was treated with dry ethereal diazomethane, the corresponding diazoketone **3** was formed almost immediately. The spectral properties of the crude material were in full accord with the assigned structure and it was now possible to attempt the initially proposed cyclization.

When the diazoketone **3** was refluxed in cyclohexane in the presence of cupric sulfate (26) for 1.5 h, a remarkably clean and high-yielding intramolecular cyclization occurred, producing two isomeric ketones, (±)-β-cubebene norketone (**24**) and (±)-1,6-epi-β-cubebene norketone (**25**), in a ratio (g.l.c. analysis) of approximately 3:5, respectively. The minor isomer **24**, upon treatment with methylenetriphenylphosphorane in dimethyl sulfoxide (27), gave a quantitative yield of (±)-β-cubebene (**2**) as a clear, colorless oil. The spectral properties (i.r., n.m.r., u.v., and mass spectrum) of this material were identical with those of natural β-cubebene.[9] Furthermore, the two materials were indistinguishable by g.l.c. Since β-cubebene had already been converted into α-cubebene (1), the synthesis of (±)-β-cubebene (**2**), as described above, also represents a total synthesis of (±)-α-cubebene (**1**).

It should be noted that although the synthetic work described in this paper provides unambiguous evidence regarding the stereochemistry at C-7 and -10 of the two cubebenes **1** and **2**, the nature of the synthesis is such that it supplies no conclusive information concerning the stereochemistry at C-6 of these compounds. However, Hirose *et al.* (3) have presented excellent evidence regarding this point and it thus appears safe to assume that **1** and **2** correctly represent the structure and stereochemistry of α- and β-cubebene, respectively.

Experimental

Melting points, which were determined on a Kofler block, and boiling points are uncorrected. The u.v. spectra were, unless otherwise noted, measured in methanol solution on either a Cary, model 14, or a Unicam, model SP 800, spectrophotometer. Routine i.r. spectra were recorded on a Perkin–Elmer Infracord model 137 spectrophotometer, while all comparison spectra were re-

[9]Natural β-cubebene (**2**) was isolated from Oil of Cubeb, Extra, kindly supplied by Fritzsche Brothers, Inc., New York, N.Y. The i.r. and n.m.r. spectra of this material, isolated by preparative g.l.c., were identical with those kindly supplied by Professor Y. Hirose. In addition, upon ozonolysis, the β-cubebene which was isolated from Oil of Cubeb, Extra, gave the known β-cubebene norketone, m.p. 60–60.5° (lit. m.p. 58.5–59.5° (1)).

corded on a Perkin–Elmer model 421 spectrophotometer. The n.m.r. spectra were taken in deuteriochloroform solution on Varian Associates spectrometers, models T-60, A-60, and/or HA-100. Line positions are given in the Tiers τ scale, with tetramethylsilane as an internal standard; the multiplicity, integrated peak areas, and proton assignments are indicated in parentheses. Mass spectrometric measurements were recorded on an AEI, type MS-9, mass spectrometer. The g.l.c. was carried out on an Aerograph Autoprep, model 700. The following columns were employed, with the inert supporting material being 60/80 mesh Chromosorb W in each case: column A, (30 ft × 3/8 in.), 30% Zonyl E-7; column B (20 ft × 3/8 in.), 30% SE-30; column C (10 ft × 1/4 in.), 20% SE-30; column D (10 ft × 3/8 in.), 30% Apiezon J; column E (10 ft × 1/4 in.), 10% Apiezon J; column F (10 ft × 1/4 in.), 20% Carbowax 20 M. The specific column used, along with column temperature and carrier gas (helium) flow-rate (ml/min), are indicated in parentheses. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

Preparation of Hydroxymethylene Derivatives **6**

To an ice-cooled, stirred suspension of powdered sodium methoxide (135 g, 2.46 moles) in 1500 ml of dry benzene, kept under an atmosphere of dry nitrogen, was added 154 g (1 mole) of a mixture of (±)-menthone and (±)-isomenthone (**5**). The resulting mixture was stirred for 10 min, and then 125 g (1.7 moles) of ethyl formate was added. The mixture was warmed to room temperature and allowed to stand overnight. Water was added, and the layers were separated. The organic layer was extracted with two portions of 10% aqueous sodium hydroxide. The combined aqueous layer and alkaline extracts were cooled, acidified with 6 *N* hydrochloric acid, and thoroughly extracted with ether. The combined extracts were washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residual oil under reduced pressure, gave 171 g (94%) of the hydroxymethylene derivatives **6** as a pale yellow oil, b.p. 71–73° at 0.2 mm; n_D^{20} 1.4983; u.v. λ_{max} 294 mμ (ε = 7950), λ_{max} (NaOH added) 319 mμ (ε = 17 500); i.r. (film) λ_{max} 6.15, 6.35 μ.

Anal. Calcd. for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95. Found: C, 72.49; H, 10.06.

Preparation of n-Butylthiomethylene Derivatives **7**

A solution of the hydroxymethylene derivatives **6** (137.5 g, 0.755 mole), *n*-butanethiol (75 g, 0.825 mole), and *p*-toluenesulfonic acid (50 mg) in 500 ml of dry benzene was refluxed in a nitrogen atmosphere under a Dean–Stark water separator for 12 h at which time 13 ml of water had been collected. The cooled solution was washed with saturated aqueous sodium bicarbonate, then with water, and finally dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which, upon distillation under reduced pressure, afforded 170 g (89%) of the *n*-butylthiomethylene derivatives **7**, b.p. 130–136° at 0.35 mm; n_D^{20} 1.5292; u.v. λ_{max} 311 mμ (ε = 13 600); i.r. (film), λ_{max} 6.02, 6.50 μ.

Anal. Calcd. for $C_{15}H_{26}OS$: C, 70.83; H, 10.30; S, 12.61. Found: C, 71.09; H, 10.45; S, 12.30.

Preparation of Aldehydes **10**

To a solution of the *n*-butylthiomethylene derivatives **7** (140.7 g, 0.555 mole) in 1.8 l of methanol was added 21.25 g (0.555 mole) of sodium borohydride dissolved in 55.5 ml of 0.1 *N* sodium hydroxide. The mixture was stirred at room temperature for 2 h then a further 21.25 g (0.555 mole) of sodium borohydride dissolved in 55.5 ml of 0.1 *N* sodium hydroxide was added. After a further 2 h, the methanol was removed at aspirator pressure and the remaining aqueous layer was extracted three times with ether. The ether layers were washed with water then dried over anhydrous magnesium sulfate. Removal of the solvent gave 142 g (100%) of the β-hydroxythioenol ethers **8** as a pale yellow oil, i.r. (film) λ_{max} 3.00, 6.23 μ. This material was used without further purification in the hydrolysis step as described below.

To a solution of the crude alcohol **8** (25.6 g, 0.1 mole) in 500 ml of acetone was added 100 ml of 1% aqueous hydrochloric acid. The resulting mixture was heated on a steam bath for 20 min, then the acetone was removed at water aspirator pressure. The remaining aqueous layer was saturated with sodium chloride and extracted three times with ether. The combined ether layers were washed with water and dried over anhydrous magnesium sulfate Removal of the ether, followed by distillation of the resulting oil under reduced pressure (0.35 mm) gave two fractions: fraction 1, b.p. 66–68°, 6.65 g (40%) consisted of the desired α,β-unsaturated aldehydes **10** as a clear colorless oil, n_D^{20} 1.4878; u.v. λ_{max} 233.5 mμ (ε = 18 750); i.r. (film), λ_{max} 3.75, 5.95, 6.15 μ; n.m.r. τ 0.6 (singlet, 1H, *CH*O), 3.35 (multiplet, 1H, β-vinyl H), 8.82–9.16 (multiplet, 9H, secondary methyls).

Anal. Calcd. for $C_{11}H_{18}O$: C. 79.46; H, 10.91. Found: C, 79.64; H, 10.85.

Fraction 2, b.p. 120–126°, 11.9 g (50%), consisted of the pure thioenol ether **9** as a pale yellow oil, n_D^{20} 1.5363; u.v. λ_{max} 278 mμ (ε = 22 600), λ_{sh} 286 mμ (ε = 21 100); i.r. (film) λ_{max} 6.4, 11.4 μ; n.m.r. τ 4.08 (multiplet, 1H, vinyl H), 4.37 (singlet, 1H, vinyl H), 8.85–9.15 (multiplet, 12H, three secondary methyls and one primary methyl).

Anal. Calcd. for $C_{15}H_{26}S$: C, 75.56; H, 10.99. Found: C, 75.71; H, 11.10.

Preparation of the Mixture of Alcohols **11** *and* **12**

To a solution of sodium borohydride (4.5 g, 0.12 mole in 500 ml of methanol, cooled to 0° in an ice bath, was added a solution of the mixture of aldehydes **10** (20 g, 0.12 mole) in 100 ml of methanol. The reaction mixture was stirred under an atmosphere of nitrogen for 30 min and the methanol was removed at water aspirator pressure. Cold water (200 ml) was added and the aqueous layer was extracted three times with ether. The combined ether extracts were dried over anhydrous magnesium sulfate and the ether was removed at water aspirator pressure. Distillation of the resulting oil under reduced pressure afforded 18.4 g (91%) of the mixture of alcohols **11** and **12**, b.p. 77–78° at 0.25 mm.

Preparation of Trimethylsilyl Ethers **13** *and* **14**

To a solution of the mixture of alcohols **11** and **12** (9 g, 0.053 mole) in 150 ml of dry pyridine was added 30 ml of hexamethyldisilazane and 15 ml of trimethylsilyl chloride.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The mixture was stirred under an atmosphere of nitrogen for 10 min, then the mixture was filtered and the excess reagents and pyridine were removed at water aspirator pressure. The crude product was distilled under reduced pressure to give 12.2 g (95%) of the mixture of trimethylsilyl ether derivatives **13** and **14**, b.p. 62–63° at 0.35 mm. Analysis of this mixture by g.l.c. (column A, 150°, 200) revealed that the two isomers were present in a ratio of approximately 1:1. Purification of the two isomers was achieved by preparative g.l.c. (column A, 140°, 240). The pure *trans*-isomer **14**, of shorter retention time, was a clear colorless oil and exhibited n_D^{20} 1.4544; i.r. (film) λ_{max} 8.00, 9.4, 11.4, 11.9 μ; n.m.r. τ 4.43 (broad singlet, 1H, vinyl H, $w_{\frac{1}{2}}$ = 4 Hz), 5.92 (unresolved multiplet, 2H, —CH_2—OTMS), 8.99, 9.09, 9.13 (doublets, 9H, secondary methyls, J = 7 Hz), 9.87 (singlet, 9H, Si(CH_3)$_3$).

Mol. Wt. Calcd. for $C_{14}H_{28}OSi$: 240.191. Found (high resolution mass spectrometry): 240.190.

The pure *cis*-isomer **13**, of longer retention time, was a clear colorless oil and exhibited n_D^{20} 1.4540; i.r. (film), λ_{max} 8.03, 9.45, 11.4, 11.9 μ; n.m.r., τ 4.43 (broad singlet, 1H, vinyl H, $w_{\frac{1}{2}}$ = 4 Hz), 5.92 (unresolved multiplet, 2H, —CH_2—OTMS), 8.98, 9.08, 9.13 (doublets, 9H, secondary methyls, J = 7 Hz), 9.87 (singlet, 9H, Si(CH_3)$_3$).

Mol. Wt. Calcd. for $C_{14}H_{28}OSi$: 240.191. Found (high resolution mass spectrometry): 240.191.

Preparation of Alcohol ***12***

The pure *trans*-trimethylsilyl ether **14** (600 mg. 2.5 mmoles) was refluxed in 6 ml of ethanol containing 0.2 ml of water for 2 h. The solvents were removed at water aspirator pressure and the resulting oil was distilled under reduced pressure to afford 413 mg (98%) of the alcohol **12** as a clear colorless oil, b.p. 80° (hot-box) at 0.15 mm; n_D^{20} 1.4825; i.r. (film) λ_{max} 3.0, 6.02, 9.9 μ; n.m.r. τ 4.39 (broad singlet, 1H, vinyl H, $w_{\frac{1}{2}}$ = 5 Hz), 5.92 (unresolved multiplet, 2H, CH_2O—H), 8.22 (singlet, 1H, exchangeable, CH_2OH), 8.98, 9.10, 9.14 (doublets, 9H, secondary methyls, J = 6.8, 6.4, and 6.4 Hz respectively).

Anal. Calcd. for $C_{11}H_{20}O$: C, 78.51; H, 11.98. Found: C, 78.76; H, 12.03.

Preparation of Bromide ***15***

A solution of the alcohol **12** (400 mg, 2.38 mmoles) in 10 ml of benzene containing 0.08 ml of dry pyridine was cooled to 0° in an ice-bath. To this cold stirred solution was added, from a dropping funnel, 312 mg (1.15 mmoles) of phosphorous tribromide in 1.1 ml of dry benzene. The reaction mixture was stirred for 30 min and then diluted with 5 ml of cold dilute aqueous sodium bicarbonate solution. The mixture was extracted with ether and the combined organic layers were dried over anhydrous magnesium sulfate. The solvents were removed at aspirator pressure and the resulting crude product was distilled under reduced pressure to afford 425 mg (77%) of the bromide **15**, b.p. 75° at 0.2 mm; n_D^{20} 1.5027; i.r. (film) λ_{max} 6.08, 8.30 μ; n.m.r. τ 4.30 (broad singlet, 1H, vinyl H, $w_{\frac{1}{2}}$ = 5 Hz), 6.03 (quartet, 2H, $-CH_2Br$, J_{AB} = 10 Hz), 8.95, 9.09, 9.12 (doublets, 9H, secondary methyls, J = 7 Hz).

Anal. Calcd. for $C_{11}H_{19}Br$: C, 57.15; H, 8.28. Found: C, 57.25; H, 8.27.

*(±)-trans-2-Methyl-p-mentha-2-ene (**16a**)*

To a solution of lithium aluminum hydride (50 mg, 1.3 mmoles) in 6 ml of dry tetrahydrofuran was added 300 mg (1.3 mmoles) of the allylic bromide **15**. The mixture was refluxed under an atmosphere of nitrogen for 1.5 h, then cooled to 0°. Water (1 ml) was cautiously added, and the resulting mixture was extracted with ether. The combined ether layers were dried over anhydrous magnesium sulfate and the solvent was removed at water aspirator pressure. Distillation of the resulting oil under reduced pressure gave 188 mg (95%) of (±)-2-methyl-*p*-mentha-2-ene (**16a**) as a clear colorless oil, b.p. 80° (hot-box) at 10 mm; n_D^{20} 1.4602; i.r. (film) λ_{max} 6.93, 7.23, 7.32, 11.5, 11.9 μ; n.m.r. τ 4.87 (broad singlet, 1H, vinyl H, $w_{\frac{1}{2}}$ = 5 Hz), 8.37 (singlet, 3H, vinyl CH_3), 9.05, 9.15, 9.18 (doublets, 9H, secondary methyls, J = 6.6 Hz). This material exhibited spectra (i.r., n.m.r.) identical with those obtained from an authentic sample of (+)-*trans*-2-methyl-*p*-mentha-2-ene (**16b**), the synthesis of which is described below.

Mol. Wt. Calcd. for $C_{11}H_{20}$: 152.156. Found (high resolution mass spectrometry): 152.156.

*(−)-trans-Caran-2-one(**18**)*

A solution of (+)-dihydrocarvone (**17**) (15.2 g, 0.1 mole) in 130 g of 9.4% hydrogen bromide in glacial acetic acid was stirred at room temperature for 15 min, then poured onto 500 g of crushed ice. The resulting mixture was extracted three times with ether and the combined ether extracts were washed with dilute aqueous sodium bicarbonate and water until all of the acetic acid had been removed. The ether layer was dried over anhydrous magnesium sulfate and the ether was removed at water aspirator pressure to afford 23.3 g (100%) of the crude (+)-dihydrocarvone hydrobromide.

To a solution of potassium hydroxide (5.9 g, 0.105 mole) in 250 ml of ethanol at 0° was added the crude hydrobromide (23.3 g, 0.1 mole), and the resulting mixture was stirred for 2 h at 0°. The precipitated potassium bromide was filtered off and the ethanol was removed from the filtrate at water aspirator pressure. Distillation of the resulting oil under reduced pressure gave 12.18 g (80%) of (−)-*trans*-caran-2-one (**18**), b.p. 38–40° at 0.15 mm [lit. b.p. 60° at 1 mm (19)]. This material was crystallized by dissolving it in hexane and cooling the resulting solution to −78° (acetone – Dry Ice). The mother liquors were removed with a pipet and the crystals were warmed to room temperature to give a clear colorless oil. The resulting material was recrystallized under the same conditions and any excess hexane was removed under reduced pressure (vacuum pump, 0.1 mm). A sample of material purified in this way exhibited n_D^{20} 1.4773; $[\alpha]_D^{22}$ −181° (*c*, 1.2 in methanol) [lit. $[\alpha]_D^{19}$ −162.9° (19), −153° (*c*, 5.0) (20)]; i.r. (film) λ_{max} 5.96 μ; n.m.r. τ 8.81, 8.96 (singlets, 6H, tertiary methyls,), 8.98 (doublet, 3H, secondary methyl, J = 6.3 Hz).

Preparation of Alcohol ***19***

To a solution of (−)-*trans*-caran-2-one (**18**) (1.52 g, 0.01 mole) in 50 ml of dry ether was added 15 ml of 2.13

M ethereal methyllithium (0.032 mole), and the resulting mixture was stirred for 3 days. The excess methyllithium was destroyed by the cautious addition of 2 ml of water, and the ether layer was dried over anhydrous magnesium sulfate. Removal of the ether at water aspirator pressure gave 2.1 g of a pale yellow oil. This material was purified by column chromatography on 60 g of florisil. The fractions eluted with 1:9 ether–hexane and 1:4 ether–hexane were combined to give 1.65 g (98%) of the alcohol **19**, n_D^{20} 1.4800; $[\alpha]_D^{21}$ −9.4° (*c*, 1.0 in methanol); i.r. (film) λ_{max} 2.95, 9.15, 10.95 μ; n.m.r. τ 8.3 (singlet, 1H, exchangeable, O—*H*), 8.74, 8.75, 8.95 (singlets, 9H, tertiary methyls), 9.09 (doublet, 3H, secondary methyl, J = 6.5 Hz).

Anal. Calcd. for $C_{11}H_{20}O$: C, 78.51; H, 11.98. Found: C, 78.63; H, 11.80.

(+)-trans-2-Methyl-p-mentha-2,8-diene (20)

A mixture of the alcohol **19** (836 mg, 5 mmoles) and 0.17 ml of pyridine was placed in a pyrolysis tube and sealed under an atmosphere of nitrogen. The tube was heated in an oil bath at 190° for 2 h after which time it was cooled and carefully opened. The mixture was diluted with ether and dried over anhydrous magnesium sulfate. Removal of the solvents at water aspirator pressure afforded 730 mg of colorless oil. Analysis of this mixture by g.l.c. (column B, 155°, 200) revealed that it consisted of a mixture of 70% (+)-*trans*-2-methyl-*p*-mentha-2,8-diene (**20**) and several minor unidentified components. A sample of **20** purified by preparative g.l.c. (column B, 155°, 200) exhibited n_D^{20} 1.4736; $[\alpha]_D^{20}$ +139.3° (*c*, 3.7 in methanol); i.r. (film) λ_{max} 3.25, 6.08, 11.28 μ; n.m.r. τ 4.72 (broad singlet, 1H, C_3 vinyl H, $w_{\frac{1}{2}}$ = 5 Hz), 5.27 (broad singlet), 2H, CH_3—C=C*H*$_2$, $w_{\frac{1}{2}}$ = 3 Hz), 8.27 (singlet, 6H, vinyl methyls), 8.99 (doublet, 3H, secondary methyl, J = 6.4 Hz).

Anal. Calcd. for $C_{11}H_{18}$: C, 87.93; H, 12.07. Found: C, 88.20; H, 11.85.

(±)-trans-2-Methyl-p-mentha-2-ene (16b)

The hydrogenation of the diene **20** was carried out in benzene at room temperature and atmospheric pressure using tris(triphenylphosphine)chlororhodium (22, 23) as the catalyst. The reaction solution was filtered through a small column of activity II alumina. From 240 mg of **20** there was obtained 225 mg of a clear colorless oil. Analysis of this material by g.l.c. (column C, 110°, 100) showed that it consisted of 80% (+)-*trans*-2-methyl-*p*-mentha-2-ene (**16***b*) and several other minor, unidentified components. A sample of compound **16***b* obtained by preparative g.l.c. (column D, 145°, 200) exhibited n_D^{20} 1.4602; $[\alpha]_D^{22}$ +25.4° (*c*, 0.6 in methanol). This material displayed i.r. and n.m.r. spectra and g.l.c. retention times identical with those obtained from compound **16***a*, prepared as described previously.

Mol. Wt. Calcd. for $C_{11}H_{20}$: 152.156. Found (high resolution mass spectrometry): 152.156.

Preparation of Carboxylic Acid 22

To a hot solution of carbethoxymethylenetriphenylphosphorane (24) (1.28 g, 3.7 mmoles) in 10 ml of ethyl acetate was added 425 mg of the allylic bromide **15** (1.84 mmoles). The resulting mixture was refluxed for 5 h, then cooled and the precipitated carbethoxymethyltriphenylphosphonium bromide (575 mg, 73%) was filtered off. The solvent was removed at water aspirator pressure, and the remaining crude product (**21**) was dissolved in 12 ml of 10% potassium hydroxide in 1:1 methanol–water, and the resulting solution was refluxed for 1 h. The reaction mixture was cooled and the methanol removed at water aspirator pressure. The basic aqueous layer was extracted with ether and then neutralized with 6 *N* hydrochloric acid. The resulting mixture was extracted with ether and the ether extract was dried over anhydrous magnesium sulfate. Removal of the ether followed by distillation of the oily residue under reduced pressure afforded 270 mg (69%) of the carboxylic acid **22** b.p. 120° (hot-box) at 0.15 mm; n_D^{20} 1.4818; i.r. (film) λ_{max} 3.1–3.9, 5.85 μ; n.m.r. τ 4.69 (broad singlet, 1H, vinyl H, $w_{\frac{1}{2}}$ = 4 Hz), 7.40 (singlet, 4H, —CH_2CH_2-CO_2H), 9.00, 9.13, 9.17 (doublets, 9H, secondary methyls).

Anal. Calcd. for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54. Found: C, 74.22; H, 10.53.

(±)-β-Cubebene Norketone (24) and (±)-1,6-Epi-β-cubebene Norketone (25)

The carboxylic acid **22** (242 mg, 1.15 mmoles) was dissolved in aqueous sodium hydroxide (1.32 mmoles), the water was evaporated under reduced pressure, and the residue was dried in a vacuum oven at 70°. A stirred suspension of the resulting dry sodium salt in 20 ml of dry benzene containing 0.02 ml of pyridine was cooled to 0° and 1.5 g (12 mmoles) of oxalyl chloride was added. The reaction mixture was stirred at 0° for 15 min, filtered, and evaporated under reduced pressure (vacuum pump). The solution was kept at 0° during this process. The crude acid chloride **23** (i.r. (film) λ_{max} 5.58 μ; n.m.r. very similar to that of the carboxylic acid **22** except at τ 7.00 (complex multiplet, 4H, —CH_2CH_2COCl)) thus obtained was taken up in 15 ml of dry ether and the resulting solution was added to excess alcohol free ethereal diazomethane which had been dried over potassium hydroxide. The solution was stirred for 15 min and evaporated under reduced pressure affording the crude diazoketone **3**, i.r. (film) λ_{max} 3.27, 4.78, 6.10 μ; n.m.r. τ 4.75 (broad singlet, 2H, vinyl H and COC*H*N_2, $w_{\frac{1}{2}}$ = 4 Hz), 7.64 (singlet, 4H, —CH_2CH_2COCHN_2). The crude diazoketone **3** was dissolved in 30 ml of cyclohexane and cupric sulfate (750 mg) was added. The resulting suspension was refluxed with stirring for 1.5 h after which time the i.r. absorption at 4.78 μ due to the diazoketone **3** had disappeared. The cooled mixture was filtered and the cyclohexane was removed at water aspirator pressure. Distillation of the oily residue under reduced pressure gave 185 mg (78%) of a pale yellow oil, b.p. 100–103° (hot-box) at 0.2 mm. This material was shown by g.l.c. analysis (column E, 190°, 90) to consist of approximately 36% of (±)-β-cubebene norketone (**24**) and 64% (±)-1,6-epi-β-cubebene norketone (**25**). Preparative g.l.c. (column D, 235°, 135) provided pure samples of **24** and **25**. Pure (±)-β-cubebene norketone (**24**) thus obtained exhibited n_D^{20} 1.4940; u.v. λ_{max} 206 mμ (ε = 6150); i.r. (film) λ_{max} 5.85 μ; n.m.r. τ 9.00, 9.05, 9.07 (doublets, 9H, secondary methyls, J = 6.5 Hz).

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.49; H, 10.74. Found: 81.79; H, 10.59.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Pure (±)-1,6-epi-β-cubebene norketone (**25**) obtained in the same manner exhibited n_D^{20} 1.4984; u.v. λ_{max} 205 mμ (ε = 6280); i.r. (film) λ_{max} 5.82 μ; n.m.r. τ 7.95 (broadened singlet, 4H $w_{\frac{1}{2}}$ = 2 Hz), 8.91 (doublet, 3H, secondary methyl, J = 7 Hz), 8.98 (poorly resolved multiplet, 6H, $CH(CH_3)_2$).

Mol. Wt. Calcd. for $C_{14}H_{22}O$: 206.166. Found (high resolution mass spectrometry): 206.167.

(±)-β-Cubebene (2)

A stirred suspension of sodium hydride (300 mg, 12.5 mmoles) in dry dimethyl sulfoxide (14 ml) was slowly heated under an atmosphere of nitrogen to 75° and kept at this temperature until frothing had ceased (approximately 30 min). The solution was cooled to room temperature and a solution of methyltriphenylphosphonium bromide (5.32 g, 14.8 mmoles) in 8 ml of dimethyl sulfoxide was added. The solution was stirred for 10 min and then a solution of (±)-β-cubebene norketone (**24**) (515 mg, 2.5 mmoles) in 15 ml of dimethyl sulfoxide was added. The reaction mixture was heated to 50° for 6 h, cooled, diluted with water, and then thoroughly extracted with hexane. The combined extracts were washed with water and brine, then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation of the residual oil under reduced pressure afforded 506 mg (99%) of **2** as a clear colorless oil, b.p. 80–82° (hot-box) at 0.2 mm. Analysis of this material by g.l.c. (column F, 170°, 90) revealed that it was only one component and it exhibited n_D^{20} 1.4975; u.v. λ_{max} 208 mμ (ε = 9850); i.r. (film) λ_{max} 3.26, 6.10, 11.72 μ; n.m.r. τ 5.28, 5.47 (unresolved multiplets, 2H, $\diagdown C{=}CH_2$), 9.04, 9.06, 9.10 (doublets, 9H, secondary methyl groups, J = 6.0, 6.5, 6.5 Hz respectively). This material exhibited spectra (u.v., i.r., n.m.r.) and g.l.c. retention times identical with those obtained from authentic β-cubebene, isolated from Oil of Cubeb, Extra (see footnote 9).

Mol. Wt. Calcd. for $C_{15}H_{24}$: 204.187. Found (high resolution mass spectrometry): 204.186.

Electron Paramagnetic Resonance Study of some Alkyl Substituted Cycloalkenyl Radicals

D. R. GEE[1] AND J. K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ontario
Received August 6, 1970

Well-resolved electron spin resonance (e.s.r.) spectra are reported and analyzed for the radicals produced when samples of solid adamantane doped with alkyl substituted cycloalkenes are γ-irradiated at room temperature.

Canadian Journal of Chemistry, 49, 20 (1971)

Introduction

Pyrolysis experiments (1) revealed the ease with which cycloalkenyl radicals can be generated by removal of one hydrogen atom from cycloalkene molecules. The radicals formed possess unusual resonance stability as no further hydrogen elimination is observed even at temperatures up to 400 °C. Ohnishi *et al.* (2) and Ayscough and Evans (3) subsequently attributed e.s.r. spectra observed following the irradiation of cycloalkene glasses to these cycloalkenyl radicals. These workers concluded that hydrogen elimination preferentially occurred from a carbon atom adjacent to the unsaturated linkage and that the radical generated was stabilized by electron delocalization on three carbon atoms.

In a successful attempt to improve the e.s.r. spectral resolution of these radicals, Helcke and Fantechi (4) generated cyclohexenyl and cycloheptenyl radicals by irradiating polycrystalline thiourea adducts of the parent hydrocarbons with fast electrons. We have recently initiated a systematic study of silver cycloalkenyl radicals in γ-irradiated silver cycloalkene complexes (5), and have extended the study to alkyl substituted olefins. However, a literature search reveals that little e.s.r. information is known about the parent alkyl substituted cycloalkenyl radicals. To extend this study to alkyl cycloalkenyl radicals we found that spectral resolution could be improved by slightly modifying the recently developed technique of Wood and co-workers (6). These workers achieved well resolved isotropic e.s.r. spectra of a series of amino radicals by selective radiation damage of aliphatic amines, deliberately added as impurities to a solid adamantane matrix.

This investigation reports a series of e.s.r. spectra originating from the paramagnetic species generated when samples of polycrystalline adamantane doped with cyclopent-1-ene, 1-methylcyclopent-1-ene, 1-ethyl-cyclopent-1-ene, 1- and 4-methyl-cyclohex-1-ene, 1-methyl-1,4-cyclohexadiene, and 1-methyl-cyclohept-1-ene are each γ-irradiated at room temperature. The factors influencing radical stability and the extent of hyperconjugation between the alkyl substituents and the π conjugated systems are discussed.

Experimental

The cycloalkenes were introduced as impurities into adamantane (Aldrich) by recrystallization of the solid using pure redistilled cycloalkenes (Aldrich) as recrystallizing solvent. Samples of the olefin-containing solids were filtered, dried, and irradiated in air at room temperature in a 19 500 curie source of 1.25 MeV ^{60}Co γ-rays. The dose rate used was approximately 1 Mrad/h and the total dose was 0.2–0.3 Mrad. Electron spin resonance spectra were obtained with an X-band Varian V4502 spectrometer using 100 kc modulation and auxiliary equipment. Microwave power and the modulation amplitude were adjusted to avoid saturation. Simulation of spectra was carried out by an IBM 360/50 computer using a modified version of a program originally made available by the Bell Telephone Laboratory.

Results and Discussion

γ-Irradiation of pure solid adamantane alone leads to a low yield of adamantyl radicals (7). However, when the adamantane samples doped with alkyl cycloalkenes are irradiated at room temperature, no adamantanyl radicals can be detected and formation of other radicals from the alkyl cycloalkene molecules is observed. These radicals probably result from some radiation chemical processes including energy transfer from

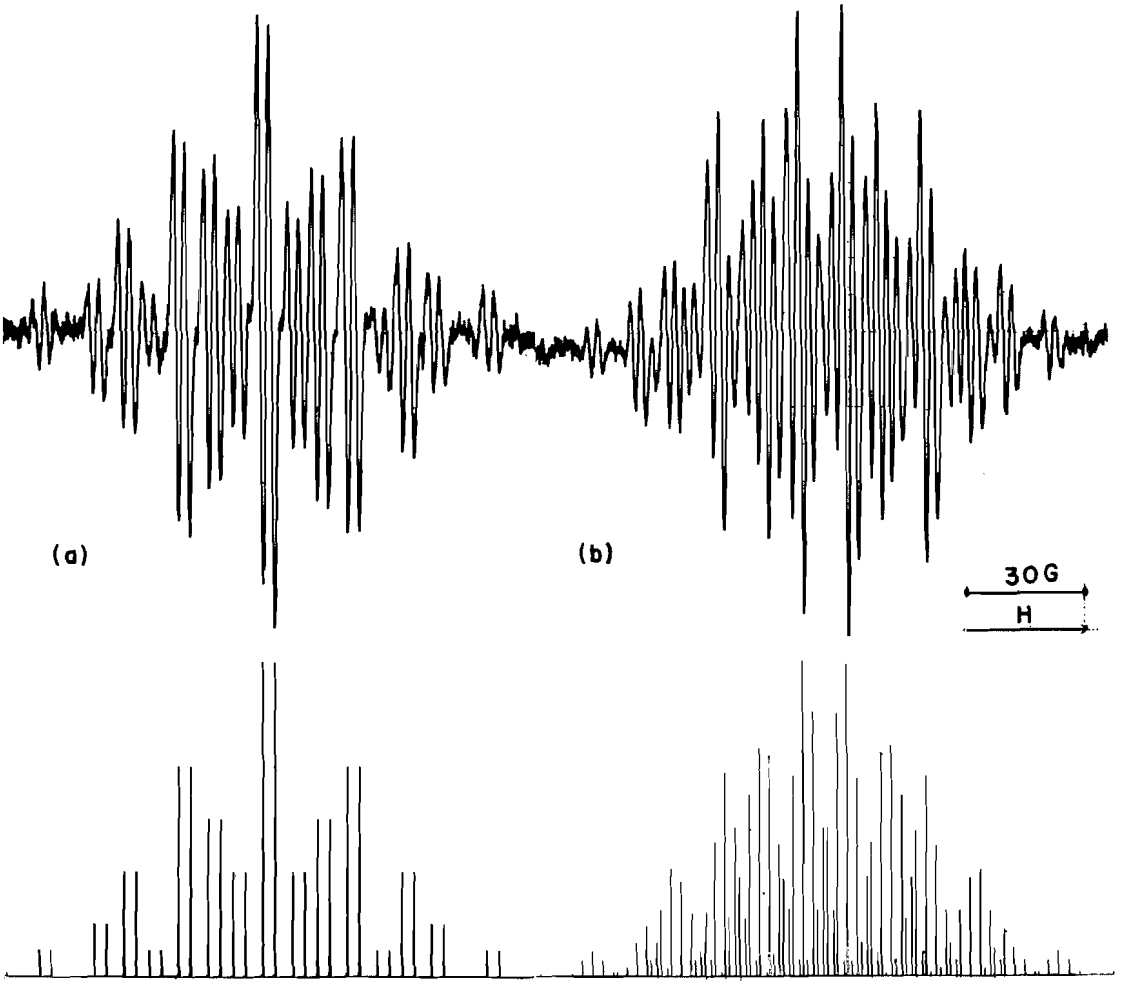

FIG. 1. Electron spin resonance spectra from free radicals trapped in an irradiated adamantane matrix (*a*) 3-cyclopentenyl radical; (*b*) 1-ethyl-3-cyclopentenyl radical.

the matrix to the cycloalkenes. Typical room temperature e.s.r. spectra of these radicals are shown in Figs. 1 to 4.

3-Cyclopentenyl Radical

The improvement of spectral resolution using the adamantane matrix trapping technique enables more accurate assignments than are possible from spectra obtained with irradiated olefin glasses (2, 8). This is demonstrated by the resolution of the small α_2 proton hyperfine splitting in the 3-cyclopentenyl radical (Fig. 1*a*). Assignments for the proton coupling constants of this radical are compared with those of Ohmae *et al.* (2) in Table 1.

Fessenden and Schuler (9) found that each methylene group adjacent to a conjugated π system tends to withdraw approximately 8% of the unpaired spin from the α carbon atoms. Hence, if a value of 0.84 is accepted for the π bonded section of the radical, the individual spin densities at each carbon may be estimated assuming a Q value of 29.6 G for each of the carbon atoms of the allylic system. For the 3-cyclopentenyl radical these calculations yield values of $\rho_{1,3} = 0.47$ and $\rho_2 = -0.1$. If these parameters are used to estimate the magnitude of the methylene proton splittings, a value of 13.8 G is obtained. The experimental coupling constant for these protons was found to be 20.0 G. Helcke and

Fantechi (4) observed a similar anomaly with the 3-cyclohexenyl and 3-cycloheptenyl radicals, which they interpreted by suggesting that although the β protons in each radical were equivalent, the rotational averaging which brings this about was not isotropic. The fact that the observed splittings are considerably larger than the isotropic values seems to indicate that the methylene protons are oriented above and below the planar conjugated π system (10, 11). The

work of Fessenden (11) predicts that the magnitude of the β splitting in such a system would indeed approximate to a value of 20 G.

1-Ethyl-3-cyclopentenyl Radical

The spectrum observed (Fig. 1*b*) when samples of adamantane doped with 1-ethyl-cyclopent-1-ene are irradiated may similarly be attributed to the corresponding 1-ethyl-3-cyclopentenyl radical using the hyperfine splitting constants presented in Table 1. A comparison of the splitting constants for this radical and those of the 3-cyclopentenyl radical reveals a decrease in the proton splitting and hence the spin densities at the α carbon atoms. Such a decrease is consistent with the observation of Fessenden and Schuler (9) that methylene groups adjacent to a conjugated π system reduce the unpaired spin density at the α carbon atoms. Since the addition of a substituent at the C_1 carbon atom renders the π conjugated system unsymmetrical, it is no longer possible to estimate accurately the spin density at each α carbon atom. In view of the fact that the proton coupling constants for the four β protons of this 1-ethyl-3-cyclopentenyl radical remain approximately the same as in the unsubstituted radical, it would seem to be reasonable that the spin densities at the C_2 and C_3 carbon positions are not drastically altered. Thus, a value of 13 ± 1 G is to be expected for the coupling constants of the methylene protons adjacent to the π conjugated system (9). The assigned splitting

*Reference 2.

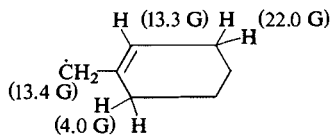
of 1.38 G for the substituent methylene protons in this radical suggests that, in contrast to the β ring protons, the averaging of these protons is essentially isotropic.

1-Methyl-cyclopentenyl Radical

A typical room temperature e.s.r. spectrum of the radical generated when 1-methyl-cyclopentene was irradiated in an adamantane matrix is shown in Fig. 2. Inspection of this spectrum reveals a predominant 1:4:6:4:1 pattern of 20 G spacing characteristic of the four β protons of 3-cycloalkenyl radicals. Spectral analysis on this basis yields the parameters of this 1-methyl cyclopentenyl radical listed in Table 1. The splitting of 14.6 G assigned for the methyl protons compares with the value of 14 ± 1 G expected for the isotropic coupling constants of methylene protons adjacent to a π conjugated system (9, 14).

1-Cyclohexene-methyl Radical

Inspection of the spectrum (Fig. 3*a*) when samples of adamantane containing 1-methyl-cyclohex-1-ene are irradiated reveals a predominant 1:2:1 splitting of 22.0 G. This contrasts with the characteristic 1:4:6:4:1 splitting of the four β protons in 3-cycloalkenyl radicals. We attribute this spectrum to the 1-cyclohexene-methyl radical with the following proton coupling constant assignments. The two β protons have a



characteristic β splitting of about 22 G (9, 12) whilst the hyperfine splittings of the substituent methylene and the α protons compare with the value of 13.8 G predicted for allylic protons (13).

4-Methyl-3-cyclohexenyl Radical

If an α hydrogen atom is removed from 4-methyl-cyclohex-1-ene, the most likely radicals to result are the 4- and 5-methyl-3-cyclohexenyl radicals. These two isomeric radicals differ as the substituents occupy respectively β and γ positions relative to the allyl system. Since interactions at γ positions are usually very small for hydrocarbons, the assignments for the hyperfine splitting constants for the 5-methyl-3-cyclohexenyl radical would be similar to those of the parent cyclohexenyl radical. Comparison of Fig. 3*b* with reported spectra assigned to the 3-cyclohexenyl radical (2–4) appears to eliminate the 5-methyl-3-cyclohexenyl radical as the species primarily responsible for the spectrum. Computer analysis of Fig. 3*b* on the basis that 4-methyl-3-cyclohexenyl radical is the predominant paramagnetic species yields the spectral parameters presented in Table 1. It appears that the addition of the methyl substituent prevents isotropic averaging of the β protons and effectively locks the β methylene groups with respect to the remainder of the radical. Hence the hyperfine splitting constants observed for the 4-methyl-3-cyclohexenyl radical compare with those quoted for the 3-cyclohexenyl radical at low temperatures (2–4). This indicates that an alkyl substituent at C_4 position does not significantly alter the unpaired spin density on the conjugated system.

1-Methyl-3-cyclohexadienyl Radical

Radiolysis studies (9, 14) on benzene and 1,4-cyclohexadiene yield spectra which have been assigned to the 3-cyclohexadienyl radical. Hence irradiation of samples containing 1-methyl-1,4-cyclohexadiene could presumably lead to formation of either 1-methyl or 2-methyl-3-cyclohexadienyl radicals, depending on the site of the hydrogen atom removal and the relative stability of the radicals formed. Since studies of 1-ethyl-cyclopent-1-ene in the adamantane matrix suggest the removal of a hydrogen atom at C_3 position, our initial attempt to interpret the

$a_{(CH_3)}$		7.85

*Taken from refs. 9 and 14.

major portion of the experimental spectrum in Fig. 4*a* was the 1-methyl-3-cyclohexadienyl radical with coupling constants listed in Table 2. By comparison with the theoretically constructed spectrum, it is conceivable that other radicals other than the 1-methyl-3-cyclohexadienyl radical may also be present.

Whiffen (15) has suggested that the methylene coupling constant of the cyclohexadienyl radical is related to the spin density at the ortho carbon atoms by the expression

$$[1] \qquad a_{(CH_2)} = Q_\beta[\rho_1^{1/2} + \rho_5^{1/2}]^2$$

where ρ_1 and ρ_5 are the spin densities at carbon atoms C_1 and C_5, respectively. Using a value of 35 G (9) for Q_β in this relationship yields a value of +0.284 for ρ_1 in the 1-methyl-3-cyclohexadienyl radical. Thus, the addition of the substituent methyl group appears to reduce the unpaired spin in the allylic system by about 6.6%. Fessenden and Schuler (9) have found a decrease of 8.1% in the spin density for each methylene group attached to the π bonded section of simple allyl radicals. These authors suggest also that the β splitting of the substituent methyl protons are related to the unpaired spin density on the adjacent α carbon atom. Using a Q value of 25.7 G in this relationship, a value of 7.3 G was derived for the methyl protons splitting in the 1-methyl-3-cyclohexadienyl radical. This compares with the experimental assignment of 7.85 G. Thus the tentative identification of this radical appears to be reasonable.

2-Methyl-3-cycloheptenyl Radical

Analysis of the observed spectrum (Fig. 4*b*) when samples of adamantane doped with 1-methyl-cyclohept-1-ene are irradiated, reveals the characteristic β proton splitting of a 3-cycloalkenyl radical (2, 4). Splitting of 13 ± 3 G expected for substituent methyl protons is however not apparent. A comparison of Fig. 4*b* with a spectrum assigned to the 3-cycloheptenyl radical (4) shows that both spectra have the same basic line structure. The hyperfine splitting of 4.5 G assigned to the C_2 protons in the 3-cycloheptenyl (4) is absent from the spectrum of the substituted radical. This seems to suggest that the predominant radical generated when adamantane containing 1-methyl-cyclohept-1-ene is irradiated is the 2-methyl-3-cycloheptenyl radical rather than the expected 1-methyl-3-cycloheptenyl radical.

The tentative assignment for this proposed radical is given in Table 1. Although the methyl substituent renders an accurate estimate of the unpaired spin density of the allylic system difficult, a comparison of the α_1 proton splitting of the substituted and parent radicals, 12.7 and 13.7 G, respectively, shows as expected a lower value for the coupling constant of the substituted radical. The hyperfine splitting of the methyl protons in the substituted radical is not resolved in the experimental spectrum. However, if free rotation of the methyl group is assumed, an estimated methyl protons coupling constant of 2 ± 0.8 G can be derived from the line width of the experimental spectrum. For the 2-methylallyl radical at low temperatures, Kochi and Krusic (16) have assigned a splitting of 3.19 G for the methyl protons. The low value is to be expected from the theoretical consideration of Nakatsuji *et al.* (17). In the absence of a quantitative assessment of the vibronic effects and the thermal motions of the cycloheptyl ring, our assignment of the methyl protons coupling constant in this tentatively identified 2-methyl-3-cycloheptenyl radical appears reasonable.

Conclusions

The predominant radicals formed when samples of solid adamantane doped with alkyl substituted cycloalkenes are irradiated at room temperature are the corresponding cycloalkenyl radicals with the α hydrogen atom removed. The reason for this is undoubtedly the high resonance stability of the allylic system. The site of the hydrogen atom removal and the relative stability of the resulted radicals are dependent upon the ring size and conformation. The major radical formed appears to be one which can most easily

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

conjugate with the unsaturated linkage to form a planar configuration.

An alkyl substituent adjacent to the allylic system reduces the total unpaired spin density of the system by about 8%. Alkyl substituents in other positions have much less influence. The extent of hyperconjugation of the substituent methylene protons is determined by the spin density on the carbon atom at which the substituent is attached. The proton coupling constant of the alkyl group of 2-alkyl cycloalkenyl radicals is much smaller than those of the corresponding 1-alkyl cycloalkenyl radicals as the singly occupied π orbital of the 2-alkyl cycloalkenyl radical has a node on the C_2 carbon atom.

The authors are indebted to Mr. L. Fabes and Professors K. E. Russell and J. A. Stone for some helpful discussions. Financial support by the National Research Council of Canada, the Defence Research Board, and the Public Health Department is gratefully acknowledged.

The Free Radical Photooximation of Alkanes by Nitrosyl Chloride[1]

MELVYN W. MOSHER
Department of Chemistry, Marshall University, Huntington, West Virginia

AND

N. J. BUNCE[2]
Department of Chemistry, University of Guelph, Guelph, Ontario

Received August 13, 1970

The mechanism of the photooximation of alkanes with nitrosyl chloride has been reinvestigated. The lack of initiation of the reaction with free radical initiators suggests that a free radical chain pathway is not involved. Nevertheless, the relative reactivities of hydrocarbons of different structure and the deuterium isotope effect are very similar to those obtained in chlorinations with elemental chlorine, and in particular, primary and tertiary hydrogens are not inert to photooximation as has been previously supposed. A probable reaction mechanism involves hydrogen abstraction from the substrate by atomic chlorine in a free radical non-chain process. This hydrogen abstraction step is shown not to be significantly reversible.

Canadian Journal of Chemistry, 49, 28 (1971)

The photooximation of alkanes with nitrosyl chloride (1, 2) has recently been the subject of intensive study (3, 4), not least because of its commercial interest (5). In particular cyclohexane may be converted in near quantitative yields to cyclohexanone oxime (6) which is used as a precursor of ε-caprolactam and ultimately nylon 6.

The mechanism of photooximation has been widely considered (7, 8) to be the free radical chain process depicted in Scheme 1.

$$\text{ClNO} \xrightarrow{h\nu} \text{Cl}\cdot + \text{NO}$$

$$\text{Cl}\cdot + \text{RH} \longrightarrow \text{HCl} + \text{R}\cdot$$

$$\text{R}\cdot + \text{ClNO} \longrightarrow \text{Cl}\cdot + \text{RNO}$$

$$\text{RNO} + \text{HCl} \longrightarrow \text{R=NOH.HCl}$$

SCHEME 1

The use of alkanes bearing hydrogens in different environments as substrates gave product ratios entirely different from those observed in free radical chlorinations using molecular chlorine. Although oximes derived from secondary hydrogens were produced almost statistically and in good yield (8), primary (other than primary benzylic) and tertiary positions appeared to be almost inert (3). Likewise alkyl chlorides (8) and aliphatic acids (9) were deactivated at the positions close to the substituent but the effect was more pronounced than that observed for abstraction by atomic chlorine (10, 11). Also, alkyl groups apparently caused steric hindrance to photooximation at nearby secondary sites (3), again in contrast with chlorinations (12). The quantum yield for the production of oximes is of the order of unity, and this, coupled with the unusual product distribution has led Müller and co-workers (3, 13) to question the free radical chain mechanism. They propose either that the reaction takes place by way of free radicals entirely within a solvent cage, or that a nitrosyl chloride molecule photo-activated with energy less than sufficient for complete dissociation is involved in a "4-centered-cage mechanism" (3). Presumably this implies some sort of vibrationally excited species or "hot" ground state. This four-centered process is proposed to be subject to severe steric restrictions and thus is explained the predominant attack at secondary carbon atoms.

The problem with a photooximation mechanism involving vibrationally excited nitrosyl chloride is that, in solution, it would be expected that the lifetime of such species would be very short. In a non-polar solvent the lifetime of vibrationally excited chlorine molecules is estimated at about 10^{-9} s (14), in good agreement with the values 2.6×10^{-9} and 1×10^{-9} s for the lifetimes of vibrationally excited liquid benzene and carbon disulfide, respectively (15). With such a short relaxation time the four-centered mechanism would have to lead to successful reaction at almost every collision if a quantum yield near unity were to be achieved; this would seem to be

[1]Presented in part at the Ninth Informal Conference on Photochemistry, Columbus, Ohio, September 1970.

unlikely in that a four-centered transition state requires a high degree of orientation of the reaction partners and this would presumably not be the case at each encounter.

The purpose of this study was to try to distinguish between the pathway involving photoexcited nitrosyl chloride molecules and a free radical mechanism. The free radical mechanism could be either a chain process (Scheme 1) or a non-chain process (Scheme 2) analogous to the course recently suggested for the mechanism of nitrosation of alkanes by *t*-butyl nitrite (16).

$$\text{ClNO} \xrightarrow{h\nu} \text{Cl}\cdot + \text{NO}$$
$$\text{Cl}\cdot + \text{RH} \longrightarrow \text{HCl} + \text{R}\cdot$$
$$\text{R}\cdot + \text{NO} \longrightarrow \text{RNO} \rightarrow \text{R=NOH}$$

SCHEME 2

Presumably it could also occur entirely within a solvent cage, when it would resemble one of the mechanisms suggested by Müller (3).

Attempts to observe free radicals directly by electron spin resonance (e.s.r.) in solutions undergoing photooximation have been unsuccessful (3); we did not attempt direct observation because the first formed nitrosation product (RNO) is itself photolabile and also gives rise to free radicals (16).

$$\text{RNO} \xrightarrow{h\nu} \text{R}\cdot + \text{NO}$$
$$\text{R}\cdot + \text{RNO} \longrightarrow \text{R}_2\text{NO}\cdot$$

Our experiments were therefore concerned with indirect methods of probing for free radical intermediates. In this paper we present new experimental data which is, we believe, compatible with a free radical mechanism in which hydrogen abstraction is by way of chlorine atoms.

Discussion and Results

In the first series of experiments, attempts were made to promote the reaction by means of free radical initiators. Of the three mechanisms being considered only the free radical chain reaction (Scheme 1) should be capable of being so initiated; successful chemical initiation would exclude an excited state of nitrosyl chloride as an intermediate.

Preliminary experiments showed that at 60° nitrosyl chloride reacts thermally with cyclohexane, cyclohexyl chloride and a little cyclohexanone oxime being produced together with very small amounts of other products. At 100° a very complex mixture is formed though these two compounds are still products. Nitrosyl chloride decomposes reversibly to chlorine and nitric oxide at a reasonable rate at these temperatures (2), as a consequence of the very weak Cl—NO bond (D(Cl—NO) = 38 kcal/mole). We suggest that the thermal reaction gives chlorocyclohexane and cyclohexanone oxime by the following course (Scheme 3).

$$\text{ClNO} \rightarrow \text{Cl}\cdot + \text{NO}$$
$$\text{Cl}\cdot + \text{ClNO} \rightarrow \text{Cl}_2 + \text{NO}$$
$$\text{Cl}\cdot + \text{RH} \rightarrow \text{HCl} + \text{R}\cdot$$
$$\text{R}\cdot + \text{Cl}_2 \rightarrow \text{RCl} + \text{Cl}\cdot$$
$$\text{R}\cdot + \text{NO} \rightarrow \text{RNO} \rightarrow \text{R=NOH}$$

SCHEME 3

When benzoyl peroxide was used as a free radical initiator no cyclohexanone oxime was produced, but 1-chloro-1-nitrosocyclohexane was obtained in addition to cyclohexyl chloride. The quantities of the two major products, however, were little more than in control experiments where the benzoyl peroxide was omitted (see Table 1). The chloronitrosocompound, found in several of these reactions, has been shown (3) to arise by the action of chlorine on the oxime. Several unidentified high boiling materials were also formed in low yield in all these reactions.

The use of azobisisobutyronitrile (AIBN) or phenylazotriphenylmethane (PAT) as initiators was somewhat more efficacious, but even here the "chain length" for the formation of the major products did not exceed unity. It was concluded that in the photochemical oximations the role of the light is not simply to serve as an initiator for a free radical chain, and that Scheme 1 must be no more than a minor reaction pathway.

Previous quantum yield studies are consistent with this conclusion. Quantum yields (for oxime formation) have been found to lie in the range 0.6–1.5 (3, 8, 13, 17). These values[3] clearly do not support a chain mechanism (though they do not exclude one) and are comparable with our "apparent chain lengths".

An important method of implicating a particular free radical as an intermediate in a free radical substitution is to study its discrimination towards hydrogen atoms in different environ-

[3]The value 1.5 has been suggested as being too high.

ments. In most studies of photooximation the reactivities of different positions in the alkane substrate have been estimated by analysis of the mixture of oximes formed, or the ketones derived from them by hydrolysis. Such determinations assume that the distribution of products reflects the distribution of the initially formed free radicals. This may not be so if the intermediates are labile as is the case for *C*-nitrosocompounds; for example, any tertiary nitrosocompound formed is presumably destroyed, being unable to give an oxime. Neither will it be the case if the products are destroyed; it has been suggested (9) that the lack of observed products from attack on primary hydrogens is a result of further reaction of the product aldoxime (*cf.* the reactivity of aldehydes towards free radicals). Lastly, reversible hydrogen abstraction may distort the distribution of the intermediate radicals initially produced; this phenomenon is well known in free radical brominations (18), and has been observed also in the photocyanation of alkanes by cyanogen chloride (19), a process at least formally analogous to photonitrosation by nitrosyl chloride.[4] The reverse of hydrogen abstraction (reaction 1) could thus modify either of Schemes 1 and 2.

[1] $$HCl + R\cdot \rightarrow RH + Cl\cdot$$

To demonstrate whether reversible hydrogen abstraction was occurring, photoinitiated reactions between nitrosyl chloride and either cyclohexane or 2,3-dimethylbutane in the presence of deuterium chloride and between nitrosyl chloride and a mixture of cyclohexane and perdeuteriocyclohexane were carried out at 0°, at which temperature the solutions of nitrosyl chloride in the alkanes were thermally stable. The alkane was recovered from the reaction mixture and analyzed by mass spectrometry for the deuterium incorporation (or scrambling) which should occur if reaction 1 is taking place (19); in every case the recovered alkane had a mass spectrum identical to that of control material, indicating that no significant degree of reversibility was involved in hydrogen abstraction. A reaction of perdeuteriocyclohexane with nitrosyl chloride in the presence of hydrogen chloride was carried out in the vapor phase to achieve a higher ratio of hydrogen chloride to nitrosyl chloride. Both the excess perdeuteriocyclohexane and the product, perdeuteriocyclohexanone oxime hydrochloride, were analyzed by nuclear magnetic resonance (n.m.r.) but no detectable increase in the amount of ^1H was found in either sample over the amount in the starting material. It would thus appear that reversible hydrogen abstraction is unimportant in photooximation and that the irregularities in the product distributions result from the lability of the first formed products.[5]

In order to obtain a reliable index of the reactivity of the nitrosation intermediate, the reactivities of different hydrocarbon substrates were obtained relative to cyclohexane. The method of relative reactivities, in which a limited amount of reagent competes for two substrates has the advantage in this case that since the disappearance of the substrates is measured, the fate of the intermediates or products is of no consequence (in the absence of reversible hydrogen abstraction). The results of this study, for a variety of alkane structures, are presented in Table 2 together with values for hydrogen abstraction by atomic chlorine for comparison. Photolyses were carried out using both tungsten lamps and a sodium vapor lamp as sources, for it has been suggested that the reaction mechanism changes according to the wavelength of the light used (3).

From an examination of Table 2 the following points may be noted. First, the discrimination of the attacking species towards the different substrates is essentially unchanged whether a sodium vapor lamp or a tungsten lamp is used. Second, the reactive intermediate displays a reactivity towards these substrates very similar to that of atomic chlorine. Third, the non-zero reactivity of tetramethylbutane and 2,3-dimethylbutane indicates that primary and tertiary hydrogens are not inert to the reagent, and we therefore conclude that atomic chlorine is at least a plausible intermediate in the reaction.

Radical reactivities are frequently reported in terms of the selectivity towards primary, secondary, and tertiary hydrogen atoms. In Table 3 are presented the selectivity data for photooxima-

[4]Abstraction of hydrogen from hydrogen chloride by an alkyl radical has also been implicated recently in the chlorination of alkanes by benzoyl hypochlorite (20) and iodobenzene dichloride (21).

[5]Müller and Trense have done similar experiments with bridgehead deuteriated bicyclic compounds (22). They found that the oximes produced had the deuterium content fully conserved. However, since Kooyman and Vegter (23) have indicated that the bridgehead positions of these alkanes are not attacked by free radicals, this observation may not be strictly relevant to this discussion.

TABLE 2. Relative reactivities of several alkanes towards nitrosyl chloride compared with chlorine

Substrate	ClNO[a,b]	ClNO[a,c]	Cl_2[a,b]	Cl_2: literature values		
Cyclohexane[d]	1.00	1.00	1.00	1.00[e]	1.00[f]	1.00[g]
Cyclooctane	1.25(1.10)[h]	1.36	1.04	—	—	—
Cyclopentane	0.81	0.75	0.73	0.83	0.86	0.78
2,3-Dimethylbutane	0.64	0.69	0.67	0.89	0.61	0.87[i]

tion, calculated from the values k(tetramethylbutane), k(cyclohexane), and k(2,3-dimethylbutane) of Table 2, again compared with the values observed for atomic chlorine at 0°. Also presented in Table 3 are values of the deuterium isotope effect for attack on saturated hydrogen by nitrosyl chloride and chlorine; both the selectivity data and the deuterium isotope effect are compatible with the attacking species being atomic chlorine.

From this conclusion follows a definite prediction of the maximum yield of oximes attainable from substrates bearing primary and tertiary, in addition to secondary hydrogens.[6] A survey of the literature using the known selectivity of the chlorine atom indicated that the maximum yield as calculated is never greater than the yield actually obtained (using the data of ref. 4), consistent with the proposed mechanism.

In conclusion, our results with the free radical initiators would seem to exclude a free radical chain mechanism as a major reaction pathway. Studies on the possible reversibility of the attack on the hydrogen atoms indicate that whatever the mechanism, this attack is not significantly reversible. The relative reactivity data, the selectivities derived therefrom, and the deuterium isotope effect are all compatible with the reactive intermediate in the reaction being the chlorine atom, indicating that primary and tertiary hydrogens are not inert to nitrosyl chloride as has been previously supposed. These observations all suggest scheme 2 as a likely course of the reaction; this non-chain free radical process is consistent with the low quantum yield for photooximation and is analogous to the recent proposal by Mackor *et al.* for photonitrosation by *t*-butyl nitrite (16). While these results do not exclude the previously proposed four-centered attack on the alkane by excited nitrosyl chloride, they do remove the necessity for postulating such an intermediate, and indicate that if this intermediate should be involved, its reactivity is comparable with that of atomic chlorine. Whether or not the reaction takes place within a solvent cage or through "free" free radicals cannot be determined on the evidence at hand.

[6]We thank a referee for suggesting this argument to us.

TABLE 3. Selectivity data and secondary deuterium isotope effect for hydrogen abstraction by nitrosyl chloride compared with chlorine, all at 0°

Reagent	Relative selectivity[a]			k_H/k_D[b]
	Primary	Secondary	Tertiary

For personal use only.

line procedures, the deuterium chloride, liberated by stirring the two reagents together for 24 h, was allowed to expand into an evacuated 2 l bulb. The product was fractionated, using a methanol slush bath (−98°) (33). The volatile material after two such fractionations was condensed into acetonitrile, which had previously been dried by the use of molecular sieve, and estimated by alkimetric titration. The hydrocarbon substrates were all commercially available, and were purified by standard procedures when necessary; their purities were ascertained to be > 99.5% by vapor phase chromatography (v.p.c.) before use; perdeuteriocyclohexane was obtained from Stohler Isotope Chemicals. The free radical initiators were available commercially, except for phenylazotriphenylmethane which was prepared by the method of Cohen and Wang (34).

Reactions were carried out in sealed evacuated Pyrex glass ampoules unless otherwise stated. The reaction mixtures to be photoinitiated were placed in a bath of melting ice and photolyzed with two 200 W tungsten lamps or a sodium vapor lamp until colorless, or nearly so. The reactions to be promoted by free radical initiators were protected from the light, and placed in a constant (±3°) temperature bath for an appropriate period. When the reactions were over, the ampoules were cooled to 77 °K and opened. Analysis was by means of v.p.c. using an appropriate column; products were identified by comparison of their v.p.c. retention times with those of authentic materials; samples were collected by preparative v.p.c. and identified by comparison of their infrared (i.r.) spectra with those of authentic samples.

Free Radical Initiated Reactions of Nitrosyl Chloride with Cyclohexane in the Dark

To samples of cyclohexane containing nitrosyl chloride and hydrogen chloride was added the free radical initiator. Control experiments were performed in which the initiator was omitted. The mixtures were degassed by the freeze–thaw method and then sealed. The reaction tubes were wrapped in foil, allowed to thaw, and placed in a constant temperature bath. The tubes were cooled to 77 °K and opened, bromobenzene added as standard and the reaction mixtures were washed once with a solution of sodium thiosulfate (1.0 *M*) to destroy any unreacted nitrosyl chloride and analyzed by v.p.c. (6 ft × ¼ in. SE-30 on 60/80 Chromosorb W programmed from 60 to 200°). The concentrations of the starting materials and the major products are reported in Table 1. Besides those listed in the table there were small amounts of unidentified high boiling materials. When AIBN was used ten such products were present, including bicyclohexyl which was isolated and identified. When PAT was the initiator seven, and with benzoyl peroxide six, such materials were present.

The reactions using benzoyl peroxide as promoter could not be carried out in the presence of hydrogen chloride because benzoyl peroxide reacts with hydrogen chloride (20). After the sodium thiosulfate treatment, these reaction mixtures were dried and the organic layer was saturated with hydrogen chloride then irradiated further, before v.p.c. analysis.

Visible Ultraviolet Spectra of Solutions of Nitrosyl Chloride with Added Hydrogen Chloride

The u.v.–visible spectrum of a solution of nitrosyl chloride in cyclohexane was obtained. The solution was then saturated with dry hydrogen chloride and the u.v.–visible spectrum redetermined. No detectable change was noted.

Nitrosation of Cyclohexane in the Presence of Deuterium Chloride

Two solutions were prepared; these contained nitrosyl chloride (1.40, 1.39 mmole), cyclohexane (1.0, 1.0 mmole), and a 1.16 *M* solution of deuterium chloride in acetonitrile (1.0, 1.0 ml). The homogeneous solutions were degassed and sealed, then irradiated at 0° until colorless. Two samples of cyclohexane were recovered from each solution by preparative v.p.c. (10 ft × ¼ in. 10% Carbowax 20 *M* on 60/80 acid-washed Chromosorb W, 70°), and analyzed by mass spectrometry. The mass spectra were identical to those of authentic samples of cyclohexane.

Nitrosation of 2,3-Dimethylbutane in the Presence of Deuterium Chloride

Two solutions were prepared; these contained nitrosyl chloride (1.36, 1.31 mmole), 2,3-dimethylbutane (1.2, 1.2 mmole), and a 1.16 *M* solution of deuterium chloride in acetonitrile (1.0, 1.0 ml). After a procedure similar to that above, it was found that the recovered hydrocarbon samples had mass spectra identical to that of authentic material.

Nitrosation of a Cyclohexane/Perdeuteriocyclohexane Mixture

(*i*) A mixture of cyclohexane (0.98 mmole) and perdeuteriocyclohexane (1.01 mmole) was saturated with nitrosyl chloride at 0°. The solution was transferred to an ampoule which was evacuated and sealed then irradiated at 0° until colorless. The alkane mixture was recovered by preparative v.p.c. (Carbowax, 100°) and analyzed by mass spectrometry. The mass spectrum was identical to that of the unreacted mixture. (*ii*) To condensed nitrosyl chloride (2.31 mmole) was added a mixture of cyclohexane (1.07 mmole) and perdeuteriocyclohexane (1.01 mmole). The above procedure was followed, but once again with similar results.

Gas Phase Photooximation of Cyclohexane in the Presence of Hydrogen Chloride

A 2 l evacuated bulb was filled with hydrogen chloride to a pressure of 228 mm Hg. The hydrogen chloride was frozen and a mixture of nitrosyl chloride and perdeuteriocyclohexane (2.18 and 23.5 mmole, respectively) was introduced. The reaction bulb was degassed, allowed to warm in the dark until the contents had vaporized, and then irradiated with one 250 W incandescent lamp placed 3 in. away, until the yellow color of nitrosyl chloride was discharged. The hydrogen chloride was now evaporated (methanol slush (33), −98°) and the residue was vacuum transferred into a small flask and methylene chloride added as a standard. The oxime hydrochloride that remained adhered to the walls of the flask was removed by washing with 1 ml of trifluoroacetic acid, then methylene chloride was added as a standard. Analysis by n.m.r. showed that no ^1H over the amount in the starting perdeuteriocyclohexane had been incorporated into either the recovered substrate or the oxime.

Competitive Nitrosation of Several Hydrocarbons

Because of the errors inherent in evaluating the rela-

tive reactivity relationship

$$k_1/k_2 = \log (RH_0/RH)/\log (SH_0/SH)$$

several determinations were made for each pair of substrates. In each case the accurately weighed solutions were prepared approximately equimolar in cyclohexane, the second alkane, and Freon 113, which served as an inert standard. To *ca.* 2 mmole of condensed nitrosyl chloride was added about twice its volume of the hydrocarbon mixture. The ampoules were evacuated, sealed, and irradiated at 0° until colorless. The original solution was analyzed by v.p.c. (13 ft × ⅛ in. 10% diisodecyl phthalate on 60/80 acid washed Chromosorb W) at an appropriate temperature and the reaction mixtures were then analyzed under identical conditions. The results obtained follow (relative to cyclohexane = 1.00). Those following "*A*" are the nitrosations carried out using nitrosyl chloride and tungsten lamps: those following "*B*" are nitrosations using a sodium vapor lamp, and those following "*C*" are the corresponding values for chlorination with elemental chlorine.

Cyclooctane: *A*: 1.03, 1.27, 1.28, 1.44; *B*: 1.34, 1.35, 1.38, 1.38; *C*: 0.99, 1.02, 1.05, 1.08.

Cyclopentane: *A*: 0.64, 0.66, 0.84, 0.93, 0.95; *B*: 0.73, 0.77, 0.73, 0.78; *C*: 0.71, 0.72, 0.74, 0.77.

2,3-Dimethylbutane: *A*: 0.56, 0.60, 0.63, 0.65, 0.67, 0.75; *B*: 0.66, 0.68, 0.69, 0.74; *C*: 0.61, 0.67, 0.68, 0.70.

2,2,3,3,-Tetramethylbutane: *A*: 0.30, 0.33, 0.34, 0.35, 0.44, 0.48, 0.53; *B*: 0.49, 0.57, 0.63, 0.66; *C*: 0.23, 0.31, 0.38, 0.40.

Bicyclo-2,2,1-heptane: *A*: 0.54, 0.54, 0.62, 0.65, 0.69, 0.71, 0.71; *B*: 0.69, 0.74, 0.84, 0.87; *C*: 0.66, 0.75, 0.76, 0.78.

Toluene: *A*: 0.21, 0.24, 0.24, 0.28, 0.29; *B*: 0.29, 0.31, 0.31, 0.36; *C*: 0.17, 0.17, 0.36, 0.48.

1-Chlorobutane: *A*: 0.24, 0.33, 0.45, 0.48, 0.52; *B*: 0.39, 0.40, 0.43, 0.57; *C*: 0.16, 0.19, 0.23, 0.25.

The deuterium isotope effect was measured by determining the relative reactivity of cyclopentane and perdeuteriocyclohexane in a similar fashion ($k(C_6D_{12}) = 1.00$).

A: 0.85, 0.92, 0.97, 1.11; *B*: 0.82, 0.90, 0.91, 0.97; *C*: 1.03, 1.02, 1.02, 1.03.

No values determined experimentally have been discarded.

We wish to thank our respective Universities and the National Research Council of Canada for financial support. We also thank Dr. D. D. Tanner and the University of Alberta for very kindly obtaining the mass spectra.

Formation, Structure, and Properties of Nitrosonium and Nitronium Fluorosulfate

A. M. QURESHI, H. A. CARTER, AND F. AUBKE[1]
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received July 27, 1970

The reactions of the nitrogen oxides, N_2O, NO, N_2O_3, $NO_2(N_2O_4)$, and N_2O_5, the oxychlorides ClNO and $ClNO_2$, and the oxyanions NO_2^- and NO_3^- with the fluorosulfonating agents $S_2O_6F_2$ and $BrOSO_2F$ are studied systematically in regard to the formation of nitrosonium and nitronium fluorosulfate. Complex reactions are found when N_2O_3 and N_2O_4 are used as substrates, resulting in mixed or impure products. An explanation involving the intermediate oxidation into N_2O_5 is put forward to explain the results.

The solid products $NOSO_3F$ and NO_2SO_3F are characterized by powder X-ray analysis, infrared and Raman spectroscopy, and their solution behavior in HSO_3F. Whereas $NOSO_3F$ has been found to have an orthorhombic lattice, NO_2SO_3F crystallizes in the monoclinic system. Unit cell parameters are reported. The vibrational spectra are interpreted in terms of ionic compounds $NO^+SO_3F^-$ and $NO_2^+SO_3F^-$. The SO_3F^- anion, however, appears to be perturbed and all the *E* modes are slightly split. No unambiguous evidence for a previously reported non-linear NO_2^+ cation is found. Force constants for this species are calculated assuming $D_{\infty h}$ symmetry.

Both compounds are found to be completely dissociated in HSO_3F as evidenced by conductometry and ^1H and ^{19}F nuclear magnetic resonance (n.m.r.) spectroscopy.

Introduction

Peroxydisulfuryl difluoride (1) $S_2O_6F_2$ and bromine(I) fluorosulfate (2, 3) $BrOSO_2F$ have been found in the past (4, 5) to be strong oxidizing and versatile fluorosulfonating agents. While studying their reactivity towards other oxidizing agents we became interested in their reactions with oxides, oxychlorides, and oxyanions of nitrogen.

Previous work has been restricted to the study of the interaction of nitric oxide NO (6, 7) and nitrogen dioxide, (6, 8), NO_2, with $S_2O_6F_2$. Whereas, in the reaction with NO, only nitrosonium fluorosulfate $NOSO_3F$ is formed, according to von Ellenrieder *et al.* (7), in a homogeneous second order reaction, there is some disagreement for the reaction with NO_2. Cady and Roberts (6) find a mixture of nitrosonium and nitronium fluorosulfate together with oxygen as reaction products when NO_2 was present in an excess, according to

$$2NO_2 + S_2O_6F_2 \rightarrow NOSO_3F + NO_2SO_3F + \tfrac{1}{2}O_2$$

The kinetic study (8) indicates a simpler reaction with the sole formation of NO_2SO_3F without oxygen release, where the dissociation of $S_2O_6F_2$ into SO_3F radicals presents the rate controlling step.

It seemed interesting to see whether departure from the gas phase reaction condition could result in a more complex course of reaction and whether an extension to other nitrogen oxides, oxyanions, and oxychlorides as substrates and to $BrOSO_2F$ as reactant would be helpful in rationalizing the findings.

The expected solid reaction products $NOSO_3F$ (9, 10) and NO_2SO_3F (10, 11) have been known for some time; however, both compounds are poorly characterized. Incomplete vibrational spectra (12, 13) are reported and only on NO_2SO_3F is the complete Raman spectrum recorded (14). The unit cell dimensions for $NOSO_3F$ have also been reported (13). Of particular interest to us was the effect of the heterocations NO^+ and NO_2^+ on the SO_3F^- anion, as reflected in the vibrational spectra.

Finally, we were interested in detailed solution studies in the parent acid HSO_3F where formation of the solvated cations NO^+ and NO_2^+ is expected. Conductometry (15) and ^1H (16) as well as ^{19}F n.m.r. should help in comparing both compounds to KSO_3F, which is known (15) to be a strong base in this solvent.

Experimental

Materials

Peroxydisulfuryl difluoride was prepared in a flow reaction of F_2 and SO_3 in an AgF_2 reactor adopted from a report by Cady and Shreeve (17). The $S_2O_6F_2$ used in some of the reactions contained small amounts of $S_2O_5F_2$, disulfuryl difluoride, as an impurity, detectable by ^{19}F n.m.r. Since $S_2O_5F_2$ is found to be inert in these reactions, no attempt at separation was made. Bromine(I) fluorosulfate was prepared as described previously (3).

Nitrous oxide, nitric oxide, and nitrogen dioxide were obtained from Matheson of Canada; the latter two were purified by trap-to trap distillation. Dinitrogen trioxide, N_2O_3, was prepared according to a published method (ref. 18, p. 487). For the preparation of N_2O_5, the method of Harris *et al.* (19) was adopted. Ozone was produced by a T-23 laboratory ozonator made by the Welsbach Corp. Nitrosyl chloride was prepared from KCl (Fisher Scientific Co.) and nitrosyl hydrogen sulfate (ref. 18, p. 511) (Columbia Organic Chemicals). Nitrylchloride was prepared by the interaction of anhydrous nitric acid (ref. 18, p. 491) with chlorosulfonic acid (Matheson, Coleman and Bell) according to Schmeisser (ref. 18, p. 513). Analytical grade KNO_3 and $NaNO_2$ were purchased from Fisher Scientific Co. Fluorosulfuric acid was obtained from Baker and Adamson Co. and purified by double distillation at atmospheric pressure (15). Potassium fluorosulfate, used as reference in the conductometric work, was prepared from KCl and HSO_3F and recrystallized from water. All volatile materials were handled in vacuum lines, equipped with Fisher and Porter teflon stem stopcocks to avoid grease contamination. The purity was checked by melting points, vapor densities, and infrared (i.r.) spectroscopy. A monel reaction vessel equipped with Whitey needle valves was used for the attempted reaction of N_2O with $S_2O_6F_2$. All solids were transferred in a dry nitrogen atmosphere (Vacuum Atmosphere Corporation Dri Lab).

Methods

For all preparations involving the oxyhalides, ClNO and $ClNO_2$, and the oxides, NO, NO_2, (N_2O_4), N_2O_3, and N_2O_5, a standard procedure was used. The reaction vessel consisted of a $\sim$ 100 ml Pyrex flask equipped with a Fisher and Porter teflon stem stopcock and a teflon coated magnetic stirring bar. Weighed amounts of the reactant were added by vacuum distillation with the reaction vessel kept at liquid nitrogen temperature, and the mixture was allowed to warm up slowly in a trichloroethylene cooling bath, initially kept at -85 °C. Reaction occurred when warming up the mixture, $S_2O_6F_2$ was found to react very vigorously with the substrate, while $BrOSO_2F$ appeared to be a milder reactant. Reaction occurred generally in the temperature range of -50 to -20 °C.

The gases non-condensable at liquid nitrogen temperature were removed first and identified mass spectrometrically. All volatile products were removed with the vessel at room temperature and subsequent gentle heating to $\sim$ 40–50 °C. The occurrence of $S_2O_5F_2$ in the volatile fraction was discovered by ^{19}F n.m.r. All steps were closely followed by weight changes.

The reactions of KNO_3 and $NaNO_2$ with $S_2O_6F_2$ were performed in $\sim$ 100 ml Pyrex reaction vessels with flat bottoms and equipped with magnetic stirring bar and Teflon stem valves. A large excess of $S_2O_6F_2$ was used. The amount of oxygen produced was measured with a Toepler pump. The reaction of $NaNO_2$ was found to be quite slow and required heating to $\sim$ 65°. The solid products formed were checked from time to time by Raman spectroscopy in order to follow the course of the reaction more closely. The occurrence of the symmetric NO_2 stretch at 1408 cm^{-1} was taken as evidence for the formation of NO_2SO_3F.

The force constants for NO_2^+ were computed by using a Fortran IV program written by Schachtschneider (46). The harmonic potential function in terms of the internal coordinates is given by the expression

$$2V = k_1\{(\Delta R_1)^2 + (\Delta R_2)^2\} + k\delta(\Delta\theta)^2 + k_{12}(\Delta R_1)(\Delta R_2)$$

where k_1 represents the force between N and O, k_{12} the interaction between the two stretchings, K_δ represents the force associated with bending, and $R_1 = R_2$ is taken to be 1.154 Å (30*b*).

Instrumentation

Infrared spectra were recorded on Perkin–Elmer 137 and 457 spectrophotometers extending the range from 4000–250 cm^{-1}. Silver chloride and KRS-5 (Harshaw Chemicals) were used with Nujol as mulling agent.

Raman spectra were obtained with a Cary 81 spectrophotometer equipped with a Spectro Physics 125 He–Ne laser. Light of 6328 Å wavelength was used at a slit width of 10 cm^{-1}. The samples were contained in flat bottom Pyrex tubes of 5 mm o.d. Proton nuclear magnetic resonance spectra were recorded on a Varian A-60 n.m.r. Spectrometer using HSO_3F as an external reference. ^{19}F n.m.r. spectra were obtained on a Varian HA-100 spectrometer. X-Ray powder photographs were obtained using a General Electric Powder Camera. The Cu–K_α radiation was filtered through nickel. Illford "Illfex" film was used for the spectra. The unit cell dimensions were calculated by least squares analysis of the powder line values using a Fortran IV program written for the IBM 7044 computer.

A Wayne-Kerr Universal Bridge No. B-221A was used for the conductometric studies. Conductivity cells and the cell constant determination have been described previously (3, 15). A Sargent Thermonitor model ST with circulating and heating unit was used in a constant temperature oil bath. The mass spectrum of the non-condensable gas was obtained with an AEI MS9 Mass Spectrometer.

Properties of $NOSO_3F$ and NO_2SO_3F

(a) Analysis

Anal. Calcd. for $NOSO_3F$: N, 9.65; F, 13.1; S, 22.1. Found: N, 9.69; F, 12.8; S, 22.5.

Anal. Calcd. for NO_2SO_3F: N, 10.85; F, 14.73; S, 24.8. Found: N, 11.1; F, 15.0; S, 25.1.

The contents of $NOSO_3F$ in mixtures of both compounds were determined by a $KMnO_4$ titration after hydrolysis.

(b) Melting Points

$NOSO_3F$, +230 °C; NO_2SO_3F, +218 °C.

(c) Densities at 25 °C

$NOSO_3F$, 2.24 (pycnometry), 2.25 (X-ray); NO_2SO_3F, 2.20 (pycnometry), 2.20 (X-ray).

(d) Powder Diagrams

The *d*-spacings together with estimated intensities are listed on the next page.

The following unit cell dimensions are found:

$NOSO_3F$: Space group *Pnma* (D_{2h}) orthorhombic, $a = 8.68 \pm 0.03$ Å, $b = 5.96 \pm 0.016$ Å, $c = 7.35 \pm 0.008$ Å, $\alpha = \beta = \gamma = 90°$, $U = 381.0$ Å^3, $Z = 4$.

NO_2SO_3F: Space group $C_1 2/c_1$ monoclinic, $a = 9.275 \pm 0.004$ Å, $b = 7.00 \pm 0.012$ Å, $c = 7.36 \pm 0.008$ Å, $\alpha = \gamma = 90°$, $\beta = 113.8°$, $U = 437.3$ Å^3, $Z = 4$.

Results and Discussion

All relevant reactions in this series are listed in Table 1. The following principal features emerge. Substitution of $S_2O_6F_2$ by $BrOSO_2F$ does not lead to a different course of the reaction. Nitric oxide, in agreement with previous work (6, 7) yields nitrosonium fluorosulfate as the sole solid product. On the other side, nitrogen pentoxide forms with both reactants the nitronium fluorosulfate only; the expected amount of oxygen is released. This reaction type has been found previously in the reaction of I_2O_5 and $S_2O_6F_2$ (20). Use of ClNO and $ClNO_2$ as substrates results in a straightforward replacement of chlorine and the formation of nitrosonium and nitronium fluorosulfate, respectively. All these reactions are good and convenient preparative routes to the fluorosulfates. The failure of N_2O to react under the conditions described is not unexpected; the chemical inertness of this species is generally recognized.

All reactions involving N_2O_3 or N_2O_4 as substrates show a greater complexity than suggested either by the kinetic study in the gas phase (8) or the reaction described by Roberts and Cady. Since the reaction of dinitrogen trioxide with $S_2O_6F_2$ should be considered as an exploratory experiment, the exact composition of the starting material was not determined prior to the reaction and contamination with N_2O_4 is a possibility. The main emphasis is placed on the N_2O_4 reactions (5–7).

When a large excess (more than 4:1) of the reactant is present, NO_2SO_3F becomes the main product and only trace amounts of $NOSO_3F$ are found. When, however, N_2O_4 is present in a small excess, formation of both $NOSO_3F$ and NO_2SO_3F in various ratios is found. The postulated ratio (6) of 1:1, however, has never been found; a typical composition is given in Table 1. Generally 10–20% $NOSO_3F$ was found in the solid product.

All reactions 4–7 show the formation of oxygen. Since $S_2O_6F_2$ has been found to be thermally very stable except for the reversible decomposition into SO_3F radicals (21, 22) a decomposition according to: $S_2O_6F_2 \rightarrow S_2O_5F_2 + \frac{1}{2}O_2$ appears under the reaction conditions not very likely. Also, the departure from gas phase behavior is not unexpected, because formation of NO_2SO_3F is found to occur by interaction of the radicals NO_2 and SO_3F (8) with the radical dissociation of $S_2O_6F_2$ as the rate determining step. The concentration of both radicals in the condensed phase should be too low to play any important role.

By analogy to the reaction of KNO_3 and $S_2O_6F_2$, formation of $NOSO_3F$ and NO_2SO_3F would be expected

$$K^+NO_3^- + S_2O_6F_2 \rightarrow KSO_3F + NO_2SO_3F + \tfrac{1}{2}O_2$$

$$NO^+NO_3^- + S_2O_6F_2 \rightarrow NOSO_3F + NO_2SO_3F + \tfrac{1}{2}O_2$$

when one regards N_2O_4 as "nitrosonium nitrate" as indicated by a large number of solvolysis reactions (24). Departure from the expected equimolar amounts can be rationalized by two main routes: (*a*) primary formation of $NOSO_3F$ and partial subsequent oxidation to NO_2SO_3F by $S_2O_6F_2$ or $BrOSO_2F$; (*b*) primary partial oxidation of N_2O_4 to N_2O_5 by $S_2O_6F_2$ or $BrSO_3F$ and then formation of NO_2SO_3F according to routes 8 and 9 of Table 1. The fact that no trace of NO_2SO_3F is found when NO is the substrate is strong evidence against possibility (*a*). The conversion of $NOSO_3F$ into NO_2SO_3F takes place only at temperatures above 70 °C as shown by reaction 14 of Table 1. The reaction of $NaNO_2$ with $S_2O_6F_2$ (17) has been found to proceed via $NOSO_3F$ as a primary

*Complete structural analysis is reported.

product, detectable by Raman spectroscopy on the incompletely reacted product, to the final product NO_2SO_3F only at $\sim$ 70 °C thus emphasizing the same point.

Therefore, the oxidation of N_2O_4 as the first step becomes a distinct possibility, supported also by reactions 6 and 7 of Table 1 where a large excess of the oxidizer reduces the amount of $NOSO_3F$ to a trace. Any previously reported nitrogen–oxygen polycations such as $N_2O_2^+$ and $N_2O_3^+$ (25) are far too unstable to play any part in the system as final products even though they may be formed as transient species.

In contrast to the conversion of $NOSO_3F$ to NO_2SO_3F which takes place only at elevated temperature, quantitative formation of $NOSO_3F$ from NO_2SO_3F is found, when NO and NO_2SO_3F react at room temperature. Both compounds $NOSO_3F$ and NO_2SO_3F melt sharply at 230 and 218°, respectively. In particular, the first figure is in disagreement with the literature values of 140 (9) and 156–7° (6). For NO_2SO_3F a value of 200 °C is reported (11). Since both fluorosulfates are very moisture sensitive requiring handling in dry nitrogen atmosphere, it seems likely that partial hydrolysis may have been responsible for the low values.

The results of the X-ray diffraction study on powdered polycrystalline samples are listed in Table 2, where a comparison is made with unit cell parameters for related compounds. Previously reported (13) values for $NOSO_3F$ are now slightly refined as done before (27) for KSO_3F (29). Both compounds are isostructural; the parameters show very good agreement and differ from the ones reported for $NOSO_3OH$ (28), which also crystallizes in the orthorhombic system. The unit cell volume of $NOSO_3F$ is, with 381.0 Å^3, slightly larger than for KSO_3F where a value of 370.0 Å^3 is found (27). Even though the interatomic distance for NO^+ (30) of 1.0619 Å is smaller than the ionic radius for K^+ with 1.33 Å according to Pauling (31), it has been argued (32) that the nitrosonium cation when in free rotation and acting as a sphere would have an effective radius of $\sim$ 1.40 Å. This is confirmed in our results and reported previously for the pairs $NOBF_4$ *vs.* KBF_4 (13) and $NOClO_4$ *vs.* $KClO_4$ (32).

On the other hand NO_2SO_3F has been found to crystallize in the monoclinic crystal system and to be isostructural with NO_2ClO_4 (33) with good agreement in the unit cell parameters. Density values derived from the X-ray data show excellent agreement with those found in a pycnometric determination.

The infrared and Raman frequencies for $NOSO_3F$ and NO_2SO_3F are listed in Table 3 together with the corresponding frequencies for KSO_3F and previously published Raman frequencies for NO_2SO_3F (14). Our Raman spectra are shown in Fig. 1. It is interesting to note that the previously reported value for ν_{NO} in $NOSO_3F$ (13) of 2377 cm^{-1} is not confirmed but appears to agree quite well with our value of the asymmetric NO_2 stretching frequency of NO_2^+ in nitronium fluorosulfate of 2390 cm^{-1}. The band contours are in both cases broad. Some minor disagreement is also found with a previous report of the Raman spectrum of KSO_3F (34). We have been unable to find a reported band at 821 cm^{-1} assigned $2\nu_6$, and we find a shoulder at 594 cm^{-1} indicating an unresolved splitting.

As can be seen clearly from Fig. 1 and Table 3, the observed number of vibrational bands does not agree with the expected ones for an unper-

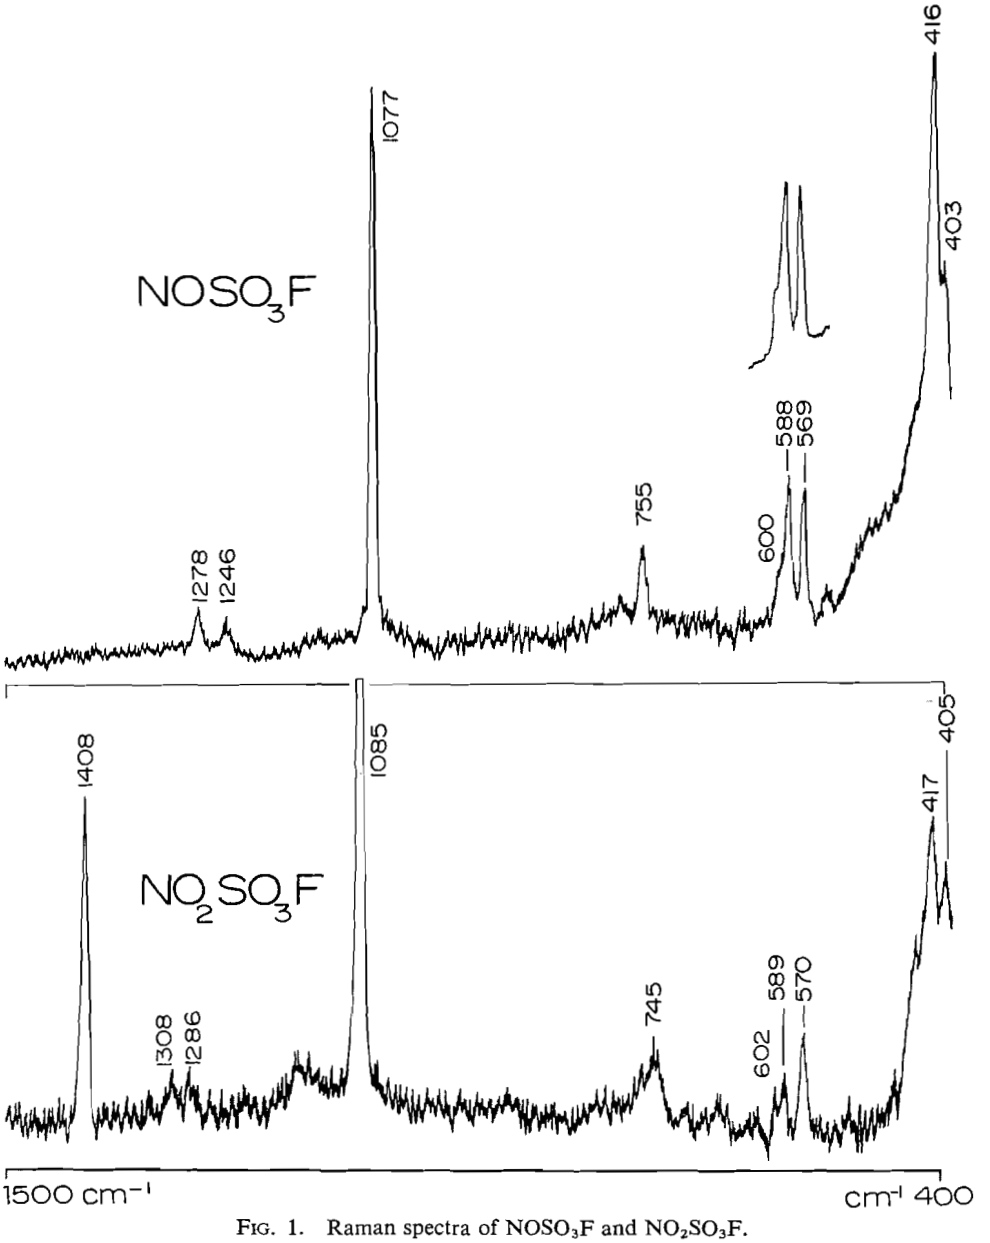

FIG. 1. Raman spectra of $NOSO_3F$ and NO_2SO_3F.

turbed SO_3F^- anion with C_{3v} symmetry. A total of six vibrational modes are expected with three A_1 and three E modes. This situation is best realized for KSO_3F where assignment of the bands is made according to previous work (29, 34–36). Perturbation of the C_{3v} symmetry, *e.g.* covalent interaction over 1 or 2 oxygen atoms will result in a symmetry lowering to C_{2v}. As a consequence all the E modes become split into two components A' and A''. Assuming that such splitting has in fact occurred one can now rationalize the observed spectra for both $NOSO_3F$ and NO_2SO_3F quite nicely. For all but one, ν_4 in $NOSO_3F$ where we were unable to resolve any splitting in the infrared spectrum, a doublet is found, both in the i.r. and the Raman spectra,

clearly visible in the well resolved Raman spectra. The peak separation is found to be between 12 and 32 cm^{-1}, by far smaller than that observed for solid fluorosulfates with bridging or terminal covalent SO_3F groups (37). The splitting of the *E* modes also appears to be slightly more pronounced for NO_2SO_3F than for $NOSO_3F$.

Our interpretation is quite different from the one presented by Vast *et al.* (14). Besides the fact that some factual disagreement exists, the SF stretching mode ν_2 is split into three components, unassigned bands at 393 and 806 cm^{-1} are observed. The following differences emerge: (*1*) except for ν_4 none of the *E* modes is split, and (*2*) a band at 587 cm^{-1} is assigned to $\nu_{2\ NO_2^+}$, which would be Raman forbidden for a linear species with $D_{\infty h}$ symmetry. The conclusion that NO_2^+ in NO_2SO_3F is not linear is mainly based on the author's assignment of the 587 cm^{-1} band. The failure to observe a complete removal of all degeneracies for SO_3F^- is inconsistent with a vibrational study of the isostructural NO_2ClO_4 (38, 39) where for NO_2^+ an ONO bond angle of 175.2 ± 1.40 is reported from X-ray diffraction (33). Here $\nu_{2\ NO_2^+}$ is found at 570 cm^{-1} and the T_d symmetry for ClO_4^- is reduced, resulting in a more complex spectrum.

The assignment for the SO_3F^- anion presented here for NO_2SO_3F seems to be more consistent and compares well with the one for $NOSO_3F$. Assignment of $\nu_{NO_2^+}$ at 601 cm^{-1} is in agreement with previous work in the compounds such as NO_2AsF_6 and NO_2SbF_6 (40) as shown in Table 4, and only in nitronium compounds as in NO_2NO_3 (41) and NO_2ClO_4 (38, 39) is a substantial lowering of $\nu_{2\ NO_2^+}$ found. However, the only substantiated case where the mutual exclusion rule for ν_2 is violated appears to be nitronium perchlorate (38, 39).

Assuming a linear configuration for NO_2^+, we have carried out force constant calculations using a program by Schachtschneider (46) on some NO_2^+ compounds. Excellent agreement between calculated and observed frequencies is observed in all cases; the results are also tabulated in Table 4 and compared to the results of previous force constant calculations on NO_2^+.

The present consistent interpretation of the vibrational spectra for $NOSO_3F$ and NO_2SO_3F, the failure to observe $\nu_{2\ NO_2^+}$ in the Raman spectrum (it may be argued that the Raman band is obscured by $\nu_{5\ SO_3F^-}$) and the good agreement between observed and calculated vibrational frequencies assuming $D_{\infty h}$ symmetry for NO_2^+, cannot be taken as unambiguous proof that this species is strictly linear in NO_2SO_3F. However, the previous claim of non-linearity (14) based on the Raman spectrum seems to be caused by a misinterpretation. A final decision will have to come from a detailed X-ray diffraction study.

The observed small splitting of the *E* modes for the SO_3F^- ion in $NOSO_3F$ and NO_2SO_3F can be explained by either a site symmetry effect or a slight polarization of the anion caused by non-spherical cations. According to Halford (47) C_s and C_2 symmetry is expected for $NOSO_3F$ and

NO_2SO_3F, respectively, but this argument should apply to KSO_3F as well, where no splitting is observed except for the weak shoulder at 594 cm^{-1}. The polarization effect appears, therefore, more likely as the cause.

The results obtained in the final part of this investigation are concerned with the solution behavior in fluorosulfuric acid. Both $NOSO_3F$ and NO_2SO_3F are extremely soluble in fluorosulfuric acid, where both behave as strong electrolytes according to

$$NOSO_3F \xrightarrow{HSO_3F} NO^+(solv) + SO_3F^-(solv)$$

$$NO_2SO_3F \xrightarrow{HSO_3F} NO_2^+(solv) + SO_3F^-(solv)$$

The specific conductivity results are shown in Table 5, together with the corresponding values for the standard KSO_3F. Small differences for the 3 solutes are explained by assuming differences in the effective ionic radii of the solvated cations resulting in different mobilities, rather than in incomplete dissociation. At higher concentrations than those normally used in conductivity studies, ^1H and ^{19}F n.m.r. provide good insight into the solution process. Production of SO_3F^- ions will result in a concentration dependent downfield ^1H shift (16) and an upfield shift for the ^{19}F n.m.r. signal. Both are observed and the results are tabulated in Table 6.

Moreover, the Raman spectrum of $NOSO_3F$ shows a strong absorption at 2320 cm^{-1} attributable to the nitrogen–oxygen stretching in NO^+. For NO_2SO_3F in fluorosulfuric acid $\nu_{1\ NO_2^+}$ is found at 1405 cm^{-1}. The observation of a ^{14}N n.m.r. signal for NO_2^+ in solution of HSO_3F has been described and discussed by us previously (48). Both solutes can be used as sources for the nitrosonium or the nitronium cation in HSO_3F, to be used in aromatic substitution reactions.

Pyrrole Chemistry. Part XI. Some Reactions of the Pyrrole Grignard Reagent with Alkyl Carbonates and Alkyl Thiocarbonates[1]

C. E. LOADER AND HUGH J. ANDERSON
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received August 5, 1970

The pyrrole Grignard reagent reacts with ethyl thiocarbonates to give good yields of ethyl 2-pyrrolethiocarboxylates.

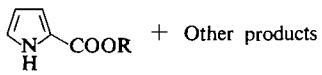
Diethyl carbonate, by contrast, in accordance with earlier reports gives almost exclusively ethyl 1-pyrrolecarboxylate.

2-Pyrrolecarbonitrile was prepared in good yield from the pyrrole Grignard reagent and ethyl thiocyanate.

Canadian Journal of Chemistry, 49, 45 (1971)

Oddo *et al.* (1) reported that the reaction of the pyrrole Grignard reagent **1** with alkyl chlorocarbonates gave very high yields of the corresponding alkyl 2-pyrrolecarboxylates **2** (eq. 1). Although this method is probably still the most convenient synthesis of 2-pyrrolecarboxylates, other workers have been unable to obtain such high yields (2). Further, the product was usually contaminated with by-products.

[1] 
1



2

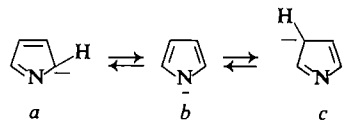
The pyrrole Grignard reagent, in common with the alkali metal salts of pyrrole, has been shown to be *N*-metallated (3). In most alkylation reactions this reagent gives predominantly the products of attack at the 2-position of the pyrrole ring. However, depending on the precise reaction conditions (*i.e.* solvents, temperature, time) and also on the alkylating agent, varying amounts of **1**, **2**, **3**, and multiple substitution may occur (4).

Because our work called for the frequent use of the pyrrole Grignard in the synthesis of pyrrole esters and thiolesters we have investigated this aspect of the reaction in some detail.

The pyrrole Grignard reagent reacts with methyl chlorocarbonate to give not only the expected methyl 2-pyrrolecarboxylate but six other products including some methyl 1-pyrrolecarboxylate and methyl 3-pyrrolecarboxylate (4).

[1]Part X. H. J. Anderson and C. W. Huang (17).

The pyrrole salts of the more electropositive metals, of lower co-ordinating ability than magnesium, such as those of sodium and potassium give largely the *N*-acylated pyrroles. The alkali salts would be expected to exist mostly in the ionic form and it seems reasonable to assume that the *N*-acylated products arise from the reaction of the pyrrole anion **3***b*. For the pyrrole Grignard reagent an equilibrium has been suggested involving the ionic **3***a–c* and the covalent **1** species (3). The covalent form would be expected to be more important in the magnesium compound and may be responsible for the differences between the reactions of this and the more ionic alkali metal salts. Hence, presumably the 2- and 3-substituted products arise from the covalent form of the reagent and the 1-substituted products from the ionic form (3).



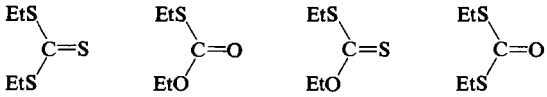
a *b* *c*

3

In the early literature there is a report that contrary to usual results of the acylation of the pyrrole Grignard reagent diethyl carbonate gave almost exclusively ethyl 1-pyrrolecarboxylate rather than the expected ethyl 2-pyrrolecarboxylate (5). We repeated the reaction using both diethyl and dimethyl carbonate and obtained the 1-pyrrolecarboxylates in about 50% yield accompanied by only a trace of the 2-pyrrolecarboxylates. The main by-product was 1,2′-dipyrrolyl ketone and not 1,1′-dipyrrolyl ketone as had been reported (5). As the 1,2′-dipyrrolyl ketone is the main product from the reaction between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

methyl 1-pyrrolecarboxylate and the pyrrole Grignard reagent it is probably formed in the same way in both reactions. Because of our interest in the synthesis of thiolesters we investigated the reaction further using thiol- and thio-carbonates



Using literature procedures (6) a series of thiol- and thio-carbonates **4**–**7** were prepared in high yields. Each of the esters was allowed to react with pyrrole Grignard reagent and the products were isolated.

Diethyl trithiocarbonate (**4**) reacted with the pyrrole Grignard reagent to give ethyl 2-pyrroledithiocarboxylate (**8***a*) (43%). There was no apparent formation of 1-substituted products.

8

a R = —CSSEt
b R = —COSEt
c R = —COOEt
d R = —CSOEt
e R = —CN
f R = —$COCH_3$
g R = —$CSNMe_2$

Diethyl thiolcarbonate (**5**) gave a mixture of ethyl 2-pyrrolethiolcarboxylate and ethyl 2-pyrrolecarboxylate. Some 1,2′-dipyrrolyl ketone was also isolated suggesting that 1-pyrrolecarboxylate or 1-pyrrolethiolcarboxylate may be formed which then undergoes further reaction to give the ketone. A trace of ethyl dithiolcarbonate was also isolated, formed by exchange between —OEt and the —SEt groups. Similarly *S*-ethyl ethyl dithiocarbonate (**6**) gave a mixture of ethyl 2-pyrroledithiocarboxylate (**8***a*) and ethyl 2-pyrrolethiocarboxylate (**8***d*) and no 1-substituted products. The symmetrical ethyl dithiolcarbonate (**7**) gave ethyl 2-pyrrolethiolcarboxylate (52%) with virtually no by-products in a very clean reaction. Most of the unused pyrrole could be recovered.

An early report (7) claimed the preparation of ethyl 2-pyrroledithiocarboxylate from the alkylation of the product from the pyrrole Grignard reagent and carbon disulfide. The b.p. disagreed with that observed for the material obtained in our work. We repeated the synthesis and obtained a small yield of a product which was identical to the ethyl 2-pyrroledithiocarboxylate obtained by us from the pyrrole Grignard reagent and ethyl trithiocarbonate, thus the reported b.p. is incorrect.

Phenyl cyanate is reported to react with the pyrrole Grignard reagent to give a poor yield of 2-pyrrolecarbonitrile (**8***e*). The readily available ethyl ester of thiocyanic acid, ethyl thiocyanate, was allowed to react with pyrrole Grignard reagent and the product was found to be 2-pyrrolecarbonitrile (50%) unchanged pyrrole and no other pyrrolic products. This reaction appears to be a useful synthesis of 2-pyrrolecarbonitrile and an improvement on other available methods. However, phenyl thiocyanate gave only a trace of 2-pyrrolecarbonitrile and a large amount of diphenyl disulfide. This is in keeping with the observations of Gronowitz and Hakansson on the reaction of phenyl thiocyanate with alkyl lithium and Grignard reagents (9).

Bean has reported that the acylation of the pyrrole Grignard reagent with ethyl acetate gave only 2-acetylpyrrole (**8***f*) whereas acetyl chloride and acetic anhydride acylate the reagent both in the 2- and 3-positions (10). In a reaction with ethyl thiolacetate the pyrrole Grignard reagent gave only 2-acetylpyrrole. Contamination by 3-acetylpyrrole was negligible as shown by g.l.c. of the crude product, and the yield of pure product was considerably higher than was obtained using ethyl acetate.

Dimethylthiocarbamyl chloride acylated the pyrrole Grignard reagent in the 2-position to give *N*,*N*-dimethyl-2-pyrrolethiocarbamide (**8***g*) in a clean reaction. Again there was no formation of 1-substituted products.

Spectra

The p.m.r. (Table 1) of the methylene group resonances in the *S*-ethyl thiolesters and the dithioesters appears at about 1.3 τ to high field of the *O*-ethyl methylene resonance in esters due to the greater shielding effect of the sulfur atom. The resonances of the ring protons in the thiolesters are closely similar both in shape and chemical shifts to those reported earlier for methyl 2-pyrrolecarboxylate and were quite different to those found in either 1- or 3-pyrrolecarboxylates (11).

Some i.r. spectral data are recorded in the Experimental section.

The 'abnormal' behavior of the alkyl carbon-

ates in their reaction with the pyrrole Grignard reagent offers a useful route to the 1-pyrrolecarboxylates. However, the selectivity of the attack at the 1-position by the alkyl carbonates cannot be extended to the thiol- and thio-carbonates. This appears to stem from differences in the reactivity of the esters. In general the more reactive the acylating agent the less selectivity there is in the attack on the pyrrole Grignard reagent. The alkyl carbonates appear to react only with the pyrrole anion **3***a* whereas the more reactive thiolcarbonates and other common acylating agents are able to react with the undissociated, covalent form of the pyrrole Grignard reagent **1** as well as with the anion **3**.

We are continuing our studies on the preparation and properties of pyrrole thiol- and thiocarboxylates with particular interest in their synthetic uses. Some other aspects of this reaction will be discussed in the next part in this series.

Experimental

Melting points were taken on a Fisher–Johns m.p. block, and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer 237B spectrophotometer. Mass spectra were recorded on a Hitachi Perkin–Elmer RMU 6E instrument. The p.m.r. spectra were determined on a Varian A-60 spectrometer at 60 MHz. The chemical shifts are in p.p.m. from TMS as an internal standard in $CDCl_3$ unless specified otherwise, and are recorded on the τ scale. Gas chromatograms were run on a Beckman GC-2A chromatograph equipped with a 13½″ column (No. 70008) packed with Apiezon L on fire brick at temperatures between 130 and 220° with helium as the carrier gas. Elemental analyses were determined by Alfred Bernhardt, Mülheim (Ruhr), Germany. Petroleum refers to the fraction b.p. 60–80° unless otherwise stated.

Reaction of Alkyl Carbonates and Alkyl Thiol- and Thiocarbonates with the Pyrrole Grignard Reagent

Dimethyl Carbonate

Dimethyl carbonate (45 g, 1/2 mole) in ether (40 ml) was added dropwise to a stirred solution of pyrrole Grignard reagent (1/2 mole) in ether (180 ml) cooled in an ice bath. The solution turned green and a thick oil was precipitated. The mixture was stirred for 2 h and then allowed to warm to room temperature and stand overnight. The mixture solidified into a thick semi-solid gel. The magnesium complex was decomposed by slow addition of water and then of 2 *N* HCl until a clear mixture was obtained. The organic layer was separated and the aqueous layer was extracted with ether. The organic layer and the ether extracts were combined, washed with water, sodium bicarbonate solution, again with water, and finally dried ($MgSO_4$). The ether was evaporated and the residual liquid was distilled under reduced pressure to give methyl 1-pyrrolecarboxylate, b.p. 55–59°/14 mm, lit. 57–59°/14 mm (12) (26 g, 42%). Some pyrrole (8 g) was recovered in the low boiling fractions. If only 0.25 mole of the dimethyl carbonate were used in the reaction and the mixture was refluxed after the addition, 1,2′-dipyrrolyl ketone was obtained as a major by-product.

In a typical experiment the yields were 1,2′-dipyrrolyl ketone (8 g), m.p. 58–60°, lit. 58.5–60° (11), methyl 1-pyrrolecarboxylate (10.9 g), and recovered pyrrole (5.5 g).

Diethyl Carbonate

Using the same method described above ethyl 1-pyrrolecarboxylate (46%) was obtained together with a trace of 1,2′-dipyrrolyl ketone (~1%). In this case the intermediate magnesium complex did not solidify.

The following experiments were conducted in the same way as the preceding experiment unless otherwise stated using a 100% excess of the pyrrole Grignard reagent in each reaction.

S-Ethyl Ethyl Dithiocarbonate

After the addition of the *S*-ethyl dithiocarbonate the reaction mixture was refluxed for 20 min. The crude product consisted of a mixture of ethyl 2-pyrroledithiocarboxylate and ethyl 2-pyrrolethiocarboxylate in about equal amounts (p.m.r. spectrum). The products were separated by fractional distillation and fractional crystallization from petroleum cooled in a solid CO_2/acetone mixture. The overall yield of products amounted to 39% consisting of ethyl 2-pyrrolethiocarboxylate (15%), b.p. 104–105°/0.2 mm, as a yellow oil; ν_{max}(film) *inter alia* 3375 (N—H str.), 3100 (C—H str.), 2970–2850 (C—H str.), 1541 (C=C str.), and 1220 (O—C str.).

The yields in this reaction were deceptively low because of the difficulties associated with separating the two products.

Ethyl Thiolcarbonate

The reaction products consisted of about equal parts of ethyl 2-pyrrolethiolcarboxylate and ethyl 2-pyrrolecarboxylate along with traces of 1,2′-dipyrrolyl ketone and 2,2′-dipyrrolyl ketone as indicated by g.l.c. and comparison with authentic samples. Some diethyl carbonate was also present in the reaction products, presumably arising from an exchange reaction of the ethyl thiolcarbonate.

Ethyl Dithiolcarbonate

Ethyl 2-pyrrolethiolcarboxylate was obtained in 62% yield (52% after recrystallization from petroleum) m.p. 28–30°, lit. m.p. 29–29.5° (13). Traces of 1,2′- and 2,2′-dipyrrolyl ketone were also detected in the reaction products (g.l.c.). Repeating the reaction using equimolar amounts of pyrrole Grignard reagent and the dithiolcarbonate the yield fell to 29%.

Ethyl Trithiocarbonate

After the addition of the ethyl trithiocarbonate the mixture was refluxed for 20 min. Ethyl 2-pyrroledithiolcarboxylate (43%) was obtained from the reaction products as a yellow oil, b.p. 119–120°/0.4 mm.

2-Pyrrolecarbonitrile

Ethyl thiocyanate (8.7 g) in ether (15 ml) was added to a stirred solution of the pyrrole Grignard reagent (0.2 mole) in ether (90 ml). The solution warmed up and eventually began to reflux. A green oily precipitate formed and fouled the stirrer blade as it became increasingly solid. The mixture was refluxed for 2 h on a steam bath and then allowed to stand at room temperature overnight. The solid complex was then hydrolyzed with 10% ammonium chloride solution (40 ml) and 2 *N* sulfuric acid (20 ml) and the ether layer was separated. The aqueous layer was extracted with ether and the ether extracts were combined with the ether layer, washed well with water, and dried ($MgSO_4$). The ether was then removed and the liquid residue was fractionally distilled. The fraction b.p. 112–115°/14 mm was 2-pyrrolecarbonitrile (4.6 g, 50%). Literature b.p. 89–90°/1.5 mm (14) identical with authentic material. The low boiling material was unchanged pyrrole and ethyl thiocyanate.

Substitution of phenyl thiocyanate for ethyl thiocyanate in the reaction gave only a trace of 2-pyrrolecarbonitrile. The main product was diphenyl disulfide, m.p. 61°, lit. m.p. 61° (15).

2-Acetylpyrrole

Using the method described by Bean for the preparation of 2-acetylpyrrole from the pyrrole Grignard reagent and ethyl acetate the pyrrole Grignard reagent was reacted with ethyl thiolacetate. The g.l.c. of the dry crude ether extract indicated the absence of the 1-acetyl- and 3-acetyl pyrrole. Distillation of products gave 2-acetylpyrrole in 31% yield, m.p. 88–89°, lit. m.p. 90° (16).

N,N-Dimethyl-2-pyrrolethiocarbamide

Under the same conditions as were used in the preparation of ethyl 2-pyrrolethiolcarboxylate the pyrrole Grignard reagent reacted with dimethylthiocarbamyl chloride to give *N,N*-dimethyl-2-pyrrolethiocarbamide (38%), m.p. 100–100.5°.

Studies of the Hot Water Extractives of the Bark and Leaves of *Populus deltoides* Bartr.[1,2]

IRWIN A. PEARL AND STEPHEN F. DARLING
The Institute of Paper Chemistry, Appleton, Wisconsin 54911

Received May 12, 1970

The hot water extractives of the fresh smooth green bark and the fresh leaves of a *Populus deltoides* Bartr. tree cut in June and processed by the Waring Blendor technique in ethanol were extracted fractionally with ethyl acetate, and the individual ethyl acetate extracts were fractionated by elution chromatography with water, 20% ethanol, and 50% ethanol on polyamide columns. Important components found in the bark were salicortin, salicin, salicyl alcohol, pyrocatechol, ω-salicyloylsalicin, grandidentatin, grandidentoside, populoside, trichocarposide, and 6-methyldihydroquercetin. Important components found in the leaves were salicortin, salicin, salicyl alcohol, pyrocatechol, 1-*O*-*p*-coumaroyl-β-D-glucoside, populoside, ω-salicyloylsalicin, chrysin-7-glucoside, and a new glucoside, deltoidin, which has been identified as 2-*O*-salicyloylsalicin.

Canadian Journal of Chemistry, 49, 49 (1971)

Introduction

In our continuing investigations on the components of the barks and leaves of *Populus* species, fresh smooth green bark and leaves of a *P. deltoides* Bartr. tree cut in Outagamie County, Wisconsin in June were extracted immediately with ethanol by the Waring Blendor technique (1). The hot water-soluble portions of the ethanol extractives were extracted fractionally with ethyl acetate, and the ethyl acetate-soluble fractions were chromatographed on columns of polyamide and eluted with water followed by 20% ethanol and 50% ethanol as employed in recent studies on the barks of other species (1, 2). As in previous studies, all eluate fractions were monitored by means of t.l.c., concentrated to small volumes, allowed to stand, filtered if crystals separated, and finally freeze dried. Weights of all fractions and of separated crystals were noted, and elution curves were obtained.

Results

Fractional ethyl acetate extraction of the hot water extractives representing 900 g of ovendry bark solids yielded 4.9% of first extract (A) and 1.7% of second extract (B). Similarly, extraction of the hot water extractives representing 700 g of ovendry leaf solids yielded 5.2% of first extract (A) and 2.4% of second extract (B), all on the dry basis.

Data for the polyamide chromatograms of the two ethyl acetate fractions of the bark and leaves are presented in Figs. 1 and 2. The weights noted in these figures are actual weights obtained experimentally from the sample aliquots applied to the polyamide column 50 mm in diameter and 80 cm in length. Major components under the peaks are noted on the figures.

The crystalline compounds noted in the elution curves of Figs. 1 and 2 were identified as described in previous papers as follows: salicin (3), salicortin (1), grandidentatin (4), grandidentoside (5), populoside (5), trichocarposide (6), ω-salicyloylsalicin (7) and 1-*O*-*p*-coumaroyl-β-D-glucose (8). Salicyl alcohol and pyrocatechol were identified under the peaks noted in Figs. 1 and 2 by t.l.c. (9).

Identification of 6-Methyldihydroquercetin

The crystals obtained upon concentration of fractions 126–128 of Fig. 1A were identified as 6-methyldihydroquercetin as follows: the specific color reactions (10) and carbon and hydrogen analyses correspond with the proposed formula. The compound was converted to the corresponding flavonol by a procedure well known to convert dihydroflavonols into flavonols (11). The resulting flavonol exhibited melting point, carbon and hydrogen analysis, and u.v. spectral analysis (10) identical in every respect with those reported for 6-methylquercetin, a flavonol which has been isolated only once (12). Unfortunately, the original authors could not supply us with an authentic sample.

Identification of Chrysin-7-glucoside

The pale yellow crystals which separated from

the concentrated fractions 126 and 127 of Fig. 2A were identified as chrysin-7-glucoside in the following manner. Acid hydrolysis gave 1 mol of chrysin and 1 mol of glucose, and carbon and hydrogen analysis corresponded with a chrysin monoglucoside. Since there are only two possible monoglucosides of chrysin, the identity of the melting point of the new glucoside and that of its acetate with melting points reported for chrysin-7-glucoside and its acetate, respectively (13), together with the fact that the properties of the only other possible compound, chrysin-5-glucoside, are entirely different (14), prove that the new glucoside is chrysin-7-glucoside.

Isolation and Identification of Deltoidin

Recrystallization from dilute ethanol of the crystals which separated from fractions 89–99 of Fig. 2B yielded colorless needles melting at 220–221°. Alkaline hydrolysis yielded salicin and salicylic acid, and analysis indicated a monosalicylic acid ester of salicin. Mass spectrometry of its acetate demonstrated that salicylic acid substitution was on the glucose moiety and suggested 2-*O*-glucose substitution (15). Thus, deltoidin is 2-*O*-salicyloylsalicin or 2-hydroxybenzyl 2-*O*-(2-hydroxybenzoyl)-β-D-glucopyranoside.

Discussion

The data of Figs. 1 and 2 demonstrate the effectiveness of the fractional ethyl acetate extraction technique in preliminary fractionation of the hot water-soluble materials so that crystalline materials can be recovered in relatively pure state from subsequent polyamide chromatography. The data further show that the recovery of crystalline products represented a comparatively small proportion of the total products recovered from the chromatograms. The t.l.c. of filtrates from the crystals noted in Figs. 1 and 2 in all instances indicated more of the specific compound together with one or more components, some in substantial amount. Further fractionations will be necessary to separate these components in order to obtain crystalline compounds for identification.

Salicortin and salicin were the components present in greatest amount in both the bark and the leaves of *P. deltoides*, and each represented several percent of the weight of the dry organs. Although all of these components did not separate from the fractions under the first large peak in all the elution curves, t.l.c. indicated that these fractions comprised essentially only these two components with only traces of other products. If desired, crystalline products could be obtained by chromatography on silica gel as described previously (1).

The yield of crystalline populoside (ω-caffeoylsalicin) obtained from eluate fractions 99–125 of Fig. 2A amounted to almost ½% of the dry leaves. As noted in Fig. 2A, the crystals in each fraction also represented a majority of the weight of each fraction. Thus, it appears that *P. deltoides* leaves are the best available source for this interesting caffeic acid ester of salicin, since it has been found previously only in small quantities in the bark of *P. grandidentata* (16) and the bark of *P. balsamifera* (2).

The spectrum of components found in the barks and leaves of the cottonwood *P. deltoides* Bartr. in the *Aigeiros* section of the *Populus* genus (17) resembles closely the components previously isolated from *P. grandidentata* Michx. in the *Leuce* section (16), whereas marked differences are apparent with the components from the cottonwood *P. trichocarpa* Torr. and Gray and its related *P. balsamifera* L. in the *Tacamahaca* section of the *Populus* genus (2, 6, 9, 18–22).

Although 6-methylquercetin has been isolated from Ponderosa pine bark (*Pinus ponderosa* Laws.) by Kurth *et al.* (12) and named pinoquercetin, its dihydro derivative has not been reported previously. Thus, 6-methyldihydroquercetin is dihydropinoquercetin or 6-methyltaxifolin.

Chrysin-7-glucoside has been isolated from *Prunus aequinoctialis* by Hasegawa (13) who named it aequinoctin and reported a melting point of 245°. The compound was synthesized by Hattori and Shimokoriyama (14) who reported a melting point of 205–210°. Our finding of preliminary congealing at 208–210° with final melting at 244–245° suggests that Hasegawa ignored the preliminary shrinking, and Hattori and Shimokoriyama reported the congealing at 205–210° as the melting point. The present work confirms the identity of the two previously reported compounds.

The acetate of deltoidin was prepared in the usual manner and subjected to mass spectrometry. The major and important peaks of the mass spectrum with their relative intensities are noted in the Experimental. Although deltoidin pentaacetate is an isomer of the acetate of ω-salicyloylsalicin, the mass spectra of the two compounds are entirely different (15). Deltoidin

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

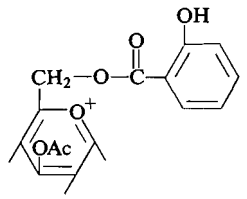
pentaacetate does not give the prominent peak at *m/e* 331, which is characteristic of the acetates of all glucosides without glucose moiety substitution (15). Instead of *m/e* 331 and related *m/e* 271 and 211 peaks due to loss of acetic acids from the unsubstituted glucose acetate moiety, deltoidin pentaacetate exhibited a major peak at *m/e* 451 corresponding with an acetylsalicyloyl ester of triacetylglucoseoxonium ion, and demonstrating that salicyloyl substitution in deltoidin is on the glucose moiety.

In an earlier study on the mass spectrometry of phenolic glucosides (15) it was demonstrated that the acetates of phenolic glucosides with aroyl substitution on the 6-*O*-glucose position gave much greater yields of ions corresponding with the loss of two acetic acids and one ketene than did the acetates of those with aroyl substitution on the 2-*O*-glucose position. In the case of monobenzoates of salicin and of ω-salicyloylsalicin, the ion involved was that at *m/e* 231, and the relative intensities were 19.2 and 1.0 for 6-*O*-benzoylsalicin and 2-*O*-benzoylsalicin, respectively, and 38.1 and 1.2 for 6-*O*-benzoyl-ω-salicyloylsalicin and 2-*O*-benzoyl-ω-salicyloylsalicin, respectively. In the mass spectrum of deltoidin pentaacetate, the corresponding peak is that at *m/e* 247. Its relative intensity of 2 suggests 2-*O* substitution on the glucose moiety. It should be noted that these considerations include the assumption that the choice of substitution is only between the 2-*O* and 6-*O* positions on the glucose, since no other type of glucose substitution has been found in naturally occurring phenolic glucosides.

The major fragmentation pattern of deltoidin pentaacetate is pictured in Scheme 1 which accounts for the important peaks in the mass spectrum.

In the fragmentation pattern of Scheme 1 the *m/e* 289 ion derived from the salicyloyltriacetylglucoseoxonium ion *m/e* 409 by loss of two acetic acids is fragmented further by loss of ketene, salicylic acid, and carbon monoxide to give ions *m/e* 247, 109, and 81, respectively, in accordance with the schemes of Biemann *et al.* (23) and Smale and Waight (24). If salicyloyl substitution were on the 6-*O* position of the glucose moiety of deltoidin, loss of two acetic acids from the *m/e* 409 ion could form only the *m/e* 289 ion pictured in Fig. 3.

The ion of Fig. 3 cannot yield an *m/e* 247 ion which can be fragmented further to give the well-known *m/e* 109 and 81 ions as noted in Scheme 1. Although it is entirely possible that the *m/e* 289 ion of Fig. 3 is an end product of fragmentation and that the *m/e* 247 and related ions of the mass spectrum of deltoidin pentaacetate are formed in accordance with a different fragmentation pattern, the fragmentation pattern as noted in Scheme 1 confirms the choice of 2-*O* substitution for the salicyloyl group in deltoidin. Thus, even though not established unequivocally, mass spectrometry suggests that deltoidin is 2-hydroxybenzyl 2-*O*-salicyloyl-β-D-glucopyranoside.



m/e 289

FIG. 3. The *m/e* 289 ion derivable from 2-hydroxybenzyl 6-*O*-salicyloyl-β-D-glucopyranoside.

Experimental

Preliminary Processing of Bark and Leaves

Fresh smooth green bark peeled from the small branches of a 6-year old *Populus deltoides* Bartr. tree cut in Outagamie County, Wisconsin on June 12, 1969 was processed within a few hours after cutting by the Waring Blendor technique (1). A total of 2000 g of fresh bark containing 900 g of oven-dry solids was processed in four equal batches to yield the starting water extractives. In similar manner, the fresh leaves from the same tree were processed at the same time. A total of 2000 g of fresh leaves containing 700 g of oven-dry solids was processed in four equal batches. The actual amounts of ethyl acetate extractives applied to the columns are noted in the results portion.

Isolation and Identification of 6-Methyldihydroquercetin

Upon concentration to small volumes under reduced pressure, eluate fractions 126–128 of Fig. 1A deposited 0.15 g of almost colorless needle rosettes which were recrystallized from ethyl acetate – petroleum ether to give colorless rosettes, melting at 194–195°, $[\alpha]_D^{25}$ + 7.42° (c = 1.3 in 95% ethanol).

Anal. Calcd. for $C_{16}H_{14}O_7$: C, 60.38; H, 4.43. Found: C, 60.37, 60.14; H, 4.43, 4.40.

Color reactions and u.v. spectral analysis (10) indicated a dihydroflavonol with dihydroquercetin type substitution.

Conversion to 6-Methylquercetin

A solution of 40 mg of the dihydroflavonol and 2 g of sodium bisulfite in 10 ml of water containing a little ethanol was boiled under reflux 45 min in accordance with the procedure employed by Kurth (11) for converting dihydroquercetin to quercetin. After cooling, the

mixture was filtered to yield 21 mg of fine yellow needles, melting at 290–291°.

Anal. Calcd. for $C_{16}H_{12}O_7$: C, 60.76; H, 3.82. Found: C, 60.42, 60.59; H, 3.87, 3.88.

Color reactions and u.v. spectral analysis (10) indicated a flavonol with quercetin type substitution.

Isolation and Identification of Chrysin-7-glucoside

When concentrated, the eluate fractions 126 and 127 of Fig. 2A deposited a total of 0.45 g of pale yellow crystals which were recrystallized from dilute ethanol to give fine, pale yellow needles, melting at 244–245° (after preliminary shrinking at 208–210°).

Hydrolysis with Acid

The pale yellow crystals were hydrolyzed by boiling 5 h under reflux with 3 *N* hydrochloric acid in 20% ethanol. The mixture was cooled and filtered to give yellow needles of chrysin, melting at 282–283° and i.r. absorption spectrum identical with that of authentic chrysin (purchased from Aldrich Chemical Co., Inc., Milwaukee, Wisconsin).

Glucose was identified in the filtrate by paper chromatography.

Chrysin-7-glucoside Pentaacetate

The chrysin glucoside was acetylated with acetic anhydride in pyridine, and the product was recrystallized from 95% ethanol to yield colorless needles, melting at 197–198°, identical with that reported for chrysin-7-glucoside pentaacetate by Hasegawa (13).

Anal. Calcd. for $C_{31}H_{30}O_{14}\cdot H_2O$: C, 57.76; H, 4.81. Found: C, 57.82, 58.02; H, 4.75, 4.77.

Isolation and Identification of Deltoidin

Eluate fractions 89 through 99 of Fig. 2B, upon concentration, deposited a total of 21 mg of colorless crystals which were recrystallized from 50% ethanol to yield colorless needles, melting at 220–221°.

Anal. Calcd. for $C_{20}H_{22}O_9$: C, 59.11; H, 5.46. Found: C, 59.05; H, 5.47.

Deltoidin fluoresces strongly under u.v. and gives a flesh-colored spot on paper when sprayed with DPNA.

Deltoidin was heated 30 min with excess *N* sodium hydroxide solution, and the mixture was cooled, acidified with dilute hydrochloric acid, and extracted with ether. Salicylic acid was identified in the ether extract by paper chromatography and spraying with ferric chloride reagent. Salicin was identified in the aqueous raffinate by t.l.c. on silica gel with 4:1 chloroform–methanol and spraying with sulfuric acid (7).

Deltoidin Pentaacetate

Deltoidin was acetylated with acetic anhydride and pyridine, and the product was recrystallized from ethanol to yield deltoidin pentaacetate as colorless crystals, melting at 140–142°, and having the following major and important *m/e* peaks in its mass spectrum: 43(43), 81(5), 109(10), 120(11), 121(65), 163(100), 169(9), 201(2), 246(2), 247(2), 289(5), 409(1), 451(13), 514(< 1), and 556(< 1).

Mass Spectrum

The mass spectrum was made on a double-focusing Hitachi RMU-6D instrument by direct introduction of the sample with a probe at 180° in the ionizing beam.

Infrared Spectra

The i.r. spectra were obtained with a Perkin–Elmer Model 621 grating i.r. spectrophotometer. Potassium bromide pellets were prepared by hand-grinding with sample before pressing.

The i.r. absorption spectra were determined by Mr. Lowell Sell of The Institute of Paper Chemistry. The mass spectrum was determined by Morgan-Schaffer Corp., Montreal, Quebec. Analyses were performed by Micro-Tech Laboratories, Skokie, Illinois. The authors wish to thank Mrs. Charlotte Robbins for her help in the processing and analytical monitoring required in this investigation.

The Transmission of Substituent Effects in Transition Metal Complexes

D. R. EATON AND K. L. CHUA
Department of Chemistry, McMaster University, Hamilton, Ontario

Received June 18, 1970

The effect of ligand substitution on bonding to other ligands has been investigated in a series of V(III) complexes. Nuclear magnetic resonance (n.m.r.) contact shifts have been utilized for this purpose. These shifts are interpreted as arising from metal to ligand charge transfer. The results obtained are contrary to those expected from simple considerations of the electron withdrawing or donating abilities of the substituents. Electron withdrawing substituents decrease the charge transfer to the substituted ligand and increase the charge transfer to the remaining ligands. Electron donating substituents have the opposite effect. A simple interpretation is proposed to account for these results. An electron withdrawing substituent on a ligand in the *xy* plane increases the occupancy of d_{xy} which cannot interact with the π system of the ligand in the *xy* plane but which is available for π bonding with the remaining ligands. Effects of this type are to be anticipated whenever the filling of the t_{2g} orbitals is not symmetrical.

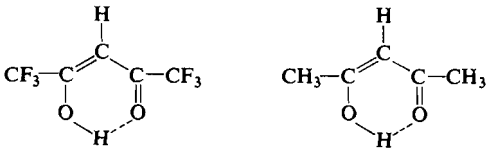
Canadian Journal of Chemistry, **49**, 56 (1971)

Introduction

The nature of the bonding in transition metal complexes has been the subject of extensive investigations. A subsection of this field deals with the effect of changes in the structure of one ligand on the bonding to another ligand. The aspect of this latter area which has received the most attention has been the so called "*trans* effect" particularly as it applies to square planar complexes (1). Examples of similar effects in octahedral complexes have also been reported (2) but have been less well documented. The detailed interpretation of the *trans* effect is still to some extent an open question, but in any event a selective transmission of electronic effects through the central metal atom is involved. Our interest in this area derives mainly from a concern with the mechanisms of homogeneous catalysis and of ligand exchange reactions. It is a common finding in this area that rather small changes in the structure of ligands not directly involved in the reaction can considerably change the reaction rates. There is a temptation to try and rationalize results in terms of the concepts of electron withdrawing and donating substituents and of inductive and resonance effects made popular by the organic chemists. In many cases this procedure is less than satisfying. We therefore thought it desirable to undertake some studies aimed at elucidating the details of the transmission of electronic effects in metal complexes. We have in mind here a rather more general phenomenon than the *trans* effect, since changes in one ligand must influence to a greater or a lesser extent the bonding to all other ligands. The work described in the present paper represents one approach to this problem.

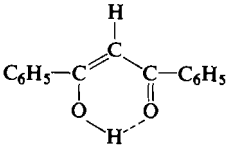
The n.m.r. spectra of paramagnetic complexes, when interpretable, offer a very convenient method of studying metal ligand bonding (3). In favorable cases admixture of metal and ligand orbitals leads to delocalization of the unpaired electrons and this is manifested in the form of "contact" shifts of the resonances of ligand protons or other magnetic nuclei. This method can be very sensitive since rather small spin densities give rise to substantial shifts and, for this reason, is particularly suitable for studying the type of problem outlined above. Our choice of system was dictated by some practical limitations of the method. Sharp n.m.r. resonances are only observed if the electron spin relaxation time is short. Vanadium(III) complexes fulfil this condition very well (4). Since we wish to study systems involving a mixture of ligands a multiplicity of resonances is expected and the basic ligand system should therefore be as simple as possible if unambiguous analyses of the spectra are to be made. We have therefore used acetylacetone and simple substituted acetylacetones as ligands. Fortunately data on the effect of substituents on the chelating properties of acetylacetone is available in the literature. Van Uitert *et al.* (5) have measured the pK_d values of a variety of β-diketones and have also measured the formation constants of a large number of β-diketone metal chelates (6). Lintvedt and Holtzclaw (7) have complemented this data with a study of the proton chemical shifts on the enolic protons of β-diketones and have discussed their results in terms of the electron donating or withdrawing abilities of the substituent. In both cases it was concluded that the extreme in electron

withdrawing properties of the compounds examined is exhibited by the hexafluoro-derivative (**1**) and in electron donating properties by the 1,3-diphenyl derivative (**3**) with acetylacetone (**2**) being intermediate.



1

2



3

Thus the pK_d values of these compounds are 6.0, 12.7, and 13.75, respectively. Recently Lintvedt and Kernitsky (8) have complemented these results with a spectroscopic study leading to similar conclusions. We have therefore chosen to investigate the bonding in mixed complexes involving these three ligands. By using mixed complexes the effect of a substituent on bonding to other ligands can be studied.

Results

The proton magnetic resonance spectrum of tris-(acetylacetonato)vanadium(III) has been reported previously (4, 9, 10). It has also been shown that ligand exchange is relatively fast for a number of β-diketone complexes (11, 12). This is also true for the V(III) compounds. Thus if increasing amounts of hexafluoroacetylacetone are added to a solution in chloroform-*d* of V(III) acetylacetonate a series of n.m.r. spectra are obtained which clearly show lines due to mixed chelates. A typical spectrum is shown in Fig. 1. The resonances due to the original compound gradually disappear and a variety of new lines appear. This result must be attributed to ligand exchange according to the equation

$$V(acac)_3 \underset{acac}{\overset{hfac}{\rightleftharpoons}} V(acac)_2(hfac) \underset{acac}{\overset{hfac}{\rightleftharpoons}} V(acac)(hfac)_2 \underset{acac}{\overset{hfac}{\rightleftharpoons}} V(hfac)_3$$

where acac = acetylacetone; hfac = hexafluoroacetylacetone. Resonance lines at the same frequencies can be obtained either by starting with $V(hfac)_3$ and adding acac or by mixing solutions of $V(acac)_3$ and $V(hfac)_3$. For all these exchange reactions equilibrium appears to have been attained in the time between mixing the solutions and examining in the n.m.r. spectrometer (3 or 4 min). There is however no significant additional broadening of the n.m.r. lines such as would be anticipated if exchange rates were comparable to chemical shifts differences. The lifetime of the mixed complexes therefore lies in the range 10^{-1} to 10^2 s.

The spectrum obtained by mixing equimolar solutions of $V(acac)_3$ and $V(hfac)_3$ is shown in Fig. 2. It may be noted that the lines due to the symmetric chelates are not visible. It appears from this that the equilibrium distribution of ligands is not statistical but that the mixed complexes are favored at the expense of the pure complexes. This result is consistent with the observations of Adams and Larsen (12) and of Pinnavaia and Fay (11) on similar mixed ligand complexes of Zr, Hf, Ce, and Th. Assignments of lines to the individual mixed complexes have been made on the basis of their relative intensities in the various mixtures. Thus on the stepwise addition of hfac to $V(acac)_3$ the two strong lines which appear initially are assigned to the two chemical distinct CH_3 groups in $V(acac)_2(hfac)$. Weaker new lines are assigned to the C—H groups of this compound. On further addition of hfac these lines diminish in intensity and a new set of lines attributable to $V(acac)(hfac)_2$ appears. Finally with a large excess of hfac a single resonance at the correct position for $V(hfac)_3$ is observed. Data on the ^{19}F resonance spectrum was obtained in a similar manner and the resulting assignments for this system are summarized in Table 1. Similar experiments have been carried out with mixtures of $V(acac)_3$ and the diphenyl ligand **3**. In this case the tris chelate cannot be prepared and addition of a rather large excess of the ligand gives no resonances which cannot be assigned to mixed chelates. The separation of the resonances from the different chelates is rather smaller in this case. A spectrum is shown in Fig. 3 and the results are summarized in Table 2. Finally, to complete the series mixtures of $V(hfac)_3$ and diphenyl ligand have been examined and the results are shown in Table 3.

*Both slope and intercept refer to $\Delta\nu$ vs. $1/T$ plot. Unit of slope is Hz °K, and intercept, Hz.

The temperature dependence of these spectra has also been examined since it has significance to the discussion below. It is found in all cases that the shifts of the n.m.r. frequencies relative to the diamagnetic ligands vary linearly with $1/T$. Some typical plots are shown in Fig. 4. These plots, however, do not pass through the origin. It must be concluded that the shifts cannot be described by a simple Curie law formula. The deviation however is not large. Values for the slopes of these plots, giving a measure of the contact contribution, and of the intercepts, giving a measure of the temperature independent contribution, are shown in Table 4.

The most noteworthy feature of these results is the large effect of ligand substitution on the chemical shifts of other ligands. Thus replacement of CH_3 by CF_3 on one ligand changes the

chemical shifts of the protons on the remaining ligands by 400–800 Hz. Substitution of a second ligand increases the effect to 900–1500 Hz. The direction of the shifts depends on the nature of the substituent. CF_3 substitution increases the shifts of the protons on other ligands, phenyl substitution decreases these shifts. Thus we obviously have a rather sensitive empirical method for studying the transmission of substituent effects through transition metal ions. It would be desirable, however, to interpret these results in terms related to the bonding in the complexes.

Discussion

In order to discuss the present results it is necessary to consider the theory of the d^2 configuration in a little more detail. We first note that in $V(acac)_3$ a trigonal distortion reduces the symmetry from O_h to D_3 splitting the t_{2g} orbital into e and a_1. It is not immediately apparent which of the latter two orbitals will be lower. If e is below a_1 the ground state configuration e^2 gives rise to a $^3A_2$ lower state. If a_1 is below e the resulting a_1e configuration results in a ^3E ground state. At first sight the orbitally degenerate ^3E state appears to offer the more attractive explanation of the observed asymmetric distribution of spin in the mixed chelates. Lin and Orgel (13) have considered a very similar problem of spin distribution in distorted d^8 tetrahedral complexes and devised an elegant explanation based on an orbitally degenerate ground state. A rather minimal modification will adopt this theory to distorted octahedral d^2 complexes. Unfortunately the distorted tetrahedral d^8 complexes which have been examined appear to have non-degenerate ground states (14) and the weight of evidence seems to favor a similar conclusion for the present d^2 complexes.

The main evidence for this latter conclusion is provided by the temperature dependence of the magnetic susceptibility reported in the literature and of the isotropic hyperfine shifts reported in the present paper. Van Vleck (15) first pointed out that if in a situation such as this, the ground state is orbitally degenerate, considerable deviation from Curie law behavior is to be anticipated. All the V(III) distorted octahedral complexes for which susceptibility data have been reported obey the Curie law rather closely. Vanadium alum has been examined most thoroughly (16). At room temperature it has a moment of 2.80 B.M., very close to the spin only value, and departs from Curie law only at very low temperatures. Detailed analysis of the data fits the theory with the inclusion of spin–orbit coupling very well and leaves little doubt that the ground state is $^3A_2$ (17). A value of 2000 cm^{-1} is obtained for the splitting due to the trigonal distortion. $V(acac)_3$ has been examined over the temperature range 80–300 °K (16). It obeys Curie law very well with $\mu = 2.80$ B.M. and a Weiss constant θ of only 2 °C. In fact it appears that the trigonal splitting of many V(III) complexes is very similar and Van Vleck (15) suggests that it may always have a common origin in the Jahn–Teller effect. In any event it seems that the ground state of $V(acac)_3$ must be orbitally non-degenerate. The temperature dependence of the isotropic n.m.r. shifts should parallel that of the magnetic susceptibility. From the plots of Fig. 4 it is apparent that the behavior of the mixed complexes parallels that of $V(acac)_3$ rather closely. It does not seem feasible that there has been any dramatic change in the nature of the ground state on forming mixed chelates, since in each case the shifts vary linearly with $1/T$. The shifts will reflect the behavior of the magnetic susceptibility regardless of their exact origin.

At this point it is perhaps appropriate to briefly review the possibility of a pseudo-contact origin (18) for these shifts. Such an explanation has previously been rejected by all the groups who have examined this problem, but it could be contended that the effect might become important in the mixed chelates because of the lower symmetry and hence larger anisotropy of the g values. We do not favor this possibility but it is difficult to eliminate it entirely. Several authors (17, 19, 20) have calculated the g values expected for a trigonally distorted d^2 complex with an orbitally non-degenerate ground state and some experimental data are available (21). We quote the results of MacFarlane (20) on vanadium corundum as being fairly typical. He found $g_\parallel = 1.919$, $g_\perp = 1.791$, *i.e.*, $\Delta g = 0.12$. For comparison Δg for Co(II) trispyrazolylborate (22), which represents a well established case where pseudo contact effects dominate (23), is 7.5. Thus other things being equal, we can very roughly estimate the expected pseudo-contact contribution to the $V(acac)_3$ shifts as 2% of the observed shifts of Co(II) trispyrazolylborate, *i.e.*, 40–100 c.p.s. at 60 Mc/s. Since there is no evidence that the excited states which determine the g values are signifi-

For personal use only.

cantly lower in energy in the mixed chelates than in $V(acac)_3$ (if they were it should be reflected in an anomalous temperature dependence of the susceptibility and shifts), we conclude that pseudo-contact interactions are unlikely to account for the large effects observed. Further experimental evidence for this conclusion is provided by the relatively small shifts of the phenyl protons in all the phenyl substituted compounds. These also show the characteristic alternation of signs for ortho, meta, and para expected for spin density in the π system but inconsistent with the geometrical dependence of pseudo-contact shifts.

Thus we shall assume that the observed shifts are predominantly contact in origin and arise from delocalization of spin in the π system of the ligand. As such they are determined by the two equations

$$[1] \qquad \frac{\Delta H_i}{H} = \frac{\Delta \nu_i}{\nu} = -a_i \frac{\gamma_e}{\gamma_N} \frac{g\beta S(S+1)}{6S'kT}$$

and

$$[2] \qquad a_i = Q\rho_c$$

In these equations ΔH_i and $\Delta \nu_i$ are the differences due to the paramagnetism in the resonance field or frequency of the nucleus i at applied field H or frequency ν, respectively; a_i is the hyperfine coupling constant of nucleus i; S is the total electron spin and S' the total spin of those unpaired electrons involved in delocalization. In the present case $S' = S = 1$. The hyperfine coupling constants a_i are related to the spin densities in the carbon pπ orbitals (ρ_c) by eq. 2 where Q is approximately constant and equal to -22.5 G for a single aromatic proton and $+27$ G for a methyl group. The other symbols have their usual significance. Thus the problem of interpreting the shifts is reduced to one of calculating the spin densities ρ_c. There are still two possibilities since the spin may reach the ligand by ligand to metal charge transfer, in which case the top bonding ligand π orbital is relevant or by metal to ligand charge transfer which will involve the bottom antibonding π^* orbital. We quote the results of the McLachlan type calculations of Röhrscheid *et al.* (10) for the spin densities in these orbitals since these are the most recent: highest energy π orbital: $\rho_\alpha = \rho_\gamma = +0.0705$, $\rho_\beta = +0.5680$; lowest energy π^* orbital: $\rho_\alpha = \rho_\gamma = +0.5598$, $\rho_\beta = -0.1659$. These results, in conjunction with eqs. 1 and 2, lead to the conclusion that the major delocalization mechanism involves metal-to-ligand charge transfer. It has previously been shown that this type of interpretation gives a consistent picture of the bonding in all the first row transition metal acetylacetonates (4).

Let us now consider the form of the spin containing orbitals in a little more detail. If the complex had O_h symmetry these orbitals would be d_{xy}, d_{xz}, and d_{yz} mixed with a small amount of the appropriate ligand π^* orbitals. The situation for a symmetrical tris chelate has been considered by Orgel (24). The symmetry is reduced to D_3 and without π bonding the orbitals are: a_1, $(1/\sqrt{3})(d_{xy} + d_{xz} + d_{yz})$; e, $(1/\sqrt{2})(d_{xz} - d_{yz})$, $(1/\sqrt{6})(2\,d_{xy} - d_{xz} - d_{yz})$. The ligand π orbitals can be classified as either ψ or χ depending on whether they are symmetric (ψ) or antisymmetric (χ) with respect to reflection in a plane perpendicular to the ligand π system. Examination of the orbitals resulting from a Hückel calculation on the acetylacetonate ligand shows that the highest energy π orbital is ψ and the lowest energy π^* orbital is χ. Orgel (24) has given the correct combinations of these π orbitals which combine with the a_1 and e d orbitals. We note for the present that if the ground state of the complex is orbitally non-degenerate, as we have argued above, the e orbital is doubly occupied and the a_1 orbital unoccupied leading to a symmetrical distribution of the electron spin.

In the mixed chelates in addition to the trigonal distortion mentioned above we must also consider a tetragonal distortion. It is convenient to first consider the case where the tetragonal distortion is very much larger than the trigonal distortion and to let the unique ligand occupy the xy plane. The appropriate symmetry is C_{2v} and the correct d orbitals are: a_1, d_{xy}; a_2, $(1/\sqrt{2})(d_{xz} + d_{yz})$; b_1, $(1/\sqrt{2})(d_{xz} - d_{yz})$. The case corresponds to that of a *cis* complex MA_4B_2 for which crystal field theory shows that the splitting of the orbitals is half as great as for the corresponding *trans* complex with the level order inverted (25). Thus if the ligand in the xy plane provides a larger crystal field than the other ligands, d_{xy} will be the unoccupied orbital and the odd electrons will be concentrated in the xz and yz planes. This will be the case for an electron donating substituent. On the other hand, with an electron attracting substituent, d_{xy} will be the lowest lying orbital and there will be a greater charge density in the xy plane than in xz or yz.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Consider now the case involving both the trigonal and the tetragonal distortion. C_2 symmetry is conserved and there are two orbitals of a symmetry and one of b symmetry. They correlate with the limiting C_{2v} and D_3 cases as follows

$$\begin{array}{lll} D_3 & C_2 & C_{2v} \\ e \rightarrow & a + b & a \leftarrow a_1 \\ a_1 \rightarrow & a & a \leftarrow a_2 \\ & & b \leftarrow b_1 \end{array}$$

Thus in all cases the unfilled orbital will be of a symmetry and separated from the next lower orbital by an energy large compared with kT as is shown by the Curie law dependence of the shifts. It will, however, vary in character according to the nature of the substituents. If the three chelating ligands are equivalent it will have the form $(1/\sqrt{3})(d_{xy} + d_{xz} + d_{yz})$ *i.e.*, it will have an equal contribution from each d orbital. In the extreme of a very large tetragonal distortion in which the odd ligand provides a strong crystal field the unfilled orbital will be d_{xy}. In the opposite extreme it will be $(1/\sqrt{2})(d_{xz} + d_{yz})$. For intermediate cases either d_{xy} or d_{xz} and d_{yz} will predominate depending on whether the odd ligand provides a stronger or a weaker crystal field than the other two ligands. The second a orbital will always be half-filled and its character will vary in a manner which is complementary to that of the empty orbital. In general the empty orbital will have the form

$$a\, d_{xy} + (\sqrt{1 - a^2}/2)(d_{xz} + d_{yz})$$

and the half-filled orbital the form

$$\sqrt{1 - a^2}\, d_{xy} - (a/\sqrt{2})(d_{xz} + d_{yz})$$

Thus $a = 1$ corresponds to an extreme electron donating substituent, $a = 0$ to an extreme electron withdrawing substituent, and $a = 1/\sqrt{3}$ to the symmetrical case. The parameter a is therefore a measure of the donating or withdrawing properties of the substituent.

In Table 5 matrix elements for the interaction of the various d orbitals in C_2 symmetry with the ligand π orbitals of ψ and χ symmetry are tabulated. If it is assumed that the spin-containing orbitals are predominantly d in character, the coefficients of the ligand orbitals will, by simple perturbation theory, be proportional to these matrix elements. The relative amounts of spin delocalized in the bottom antibonding π-orbital to the different ligands are given in Table 6 for the cases where the ligand A bears either an extreme electron withdrawing or an extreme electron donating substituent. Thus it is predicted that an electron withdrawing substituent such as CF_3 in the compound $V(acac)_2hfac$ should increase the contact shifts of the acac ligands relative to $V(acac)_3$ and decrease those of the hfac ligand relative to $V(hfac)_3$. This is indeed the case. On the other hand, the CH_3 in $V(acac)_2hfac$ may be regarded as an electron donating substituent relative to the hfac and it is predicted that the single (acac) ligand will obtain a disproportionately large share of the spin density. This again agrees with experiment. The arguments for the diphenyl ligand are reversed but entirely analogous.

This interpretation neglects ligand-to-metal charge transfer which it had previously been inferred was less important. In fact if the unfilled orbital in a D_3 complex has a_1 symmetry and if the top filled π orbital of acac has ψ symmetry, ligand-to-metal charge transfer of an α spin cannot occur. In the unsymmetrical chelates it becomes allowed and possibly would have to be taken into account in a quantitative interpretation of the data. It might also be noted that the above model predicts different shifts for the two non-equivalent methyl groups of $V(acac)_2hfac$

since d_{xy} interacts with the $p\pi$ orbitals of the carbonyl groups adjacent to one set of CH_3's and d_{xz} and d_{yz} with the carbonyl groups adjacent to the other set. The splitting of the methyl groups is therefore also a measure of the assymmetry of charge distribution.

These results therefore lead to a consistent picture for the transmission of electronic substituent effects in these octahedral metal complexes. At first sight the experimental results appear to be contrary to the expected substituent effects. Electron attracting substituents such as CF_3 diminish the charge transferred to the substituted ligand and enhance delocalization to the remaining ligands. Electron donating substituents have the opposite effect. However, this result follows naturally from the geometry of the spin containing d_{xy}, d_{xz}, and d_{yz} orbitals. An electron attracting substituent on a ligand in the xy plane tends to concentrate electron density in this plane since d_{xy} is most favorably oriented with respect to the substituted ligand. Electron density in d_{xy} is not available for delocalization to the π system of the ligand in the xy plane for reasons of symmetry but is available to the other two ligands. An electron donating substituent has the opposite effect. The important parameter is the charge density on the oxygen, a conclusion identical to that reached by Lintvedt and Kernitsky (8) from spectroscopic studies of substituent effects. It is interesting to note that these results provide another example of a recurring theme in transition metal bonding, namely the movement of charge in opposite directions in the σ and π bonding systems. The particular mechanism discussed above can, however, only operate for a limited number of d electron configurations since the possibility of an asymmetric distribution of the d electrons is required, the t_{2g} orbitals should not be either filled or half-filled.

We have not attempted to evaluate the mixing parameter a from our experimental results since the theory involves a number of obvious approximations. In particular consideration of only π interactions is a doubtful assumption. We do, however, intend to extend these studies of mixed chelates to include other substituted acetylacetonates and related ligands with the objective of developing at least an empirical scale of substituent effects. Preliminary results in this area are entirely consistent with the results of the present paper.

Experimental

V(III) trisacetylacetonate was obtained from the Research Organic/Inorganic Chemical Co., acetylacetone from Fisher Scientific, hexafluoroacetylacetone from Penninsular Chem. Research Inc., and 1,3-diphenyl-1,3-propanedione from Eastman Organic Chemicals. V(III) trishexafluoroacetylacetonate was prepared by a method analogous to that described by Morris *et al.* (26) for the corresponding aluminum compound.

Vanadium trichloride and hexafluoroacetylacetone dissolved in carbon tetrachloride, were refluxed into dry nitrogen for 45 min. The resulting solution was filtered into nitrogen while hot and the filtrate allowed to cool after which the solvent was removed by vacuum evaporation. The resulting reddish brown solid was purified by recrystallization from carbon tetrachloride. The final product had m.p. 76 °C and was characterized by the single contact shifted resonances in both the H and ^{19}F n.m.r. spectra.

Proton spectra were obtained on a Varian DP 60 instrument using TMS internal reference. ^{19}F spectra were obtained similarly with $CFCl_3$ internal reference. ^{19}F spectra were obtained at 56.4 Mc/s and the shifts converted to 60 Mc/s for comparison with the proton shifts.

All n.m.r. samples were carefully prepared in a dry nitrogen atmosphere. These V(III) complexes oxidize easily to V(IV) and this is manifested in the n.m.r. spectra by excessive broadening of the lines. The n.m.r. line width which is 20–30 c.p.s. in fact provides quite a sensitive probe for the sample purity.

We are indebted to the National Research Council of Canada for financial support of this research.

Temperature Dependence of the Diffusion of Carbon Tetrachloride, Chloroform, and Methylene Chloride Vapors in Air by a Rate of Evaporation Method[1]

HARRY WATTS
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received June 8, 1970

The diffusion coefficients in air of carbon tetrachloride, chloroform, and methylene chloride have been measured over a temperature range from room temperature to close to their boiling points by a modified rate of evaporation method. It was shown that considerable error can occur in diffusion coefficients determined by the rate of evaporation method when gas imperfections are ignored.

Canadian Journal of Chemistry, 49, 67 (1971)

Introduction

Many motives, relating both to the results, and the experimental methods used in obtaining them, prompted the measurements presented in this paper.

Data on the diffusion of chlorinated hydrocarbons through air at elevated temperatures are of value in assessing hazards associated with the use of commercial solvent systems. Recently, Lugg (1) published a monumental investigation of diffusion of 147 compounds in air at 25 °C, which included measurements on several halogenated hydrocarbons. Measurements on chlorinated hydrocarbons at other temperatures appear to be non-existent. The values plotted by McGovern (2) were calculated from theory.

An earlier variation (3) of the rate of evaporation method for determination of vapor diffusion coefficients seemed eminently suitable for adaptation to high temperature operation. Evaluation of this method at high temperatures has been made.

Measurements of diffusion coefficients in a Ney and Armistead type diffusion cell revealed a small, but statistically significant difference between the results of duplicate experiments made in two different diffusion cells (4). The present experiments were designed to enable further investigation of this effect.

In calculation of results of vapor diffusion measurements almost all previous authors have ignored gas imperfections and assumed that the saturated vapor concentration is proportional to the vapor pressure of the liquid. A test of the validity of this assumption seemed desirable and was made.

[1]Contribution No. 180.

Experimental

Materials

Carbon tetrachloride was purified as described previously (5).

Chloroform was treated as described by Francis and McGlashan (6). Gas chromatographic (g.c.) analysis revealed the following impurities: 1,1-dichloroethane, 60 p.p.m.; carbon tetrachloride, 100 p.p.m. Ethanol (100 p.p.m.) was added to inhibit aerial oxidation of the chloroform to phosgene.

Methylene chloride was selected from the production of Dow Chemical of Canada, Limited. The g.c. analysis showed the following impurities: methyl chloride, 50 p.p.m.; chloroform, 80 p.p.m.; vinylidene chloride, 10 p.p.m.

Apparatus

Figure 1 shows a diffusion cell. It consists of a Swagelok reducing union (Crawford Fitting Company) A, drilled to allow a length of Veridia precision bore capillary B to pass through it into a glass bulb C of volume 5 cc. The tube and bulb are sealed in place by Teflon ferrules D. Tubes used in these experiments had internal diameters of 0.200 ± 0.001 and 0.300 ± 0.001 cm and lengths in the range 3–6 cm. The liquid E under study was placed in the bulb to a level just below the lower end of capillary, B. This method of mounting the capillary, which allows interchange of capillaries of different size, constitutes an improvement over earlier cell design (3).

Six cells were suspended in a container as shown in Fig. 2. The glass container, A, was fitted with a perspex lid, B, sealed with a greased O-ring, C. A perspex tube, D, was sealed to the lid, B, to allow an extension hook, E, from an analytical balance to pass into the container. The cells, F, were suspended by wire hooks from six spokes radiating from a rotatable rod, H. For clarity, only two cells are shown. Manipulation of H enabled each cell in turn to be suspended from E and weighed. The outer end of tube D was sealed with a rubber serum cap which was removed during weighing of the cells. A dry air stream was preheated to thermostat temperature by passage through a copper coil immersed in the thermostat and passed through A to flush vapor that had diffused from the cells. This air stream enters at K and exits at L.

Procedure

Cells were filled with the liquid under investigation and the cell assembly was placed in the thermostat. Diffusion

was allowed to proceed overnight to permit steady state conditions to be attained. Each cell was then weighed at the beginning and end of an appropriate measured time interval. Observations were made for two consecutive intervals to ensure that steady state conditions had in fact been obtained. The time was usually between 8 h and 3 days and depended on the nature of the liquid and the temperature. The barometric pressure was recorded at intervals during the experiment and averaged. The thermostat temperature was measured with a quartz thermometer (Hewlett–Packard Company). The total pressure and temperature fluctuations during an experiment were about 2 mm of mercury and 0.02 °K, respectively.

Calculation of Results

The diffusion coefficient of a vapor through air in a rate of evaporation experiment is calculated (7) using the expression

$$[1] \qquad \mathscr{D} = (WL)/(MAct \ln[c/(c - c_s)])$$

In eq. 1, W is the weight of liquid of molecular weight M evaporated in time t, c_s is the saturation concentration of vapor in the air space at the liquid surface while c is the total concentration of air plus vapor, L and A are the length and cross-sectional area of the diffusion path, respectively, and $\mathscr{D}$ is the diffusion coefficient. In the conventional rate of evaporation method the liquid is contained in the bottom of a vertical tube of uniform bore; the same tube thus serves as liquid container and defined diffusion path. Under these conditions L changes with time as the liquid evaporates and appropriate allowance must be made. In the present experimental modification since the diffusion path is a capillary tube the lower end of which protrudes into the vapor space above liquid contained in a bulb, the diffusion path L does not change during the course of an experiment. The apparatus thus resembles a Ney and Armistead type (8) two bulb diffusion cell with one bulb (the atmosphere outside the cell) of infinite size. Thus, as in the Ney and Armistead experiment, it is appropriate to adjust the tube length L for end effects to give an effective length L_{eff}, given by

$$[2] \qquad L_{eff} = L + 0.82d$$

where d is the diameter of the tube.

The assumption of ideality of the air–vapor mixture has been made, almost without exception, by previous workers, who have put

$$[3] \qquad c/(c - c_s) = P/(P - P_s)$$

where P_s is the saturation vapor pressure of the liquid and P is the total pressure, and

$$[4] \qquad c = P/RT$$

where R is the gas constant and T the absolute temperature.

In the present experiments two methods of calculation have been used, in one the assumption of ideality has been made; in the other, corrections for gas imperfections have been made by the method outlined below.

The temperature dependence of the diffusion coefficient for each system studied was obtained by fitting the experimental results to the equation

$$[5] \qquad \mathscr{D} = D_0 T^v$$

where D_0 is a constant and v is, in general, a non-integral exponent.

Correction for Non-Ideality

Ewald, Jepson, and Rowlinson (9) have derived an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

expression giving the mole fraction of the vapor of a solid in a compressed gas with which it is in contact. The same expression would be applicable for a liquid in contact with a gas, provided the solubility of the gas in the liquid is low and insufficient to cause a change in the thermodynamic activity of the liquid. This condition is expected to hold, within experimental error, in the present experiment. Ewald *et al.* gave their derivation only for low mole fractions of vapor. Following their derivation it may be readily shown for the general case that the mole fraction of vapor is given by

$$[6]\quad \ln x_i = \ln (V_M/V_i) + 2B_{ii}/V_i - 2(x_iB_{ii} + x_jB_{ij})/V_M + V_i^L(P_M - P_{is})/RT$$

where the subscripts i and j refer to the vapor and air respectively, x is the mole fraction, the B_{ij} are second virial coefficients, V_M, V_i, and V_i^L are the molar volumes of the air–vapor mixture, the pure saturated vapor, and the pure liquid, respectively.

The molar volumes V_i and V_M are expressed in terms of second virial coefficients

$$[7]\quad V_i = RT/P_{is} + B_{ii}$$

$$[8]\quad V_M = RT/P + (x_i^2B_{ii} + 2x_ix_jB_{ij} + x_j^2B_{jj})$$

In general, experimental values of the second virial coefficients are not available. However, Cruickshank, Windsor, and Young (10) have shown that second virial coefficients for mixtures may be calculated, within experimental error, by the McGlashan–Potter (11) equation

$$[9]\quad B/V^c = 0.430 - 0.886(T^c/T) - 0.694(T^c/T)^2 - 0.0375(n-1)(T^c/T)^{4.5}$$

using the Hudson–McCoubrey (12) combining rules for T_{ij}^c and V_{ij}^c, the critical temperature and volume of the mixture.

$$[10]\quad T_{ij}^c = (T_{ii}^cT_{jj}^c)^{1/2}\left\{\frac{2(I_iI_j)^{1/2}}{I_i + I_j}\right\} \times \frac{2^6 \cdot V_{ii}^cV_{jj}^c}{[(V_{ii}^c)^{1/3} + (V_{jj}^c)^{1/3}]^6}$$

$$[11]\quad V_{ij}^c = 1/8[(V_{ii}^c)^{1/3} + (V_{jj}^c)^{1/3}]^3$$

The parameter n in eq. 9 bears a relationship to molecular size. If the vapor under consideration is a normal hydrocarbon then n is the number of carbon atoms. For other substances, values of n may be estimated by the method of Guggenheim and Wormald (13). For mixtures, a combining rule for n is used (10)

$$[12]\quad n_{ij} = 1/2(n_i + n_j)$$

The procedure in using the above equations to allow for gas imperfections in the calculated diffusion coefficient is as follows. The B_{ii} and B_{jj} are calculated for the vapor and for air using eq. 9, and B_{ij} is calculated using eq. 9 together with pseudo-critical parameters for the mixture obtained from eqs. 10, 11, and 12. Calculations verified that treating air as a single component was justified in that the second virial coefficient for mixtures of carbon tetrachloride and air obtained by treating it as a two-component mixture and as a three-component mixture of carbon tetrachloride, oxygen, and nitrogen differed by about 1%; the effect of this variation in the virial coefficient is well within experimental error on the measured diffusion coefficients. The mole fraction x_i of the vapor was then calculated by an iterative procedure. The mole fraction was assumed to a first approximation to be equal to the partial vapor pressure given by the Antoine equation

$$[13]\quad \log P_x = \alpha - \beta/(\gamma + t)$$

where α, β, and γ are constants and t is the temperature in degrees Celsius. This mole fraction was used in eqs. 8 and 6 to calculate a new value of x_i. The calculation was recycled until the change in x_i during a cycle was less than 0.01%. Then the substitutions

$$[14]\quad c/(c - c_s) = 1/(1 - x_i)$$

and

$$[15]\quad c = 1/V_M$$

were used in eq. 1 to calculate the diffusion coefficient. All calculations were performed on an IBM 360-30 computer. Values of all constants used in the calculations are given in the appendix.

Results

Table 1 gives the constants D_0 and ν in eq. 5 for the three systems studied. The constants of this equation relevant to diffusion coefficients calculated assuming the systems to behave as ideal gases and calculated allowing for gas imperfections are given. The standard deviations given were calculated from the deviations of all the experimental points from the fitted line.

Discussion

Consideration will be given first to the experimental method. Originally, diffusion tubes of length 3, 4.5, and 6.0 cm were used in the diffusion cells, there being one tube of each length of diameter 0.2 and 0.3 cm. An analysis of variance (14) performed on results obtained on these tubes showed that diffusion coefficients measured using 3 cm tubes were significantly lower than those using 4.5 and 6 cm tubes, while there was no significant difference between results obtained on the two longer tubes. Careful examination of the apparatus showed that the short diffusion tubes (A in Fig. 1) did not extend down into the bulb B, but the lower end was inside the neck of the bulb. Thus it is inferred that this result indicates that bad cell geometry had been incorporated in the cells with shorter tubes and, provided cell geometry is satisfactory there is no effect of tube length on diffusion coefficient. It is now believed that the observation

TABLE 1. Constants in eq. 5 for diffusion of stated component in air

Second component	Temperature range (°K)	Number of data	Assumed ideal		Corrected for non-ideality		Standard deviation
			D_0	ν	D_0	ν

$CHCl_3$	298–328	62	5.830×10^{-6}	1.694	1.438×10^{-6}	1.532	±0.0015
CH_2Cl_2	278–308	20	2.522×10^{-5}	1.462	5.611×10^{-5}	1.351	±0.0019

reported earlier (4) in which the results obtained in two diffusion cells differed significantly was caused by a small difference in cell geometry and not to difference in the lengths of the diffusion tubes. The statistical analysis showed no significant difference between results obtained using tubes of different diameter. After this had been established, all the results obtained with 3 cm tubes were rejected and these tubes were replaced with others of length 5 cm. On all results obtained after that time, no effect of tube length is discernable.

Cells similar in design to the present ones have been used previously by the author (3) to measure diffusion coefficients, and by McKelvey and Hoelscher (15), Fortuin (16), and Altshuller and Cohen (17), to produce low vapor concentrations in an air stream. The two last named groups appear to have had difficulty in obtaining consistent results and preferred to use Stefan's original design of one vertical tube used both as liquid container and diffusion path. No difficulty was experienced in the present work and it is believed that the present method is superior because the diffusion path length is not changing with time. The end correction as used in a Ney and Armistead type (8) apparatus must be applied at both ends of the diffusion tube because there is no forced flow of air streamlining across the top of the tube as in the experiments of Wilke and co-workers (18, 19). In the present experiments the air flow merely serves to flush the diffusate from the cell container. Results obtained using tubes of different lengths and applying the end correction are consistent. With cells of the present design, it is not necessary, as with conventional Stefan diffusion tubes, to extrapolate results obtained with several tube lengths to remove the meniscus effect (18).

The greatest source of error in these experiments is probably fluctuation of atmospheric pressure. Some experiments were performed in which the cell container pressure was controlled with a Cartesian Manostat. The pressure fluctuations were then greater than atmospheric pressure fluctuations except during periods of inclement weather. Therefore, attempts at pressure control were abandoned.

The most striking conclusion to be drawn from the present results is that the assumption of perfect gas behavior is grossly in error. Reference to Tables 1 and 2 shows that neglect of the correction for gas imperfections causes an error of $\sim 2\%$ in the measured diffusion coefficients at 298 °K while at higher temperatures the error rises to 4%. Non-ideality of the vapor–gas mixture has been largely ignored by previous workers on diffusion coefficients measured by the rate of evaporation method. Kohn and Romero mention a correction for non-ideality, but their published results are uncorrected (20). O'Connell, Gillespie, Krostek, and Prausnitz (21) in a recent study of diffusion of water vapor in non-polar gases corrected for gas imperfections using experimental virial coefficients, but they did not mention the magnitude of the error introduced by ignoring these corrections. However, it remains necessary to quote diffusion

coefficients both corrected and uncorrected for gas imperfections; the former are needed for theoretical calculations, the latter are needed in some practical problems where it is required to calculate the amount of substance diffusing at a given partial pressure.

Mrazek, Wicks, and Prabhu (22) report measurements of a concentration effect of diffusion coefficients measured by a rate of evaporation method. For the methanol–air system at 55 °C the effect is of the order of 1%. These authors neglected to correct for gas imperfections. In view of the magnitude of corrections for non-ideality demonstrated in the present work, it is difficult to believe that these authors observed anything other than a variation of the magnitude of the non-ideality correction in air–vapor mixtures of different composition at the same temperature. However, the claimed concentration variation of diffusion coefficient was of the order of 9% in the system chloroform–air at 50 °C. Compare this with the present measurements in Table 3. Part of this apparent variation is no doubt due to the neglect of gas imperfections. In the first few experiments with chloroform, the present author used chloroform from which all inhibitor had been removed. It was only when traces of phosgene were detected in the chloroform at the end of an experiment that 100 p.p.m. of ethyl alcohol inhibitor was included in the chloroform. However, the results obtained with uninhibited chloroform were self-consistent and in agreement with those obtained with inhibited chloroform at 298 °K. As the temperature was raised to 328 °K the results with uninhibited chloroform deviated from those obtained with inhibited chloroform and the precision of the results decreased. Comparison of these two sets of results is made in Table 4. The magnitude of the diffusion coefficient obtained by Mrazek *et al.* is very close to that obtained with uninhibited chloroform. Mrazek *et al.* do not give an analysis of their chloroform, but it can only be suspected that they ran into difficulties of which they were unaware. In preparing a chloroform loaded air stream, they passed air through liquid chloroform; under such conditions one may expect any oxidation inhibitor in their chloroform to be rapidly consumed and allow oxidation to occur with subsequent effect on the measured diffusion coefficient. In view of this, their conclusions regarding the magnitude of the concentration dependence of diffusion coefficient in the chloroform–air system must be treated with caution.

Comparison of the present results with those of Lugg (1) is made in Table 3. Lugg did not correct for non-ideality. His results for methylene chloride and chloroform agree with the present results within experimental error. With carbon tetrachloride the agreement is not good. Great care was taken in purification of materials in the present work, while Lugg does not give full details of purity of materials, so the present results are preferred.

Originally it was planned to calculate molecular interaction parameters from the experimental results. Unfortunately, the temperature range is too small to allow calculation of meaningful parameters. Consequently the reverse procedure had been adopted. Interaction parameters for air and the three compounds studied calcu-

lated from viscosity measurements and tabulated by Hirschfelder, Curtiss, and Bird (23) have been used to calculate diffusion coefficients at several temperatures. In the calculation the equation (23)

$$[16] \quad D_{12} = 2.628 \times 10^{-5} \frac{(T^3(M_i + M_j)/2M_iM_j)^{1/2}}{P\sigma_{ij}{}^2\Omega_{ij}(T_{ij}{}^*)}$$

was used. Here M is the molecular weight, $\Omega_{ij}(T_{ij})$ is a collision integral at a reduced temperature $T_{ij}{}^* = kT/\varepsilon_{ij}$, and σ_{ij} and ε_{ij}/k are molecular interaction parameters. Values of the collision integral for a Lennard–Jones 6–12 potential function have been tabulated (23). The Hudson–McCoubrey combining rules (12) were used in calculation of σ_{ij} and ε_{ij}/k from values for the pure components. Diffusion coefficients obtained from the smoothed curve through the experimental data are compared with those calculated from theory in Table 2. With methylene chloride the agreement is good, with carbon tetrachloride the agreement is fair, while with chloroform the agreement is bad. Thus molecular interaction parameters obtained from viscosity data for the first two named substances may be used to calculate reasonable values of diffusion coefficients.

The system air – methylene chloride has a low value of the temperature exponent ν, when compared to the other systems and to the average value of 1.75 for many data in the literature (28). The number of data obtained was lower and their standard deviation was higher than with the other systems. Hence, it is believed that this value of ν is probably lower than would be found over a wider temperature range with more data.

Gas chromatographic analyses were performed by C. Kuley. The author is indebted to Professor M. L. McGlashan for a helpful discussion.

Diffusion of Methane and Chloromethanes in Air[1]

M. COWIE[2] AND HARRY WATTS
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received June 8, 1970

The binary gaseous diffusion coefficients of air with methane, methyl chloride, methylene chloride, chloroform, and carbon tetrachloride at 298.2 °K and 1 atm have been determined. A simple diffusion cell was used, in which concentration changes of the diffusing gas were followed by infrared spectrophotometry.

Canadian Journal of Chemistry, 49, 74 (1971)

Introduction

The experimental method described in this paper was developed as a simple technique for determination of the diffusion coefficients of gases and vapors in air. The apparatus was derived from the Ney and Armistead (1) two bulb diffusion cell by making one bulb of infinite size; this bulb in fact was constituted by the atmosphere. Concentration changes of the diffusing gas in the other bulb were followed by infrared (i.r.) spectrophotometry. To evaluate the technique, measurements were made on a number of compounds for which the diffusion coefficients in air were known.

Experimental

Materials

Carbon tetrachloride, chloroform, and methylene chloride were taken from samples used previously (2). Methyl chloride was selected from the production of Dow Chemical of Canada, Limited and contained 17 p.p.m. vinyl chloride; other impurities were below the limits of detection by gas chromatographic analysis (< 10 p.p.m.). Methane (purity 99.95 mole %) was obtained in cylinders from the Phillips Petroleum Company.

Apparatus and Procedure

The diffusion cell is shown schematically in Fig. 1. It consisted of a stainless steel Tee A closed by rock salt windows B which were sealed in place by epoxy resin or by a screw cap fitting and O-rings. Gas contained in the cell diffused out into the atmosphere through the tube C which was mounted in a Swagelok fitting (Crawford Fittings) using Teflon ferrules. Thus the glass and stainless steel tubes used were readily interchangeable. The cell was placed in the beam of a Perkin–Elmer Model 221 IR spectrophotometer and the concentration of gas in the cell determined by scanning an appropriate absorption band. The decrease in concentration of the gas due to diffusion from the cell was followed by repeating the scan of the selected absorption band at suitable time intervals.

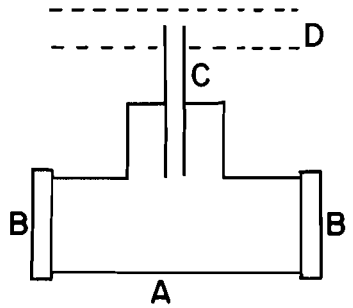

FIG. 1. Schematic diagram of diffusion cell. *A*, Tee piece; *B*, rock salt windows; *C*, capillary tube; *D*, proposed tube of sweep gas. Drawing not to scale.

The best dimensions for the tube C depended upon the cell volume. Two cells of volume 60 ml and 14 ml were used. The length of C was about 6 cm in each cell and the internal diameters were 0.5 cm in the larger and 0.3 cm in the smaller cell. The smaller cell was wrapped in a copper tube through which water from a thermostat at 25 °C was passed. The temperature of the larger cell was determined by measuring the air temperatures near the cell and taking the average. Comparison of results obtained in the two cells showed that the small fluctuations in temperature (± 1 °C) in an air conditioned room were insufficient to cause significant errors with the unjacketed cell.

In the conduct of an experiment, the cell was first charged with air laden with the gas or vapor under study so that the i.r. transmittance at the selected absorption frequency was about 30%. The diffusion was followed until the transmittance became about 70%. Depending on the magnitude of the diffusion coefficient, the duration of an experiment was 3–8 h; about ten scans of the spectrum were made in this time. The barometric pressure was recorded and averaged during each experiment.

Theory and Calculation of Results

The diffusion flux in a system at steady state is given by Fick's first law

$$[1] \qquad J = -\mathscr{D}\frac{\partial c}{\partial x}$$

where J is the flux in moles diffusing through unit

cross-sectional area in unit time, $\partial c/\partial x$ is the concentration gradient in the direction of diffusion, and $\mathscr{D}$ is the diffusion coefficient. Ney and Armistead (1) derived an expression for calculation of results for their two bulb experiment by solving eq. 1 for the appropriate boundary conditions. Specialization of their expression for the present experiment by setting one bulb volume equal to infinity leads to a triviality. The solution of eq. 1 valid for diffusion from a bulb through a capillary into infinite volume is given below. The method of solution follows closely the derivation of Ney and Armistead and is based on the same assumptions. These are: (*1*) the concentration gradient in the capillary is linear; (*2*) the concentration in the bulb is uniform; (*3*) the concentration outside the bulb is zero; (*4*) at all times the conditions approximate to steady state, *i.e.* the concentration gradient in the tube and the diffusion flux at any instant are those that would be found if the concentration in the bulb was maintained constant at the instantaneous value. The validity of these assumptions has been discussed by Ney and Armistead (1).

If c is the concentration in the bulb and l and A are the length and cross-sectional area, respectively, of the tube

$$[2] \qquad -\mathscr{D}\frac{\partial c}{\partial x} = -\mathscr{D}c/l$$

we can put

$$[3] \qquad J = v/A\,\frac{\delta c}{\delta t}$$

where v is the cell volume and δc is the infinitesimal change in concentration in the cell during the time interval δt. Equating [2] and [3] gives

$$[4] \qquad \frac{\delta c}{\delta t} = -\mathscr{D}Ac/lv$$

Taking the limit $\delta t \to 0$ and integrating gives

$$[5] \qquad \ln c = -\mathscr{D}At/lv + B$$

where B is a constant of integration. Thus a graph of $\ln c$ against t is linear and the slope is $-\mathscr{D}A/lv$.

In the calculation of diffusion coefficients the i.r. transmittance readings were converted to absorbance in the usual way (3), the absorbance of the empty cell was deducted to find that due to the compound. If Beer's law is assumed to hold, the concentration is proportional to the absorbance; conveniently we are spared the need of knowing the proportionality constant because in the calculation of $\mathscr{D}$, we are concerned only in variations of the logarithm of concentration. Here then is one advantage of the present method; it is not necessary to calibrate and determine absolute concentrations of the diffusing gas. Thus we can rewrite eq. 5

$$[6] \qquad \ln \alpha = -\mathscr{D}At/lv + B$$

where α is the i.r. absorbance due to the diffusing gas at time t. In using eq. 6 to calculate diffusion coefficients, the slope of the best straight line through the experimental points was found by a least squares fit.

The usual end correction was made so that the tube length l used in eq. 6 is given by

$$l = l_{act} + 0.82d$$

where l_{act} is the actual tube length and d is the diameter (1).

Results and Discussion

Diffusion coefficients, calculated from these experimental measurements as described in the next section, were corrected to 1 atm pressure in the usual way using the relationship that the diffusion coefficient is proportional to the reciprocal of pressure. Five determinations of the diffusion coefficient were made for each substance. The values were averaged and are given, together with their standard deviations, in Table 1. The frequencies of the i.r. absorption peaks used to follow the diffusion are also given in this table.

The mean diffusion coefficients given in Table 1 agree, within combined experimental errors, with values obtained by other methods in this laboratory (2) and in other laboratories (4, 5), with one exception. The value for carbon tetrachloride is in good agreement with a recent value obtained by one of us (2) but is not in agreement with that of Lugg (5). We prefer our lower value for the following reason. The i.r. method used for measurement of concentration is not suceptible to interference by impurities, provided any i.r. absorption by the impurities occurs at a frequency other than that of the compound under study. The carbon tetrachloride used was of high purity. That the presence of small amounts of impurity is un-

[c]Reference 5.

likely to interfere with the diffusion and affect the magnitude of the measured diffusion coefficient is indicated by several recent studies on diffusion in multicomponent mixtures (see, for example, ref. 6). Impurities can upset measurements by the rate of evaporation method used in determination of the quoted values for carbon tetrachloride (2, 5) because of their effect on vapor pressure, and vapor pressure is used as a measure of concentration of the diffusing substance. Lugg used the rate of evaporation method and did not make the necessary correction (2) for gas imperfections. Had he done so the agreement between his and our results would have been improved but there would still be a discrepancy with carbon tetrachloride. The results from our earlier work (2) corrected to true vapor concentration by allowing for gas imperfections were taken for comparison with our present results because the i.r. method measures true concentration. The surprising agreement between the present value and one earlier value (2) for carbon tetrachloride is regarded as an embarrassing coincidence!

Diffusion coefficients for the compounds studied in this paper were calculated by a kinetic theory equation (7) using the Lennard–Jones 6–12 potential function, for which values of the collision integral have been tabulated (7). In computing values of the molecular interaction parameters for like–unlike interactions, molecular interaction parameters for like–like interactions obtained from viscosity measurements and tabulated by Hirschfelder *et al.* (7) were used in conjunction with the Hudson–McCoubrey combining rules (8) and ionization potentials tabulated by Herzberg (9). The relevant equation and data are given in the Appendix.

For methane, two sets of interaction parameters were given (7) and the diffusion coefficient calculated from each set agrees with the experimental value within experimental error. For methyl chloride the calculated and experimental values agree within about 7%. For carbon tetrachloride, chloroform, and methylene chloride, the agreement is similar to that observed previously. It is not surprising that, of the substances studied, the best agreement between theory and experiment is shown with methane, since it is well established that, within experimental accuracy, methane obeys, while the other substances deviate from, the principle of corresponding states (10).

One experimental disadvantage was discovered in determination of the diffusion coefficient of methane. Initially experiments were made in a cell of length 3.5 cm. With this length, the methane concentration required to obtain an i.r. absorption in the optimum range apparently exceeded the limit for validity of Beer's law for this substance. A plot of the logarithm of the absorbance against time was initially curved and tended asymptotically towards a straight line, the slope of which gave the correct diffusion coefficient; the initial slope of the curve gave about half that value. With a cell of double that path length no such difficulty was encountered. It is apparent that the method includes a built-in test of the assumption of validity of Beer's law for each substance.

The main advantage of the present method is its simplicity. The method is readily adaptable for the study of diffusion in multicomponent mixtures if components are selected having i.r. absorption peaks at different frequencies. With slight modification to the apparatus it would be possible to measure diffusion into gases other than air. All that is required is to pass the outer

Anodic Oxidation of Ethylene Glycol on Platinum: a Mechanistic Study[1]

ASHOK K. VIJH[2]
Institute of Research, Hydro-Quebec, Varennes, Quebec

Received April 20, 1970

Anodic oxidation of ethylene glycol (EG) has been examined on platinum in 1 N H_2SO_4 by means of potentiostatic and potentiodynamic techniques. Experimental results consist of steady-state, potential–current relationships, reaction order derivatives, inhibition inflections, potentiodynamic profiles, and product analysis. Reaction mechanism has been proposed by combining these results with the previous information on the adsorption of EG on platinum, and on the pH effects in the anodic oxidation of EG. An analysis of these data has been presented in terms of kinetics under both Langmuir and Temkin conditions of electrode coverage. Inhibition inflections have been interpreted in terms of the kinetic theory of passivation effects proposed by Gilroy and Conway. It has been suggested that a chemical step of the type Pt.EG + Pt.OH → Pt.R + H_2O + Pt is the likely rate-determining-step (r.d.s.). The data indicate that quasi-equilibria prior to the r.d.s. are probably different in the ascending and descending direction of potentials (on the potential–current curves), owing to the presence of different extents of oxygenated (Pt.OH or Pt.O) adsorbed species and the associated effects of coverage on kinetics.

Canadian Journal of Chemistry, **49**, 78 (1971)

Introduction

The electrodic oxidation of various organic substances has been intensively studied in recent years from a fundamental mechanistic point of view (1–12). In the present investigation, an attempt has been made to elucidate the detailed mechanism of anodic oxidation of ethylene glycol on smooth platinum in (aqueous) 1 N H_2SO_4.

Most of the interest in the mechanisms of anodic oxidation of organic compounds has been generated undoubtedly by their possible use as anodic fuels in the fuel cells. The present work, however, was carried out because of the importance of oxidation of ethylene glycol in electrolytic capacitors.

Experimental

The general experimental procedures were similar to those used in our previous work (4) and in other recent work in electrode kinetics (13, 14). Some specific features are listed below, however.

A three-compartment Pyrex cell provided with solution-sealed stop-cocks, gas inlets and outlets, "tru-bore" tubing electrode holders, and other appropriate accessories was used.

Bright platinum working electrodes were sealed into Pyrex in open flame (natural gas and oxygen) and were subsequently degreased in boiling trichloroethylene, cleaned in chromic acid, and thoroughly washed in deionized-distilled water. Bright platinum counter electrodes and hydrogen reference electrodes were used.

A helium atmosphere was always maintained in the working compartment and no electrolysis (even pre-electrolysis) was conducted until all the oxygen had been purged from the working compartment. This procedure eliminated the possibility of formation of traces of H_2O_2 by reduction of dissolved O_2. Commercial helium without further purification was used (15) whereas H_2 gas for the reference compartment was deoxygenated by passing over a palladium catalyst. Optimum pre-electrolysis, both cathodic and anodic, of the 1 N H_2SO_4 was carried out *before* adding the measured amounts of ethylene glycol. Ethylene glycol was comparable to the electronic grade in purity. Sulfuric acid was A.C.S. grade (Allied Chemicals).

An Anotrol potentiostat (Magna Corporation, Model 4700M) was used both for potentiostatic and potentiodynamic work. Potentiodynamic curves were recorded on a Moseley 7035A X–Y recorder (Hewlett–Packard). Circuitries were similar to those described previously and were routine potentiostatic and potentiodynamic configurations (4, 16).

All experiments were carried out at room temperature.

It may be mentioned that in the various graphs to follow, the electrode potentials $E_H(V)$ are in volts and refer to the hydrogen electrode in the *same* solution. In the rate equations and various reaction order derivatives, the electrode potential, $E_H(V)$, has been simply represented by V for the purposes of brevity.

Results

(1) Products of Electrolysis

In agreement with the results of Bagotskii and co-workers (11), it was observed that at room temperature, electro-oxidation of EG does not proceed all the way to CO_2. Non-gaseous products, in which C—C bond in EG is not ruptured, were predominantly formed and were qualita-

[1]This work was carried out in the Research and Development Laboratories of Sprague Electric Company, North Adams, Massachusetts.

[2]Also Visiting Professor in the Energy Center of the National Institute of Scientific Research, University of Quebec at Varennes, Quebec.

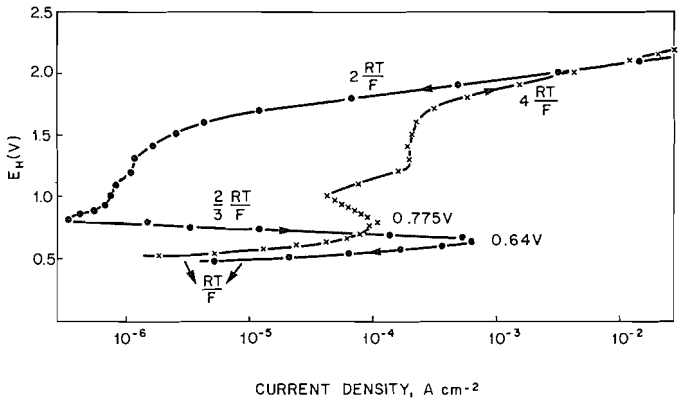

FIG. 1. A steady-state, potentiostatic (point by point), potential – log (current density) relationship on smooth platinum in 1 N H_2SO_4 and 2.5×10^{-1} M ethylene glycol. Helium atmosphere in the working compartment: X, ascending direction potentials; ●, descending direction of potentials.

tively detected (17). In a prolonged electrolysis, the products formed at 0.68 ± 0.02 V were glyoxal and oxalic acid; this confirms the previous observations of Bagotskii and co-workers (11). No formaldehyde, formic acid, glycolaldehyde, acetaldehyde, and acetic acid were detected. Glycolic acid and glyoxalic acid were indicated (17) but could not be confirmed. Attempts to accumulate, and subsequently to isolate, the products of electrolyses for quantitative analyses were unsuccessful because prolonged electrolysis at 0.68 ± 0.02 V (or any other potential for that matter) results in very low current densities, presumably because of long term poisoning effects caused by either intermediate and/or terminal products of electrolysis.

(2) Current–Potential Relationships

In the steady-state, potentiostatic (point-by-point) current–potential relationship the major features, *e.g.*, inhibition inflections and hysteresis effects, were similar to those reported for other electro-organic oxidations by Conway and co-workers (18, 19). The criterion for steady-state was that defined by Wroblowa *et al.* (20), which tends to avoid complications that may arise due to long-term poisoning effects by intermediates and/or products of electrolysis. A typical current–potential relationship has been presented in Fig. 1. In the ascending direction (Fig. 1) a marginal Tafel region of 70 mV is followed by a wide (on the potential scale) inhibition inversion, with a maximum current density of 1×10^{-4} A cm^{-2} in solutions containing 2.5×10^{-1} M EG. The current–potential line in the negative direction of this inhibition inflection extends over too narrow a range of current density to permit the deduction of any negative Tafel slopes. The wide inhibition maximum indicates a Temkin type of adsorption (19) (*i.e.*, activation energy for adsorption changes with coverage) and is consistent with the results of Bagotskii and Vasile'v on electrode coverage (11, 12). This inhibition inflection is followed by a brief increase in rate with increasing potential which, in turn, enters into a transition region, the latter terminating finally into a Tafel region for oxygen evolution (o.e.r.) with anomalously high Tafel slope (220 mV). In the descending direction a Tafel line for o.e.r. with normal slope (130 mV) is followed by a transition region. At 800 mV this transition region enters into a huge (spread over three decades of current density) inhibition inversion "loop" which is narrow and, hence, shows Langmuirian kinetics. The positive Tafel slope of this inhibition inflection is 70 mV and the slope for the negative Tafel line is 40 mV. The ascending and descending curves show a large hysteresis which is usually diagnostic of the presence of oxide and other irreversibly adsorbed species.

It may be added that these current–potential relationships are not vitiated by diffusion effects, which were shown to be unimportant in the oxidation of EG (10).

(3) Reaction Orders

Current–potential relations (ascending directions) as a function of EG concentration have been presented in Fig. 2 for the potential region

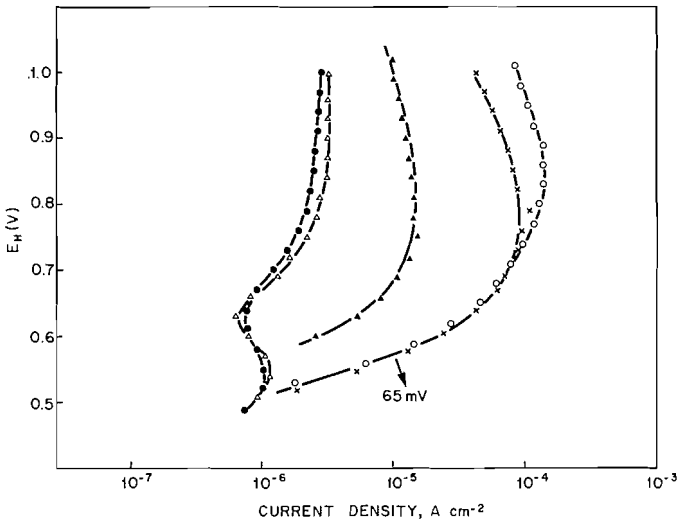

FIG. 2. Steady-state, potentiostatic (point by point) potential – log (current density) relationships in the ascending direction of potentials on platinum in 1 N H_2SO_4 solutions containing the following concentrations of EG: ●, 4.4 × 10^{-3} M; △, 8.8 × 10^{-3} M; ▲, 2.1 × 10^{-2} M; X, 2.5 × 10^{-1} M: ○, 2.1 M. These relationships at potentials more anodic than 1.0 V purposely not shown since no new information relevant to the oxidation of EG can be derived from them.

in which EG is known to undergo significant oxidation, approximately 0.48 to 0.88 V (see Fig. 1). It may be noted that the marginal Tafel line with a slope equal to RT/F is obtained only in solutions with rather high EG concentration. The apparent potentiostatic reaction order, R, *i.e.*, $(\partial \log i/\partial \log c)_{V,\psi,T,\ldots}$ tends to approach zero at 0.5 V. At the potential of maximum current (*ca.* 0.8 V), however, R tends to one (Fig. 3) except for very high EG concentration.

Current–potential relations for the descending direction, as a function of EG concentration, have been presented in Fig. 4. The behavior at the lowest concentration does not fit the systematic trend to Fig. 4, probably because the current densities are very low and approach those of the background electrolyte, thus diminishing the significance of that particular relationship. The values of R obtained from Fig. 4 are fractional and positive (Fig. 5). At the lowest concentrations there is some indication

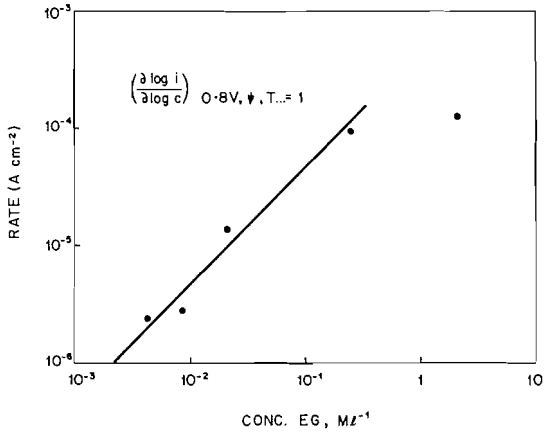

FIG. 3. A plot for obtaining reaction order derivatives, $\partial \log i/\partial \log C$, in the ascending direction of potentials. This plot is based on data in Fig. 2.

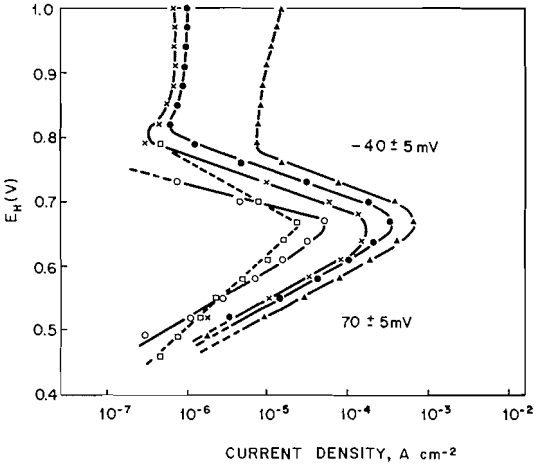

FIG. 4. Steady-state, potentiostatic potential – log (current density) relationships in the descending direction of anodic potentials, at various concentrations of EG listed below: □, 4.4 × 10^{-3} M; ○, 8.8 × 10^{-3} M; X, 2.2 × 10^{-2} M; ●, 2.5 × 10^{-1} M; ▲, 2.1 M.

that R changes significantly but this may be because of the aforementioned difficulty.

The reaction order derivative $(\partial V/\partial \log c)_{i,\psi,T,\ldots}$ obtained from Fig. 4, both for the positive and negative Tafel lines, is also of rather small magnitude, as would be expected. For the positive Tafel line in Fig. 4, the value of $(\partial V/\partial \log c)_{i,\psi,T,\ldots}$ is 14 mV and for the negative Tafel line, 22 mV.

(4) Potentiodynamic Profiles

The peaks observed in the single sweep (from prior steady-state potential) potentiodynamic profiles (Figs. 6 (*a*) and (*b*)) in this system are similar to the current-reversal effects (19) observed in the steady-state, point-by-point, potentiostatic current–potential relationship (Fig. 1). As pointed out previously (7), this would indicate that the potentiodynamic peaks at these sweep rates (16.8 to 720 mV s^{-1}) are probably *kinetic* in origin and are, in fact, inhibition inflections of the type reported by Gilroy and Conway (19). Further, when the potentiodynamic peaks are tested for pseudo-Faradaic nature (plot of peak current *vs.* scan rate) or for diffusion control (peak current *vs.* square root of scan rate) (Fig. 7), *no* linear relation passing through the origin is obtained, thus confirming our conclusion that the potentiodynamic peaks, both in ascending and descending direction, are mainly kinetic in origin.

It is possible to obtain better resolution of the potentiodynamic profiles at certain sweep rates (Fig. 8). In this profile the following important points may be noted.

(*i*) Hydrogen peaks are "masked" and appear as hysteresis.

(*ii*) The huge anodic peak at 0.6 V appears on the descending sweep (1.2 → 0 V) instead of the usual *cathodic* oxide reduction peak. This would show recombinative removal, by a chemical surface reaction, of the oxide (or OH) and the anodic current would arise from the normal Faradaic reaction of glycol oxidation on the bare surface sites remaining after reaction of adsorbed glycol species with the oxide. This situation is somewhat similar to that observed for the oxidation of formic acid (21). The smaller peak around 0.6 V is the same peak but in the ascending (0 → 1.2 V) direction of the sweep.

(*iii*) A tiny, incipient peak around 1.03 V may be noted. From Bagotskii's work (10), this peak would correspond to the oxidation of oxalic acid.

(*iv*) Based on previous work on the anodic oxidation of organic substances (10), the anodic peak on the ascending curve around 0.9 V is the kinetic peak corresponding to the oxidation of EG (with or without coadsorbed oxygenated species, see Discussion).

If, subsequent to the commencement of the first sweep from prior steady-state potential, the potentiostat is driven by the repetitive sweeps, profiles similar to the ones shown in Fig. 9 may be obtained. The *asymmetric* shifts in the large anodic peak produced by repetitive sweeps are believed to have qualitative mechanistic signifi-

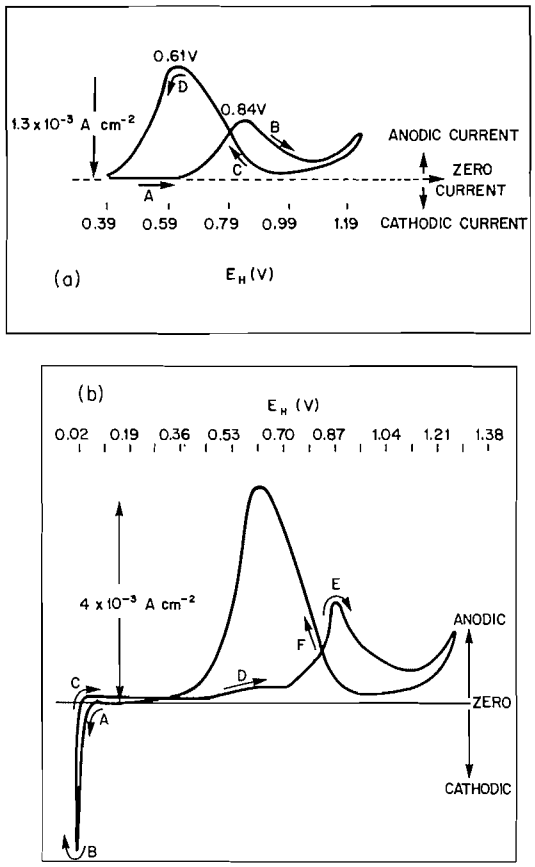

FIG. 6. (*a*) A single sweep potentiodynamic profile (dV/dt = 16.8 mV s^{-1}) triggered from prior steady-state potential (0.39 V) corresponding to complete coverage by ethylene glycol, on platinum in 1 *N* H_2SO_4 containing 2.5 × 10^{-1} *M* EG. (*b*) Similar to Fig. 6(*a*) above except that the steady-state potential prior to the commencement of the single sweep was 60 mV; at this potential the electrode coverage by EG is vanishingly small (see Fig. 10), dV/dt is 50 mV s^{-1}.

cance which will be explained in Discussion section. At potentials more cathodic than 0.1 V, cathodic current appears both in the ascending and descending direction. The position and general shape of the profiles in this region indicates that some current associated with diffusion-controlled oxidation–reduction of intermediate products of electrolysis is probably superimposed on the normal kinetic current. No straightforward quantitative analysis can, however, be extended in this region.

(5) Electrode Coverage

It has been reported by Bagotskii *et al.* (11, 12)

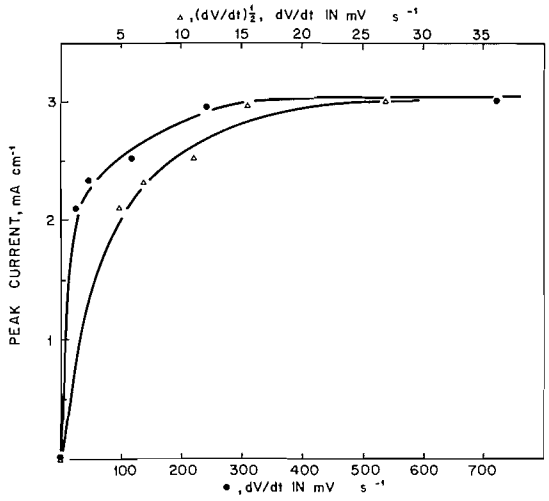

FIG. 7. Plot of peak current *vs.* dV/dt, (●) and $(dV/dt)^{\frac{1}{2}}$, (△) for peak at *ca.* 0.61 V (see Fig. 6*a*).

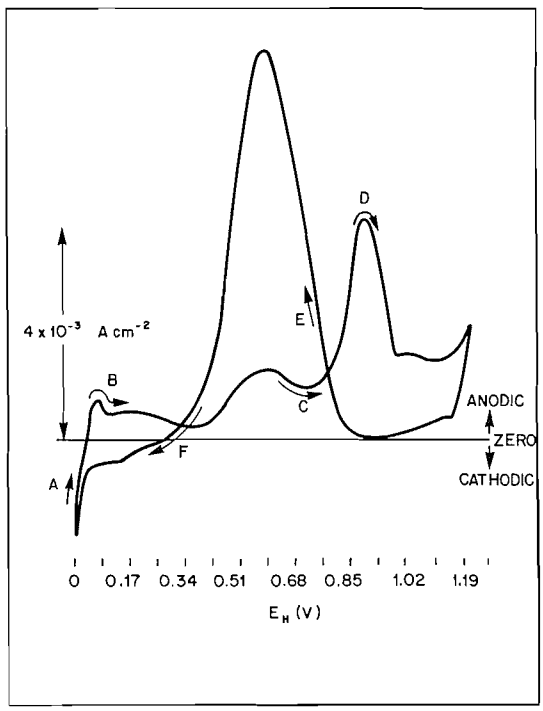

FIG. 8. A single sweep potentiodynamic profile obtained at a sweep rate (240 mV s^{-1}) which yields the maximum resolution of peaks. Steady-state potential prior to the commencement of the sweep was 0 V. A slight incipient anodic peak around 1030 mV, which probably corresponds to the oxidation of oxalic acid (see text and ref. 10), may be noted.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

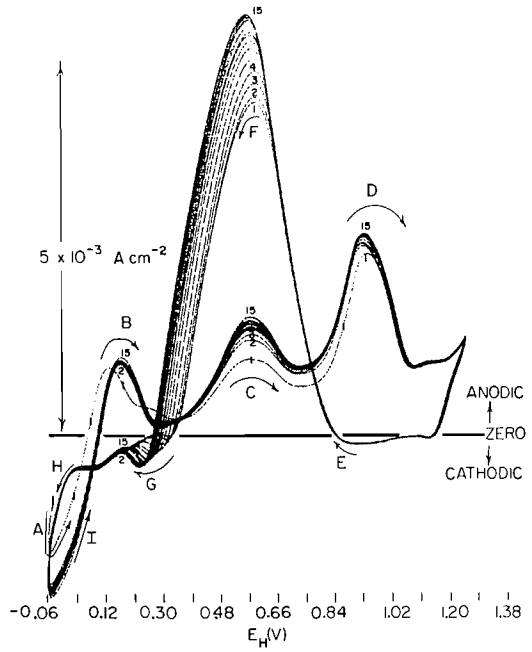

FIG. 9. Similar to Fig. 8 except that after the first sweep triggered from a prior steady-state potential (60 mV) the potentiostat was driven to yield repetitive sweeps. Sweep rate is 354 mV s^{-1}. Numerals refer to the sweep number.

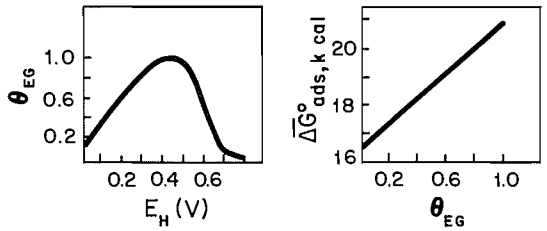

FIG. 10. This figure reproduces Bagotskii's results (ref. 12) on electrode coverage of platinum by EG in 1 *N* H_2SO_4 at 50 °C. EG concentration is 1×10^{-2} *M*. (*a*) Electrode coverage by EG, θ_{EG}, *vs.* electrode potential, E_H; (*b*) apparent standard free energy of adsorption of EG, $\Delta\bar{G}_{ads}^{0}$, as a function of θ_{EG} at 0.4 V and 50 °C. Steady-state adsorption from 1 *N* H_2SO_4 containing 1×10^{-2} *M* EG. The electrode history in this case corresponds to the ascending direction of potentials in our work. It may be noted that adsorption of EG on platinum obeys a Temkin isotherm.

that electrode coverage by EG in this system shows Temkin behavior (Fig. 10); *i.e.*, activation energy for adsorption varies linearly with coverage.

Discussion

(1) Probable Reaction Mechanism

In order to deduce the reaction mechanism, it would be convenient to proceed as follows:

(*i*) Since the Tafel slope for EG oxidation both in the ascending and descending direction (Fig. 1) is *RT/F*, no step which occurs during or after the third charge transfer may be rate-determining (1). It may be readily shown that such a step, if rate-determining under either Langmuir or Temkin conditions of electrode coverage, will result in a Tafel slope equal to or less than *RT/2F*.

(*ii*) Initial charge transfer may not be the r.d.s. since it will result in a Tafel slope equal to *2RT/F*. Further, such a step would require electrode coverage to approach zero, a requirement not sustained by experimental results (Fig. 10).

(*iii*) The observed Tafel slope can arise only under one of the following conditions:

(*a*) When surface diffusion (23) of an adsorbed species is the r.d.s.; such a step, however, is unlikely in the present case since it is important only in metal deposition or occasionally, in the hydrogen evolution reaction.

(*b*) When the rate-determining terminal desorption results in gas evolution which is chemisorbed under Temkin conditions of *activated* adsorption as may be possible in the anodic oxidation of ammonia or hydrazine. This situation is clearly inapplicable in the present case.

(*c*) When an initial charge transfer results in an intermediate adsorbed under Langmuirian conditions, *e.g.*, Pt.OH, which subsequently undergoes a first order chemical heterogeneous step (24) (*cf.* Kolbe reaction in ref. 24). (Note that *kinetically*, this situation would be similar to the Scheme (*A*), Discussion section (*6*), based on Bagotskii's results.)

If the r.d.s. involves only EG as the reactant, the expected kinetics would clearly be Temkin, since adsorption of EG obeys Temkin isotherm (Fig. 10). If, however, the r.d.s. involves another species in addition to EG, the kinetics may become Langmuirian since either the *total* coverage by all species involved in the r.d.s. or the coverage by the second species alone in that case may not obey Temkin kinetics. It is believed that the foregoing modification when applied to generalization (*iii c*) can yield a possible r.d.s. A mechanism consistent with the foregoing considerations is as follows.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

[1] $$Pt + H_2O \rightleftharpoons Pt.OH + H^+ + e \text{ (Langmuir)}$$

[2] $$RH_{solution} + Pt \rightleftharpoons Pt.RH_{d.l.}$$

where RH represents the EG.

[3] $$Pt.RH + Pt.OH \xrightarrow{\text{r.d.s.}} Pt.R + H_2O$$

The reaction products may then be formed in steps subsequent to the r.d.s., with or without participation of PtO.

It is important to note here that from the product analysis, no step involving *fission* of the C—C bond in EG may be postulated as the r.d.s.

(*d*) Alternatively, one could propose a mechanism involving a similar r.d.s. as above (3) but with *two* prior charge transfers leading to potential-dependent Temkin type adsorption of two different reaction intermediates, *viz.*, Pt.OH and Pt.R. The reaction scheme in that case would be as follows

[1] $$Pt + H_2O \rightleftharpoons Pt.OH + H^+ + e \quad \text{(Temkin)}$$

[4] $$Pt + RH \rightleftharpoons Pt.R + H^+ + e \quad \text{(Temkin)}$$

[5] $$Pt.R + Pt.OH \xrightarrow{\text{r.d.s.}} Pt.R' + H_2O + Pt$$

The rate equation in this case would be (22)

[6] $$v_5 = k_5\,\theta_{OH}\,\theta_R \times \exp[\alpha r\theta_{OH/RT}] \exp[\alpha r\theta_{R/RT}]$$

where the various symbols have the usual significance (22, 23). (Note that *kinetically* this mechanism would be identical with Scheme (*B*), Discussion section (*6*), which is based on Bagotskii's results.)

If θ_{OH} and θ_R are determined by potential-dependent quasi-equilibria 1 and 4 (characterized by constants K_1 and K_4), respectively, one obtains (22, 23)

[7] $$\ln K_1 + \ln C_{H_2O} + VF/RT = r\theta_{OH}/RT$$

and

[8] $$\ln K_4 + \ln C_{RH} + VF/RT = r\theta_R/RT$$

or

[9] $$\ln K_1 + \ln K_4 + \ln C_{H_2O} + \ln C_{RH} + 2VF/RT = r(\theta_{OH} + \theta_R)/RT$$

Therefore,

[10] $$\ln v_5 = \ln k_5 + \ln \theta_{OH} + \ln \theta_R + \alpha \ln K_1 + \alpha \ln K_4 + \alpha \ln C_{RH} + \alpha \ln C_{H_2O} + 2\alpha VF/RT$$

It follows that

[11] $$\partial V/\partial \log v_5 = 2.3 \times RT/F$$

[12] $$\partial \log v_5/\partial \log C_{RH} = 0.5$$

[13] $$\partial \log v_5/\partial \log C_{H_2O} = 0.5$$

Since in aqueous acidic solutions, reaction order w.r.t. H_2O will be pseudo-zero order, eq. 13 will be meaningless. However, eq. 13 will assume significance if either the non-aqueous solution contains only small, measured amounts of water or the solution is alkaline; in the latter case eq. 13 will be written as: $\partial \log v_5/\partial \log C_{OH^-} = 0.5$ (13*a*).

Since the adsorption of EG (ascending direction) follows a Temkin isotherm (Fig. 10) and the kinetics in the ascending direction shows Temkin characteristics (Figs. 1, 2), the mechanism proposed in this section is probably more plausible than the one in section (*iii c*). It is important to note, however, that both mechanisms involve a very similar r.d.s. It is possible that in the ascending direction of potentials Temkin kinetics is obeyed (Figs. 1, 2), whereas in the descending direction kinetics becomes Langmuirian (Figs. 1, 4, and 11) because of high surface coverage by oxygenated species. It may be noted that the reaction order predicted for Temkin adsorption (eq. 12) is observed only in the descending direction of potential and not in ascending direction, as would have been expected. No explanation can be offered for this observation at present.

It may be noted that information on the adsorption of EG under conditions corresponding to descending direction of potentials, *i.e.*, in presence of significant amounts of PtO and Pt.OH, is not available. It may not even be possible to obtain such data reliably because of the "chemical" heterogeneous reaction between adsorbed EG and the surface oxide. It is important to emphasize that independent knowledge of adsorption isotherms in the ascending and descending directions is *not* indispensable for the interpretation of present work. This is because indications of Temkin type kinetics in the ascending direction of potentials (Figs. 1, 2) and Langmuirian kinetics in the descending direction (Figs. 1, 4, and 11), are quite strong (19, 23),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

irrespective of the availability of the adsorption isotherms.

(*e*) That the Tafel slope equals 2.3 RT/F may also be predicted on the basis of some other mechanisms; *e.g.*, an electrochemical discharge step as r.d.s. under certain conditions of electrode coverage (24*a*). Such a mechanism is unlikely in the present case since the experimental evidence tends to favor a chemical r.d.s., Discussion section (*5*), in the electrooxidation of a large number of organics, including ethylene glycol.

An examination will now be attempted of the significance of the rest of the results in relation to the foregoing mechanistic proposal.

(2) Inhibition Effects

In the ascending direction of potentials, the negative "Tafel" line following current reversal is too brief to lend itself to quantitative interpretations (Fig. 1). In the descending direction of potentials, however, the inhibition "loop" may be examined theoretically in terms of kinetic theory of passivation effects developed by Gilroy and Conway (19). It has been observed (Fig. 11) that the experimental data fit best, up to a point (marked by arrow in Fig. 11), the inhibition loop predicted for reactions of the type, under Langmuirian conditions of adsorption,

[14] $\quad Pt + Pt.x \rightarrow Pt.Y + Pt.Z$ or $Pt.\overline{Y—Z}.Pt$

with or without the subsequent desorption of Y and Z. Since the fission of C—C bond in EG

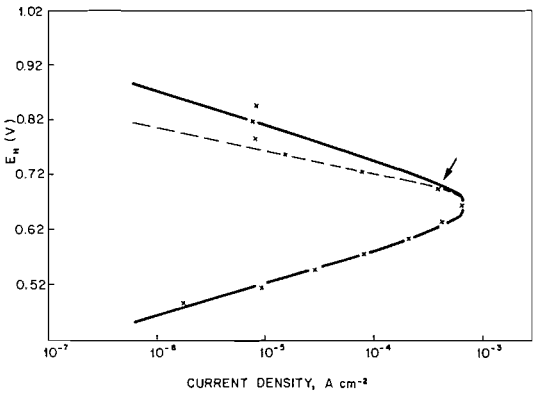

FIG. 11. A typical experimental inhibition inflection (crosses) examined in relation to the theoretical curve of Gilroy and Conway for inhibition, under Langmuirian conditions of adsorption, of the type (see Fig. 2 in ref. 19): Pt.X → Pt.Y—Pt.Z (or $Pt.\overline{Y—Z}.Pt$). Our experimental points refer to the descending potentiostatic curve obtained in solutions containing 2.1 *M* EG (see Fig. 4).

is not indicated in the product analysis, it is preferable to write the right hand side of eq. 14 as $Pt.\overline{Y + Z}.Pt$. At potentials more anodic than 0.7 V, the experimental negative Tafel line departs from the theoretical one and results in a slope of *ca.* 40 mV. Such a deviation from the theoretical curve would indicate that inhibition behavior originating from competitive effects associated with quasi-equilibria of the following type may be important (19)

[1] $\quad Pt + H_2O \rightleftharpoons Pt.OH + H + e$

[15] $\quad 2Pt.OH \rightleftharpoons Pt.O + H_2O + M$

or

[16] $\quad Pt.OH \rightleftharpoons Pt.O + H^+ + e$

It is clear that reactions of the type 15 and 16 are not important below 0.7 V (descending direction) *i.e.*, in the potential range in which, under steady-state, PtO would tend to be reduced.

Langmuirian kinetics in the descending direction of potentials indicated by Fig. 11 would be quite consistent with the r.d.s. suggested in Discussion section *1* (*iii c*).

Further, if the r.d.s. (3) or (5) results in a radical (R or R′ respectively) which is chemisorbed by occupying several surface sites, as indeed is indicated by the results of Bagotskii *et al.* (11, 12), an inhibition of the type

[14] $\quad Pt + Pt.X \rightarrow Pt.\overline{Y + Z}.Pt$ or $Pt.Y + Z.Pt$

would follow (11, 12). Hence, it is concluded that the general features of the inhibition inflection (Fig. 11) are consistent with the suggested r.d.s.

As was mentioned in the Results section, the potentiodynamic peaks (Figs. 6, 8, 9) in general have the same significance as the kinetic inhibition effects depicted in Figs. 1 and 11. It is believed that the inhibition effects (Figs. 1, 4, 6) do not originate from specific adsorption of sulfate ions (25), since Vetter's (26) analysis of Schuldiner's proposal (25) is rather persuasive.

(3) Effect of pH

From the results of Bagotskii *et al.* on the oxidation of several organics, including ethylene glycol (10), a positive value of chemically significant (23) reaction order, $(\partial \log i/\partial \log C_{OH^-})_\phi$, may be concluded. This would be consistent with the r.d.s. proposed here as is clear from eq. 13*a*.

(4) Reaction Orders

The various reaction order derivatives for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

reactant EG observed in the present investigation are rather complex. The general significance of these derivatives, however, does lend further support to the mechanism suggested here. For example, positive but fractional reaction orders R observed in the descending direction (Fig. 5) would suggest a chemical step as the r.d.s. as proposed here and would be consistent with the value (0.5) predicted by eq. 12.

In the ascending direction, values of R approach zero (Fig. 2) around 0.5 V which is the potential of saturation coverage by EG (Fig. 10), and, hence it is suspected that this R value is probably *pseudo*-zero order. At potentials at which saturation coverage of EG does not obtain, *e.g.*, at 0.8 V (Fig. 10), reaction order R approaches one, except at the highest concentration of EG at which appearance of *pseudo*-zero order again would not be entirely unexpected (Fig. 3). The significance of various reaction orders in the ascending direction of potentials (Figs. 2, 3) is greatly diminished, however, by the fact that the Tafel line, which is rather marginal, is only observed at high EG concentrations (Fig. 2). In the descending direction of potentials, however, satisfactory Tafel lines are obtained at several concentrations (Fig. 4), yielding more meaningful R values which are further discussed below.

An attempt will now be made to estimate the R values from the data of Bagotskii *et al.* and compare it with our values obtained at an approximately comparable electrode potential (0.5 V), in the descending direction of potentials (Fig. 4).

According to Conway *et al.* (22), if the current density i is assumed to be a linear function of θ^n, the apparent potentiostatic reaction order, $(\partial \log i/\partial \log C)_{V,\psi,T,\ldots} = R$, may be written as

$$[17] \qquad R = \frac{\partial \log i}{\partial \log C} = \frac{\partial \log i}{\partial \log \theta}\frac{\partial \log \theta}{\partial \log C}$$

An estimate from the data of Bagotskii *et al.* (11, 12) yields that

$$\left(\frac{\partial \log i}{\partial \log \theta}\right) = 0.6 = n \qquad \text{(ref. 12, Fig. 8)}$$

and

$$\left(\frac{\partial \log \theta}{\partial \log C}\right) = 0.25 \qquad \text{(ref. 11, Fig. 6)}$$

The value of R may thus be deduced as 0.15 from eq. 17. Even though this R value refers to 0.4 V and 50 °C, a qualitatively favorable comparison with our R value (0.2) at 0.5 V and room temperature (Fig. 5) may be made. It may be added that since the coverage by EG is identical at 0.4 and 0.5 V (Fig. 10) and the temperature affects only the time of adsorption necessary to reach a given coverage (11, 12) (a factor irrelevant for steady-state adsorption), such a comparison of R values as attempted here is probably valid.

(5) Miscellaneous Evidence and Arguments Corroborating the Proposed Mechanism

(*i*) There is virtually no oxidation of EG in the potential range 0.3 to 0.5 V (Figs. 1, 2, and 4) even though the electrode is highly covered (Fig. 10). This strongly suggests that virtual absence ($\theta < 0.1$) of steady-state coverage by Pt.OH in this potential range (1) is responsible for lack of significant, steady-state oxidation of EG.

(*ii*) In the ascending direction (Fig. 1), the current reversal commences around 775 mV presumably because the reactant Pt—OH is gradually converted (1) to PtO above *ca.* 800 mV. Similarly in the descending direction (Fig. 1), rate becomes appreciable only in the potential range in which PtO is reduced, probably *via* Pt.OH.

(*iii*) In the repetitive sweep potentiodynamic profiles (Fig. 9) the trend in the shift of the large, kinetic anodic peak qualitatively indicates that, prior to the r.d.s., two quasi-equilibria are probably involved. The extents of departure from equilibrium of these quasi-equilibria, as a result of repetitive sweep, are probably different, hence the asymmetric "half-shifts" in the peak (Fig. 9).

(*iv*) The suggested mechanism which involves a *chemical* r.d.s. is completely consistent with the mechanistic proposals put forward for the oxidation of a large variety of organics by Bockris *et al.* (1), Frumkin and co-workers (6, 9), Brummer (27), and Bagotskii and Vasile'v (10). It seems that a great variety of organics undergo electrodic oxidation through a chemical r.d.s., and hence are quite similar in their kinetic behavior in this particular respect.

(*v*) The conclusion that in electro-organic oxidations, Pt.OH is probably a reactant and PtO a likely inhibitor (Fig. 11) is, again, in agreement with the observations of Bagotskii

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and Vasile'v (10) and Bockris *et al.* (14) based on somewhat different types of arguments. Hence, the conclusions drawn here are sustained by previous mechanistic work on the anodic oxidation of organic compounds.

(6) Comparison with Previous Mechanistic Proposals

Bagotskii and co-workers (11, 12) have proposed a scheme in which four initial dehydrogenations proceed by chemical (rather than electrochemical) dissociation steps and the four adsorbed hydrogen atoms are ionized ("drained off") (18) in a rapid *parallel* reaction. The carbonaceous residue then left on the electrode presumably undergoes oxidation at higher (> 0.5 V) anodic potentials, *i.e.*, at potentials at which significant steady-state oxidation of EG is sustained. The mechanism of Bagotskii *et al.* was based mainly on evidence related to the coulometry (28) of the deposition or ionization of the adsorbed species and decay of rate with time at a given controlled potential. No steady state kinetic data were presented. It may be readily shown, however, that the conclusion of Bagotskii and co-workers can be reconciled with the *kinetic* data obtained in the present investigation. For example, subsequent to the four chemical dehydrogenations of EG, the adsorbed carbonaceous residue, C, may be oxidized by one of the following Schemes

Scheme A

[1] $Pt + H_2O \rightleftharpoons Pt.OH + H^+ + e$ (Langmuir)

[18] $Pt.OH + Pt.C \xrightarrow{\text{r.d.s.}} \text{Products}$

Scheme B

[1] $Pt + H_2O \rightleftharpoons Pt.OH + H^+ + e$ (Temkin)

[16] $Pt.OH \rightleftharpoons Pt.O + H^+ + e$ (Temkin)

[19] $Pt.C + Pt.O \xrightarrow{\text{r.d.s.}} \text{Products}$

Scheme *B* presented here is unlikely, though consistent with the kinetic data, since Pt.O is indicated as an inhibitor rather than a reactant.

In conclusion, it is not possible to distinguish our mechanism from that of Bagotskii and co-workers on the basis of kinetic data presented here. However, in Fig. 10, which is based on results of Bagotskii and co-workers it seems to imply that the adsorption of EG is more or less reversible. If four initial hydrogenations were involved, one would expect to observe a much higher potential-dependence of EG adsorption than is indicated by Fig. 10. From these comments it seems likely that the mechanism proposed by Bagotskii and co-workers is not entirely sound.

It may be added, however, that the open circuit behavior of the system examined previously (11, 12) seems to be explained rather well by the mechanism of Bagotskii and co-workers. It may, therefore, be concluded that no unambiguous mechanistic assignments are possible at present. The proposals put forward by us may hence be regarded only as one of the possible kinetic schemes which seems to be consistent with the available data.

Thanks are due to Dr. R. S. Alwitt and Dr. S. D. Ross for some discussions. Contributions made by Mr. R. W. Santway and Mr. J. Barry to the product analysis are gratefully acknowledged. Dr. J. Parry of Tyco Laboratories is thanked for providing some reprints on the anodic oxidation of ethylene glycol. Helpful comments by Professor B. E. Conway and Dr. P. Lenfant on the rough draft of the manuscript are gratefully acknowledged.

Spin–Spin Coupling Constants Between Protons and Carbon in 1,3-Dithiole-2-thione and 1,3-Dithiole-2-one. Relationship of *cisoid* H–H to Two-bond ^{13}C–H Couplings in Ethylene Derivatives and Aromatic Compounds

D. M. McKINNON AND T. SCHAEFER
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received July 22, 1970

Precise analyses of the p.m.r. spectra of 1,3-dithiole-2-thione and 1,3-dithiole-2-one containing ^{13}C at positions 4 and 2 yield all proton–proton and proton–carbon spin–spin coupling constants. The two-bond proton–carbon couplings are discussed relative to directly bonded proton–carbon couplings in terms of hyperconjugative effects and it is suggested that d orbital participation in sulfur bonding is unimportant in these compounds. A linear correlation of two-bond proton–carbon with *cisoid* proton–proton couplings in some ethylene derivatives and aromatic compounds indicates that the above two compounds behave like ethylene derivatives in this respect, in contrast to benzene, furan, and thiophene. Practical use of the correlation in the analysis of complex ^{13}C resonance spectra is indicated.

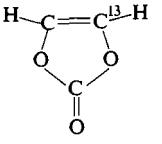
Canadian Journal of Chemistry, **49**, 89 (1971)

Introduction

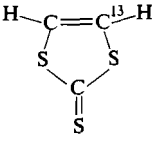
The four-electron molecular orbital treatment of geminal proton–proton coupling in the fragment H—C—H (1), in which inductive and hyperconjugative interactions of a substituent with the fragment orbitals are distinguished, can be qualitatively applied to two-bond carbon–proton couplings in the fragment ^{13}C—C—H. Such an application was made in a study of vinylene carbonate (1,3-dioxole-2-one (**1**)) (2). When $J(^{13}C—C—H)$ is plotted *vs.* $J(^{13}C—H)$ for a number of model compounds significant deviations from the plot are a measure of the hyperconjugative effect of the substituent on $J(^{13}C—C—H)$, the plot itself being a calibration of rehybridization and direct electronegativity (3, 4) effects on $J(^{13}C—H)$ and $J(^{13}C—C—H)$. Calculations in the CNDO/2 approximation of $J(^{13}C—C—H)$ in carbonyl compounds can be qualitatively interpreted in a similar way (5).

The extended Hückel method is not successful in calculating nonbonded carbon–proton coupling constants (6). The CNDO/2 and INDO calculations (7) show promise in reproducing the observed $J(^{13}C—C—H)$. Jameson and Damasco (8) discuss in detail the quantum mechanical basis of $J(^{13}C—C—H)$ in a variety of compounds. Their theory agrees with experiment in predicting a relatively narrow spread of values (9) within each set of bonding situations for the carbon atoms. An exception to the narrow spread of values of $J(^{13}C—C—H)$ occurs for derivatives of ethylene and their theory accounts for this situation as well. Nevertheless, precise agreement between theory and experiment is hardly expected and is not attained for such complex molecules.

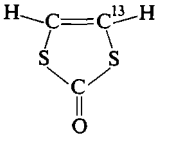
Consequently the qualitative approach described for vinylene carbonate is still useful, particularly as it allows a discussion in terms of inductive and hyperconjugative substituent effects, of interest when comparing the results for the title compounds, **2** and **3**, with those for vinylene carbonate (**1**).



1



2



3

In a variation on the above approach we find it useful to compare $J(^{13}C—C—H)$ with *cisoid* $J(H—C—C—H)$ in **1**, **2**, **3**, certain ethylene derivatives, and in benzene, thiophene, and furan. A correlation of these couplings is established below and serves as one measure of aromaticity or potential aromaticity in a compound. In addition, the assignment of $J(^{13}C—C—H)$ couplings in some molecules is bedevilled by complexities (6) and the correlation can be used in a confirming role in such instances.

Experimental

(1) Preparation of Compounds

1,3-Dithiole-2-thione (2)

This was prepared according to the methods of Klingsberg (10). The product was further purified by chromatography on alumina in benzene.

*In Hz.
†This coupling occurs in the molecule containing ^{13}C at position 2.
‡In Hz at 60 MHz to low field of internal TMS. The value for I is from ref. 15 and was measured at infinite dilution in TMS.
§The isotope shifts caused by substitution of ^{13}C for ^{12}C are given in Hz at 60 MHz relative to the proton shifts in the molecule containing only ^{12}C.

1,3-Dithiole-2-one (3)

This was prepared from the corresponding thione **2** by treatment with mercuric acetate as described in (11).

(2) Proton Magnetic Resonance Measurements

Samples were degassed by the freeze–pump–thaw technique and, for reasons of signal to noise ratios, contained only enough carbon disulfide to produce a liquid solution at room temperature. A small amount of tetramethylsilane acted as an internal reference and produced a lock signal for the DA-60 I spectrometer operated in the frequency sweep mode. Peak positions for **2** and **3** were calibrated repeatedly by reading sweep and manual oscillator frequencies and the sign of $J(^{13}C—C—H)$ was found by double resonance measurements as described for vinylene carbonate **2**.

Results and Discussion

(1) Analysis of Spectra

The proton resonance spectra of **2** and **3** are ABX where X = ^{13}C. The observable AB region consists of eight peaks as previously illustrated for **1** (2). With the knowledge of a positive $J(^{13}C—C—H)$ relative to $J(^{13}C—H)$ from the tickling experiments and the further certainty that $J(H—C—C—H)$ is positive (2), these peaks can be unequivocally assigned. A careful ABX analysis gave spectral parameters which reproduced the observed peak positions to within 0.005 to 0.01 Hz of the experimental ones. Consequently confidence can be placed in the isotope shifts of the protons given in Table 1, where the other parameters obtained for **2** and **3** are compared with those of **1**. The sign of $J(^{13}C—X—C—H)$ cannot be determined[1] in the isotropic phase but is almost certainly positive (12).

[1]For the molecules in which ^{13}C occurs at position 2.

(2) $J(^{13}C—C—H)$ Compared with $J(^{13}C—H)$

In the original plot of $J(^{13}C—C—H)$ *vs.* $J(^{13}C—H)$ the reference line was defined by the parameters for ethane, ethylene, acetylene, vinylene carbonate, vinyl bromide, and sym-tetrabromoethane (2). Marked deviations from this line were interpreted in terms of hyperconjugative interaction of substituent orbitals with the $^{13}C—C—H$ fragment orbitals. For reasons of space the plot is not reproduced here. However, the parameters for **2** and **3** fall almost precisely on the reference line of the plot, suggesting no hyperconjugative interaction of sulfur orbitals with the $^{13}C—C—H$ fragment in **2** or **3**. In this respect **2** and **3** are similar to the oxygen analog **1**. If, however, the sulfur 3d orbitals participated to any extent in the bonding a positive deviation from this line might be expected, inasmuch as some of the 3d orbitals for the participating divalent sulfur atoms have the required symmetry.

The present indication of little or no participation of the 3d orbitals from the divalent sulfur agrees with the electron spin resonance data on the 2,4,6-triphenylthiapyryl radical, where the hyperfine splittings can be adequately interpreted without invoking d orbital participation of the divalent sulfur (13). In a similar vein, CNDO/2 calculations on thiophene yield a good fit to the relative magnitudes of H–H and ^{13}C–H coupling constants when 3d, 4s, and 4p orbitals are neglected (14).

(3) $J(^{13}C—C—H)$ Compared with cis $J(H—C—C—H)$

A tentative explanation (8) in terms of substituent effects on resonance integrals has been

11	Benzene	7.54 ± 0.05	1.0	12, 34
12		1.75 ± 0.05	(H_1) 14.0 ± 0.1 (H_2) 7.0 ± 0.1	6, 35
13		4.7 ± 0.1	(H_1) 4.7 ± 0.1 (H_2) 7.4 ± 0.1	6, 36
14		5.5 ± 0.1	(H_1) 3.4 ± 0.1 (H_2) 5.6 ± 0.1	22

given for the relatively wide variation of $J(^{13}C—C—H)$ when both carbon atoms are sp^2 hybridized. For practical purposes, an empirical prediction of this coupling in terms of an experimentally more easily accessible parameter is desirable. In Table 2 *cisoid* J(H—C—C—H) values together with the available $J(^{13}C—C—H)$ values are collected for a series of compounds corresponding to an $sp^2 = sp^2$ situation. In Fig. 1 a plot of J(H—C—C—H) *vs.* $J(^{13}C—C—H)$ displays two correlation lines for these parameters, one for benzene, thiophene, and furan and the other for ethylene derivatives including **1**, **2**, and **3**.

Note that only an average value of $J(^{13}C—C—H)$ is plotted for each compound. For example, in vinyl cyanide the average of the two values involving the protons giving rise to J(H—C—C—H) is plotted in Fig. 1. For allyl bromide only one $J(^{13}C—C—H)$ value is avail-

For personal use only.

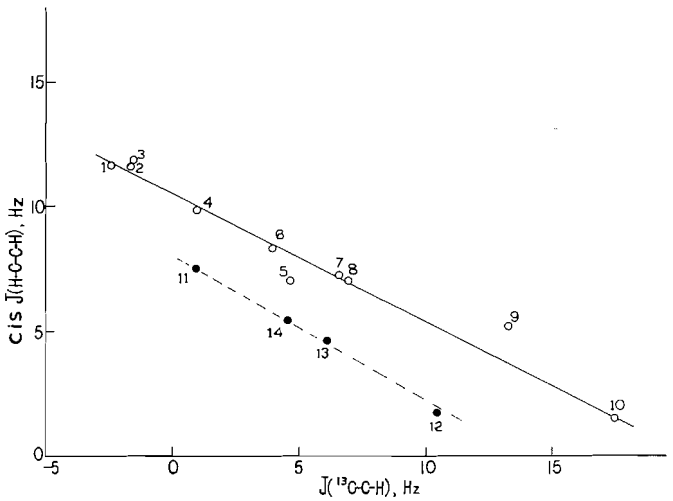

FIG. 1. The carbon–proton coupling over two bonds, $J(^{13}C—C—H)$, is plotted *vs.* the *cisoid* proton–proton coupling over three bonds for the compounds in Table 2. Only one point is given for each compound. (See text for an explanation).

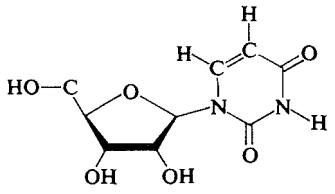
able and is plotted in Fig. 1. Although the theoretical basis underlying the correlations in Fig. 1 is not obvious, their practical use is apparent in the assignment of complex ^{13}C resonance spectra. For example, in cyclic olefins J(H—C=C—H) is strongly dependent on ring size (24–26) and the present correlation allows a prediction of certain two-bond C—H couplings in their ^{13}C spectra. They are predicted to vary widely from the value of -2.4 Hz in ethylene. As another example, the disputed values of the coupling constants in benzoquinone-$^{13}C_2$ could possibly be more firmly assigned (26, 27).

In terms of the present correlations, thiophene and furan are "aromatic", although this is not meant to imply anything about properties such as their reactivity towards electrophiles. Nevertheless, the correlation is interesting in view of the arguments for and against the use of ring currents as a measure of aromaticity (28–33) in thiophene and furan.

Compounds **1**, **2**, and **3** behave much like ethylene derivatives in Fig. 1 although **2** deviates towards the aromatic line. In any case, it seems clear that in these compounds the C=C bond has a mobile bond order near 1, in contrast to benzene, furan, and thiophene. No firm conclusions about the aromatic character of the related 1,2-dithiole-3-ones and thiones could be reached on the basis of chemical shifts or allylic proton couplings (38).

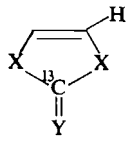
Finally a tentative application to chemical systems of biological interest is suggested by Fig. 1. For example, measurement of the two parameters in a molecule like uridine (**4**), which contains the fragment H—C=C—H in the base, should allow conclusions concerning the delocalization of the π electrons in the base.



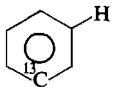
4

(4) Vicinal Carbon–Proton Coupling

In **1**, **2**, and **3**, the vicinal carbon–proton coupling can be represented as in **5** and is analogous to a *trans* coupling. In benzene (**6**) $J(^{13}C—C—C—H) = +7.4$ Hz (12), somewhat



5



6

smaller than in any of the cases **5**. This may well be a consequence of the higher effective nuclear charge (3) in the radial part of the 2s orbital at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the coupled carbon in **1**, **2**, and **3**, arising from the electronegative substituents at that position. Within the sequence **1**, **2**, **3** the effective nuclear charge is smallest in **2** resulting in the lowest $J = 8.7$ Hz. Simple Hückel type molecular orbital calculations (39) indicate larger mobile bond orders for the relevant fragments in **3** than in **2**, suggesting shorter bonds in **3**. It is therefore not surprising (40) to find the large $J = 10.4$ Hz for **3**.

(5) Isotope Shifts of the Proton Resonance

Carbon-13 isotope shifts of up to $+0.007 \pm 0.004$ p.p.m. are observed (41) for directly bonded protons in methane derivatives. A similar shift of $+0.004 \pm 0.003$ p.p.m. occurs in $F(Cl)C{=}C^{13}H_2$ (42). The isotope shifts given in Table 1 for **2** and **3** are the most precise values known to date and decrease from $+0.0035 \pm 0.0004$ p.p.m. for directly bonded protons to 0.0013 ± 0.0004 p.p.m. for a proton separated by three bonds from ^{13}C. Their interpretation for such complex molecules is by no means clear (43).

(6) $J(^{13}C{-}C{-}H)$ and cis $J(H{-}C{-}C{-}H)$ in Cyclopropane

The $J(^{13}C{-}C{-}H)$ value in cyclopropane is -2.55 Hz (44) and *cis* $J(H{-}C{-}C{-}H)$ is 8.97 Hz (45) (one proton bonded to ^{13}C). The point defined by these values would fall very nearly on the benzene line in Fig. 1. This is not to say that cyclopropane is aromatic, although a substantial ring current has been attributed to it (46).

Crecely *et al.* find interesting correlations between long-range C^{13}–H couplings and the vicinal and geminal proton–proton couplings in some monosubstituted cyclopropane derivatives (44) but it is not clear how they relate to the correlation discussed here.

We are grateful to the National Research Council of Canada for financial support.

Proton Magnetic Resonance Spectrum of Parafluorotoluene. Sigma and Pi Electron Contributions to $J_p^{H,F}$

R. WASYLISHEN[1] AND T. SCHAEFER
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received July 31, 1970

The p.m.r. spectrum of a 15 mole % solution of *p*-fluorotoluene in acetone-d_6 is analyzed at 100 MHz using LAOCN3 and LAME computer programs. The resulting spectral parameters satisfactorily reproduce the methyl proton resonance at 60 MHz. The coupling over six bonds between the fluorine nucleus and the methyl protons is 1.15 ± 0.02 Hz and is taken as a measure of the π electron contribution to the coupling over five bonds between the fluorine nucleus and the proton in *p*-fluorobenzene. The σ electron contribution to this coupling is discussed for some fluorobenzene derivatives and is shown to depend on the electronegativity of the substituents in a manner completely analogous to proton–proton and other proton–fluorine couplings in benzene and pyridine derivatives.

Canadian Journal of Chemistry, 49, 94 (1971)

Introduction

The long-range spin–spin coupling constants between methyl and ring protons in the para position, $^6J_p^{H,CH_3} < 0$, in toluene derivatives arise from a π electron mechanism (1). In a derivative of parafluorotoluene, $J_p^{F,CH_3} > 0$ and has a greater magnitude than J_p^{H,CH_3} in toluene derivatives (2). For a π electron mechanism $J_p^{H,CH_3} \alpha Q_{CH}$ and $J_p^{F,CH_3} \alpha Q_{CF}$, where Q_{CH} and Q_{CF} are the hyperfine interaction constants between an electron in a π orbital on carbon and the proton and fluorine nucleus, respectively (2). But $|Q_{CF}| > |Q_{CH}|$ and $Q_{CF} > 0$, $Q_{CH} < 0$, therefore supporting a π electron mechanism for J_p^{F,CH_3}. A similar conclusion holds for $^4J_p^{F,CH_3}$ in 2-fluoro-3-methylpyridine (3).

The long-range coupling to the methyl protons in benzene derivatives is remarkably insensitive to substituent effects (1–5). Coupling between the ring protons shows a characteristic, probably alternating, dependence on the electronegativity of the substituents (6, 7). The implied inductive effect via the σ system is accentuated for ring proton – ring fluorine couplings, particularly when the electronegative group is situated near the C—F bond (3, 8).

The coupling over five bonds, $^5J_p^{H,F}$, in fluorobenzene derivatives is sensitive to ring substitution, suggesting the presence of a σ electron contribution to $J_p^{H,F}$. A σ contribution can also be inferred from the relative magnitudes and signs of $^5J_p^{H,F}$ and $^6J_p^{F,CH_3}$. The former is small and positive in fluorobenzene but becomes large and negative in the presence of highly electronegative ring substituents. The latter is positive in a fluorotoluene derivative (2) and is much less sensitive to ring substituents.

The purpose of this paper is to establish the π contribution to $^5J_p^{H,F}$ in fluorobenzene and thus to determine the σ contribution to $^5J_p^{H,F}$, known for a series of fluorobenzene derivatives. Hence the p.m.r. spectrum of parafluorotoluene is fully analyzed.

The assumption that coupling constants in the benzene ring can be discussed in terms of σ and π electron contributions is an approximation but it is a natural one to make as long as quantum mechanical calculations, which take all valence electrons into consideration (9), have difficulties in accurately reproducing experimental values, particularly for couplings involving fluorine nuclei. The approximation has been profitably employed in discussing the coupling constants in 2-fluoro-3-methyl pyridine (3) and, more generally, in the interpretation of chemical shifts, nuclear quadrupole frequencies, and the intensities of i.r. spectra of benzene derivatives (10).

Experimental

Parafluorotoluene from Koch–Light was prepared as a degassed, 15 mole % solution in acetone-d_6, containing internal tetramethylsilane (TMS) as an internal reference and locking material. The p.m.r. spectra were recorded at a sweep rate of 0.02 Hz/s in the frequency sweep mode on HA100D and DA60I spectrometers. Ring proton spectra were also recorded while decoupling the methyl protons using an HP4204A audiooscillator. Peak positions were repeatedly calibrated by reading sweep and manual oscillators in the period mode of an HP5323A counter.

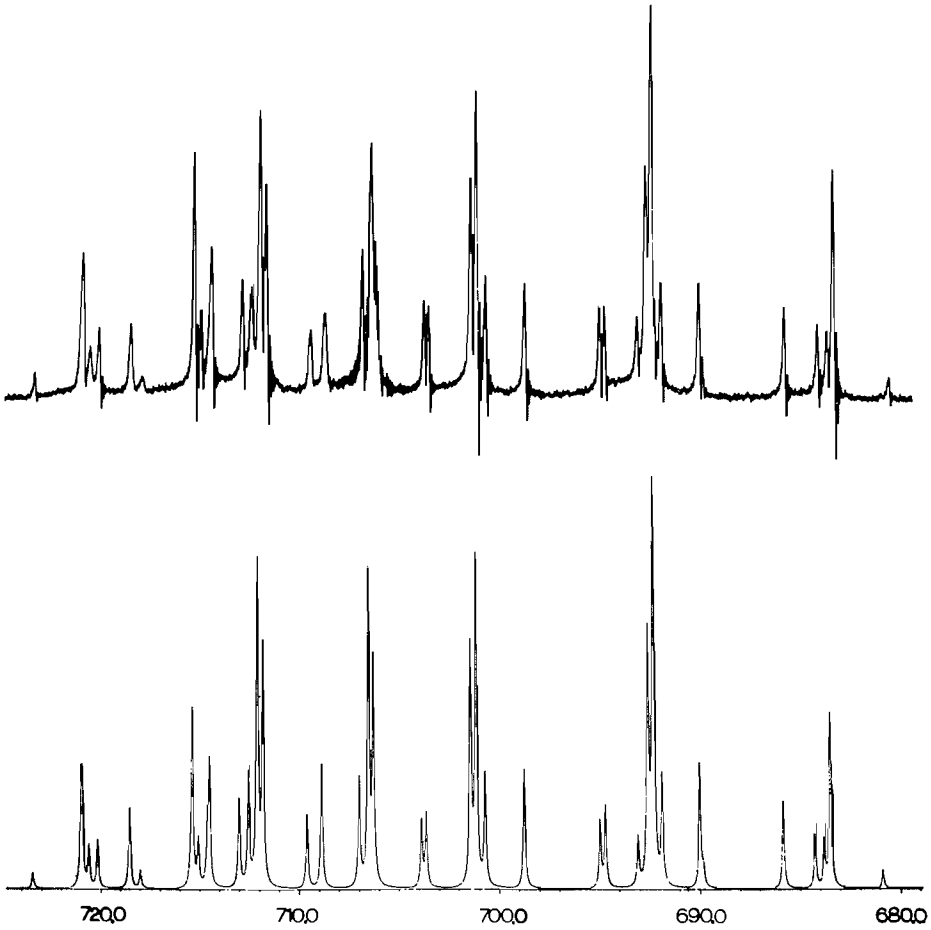

FIG. 1. The observed and calculated ring proton spectrum of a 15 mole % solution of *p*-fluorotoluene in acetone at 100 MHz when the methyl protons are decoupled. The scale is in Hz to low field of internal TMS. The spectrum was taken at a sweep speed of 0.02 Hz/s. The calculated spectrum corresponds to an effective T_2 of 2.80 s and uses the parameters in column 2 of Table 1. Note the unavoidable "beat frequency" in the observed spectrum near 706.5 Hz.

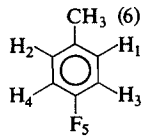
Results and Discussion

(1) Analysis of Spectra

The procedure using LAOCN3 (11) was similar to that adopted by Williamson *et al.* for toluene (4). With the methyl protons decoupled, an iterative fit to the ring proton spectrum was obtained. Initial coupling parameters were estimated from those of benzene, toluene, and fluorobenzene (4, 12, 13). In Fig. 1 the final calculated and observed spectra are displayed at 100 MHz. The iteration was carried out on 45 assigned peaks and column 2 of Table 1 gives the parameters found in this way. The numbering of parameters follows from **1**.



1

Now, because the program accommodates seven spins and because the complete spectrum of **1** is $[AB]_2X_3R$, *i.e.* eight spins, a subspectral analysis was undertaken. The methyl protons are represented by X_3 and therefore the undecoupled ring proton resonance consists of a superposition of four subspectra corresponding to the spin states $\pm 1/2$, $\pm 3/2$ of the composite

spin states of the methyl protons. Of course, the subspectra corresponding to $\pm 1/2$ have three times the intensity of the subspectra corresponding to $\pm 3/2$.

Taking values of $^4J_o^{H,CH_3}$ and $^5J_m^{H,CH_3}$ from toluene (4), the $\pm 1/2$ subspectra were generated and compared to 101 assignable peaks in the ring and methyl proton spectra. An initial value of $^6J_p^{F,CH_3}$ was extracted on a first-order basis from the methyl spectrum. An ensuing iterative fit, allowing the variation of all parameters, gave the results in column 3 of Table 1.

Sixty one peaks from the $\pm 3/2$ subspectra were then assigned and iteration on the ring protons, allowing all parameters to vary, gave the parameters in column 4 of Table 1. The Calcomp plot for the complete ring spectrum is shown in Fig. 2, together with the observed spectrum. The agreement is apparently satisfactory. The probable errors in the parameters are small and multiplication by 8 still yields an acceptably small error estimate in the coupling constants. The parameters obtained from the $\pm 1/2$ subspectra are felt to be more reliable. In Fig. 3, the methyl proton resonance is shown together with the calculated spectrum. The LAME results (see below) are used but the LAOCN3 parameters give substantially the same calculated spectrum.

Comparison of the shift parameters for the decoupled and undecoupled spectra suggests that the decoupling conditions were such as to cause very small (about 0.03 Hz) frequency shifts; due either to the Bloch–Siegert effect or to a bias in the lock signal.

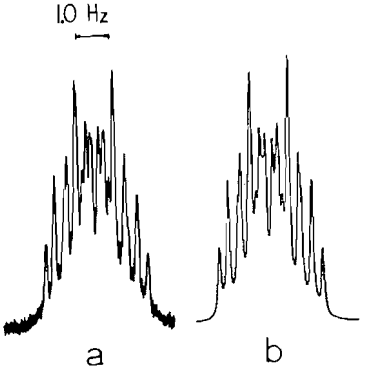

FIG. 3. The experimental and calculated methyl proton spectra at 100 MHz. The experimental spectrum was taken at a sweep speed of 0.01 Hz/s. The effective T_2 of the calculated spectrum was 2.90 s and the parameters are taken from column 5 of Table 1.

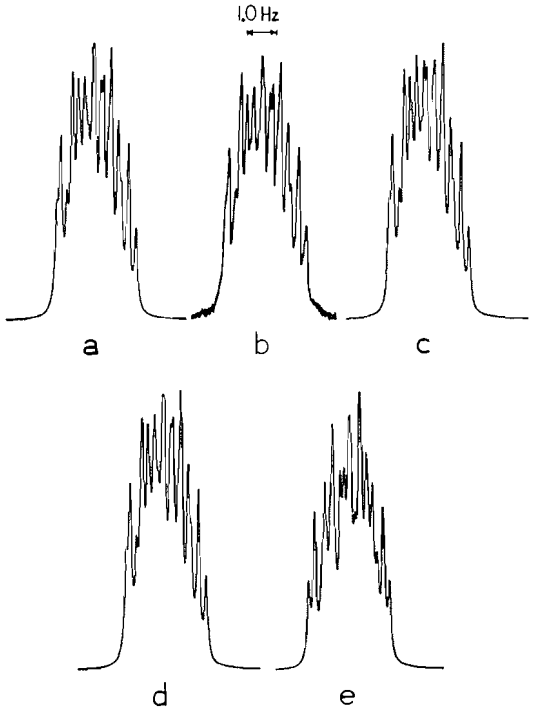

FIG. 4. The experimental methyl proton resonance at 60 MHz, taken at a sweep rate of 0.01 Hz/s, is shown in (*b*). In (*a*) the calculated spectrum is shown using parameters from column 5 of Table 1 but with $J_p^{F,CH_3} = 1.154$ Hz. In (*d*) and (*e*) the same parameters are again used but $J_p^{F,CH_3} = 1.149$ and -1.149 Hz, respectively. In (*c*) the parameters from columns 3 and 4, weighted 3:1 in favor of the $\pm 1/2$ subspectra, are used, $J_p^{F,CH_3} = 1.135$ Hz. In all calculated spectra the effective $T_2 = 2.50$ s.

The parameters obtained from the LAOCN3 analysis were weighted 3:1 in favor of those from the $\pm 1/2$ subspectra and were then employed in the generation of the methyl proton spectrum at 60 MHz (Fig. 4*c*). The observed spectrum at 60 MHz in Fig. 4*b* displays asymmetry about its shift position. The asymmetry depends on the sign[2] of J_p^{F,CH_3}. Although the agreement between calculated and observed spectra is close, it is clear that the positions of a few peaks in the central region of the observed and calculated spectra differ by some hundredths of a Hz.

The reason for the disagreement most likely lies in the value of J_p^{F,CH_3}. Analysis of the proton spectrum at 100 MHz using the computer program LAME (see below) gave $J_p^{F,CH_3} = 1.149$ Hz,

[2]Tickling experiments along the lines described for *p*-fluorobenzaldehyde (14) confirmed the positive sign of J_p^{F,CH_3}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

an increase of 0.014 Hz over the value obtained from LAOCN3. In Fig. 4*d* the calculated methyl spectrum at 60 MHz now agrees almost perfectly with the observed spectrum in Fig. 4*b*. Increasing J_p^{F,CH_3} by another 0.005 Hz produced somewhat better agreement with the observed spectrum (see Fig. 4*a*). The sensitivity to this parameter indicates to us that the accuracy in J_p^{F,CH_3} is 0.02 Hz, *i.e.*, $J_p^{F,CH_3} = 1.15 \pm 0.02$ Hz.

An analysis using the program LAME (14*a*) was also performed. Transitions are all weighted equally and standard deviations are given in brackets in Table 1. The average deviation between observed and calculated peaks lies near 0.01 Hz. In the correlation matrix (12 parameters) there are four values between 0.2 and 0.3, 11 values between 0.1 and 0.2, and the rest are below 0.1 in magnitude. A relatively large correlation of 0.27 between $J_p^{H,H}$ and $J_o^{H,H}$ can be understood on noting that, as is more easily seen for a case $[AB]_2$, the separation between certain sets of intense peaks is given by $J_p^{H,H} + J_o^{H,H}$.

(2) The Chemical Shifts and Ring Proton–Proton and Ring Proton–Fluorine Couplings

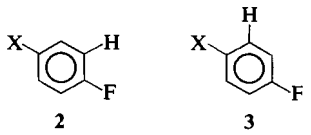
The chemical shifts are solvent dependent (15) and will not be further discussed.

(a) Proton–Proton Couplings

The additivity of substituent effects on $J^{H,H}$ is established, particularly for disubstituted benzenes (12, 16). There is a small solvent effect on some $J_m^{H,H}$ values (17, 18). Loemker and Goldstein analyzed the proton resonance spectrum of fluorobenzene as a 10 mole % solution in acetone (18). An additivity scheme using their parameters and those of benzene and toluene as reported by Williamson *et al.* (4), yields predicted values of *p*-fluorotoluene as follows: $J_{12} = 2.32$, $J_{13} = 8.46$, $J_{14} = 0.40$, $J_{34} = 2.87$ Hz. The excellent agreement between these numbers and those given in Table 1 can be taken as indicating the validity of the present analysis of the spectrum of *p*-fluorotoluene. Note that the initial parameters for our analysis were estimated from the analysis of fluorobenzene in carbon tetrachloride solution and not from the analysis of Loemker and Goldstein in acetone solution.

(b) Ring Proton–Fluorine Couplings

In a 10 mole % solution of fluorobenzene in acetone (18) $J_o^{H,F} = 9.31$ Hz and $J_m^{H,F} = 5.79$ Hz. In *p*-fluorotoluene as a 15 mole % solution in acetone, where the relatively strong solvent dependence of these two couplings (19–21) should be very nearly equal in the two compounds, we have $J_o^{H,F} = 8.96$ Hz and $J_m^{H,F} = 5.43$ Hz. The decrease by 0.35 Hz of both couplings on introduction of the methyl group originates in the electronegativity of CH_3 which is higher than that of H. According to the alternating substituent effect rule (6, 7), $J_o^{H,F}$ increases if X is placed ortho to H or F but should decrease if X is



2 **3**

situated meta to H or F in **2**, as we observe. The $J_m^{H,F}$ value in **3** has been observed to decrease in a series of compounds (8), and this behavior is consistent with that of other couplings as is discussed further below.

(3) The Long-range Methyl Couplings

(a) With Ring Protons

These agree to within experimental error with those found in toluene (4) where $J_o^{H,CH_3} = -0.746 \pm 0.026$ Hz and $J_m^{H,CH_3} = 0.356 \pm 0.006$ Hz (errors given are the mean of the difference in the values found from the different subspectra). The conclusions concerning the σ and π electron mechanisms are as recently discussed (1, 4), both couplings having some σ electron contribution in contrast to J_p^{H,CH_3}.

(b) With Fluorine

From Table 1, $J_p^{F,CH_3} = 1.15 \pm 0.02$ Hz in *p*-fluorotoluene. On the assumption that J_p^{F,CH_3} is dominated by a π electron mechanism (2), write

$$[1] \qquad {}^{\pi}J_p^{F,CH_3} \alpha Q_{CF} Q_{CCH}$$

eq. 1, where both hyperfine interaction constants are positive. The Q_{CF} term is composite, varying in magnitude from radical to radical (22–26). In the present connection, the most appropriate Q_{CF} value is one for radicals which approximate as closely as possible to a closed-shell system in the fragment containing the C—F bond. The most likely candidates are the nickel(II) aminotroponeimineate derivatives containing fluorosubstituted phenyl groups (27), where a small spin density from the nickel orbitals is delocalized into the phenyl groups. In such compounds $Q_{CF} = 41.1$ G for the *p*-fluorophenyl derivative (27).

A calibration of the proportionality in eq. 1

*The accuracy probably lies between 0.05 and 0.1 Hz.
†The electronegativity, E_X is taken from ref. 39 where $J^{H,H}$ values in benzene derivatives are plotted *vs.* $E_X - E_H = 2.20$.
‡In dimethylformamide (18) $J_p^{H,F}$ is evidently as high as 0.5 Hz.

may be obtained by writing eq. 2, for toluene,

$$[2] \qquad {}^{\pi}J_p^{H,CH_3} \alpha Q_{CH} Q_{CCH}$$

and noting that, by the methyl group replacement technique (28), J_p^{H,CH_3} arises from a π mechanism. Then, assuming that the mobile bond order between C-1 and -4 in toluene, *p*-xylene, and *p*-fluorotoluene does not vary significantly (29), take $Q_{CH} = -22.5$ G (30), $Q_{CF} = 41.1$ G (27), and $J_p^{H,CH_3} = -0.62$ Hz (4). Consequently ${}^{\pi}J_p^{F,CH_3} = -0.62 \times 41.1/-22.5 = 1.16$ Hz.

The close agreement between experiment and model is an indication of the Q_{CF} value appropriate to neutral molecules. It is unlikely that other than a π mechanism is important for a coupling over six bonds. Then −1.15 Hz represents the π electron contribution to J_p^{HF} in fluorobenzene.

(c) Sigma Electron Contribution to $J_p^{H,F}$ in Fluorobenzene Derivatives

On the assumption that the π contribution to $J_p^{H,F}$ is not substantially altered by the substituents in fluorobenzene derivatives[3,4] an assumption which holds to within experimental error for $J_p^{H,H}$ in benzene derivatives (1–5), the σ electron contribution to $J_p^{H,F}$ in fluorobenzene and its derivatives can be discussed as follows. The $J_p^{H,F}$ value in fluorobenzene lies between 0.2 and 0.4 Hz depending on solvent and analytical conditions (13, 20, 21). Writing $J(\text{obs}) = {}^{\pi}J + {}^{\sigma}J$, it follows that ${}^{\sigma}J_p^{H,F} \approx 1.4$ Hz in fluorobenzene.

In Table 2 values of $J_p^{H,F}$ are collected for a few pertinent fluorobenzene derivatives. In Fig. 5, $J_p^{H,F}$ is plotted *vs.* the electronegativity, E_X, of the substituent X in some 2-X fluorobenzenes.

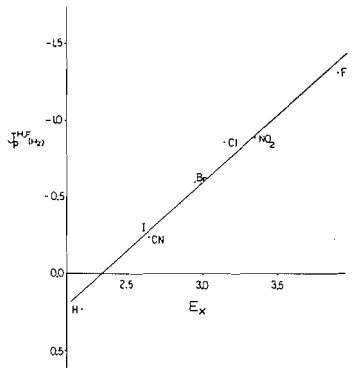

FIG. 5. The $J_p^{H,F}$ value in a number of monosubstituted fluorobenzene derivatives is plotted *vs.* the electronegativity, E_X, of the substituent X. Values are taken from Table 2. The least squares line is given by $J(\text{Hz}) = (-0.882 \pm 0.047)E_X + 2.06 \pm 0.143$. The correlation coefficient, $r = 0.990$.

[3]In 4-fluoro-2-iodotoluene (2) $J_p^{F,CH_3} = 1.28 \pm 0.07$ Hz while preliminary analyses of 2-nitro-4-fluorotoluene and of 3-bromo-4-fluorotoluene in this laboratory show that J_p^{F,CH_3} is constant to within about 0.1 Hz. In pentafluorotoluene, $J_p^{F,CH_3} = 1.4 \pm 0.2$ Hz (32).

[4]Solvent effects on J_p^{F,CH_3} are negligible. Thus we find that even partial protonation of 2-fluoro-5-methylpyridine does not change J_p^{F,CH_3}.

Relative magnitudes of Δ: $\Delta_1 < \Delta_2 < \Delta_3 < \Delta_4 < \Delta_5$

CHART 1

From Table 2 it is apparent that the decrease in $J_p^{H,F}$ as E_X increases is somewhat larger for X placed ortho to F than for X placed ortho to H. Similar plots can be constructed for more heavily substituted fluorobenzenes, data on which can be found in refs. 19, 34–38. The lowest value of $J_p^{H,F}$ is -2.7 Hz in pentafluorobenzene (38).

The data in Table 2 are collected to demonstrate that the observed dependence of $J_p^{H,F}$ on E_X is exactly as expected from previous observations on the E_X dependence of $J_{o,m,p}^{H,H}$ and $J_{o,m}^{H,F}$ in derivatives of benzene, fluorobenzene and pyridine derivatives (3, 6–8, 39). The various J, E_X relationships can be most clearly and economically represented by the diagrams in Chart 1. Let the rate of change of J with E_X be represented by Δ. Then the signs of Δ are as given inside the regular hexagon and the relative magnitudes of Δ are as given at the bottom of Chart 1. In other words, the sign of Δ alternates (6) with the number of bonds separating X from the nucleus involved in the spin–spin coupling. The magnitude of Δ decreases as the number of intervening bonds increases, as predicted on the basis of an inductive effect via the σ system. The alternation has been related (7) to charge alternation predicted by CNDO calculations (40), thus

$$\begin{array}{r} \Delta+\ \Delta\Delta-\ \Delta\Delta\Delta+ \\ X\leftarrow C-C-C- \end{array}$$

In summary, H–F couplings in aromatic compounds show the same qualitative dependence on E_X as do H–H couplings, but the magnitude of the changes is larger for H–F than for H–H couplings. In contrast (41), the analogous F–F couplings behave quite differently.

(4) Sigma or Pi Mechanism for $J_p^{H,H}$ in Benzene

In benzene $J_p^{H,H} = 0.63$ Hz (4), while in toluene $J_p^{H,CH_3} = -0.62$ Hz (4). By the methyl group replacement technique (28) it follows that $J_p^{H,H}$ in benzene itself arises from a π electron mechanism. This conclusion is reinforced by the observation of $J_p^{CH_3,CH_3} = 0.62$ Hz in a derivative of *p*-xylene (1).

Now J_p^{H,CH_3} in toluene derivatives is independent of substituents. For example, $J_p^{H,CH_3} = -0.63$ and -0.59 Hz in 2,6-dichlorotoluene and 3,5-dichlorotoluene respectively,[5] and $J_p^{H,CH_3} = -0.63$ Hz in 2,3,5,6-tetrachlorotoluene (42). Yet $J_p^{H,H}$ decreases, although never to less than 0.2 Hz, on substitution in the benzene nucleus (17). In terms of the present model, the substituent distorts the σ core near the coupled proton leading to a negative σ electron contribution to $J_p^{H,H}$. In other words, the σ electron contribution to $J_p^{H,H}$ vanishes in benzene, is negative in benzene derivatives (apart from compounds like phenyllithium, presumably) and is positive in pyridine derivatives ($J_p^{H,H} = 0.99$ Hz in pyridine (43)). In contrast, the σ and π electron contributions to $J_p^{H,F}$ in fluorobenzene are sizeable but nearly equal in magnitude.

Nature of the Coordination Bond in Metal Complexes of Substituted Pyridine Derivatives. VI. Electronic Spectra of Some Complexes of Copper(II)

MISS M. TONG AND D. G. BREWER
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received July 27, 1970

The electronic spectra of some substituted pyridine complexes of copper(II) have been studied. The effects of bonding on the spectroscopic data are discussed, and compared with the R_π values determined from infrared measurements.

Canadian Journal of Chemistry, 49, 102 (1971)

Introduction

The comments of a referee of an earlier paper from this laboratory (1) have prompted us to investigate the electronic spectra of some substituted pyridine complexes of copper(II). König and Schläfer (2, 3) found in the electronic spectrum of $Cupy_2Br_2$ a high intensity band at 410 mμ, which was assigned to the excitation of the metal "d" electron to the empty π-antibonding orbitals of the pyridine. The energy of the metal-to-ligand charge transfer band changes when the oxidizability of the metal or the reducibility of the ligand is altered (4). Thus, in the copper complexes of pyridine with different substituents in the para position, a variation in the energy of the metal-to-ligand charge transfer band is expected.

In our previous paper, a parameter R_π was introduced to indicate the relative π-contribution to the coordination bond in a series of complexes. This parameter was determined from a comparison of the infrared spectra of the metal complex with that of a protonated species where only σ bonding occurs. The extent of "d" orbital splitting in transition metal complexes is also known to be sensitive to metal–ligand π-bonding (5). The question arises as to whether the ligand field splitting parameters would be as sensitive to the substituent on the pyridine ligands as the R_π parameter, and this investigation attempts to answer that query.

Experiment

The method for the preparation of the copper bromide complexes CuL_2Br_2 (L = pyridine, 4-methylpyridine, 4-carbinylpyridine, 4-acetylpyridine, 4-carbomethoxypyridine, 4-cyanopyridine, and 4-nitropyridine) was similar to that reported elsewhere (1).

4-Nitropyridine was prepared and purified according to the procedure of Ochiai (6).

The infrared absorption spectra were recorded on a Beckman IR 12 filter/grating spectrophotometer, using the KBr disc method.

The visible absorption spectra were recorded on a Hitachi Ratio Recording spectrophotometer, model EPS-3T. Most of the selected complex compounds were almost insoluble in ordinary solvents. The spectra of the solid samples were obtained using Nujol mull (7). At room temperature the copper-to-pyridine charge transfer band near 410 mμ appeared as a shoulder and could not be resolved. For this reason, low temperature studies were carried out, using liquid nitrogen, and the two nicely separated peaks as shown in Fig. 1 were obtained. This low temperature method has been described by Rowley and Drago (8).

The position of the absorption peaks was determined by the computer program written by Pitha and Jones (9).

Results

The electronic spectra of all the copper complex compounds showed two absorption peaks

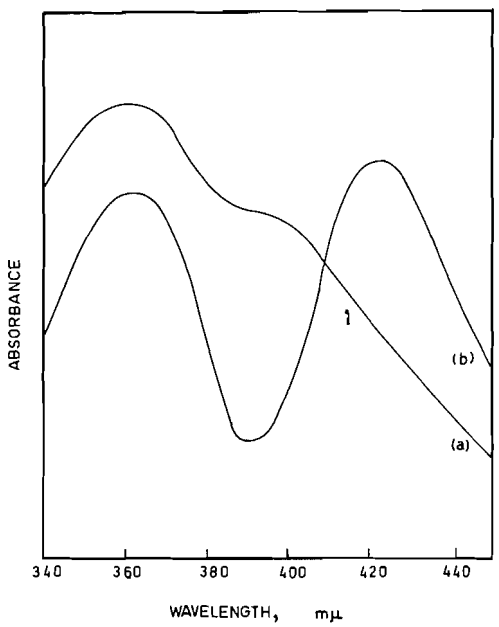

FIG. 1. Electronic absorbance spectra of $Cupy_2Br_2$ in Nujol mull: (*a*) at room temperature; (*b*) at liquid nitrogen temperature.

TABLE 1. Electronic spectral data

Compound	Bromine charge-transfer band (mμ)	Pyridine charge-transfer band (mμ)	d–d Transition (mμ)	R_π	pK_a
$Cu(4\text{-}CH_3py)_2Br_2$	360	407	672 (14 880 cm^{-1})	5.5	6.03*
$Cu(4\text{-}CH_2OHpy)_2Br_2$	361	410	658 (15 200 cm^{-1})	14.5	5.40†
$Cu(py)_2Br_2$	359	416	700 (14 290 cm^{-1})	15.5	5.21*
$Cu(4\text{-}COOCH_3py)_2Br_2$	359	417	691 (14 470 cm^{-1})	32.5	3.49*
$Cu(4\text{-}COCH_3py)_2Br_2$	359	418	690 (14 490 cm^{-1})	36.6	3.50†
$Cu(4\text{-}CNpy)_2Br_2$	360	418	688 (14 530 cm^{-1})	58.6	1.86*
$Cu(4\text{-}NO_2py)_2Br_2$	360	418	683 (14 680 cm^{-1})	60.6	1.39*

†From ref. 1.

between 350 to 420 mμ. For the $Cupy_2Br_2$ complex, the first peak appeared at 359 mμ and remained almost the same for the whole series of complexes with different substituted pyridine ligands, and therefore was assigned as the bromine-to-metal charge transfer band. The second peak, which appeared at 416 mμ and shifted either to lower or higher wavelengths depending upon the substituents, was assigned as the pyridine charge transfer band. This peak was also observed to disappear when pyridine was replaced by ammonia which does not possess any suitable π-acceptor orbitals. A d–d transition band of relatively low intensity appeared in the region between 650 to 700 mμ for all the compounds studied. The ligand field splitting parameter 10 Dq was taken as being equal to the energy of this transition band (3). The electronic spectral data are reported in Table 1, together with the R_π and the pK_a (1, 10) values for each complex compound. R_π values are calculated from the equation: $R_\pi = \nu_{ML} - (1.002\nu_L - 3.60)$ where ν_{ML} and ν_L are the ν_{12} vibration frequencies of the complex and the free ligand, respectively.

Discussion

Dibromobispyridinecopper(II) has been shown to have a distorted octahedral arrangement of ligands around the copper atom, with the pyridine rings *trans* to each other (Fig. 2) (11). The substitution of a functional group in the para position of pyridine should have a very small steric effect. Thus, as a first assumption, we have taken that all the 4-substituted pyridine copper(II) complexes have the same configuration as $Cupy_2Br_2$.

The 10 Dq values shown in Table 1 for the series of CuL_2Br_2 complexes are quite different. It is of interest to consider the origin of such a variation. According to Dunn (12), 10 Dq values

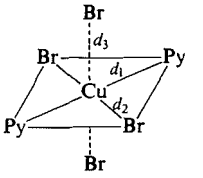

FIG. 2. Structure of $Cupy_2Br_2$: d_1 = 1.99 Å; d_2 = 2.46 Å; d_3 = 3.17 Å.

are influenced by at least four factors: (*i*) purely electrostatic perturbation, (*ii*) the effect of σ-lone pairs belonging to the ligand; that is, the effect of the basic strength of the ligand, (*iii*) the effect of metal-to-ligand π-bonding, and (*iv*) the effect of ligand-to-metal π-bonding. Of all the contributions to 10 Dq, we can neglect (*i*) as we are dealing with the same donor atom. The increase of the basic strength of the ligand would tend to increase the relative magnitude of the σ-bond. On this basis, 4-methylpyridine and 4-carbinylpyridine, which have greater basicity than pyridine, as judged by their pK_a values, will impose a stronger splitting on the copper metal d-orbitals, and should show a higher 10 Dq value than pyridine. This is observed experimentally. However, the 10 Dq value of the 4-carbinylpyridine complex is higher than that of the 4-methylpyridine. This is not expected, since the pK_a value of the latter is higher. It is doubtful, in this case, that the larger 10 Dq value can be attributed to the σ-bonding alone. We suspect that the structure of the complex may also play an important role. Recently, Graddon *et al.* proposed a polymeric octahedral structure for the cobalt(II) complex of 4-carbinylpyridine with the oxygen atom in the carbinyl group taking part in the coordination (13). Whether the same situation occurs in the copper 4-carbinylpyridine bromide complex needs further investigation.

For the compounds containing an electron-

For personal use only.

donating substituent, the effect of π-bonding on the 10 Dq value is expected to be relatively small (1), and any observed variation in 10 Dq can be attributed largely to σ-bonding changes (*i.e.*, basicity) of the ligand. On the other hand, with electron-withdrawing substituents, the π-bonding is expected to be greatly increased at the expense of the σ-bonding, via a synergic mechanism (14). Hence, 10 Dq should be greatly influenced by π-bonding in these particular complexes, *viz.*

$$4\text{-}NO_2py > 4\text{-}CNpy > 4\text{-}COCH_3py > 4\text{-}COOCH_3py > py.$$

Unlike the bromine charge-transfer band, which is not sensitive to the substituents in the pyridine ring, the metal-to-ligand pyridine charge transfer band of the whole series of complex compounds can be divided into two groups. For complexes with electron-donating substituents such as $4\text{-}CH_3py$ and $4\text{-}CH_2OHpy$, which inhibit π-back donation, an increase in the energy of the metal-to-ligand charge transfer band occurred. For complexes with electron-withdrawing substituents, such as $4\text{-}NO_2py$, 4-CNpy, $4\text{-}COCH_3py$, and $4\text{-}COOCH_3py$, which should enhance the π-back donation, no significant change in the energy of the metal-to-ligand charge transfer band can be observed. Hence, one can conclude from the electronic spectral data that there is no π-bonding at all, or that the charge transfer process is insensitive to π-bonding.

If R_π is taken to represent the extent of π-bonding, there is clearly an increase in such bonding from $—CH_3$ to $—NO_2$ as expected. It can be concluded that R_π is a much more sensitive parameter than the others examined.

We are indebted to the National Research Council of Canada for the necessary funds for this investigation.

Pyrazolines XI.
Determination of the Stereochemical Changes at Carbons-3 and -5 of 1-Pyrazolines on Their Thermal Conversion to Cyclopropanes[1]

D. E. McGreer and J. W. McKinley
Department of Chemistry, The University of British Columbia, Vancouver, British Columbia

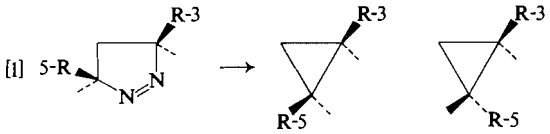
Received June 22, 1970

Six 3,3,4,5-tetrasubstituted pyrazolines have been prepared and the product distribution from their pyrolysis reactions have been determined. This has permitted for the first time the unambiguous evaluation of the stereochemical fate of C-3 and -5 of the pyrazolines on conversion to cyclopropanes. A stereoselectivity is noted for these systems which can be related to the structure of the initial pyrazoline. This suggests that the transition state for reaction retains many of the stereochemical factors present in the pyrazoline. Such a condition would be the case for concerted breaking of the two C—N bonds with a developing overlap of the new bonds being formed at the transition state. That this reaction is not restricted by symmetry constraints suggests that the three carbon fragment can act as a symmetric or antisymmetric unit and that these are not separated by more than a few kcal of energy.

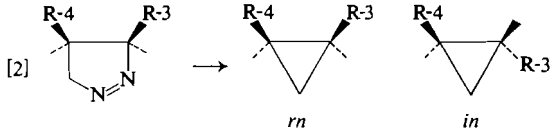
Canadian Journal of Chemistry, 49, 105 (1971)

The pyrolysis of pyrazolines leads, by loss of nitrogen, to cyclopropane and olefin products. Van Auken and Rinehart (1) were the first to make a serious attempt to determine a relationship between the stereochemistry in the cyclopropane formed and the pyrazoline used. Since then extensive studies have been made providing varying amounts of information concerning the stereochemical outcome at carbons originally at C-3 or -5 in the pyrazoline. For the present paper we wish to identify the stereochemical fate of C-3 and -5 by the symbols *n* (no information), *r* (retention), or *i* (inversion) and thus *ir* will mean inversion at C-3 and retention at C-5. Results in the literature can be cataloged into three classes.

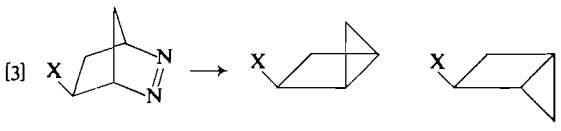
Class I, with selected examples in Table 1, provides relative stereochemical change at C-3 and -5 of a pyrazoline. This situation is found for systems that have a stereochemical label at C-3 and -5, but nowhere else, as in eq. 1.[2]

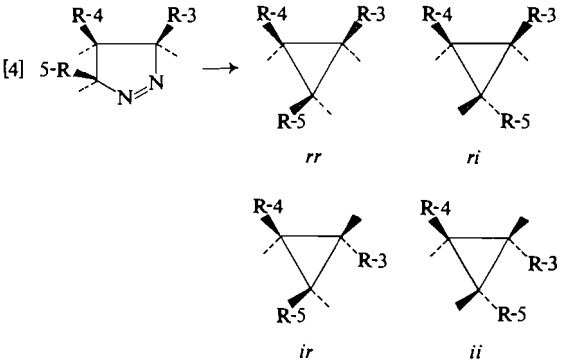


Class II, with selected examples listed in Table 2, provides precise information at one of C-3 or -5 with reference to some other part of the molecule. An example is illustrated in eq. 2.



Class III, with selected examples listed in Table 3, provides precise information at both C-3 and -5 and is illustrated by eqs. 3 and 4.





[1]Taken in part from the M.Sc. Thesis of J. W. McKinley (24). Presented in part at the ACS-CIC conference in Toronto, May 1970.

[2]For illustration we have drawn one enantiomer of a racemic pair and have used the *cis* stereoisomer for convenience only. The projection in the Tables corresponds to a view from outside the ring along a line through C-4 and bisecting the N=N group.

The literature to date lacks examples of eq. 4. In the present paper we report on the preparation of six new pyrazolines in this class and report on product analyses from the pyrolysis reaction.

Preparation and Identification of Stereochemistry

Three sets of C-5 epimeric pyrazolines were prepared by (*a*) addition of phenyldiazomethane to 3-methyl-3-pentene-2-one, (*E*)-, (*b*) addition of phenyldiazomethane to 3-methyl-3-pentene-2-one, (*Z*)-, and (*c*) addition of diazoethane to 3-methyl-4-phenyl-3-butene-2-one, (*E*)-.

The pyrazolines prepared according to (*a*)–(*c*) were expected to be **1** and **2**, **3** and **4**, and **5** and **6** respectively since it is known that the addition of diazoalkanes does not affect the stereochemistry of the α and β positions of the unsaturated ketone (1).

The pyrazoline assigned structure **5** crystallized from a mixture of **5** and **6** in an ether – petroleum ether solution and was obtained pure. None of the other pyrazolines could be prepared pure. Compounds **3** and **4** were solids and on one occasion could be separated after a crystallization which yielded two crystal sizes, thus the isomers were obtained 95 and 75%[3] pure respectively. Pyrazolines **1**, **2**, and **6** were never crystallized and are assumed to be liquids. In acetone, **1** pyrolyzed at room temperature considerably faster than **2** permitting the isolation of a sample of **2** of 95% purity. Column chromatography on silica gel using ether – petroleum ether (5:95) permitted partial separation of the pyrazolines and in this way **1**, **2**, and **3** were enriched to 85, 62, and 72% purity, respectively.

The identification of pyrazolines **1** to **6** is based on their n.m.r. spectra presented in Table 4, the relative rates of pyrolysis of C-5 epimeric pairs and the proportion of olefin to cyclopropane derivatives in the pyrolysis product.

For a discussion on the use of n.m.r. in this structural determination it is necessary to recognize that pyrazolines adopt a non-planar conformation (**5**) with the plane of the three carbon atoms at an angle (θ) to the plane of C-3, -5, and

[3]Purity in percent refers to the proportion of the two isomers as estimated by n.m.r.

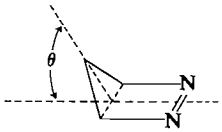
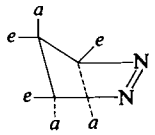
the two nitrogens. 1-Pyrazoline has a potential minimum at 19.7° (11) and pyrazolines held in one conformation have dihedral angles (θ) of 22–31° (3, 5, 8). Thus depending on the substitution pattern we can have principally one conformer or an equilibrium between two conformers which are not necessarily of equal thermodynamic stability. Earlier studies have indicated a preference by bulky groups to adopt the pseudo equatorial positions (5, 12). This factor is strongest for a 3,5-*cis*-disubstituted pyrazoline.



5



6

Pyrazolines **1**, **3**, and **5** can have three groups pseudo equatorial and are expected to be predominantly in this form. They will, in this form, have the C-4 and -5 hydrogens in a *trans* orientation with a dihedral angle close to 180°, leading to large coupling constants (with a potential maximum of about 11 Hz (7)). Were there an appreciable amount of the other conformer the coupling constant would be reduced to a value of 7–8 Hz corresponding to that for systems with equal conformer populations. Thus coupling constants of 10.4, 9.8, and 8.4 Hz for **1**, **3**, and **5** imply that each of these compounds is predominantly in the conformation shown in Table 4, with the magnitude of θ being greatest for **1** and least for **5**. The coupling of 8.4 Hz for **5** implies either the presence of some of the other conformer or a smaller value of θ.

The presence of two methyls on C-4 in 4,4-dimethyl-1-pyrazoline considerably reduces its rate of pyrolysis (3) by interfering with the loss of nitrogen through a stretching mode perpendicular to the plane of C-3, -4, and -5. In a similar way for pyrazolines locked in one conformation the presence of a pseudo axial group at C-4 would reduce the rate of pyrolysis. Thus the fact that **1** pyrolyzes nine times faster than **2** supports the structural assignment to these compounds. Similarly **3** pyrolyzes more than five times faster than **4**.

Pyrazolines **2**, **4**, and **6** can have only two groups pseudo equatorial and are expected to prefer the conformation with C-3 and -5 having equatorial substituents. There should, however, be more flexibility in these systems. These compounds all have a *cis* orientation between the C-4 and -5 hydrogens. The increased flexibility and the *cis*-orientation are in line with coupling

		$\Delta = 0.75$				

constants of 7–8 Hz and thus coupling constants provide a lead to the assignments of structure.

In addition, however, the above arguments on conformation can be applied to chemical shifts which are principally affected by the anisotropy of the N=N double bond. Groups in the pseudo axial position are placed in the shielding cone of the N=N group and are shifted to higher field. Such groups are emphasized in Table 4 by underlining the observed chemical shift positions and a comparison of values between C-5 epimers is consistent with the structural assignments. The spread in the values of the chemical shifts of the C-5 hydrogen for C-5 epimers can be related to conformer populations. A large angle θ would be expected to increase the shielding of this hydrogen by the azo group as in **1** and **3**. Increased flexibility leading to a mixture of conformers would de-

crease this shielding. For comparison we can consider the 4.80 τ position of the C-5 hydrogen in *cis* 3,5-bis(*p*-anisyl)-1-pyrazoline which is rigid with a large θ and the 4.25 τ value for the *trans* isomer which is an equilibrating system with two equally populated conformations. The epimers **5** and **6** do not lend themselves to this treatment as they have the additional factor of a phenyl group on C-4 which in one case is *cis* to the hydrogen at C-5 and the other case is *trans*.

We have estimated the relative magnitude of θ for **1**, **3**, and **5** from coupling constants of the ring hydrogens. An alternative approach using chemical shifts results if we compare chemical shift position of the C-3 methyl to that of the acetyl methyl. The differences (Δ) are recorded in Table 4. We again anticipate that the value for the axial group will be raised by shielding from the azo group and thus a large value for Δ implies that the C-3 methyl is axial and a small Δ implies the C-3 methyl is equatorial, since the C-3 methyl is always to higher field than the acetyl methyl. For comparison the conformationally labile 3-methyl-3-acetyl-1-pyrazoline has a Δ value of 0.84 and *cis* and *trans*-3,5-dimethyl-3-acetyl-1-pyrazoline have Δ values of 0.62 and 0.98. These latter two compounds provide reference points for evaluating the locking of individual conformations. Values of Δ greater than 0.98 imply an axial C-3 methyl and for these compounds the larger value of Δ correlates with larger values of θ. Values of less than 0.62 imply an equatorial C-3 methyl and in these cases the smaller the value of Δ the greater the value of θ. Thus **1** is strongly locked, **3** and **4** are less so, and **2** is likely flexible. It is difficult to evaluate clearly the situation for **5** and **6** due to the presence of the phenyl at C-4 which appears to be shielding the *cis* methyl, however, other evidence (coupling constants, product results, etc.) indicates **5** has a larger value of θ than does **6**.

Olefins from 1-pyrazolines in this series are known to be formed by migration of hydrogen from the pseudo equatorial position at C-4 by a concerted *trans* migration with loss of nitrogen (8). Olefin formation is strongly favored by a phenyl at C-4 and moderately favored by a methyl at C-4. The absence of olefin product from **1**, **3**, and **5** is in accord with a structure favoring a conformation having a methyl or phenyl in the pseudo equatorial position. That **6** on the other hand gives 67% olefin product provides the best evidence for the structural assignment to **5** and **6**.

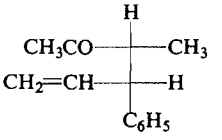
Pyrolysis Results

Cyclopropanes

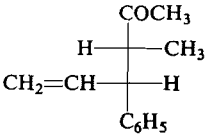
There are four cyclopropane products possible from pyrolysis of pyrazolines **1** to **6**. These are listed in Table 5 with the n.m.r. data obtained for the three isolated cyclopropanes. Two of these cyclopropanes do not give the ring opening reaction at temperatures above 250° expected for compounds having a methyl *cis* to an acetyl group (13). The vicinal ring hydrogen coupling constants in this pair are 7.0 and 9.8 Hz identifying them to be **8** and **9** respectively based on the observations of Patel *et al.* (14) that *cis* couplings (8.0–11.2 Hz) are larger than *trans* couplings (5.2–7.0 Hz) for vicinal ring hydrogens.

The coupling constant for the vicinal ring hydrogens of the third isolated cyclopropane was 6.4 Hz, clearly that of a *trans* orientation. Since this compound at 227° readily ring opens it is identified to be **7** and the ring opened products would be **11** and **12**, eq. 5.

[5] 
7



11



12

The effect of phenyl on a vicinal methyl or acetyl group is one of shielding as seen by the chemical shift positions of the C-1 methyl and acetyl groups. Thus the C-1 methyl of **7** and **9** is to higher field than that of **8** and the C-1 acetyl of **8** is to higher field than that of **7** and **9**. That the phenyl gives a shielding effect is undoubtedly due to the crowding in the molecules which would force the plane of the phenyl group towards a dihedral angle of 90° with the plane of the cyclopropane ring.

There was no evidence for the presence of compound **10** in any of the pyrolysis fractions. Since its presence would be detected by a shift of a chromatographic peak after heating the sample,

due to conversion to a γ,δ-unsaturated ketone, we feel the presence of **10** is in no case greater than 2%.

Olefins

Except for the pyrolysis of **6** olefins are minor products from these pyrazolines. There are four α,β-unsaturated ketones anticipated, two from **1** to **4** and two from **5** to **6**. These four were prepared as *cis,trans* pairs by Wittig procedures. Thus 3-methyl-4-phenyl-3-hexene-2-one (**13**), (*E*)- and (*Z*)- were prepared as a mixture with a β,γ-isomer (50%) by eq. 6. No decision was made on the stereochemistry of these olefins for although the acetyl group might have been expected to give preferential deshielding to the *cis* alkyl group this is not always the case. In **14**, (*E*)- and (*Z*)- (eq. 7) and also in 3-methyl-3-pentene-2-one (14) the shift is in the wrong direction or too small to be observed.

3-Methyl-4-phenyl-3-hexene-2-one (**14**), (*E*)- and (*Z*)-, were prepared by eq. 7. The higher chemical shift for the acetyl resonance at 8.51 (shielding by the *cis* phenyl) in the major product, compared to 7.95 in the minor product, was used to make a tentative structural assignment of the

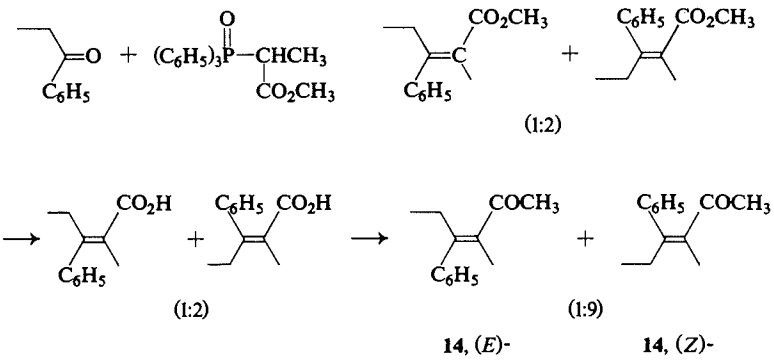
[7]



Z configuration to the major product. Similarly the α-methyl of the *E* isomer appears to higher field (8.34 τ) than does that of the *Z* isomer (8.10 τ).

The only β,γ-unsaturated compound detected as a pyrolysis product was 3-methyl-4-phenyl-4-hexene-2-one (**15**) which was isolated admixed with **14** and some other minor components in the pyrolysis of **6**. The presence of **15** was indicated by its n.m.r. spectrum, however, it was not isolated pure and its stereochemistry was not determined.

Table 6 gives the estimated product compositions from pyrazolines **1** to **6** on the basis of product analysis from samples of the following degrees of purity: **1** (85%), **2** (90%), **3** (95%), **4** (75%), **5** (100%), and **6** (72%). The stereochemical results for the cyclopropane products are given in Table 6. The absence of dihydrofurans is noteworthy in view of their formation from other 3-acetyl-1-pyrazolines (12). Their absence is not due to their instability as we have made them by other means. Formation of the olefin **14** (*E*)- as the major α,β-unsaturated olefin from **6** would be consistent with our structural assignment to **6** on the basis of earlier stereochemical studies of the olefin-forming reaction which indicate a concerted migration of hydrogen transoidal to the loss of nitrogen (5, 8).

Discussion

It is clear from the results in Table 6 and earlier results that the conversion of 1-pyrazolines to cyclopropanes is stereoselective. This stereoselectivity can give product with retention at C-3 and -5, retention at one of C-3 or -5 and/or, inversion of C-3 and -5. The stereochemistry in the product lacks the randomness expected for a process proceeding by successive steps in which rotation around single bonds in the intermediate might give mixed stereochemistry in the product. Inversion at one or both of C-3 and -5 has been observed and thus an initial cleavage of the C-3 to N bond followed by S_N2 displacement of nitrogen from C-5 is not indicated.

Stereoselectivity implies concertedness for this reaction and therefore symmetry should play an important role. Bergman and Carter (15) have pointed out that if one assumes little or no interaction by the bonds on C-4 with the breaking bonds then the pyrolysis reaction can be thought of as the reverse of a 2 + 2 cycloaddition of N_2 to a cyclopropane C—C bond. This approach requires a highly strained transition state for

formation of product in which the stereochemical change can be *ri* or *ir*.

Presumably product with retained or inverted stereochemistry at both centers would require antarafacial bond formation in the formation of the N_2 unit. In at least one case where *trans* expulsion of nitrogen is called for by symmetry considerations the system has found an alternative path (16) such that the thermal and photochemical processes gave the same stereochemical result.

The tendency for the photochemical process to give the opposite stereochemistry from that of the thermal reaction can be used as a means of detecting symmetry control in a reaction. Existing data on the photochemistry of pyrazolines is given in Tables 1 and 2. Reversal of the stereochemistry is noted for *cis* and *trans*-3,5-dimethyl-3-carbomethoxy-1-pyrazoline. However, in general the data is best summarized by a tendency for the photochemical product to more closely retain the stereochemistry of the starting pyrazoline than does the thermal product. This is in line with the early observations of Van Auken and Rinehart (1).

Good evidence for a trimethylene intermediate has been found for the pyrolysis of alkyl substituted pyrazolines. Calculations of the energy of such a unit for differing central angles show that at small angles the symmetric molecular orbital picture is more stable than the antisymmetric while at greater angles than 100° the antisymmetric form is more stable (17). This calculation makes use of mixing with the C—H orbitals on the middle carbon. That these two symmetry states can be close in energy has been used to explain the stereochemical outcome from *cis* and *trans*-3,5-dimethylpyrazoline (3) and *cis* and *trans*-2,4-dimethylthietanonium salts (18) where both conrotation and disrotation from the trimethylene intermediate are observed.

We wish to propose that a similar interaction between the breaking C—N bonds and the bonds to C-4 can take place before loss of the nitrogen and that steric and substituent factors can force the three carbon unit to act as either a symmetric or antisymmetric component. Thus a variety of stereochemical results are possible in competition with each other. We prefer this proposition to others available since the cyclopropanes are normally formed in competition with olefins which are formed by a concerted symmetry allowed process (5, 8), suggesting therefore that all of the products are formed by symmetry allowed sequences.

Experimental

General

Melting points and boiling points are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 137 spectrophotometer. All spectra were measured as liquid films using sodium chloride plates. The 60 MHz magnetic resonance spectra were recorded on either a Varian Associates Model A-60 spectrometer or a Jeolco Model C-60 spectrometer. The 100 MHz n.m.r. spectra were recorded on a Varian Associates Model HR-100 spectrometer. The spectra were run as solutions either in carbon tetrachloride or deuteriochloroform (Merck, Sharp and Dohme) with tetramethylsilane as the internal reference. The v.p.c. units used were an Aerograph Model A-90-P and an Aerograph Model A-90-P3. All columns used were 10′ × 1/4″ unless otherwise indicated. Petroleum ether refers to the fraction boiling between 30–60°.

3-Methyl-3-pentene-2-one, (Z)-

Irradiation of 12 g (0.12 mole) of 3-methyl-3-pentene-2-one, (*E*)- (Aldrich) in 100 ml of ether for 16 h in a silica tube using a Hanovia 450 W lamp (2537 Å) resulted in approximately 25% conversion to the desired *Z* isomer as determined by v.p.c. (didecyl phthalate, 138°, 120 ml per min). The retention times for the *Z* and *E* isomers were 8.6 and 11.0 min, respectively (lit. (12): b.p. 124 and 147°, respectively). The ether was removed and a simple distillation gave a fraction distilling between 131–136° which consisted of a 50:50 mixture of the *Z* and *E* isomers. A further distillation using a Nester and Faust stainless steel spinning-band apparatus gave a fraction distilling from 124–130° which consisted of a 90:10 ratio of the *Z* and *E* isomers, respectively. Final purification by v.p.c. gave 1.8 g (0.18 mole) of greater than 95% purity.

3-Methyl-4-phenyl-3-buten-2-one

The title compound was prepared by the acid condensation of benzaldehyde and methyl ethyl ketone to give a product which melted at 37–40° (lit. (19), m.p. 38–40°).

Addition of Phenyl Diazomethane to 3-Methyl-3-pentene-2-one, (E)-

To an ether solution of 9.8 g (0.1 mole) of 3-methyl-3-pentene-2-one, (*E*)- was added phenyl diazomethane, prepared in 70 ml of petroleum ether from 12 g (0.1 mole) of benzaldehyde hydrazone and 21.6 g (0.1 mole) of yellow mercuric oxide in the presence of 1 ml of saturated potassium hydroxide in ethanol. The solution was left at −5° for 10 days. Pyrazoline formation was followed by use of n.m.r. The ratio of the two pyrazolines **1** and **2** was estimated in the crude reaction mixture as 2:1 respectively. The pyrazolines were stored as a solution in ether – petroleum ether at −5°.

Column chromatography (silica gel, ether – petroleum ether, 5:95 increasing to 10:90) of the crude reaction mixture gave two main fractions, the second of which yielded the pyrazoline mixture of **1** and **2** as a clear

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

colorless liquid. Further fractionation gave **1** of 85% purity and **2** of 62% purity. Pyrazoline **2** had the larger R_f value. Partial pyrolysis of 6 g of **1** and **2** in refluxing acetone after 12 h yielded 0.6 g of unreacted **2** of 95% purity.

Anal. Calcd. for $C_{13}H_{16}ON_2$ (as a mixture of **1** and **2**): C, 72.19; H, 7.46; N, 12.95. Found: C, 72.29; H, 7.36; N, 13.11.

The n.m.r. peaks for **1** and **2** in addition to the aromatic resonances at 2.7 τ, are listed in Table 4 and are the basis of their identification.

Addition of Phenyl Diazomethane to 3-Methyl-3-pentene-2-one, (Z)-

To an ether solution of 1.8 g (0.18 mole) of 3-methyl-3-pentene-2-one, (*Z*)- was added phenyl diazomethane (from 3.2 g (0.27 mole) of benzaldehyde hydrazone). The solution was left at −5° for 2 weeks. Pyrazoline formation was followed by n.m.r. The ratio of the two pyrazolines **3** and **4** was estimated in the crude reaction mixture as 2:1 respectively. The pyrazolines **3** and **4** were stored as a solution in ether – petroleum ether at −5°.

Column chromatography (silica gel, ether – petroleum ether, 5:95 increasing to 10:90) of the crude reaction mixture gave two main fractions, the second of which yielded the pyrazoline mixture of **3** and **4** as a white solid. Further fractionation gave **3** of 80% purity and **4** of 50% purity. Pyrazoline **4** had the larger R_f value. On one occasion the pyrazoline mixture being crystallized from ether – petroleum ether (10:90) at −5° yielded two crystal sizes. Separation of these gave **3** of 95% purity and **4** of 75% purity.

Anal. Calcd. for $C_{13}H_{16}ON_2$ (as a mixture of **3** and **4**): C, 72.19; H, 7.46; N, 12.95. Found: C, 72.40; H, 7.40; N, 12.70.

The n.m.r. peaks for **3** and **4**, in addition to the aromatic resonances at 2.7 τ, are listed in Table 4 and are the basis of their identification.

Addition of Diazoethane to 3-Methyl-4-phenyl-3-butene-2-one, (E)-

To an ether solution of 11.2 g (0.07 mole) of 3-methyl-4-phenyl-3-butene-2-one, (*E*)-, was added diazoethane (from 23.4 g (0.20 mole) of *N*-nitroso-*N*-ethyl urea). The solution was left for 1 week at −5° and became clear and colorless. Pyrazoline formation was followed by use of n.m.r. The ratio of the two pyrazolines **5** and **6** was estimated in the crude reaction mixture as 9:1 respectively. The first treatment with diazoethane resulted in about 35% conversion to pyrazoline products. Two more treatments with equal amounts of diazoethane with a one week interval between the second and third treatment were made. The pyrazolines **5** and **6** were stored as a solution in ether – petroleum ether at −5°.

Two weeks after the third treatment the solvent was removed with a rotatory evaporator. The crude reaction product was triturated with petroleum ether to give white crystals. Recrystallization from petroleum ether – ether (95:5) yielded the pure pyrazoline **5** as a white solid: m.p. 65–68°, dec. 107°.

Anal. Calcd. for $C_{13}H_{16}ON_2$: C, 72.19; H, 7.46; N, 12.95. Found: C, 71.96; H, 7.61; N, 12.95.

The n.m.r. peaks for pyrazoline **5**, in addition to the aromatic resonances at 2.8 τ, are listed in Table 4 and are the basis of its identification. The mother liquor from the above recrystallization was shown by n.m.r. to be approximately a 50:50 mixture of the two pyrazolines. The solvent was removed from the mother liquor and then diluted with 10 ml of petroleum ether – ether (95:5) and seeded with pure crystals of the pyrazoline **5**. The solution was left for 1 week at −5°, after which time it was observed that not only additional crystals of **5** were present but also a liquid, presumably the pyrazoline **6**. After the removal of the solid white crystals, the mother liquor was then fractionated by column chromatography (silica gel, petroleum ether – ether, 95:5 increasing to 90:10). Three fractions were used for the product distribution study. The ratio of the two pyrazolines **5** to **6** in the three fractions, as determined by the integration of the two acetyl peaks, was 28:72, 32:68, and 36:64 respectively. By considering successive fractions, it was found that the pyrazoline **6** had the larger R_f value.

Pyrolysis of Pyrazolines 1 and 2 and Product Identification

The following components were identified from the pyrolysis of **1** and **2** either as a neat sample at 100–120° or as a neat sample pyrolyzed in the injector of the v.p.c. The v.p.c. (FFAP, 218°, 120 ml per min) showed 6 peaks with retention times 8.6 (trace), 12.2, 13.6, 16.4, 17.6 (trace), and 20.0 min respectively. The product distribution calculated for each pyrazoline from data in Table 7 is given in Table 6.

The 12.2 min component was isolated and identified to be a mixture of **7**, **11**, and **12** by n.m.r. (CCl_4) peaks at 8.93, 8.86 (d), 7.82, and 7.16 (d) for **7** (66%) and at 9.18 (d), 8.26, and 7.96 for the γ,δ-isomers **11** and **12** (34% total).

The 13.6 min component was isolated and identified as the cyclopropane **8**. The structural assignment was based on the n.m.r. ($CDCl_3$) given in Table 5 plus aromatic hydrogens at 2.8 τ, and i.r. band at 1695 cm^{-1} (carbonyl) with no evidence of a C=C band and by the fact that this compound is stable to thermal rearrangement at 250°.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 83.06; H, 8.55.

The 16.4 and 17.6 min components could be enriched to about 15% of a fraction with **9** and as such could only be identified by their retention times and the presence of peaks at 6.52 and 6.60 τ in the n.m.r. (CCl_4) attributable to the benzylic protons of 3-methyl-4-benzyl-3-pentene-2-one, (*E*)- and (*Z*)- (**13**).

TABLE 7. Distribution* of products for the pyrolysis† of different ratios of the pyrazolines **1** and **2**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The 20.0 min component was isolated and identified as the cyclopropane **9**. The structural assignment was based on the n.m.r. ($CDCl_3$) given in Table 5 plus aromatic hydrogens at 2.9 τ, an i.r. band at 1690 cm^{-1} (carbonyl) with no evidence of a C=C band, and stability of this compound to thermal rearrangement at 250°.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 82.89; H, 8.75.

Pyrolysis of Pyrazolines 3 and 4 and Product Identification

The following components were identified from the pyrolysis of **3** and **4** neat at 130–140°. The products of pyrolysis were analyzed using the v.p.c. (FFAP, 218°, 120 ml per min) which showed 6 peaks, with retention times of 8.4 (trace), 12.2, 13.6, 16.4, 18.6 (trace) and 20.0 min respectively. The product distribution calculated for each pyrazoline from data in Table 8 is given in Table 6.

The 12.2 min and 13.6 min components were isolated together. Their retention times and the n.m.r. (CCl_4) showed these to be a mixture of **7**, **11**, **12**, and **8** with peaks at 8.93, 8.87 (d), 7.82, and 7.15 (d) for **7** (65%), 9.19 (d), 8.26, and 7.96 for **11** and **12** (22%), and 8.54 and 8.32 for **8** (13%).

The 16.4 min component was present in only small amounts and therefore could not be isolated. Its retention time does however, fall into the same region as one of the α,β-unsaturated ketones **13**, (*E*)- and (*Z*)-. The fact that on heating the products of pyrolysis at 220° for 2 h resulted in no decrease in this component suggests that it could not be the cyclopropane **10** which under these conditions would rearrange to a pair of γ,δ-olefins.

The 20.0 min component was isolated and identified by n.m.r. (CCl_4) peaks at τ 9.98 (d), 8.92, 7.88, and 7.33 (d) (9.5 Hz) to be the cyclopropane **9**.

Pyrolysis of Pyrazolines 5 and 6 and Product Identification

The following components were identified from the pyrolysis of **5** and **6** neat at 140–145°. The products were analyzed by v.p.c. (FFAP, 208°, 120 ml per min) which showed five peaks with retention times of 12.2 ,13.4, 14.0, 21.0, and 23.5 min respectively. The product distribution calculated for each pyrazoline from data in Table 9 is given in Table 6.

The 12.2 min component was isolated and found to consist of a mixture of olefins. Two of these are identified as the *E*, *Z* pair of 3-methyl-4-phenyl-3-hexene-2-one (**14**) by comparison of the n.m.r. ($CDCl_3$) with that of authentic samples. Peaks attributable to the *E* isomer (42%) at 100 MHz appear at 7.93, 8.35, 9.11 (triplet J = 7.3 Hz), 7.60 (quartet showing long range coupling J = 7.3 Hz), and 2.8 τ. Peaks due to the *Z* isomer (3%) at 100 MHz appear at 8.50, 8.10, and 9.07 τ (triplet J = 7.5 Hz). A further olefin (55%) was tentatively identified as 3-methyl-4-phenyl-4-hexene-2-one, (**15**) on the basis of the following data: i.r. 1715 cm^{-1}; n.m.r. (100 MHz in $CDCl_3$) 7.78 (singlet) acetyl methyl, 8.88 and 8.45 (doublets J = 7.0 Hz) C-3 and -5 methyls respectively, 6.65 (quartet J = 7.0 Hz) C-5 hydrogen, 4.43 (quartet J = 7.0 Hz) vinyl hydrogen, 4.43 (quartet J = 7.0 Hz) vinyl hydrogen, and 2.8 τ (multiplet) aromatic hydrogens. This isomer is assumed to be the *E* isomer based on the mechanism of the olefin-forming reaction. It was not possible to conclude if any of the remaining extraneous peaks in the n.m.r. were due to the other β,γ-isomer 3-methyl-4-phenyl-4-hexene-2-one, (*Z*)- since an authentic sample was not available for comparison.

Anal. Calcd. for $C_{13}H_{16}O$ (olefin mixture): C, 82.93; H, 8.57. Found: C, 83.10; H, 8.71.

Heating the product to over 200° converts the 14.0 min component into the 13.4 min component and this conversion undoubtedly occurs on every pass through the v.p.c. A sample of the 14.0 min component of maximum purity (80%) was indicated to be the cyclopropane **7** by its n.m.r. (CCl_4) given in Table 5 plus aromatic hydrogens at 2.9 τ, i.r. at 1690 cm^{-1}, and its susceptibility to thermal rearrangement.

Anal. Calcd. for $C_{13}H_{16}O$ (mixture of **7**, **11**, and **12**): C, 82.93; H, 8.57. Found: C, 82.83; H, 8.78.

The 13.4 min component had the retention times of the γ,δ-olefins **11** and **12** and was not isolated.

The 21.0 min component was identified as cyclopropane **8** on the basis of its retention time only.

The 23.5 min component was isolated and identified as the cyclopropane **9** by its retention time and n.m.r. (CCl_4) peaks at 9.01 (d), 8.93, 7.89, and 7.30 τ (d) (9.5Hz) which were identical to the same cyclopropane isolated from the decomposition of the pyrazolines **2**, **3**, and **4**.

Rearrangement of Cyclopropane 7 to erythro- and threo-3-Methyl-4-phenyl-5-hexene-2-one (11 and 12)

Four 50 mg samples of the cyclopropane **7** already containing some of the γ,δ-olefins were sealed in Pyrex tubes (2 mm i.d.) and placed in a furnace maintained at 227° for 3.5 h. The v.p.c. (DC 550, 210°, 120 ml per min) indicated that the cyclopropane **7** had completely rearranged to the γ,δ-olefins **11** and **12**. The ratio of the *erythro*-**11** to the *threo*-**12** was estimated by n.m.r. to be 1:2. It was not possible to separate the two γ,δ-isomers by v.p.c. The rearranged products could however be collected as a mixture on the v.p.c. as a clear colorless liquid: i.r. 1723 cm^{-1} (carbonyl stretching frequency); n.m.r. (100 MHz) 7.95 and 8.25 (singlets) acetyl methyls of **11** and **12** respectively, 9.16 and 8.92 (doublets J = 6.9

Hz) C-3 methyls of **11** and **12** respectively, 6.60 (triplet $J = 9.0$ Hz) C-4 hydrogens, 7.17 (multiplet of 8 lines) C-3 hydrogens, 4.12 (complex multiplet 40 Hz wide of area one), and 5.03 τ (complex multiplet 32 Hz wide of area two) vinyl hydrogens.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 8.71; H, 8.75.

Let us assume that the favored conformations for these isomers will have the C-4 and C-3 hydrogens *trans*. This is suggested by the common chemical shift for the hydrogen at C-4 for both compounds and the apparent coupling constant of 9.0 Hz, then the *erythro*-isomer will have the C-3 methyl more shielded and the *threo*-isomer will have the acetyl group more shielded by the phenyl group (20).

Trimethyl α-Phosphonopropionate

Trimethyl α-phosphonopropionate was prepared according to the procedure given by Kinstle (21). The resulting reaction mixture was distilled to give a 31% yield of product distilling from 93–100° at 0.3 mm.

Methyl 2-Methyl-3-benzyl-2-butenoate, (E)- and (Z)-

The procedure according to Kinstle (21) was used. To a slurry of 4.32 g (0.18 mole) of sodium hydride (Ventron) in 200 ml of dry 1,2-dimethoxyethane maintained at 15° was added dropwise in 1 h 35.3 g (0.18 mole) of trimethyl α-phosphonopropionate. After the addition, the grey solution was stirred for 1 h at room temperature and for 5 min at 35°. The solution was cooled to 15° and 24.1 g (0.18 mole) of freshly distilled phenyl acetone (Eastman) was added dropwise over 20 min with rapid stirring. The mixture was warmed to room temperature and stirred vigorously for 15 min and then 20 min at 65°. Ice (300 g) was added with stirring. The mixture was extracted with five 100 ml portions of ether. The combined ether extracts were washed with two 100 ml portions of water to remove the glyme. The ether layer was dried over sodium sulfate and the ether was removed to give 20.8 g (54%) of crude product. The v.p.c. (Ap J, 222°, 120 ml per min) showed at least three products with retention times 18.6, 19.6, and 21.1 min with the first two peaks overlapping considerably. The n.m.r. indicated the presence of both α,β- and β,γ-isomers in approximately a 70:30 ratio respectively. For the α,β- and β,γ-unsaturated esters: i.r. 1715–1740 cm^{-1} (overlapping carbonyl stretching frequencies); n.m.r. (CCl_4) 8.68 (doublet $J = 7.2$ Hz) methyl on C-2 of the β,γ-isomer, 8.0–8.4 (multiplets) vinyl methyls, 6.80 (quartet $J = 7.2$ Hz) hydrogen of C-2 of the β,γ-isomer, 6.54 (broad singlet) benzylic hydrogens of the α,β-isomer, 6.3–6.4 carbomethoxy methyls, 3.65 (broad singlet) vinyl hydrogen, and 2.8–2.9 τ aromatic hydrogens.

Anal. Calcd. for $C_{13}H_{16}O_2$ (mixture of three components): C, 76.43; H, 7.90. Found: C, 76.20; H, 8.10.

*3-Methyl-4-benzyl-3-pentene-2-one (**13**, E- and Z-)*

In a 100 ml flask was refluxed 6 g of the crude esters in 50 ml of 20% sodium hydroxide for 2.2 h (22). The crude reaction mixture was cooled and extracted twice with ether and then acidified with hydrogen chloride. The resulting solution was extracted twice with ether and the ether layer was dried with magnesium sulfate. Removal of ether gave 2.1 g of a white solid containing the crude acids.

The conversion of the acids to the corresponding methyl ketones was done according to the procedure of DePuy *et al.* (23). Into a 50 ml three-necked round bottom flask equipped with a condenser, mechanical stirrer, and nitrogen was placed 2.1 g (0.011 mole) of the crude acids and 25 ml of anhydrous ether. Methyl lithium in ether (0.022 mole) was added dropwise. After the addition, saturated ammonium chloride was added dropwise to destroy the excess methyl lithium. Two clear layers resulted and the ether layer was separated and washed with a saturated ammonium chloride solution, twice with water, and dried over magnesium sulfate. The ether was removed to yield 1.0 g of crude ketone. Bulb-to-bulb distillation yielded 0.8 g (0.004 mole). The yield from the acids was 38% and from phenyl acetone was 8%.

The v.p.c. (FFAP, 218°, 120 ml per min) showed three main peaks with retention times of 15.8, 16.3, and 17.6 min and with an area ratio of 3:1:2 respectively. The α,β to β,γ ratio in the crude reaction mixture was estimated at 50:50 by n.m.r. Thus the 15.8 min component was assumed to be the β,γ-isomer and the latter two peaks to be the α,β-unsaturated ketones **13** (*E*)- and (*Z*)-. These latter peaks had the same retention times as peaks found in the pyrolysis product of pyrazolines **1**, **2**, **3**, and **4**.

The i.r. bands at 1680 and 1685 cm^{-1} were assigned to **13** *E*- and *Z*- and at 1710 cm^{-1} to the β,γ-isomer. The n.m.r. (100 MHz, CCl_4) peaks at 7.81 and 7.82 (singlets) acetyl methyls, 8.25 and 8.26 (singlets) C-3 methyls, 6.54 and 6.59 τ (broad singlets of areas 1:2 respectively) benzylic hydrogens were assigned to the α,β-isomers and peaks at 7.91 (singlet) acetyl methyl, 8.80 (doublet $J = 6.9$ Hz) C-3 methyl, 6.77 (quartet $J = 6.9$ Hz) C-3 hydrogen, and 3.58 τ (broad singlet) vinyl hydrogen were assigned to the β,γ-isomer. Multiplets at 8.08, 8.14, and 8.41 τ (vinyl methyls) could not be clearly assigned.

Anal. Calcd. for $C_{13}H_{16}O$ (mixture of three isomers): C, 82.93; H, 8.57. Found: C, 82.51; H, 8.66.

Methyl-2-methyl-3-phenyl-2-pentenoate, (E)- and (Z)-

The procedure according to Kinstle (21) was used as previously described for the preparation of 25 g (67%) of the esters from 24.1 g of propiophenone. A bulb-to-bulb distillation of the crude reaction product gave a clear colorless liquid whose v.p.c. (FFAP 212°, 120 ml per min) showed one peak with retention time 10.7 min. The n.m.r. indicated that the peak consisted of the expected *E*- and *Z*- α,β-unsaturated esters in a 2:1 ratio: i.r. 1725 and 1735 cm^{-1} (overlapping carbonyl stretching frequencies); n.m.r. 6.29 and 6.77 (singlets) carbomethoxy methyls respectively, 8.32 and 8.00 (singlets) alpha methyls respectively, 9.05 (triplet $J = 3.8$ Hz) C-5 hydrogens, 6.5–6.6 (overlapping quartets) C-4 hydrogens, and 2.9 τ aromatic hydrogens.

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.43; H, 7.90. Found: C, 76.02; H, 7.91.

*3-Methyl-4-phenyl-3-hexene-2-one (**14**, E- and Z-)*

Hydrolysis of 17 g of esters by the above procedure gave 1.7 g of solid acids after 24 h reflux: n.m.r. 7.96 and 8.30 (singlets) alpha methyls, 9.06 (triplet $J = 3.8$ Hz) C-5 hydrogens, 7.26 and 7.52 (quartets) C-4 hydrogens, and −0.95 τ (broad singlet) acid proton.

Conversion of 1.5 g of the acids to methyl ketones by the method of DePuy *et al.* (23) gave 160 mg of crude and 120 mg (8.0%) of purified ketones.

The v.p.c. (FFAP 215°, 120 ml per min) showed as the major product two overlapping peaks with retention times of 9.0 and 9.4 min. The n.m.r. indicated that the two ketones **14** *E*- and *Z*- were present in a ratio of 10:90 although the corresponding acids from which they were prepared were in a ratio of 28:72 respectively. Assignment of the structure was based on an assumed shielding by a *cis* phenyl on the α-methyl or acetyl groups. The acetyl peaks were the sharper peaks in the n.m.r. spectrum as the α-methyls had long range coupling to them.

For the ketones **14** *E*- and *Z*- respectively: i.r. 1680–1690 cm^{-1} (overlapping carbonyl stretching frequencies); n.m.r. (CCl_4) (100 MHz) 7.95 and 8.51 (singlets) acetyl methyls, 8.34 and 8.10 (multiplets) alpha methyls, 9.00 and 9.10 (triplets $J = 7.4$ Hz) C-6 hydrogens, and 7.53 τ (quartet $J = 7.4$ Hz) C-5 hydrogens of **14** *Z*-.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 83.05; H, 8.58.

Received June 30, 1970

The ^1H and ^{19}F n.m.r. spectra of the α- and β-anomers of 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-D-glucopyranosyl fluoride and of the corresponding D-manno derivatives have been fully analyzed. The signs of most of the ^{19}F–^1H and of all the ^{19}F–^{19}F couplings have been determined by a heteronuclear double-resonance method. The vicinal ^{19}F–^{19}F couplings are absolutely negative in sign, with $J_{a,a} = -20.0$ Hz, and $J_{a,e}$ and $J_{e,e} = -13.5$ to -18.8 Hz. Sizeable *long-range* couplings (^4J) between an axial fluorine and an axial proton are absolutely positive in sign.

Canadian Journal of Chemistry, 49, 118 (1971)

Introduction

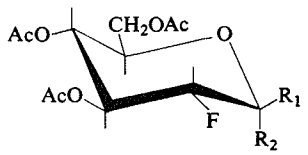
The configurations and conformations of fluorinated carbohydrates can be defined in many cases on the basis of ^1H–^1H couplings, thus enabling a study of the angular and configurational dependencies of vicinal (2–4), geminal (2), and long-range (5) (^4J and ^5J) ^{19}F–^1H couplings.

Extension of this technique to 2-deoxy-2-fluorohexopyranosyl fluorides provides information on the magnitude and absolute sign of vicinal ^{19}F–^{19}F couplings in the four steric relationships possible in a pyranose ring. The purpose of this communication is to report such data for 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-α-D- and β-D-glucopyranosyl fluorides and for the corresponding α-D- and β-D-mannopyranosyl fluorides.

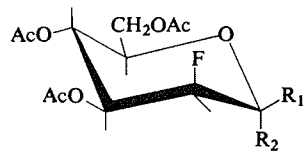
Results and Discussion

Treatment (1) of a solution of 3,4,6-tri-*O*-acetyl-D-glucal in trichlorofluoromethane at $-70°$ with fluoroxytrifluoromethane (6) afforded a mixture of trifluoromethyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-α-D-glucopyranoside and the β-D-*manno* isomer and 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-α-D-glucopyranosyl fluoride (**1**) and the β-D-*manno* isomer (**4**). Dissolution of **4** in anhydrous hydrogen fluoride at *ca.* $-10°$ resulted in equilibration (7) to give 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-α-D-mannopyranosyl fluoride (**3**). The fourth difluoride, 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-β-D-glucopyranosyl fluoride (**2**) was obtained by treatment of 2-deoxy-2-fluoro-D-glucose (1) in sequence with acetic anhydride – pyridine, hydrogen bromide – acetic acid, and silver fluoride – acetonitrile. Although the intermediates were not characterized there can be little doubt that the use of hydrogen bromide – acetic acid affords an α-D-glucopyranosyl bromide derivative. Moreover, such compounds are known (2, 7, 8) to react with silver fluoride to give β-D-glucopyranosyl fluorides. Each of the vicinal difluorides **1**–**4** showed a plain positive optical rotary dispersion curve.

The normal ^1H n.m.r. spectra of the difluorides **1**–**4** were reasonably complex and it was not easy to make a direct assignment. Spectra measured



1 $R_1 = H$; $R_2 = F$
2 $R_1 = F$; $R_2 = H$



3 $R_1 = H$; $R_2 = F$
4 $R_1 = F$; $R_2 = H$

*All signs are related to the H_1–F_1 coupling, which is known to be absolutely positive (11). All values are first-order splittings which have been shown to be the coupling constants by second-order analysis (see footnote ‖).
†Non-determinable, non-zero coupling.
‡Unresolved coupling; estimate obtained by decrease in half-height width on decoupling.
§All couplings shown as 0 Hz were taken from spin multiplets which showed no detectable changes in the half-height widths of relevant transitions when a powerful decoupling field was applied to the fluorine resonances. Any coupling > 0.2 Hz would have been detected in such an experiment.
‖These are corrected values; the first-order splittings were 21.4 and 3.0 Hz respectively.

with simultaneous irradiation, in turn, of each fluorine resonance enabled a more facile identification of the various ^{19}F–^1H and ^1H–^1H couplings. The spectra shown in Fig. 1 illustrate the success of this approach. The data obtained by first-order analyses of the spectra of the four difluorides are given in Tables 1 and 2.

The structures of the products described above were based on conventional analytical data and, in particular, on the ^1H–^1H coupling constants. From the values of $J_{3,4}$ and $J_{4,5}$ (7.5–10.0 Hz) it is concluded that each of the compounds has an approximate $^4C_1$(D) conformation. The magnitudes of the ^1H–^1H couplings, $J_{2,3}$, provide unequivocal evidence for the configurations assigned at C-2; derivatives in the D-*gluco* series have couplings of 7.9 and 9.6 Hz whereas those in the D-*manno* series have $J_{2,3}$ = 2.5 Hz. In the D-*gluco* series, the values of $J_{1,2}$ provide equally incisive evidence concerning the anomeric con-

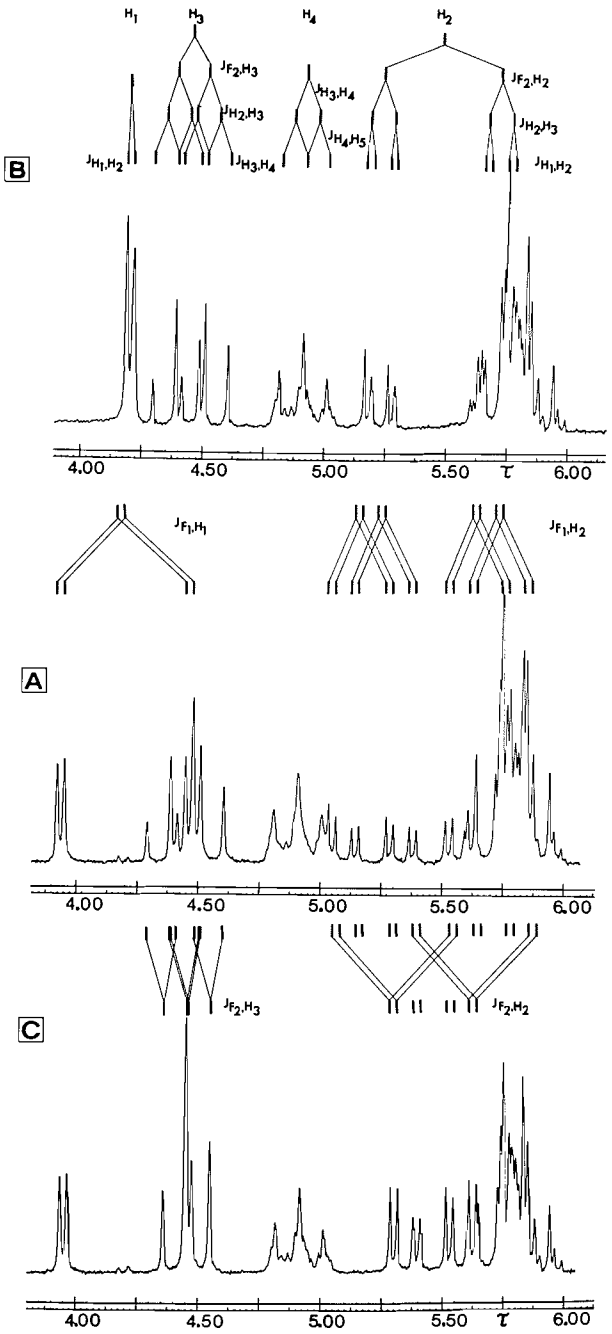

FIG. 1. Partial ^{1}H n.m.r. spectra (100 MHz) of 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-α-D-glucopyranosyl fluoride in deuterochloroform solution. A, Normal spectrum. B, Spectrum with simultaneous irradiation at the F-1 resonance frequency (94, 079, 950 Hz). C, Spectrum with simultaneous irradiation at the F-2 resonance frequency (94, 074, 950 Hz).

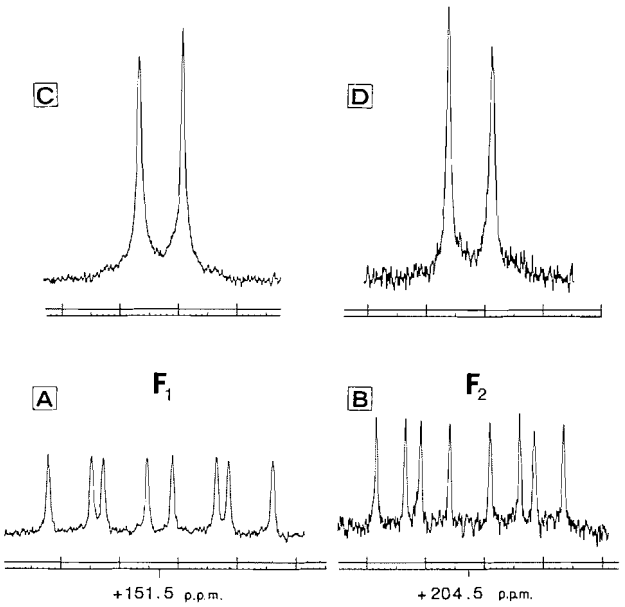

FIG. 2. ^{19}F n.m.r. spectra (94.07 MHz) of 3,4,6-tri-*O*-acetyl-2-fluoro-α-D-glucopyranosyl fluoride in deuterochloroform solution. A, Normal spectrum of the F-1 resonance and B, normal spectrum of the F-2 resonance. The spectra in C and D are the corresponding resonances, measured with simultaneous irradiation of the entire ^1H spectrum using a noise-modulated decoupling field.

figuration; for the α-anomer $J_{1,2}$ = 2.9 Hz and in the β-series, $J_{1,2}$ = 6.1 Hz. Although both of the D-*manno* compounds have similar values for $J_{1,2}$, as expected, it was possible to make a configurational assignment on the basis of the chemical shifts of H-5. In accord with the results of Lemieux and Stevens (9), H-5 of the α-anomer resonated at lower field than did H-5 of the β-anomer.

The magnitudes of the various ^{19}F–^1H couplings were in accord with the same structural assignments (however, see later).

The ^{19}F spectra of the four glycosyl fluoride derivatives were measured in the usual fashion and a typical example is given in Fig. 2A. Although the magnitude of the *vicinal* ^{19}F–^{19}F coupling could be estimated directly from the normal spectrum, it was more convenient to irradiate simultaneously the entire ^1H spectrum, thereby eliminating all the ^{19}F–^1H couplings and enabling a more accurate determination of the ^{19}F–^{19}F coupling; the result of a typical experiment is shown in Fig. 2B.

The signs of many of the ^1H–^1H and ^{19}F–^1H couplings were determined by the "off-resonance" heteronuclear double resonance method previously developed (10) in this laboratory. In this method, a radio-frequency field of moderate strength is placed in the near vicinity of one of the ^{19}F resonances; this results in the selective collapse of individual splittings in the ^1H spectrum. The relative extent of this spin-decoupling effect is a function of the magnitudes and the signs of the individual couplings, and can be interpreted in a reasonably direct fashion. These experiments only give the *relative* signs of the couplings. To convert these to an *absolute* basis it is necessary to refer them to a coupling of known sign; in the present study all signs were related to that of the geminal coupling ($J_{1,F}$) which is known (11) to be absolutely positive in sign.[4]

Before the significance of the ^{19}F parameters of the four glycosyl fluorides is discussed it is important to note that although the ^1H n.m.r. parameters of all these derivatives accord with the assigned structures, there are several marked differences between the coupling constants of the α- and β-anomers of the D-gluco derivatives (**1** and **2**), and of the D-manno derivatives (**3** and **4**), particularly for the latter compounds. For example, the values of $J_{3,4}$ and $J_{4,5}$ are signifi-

[4]For a discussion of this procedure see ref. 12.

cantly lower for **4** than for **3**. The same is true for the H_3–F_2 couplings of the two D-*manno* derivatives. It is tempting to suggest that these differences reflect an increase in the population of the $^1C_4$ (D) conformation for the β-anomer (**4**), which would accord with the known, large "anomeric" effect (13) of a C-1 fluorine substituent (14). Attempts to confirm this rationalization by low temperature ^{19}F n.m.r. measurements were unsuccessful; even at −90 °C, no evidence could be obtained for the presence of molecules in the $^1C_4$ (D) conformation. Nevertheless, it is important to bear in mind during the following discussion that the data for the β-anomers might be influenced to some extent by conformational time-averaging, or by conformational distortion of the pyranose ring.

The *vicinal* ^{19}F–^{19}F couplings of derivatives **1**–**4** are of particular interest. It was found that these are all absolutely negative in sign, in contrast to *vicinal* ^1H–^1H and ^{19}F–^1H couplings which are all absolutely positive in sign (12, 15). Furthermore, in marked contrast with the usual observation for *vicinal* ^1H–^1H (16) and ^{19}F–^1H (2–4) couplings where $J_{trans} > J_{gauche}$, the value of the *trans* ^{19}F–^{19}F coupling (**3**, −20.0 Hz) is approximately the same as that of the *gauche* couplings (**1**, −18.8; **2**, −15.8; **4**, −13.5 Hz). It is obvious from this behavior that *vicinal* ^{19}F–^{19}F couplings have some interesting characteristics (1) which merit further investigation; this point will be discussed elsewhere (17).

There does not appear to be any simple rationalization for the values of the ^{19}F chemical shifts, beyond the fact that the anomeric fluorine substituent always gives the lower field resonance of the two. The F-2 shift of the β-D-*manno* derivative is abnormally high for a secondary fluorine substituent[5] since it comes *ca.* 40 p.p.m. to high field of *any* shift we have measured previously for a fluorinated carbohydrate derivative.

Although the magnitude of the H_1–F_1 couplings are smaller for the D-*manno* derivatives than for the D-*gluco* derivatives, an observation which is in accord with previous findings (2), the H_2–F_2 couplings show no similar trend.

It was possible to measure the magnitudes of several long-range ^{19}F-^1H couplings for these derivatives; unfortunately it was not always possible to determine their signs. In accord with previous experience (5) the $^4J_{Fa,Ha}$ coupling between F-1*a* and H-3*a* of the α-D-*gluco* derivative (**1**) is small. However, for the corresponding α-D-*manno* derivative the corresponding coupling is +2.5 Hz. It is not possible to rationalize this behavior unequivocally, although it is tempting to implicate the inversion of configuration at C-2. A $^4J_{Fa,Ha}$ coupling of similar magnitude (+2.0 Hz) occurs between F-2*a* and H-4*a* of the β-D-*manno* derivative (**4**). Again there is the possibility that this reflects an abnormality of the system, since there is other evidence that **4** does not exist wholly in a normal $^4C_1$ (D) conformation. Nevertheless, these two observations of detectable ^4J couplings indicate that some caution may be necessary before such couplings are used for configurational assignments of carbohydrates which have a fluorine substituent attached to a secondary ring-carbon.[6] It should be noted also that several $^5J_{F,H}$ couplings have been found in the n.m.r. spectra of these derivatives and these data will be discussed in detail elsewhere.

Experimental

The general methods used here have been described previously (3).

All n.m.r. spectra were measured with a modified Varian HA-100 instrument as described previously. The noise-modulated heteronuclear decoupling experiments used the same basic components as before (18) with the sole exception of the noise-source; we now use a pseudo-random sequence generator whose effective band-width is controlled by a square-wave function generator, either a Wavetek, model 113 or Heathkit, model IG 82.

*3,4,6-Tri-O-acetyl-2-deoxy-2-fluoro-*β*-D-glucopyranosyl fluoride (2)*

2-Deoxy-2-fluoro-D-glucose (1) (500 mg) was stirred overnight with acetic anhydride (4 ml) and pyridine (2 ml). The mixture was then evaporated *in vacuo* and the syrupy residue was dissolved in hydrogen bromide – glacial acetic acid (5 ml, 45% w/v). After 3 h at room temperature the solution was evaporated *in vacuo*. A solution of the syrupy residue[7] in acetonitrile (5 ml) was

[5]This value was carefully remeasured several times.

[6]Until the present investigation, we had never encountered $^4J_{Fa,Ha}$ couplings in the spectra of glycopyranosyl fluorides; the observed $^4J_{Fe,He}$ couplings for such derivatives were between +3.6 and +4.2 Hz. However, the glycosyl fluorides of deoxy-fluoropyranose sugars examined thus far do show evidence of $^4J_{Fa,Ha}$ couplings.

[7]Note added after submission of manuscript:
In subsequent experiments this compound was characterized as 3,4,6-tri-*O*-acetyl-2-deoxy-2-fluoro-α-D-glucopyranosyl bromide, m.p. 79–80° (from ether), $[\alpha]_D$ +22.9° (*c* 0.7, chloroform). The n.m.r. data ($CDCl_3$), $J_{1,2}$ 3.5, $J_{F,1}$ 0.5 Hz.
Anal. Calcd. for $C_{12}H_{16}BrFO_7$: C, 38.8; H, 4.3; F, 5.1; Br, 21.6. Found: C, 38.9; H, 4.4; F, 5.1; Br, 21.3.

treated with a slurry of silver fluoride (1 g) in acetonitrile (5 ml). The mixture was stirred in the dark for 17 h, silica gel (Merck, 7734, 5 g) was added, and the mixture was evaporated. The residue was added to the top of a column of silica gel and eluted with light petroleum (b.p. 40–60°) – ether (2:1). Evaporation of the combined fractions containing the major product followed by recrystallization of the product from light petroleum – ether afforded the title compound (354 mg, 41%), m.p. 99–101°, $[\alpha]_D^{25}$ + 75° (*c* 1, chloroform), ϕ +2880° (350 nm), +12 300° (200 nm)[*cf.* α-D-*gluco* isomer **1**, ϕ +1560° (300 nm), +18 700° (195 nm)].

Anal. Calcd. for $C_{12}H_{16}F_2O_7$: C, 46.45; H, 5.2; F, 12.3. Found: C, 46.7; H, 5.25; F, 12.2.

3,4,6-Tri-O-acetyl-2-deoxy-2-fluoro-α-D-mannopyranosyl fluoride (3)

3,4,6-Tri-*O*-acetyl-2-deoxy-2-fluoro-β-D-mannopyranosyl fluoride (650 mg) was stirred with anhydrous hydrogen fluoride (5 ml) at 0 – −10° for 15 min, then at room temperature for 10 min. The solution was poured into saturated aqueous sodium hydrogen carbonate (50 ml) and the product, extracted with chloroform (3 × 50 ml) in the usual manner, crystallized on trituration with light petroleum. Recrystallization from light petroleum (b.p. 60–80°) – ether afforded the title compound (504 mg, 77%), m.p. 89–90°, $[\alpha]_D^{25}$ +27°, ϕ +3800 (200 nm)[*cf.* β-D-*manno* isomer (**2**), ϕ +3600° (200 nm)].

Anal. Calcd. for $C_{12}H_{16}F_2O_7$: C, 46.45; H, 5.2; F, 12.3. Found: C, 46.4; H, 5.3; F, 12.2.

It is a pleasure for one of us (L.D.H.) to thank the National Research Council of Canada for their generous financial support, especially for the equipment which forms the basis of the heteronuclear decoupler. This work was supported in part by a grant (No. 352) from N.A.T.O. and by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council of Great Britain and the Cancer Research Campaign.

A New Tetrahydroprotoberberine Alkaloid from *Corydalis caseana* A. Gray

C. K. YU AND D. B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ontario
AND
R. G. A. RODRIGO AND R. H. F. MANSKE
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received June 12, 1970

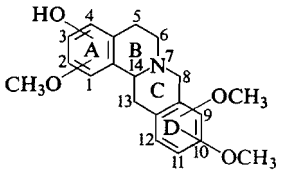
The isolation and structure of a new tetrahydroprotoberberine alkaloid from *C. caseana* is reported. This alkaloid, named caseanadine, has a phenolic hydroxyl at C-1 and methoxyls at C-2, -9, and -10. Its structure has been deduced from an analysis of its p.m.r. mass, and i.r. spectra. The alkaloid has a substitution pattern different from other members of this group of alkaloids of established structure.

Canadian Journal of Chemistry, 49, 124 (1971)

An examination of *C. caseana* was reported in 1938 by Manske and Miller (1) who isolated ten alkaloids. Five of them were known at that time, namely, protopine, allocryptopine, bicuculline, corypalmine, and scoulerine. Of the alkaloids of unassigned structure caseanine (F-36) is now known to be identical with *l*-tetrahydropalmatine, casealutine (F-32) to be identical with isocorypalmine and F-34 to be identical with cryptopine (2). The alkaloids designated F-33 and F-35 have been named caseamine and caseadine, respectively, and have been shown to be tetrahydroprotoberberines with a novel substitution pattern (3, 4). Of the ten alkaloids of known structures six are tetrahydroprotoberberines, three are of the protopine type, and one is a phthalide isoquinoline.

We report here a new alkaloid, $C_{20}H_{23}NO_4$, m.p. 170° from this source to which we assign the trivial name, caseanadine (**1**). The u.v. spectrum has λ_{max}(MeOH) 282 mμ and the i.r. spectrum $\nu_{max}(CHCl_3)$ 3540 cm^{-1} (OH absorption) and bands in the region 2700–2800 cm^{-1} (Bohlmann bands). The spectral properties are not inconsistent with a tetrahydroprotoberberine. The mass spectrum of caseanadine shows a molecular ion at *m/e* 341 (100) as expected and fragment ions at *m/e* 326 (7), 310 (20), 178 (8), 176 (6), 164 (82) and 149 (38). This pattern is characteristic of tetrahydroprotoberberines (5) substituted with two methoxyl groups in ring D and with one hydroxyl and one methoxyl group in ring A as in structure I. Unfortunately, the mass spectrum does not define the sites of substitution in rings A and D.

The 100 MHz p.m.r. spectrum of caseanadine in $CDCl_3$ is shown in Fig. 1. The spectrum con-



I

firms the presence of four aromatic protons and three methoxyl groups. The presence of the doublet centered near 4.2 δ is characteristic of protoberberines in which ring D carries an oxygen substituent at C-9 (5). This signal constitutes one-half of an AB quartet associated with the protons at C-8. The other half of this signal is obscured in this spectrum by the methoxyl signals. The aromatic region definitely shows one AB system with indications that another may also be present.

The partial spectrum of caseanadine (Fig. 2) in DMSO-d_6 was more informative, particularly in the aromatic region. The presence of two AB systems is clearly discernible there and thus the substituents in ring A must be at the 1,2- or 3,4-positions. The previous demonstration that caseamine and caseadine have substituents at the 1- and 2-position suggests that caseanadine may be similarly substituted in ring A. The presence of two AB quartets in the aromatic region along with the p.m.r. evidence that C-9 carries an oxygen substituent defines the substitution in ring D. Thus caseanadine may be represented as in II where $R_1 + R_2 = H + CH_3$. The assignment of the OH group to C-1 rests on decoupling evidence on caseanadine and on an examination of the p.m.r. spectrum of its *O*-acetyl derivative **2** shown in Fig. 3.

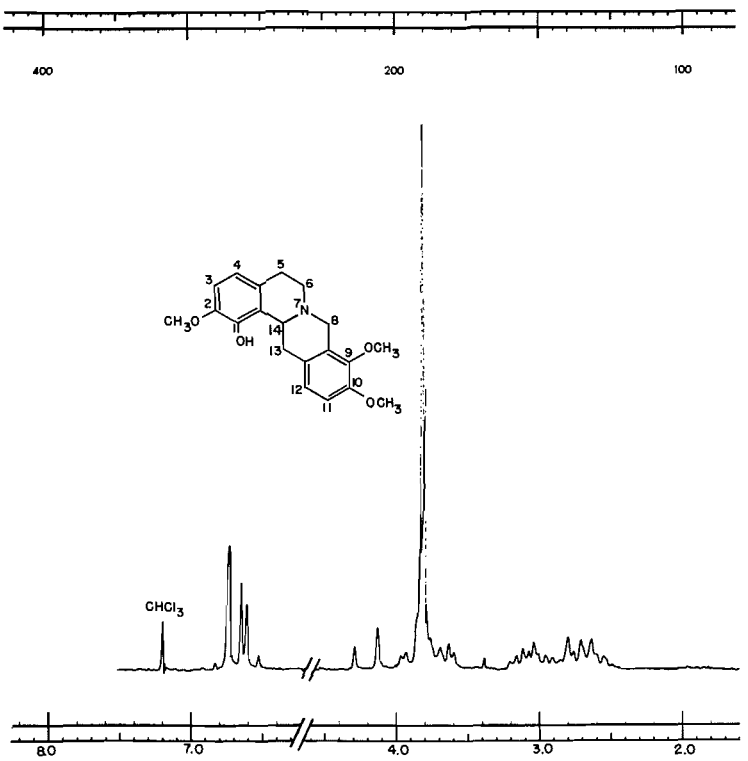


FIG. 1. The 100 MHz p.m.r. spectrum of caseanadine (**1**) in $CDCl_3$.

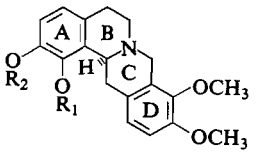

II

$R_1 + R_2 = H + CH_3$

The p.m.r. spectrum of **2** shows that two aromatic protons have shifted downfield in **2** and, therefore, they must be in the ring carrying the *O*-acetyl group. The chemical shift of the remaining (ring D) protons has not changed appreciably. Moreover, it is obvious from the height of the signals that the lowest field proton of **2** is the highest field proton of **1**. The magnitude of the shift (*ca.* 0.4 p.p.m.) is expected for a proton para to a phenolic hydroxyl group which has undergone acetylation (6). The high field signal of **1** and the low field signal of **2** are both broader (less sharp) than the proton to which they are coupled. This suggests that these protons are broadened by ortho-benzylic coupling whereas the protons to which they are coupled are less strongly long-range coupled to meta and/or para protons (7). Double irradiation experiments lend support to the assignment of structure I ($R_1 = H$; $R_2 = CH_3$).

Irradiation of **2** in the region 280–324 Hz from TMS caused the low field proton to sharpen relative to that proton to which it is directly coupled. The effect is most pronounced in the region 294–310 Hz from TMS. The effect is shown in Fig. 4*a*. A similar effect is observed in **1** when the solution in DMSO-d_6 is subjected to irradiation in the region 265–284 Hz as shown in Fig. 4*b*. The signals which are under irradiation in both systems must be one or other of the signals associated with the protons at C-5 or -13. With the orientation of substituents of structure II irradiation at C-13 would not affect the protons of ring A. The only other benzylic proton which can be long-range coupled to the aromatic protons of ring A is situated at C-14. This proton has not been assigned in this spectrum but since it is benzylic and alpha to nitrogen one would expect to find it at lower field than 3 p.p.m. from TMS. In the

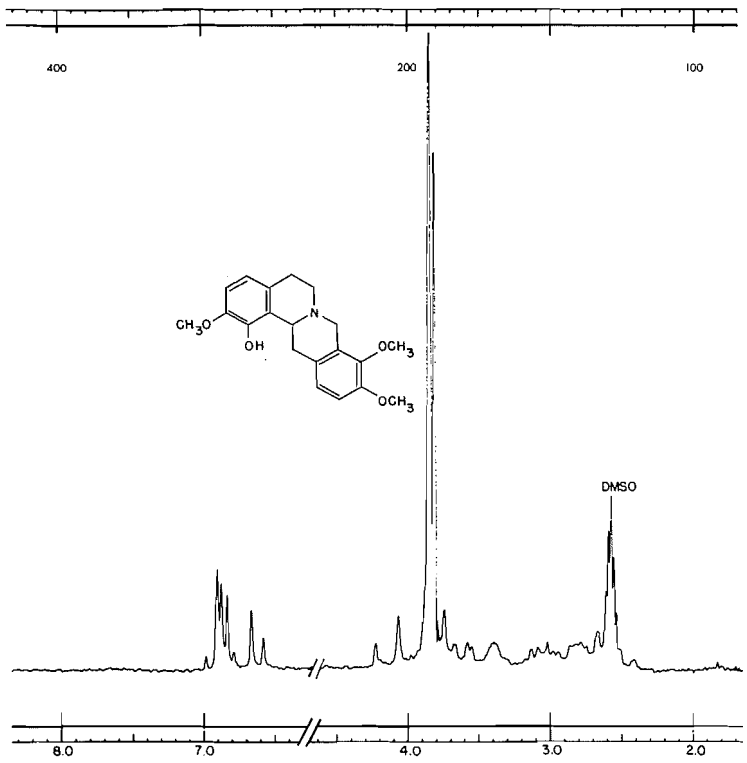

FIG. 2. The 100 MHz p.m.r. spectrum of caseanadine (**1**) in DMSO-d_6.

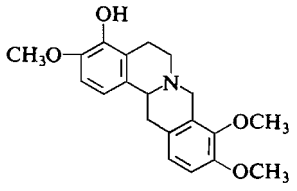
13-methylprotoberberines this proton is clearly defined and appears in the region 3.7 ± 0.1 (8).

The alternative structure, III, although unlikely on biogenetic grounds, must also be considered. If III were the correct structure, the low field proton of the AB quartet of **2** in ring A would be that at C-1, and the high field proton of the AB quartet of **1** in ring A would be that at C-1.



III

Irradiation at C-5 would affect the proton at C-1 less than that at C-2 since meta-benzylic coupling is weaker than para (7), a circumstance which is contrary to the observed result. In any event, in structure III the proton at C-1 would be expected to be broader, even after irradiating C-5, than that at C-2 because it would still be ortho-benzylic coupled to C-14. Such is not the case. Nevertheless, the irradiating field may be affecting the protons at C-13. These protons will not be long-range coupled to C-1 but irradiation at C-13 might increase the area of the proton at C-1 through a nuclear Overhauser effect (9) and give the misleading impression that a decoupling had occurred. An examination of the peak width at half height definitely shows a decoupling of the low field aromatic proton of **2** and the high field aromatic proton of **1**. For **1** the width at half height of the high field aromatic proton is 1.9 Hz in the uncoupled spectrum, and in the decoupled spectrum, 1.0 Hz. For the other half of the AB quartet the figures were 1.4 and 1.0 Hz. Only structure II (R = H; R_2 = CH_3) is compatible with these observations.

Thus, the decoupling experiments establish the orientation of the substituents in ring A. A *trans*-quinolizidine conformation of rings A and B in caseanadine is indicated by the presence of Bohlmann bonds in its i.r. spectrum (10). The large negative optical rotation of caseanadine in $CHCl_3$ suggests the absolute configuration shown in the diagram in which the C-14 hydrogen has an α-orientation (11).

Experimental

Methods

Mass spectra were recorded on a CEC 21-110B double-focusing mass spectrometer. For high resolution work spectra were recorded on plates and accurate mass measurements were made using perfluorokerosene as a marker (12).

The p.m.r. spectrum was recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V4315 frequency counter incorporated in the instrument. Double irradiation was achieved by employing a Hewlett–Packard 201C audiogenerator at the desired frequency. A Beckmann IR 10 spectrometer was used to record i.r. spectra and a Cary 14 spectrometer was used for the u.v. spectrum.

Isolation of Caseanadine

The mother liquor from which the tetrahydropalmatine (caseanine) had been removed (1) as completely as possible (both as the free base and as its hydrochloride) was again taken up in dilute hydrochloric acid. The clarified solution was basified with excess potassium hydroxide and the liberated bases taken up in ether. Much of the ether from the dried (KOH) solution was removed by evaporation. From the concentrated solution a mixture of bases separated in the course of several days. There was a fraction sparingly soluble in warm methanol which proved to consist largely of protopine and allocryptopine. The moderately soluble base consisted of fine flat needles (melting not sharply at 151°) which when recrystallized from methanol changed to less soluble stout prisms which when placed in a melting point bath at 150° melted at 170° with some shrinking at 165° $[\alpha]_D(CHCl_3) = -212°$.

Anal. Calcd. for $C_{20}H_{23}NO_4$: C, 70.4; H, 6.8; N, 4.1. Found: C, 71.0; H, 6.6; N, 4.4.

Accurate mass measurement of the molecular ion gave the following result: calcd. for $C_{20}H_{23}NO_4$, 341.1627; found, 341.1657.

O-Acetylcaseanadine

Caseanadine (10 mg) was dissolved in acetic anhydride (2 ml) and pyridine (0.5 ml). The mixture was allowed to stand at room temperature for 12 h when it was evaporated to dryness under reduced pressure. The residue, after neutralization, was dissolved in ether, washed several times with aqueous sodium carbonate, and the solution dried over anhydrous potassium carbonate. The residue obtained upon evaporation of the solvent failed to crystallize. The t.l.c. showed only one spot which had a different R_f value from the starting material. The p.m.r. spectrum, Fig. 3, demonstrates the presence of the *O*-acetyl group and clearly indicates the absence of unacetylated material. The mass spectrum has a molecular ion at *m/e* 385 (55) with major fragment ions at *m/e* 164 (100) and 149 (53). Insufficient material was available for a combustion analysis. Accurate mass measurement of the molecular ion gave the following result: calcd. for $C_{22}H_{25}NO_5$, 383.1733; found, 383.1685.

We thank the National Research Council of Canada for financial support of this work. We wish to acknowledge the assistance and advice of J. K. Saunders with the p.m.r. measurements.

Studies on the Decomposition of Tetra-alkylammonium Salts in Solution. IV. The α-Deuterium Secondary Isotope Effect

E. C. F. Ko AND K. T. Leffek
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received June 18, 1970

The secondary deuterium isotope effect is reported for the decomposition of benzyl-α-d_2-phenyldimethylammonium bromide in both chloroform and acetone solvent, over a temperature range of 25 to 30°. The magnitudes of the rate ratios are compared to literature values for S_N1 reactions, from which it is concluded that the mechanism of the decomposition involves a carbonium ion or ion-pair. The variation of the isotope effect with solvent is rationalized in terms of specific solvent interaction with the benzyl group.

Canadian Journal of Chemistry, **49**, 129 (1971)

Introduction

Previous papers (1–3) have presented evidence that the thermal decomposition of quaternary ammonium iodides and bromides, which contain a benzyl group, decompose completely in chloroform and acetone solvents to yield a benzyl halide and a tertiary amine, by a mechanism which was described as an "ionic internal nucleophilic substitution (1)". This mechanism is envisaged as an essentially unimolecular process and the reaction gives first order kinetics when the rate constant is evaluated with respect to the concentration of the ammonium ion, as distinct from that of the ammonium halide ion-pair, in which latter form most of the substrate exists under the experimental conditions. The transition state of the reaction may contain, in addition to the ammonium ion itself, some anions and solvent molecules, but the covalency change is postulated to involve only the carbon atom of the benzyl group and the nitrogen atom.

If this postulate is true, the substitution of the two hydrogen atoms attached to the benzyl carbon by deuterium should result in a change in the rate of reaction of the same order of magnitude as is observed for α-deuteration in typical S_N1 reactions. When the secondary α-deuterium isotope effects were first observed in 1957 (4–6), they were immediately recognized (6) as an additional diagnostic test for the unimolecular and bimolecular mechanisms in nucleophilic substitutions. Subsequent work, particularly in the solvolysis reactions of methyl compounds (7–9) established the test more firmly.

The basis of the secondary α-deuterium isotope effect test of mechanism is as follows. Isotope effects on rates of reactions result from changes in vibrational frequencies which involve the isotopically substituted atom. The effect of α-deuteration is assumed to be dominated by changes in the bending modes of vibration of C—H and C—D, between the initial and transition states. In an S_N1 reaction the transition state is less crowded than the initial state, therefore the frequencies of the bending modes of vibration of C—H and C—D are decreased during the activation process and this decrease is less for the deuterated compound since C—D has a lower zero-point energy ($\sum \frac{1}{2}h\nu_i$) than C—H in the initial state. Thus the difference in the zero-point energies between the two compounds is less in the transition state than in the initial state, which gives the deuterated compound a larger energy of activation and a smaller rate constant. The isotope effect, quoted as k_H/k_D, is therefore greater than unity (normal) for S_N1 reactions.

The same argument when applied to an S_N2 reaction, in which the transition state is more crowded than the initial state predicts an increase in the frequencies of the bending vibrations during activation and values of k_H/k_D less than unity (inverse).

Reviews of these isotope effects in 1961 by Weston (10) and by Seltzer (11) showed that reactions usually considered S_N1 gave free energy of activation differences $\Delta\Delta G^{\ddagger}$ ($= RT/n$ ln k_H/k_D, where n is the number of deuterium atoms) in the range of 55 to 80 cal/mole. Seltzer (11) concluded that the limiting value for an S_N1 reaction was $k_H/k_D = 1.12$ at 105 °C ($\Delta\Delta G^{\ddagger} \simeq 85$ cal/mole^{-1}) and used this criterion to deduce the mechanism of a non-solvolytic decomposition reaction. This value has been accepted generally (12–14).

For personal use only.

However, the approximate nature of the theory is shown by the observation of small normal isotope effects (up to $\Delta\Delta G^{\ddagger} = 27$ cal/mole^{-1}) for some non-solvolytic S_N2 reactions (15–19), but despite this, there is a clear difference in magnitude between the two mechanisms.

Results and Discussion

Rate constants for the decomposition of normal and deuterated tetra-alkylammonium bromides at various temperatures are presented in Table 1. The rate ratios, k_H/k_D in the right hand column, which show only a slight dependence on temperature, are approximately 1.25 in chloroform solvent and 1.20 in acetone solvent. Since there are two deuterium atoms present in the molecule, the magnitude of the isotope effect is $\Delta\Delta G^{\ddagger} \simeq 70$ cal/mole^{-1} in chloroform and 57 cal/mole^{-1} in acetone. These values are considerably larger than the largest observed normal isotope effect for non-solvolytic S_N2 reactions and, at least in chloroform, quite close to the S_N1 limiting value of 85 cal/mole^{-1}. Previous measurements made on α-deuterated benzyl compounds gave $k_H/k_D = 1.25$ at 50 °C for the solvolysis of benzyl-1,1-d_2 *p*-toluenesulfonate in acetic acid (6), corresponding to $\Delta\Delta G^{\ddagger} = 72$ cal mole^{-1}, as opposed to $k_H/k_D = 1.05$ at 40 °C or $\Delta\Delta G^{\ddagger} = 15$ cal mole^{-1} for the radiochloride exchange with benzyl-1,1-d_2 chloride in *N,N* dimethylformamide solvent (17). Also, Shiner *et al.* (14) have recently reported α-deuterium isotope effects on the rates of solvolysis of several benzyl derivatives in a number of solvent mixtures and correlated the magnitude of the effects with mechanism.

TABLE 1. Rate data for the decomposition of benzyl-α-d_2-phenyldimethylammonium bromide and its normal analogue in solution

50	22.1	18.1	1.22_1
55	40.1	33.3	1.20_4

*Specific first order rate constant.

In comparison with the above values, the results in Table 1 strongly favor a transition state for the ammonium ion decomposition in which a carbonium ion is being formed, although this carbonium ion may have an extremely short life-time before it forms an ion-pair with a bromide ion. Alternatively, if an appropriate definition of an ion-pair is assumed the transition state may be pictured as a loose solvent-separated ion-pair, but in either case the results require that the anion is not involved in covalency change during the activation process.

The activation parameters and their standard deviations are reported in Table 2 together with the isotope effects on these parameters. The latter were calculated by fitting the observed rate ratios to eq. 1 by the method of least squares. It

$$[1]\quad \log_{10} k_H/k_D = \frac{(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})}{2.303RT} - \frac{(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})}{2.303R}$$

may be seen that the entropy contribution to the free energy of activation difference is larger than that of the enthalpy. This does not invalidate the above argument made in terms of free energy of activation since it has been shown by Wolfsberg and Stern (20) using model calculations, that secondary deuterium isotope effects entirely in the entropy term may be accommodated by the transition state theory provided the appropriate changes in vibrational frequencies take place during the reaction. However, the results in Table 2 give rise to a feeling that perhaps a model for a reaction which ignores the solvent completely makes too gross an approximation. On the other hand the nature of solvation effects on secondary isotope effects is, at present time, suited only to an empirical approach.

Table 1 shows that there is a significant difference between the rate ratios in the two solvents, with the more polar acetone giving the smaller isotope effect. This difference, in comparison to solvent effects on α and β deuterium isotope rate effects already reported (12, 13, 18, 21–25) is large, but not exceptionally so.

TABLE. 2. Activation parameters for the decomposition of benzylphenyldimethylammonium bromide and isotope effects for the benzyl-α-d_2 analogue

Solvent	$\Delta H_H^{\ddagger}$(kcal mole^{-1})	$\Delta S_H^{\ddagger}$(cal mole^{-1} deg^{-1})	$(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$*	$(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$*
$CHCl_3$	26.3 ± 0.4	6.1 ± 1.1	0.031 ± 0.03	−0.35 ± 0.1
$(CH_3)_2CO$	26.8 ± 0.2	7.5 ± 0.7	−0.134 ± 0.09	−0.80 ± 0.3

*Calculated from k_H/k_D values given in Table 1, using method of least squares.

Several years ago Shiner and Verbanic (26) recognized the difficulty of explaining large solvent effects on isotope rate effects without invoking specific solvation at the site of isotopic substitution. In the ammonium ion decomposition there must be a specific interaction between the α-hydrogen (or deuterium) atoms or the benzyl carbon atom and the solvent molecules to give the different isotope effect for the two solvents, because if it were merely a matter of general solvation of the positive charge, the rate ratio would be larger in acetone than in chloroform. Since this is not the case, it is postulated that a specific interaction contributes a component to the observed isotope effect. It has been postulated by Weiner and Sneen (27, 28) that under some conditions during nucleophilic substitution reactions, acetone is sufficiently nucleophilic to interact with the substrate molecule to form an unstable intermediate. If this postulate were extended to the present work, the interaction would be between the carbonyl group and the benzyl carbon atom, rather than the hydrogens attached to the benzyl carbon atom. The experimental observations do not allow a sufficiently precise definition of the interaction to distinguish between these two similar alternatives, but the isotope effects do clearly show that the α-hydrogens are involved in an important manner. Bearing this in mind, an explanation of the solvent effect on the rate ratio may be formulated in the following way, using "α-hydrogen interaction" as a description of the involvement of the acetone, since this allows the argument to be put most succinctly.

The interaction between the α-hydrogen (deuterium) atoms and the solvent will be stronger the more positive the charge on these atoms. This charge on the α-hydrogen atoms increases during the activation process as the positive charge is transferred from the nitrogen to the benzyl carbon atom. Since C—D releases electrons under the influence of a positive charge to a greater extent than C—H (29), the α-hydrogen-solvent interaction is greater for the deuterium compound than for the hydrogen compound. Also, this interaction is greater in the transition state than in the initial state. Thus, the entropy of the deuterium system will be lower than that of the hydrogen system and the difference between the two systems will be less in the transition state than in the initial state. Therefore, the contribution to $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ from this source is positive. Since this effect should be larger in the more polar solvent, this positive contribution to $\Delta\Delta S^{\ddagger}$ renders the observed value in Table 2 for acetone less negative than it otherwise would be, compared to the value for chloroform. The less negative value in turn yields a smaller positive $\Delta\Delta G^{\ddagger}$ for acetone and hence a smaller rate ratio.

This type of solvent effect is, of course, a minor component of the overall isotope effect which results from the quite substantial positive values of $\Delta\Delta G^{\ddagger}$ noted earlier.

Thus, the α-deuterium isotope effect is consistent with the type of transition state envisaged in the previous work (1–3) and its variation with the solvent may be explained reasonably in terms of a specific solvent participation in the reaction.

Experimental

Toluene-α-d_3 was purchased from Merck, Sharpe and Dohme of Canada Limited and converted into benzyl-α-d_2 bromide by *N*-bromosuccinimide containing a trace of benzoyl peroxide. The preparation was carried out on a 1 g scale using the conditions given by Johnstone and Stevens (30). A nearly quantitative yield was obtained and the product was purified by distillation; boiling range 135–138° at 22 mm Hg.

Benzyl-α-d_2-phenyldimethylammonium bromide was prepared from the deuterated benzyl bromide and dimethylaniline and purified by recrystallization as described previously (3); melting range 155–157°.

The purification of the solvents and the procedure for the kinetic measurements and calculation of results were exactly the same as in the earlier work (1, 3).

Photolysis of Acyl Group IV Metalloids: the Formation of Silyl Radicals

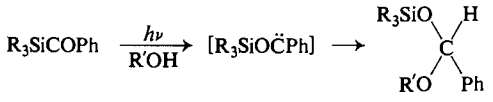
A. G. Brook, P. J. Dillon, and R. Pearce
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received August 12, 1970

The photolyses of several acylsilanes and one acylgermane in carbon tetrachloride have been shown to involve Norrish Type I cleavage of the metalloid–acyl bond to give metalloidal radicals. These radicals readily abstract chlorine from the solvent.

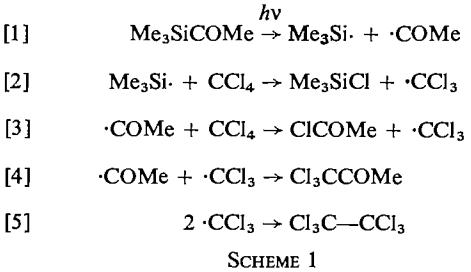
Canadian Journal of Chemistry, **49**, 133 (1971)

Recently, the photolyses of acetyltriphenylsilane and (−)-acetyl-1-naphthylphenylmethylsilane in carbon tetrachloride were shown to involve the formation of silyl radicals which subsequently abstracted halogen from the solvent, in the latter case with significant retention of optical configuration (1). In other studies it was demonstrated that photolysis of acylsilanes in alcohols proceeded via a siloxycarbene intermediate (2).



In order to further investigate the apparent duality of the reaction pathway (radical or siloxycarbene formation) a more detailed investigation was begun; the photolysis of a variety of acylsilanes in carbon tetrachloride is reported here.

The photolysis of acetyltrimethylsilane in carbon tetrachloride produced trimethylchlorosilane (99%), acetyl chloride (67%), 1,1,1-trichloropropanone (30%), and hexachloroethane (61%). These results are in accord with those found previously for acetyltriphenylsilane (1). The nature of the products suggests that acetyl and trimethylsilyl radicals are formed by Norrish Type I cleavage of the acyl–silicon bond followed by reactions of the radicals with the solvent, as shown in Scheme 1.



Scheme 1

If Scheme 1 adequately describes the overall process, then the sum of the yields of acetyl chloride and 1,1,1-trichloropropanone, representing products derived from the acetyl radical, and the sum of the yields of 1,1,1-trichloropropanone and hexachloroethane, representing products derived from the trichloromethyl radical, will each be 100%. These were found to be 97 and 91% respectively.

The possible occurrence of other minor reactions was briefly investigated. Hexamethyldisilane, which would result from a combination of trimethylsilyl radicals, trimethylsilane from hydrogen abstraction, and trichloromethyltrimethylsilane from cross-combination of radicals, could not be detected in the reaction mixture. It can be concluded therefore, that the reaction pathways depicted in Scheme 1 adequately describe the photolysis of acetyltrimethylsilane in carbon tetrachloride.

The yields of 1,1,1-trichloropropanone, acetyl chloride and hexachloroethane were found to be temperature dependent, the yield of trichloropropanone being observed to decrease with increasing temperature while the yields of acetyl chloride and hexachloroethane increased with increasing temperature, as shown in Table 1. These observations are explained if the activation energy for the abstraction of chlorine by the acetyl radical, step 3, Scheme 1, is greater than that for the radical combination reactions, steps 4 and 5, as would be expected.

Table 1. Yields of photolysis products at various temperatures

	Temperature (°C)		
Product	−23	0	76
Me_3SiCl	100	99	99
Cl_3CCOMe	38	30	14
MeCOCl	63	67	74
Cl_6C_2	48	61	63

TABLE 2. Products of photolyses in carbon tetrachloride

Acylmetalloid*	Products
$Me_3SiCOEt$	Me_3SiCl (~ 100%), EtCOCl (53%), Cl_6C_2 (54%), Cl_3CCOEt (yield undetermined)
$Et_3SiCOMe$	Et_3SiCl (94%), MeCOCl (65%), $MeCOCCl_3$ (35%), Cl_6C_2 (64%)
n-$Pr_3SiCOMe$	*n*-Pr_3SiCl, MeCOCl, $MeCOCCl_3$, Cl_6C_2 (yields undermined)
n-$Bu_3SiCOMe$	*n*-Bu_3SiCl, MeCOCl, $MeCOCCl_3$, Cl_6C_2 (yields undetermined)
$Me_3SiCOPh$	Me_3SiCl (87%), PhCHO, PhCOCl, Cl_6C_2
$Ph_3SiCOPh$	No reaction
$Ph_3GeCOPh$	Ph_3GeCl (94%), PhCOCl (91%), Cl_6C_2 (98%)
	$Me_2ClSi(CH_2)_4COCl$ (48%), $Me_2ClSi(CH_2)_4COCCl_3$ (14%),† Cl_6C_2 (yield undetermined)

*In all photolyses 0.2 g of acylmetalloid was irradiated in 5 ml of dry carbon tetrachloride at 0° under nitrogen for about 1–2 h using a low pressure 100 W mercury lamp.
†Yields are those of product isolated by fractional distillation.

The photolysis of a number of other acylsilanes and one acylgermane in carbon tetrachloride were also investigated and analogous results were obtained for all other acylmetalloids studied (except benzoyltriphenylsilane), as shown in Table 2.

When benzoyltrimethylsilane was photolyzed, benzaldehyde was found, presumably because the benzoyl radical abstracts hydrogen from the trimethylsilyl group. This is supported by the observation that no benzaldehyde was formed in the photolysis of benzoyltriphenylgermane, where only aromatic protons are available. Acetaldehyde was not observed in the reactions involving the acetyl radical.

Benzoyltriphenylsilane was inert to photolysis even over prolonged periods of time. This is in marked contrast to its rapid photochemical decomposition in the presence of alcohols (2) and its unique behavior is not understood. Benzoylsilanes and benzoylgermanes exhibit an $n \rightarrow \pi^*$ absorption maximum at about 420 mμ, whereas acetylsilanes and acetylgermanes have a maximum at about 380 mμ. The energy absorbed appears sufficient to cause rupture of the silicon–acetyl bond on one hand, but is insufficient to break the silicon–benzoyl bond. Since the carbon–germanium bond is considerably weaker than the silicon–carbon bond, the photolytic decomposition of benzoyltriphenylgermane is not unexpected. This explanation of the above observations does not, however, satisfactorily explain the photolysis of benzoyltrimethylsilane, whose absorption maximum is virtually identical to that of benzoyltriphenylsilane.

The reaction of the cyclic acylsilane, 1,1-dimethyl-1-silacyclohexan-2-one, is noteworthy. Preliminary investigations of the photolytic decompositions of cyclic acylsilanes in a variety of media have indicated that cyclic siloxycarbenes are involved (3–5). The products obtained on photolysis of the silacyclohexanone in carbon tetrachloride are 5-(chlorodimethylsilyl)pentanoyl chloride and 1,1,1-trichloro-6-(chlorodimethylsilyl)hexan-2-one as expected from a simple Norrish Type I cleavage of the silicon–carbonyl bond followed by reactions as in Scheme 1; thus siloxycarbenes do not appear to be involved under these conditions.

From the preceding results it appears that aliphatic acylsilanes when photolyzed in carbon tetrachloride undergo Norrish Type I cleavage exclusively: further work is underway to establish more clearly the factors which determine whether siloxycarbene formation or Norrish Type I cleavage will occur in other solvents.

Experimental

General

The n.m.r. spectra were recorded on either a Varian A-60 or A56/60 instrument using carbon tetrachloride. The i.r. spectra were obtained on a Perkin–Elmer Model 237-B IR Spectrometer. The u.v. spectra were obtained

on a Unicam SP800 Spectrometer. A Varian Aerograph Series 200 Gas Chromatograph was used for product analysis with a 20′ × 1/4″ aluminum column containing 20% SE30 on Chromasorb B. The photolysis employed a PAR-38 100 W mercury floodlamp.

Preparation of Acylmetalloids

All acylmetalloids were prepared by previously described methods (6–8). Physical data of new acylmetalloids are listed in Table 3 and spectroscopic data are given in Table 4.

Photolysis of Acylmetalloids in Carbon Tetrachloride

Products were identified by i.r. and n.m.r. spectroscopy, and by v.p.c., each product being identified by comparison of the retention time of an authentic sample with that of the appropriate peak in the v.p.c. Trichloromethyltrimethylsilane was prepared for comparison purposes by the method of Bamford and Pant (9). Its absence in the photolysate of acetyltrimethylsilane in carbon tetrachloride was demonstrated by v.p.c. Yields of all products were determined using an internal standard and the peak-weight method.

In the case of the cyclic acylsilane, the photolysate from the acylsilane (3.75 g) in CCl_4 (300 ml) was evaporated and the residual liquid was distilled on a semi-micro, spinning-band column to give 5-(chlorodimethylsilyl)pentanoyl chloride, 2.7 g (48%), b.p. 48–50°/0.12 mm, and somewhat impure 1,1,1-trichloro-6-(chlorodimethylsilyl)hexan-2-one, 1.1 g (14%), b.p. 73–74°/0.10 mm.

Chlorination of Pyrroles. Part I

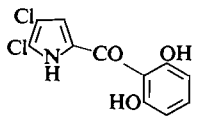
D. G. DURHAM AND A. H. REES
Department of Chemistry, Trent University, Peterborough, Ontario

Received June 5, 1970

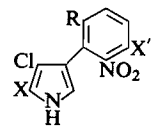
Formylation of 1-phenylpyrrole gave mainly the 2-aldehyde which was converted to the methyl ester. Chlorination produced the 4- and 5-monochloro, the 4,5-dichloro and the 3,4,5-trichloro derivatives and 2-methoxycarbonyl-5-oxo-1-phenyl-2,3,4-trichloro-3-pyrroline which were identified spectroscopically. The mass spectral cracking patterns of the chloropyrrole esters have been interpreted.

Canadian Journal of Chemistry, 49, 136 (1971)

The natural occurrence of chloropyrroles such as pyoluteorin (**1**) (1, 2) and the pyrrolnitrins (**2**) (3–7) led us to investigate the chlorination of some pyrroles including 2-methoxycarbonylpyrrole (8) and 2-methoxycarbonyl-1-phenylpyrrole (**3**, X = Y = Z = H, R = COOMe) (9) which we now report.



1



2

3

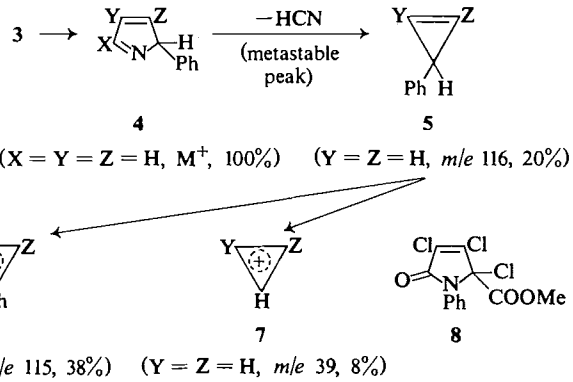
Formylation (10) of 1-phenylpyrrole gave a 14:1 mixture of 2- and 3-aldehydes. The 2-isomer was converted (8) to the acid **3** (X=Y=Z=H, R = COOH) and its methyl ester. Chlorination of this ester with varying amounts of chlorine in acetic acid gave mixtures of products plus starting material. Attempts to resolve these mixtures were only successful by g.l.c. Chlorination (2 equiv) gave products identified as the 4-chloro (8%), 5-chloro (20%), 4,5-dichloro (40%), and 3,4,5-trichloro (25%) esters by consideration of their n.m.r. and mass spectra. Esters without a 5-chloro substituent had n.m.r. spectra in which the phenyl protons resonated as a singlet (Table 1).

The mass spectra suggest a 1- to 2-phenyl shift (see Scheme 1).

A similar breakdown was observed in the mass spectra of the esters **3** (R = COOMe) after loss of OMe then CO. The esters also lost the methoxycarbonyl group with hydrogen transfer giving M-58 ions **3** (R = H), Table 2, a pathway also observed in 2-methoxycarbonyl furans (11).

We also record *m/e* 77 (Ph^+) and regard its intensity as a measure of the electrophilic character of the pyrrole ring.

Chlorination of ester **3** (X = Y = Z = H, R = COOMe) with four molar equivalents of chlorine gave a product $C_{12}H_8Cl_3NO_3$ having carbonyl absorption at 1770 (α-chloroester) and 1740 (lactam) cm^{-1}. Following known chlorination of pyrrole (12), we assigned to the above compound the structure **8**. There was no indication of chlorination in the phenyl ring.



4 (X = Y = Z = H, M^+, 100%) **5** (Y = Z = H, *m/e* 116, 20%)

6 (Y = Z = H, *m/e* 115, 38%) **7** (Y = Z = H, *m/e* 39, 8%) **8**

Experimental

The g.l.c. was done on a Dynatronics Instrument Corp. Chrom-Alyzer-100 with 8′ × ¼″ column of 30% SE 30 silicone, using helium at 235°.

Formylation of 1-Phenylpyrrole

1-Phenylpyrrole, 10 g, was formylated (10) giving 70% distilled 2-aldehyde which after g.l.c. had ν_{max} (film) 1665, 1600, 1530, 1500, 1330 cm^{-1}; mass spectrum *m/e*, (relative intensity) 171 (100), 170 (50), 115 (15), 93 (40), 78 (12), 77 (10), 51 (12), 39 (6).

The 2-aldehyde was characterized as its semicarbazone, m.p. 181–183°, crystallized from methanol, depressed in mixed m.p. with the semicarbazone of **3** (X = Y = R = H, Z = CHO) below.

Anal. Calcd. for $C_{12}H_{12}N_4O$: C, 63.15; H, 5.3; N, 24.5. Found: C, 63.0; H, 5.2; N, 24.6.

The pure 3-aldehyde was obtained by preparative g.l.c. with ν_{max} (film) 1670, 1595, 1535, 1510, 1260, 1200 cm^{-1}. Mass spectrum 171 (95), 170 (100), 115 (15), 77 (13), 51 (12), 39 (7). The semicarbazone had m.p. 188–190° recrystallized from methanol.

Anal. Calcd. for $C_{12}H_{12}N_4O$: C, 63.15; H, 5.3; N, 24.5. Found: C, 63.5; H, 5.3; N, 24.2.

Preparation of 2-Methoxycarbonyl-1-phenylpyrrole

The 2-aldehyde, 11 g, in 100 ml methanol was oxidized (8) giving 9.4 g, 85% of acid, m.p. 164–166°, crystallized from benzene [lit. (9) m.p. 165°]. Esterification with diazomethane gave the ester, m.p. 87–88°, crystallized from light petroleum [lit. (9) m.p. 88°], ν_{max} (Nujol) 1700, 1595, 1270, 1120, 1040, 950, 810 cm^{-1}; u.v. max 264 mμ (ε 24 900).

Chlorination of 3 (X = Y = Z = H, R = COOMe)

Chlorination (2 mol) in acetic acid (8), gave after evaporation of the solvent, a mixture of chloroesters. This was taken up in ether and the solution washed with sodium bicarbonate solution, then with water, and dried ($MgSO_4$). After concentration the residue was resolved by g.l.c. giving the following products:

5-Chloro-2-methoxycarbonyl-1-phenylpyrrole (3, X=Cl, Y = Z = H, R = COOMe), an oil which could not be induced to crystallize, ν_{max} (film) 1715, 1595, 1275, 1150 cm^{-1}.

Anal. Calcd. for $C_{12}H_{10}ClNO_2$: C, 61.3; H, 4.3; Cl, 14.9; N, 5.95. Found: C, 61.5; H, 4.35; Cl, 15.0; N, 5.75.

4-Chloro-2-methoxycarbonyl-1-phenylpyrrole (3, Y=Cl, X = Z = H, R = COOMe), prisms, m.p. 78–80°, recrystallized from light petroleum, ν_{max} (Nujol) 1710, 1595, 1260, 1140, 950, 810 cm^{-1}.

Anal. Calcd. for $C_{12}H_{10}ClNO_2$: C, 61.3; H, 4.3; Cl, 14.9; N, 5.95. Found: C, 61.4; H, 4.4; Cl, 14.0; N, 6.1.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

4,5-Dichloro-2-methoxycarbonyl-1-phenylpyrrole (3, X = Y = Cl, Z = H, R = COOMe), plates, m.p. 97–99°, recrystallized from light petroleum, ν_{max} (Nujol) 1710, 1595, 1270, 1020, 955, 830 cm^{-1}; u.v. max 275 mμ (ε 20 400).

Anal. Calcd. for $C_{12}H_9Cl_2NO_2$: C, 53.4; H, 3.4; Cl, 26.2; N, 5.2. Found: C, 53.3; H, 3.4; Cl, 26.4; N, 5.2.

2-Methoxycarbonyl-1-phenyl-3,4,5-trichloropyrrole (3, X = Y = Z = Cl, R = COOMe), prisms, m.p. 79–81°, recrystallized from light petroleum, ν_{max} (Nujol) 1710, 1595, 1280, 840 cm^{-1}.

Anal. Calcd. for $C_{12}H_8Cl_3NO_2$: C, 47.3; H, 2.65; Cl, 34.9; N, 4.6. Found: C, 47.5; H, 2.7; Cl, 35.1; N, 4.65.

Chlorination (4 mol) as described above, gave **8** which came out of the ether solution, needles, m.p. 132–135°, recrystallized from aqueous ethanol: u.v. max 227 mμ (ε 13 500), n.m.r. Table 1; mass spectrum *m/e*, 319 (M^+, 22), 77 (100).

Anal. Calcd. for $C_{12}H_8Cl_3NO_3$: C, 45.0; H, 2.5; Cl, 33.2; N, 4.4. Found: C, 45.0; H, 2.5; Cl, 33.0; N, 4.4.

Structure of Fumarophycine

M. CASTILLO, J. K. SAUNDERS, AND D. B. MACLEAN
Department of Chemistry, McMaster University, Hamilton, Ontario
AND
N. M. MOLLOV AND G. I. YAKIMOV
Institute of Organic Chemistry, Bulgarian Academy of Science, Sofia, Bulgaria

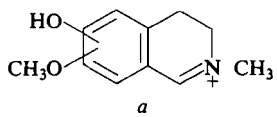
Received August 12, 1970

Fumarophycine, an alkaloid derived from *Fumaria officinalis* of Bulgarian origin, is shown by spectroscopic methods to be a new member of the spiroisoquinoline group. It has been related by chemical methods to the alkaloid, fumaritine, of known constitution.

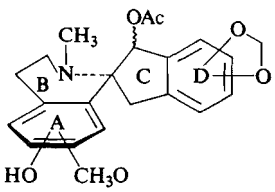
Canadian Journal of Chemistry, 49, 139 (1971)

The alkaloids of *Fumaria officinalis* were first examined by Manske (1) in 1938. More recently he has reported (2) the isolation of two other minor alkaloids from this source. Alkaloids belonging to the protoberberine (1), protopine (1), and the spiroisoquinoline (3–5) groups are now known to be elaborated by this species. A few years ago Mollov *et al.* (6) examined *F. officinalis* of Bulgarian origin from which fumarophycine, **1**, was isolated as the major alkaloid along with smaller amounts of protopine, cryptopine, and sinactine. They assigned to fumarophycine the formula, $C_{22}H_{23}NO_6$, and from its properties inferred that it was a new alkaloid. By p.m.r. spectroscopy, it was shown that fumarophycine had a methylenedioxy group, an *O*-methyl group, a phenolic hydroxyl group, an alcoholic *O*-acetyl group, an *N*-methyl group and four aromatic protons. Alkaline hydrolysis of fumarophycine gave a compound of the expected mass while methylation with diazomethane gave *O*-methylfumarophycine thus confirming the character of the *O*-acetyl and hydroxyl functions. Further examination of fumarophycine using high resolution mass spectrometry and 100 MHz p.m.r. spectroscopy has enabled us to assign its structure.

The mass spectrum of fumarophycine provided the first clue that it was a new representative of the spiroisoquinoline group of alkaloids. In the high mass region besides a molecular ion peak at *m/e* 397 (25)[1] there were peaks at 355 (26), M-C_2H_2O, 354 (100), M-C_2H_3O, and 337 (48), M-$C_2H_4O_2$. The most significant peak in the spectrum appeared at *m/e* 192 (6) of composition $C_{11}H_{14}NO_2$. Previous examination (5, 7) of the mass spectra of spiroisoquinoline alkaloids containing a hydroxyl group in the spiro system has shown that they fragment to dihydroisoquinolinium ions and these ions are often the most intense in the spectra. The low intensity of this ion, to which we assign structure *a*, in the case of fumarophycine, is not surprising since the hydroxyl group is acetylated. Fragmentation to give *m/e* 192 could occur only after loss of ketene. Thus from its mass spectrum and from its origin it appears that fumarophycine is another example of the spiroisoquinoline group of alkaloids as represented in partial structure *b*. The methoxyl and hydroxyl groups are placed in ring A because of the composition of ion *a*. The mass spectrum does not, however, provide any information concerning the substitution pattern. It was necessary, therefore, to turn to p.m.r. spectroscopy which has been used so successfully with other members of this series (3–5, 7, 8) to confirm the structure and to define the substitution pattern and the relative stereochemistry.



a



b

[1]Ion intensities are given in brackets. The composition of the ions has been established by accurate mass measurement.

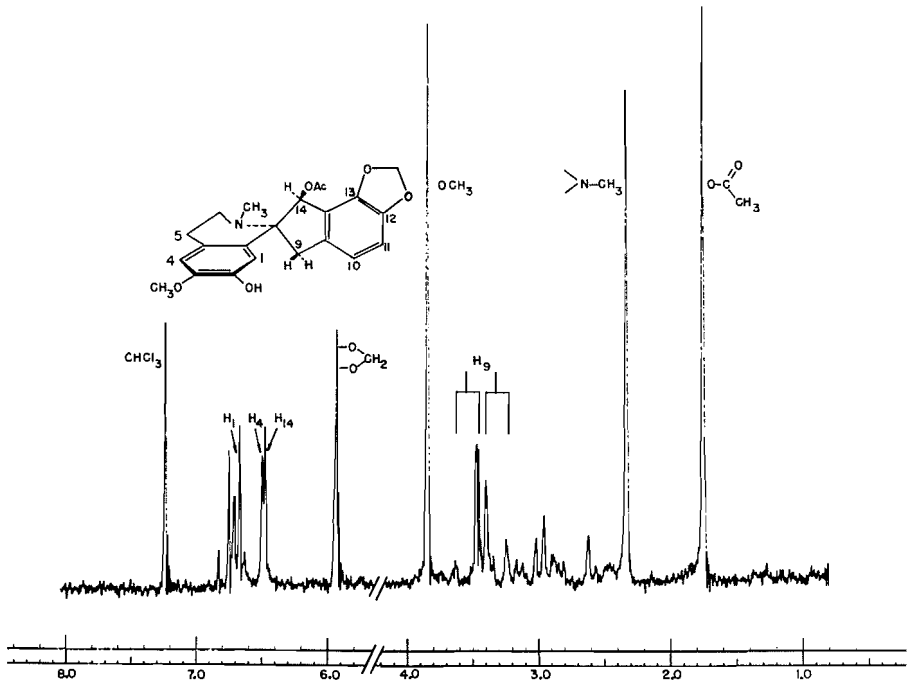


FIG. 1. The 100 MHz p.m.r. spectrum of fumarophycine.

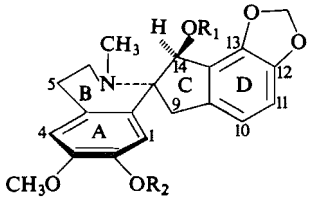
The 100 MHz p.m.r. spectrum of fumarophycine, Fig. 1, has confirmed the original assignment of substituent groups made by Mollov *et al.* Thus, we find a signal of area 2 at 5.94 δ assigned to the methylenedioxy group and three singlets of area 3 at 1.74, 2.32, and 3.94 which are assigned, respectively, to acetyl-methyl, *N*-methyl and *O*-methyl groups. In the region 2.32 to 3.94 δ there are signals corresponding to six aliphatic protons. Two of these are present as an AB quartet, δ H_A = 3.32, H_B = 3.55, J_{AB} = 16 Hz. These signals are assigned to the benzylic protons at C-9. The remaining four protons in this region may be attributed to those at C-5 and -6. In the region 6.0–7.0 δ there are signals corresponding in area to five protons. Two of these are present as an aromatic AB quartet, δ H_{10} = 6.66, H_{11} = 6.79, $J_{H_{10}H_{11}}$ = 8.0 Hz while the other three are singlets at 6.67, 6.50 and 6.48 δ representing the protons at C-1, -4, and -14 respectively. The assignment of these signals to specific protons in the system is based on measurement of nuclear Overhauser effects (n.O.e.) (9).

The n.O.e. measurements were used in the elucidation of the structure of other alkaloids of this ring system (4, 5, 7, 8). When this technique was applied to **1**, the following results were obtained. Irradiation of the signal at 2.32 δ (*N*-CH_3) resulted in an increase of area of 25% for the signal at 6.48 δ. Accordingly, we can assign the latter signal to the proton geminal to the acetoxy group at C-14 and at the same time we have established its relative stereochemistry. Irradiation at the center of the benzylic AB quartet increased the area of the signal at 6.67 δ by 25% which permits assignment of this singlet to the proton at C-1. The singlet at 6.50 δ must then be attributed to C-4. This has been confirmed by the observation that there is an increase in area of 8% for this signal on irradiation of the axial proton at C-5 (3.50 δ). There is no observable change in area of the signal at 6.67 δ as a result of this latter irradiation. The assignment of the methoxyl group at C-3 is based on the evidence that irradiation of the methoxyl signal at 3.94 δ increases the area of the signal at 6.50 δ by 24% but does not affect the signal at 6.67 δ. Finally we are able to assign the protons of the aromatic AB quartet to C-10 and -11. Irradiation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

protons of the benzylic AB quartet increased the area of the signal at 6.66 δ by 20%. This is compatible with the observation that the higher field doublet of this AB quartet is broader than its lower field counterpart, a reflection of the fact that ortho-benzylic coupling is stronger than meta (10).

The presence of the acetyl group in fumarophycine has deshielded the proton at C-1 relative to non-acetylated analogues (5). Moreover, the relatively high field absorption of the acetyl-methyl suggests that it is shielded by one or other of the aromatic rings (probably ring A) of this system. Similar effects have been observed in the spectrum of diacetyl ochrobirine (8).



1 R_1 = Ac; R_2 = H
2 R_1 = H; R_2 = H
3 R_1 = Ac; R_2 = Ac
4 R_1 = H; R_2 = CH_3

The p.m.r. data are thus compatible with the spiroisoquinoline structure and indeed demonstrate that **1** is the only satisfactory formulation of fumarophycine. It is, therefore, a derivative of fumaritine **2** (5) whose structure has been confirmed by synthesis (11). We were able to establish a direct relationship by converting both **1** and **2** by acetylation to the common derivative **3**. The i.r. and p.m.r. spectra of **3** prepared from **1** and **2** were identical in all respects.

One feature of the chemistry of fumarophycine remains unresolved. In their initial report Mollov *et al.* (6) reported on the alkaline hydrolysis of fumarophycine to fumarophycinol, m.p. 128–30°, and its subsequent methylation with diazomethane to *O*-methylfumarophycinol, m.p. 134–137°. According to the structure which has been established for fumarophycine, fumarophycinol would be expected to be identical with fumaritine and *O*-methylfumarophycinol with fumaricine (**4**) but they were not. For each pair the melting points were different, the mass spectra were virtually identical, but the p.m.r. spectra, although similar, showed minor but distinct differences. The reason for these differences has not been established and their investigation must await the availability of further supplies of the alkaloid.

Experimental

Methods

Mass spectra were recorded on a CEC 21-110B double-focusing mass spectrometer. For high resolution work spectra were recorded on plates and accurate mass measurements were made using perfluorokerosene as a marker (12).

The p.m.r. spectrum was recorded using the frequency sweep mode of a Varian HA-100 spectrometer. Samples were dissolved in $CDCl_3$ using added TMS as the internal locking signal. Chemical shifts were measured relative to TMS using a V4315 frequency counter incorporated in the instrument. Double irradiation was achieved by employing a Hewlett–Packard 201C audiogenerator at the desired frequency.

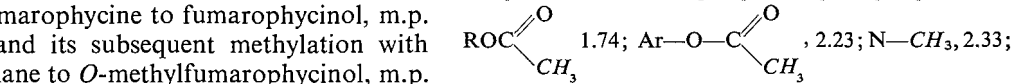
Fumarophycine

The isolation and properties of this compound have been described (6). The molecular formula of fumarophycine has been confirmed by high resolution mass spectrometry.

Mol. Wt. Calcd. for $C_{22}H_{23}NO_6$: 397.153. Found: 397.154.

O-Acetylfumarophycine

Fumarophycine (10 mg) was dissolved in acetic anhydride (5 ml) containing pyridine (0.1 ml) and the mixture was allowed to stand at room temperature for 24 h. The excess anhydride and pyridine were evaporated under reduced pressure, the residue triturated in aqueous sodium carbonate, and the suspension extracted several times with chloroform. The chloroform extract was dried over sodium sulfate, and evaporated to a residue which was purified by preparative t.l.c. on silica gel using $CHCl_3$:MeOH = 99:1 to develop the plate. The residue obtained upon elution could not be induced to crystallize but on an analytical thin layer plate it showed only a single spot. The mass spectrum showed a molecular ion at *m/e* 439. The i.r. spectrum had two bands in the carbonyl region at 1730 and 1760 cm^{-1} attributed to alcoholic *O*-acetate and phenolic *O*-acetate groups, respectively. The p.m.r. spectrum of **2** is similar to that of **1** but shows a new peak attributed to the methyl of the phenolic-*O*-acetate group. The principal peaks are



OCH_3, 3.79; and methylenedioxy, 5.96 δ.

O,O-Diacetylfumaritine

Fumaritine was acetylated in the same manner as fumarophycine and the product worked up and purified as described above. Its properties were identical in all respects with those of *O*-acetylfumarophycine.

Nuclear Magnetic Resonance Study of Several Derivatives of 1,3,5,7-Tetramethyltricyclo[5.1.0.0^{3,5}]octane. Stereochemical Assignments by Nuclear Overhauser Enhancements[1]

M. GORDON, W. C. HOWELL, C. H. JACKSON, AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London 72, Ontario

Received July 22, 1970

Measurements of the nuclear Overhauser enhancements in the title series permit unequivocal assignments of the 6-substituent in a series of 1,3,5,7-tetramethyltricyclo[5.1.0.0^{3,5}]octan-2-ones and derivatives. Supporting evidence provided by long-range coupling interactions through four σ-bonds is also presented. The proton shifts in these systems appear to depend primarily on the degree of steric hindrance; this aspect is discussed.

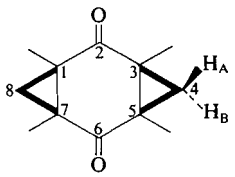
Introduction

The synthesis of 1,3,5,7-tetramethyltricyclo-[5.1.0.0^{3,5}]octan-2,6-dione (**1**) by acid-catalyzed decomposition of the dipyrazoline, formed from duroquinone and diazomethane, has been described (1) and the stereochemistry of the cyclo-



1

propyl rings established as *syn* by partial reduction to two diastereomeric ketoalcohols, **2** and **3**. The stereochemical assignments for the latter, however, were not made since unequivocal evidence was lacking. It is the purpose of this paper to report results of a detailed n.m.r. study of these ketoalcohols and several derivatives which allow us to complete the configurational assignments. Determinations of certain nuclear Overhauser enhancements (n.O.e.) (2) and some long-range coupling constants provide unequivocal evidence for the conclusions presented. The chemical transformations investigated in this study are summarized in Scheme 1, which illustrates the routes employed to prepare 12 new derivatives of the little known tricyclo[5.1.0.0^{3,5}]-octane system. For convenience and clarity the stereochemistry of the various members in this series is indicated in Scheme 1, while the experimental basis of these assignments is discussed later.

[1]This paper represents Part XXII in the series on n.m.r. studies; Part XXI, A. W. Brinkmann *et al.* (25).

Results

Chemical Transformations

The reduction of **1** with one equivalent of sodium borohydride gave a mixture of keto-alcohols, **2** and **3**. After separation by column chromatography, **2** was esterified with acetyl chloride in benzene containing some pyridine to give **4**, the corresponding ketoacetate; treatment of **4** with alcoholic potassium hydroxide, under reflux, regenerates **2**. Catalytic reduction of **1** also yields a mixture of ketoalcohols, **2** and **3**, but **3** predominates. In the manner first described, **3** gives the corresponding ketoacetate **5**; upon refluxing **3** in acetic acid or acetic acid/acetic anhydride, however, ketoacetate **4** is formed exclusively. Treatment of either **2** or **3** with thionyl chloride in benzene leads to the formation of the same chloroketone, **6**; similarly, reaction with phosphorus tribromide in benzene yields one bromoketone, **7**.

A mixture of diols is obtained by borohydride reduction of **2** from which the major component, **8**, is readily separable by t.l.c. Both **8** and **9** can be esterified to the corresponding acetates, **10** and **11**, with retention of configuration at C-2 and -6. Borohydride reduction of **4** yields the hydroxyacetate, **12**, whose structure was confirmed by acetylation to **10**. In contrast to the behavior of **2**, borohydride reduction of **3** yields a single diol, **9**, identical to the minor component formed from **2**. Similarly, reduction of **5** with excess sodium borohydride gave a single hydroxyacetate, **13**, which may be acetylated to give **11**.

In an attempt to obtain a monofunctional derivative of this tricyclo[5.1.0.0^{3,5}]octane system, reductions of the bromoketone, **7**, were investigated. Sodium in *t*-butyl alcohol causes ring opening to form 1,3,5,7-tetramethylbicyclo-

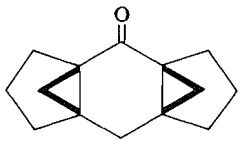
[5.1.0]oct-5-en-2-ol, **14**, whose structure and stereochemistry may be ascertained from its proton spectrum and that of the product obtained by reaction in *t*-butyl alcohol-*d*, as discussed below. Reaction of **7** with excess sodium borohydride in aqueous *t*-butyl alcohol, however, yields, as the major product, the alcohol, **15**, which may be oxidized with manganese dioxide to the corresponding ketone, **16**. It is interesting that reduction of **16** with lithium aluminum hydride yields a single alcohol, **15**. In contrast, Winstein and coworkers (4) found that reduction of the closely related ketone, **17**, gives both epimeric alcohols in a 1:1 ratio.



17

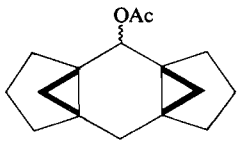
Proton Spectra

The proton spectra of the series **1–13** are similar. Each exhibits an AB pattern for the cyclopropyl methylene protons, two singlets for the two pairs of methyl groups on quaternary carbon (except the symmetrical cases) and signals for the methine protons at C-6 (and C-2). In these systems, δ_{AB} is relatively large, in the range 0.95–1.21 p.p.m., with J_{AB} 5.52–6.10 Hz. The methine signals for the series **2**, **4**, **6**, **7**, and **10**, appear as triplets with $J \sim 1.0$ Hz indicating long-range coupling with the cyclopropyl methylene protons. Accordingly one-half of the AB pattern, the B portion at higher field, exhibits these small splittings which may be eliminated by spin decoupling. In some cases a smaller long-range coupling of the A portion is also apparent, J 0.1–0.2 Hz. Detailed n.m.r. studies were not carried out on **12** and **13**, while the relative insolubilities of **8** and **9** in chloroform, the solvent used for all other analyses, precluded extensive n.m.r. examination. The proton spectral data for the tricyclic derivatives are collected in Table 1.

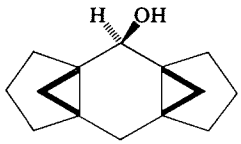
Discussion

The exclusive formation of **4** by acetolysis of **3** bears direct analogy with the findings of Winstein and coworkers (3) for the closely related system, **18**. Solvolysis of either of the epimeric acetates, **18**, gave the same mixture of epimeric alcohols,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



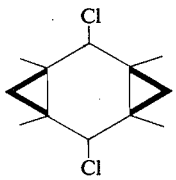
18



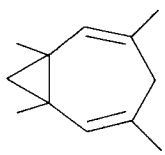
19

one of which constitutes more than 99% of the mixture and was assigned structure **19**, with the hydroxyl group *cis* to the cyclopropyl rings. In fact **18** is one of the most reactive secondary ester systems yet reported indicating the formation of a remarkably stable carbonium ion, a biscyclopropylcarbinyl system. In methanolic potassium hydroxide, only partial saponification occurs along with the formation of a substantial amount of solvolysis product, the methyl ether corresponding to **19** (4). Undoubtedly a similar carbonium ion, or mixture of ions, is generated in the present system. The formation of a single haloketone from either epimeric alcohol, **2** or **3**, is additional evidence of the intermediacy of this species.

The remarkable reactivity of this system suggested possible routes to monofunctional derivatives. A variation of the carbonium-ion trapping method (5) was successful whereby solvolysis of the bromoketone, **7**, in aqueous *t*-butyl alcohol containing a large excess of sodium borohydride leads to the monoalcohol, **15**. To minimize alcoholysis, the bulky *t*-butyl alcohol was chosen enabling the intermediate to be efficiently trapped by borohydride ion. Simple reduction of **7** with sodium in *t*-butyl alcohol, however, leads to **14** apparently following a reaction course analogous to the 1,4-homoelimination found by Winstein (6) for the dichloro derivative, **20**, which, with lithium/*t*-butyl alcohol in tetrahydrofuran, gives 1,3,5,7-tetramethylbicyclo[5.1.0]octa-2,5-diene, **21**.



20



21

The structure and probable conformation of **14** can be assigned from its proton spectrum which contains two singlets δ 1.03, 1.08 for methyl groups on quaternary C-1 and -7 and two doublets, δ 1.01 (J 7 Hz), 1.71 (J 1 Hz), also assignable to methyl groups, on saturated carbon (Me—C_3—H) and on the olefin carbon (C-5), respectively. The small coupling for the latter is indicative of a trisubstituted double bond and, as confirmation, a single olefinic proton (C-6), δ 5.32, was shown to be coupled to the 1.71 p.p.m. methyl signal by spin decoupling. An AB pattern typical of the cyclopropyl methylene protons is clearly apparent, δ_A 0.44, δ_B 0.26, J_{AB} 4.5 Hz, as is the hydroxyl signal, confirmed by deuterium exchange. In addition, a doublet centered at δ 2.65 with J = 10 Hz may be assigned to a carbinyl proton, H—C_2—O. Complex patterns in the region 2.4–2.7 and 1.4–1.9 p.p.m. were shown to arise from one and three additional protons respectively. Synthesis of **14** using *t*-butyl alcohol-*d* gives a product whose spectrum confirms the assignments of the carbinyl proton and shows that a second position is deuterated since the higher field multiplet decreases in intensity. These results are in accord with a two-step process whereby the initial product is the unsaturated enol, **22**, which upon ketonization (with incorporation of a deuterium atom) is reduced to the unsaturated alcohol, 1,3,5,7-tetramethylbicyclo[5.1.0]oct-5-en-2-ol (**14***a*) with a total incorporation of two deuterium atoms. The protons at C-2 and -3 appear to be *trans*-diaxial, or nearly so, because of the 10 Hz vicinal coupling found for the carbinyl proton. In addition, its relatively high shielding, δ 2.65, compared to that, for example, in the ketoalcohols, **2** and **3**, δ 4.01 and 4.13, respectively, suggests that this proton is lying over the olefinic bond. The well-known long-range shielding effect of the olefinic bond tends to shield nuclei in this orientation (7). Inspection of molecular models indicates a likely conformation may be represented as **14***b*, although **14***c* would appear to have smaller destabilizing nonbonded interactions. It would also retain the diaxial disposition of the C-2 and -3 protons, but there would be no explanation for the pronounced upfield shift of the carbinyl proton. The assignment of the relative orientation of the hydroxyl and cyclopropyl groups in **14***a* follows from the results for the other derivatives but this stereochemistry is not established. Alternatively the unsaturated bicyclic alcohol may have structure **14***d* for which there are also two conformations corresponding to **14***b* and *c*;

14*d*

the boat-like form similarly places the carbinyl proton over the double bond while retaining its *trans*-diaxial disposition relative to the C-3 proton. The much smaller shift difference between the cyclopropyl protons, δ_{AB} 0.18, compared to that in the tricyclic systems suggests that the deshielding influence of closely neighboring protons has been eliminated so that one of these protons is not sterically crowded.

The use of n.O.e. measurements to determine the relative orientations of protons in a wide variety of molecules is becoming increasingly popular (2, 8–10). It has been amply demonstrated that closely-neighboring protons provide a major mechanism for spin-lattice relaxation of each proton such that saturation of one of the neighbors causes an increase in the integrated intensity of the other's absorption. Thus the spatial relationship of various nonequivalent protons in a given molecule may be determined. The present system seems ideally suited for n.O.e. measurements since the methine proton at C-6 (-2) which is *trans* to the cyclopropyl rings must lie close to the vicinal methyl groups with the *cis*-methine proton further removed. Consequently, differential n.O.e. results may be expected for these protons in **2**–**16** such that the orientation of the oxygen function may be unequivocally established. Similarly, a distinction between the cyclopropyl methylene protons should be possible since the proton *cis* to the methyl groups should be affected more than its geminal partner. It has been shown (9), however, that the n.O.e. for a methylene proton caused by saturation of vicinal or further separated protons is small because the major relaxation occurs by interaction with its geminal neighbor. In any event the enhancement is sufficient to determine unequivocally the relative orientations. For the present series, the n.O.e. results are listed in Table 2.

From these results it is apparent that the n.O.e. for the carbinyl methine protons in the epimeric alcohols, **2** and **3**, and acetates, **4** and **5**, differ appreciably. The much larger values for **2** and **4** confirm the *cis* orientation of the oxygen functions with respect to the cyclopropyl rings. The even larger enhancements in the chloro- and bromoketones, **6** and **7**, are strong evidence for the assigned stereochemistry although the epimers are not available for direct comparisons. Similarly the high field B proton of the cyclopropyl methylene group is appreciably affected by saturation of the methyl protons. The one exception, **4**, is

puzzling but an explanation is not evident to us. It must be noted, however, that the high field portion of the AB pattern exhibits the larger long-range coupling with the methine proton strongly indicating that this proton is indeed *cis* to the methyl groups (see below). The fact that significant enhancements are found for the methine protons *trans* to the methyl groups in **3**, **5**, and **16** clearly shows that appreciable relaxation occurs via the methyl protons, but the much larger n.O.e. in each epimeric case (**2**, **4**, and **16**) confirms the assignments. In the extreme case, **11**, the n.O.e. is the same for both the *cis* and *trans* methine protons indicating that the central ring must be nearly planar. It seems reasonable that the geometry of the six-membered ring depends on the nature of the 2- and 6-substituents and the variations in the n.O.e. results may be taken as evidence for this idea. Unfortunately it is not possible to derive even semi-quantitative estimates of the ring geometry from the available data. It is interesting that the geminal proton enhancements, *i.e.* $H_A\{H_B\}$ etc., are somewhat smaller than those found for a variety of methylene groups in other systems (9); the values for the C-6 methylene protons in **16** were found to be 19 and 24% for the upfield and downfield protons, respectively. These results, with those in Table 2, indicate that other pathways also make substantial contributions to the overall relaxation for these protons.

The long-range coupling constants of *ca.* 1 Hz (J_{BX}) exhibited by the *trans* C-6 proton with the upfield cyclopropyl proton constitute confirmatory evidence for the assignments in **2**, **4**, **6**, **7**, **10**, **14**, and **15**. These are four-bond couplings through a saturated network for which it is known that the maximum interaction occurs for a "W" configuration (11, 12) which is closely approached for the *trans* methine proton and the cyclopropyl proton *cis* to the methyls. It is expected that the long-range interaction between the remaining cyclopropyl methylene proton and the *trans* C-6 proton (J_{AX}) will be much smaller; the results in Table 1 (J_{AX}) are in complete agreement with this expectation. The J_{BX} values for **3** and **5**, on the other hand, are very small, $\leqslant 0.1$ Hz, indicating that the relative orientation of the cyclopropyl and methine protons does not approach the "W" configuration; analogous results are well documented (11–14). It is interesting that the long-range couplings in **11**, having both *cis* and *trans* acetoxyl groups, are almost equal but small, 0.2 Hz. These data indicate that the central six-membered ring has a geometry appreciably different from that in the other disubstituted tricyclic systems. It may be suggested that this ring is flatter in **11** since the *cis*-diacetate exhibits a long-range coupling of 0.7 Hz, significantly smaller than that in **2**, **4**, **6**, or **7**, and one would expect appreciable steric interaction between the *cis* acetoxyl groups. In addition, the n.O.e. results for **11** show no difference between the *cis* and *trans* methine protons (Table 2). The larger couplings in the keto derivatives indicate that the carbonyl group tends to hold the central ring in a geometry more favorable for long-range interactions through the four σ-bonds. The smaller values for monoalcohol **15** may arise because of somewhat greater flexibility of the six-membered ring.

Although the geminal coupling constants, J_{AB}, for the cyclopropyl methylene groups vary, 5.1–6.1 Hz, no correlation with a specific structural feature is evident; the values are in the usual range for three-membered ring compounds (15). The J_{gem} values for the methylene groups in the monofunctional derivatives, **15** and **16**, are 14.5 and 14.6 Hz, respectively, indicating that no major changes in ring geometry or electron density occur in these H—C_6—H bonds with a change in hybridization at C-2 (16).

Although the chemical shift data, in themselves, do not provide unequivocal evidence on the basis of which stereochemical assignments can be deduced, some interesting trends are apparent.

One of the cyclopropyl methylene protons in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

the ketone derivatives absorbs at significantly lower field than those of the saturated compounds. This is the proton *trans* to the methyls as shown by the foregoing results. The nearly orthogonal relationship between the planes of the carbonyl group and the cyclopropane ring has been postulated to result in orbital overlap between these two groups (17–19). Ground-state electron withdrawal by this mechanism may account for the downfield shifts as well as the low carbonyl stretching frequencies observed (**1**, $\nu_{CO}(CHCl_3)$ 1667 cm^{-1}; **15**, 1641 cm^{-1}; cyclohexane-1,4-dione, 1727 cm^{-1} (20); cyclohexanone, 1710 cm^{-1} (21)). This interaction is consistent with the observation of the enormous accelerating effect of the cyclopropyl groups in the hydrolysis of **18** and the corresponding *p*-nitrobenzoates (3). One would expect, however, that an electronic effect of this nature would affect both methylene protons nearly equally, but only one is appreciably shifted to lower field; this downfield shift of one of the cyclopropyl protons, however, is explicable in terms of a dispersion effect. In this tricyclic skeleton the cyclopropyl protons *trans* to the methyl groups are closely-lying neighbors and it is known that the close approach of neighboring protons leads to a deshielding of each (22). It has been noted above that δ_{AB} is very much smaller, 0.18 p.p.m., in the ring-opened bicyclic derivative, **14**, which is consistent with the above since the bicyclic system is not constrained to a form in which another proton is in close proximity to one of the cyclopropyl protons. The possible contribution of the carbonyl group, owing to its anisotropy, to the differential shift of one of the cyclopropyl protons cannot be neglected but it is difficult to account for the observed trend in terms of the usual model of its long-range shielding effect (7); the situation is not improved by the use of a recent modification (23) of this model. In each case, the models predict either a shielding effect at the "inner" cyclopropyl protons or a weak deshielding effect, depending on the geometry of the central ring, which is either planar or a flattened boat to judge from the n.O.e. data.

The shifts of the *trans* proton at C-6 in the keto derivatives are unexceptional although these protons absorb at higher field than the *cis* protons in the corresponding isomers (*cf.* **2** *vs.* **3**, **4** *vs.* **5**, **16**). The downfield shift probably arises from steric interaction of the *cis* C-6 protons with the two neighboring cyclopropyl protons (22) since such an interaction would increase δ_{AB} for the cyclopropyl methylene group. In the saturated systems, the *cis* methine proton appears at higher field than the corresponding *trans* hydrogen. It seems likely that in the saturated compounds there is an increase in ring flexibility which allows the cyclopropane rings to move further apart than in the ketones. If this is the case, models indicate that the *trans* C-6 proton is much closer to the C-5 and -7 methyl groups than the *cis* proton is to the cyclopropyl hydrogens; thus, steric interaction between the *trans* proton and the methyl hydrogens would account for the observed downfield shift. It should be noted that the compounds in which this effect can be observed possess both 2- and 6-substituents. In the monoalcohol, **15**, the trend is reversed indicating that nonbonded interaction between the 2- and 6-substituents affects the geometry of the central ring appreciably.

Experimental

Proton Spectra

The chemical shifts were determined on a Varian A-60 spectrometer using dilute solutions in chloroform and are accurate to ±0.05 p.p.m. The coupling constants and n.O.e. were obtained on degassed chloroform solutions containing small amounts of TMS as a standard and some benzene to provide a "locking" signal for the Varian HA-60IL spectrometer. The coupling constants reported are the average of at least three scans at a 50 Hz sweep width and were calibrated using a Hewlett-Packard 5245L counter; these are judged to have a precision of ±0.05 Hz. All integrated intensities were the average of at least ten determinations obtained by irradiating, using low power, the appropriate resonant frequencies and blank regions of the spectrum. The enhancements reported are accurate to ±3%.

Materials

1,3,5,7-Tetramethyltricyclo[5.1.0.0^{3,5}]octan-2,6-dione (1)

The dipyrazoline (1.5 g), formed from reaction of diazomethane and duroquinone in ether (1), was dissolved in glacial acetic acid (50 ml) and treated with 70% perchloric acid (30 drops). After effervescence had ceased, the reaction mixture was poured into water and **1** was isolated by extraction with chloroform. The crude crystalline product (1.1 g) was recrystallized from petroleum ether (60–80°) to give 0.46 g (40%) of **1**, m.p. 143.5–145° (lit. (1): m.p. 144–145°).

Ketoalcohol 3

Diketone **1** (1.92 g) dissolved in absolute ethanol (75 ml) containing platinum oxide (0.29 g) was hydrogenated, using a Parr apparatus, at 44 p.s.i. for 29 h. Chromatography on alumina with benzene:ether (93:7) as eluant gave a mixture of ketoalcohols **2** and **3** but further elution with ether gave a solid (0.83 g) which was recrystallized from benzene to give ketoalcohol **3** (0.63 g, 33%) m.p. 166–167° (lit. (24): 167–168°).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Ketoalcohol **2**

To diketone **1** (1.14 g) dissolved in isopropyl alcohol (50 ml) was added 50% aqueous isopropyl alcohol (10 ml) containing sodium borohydride (0.07 g) and the mixture stirred for 6.5 h. After evaporation of the isopropyl alcohol and addition of water, the product was isolated by extraction with chloroform followed by chromatography on alumina. After the unreacted starting material (0.1 g) was eluted with benzene:hexane (4:1), elution with benzene:ether (92:8) gave a solid (0.73 g) which was recrystallized from benzene to yield the ketoalcohol **2** (0.63 g, 54%) m.p. 159–160° (lit. (24): 160–161°). With ether as eluant a mixture of ketoalcohols **2** and **3** was recovered from the alumina column.

cis-Diol **8**

Reduction of ketoalcohol **2** with excess sodium borohydride gave a mixture of diols **8** and **9** (80:20). Chromatography, on alumina, followed by recrystallization from benzene afforded the major product, **8**, m.p. 185.5–186.5°.

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27. Found: C, 73.41; H, 10.25.

trans-Diol **9**

Similarly sodium borohydride reduction of ketoalcohol **3** gave *trans*-diol **9** exclusively, m.p. 168–173°.

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27. Found: C, 73.26; H, 10.28.

Hydroxyacetate **12**

Reduction of ketoacetate **4** with excess sodium borohydride gave the hydroxyacetate **12** as the major product, m.p. 140.5–141.5°.

Anal. Calcd. for $C_{14}H_{22}O_3$: C, 70.55; H, 9.31. Found: C, 70.19; H, 9.54.

Hydroxyacetate **13**

In an analogous manner, sodium borohydride reduction of **5** yielded hydroxyacetate **13** as the major component, m.p. 96.5–97.5°.

Anal. Calcd. for $C_{14}H_{22}O_3$: C, 70.55; H, 9.31. Found: C, 70.48; H, 9.22.

Monoalcohol **15**

To bromoketone **7** (0.25 g) dissolved in *t*-butyl alcohol (10 ml) was added, with stirring, 10 ml of 50% aqueous *t*-butyl alcohol containing sodium borohydride (0.6 g). The mixture was stirred at room temperature for 1 h and then poured into water. After extraction with chloroform and concentration of the extracts, a colorless material (0.13 g) was extracted with cold hexane which crystallized from *n*-pentane to give monoalcohol **15**, m.p. 74–75°.

Anal. Calcd. for $C_{12}H_{20}O$: C, 79.94; H, 11.18. Found: C, 79.87; H, 11.39.

The residue of the chloroform extract was identified as *cis*-diol **8**.

Monoketone **16**

Manganese dioxide (1.5 g) was added to an ethereal solution of **15** (0.39 g in 20 ml ether) and the mixture stirred for 39 h at room temperature. After removal of the solids by filtration and evaporation of the ether, **16** (0.16 g), m.p. 85–86°, was obtained in 43% yield by recrystallization from hexane.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.85; H, 10.18. Found: C, 80.93; H, 10.01.

Acetylation of **2**, **3**, **8**, **9**, **12** *and* **13**

Acetyl chloride (1.5 ml) was added dropwise to a cold (~0°) solution of **2** (0.29 g) in benzene (15 ml) and pyridine (3 ml). After the addition was complete the mixture was warmed to room temperature and allowed to stand for 1 h. The product was isolated by extraction with chloroform followed by chromatography on alumina with benzene:hexane (4:1) as eluant. Recrystallization from 60–80° petroleum ether gave ketoacetate **4** (0.32 g) m.p. 123–124° in 88% yield. (lit. (24): 124.5–125.5°).

The above procedure with ketoalcohol **3** gave **5** m.p. 135.5–137° (lit. (24): 135.5–136°).

The diacetates, **10** and **11**, were obtained in two ways, *viz.* from either the corresponding diol or hydroxyacetate. Acetylation of *cis*-diol **8** gave **10**, m.p. 137.5–138.5°.

Anal. Calcd. for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63. Found: C, 68.48; H, 8.59.

Similarly the *trans*-diacetate **11**, m.p. 49.5–50.5°, was obtained from *trans*-diol **9**.

Anal. Calcd. for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63. Found: C, 68.93; H, 8.60.

Chloroketone **6**

To a cold (~5°) solution of **2** (0.23 g) in benzene (10 ml) was added a solution of thionyl chloride (5 ml) in benzene (10 ml) after which the solution was warmed to room temperature and allowed to stand for 2 h. Concentration of the reaction mixture gave a residue which was recrystallized from petroleum ether (60–80°) to yield chloroketone **6** (0.18 g, 73%) m.p. 139.5–141°.

Anal. Calcd. for $C_{12}H_{17}OCl$: C, 67.78; H, 8.06; Cl, 16.67. Found: C, 67.27; H, 7.75; Cl, 16.68.

Chlorination of ketoalcohol **3**, in a similar manner gave the same chloroketone.

Bromoketone **7**

Phosphorous tribromide (3 ml) was added to a cold solution of **2** (0.26 g) in benzene (25 ml) and the mixture allowed to stand overnight at room temperature. Chloroform extraction of the reaction mixture yielded a product which was recrystallized from hexane:benzene (100:1) to give bromoketone **7** (0.30 g, 88%) m.p. 151.5–153°.

Anal. Calcd. for $C_{12}H_{17}OBr$: C, 56.06; H, 6.67; Br, 31.08. Found: C, 56.43; H, 6.24; Br, 31.35.

In this way **7** was also prepared from **3**.

Sodium/t-Butyl Alcohol Reduction of Bromoketone, **7**

Small pieces of sodium metal (0.20 g) were added to a solution of **7** (0.17 g) in *t*-butyl alcohol and the mixture stirred under nitrogen at room temperature for 1.5 h. Fresh sodium metal (0.10 g) was added and stirring under nitrogen continued for a further 2.5 h. Work-up in the usual manner, *i.e.* chloroform extraction and chromatography on alumina, yielded, with 50:50 benzene:hexane as eluant, monoalcohol, **14**, in 66% yield after recrystallization from hexane, m.p. 120.5–121.5°.

Anal. Calcd. for $C_{12}H_{20}O$: C, 79.94; H, 11.18. Found: C, 79.40; H, 11.02.

This procedure with *t*-butyl alcohol-*d* afforded **14***a* partially deuterated at C-1 and -2.

Mechanism of Sulfonation of 4-Hydroxyazobenzene

E. BUNCEL AND W. M. J. STRACHAN
Department of Chemistry, Queen's University, Kingston, Ontario

AND

H. CERFONTAIN
Laboratory for Organic Chemistry, Nwe Achtergracht 129, University of Amsterdam, The Netherlands

Received April 8, 1970

The mechanism of sulfonation of 4-hydroxyazobenzene and of 4-hydroxyazobenzene-4′-sulfonic acid in concentrated sulfuric acid media is examined through rate correlations and comparison is drawn with sulfonation of alkyl- and halogenobenzenes by means of log k *vs.* log $a_{H_2S_2O_7}$ plots. It is concluded that several mechanisms are operative in the hydroxyazobenzene system and that the curvature of the plot is the result of a change in rate-determining step from σ-complex formation to proton abstraction.

Canadian Journal of Chemistry, 49, 152 (1971)

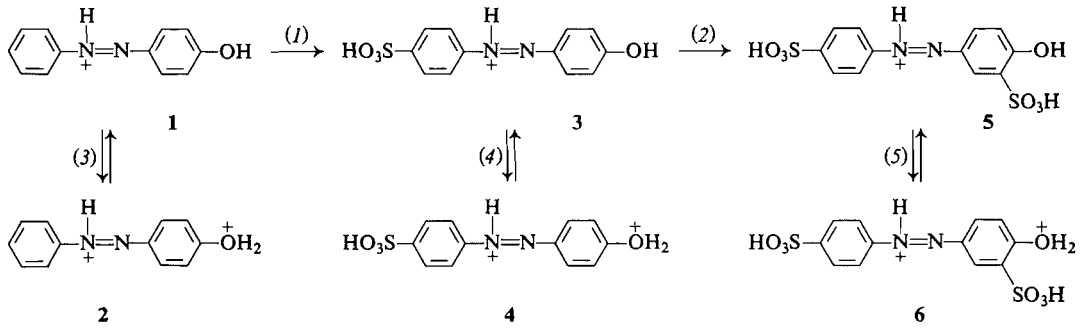
As part of a study concerned with elucidation of the Wallach rearrangement processes (1), the kinetics of sulfonation of 4-hydroxyazobenzene were determined for the 90–100% H_2SO_4 region (2). In Scheme 1 are shown the various processes which were observed in the spectral study with 4-hydroxyazobenzene (2). In 90% H_2SO_4 the substrate is present completely in its monoprotonated form **1** ($pK_a^1 - 1.0$, corresponding to 99.9% protonation in 55% H_2SO_4). There are two consecutive sulfonation processes (Scheme 1, reactions *1* and *2*) yielding the mono-sulfonic acid **3** and disulfonic acid **5**,[1] and three concurrent equilibria (reactions *3*, *4*, and *5*) involving the diprotonated species **2**, **4**, and **6**. In 100.0% H_2SO_4 reaction 1 has a half-life of 5 min at 25°, while reaction 2 has a half-life of 28 h (2). Now the Wallach rearrangement of azoxybenzene to 4-hydroxyazobenzene in 99.99% H_2SO_4 occurs with a half-life of 20 s at 25°, with a somewhat faster rate expected in 100.0% H_2SO_4 (3). Hence spectral examination of azoxybenzene in 100.0% H_2SO_4 some minutes after mixing reflects merely the processes of Scheme 1 undergone by the already formed 4-hydroxyazobenzene (4).

The mechanism of the sulfonation reactions was commented on briefly in a previous paper (2). A reaction scheme was presented showing electrophilic attack by SO_3 on mono-protonated 4-hydroxyazobenzene (**1**) as the initial step. The non-reactivity toward sulfonation of diprotonated substrate **2** was further indicated by the extended linearity of the rate–H_0 plot when account for diprotonation was taken by plotting log $k_{obs} - \log c_{SH^+}/(c_{SH^+} + c_{SH_2^{++}})$ *vs.* H_0.

In this paper we treat in greater depth the mechanism of the sulfonation processes. An analysis is made of rate correlations on the basis of attack by various possible electrophilic species, the formation of two σ-complex intermediates, and subsequent product-forming steps in which various bases may abstract a proton from aryl carbon. Results from previous work (2) have been re-calculated according to a revised H_0 scale (5).

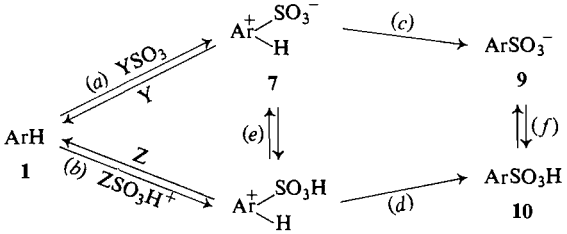
The generalized kinetic scheme (*cf.* ref. 6) on the basis of which the sulfonation of 4-hydroxyazobenzene may be considered is shown in Scheme 2. The reactive substrate **1** is denoted by ArH. There are two distinct σ-complex intermediates **7** and **8** (transfer of SO_3 from the electrophile YSO_3 to **1** yields **7** whereas transfer of SO_3H^+ from ZSO_3H^+ yields **8**), which lead to product species **9** and **10** by proton abstraction processes. Intermediates **7** and **8** are joined through a rapidly attained equilibrium process *e* by means of an acid/base pair such as H_2SO_4/HSO_4^- or $H_3SO_4^+/H_2SO_4$, and the product species **9** and **10** are similarly interconnected in process *f*. The rate-determining steps may be either attack by electrophile on **1** (reactions *a* and *b*), or proton abstraction from the σ-complexes (reactions *c* and *d*), or a combination of these. Electrophilic species to be considered in the sulfonation processes are SO_3, H_2SO_4,

[1]The spectral identification of the disulfonic acid product did not enable a complete structural proof to be deduced. Assignment of orientation in reaction *2* is hence tentative (2).



SCHEME 1

$H_2S_2O_7$, HSO_3^+, $H_3SO_4^+$, and sulfuric acid solvates of these (5–12). Basic species in this system are then HSO_4^-, H_2SO_4, and $HS_2O_7^-$ (5).



SCHEME 2

Rate correlations for sulfonation were made considering as sulfonation mechanism eq. 1 in which X is the electrophilic species and B the

$$[1]\quad ArH + X \underset{-1}{\overset{1}{\rightleftharpoons}} Ar\begin{matrix}X\\H\end{matrix} \xrightarrow{B,\ 2} ArX + BH^+$$

proton-abstracting base. Assuming that the σ-complex intermediate (ArXH) is present in steady-state concentration, one obtains an expression relating the variables of eq. 1 to the observed pseudo first-order rate constant for reaction (k_{obs}). In eq. 2, k_{SH^+} signifies reaction via the monoprotonated substrate, *i.e.* $k_{obs} = k_{SH^+} \cdot c_{SH^+}/(c_{SH^+} + c_{SH_2^{++}})$; the *a* terms signify activities, and the *f* terms activity coefficients.

$$[2]\quad k_{SH^+} = \frac{k_1 k_2 a_X a_B}{k_{-1} + k_2 a_B} \cdot \frac{f_{ArH}}{f^{\ddagger}}$$

Equation 2 may be simplified under two limiting conditions. In the first case, step 1 in eq. 1 is rate-determining, *i.e.* $k_2 a_B \gg k_{-1}$, and eq. 3 results. In the second case, step 2 in eq. 1 is rate determining and eq. 4 results.

$$[3]\quad k_{SH^+} = \frac{k_1 a_X f_{ArH}}{f_1^{\ddagger}}$$

$$[4]\quad k_{SH^+} = \frac{k_1 k_2 a_X a_B f_{ArH}}{k_{-1} f_2^{\ddagger}}$$

The activities of the various entities (X and B) in solution can be related to the known values of $a_{H_2SO_4}$ (13), a_{H_2O} (13), and $a_{HSO_4^-}$ (14), through equilibria applicable to the sulfuric acid – water system. These equilibria, and the various assumptions necessary in the derivations, have been previously described (5, 6, 15, 16). One thus obtains relationships shown in eqs. 5–8.[2]

$$[5]\quad a_{SO_3} = K_1 \frac{a_{H_2SO_4}}{a_{H_2O}}$$

$$[6]\quad a_{H_2S_2O_7} = K_2 \frac{a_{H_2SO_4}^2}{a_{H_2O}}$$

$$[7]\quad a_{HSO_3^+} = K_3 \frac{a_{H_2SO_4}^2}{a_{H_2O} a_{HSO_4^-}} = K_3' \left(\frac{a_{H_2SO_4}}{a_{H_2O}}\right)^{3/2}$$

$$[8]\quad a_{H_3SO_4^+} = K_4 \frac{a_{H_2SO_4}^2}{a_{HSO_4^-}} = K_4' \left(\frac{a_{H_2SO_4}^3}{a_{H_2O}}\right)^{1/2}$$

The kinetic data for sulfonation may be tested against rate expressions which can be derived for various sequences and X/B combinations in Scheme 2, on the basis of one of the limiting conditions, eqs. 3 and 4. We have considered a number of such "intuitively reasonable" reaction paths and X/B combinations and derived the appropriate rate expressions, in each case plot-

[2]Assuming that $a_{HSO_4^-}/a_{H_3O^+} \simeq 1$ (*cf.* refs. 14, 16) in > 80% H_2SO_4 it follows that $a_{HSO_4^-} = K_5 a_{H_2O}^{\ddagger} a_{H_2SO_4}^{\ddagger}$.

TABLE 1. Consideration of reaction pathways and rate correlations for sulfonation of 4-hydroxyazobenzene and 4-hydroxyazobenzene-4′-sulfonic acid according to Scheme 2

Function plotted against $\log k_{SH^+}$	Reaction pathway tested in Scheme 2		
	X*	B†	Predicted slope‡
A $\log a_{H_2SO_4}$	$H_3SO_4^+$ (fast)	HSO_4^-	2.0
B $\log a_{H_2SO_4}/a_{H_2O}$	SO_3 (slow)		1.0
	HSO_3^+ (slow)		1.5
C $\log a_{H_2SO_4}^2/a_{H_2O}$	$H_2S_2O_7$ (slow)		1.0
	SO_3 (fast)	H_2SO_4	1.0
	HSO_3^+ (fast)	HSO_4^-	1.0
D $\log a_{H_2SO_4}^3/a_{H_2O}$	$H_3SO_4^+$ (slow)		0.5
	SO_3 (fast)	HSO_4^-	0.5
	$H_2S_2O_7$ (fast)	H_2SO_4	1.0

*Specifies the X entity in paths *a* or *b* of Scheme 2 and whether reaction by X is the slow (eq. 3) or the fast (eq. 4) step. When X is SO_3 or HSO_3^+ the paths are restricted to (*a*) and (*b*) respectively but with the other electrophiles either reaction path is possible in theory.
†The basic entity is specified only when proton abstraction, processes *c* or *d*, is rate-limiting (eq. 4).
‡See eqs. 5–8 and footnote 2.

ting a function against $\log k_{SH^+}$.[3] Such plots assume the constancy of various equilibrium K's and of activity coefficient ratios of $f_{ArH}/f^{\neq}$ over the acid range tested. The functions plotted and the reaction pathways so tested are given in Table 1.

The actual plots corresponding to functions A–D of Table 1 are all curved, for both substrates (**1** and **3**); typical plots are shown in Fig. 1 and discussed further below. It can hence be concluded that no single kinetic expression fits the rate data exactly, which suggests that the sulfonation process does not follow a single mechanism throughout the acid range studied for either substrate, or that assumptions concerning constancy of activity coefficient ratios and equilibrium constants may be invalid. The plot which is most nearly linear is the $\log k_{SH^+}$ *vs.* H_0 plot for sulfonation reaction *1* of Scheme 1. However no mechanistic significance is attached to this finding (19, 20).

As an alternative to the analytical approach described above, one may gain insight into mechanisms by comparison with systems in which the reaction pathway has been established with some confidence. Extensive studies of aromatic sulfonation processes have recently been described (21–23). The mechanism proposed (14, 21–23) for the sulfonation of alkyl- and halogenobenzenes in sulfuric acid, which is applicable to the present system, is discussed according to Scheme 2 and Fig. 1. At low sulfuric acid concentrations the rate-limiting step is (*b*) with $H_3SO_4^+$ as the electrophile and the product is formed via steps *e* and *c* with HSO_4^- as the proton abstracting agent. At higher sulfuric acid concentration the rate-limiting step is again (*b*) but the electrophile becomes $H_2S_2O_7$ and the product is again mainly formed via steps *e* and *c*. At yet higher acid concentrations, which are still below 100% H_2SO_4, step *e* becomes in part rate-determining because of the sharp decrease in the ratio $a_{HSO_4^-}/a_{H_2SO_4}$ (22), being preceded by electrophilic attack by $H_2S_2O_7$, path *b*. At even higher acid concentrations the sulfonic acid product **10** will be formed by the sequence (*b*), X = $H_2S_2O_7$, and (*d*), B = H_2SO_4 rather than HSO_4^-, because of a further decrease in $a_{HSO_4^-}/a_{H_2SO_4}$; furthermore the rate of step *d* will increase relative to that of step $-b$ and this will lead to an increase in $d(\log k)/d(\log a_{H_2S_2O_7})$.

For 4-hydroxyazobenzene in the region of 94–99.7% H_2SO_4 the graph of $\log k_{SH^+}$ *vs.* $\log a_{H_2S_2O_7}$ (Fig. 1) is linear with a slope of 0.79 instead of the unit slope required according to path *b* with X = $H_2S_2O_7$ rate-limiting (*cf.* C in Table 1). This behavior is similar to that observed for benzene (12), bromobenzene (23), chlorobenzene (22), and *p*-nitrotoluene (8).[4] With 4-

[3]The $\log k_{SH^+}$ values of ref. 2 have been recalculated using the combined H_0 scales of Jorgenson and Hartter (17) and Gillespie and Robinson (5) to evaluate the extent of diprotonation. The pK_a^2 values (18) have been adjusted accordingly to −11.1 for **1** ⇄ **2** and −12.0 for **3** ⇄ **4**. The usual expression, $\log c_{SH_2^{++}}/c_{SH^+} = pK_a^2 - H_0$, was used to calculate the term $\log c_{SH^+}/(c_{SH^+} + c_{SH^{++}})$ which operates on $\log k_{obs}$.

[4]Account has been taken of the slight protonation of *p*-nitrotoluene (9% in 99% H_2SO_4). The reported pK_a value (9*a*) has been adjusted according to the new H_0 scale (5).

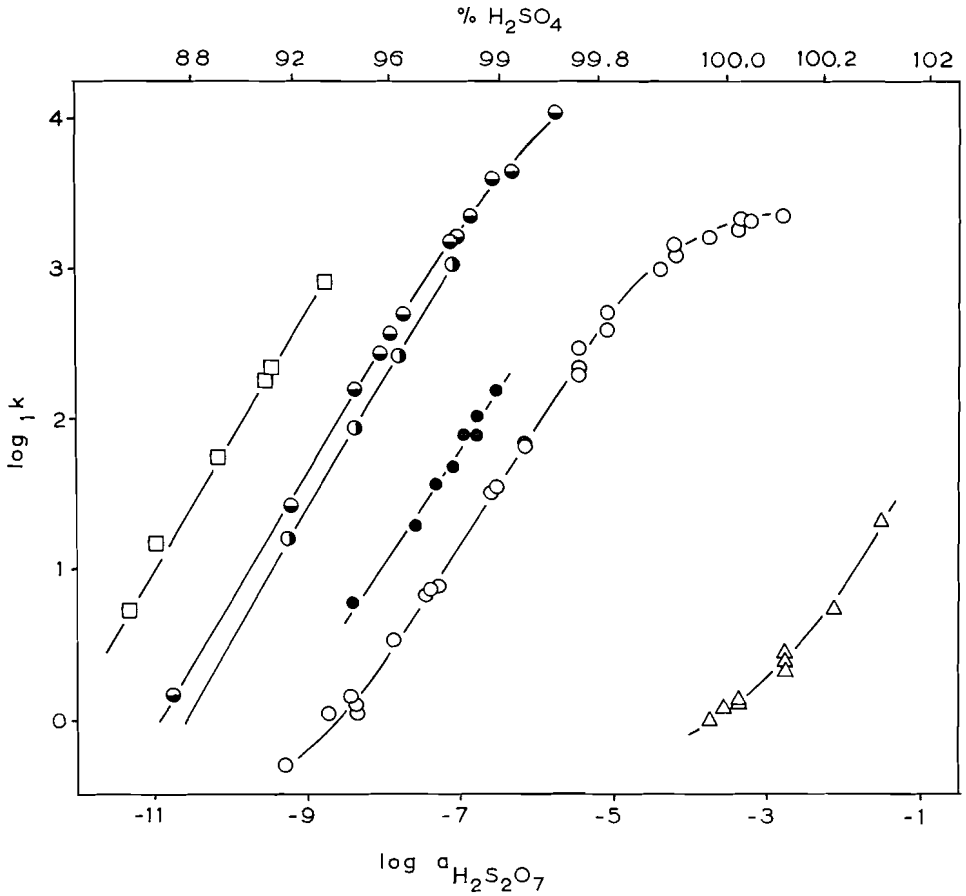

FIG. 1. Correlations of pseudo first-order rate constants (s^{-1}) for sulfonation at 25° with log $a_{H_2S_2O_7}$. (The $a_{H_2S_2O_7}$ data for 97–101% H_2SO_4 were taken from ref. 21; the variation in $a_{H_2S_2O_7}$ at lower acid concentrations was calculated by eq. 6).

Substrate	Ordinate	Slope	Reference
□ Benzene	log k + 5	0.86	12
◒ Chlorobenzene	log k_{para} + 5	0.88–0.5	22
◑ Bromobenzene	log k_{para} + 5	0.88	23
● *p*-Nitrotoluene (96.5°)	log k_{SH+} + 7	0.80	8
○ 4-Hydroxyazobenzene	log k_{SH+} + 5	0.79–0.15	2
△ 4-Hydroxyazobenzene-4′-sulfonic acid	log k_{SH+} + 5	0.40–0.87	2

hydroxyazobenzene and chlorobenzene, the slope d(log k)/d(log $a_{H_2S_2O_7}$) decreases at acid concentrations >99.8 and >98% H_2SO_4 respectively, indicating that step *e*, Scheme 2, with B = HSO_4^- becomes in part rate-determining at these acid concentrations. The decrease in slope below 94% H_2SO_4, if significant, may be explained in terms of additional formation of σ-complex **8** by step *b* with $H_3SO_4^+$ as the electrophile. The increase in slope observed for 4-hydroxyazobenzene-4′-sulfonic acid in the region of 100% H_2SO_4 is similar to that observed for *p*-difluorobenzene in the region of 99% H_2SO_4 (23). It may also be explained similarly, *i.e.*, in terms of a decrease in the rate of step $-b$ with B = HSO_4^-, relative to that of step *d* with B = H_2SO_4.

In summary, the principal process in the sulfonation of 4-hydroxyazobenzene is concluded to be rate-determining electrophilic attack by $H_2S_2O_7$ with formation of intermediate complex **8**. Below 94% H_2SO_4, electrophilic attack by

For personal use only.

$H_3SO_4^+$ may also be important. However, in ~100% H_2SO_4 and above, proton abstraction becomes in part rate-limiting.

Structure of the Acetone–Indanedione Adduct

STEPHEN J. KUHN
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

AND

IAN D. RAE
Department of Chemistry, Monash University, Clayton, Victoria, 3168, Australia

Received June 10, 1970

A compound formed by condensation of 2 mol of indanedione and 2 of acetone is shown to have structure **2**. This reinterpretation, largely based on p.m.r. and i.r. evidence, is supported by the structures assigned to an enol acetate and a dihydro derivative of **2**.

Canadian Journal of Chemistry, **49**, 157 (1971)

The product, $C_{24}H_{18}O_3$, of base-catalyzed condensation between acetone and indane-1,3-dione has recently been assigned structure **1** (1). We wish to offer a reinterpretation of the p.m.r. and i.r. spectroscopic data for this compound which requires its formulation as **2**. New structures are also assigned to derivatives of **2** which help to confirm our reinterpretation.

Degradation of the condensation product by hydroxylamine and subsequent hydrolysis of the intermediate dioximes yields **3** and indane-1,3-dione, see Scheme 1. The reaction sequences show that the degradation product would be the same whether the original adduct had structure **1** or **2**. A comparison of the n.m.r. spectra of **3** and the original adduct provides a vital clue to the structure of the adduct. In the transformation of **1** to **3** the resonance position of the aromatic protons should be most affected; however, they remain virtually undisturbed. The

protons whose resonance positions are most affected are the olefinic H-4 (shifted from 8.78 to 6.53 p.p.m.) and one of the H-2 pair (shifted from 4.06 to 2.4 p.p.m.) as would be expected in the transformation of **2** to **3**. This identifies C-3, and not C-9 (in structure **3**) as the point of attachment for the indanedionyl moiety.

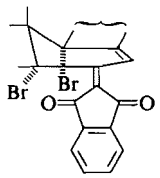
The geometry of the cyclohexene ring in **2** is such that the olefinic proton and one of the C-2 methylene protons are almost in the plane of the indanedione moiety and thus suffer pronounced deshielding. The other methylene proton is pseudo-axial and shows long-range coupling to the olefinic proton (2, 3). Substitution in the tetrahydrofluorene skeleton of **2** involves first the replacement of the 9*a*-proton, the new substituent (CH_3, Br) occupying this pseudo-axial position (1). Bromination also introduces a second substituent, replacing one of the methylene protons at C-2. The remaining aliphatic proton is allylic and adjacent to a bromine atom, but proximity to the carbonyl is also required to rationalize its extreme chemical shift (6.5 p.p.m.; the downfield shift of 2.44 p.p.m. on bromination is close to that predicted by Shoolery's rules (4)). Thus the second bromine must also occupy a pseudo-axial position (partial structure **4**) where the unfavorable steric interaction with the other bromine is apparently preferable to the dipole–dipole interaction which a pseudo-equatorial bromine would have with the nearby carbonyl (*cf.* the axial haloketone rule (5)). The long-range coupling to H-4 is now exhibited by the pseudo-equatorial C-2 proton but so little is known about the dependence of such couplings on geometry and electronegativity that the significance of such an observation in structural terms is quite low (2).

A comparison of the i.r. spectra of the original adduct and the degradation product **3** also provides some useful information about the structure of the original adduct. The i.r. spectrum of the original adduct has three strong bands in the carbonyl region at 1716, 1680, and 1679 cm^{-1}. The i.r. spectrum of the degradation product **3** has two bands in the carbonyl region at 1718 and 1655 cm^{-1}. The band in compound **3** at 1718 cm^{-1} is assigned to a tetrahydro fluorenone type of carbonyl (7, 8) and the band at 1655 cm^{-1} to the conjugated cyclohexene carbonyl group. Structure **1** for the original adduct has no fluorenone type of carbonyl group. The band at 1716 cm^{-1} could be due to one of the indanedionyl carbonyl groups; however, the band did not disappear on the removal of the indanedionyl group in the transformation of the original adduct to **3**. These results also indicate that **2** is the correct structure for the original adduct.

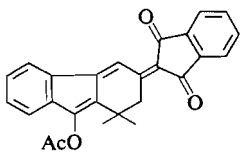
An enolacetate of the original adduct has been prepared by reaction with acetic anhydride in the presence of *p*-toluenesulfonic acid monohydrate. A singlet at 8.93 p.p.m. in its p.m.r. spectrum is assigned to the olefinic proton H-4 and its chemical shift indicates that the acetate formation did not take place on groups on C-3 forming either **6** or **6***a*.

In the structure **6** the indanedionyl moiety, free to rotate from the plane of the olefinic system, would no longer exert the powerful deshielding effect on proton C-4. The destruction of the carbonyl group on C-3 in the transformation of **1** to **6***a* would also change the shielding of H-4 considerably. Structure **5** is in complete agreement with the p.m.r. spectrum of the enolacetate; however structure **6***b* derived from structure **1** should also be discussed. A comparison of the i.r. spectra of the original adduct and its enolacetate again provides some useful information. The strong carbonyl band in the original adduct at 1716 cm^{-1} is completely missing from the i.r. spectrum of the enolacetate and a new band at 1779 cm^{-1} corresponding to a vinyl ester type of carbonyl appears. The indanedionyl carbonyls appear as a single strong band at 1680 cm^{-1} in the enolacetate. These results indicate that the enolacetate formation takes place on a carbonyl other than the indanedionyls, thus supporting structure **5** for the enolacetate and structure **2** for the original adduct. The *gem*-dimethyl and methylene protons of **5** give rise to a slightly broadened singlet in the p.m.r. spectrum at 40 °C (1.37 and 3.47 p.p.m. respectively), indicating a conformational averaging process in the six-membered ring.

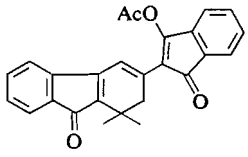
Reduction of compound **2** with sodium dithionite gives a mixture of at least two new compounds, but equilibration of the mixture with strong base produces largely the one product to which we assign structure **7** (R = H). The definitive resonances in the p.m.r. spectrum of this compound are those of the 9*a*-proton (2.88 p.p.m.) and the olefinic proton at C-4 (6.15 p.p.m.), the chemical shift of the latter indicating



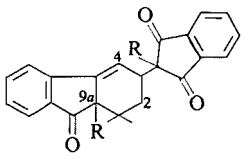
4



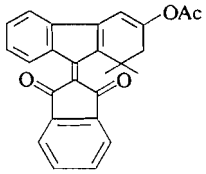
5



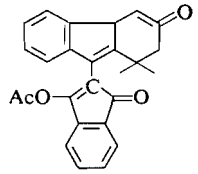
6



7



6a



6b

that the two portions of the molecule are no longer coplanar. Due to the near equality of $J_{3,4}$, $J_{4,9a}$, and $J_{3,9a}$ (each approximately 2 Hz) these two resonances are apparent triplets and mutual decoupling experiments serve to reduce each to a clean doublet. The C-3 proton gives rise to a complex multiplet centered at 3.25 p.p.m., superimposed on which is the signal of the proton of the indane-1,3-dione moiety. This latter and the 9*a*-proton triplet are removed on deuteration to give **7** (R = D) in which the C-4 proton gives rise to a doublet ($J_{3,4}$ approximately 2 Hz).

Experimental

The preparation of the acetone–indanedione condensation product and some of its derivatives has been described in an earlier paper (1).

Reduction of **2** *by Sodium Dithionite*

The amount of sodium dithionite prescribed by Geita and Vanags (6) for the reduction of **2** resulted in incomplete reduction. Using a large excess of reducing agent led to complete reduction of **2** in good yield.

A mixture of 5 g of **2** and 25 g of sodium dithionite in 400 cc of 50% aqueous ethyl alcohol was heated under reflux for 3 h. After cooling the reaction mixture was diluted with 2000 ml of cold water and the precipitate was filtered. The product was crystallized from ethyl alcohol, m.p. 157–161 °C. Yield 4.5 g.

Anal. Calcd. for $C_{24}H_{20}O_3$: C, 80.9; H, 5.6. Found: C, 81.0; H, 5.45.

The n.m.r. spectrum of the reduction product indicates that it is a mixture of **7** and its isomer. Equilibration, by dissolving 3 g of the reduction products in a solution of 10 g of potassium hydroxide in 50 ml of 50% methanol and heating the mixture at 40 °C for 30 min, followed by filtration and pouring of the filtrate into excess 10% aqueous acetic acid results in a product which consists of 90% of **7** and has m.p. 170–172 °C.

Anal. Calcd. for $C_{24}H_{20}O_3$: C, 80.9; H, 5.6. Found: C, 80.8; H, 5.65.

Preparation of the Enolacetate of **2**

A solution of 2 g of **2** and 1 g of *p*-toluenesulfonic acid monohydrate in 60 ml of acetic anhydride was distilled slowly through an empty column until most of the acetic anhydride had been removed (4 h). After cooling, 25 ml of water was added to the residue and it was extracted with ether. Evaporation of the ether gave 1.9 g of brick red product, the m.p. 258–259 °C.

Anal. Calcd. for $C_{26}H_{20}O_4$: C, 78.8; H, 5.02. Found: C, 78.75; H, 5.1.

Deuteration of **7**

To a solution of 5.5 g of $NaOCH_3$ in 30 ml of CH_3OD–D_2O (1:1 volume) was added 2 g of **7**. Upon shaking a homogeneous solution was obtained, which was poured into a solution of 15 g of CH_3COOD in 30 g of D_2O. The yellow precipitate was filtered, washed twice with 5 ml of D_2O and dried (m.p. 168–171 °C). The dry product weighed 1.8 g. The n.m.r. spectrum of the compound showed that proton 9*a* and the indanedionyl pro-

Magnetic Resonance Studies of Metal Olefin Complexes. II. Electron Spin Resonance Spectra of γ-Irradiated Silver Complexes with Cyclohexadienes and 1-Methyl Cyclopentene

D. R. GEE[1] AND J. K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ontario

Received August 31, 1970

Electron spin resonance studies of silver cycloalkenyl radicals by γ-irradiation of polycrystalline silver cycloalkene complexes have been extended to include the effect of alkyl substitution at the double bond, the effect of conjugation in cyclic diolefins and the effect of anions, on the formation of these silver cycloalkenyl radicals.

Canadian Journal of Chemistry, 49, 160 (1971)

Introduction

Studies (1, 2) of the stability of silver alkene and 1-alkyl alkene complexes indicate that both steric and basicity effects are important. Uncertainty remains as to whether the steric effects of the 1-alkyl substituent result in a weaker metal–olefin bond or only a larger entropy change for the system upon complex formation. In contrast, Quinn and Van Gilder's infrared studies (3) suggest that a stronger silver–olefin interaction accompanies the increased basicity of cycloalkenes which have an alkyl group at the double bond. Dewar (4) further postulates that there may also be a weakening of the π component of the coordination bond concurrent with the strengthening of the σ component by the electron donating alkyl substituent. This latter effect may be relatively unimportant, as it is thought (5) that the σ component of the coordinate bond predominates in silver olefin complexes.

Factors other than olefin basicity and the steric effects of substituents which can affect the stability of the silver complexes include the strength of interaction between cations and anions (1), and the effect of conjugation in diolefin complexes on weakening of the coordination bond (6).

As a parallel study to silver olefin complexes, we have initiated a systematic investigation of silver alkenyl radicals generated by γ-irradiation of the parent complexes (7–9). In the present report we have extended our studies of silver alkenyl radicals to include silver 1-methylcyclopentenyl radical and the corresponding uncomplexed 1-methyl-cyclopentenyl radical, the silver cyclohexadienyl radicals generated from the 1,3- and 1,4-cyclohexadiene silver perchlorate and silver tetrafluoroborate complexes.

Experimental

All cycloalkenes were obtained from Aldrich. Anhydrous silver perchlorate and silver tetrafluoroborate were supplied by Alfa Inorganic and Ozark Mahoning, respectively. 1,4-Cyclohexadiene-3,3,6,6-d_4 was prepared by the method of Campbell (10). The silver complexes were prepared using the methods of Comyns and Lucas (11) and Quinn and Van Gilder (12). Silver analyses of all these complexes were within 0.02% of the values predicted. Sample irradiation has been described previously (8). Electron spin resonance (e.s.r.) spectra were

Magnetic Resonance Studies of Metal Olefin Complexes. II. Electron Spin Resonance Spectra of γ-Irradiated Silver Complexes with Cyclohexadienes and 1-Methyl Cyclopentene

D. R. GEE[1] AND J. K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ontario

Received August 31, 1970

Electron spin resonance studies of silver cycloalkenyl radicals by γ-irradiation of polycrystalline silver cycloalkene complexes have been extended to include the effect of alkyl substitution at the double bond, the effect of conjugation in cyclic diolefins and the effect of anions, on the formation of these silver cycloalkenyl radicals.

Canadian Journal of Chemistry, 49, 160 (1971)

Introduction

Studies (1, 2) of the stability of silver alkene and 1-alkyl alkene complexes indicate that both steric and basicity effects are important. Uncertainty remains as to whether the steric effects of the 1-alkyl substituent result in a weaker metal–olefin bond or only a larger entropy change for the system upon complex formation. In contrast, Quinn and Van Gilder's infrared studies (3) suggest that a stronger silver–olefin interaction accompanies the increased basicity of cycloalkenes which have an alkyl group at the double bond. Dewar (4) further postulates that there may also be a weakening of the π component of the coordination bond concurrent with the strengthening of the σ component by the electron donating alkyl substituent. This latter effect may be relatively unimportant, as it is thought (5) that the σ component of the coordinate bond predominates in silver olefin complexes.

Factors other than olefin basicity and the steric effects of substituents which can affect the stability of the silver complexes include the strength of interaction between cations and anions (1), and the effect of conjugation in diolefin complexes on weakening of the coordination bond (6).

As a parallel study to silver olefin complexes, we have initiated a systematic investigation of silver alkenyl radicals generated by γ-irradiation of the parent complexes (7–9). In the present report we have extended our studies of silver alkenyl radicals to include silver 1-methylcyclopentenyl radical and the corresponding uncomplexed 1-methyl-cyclopentenyl radical, the silver cyclohexadienyl radicals generated from the 1,3- and 1,4-cyclohexadiene silver perchlorate and silver tetrafluoroborate complexes.

Experimental

All cycloalkenes were obtained from Aldrich. Anhydrous silver perchlorate and silver tetrafluoroborate were supplied by Alfa Inorganic and Ozark Mahoning, respectively. 1,4-Cyclohexadiene-3,3,6,6-d_4 was prepared by the method of Campbell (10). The silver complexes were prepared using the methods of Comyns and Lucas (11) and Quinn and Van Gilder (12). Silver analyses of all these complexes were within 0.02% of the values predicted. Sample irradiation has been described previously (8). Electron spin resonance (e.s.r.) spectra were

obtained with a Varian V4502 spectrometer and auxiliary equipment. Simulation of spectra was done on an IBM 360/50 computer using a modified version of a program made available by the Bell Telephone Laboratory.

Results and Discussion

Silver 1-Methyl-Cyclopentyl Radical

To study the effect of alkyl substitution at the double bond of silver cycloalkenyl radicals, a large number of other alkyl substituted cycloalkene–silver complexes have been included in this study. However, most of them either decompose under γ-irradiation or lead to only unresolved single broad-line e.s.r. spectra. Only the silver 1-methyl-cyclopent-1-ene was stable enough and gave reasonably resolved e.s.r. spectra.

The e.s.r. spectra observed when silver perchlorate 1-methyl-cyclopentene complex was irradiated almost certainly results from Ag^+ 1-methyl-3-cyclopentyl radical (8). Computer analysis of the experimental spectra on this basis yields the parameters presented in Table 1.

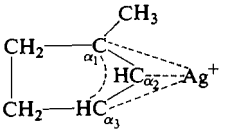

TABLE 1. Summary of hyperfine coupling constants for Ag^+ 1-methyl-3-cyclopentenyl radical

Splitting constant	Value (G)	
	Ag^+ 1-methyl cyclopentenyl	Ag^+ cyclopentenyl*
$a_H(\alpha_1)$		10.9
$a_H(\alpha_2)$	2.5±0.3	3.0
$a_H(\alpha_3)$	7.1	10.9
$a_H(\beta)$	20.4	22.0
a_{CH_3}	11.9	
a_{Ag}	38.5	30.5
Spin density on Ag%	5.8	4.6

*Taken from ref. 8.

The experimental β proton coupling constants of this silver 1-methyl-cyclopentyl radical compare with those assigned to the uncomplexed methyl cyclopentenyl radical (13). This appears to support previous observations that little ring distortion occurs in the complexation (3, 14).

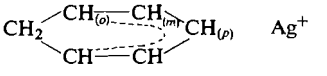
A comparison of the derived spin densities on the silver ion for the substituted and unsubstituted Ag^+ methyl-cyclopentenyl radicals (Table 1) reveals an increase in silver spin density with alkyl substitution. If, as presently seems probable, the spin density on the silver ion arises primarily from spin polarization of the σ coordinate bond, it would appear that our results indicate that methyl substitution at the double bond brings about a stronger interaction between the alkenyl and the silver ion. Quinn and Van Gilder (3) from their infrared observations of the perturbation in $\nu_{C=C}$ of the olefin, upon complex formation, have reached a similar conclusion for the parent silver complexes. Thus the effect of the electron donating methyl substituent is to increase olefin basicity and give a stronger coordinate bond. Steric effect, however, probably accounts for previous reports (2, 5) that 1-methyl substituted olefins form complexes less stable than the unsubstituted olefins.

Further inspection of the changes in proton coupling constants of the complexed radical (Table 1) reveals an apparent increase in the asymmetry of the spin distribution on the cycloalkenyl part of the radical. In a nuclear magnetic resonance (n.m.r.) study of the parent complexes Quinn and Van Gilder (3) have suggested that the deshielding effect of the methylene protons adjacent to the double bond is due to the positioning of the silver ion closer to the carbon-2. Such explanation can be applied also to the results of the silver methyl cyclopentenyl radical.

Silver Cyclohexadienyl Radicals

A number of silver complexes of conjugated olefins, including benzene, have been studied. Only silver cyclohexadienyl complexes led to reasonably resolved e.s.r. spectra.

A typical room temperature e.s.r. spectrum observed when either $AgClO_4$– or $AgBF_4$–1,4-cyclohexadiene is irradiated is shown in Fig. 1*a*. Similar spectra were obtained with the irradiated silver 1,3-cyclohexadiene complexes. Thus, it appears that the radicals generated in both isomers have essentially the same structure, probably the silver cyclohexadienyl radical.



Computer analysis of the experimental spectra on the basis of this silver cyclohexadienyl radical yields the parameters presented in Table 2. Despite the small asymmetric linewidth variation

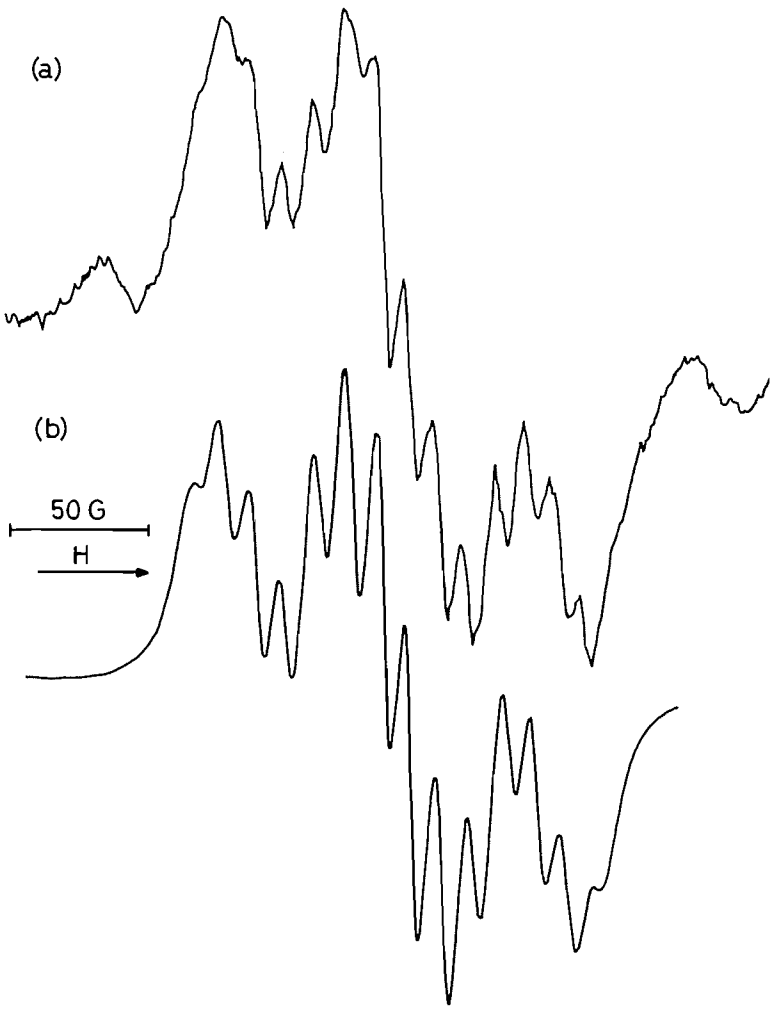

FIG. 1. Electron spin resonance spectra of γ-irradiated silver perchlorate 1,4-cyclohexadiene complex: (*a*) experimental spectrum; (*b*) computer simulated spectrum of Ag^+ cyclohexadienyl radical.

in the experimental spectrum, reasonable agreement is observed when computed spectra simulated using the data in Table 2 are compared with those obtained experimentally. The broad outer lines in the experimental spectra in Fig. 1*a* were only observed with the perchlorate as anion and may be due to some other trapped radicals. To confirm the spectral assignments, the silver complex of cyclohexadiene-3,3,6,6-d_4 was studied. The deuterated spectra agree with the assignments using an a_D/a_H ratio of 0.1535.

The proton coupling constants of the silver cyclohexadienyl radical are essentially identical with the values for the uncomplexed cyclohexadienyl radical (15). Again this indicates that little ring distortion occurs in the complexed radical. The derived spin density of $3.0 \pm 0.3\%$ on the silver ion of the silver cyclohexadienyl radicals compares with the value of 3.4% estimated for silver cyclohexenyl radical (8). This suggests that some small weakening of the coordinate bond occurs probably as a result of the conjugation in the cyclodienyl system. Similar observations of the parent silver complexes have been reported (6).

X-Ray data for the silver cyclooctatetraene (16) and silver benzene complexes (17) indicate that the silver ion in these complexes is positioned

TABLE 2. Spectral parameters for Ag^+ cyclohexadienyl radicals

Splitting constant	Value (G)			
	1,3-Cyclohexadiene $AgClO_4$	1,3-Cyclohexadiene $AgBF_4$	1,4-Cyclohexadiene $AgClO_4$	1,4-Cyclohexadiene $AgBF_4$

above the plane of the ring. If the silver ion also occupies a similar position in the silver cyclohexadienyl radical, it would explain the small difference in the derived spin densities of the silver ion in the radicals formed from 1,3- and 1,4-cyclohexadienes, as greater orbital overlap would be expected with the more symmetrical parent 1,4-cyclohexadiene. Our results also indicate the formation of these silver cyclohexadienyl radicals being independent of the anion, at least for the ClO_4 and the BF_4 anions.

The authors are indebted to Dr. A. Rudge for some technical assistance, and to Dr. H. W. Quinn of the Dow Chemical Company of Canada, Sarnia, for sending some preprints of his work. Reaction of Methyl-lithium with Phosphonitrilic Fluorides: a Novel Orientation Pattern

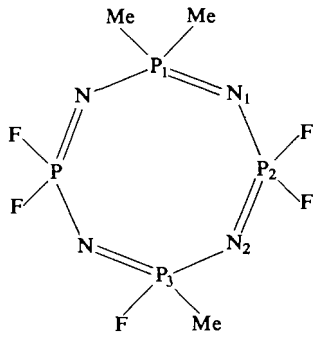
N. L. PADDOCK[1] AND T. N. RANGANATHAN
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia
AND
S. M. TODD
Department of Chemistry, University of Manchester, Manchester 13, England

Received October 9, 1970

The reaction of methyl-lithium with the phosphonitrilic fluorides $(NPF_2)_{3-5}$ follows a predominantly geminal course, the third and fourth substituents in the tetrameric ring entering antipodally to the first two. This behavior, and the competitive occurrence of an addition reaction, is attributed to the π-inductive effect of the substituents on a delocalized homomorphic π-system.

Canadian Journal of Chemistry, **49**, 164 (1971)

Although many investigations have been carried out on the orientation of substituents entering the phosphonitrilic ring and the structural changes which they induce, there has hitherto been no attempt to relate the observed pattern to the structure of the π-electron system. We have investigated the point directly through a study of the reactions of the phosphonitrilic fluorides $(NPF_2)_{3-5}$ (which measurements of ionization potentials (1) show to have a strongly developed π-system) with methyl-lithium in diethyl ether (which should introduce no π-conjugative or steric (2) complications). A novel orientation pattern is found for the methylation of $N_4P_4F_8$ in that, as indicated by ^1H and ^{19}F n.m.r. spectroscopy, geminal di-substitution is followed predominantly by antipodal entry of the third substituent, as shown. Both findings are unexpected on electrostatic grounds. The methyl group would be expected to be electron-releasing relative to fluorine, causing the second substituent to enter antipodally to the first, as in the amination of $N_4P_4Cl_8$ (3). On the other hand, where geminal di-substitution at P-1 has an electrostatic origin, as in the substitution of chlorine by fluorine in $N_4P_4Cl_8$ (4), the third substituent enters at P-2. The course of methylation of $N_4P_4F_8$, distinct from both these patterns, can be understood in terms of the effect of π-inductive interactions on the atomic π-charges; by analogy with the bimolecular substitution reactions of phosphoryl compounds, reactivity is expected to correlate (inversely) with electron density of the reaction center (5). The induced charges (6) are given in Table 1 for six- and eight-membered rings. Since $\delta\alpha$ is negative, the charges have the same sign as the tabulated values, and, from this cause alone, a second nucleophilic substitution should take place principally at P-1, as found. The substitution of the third group can be expected to occur where the π-induced negative charge is least, *i.e.* at P-3 if the electronegativity difference between the π-orbitals at P and N is great enough. The recognition of this orientation effect, with a similar basis to that of substitution in the benzene ring, reinforces the conclusions of a study of bond length inequalities (7).



Methylation of $N_3P_3F_6$ also takes place geminally, but a competitive addition reaction

*Hückel molecular orbital calculations, $\alpha_N = \alpha_p + \rho\beta$.

prevents the formation of simple N_3P_3 derivatives containing more than two methyl groups and, in the reaction with $N_5P_5F_{10}$, reduces the yield of $N_5P_5Me_{10}$; by contrast, a good yield (~70%) of $N_4P_4Me_8$ is obtainable from $N_4P_4F_8$. Exhaustive methylation of $N_3P_3F_6$, followed by treatment with methyl iodide, gives a product of composition $N_3P_3Me_{11}Li$, in which each phosphorus atom evidently carries three methyl groups. Table 1 shows that the positive charge on P-1 induced by two methyl groups is highest in the six-membered ring and for homomorphic interactions (8) and the addition of a third methyl group to P-1 is most likely in this case. For the N_5P_5 ring ($\rho = 1$), $\pi_{1,1} = 0.305$ (homomorphic) and 0.283 (heteromorphic). Experimentally, the relative importance of the substitution reaction, as measured by the yields of methylphosphonitriles $(NPMe_2)_n$ increases in the order $n = 3, 5, 4$, the order of decreasing $\pi_{1,1}$ (homomorphic). Insofar as the orientational effects are those of the uppermost π-system, the chemical and physical (1) results agree with the assignment of its symmetry type as homomorphic.

The Crystal Structure of a Thiathiophthen Nitrogen Isostere, 3,5-Epidithio-2,5-diphenyl-2,4-pentadienylidene-3-aminoquinoline

F. LEUNG AND S. C. NYBURG

Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received August 11, 1970

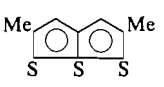
The crystal structure of a thiathiophthen nitrogen isostere (7) has been solved by X-ray analysis. The crystal belongs to the triclinic system with unit cell dimensions: $a = 11.275(11)$, $b = 9.558(10)$, $c = 10.797(10)$ Å, $\alpha = 92.50(10)$, $\beta = 116.98(10)$, $\gamma = 92.61(10)°$. There are two molecules per unit cell, space group $P\bar{1}$. The data were collected by diffractometer with Cu$K\alpha$ radiation. The structure was solved by symbolic addition procedures, and fully refined anisotropically using full-matrix least squares to an R factor of 6.3%.

The S—S and S—N bond lengths were found to be 2.364 and 1.887 Å, respectively. This reveals the partial bonding character between S...S...N atoms.

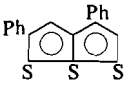
Canadian Journal of Chemistry, 49, 167 (1971)

Introduction

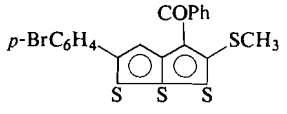
The crystal structure determination of the symmetric molecule 2,5-dimethyl-thiathiophthen **1** in 1958 (1) revealed an anomalous S...S distance of 2.36 Å, substantially longer than a single bond (2.08 Å) and far shorter than a van der Waals contact (*ca.* 3.5 Å). Similar anomalous distances have been found in a large number of other molecules containing at least one S atom at the end of an "open" five-membered ring, for example, in the unsymmetric thiathiophthen derivatives **2** (2) and **3** (3) and in the selenium and oxygen isosteres **4** (4) and **5** (5).



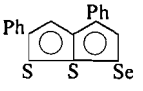
1



2



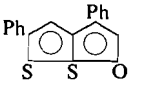
3



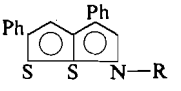
4

Derivatives of thiathiophthen usually show in the crystal one short (2.12–2.22 Å) and one long (2.45–2.57 Å) S...S distance unless crystallographic symmetry is required. At one time it was thought that 2,5-dimethylthiathiophthen, **1**, although required crystallographically to be symmetric, may have been a statistically disordered assembly of asymmetric molecules. A re-examination of its crystal structure in this laboratory, however, indicates that this is not so (6).

The nitrogen isosteres **6** have recently been synthesized by Klingsberg (7) and it is of some interest to know whether there is an S...N interaction in these molecules. A preliminary report showing that there is such an interaction has been published (8).



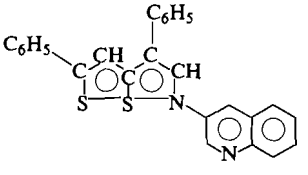
5



6

Experimental

The specimen of 3,5-epidithio-2,5-diphenyl-2,4-pentadienylidene-3-aminoquinoline (7) supplied by Klingsberg was recrystallized as red prisms from nitromethane.



7

The unit cell dimensions were determined from diffractometer measurements and refined by a least squares procedure.

$C_{26}S_2N_2H_{18}$ f.w. = 422.6.

Triclinic, $a = 11.275(11)$, $b = 9.588(10)$, $c = 10.797(10)$ Å, $\alpha = 92.50(10)$, $\beta = 116.98(10)$, $\gamma = 92.61(10)°$, $V = 1033.2$ Å^3, $Z = 2$, $D_c = 1.36$ g/cc, $D_m = 1.35$ g/cc, space group $P\bar{1}$ (No.2), $\mu = 23.7$ cm^{-1}, (CuKα, $\lambda = 1.5418$ Å).

The intensities were collected at room temperature on a Picker four circle automatic diffractometer (Ni-filtered, Cu radiation), and all independent reflections with $\sin\theta < 0.9063$ were measured in 2θ scan mode. A total of 3522 reflections were measured, of which 149 were unobservably weak.

Structure Determination

The structure was solved by obtaining phases from the normalized structure factor magnitudes using the symbolic addition procedure (9). A comparison between the theoretical and experimental statistical averages and distributions of the $|E|$'s shown in Table 1 clearly indicates that the crystal belongs to a centrosymmetric space group.

The signs of 447 reflections with $|E|$ greater than 1.5 were determined using the Σ_2 equation

$$sE_h \simeq s \sum_{k,} E_k E_{h-k}$$

(where "s" means "the sign of"). The starting phases were those of three origin-specifying reflections and five others given the symbolic phases of Table 2. There are numerous Σ_2 relationships indicating $c = d =$ positive, $a = b = e$. If a is positive, all the signs determined would be positive, which is an improbable solution, therefore an E-map with a assigned negative was computed. This E-map unambiguously revealed the whole structure.

Refinement

The atomic coordinates as read from the E-map were refined by full-matrix least squares using the XFLS variant of ORFLS (10). Using atomic scattering factors derived from Hartree–Fock wave functions (11) and hydrogen positions from a difference Fourier map, refinement reached an ultimate conventional R of 0.063. Hydrogen atoms were given anisotropic temperature factors of the atoms to which they are bonded. Final F_o and F_c values have been placed in the Depository for Unpublished Data.[1] The positional and thermal parameters with standard

deviations as obtained in the least squares refinement are given in Tables 3 and 4. The β_{ij} in Table 5 are the coefficients in the expression

$$\exp(-(\beta_{11}h^2 + \beta_{22}k^2 + \beta_{33}l^2 + 2\beta_{13}hl + 2\beta_{12}hk + 2\beta_{23}kl))$$

The bond distances and angles in the molecule are shown in Fig. 1, the average standard deviations of the angles being 0.5°.

Discussion

The S...S distance of 2.364(7) Å is almost identical to that found in 2,5-diphenyl- and in 2,5-dimethyl-thiathiophthen. Apparently (12) the S...S distance can span the range from 2.0 to 2.6 Å.

The S—N bond length seems to be greater than that found in **8** (13), **9** (14), and **10** (15) which are 1.632, 1.663, and 1.740 Å for S(2)—N(1), respectively. The C(5)—N(1) distance compares favorably with the value obtained in *s*-triazine (16), where the C—N distance was found to be 1.319 Å.

The interior angles at C(3), C(4), and C(5) in the five-member ring S(2), C(3), C(4), C(5), N(1) are substantially less than the 120° expected for

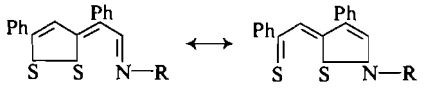
The molecule may be considered as a resonance hybrid of both dithiole (**11***a*) and isothiazole, (**11***b*), bearing in mind that this "single-bond



11*a* **11***b*

no-bond" concept fails to explain the unequal S—S lengths in the unsymmetrical thiathiophthen derivatives **2** and **3** and even more so in the symmetrical molecule **12** recently reported by Johnson and Paul (17).

The nature of the bonding in these compounds is not well understood although some theories have been proposed (18, 19). The bond between

the sulfur atoms in these systems is weak and small differences in intermolecular forces acting on the atoms might be the cause of differences in observed bond lengths. A detailed analysis of intermolecular forces may give a clue to this question.

The S...S distances and difference of electronegativities between S and X for the S...S...X systems with similar diphenyl substitution are shown in Table 5. The S...S distance decreases as the difference in electronegativity increases. This may be due to an increase in ionic character of the S...S interaction, an effect which could be confirmed by structural analyses of similar compounds having X elements with a range of electronegativities.

The bond lengths in the quinolyl ring agree extremely well with those found in 5-acetoxy-6-methoxy-8-nitroquinoline (20). In no case does the difference in bond length exceed 2.5σ and the average is only 1.0σ. Neither this latter structure nor ours give such good bond length agreement with those cited for 8,8′-dibromo-2,2′-methylenediquinoline (21) and even less with those cited for 1-methyl-2-quinolone (22) where a predominant quinolinium-type contribution is suspected to be present.

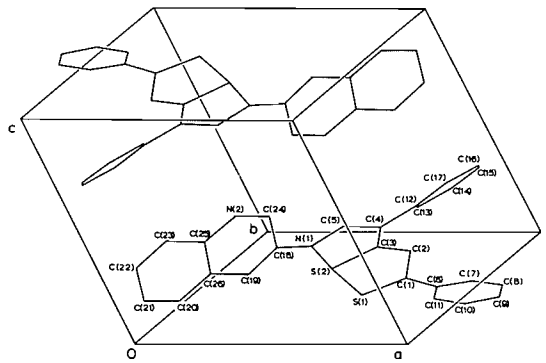

FIG. 2. Packing of molecules in the unit cell.

Coefficients for the best least squares planes through (*i*) the "thiathiophthen moiety" (S(1), S(2), N(1), C(1), C(2), C(3), and C(5)), (*ii*) the two phenyl rings, and (*iii*) the quinolyl group are listed in Table 6. In no case does the maximum deviation from planarity exceed 0.03 Å. Doubtless the interaction between hydrogen atoms at C(2) and C(17) causes the phenyl ring at C(4) to be twisted 49° from the central ring plane (Table 6). On the other hand, interaction between hydrogen atoms at C(2) and C(7) at C(5) and C(24) is weaker so that the phenyl ring at C(1) and the quinolyl ring are twisted only 20 and 27°, respectively.

The packing of the molecules in the unit cell is shown in Fig. 2. There are no especially short intermolecular contacts.

We are grateful to Dr. E. Klingsberg for supplying the crystals and to Mr. J. C. Rylaarsdam for help with the diagrams. F.L. was in receipt of a Province of Ontario Graduate Fellowship during this work, which was generously supported by the National Research Council of Canada.

Extractive-photometric Investigation of Cadmium Chelates of 4-(2-Thiazolylazo)-resorcinol (TAR)

O. NAVRATIL[1] AND R. W. FREI[2]

Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received June 15, 1970

A quantitative interpretation of the extractive distribution of cadmium chelates of TAR (= H_2A) between liquid organic and water phases has been made and two groups of extractable species have been determined: (*a*) uncharged complexes of the type CdA in which co-ordinated water is replaced by suitable uncharged organic base (2,9-dimethyl-1,10-phenanthroline) and (*b*) charged complexes CdA_2^{2-} which are extracted as ionic pairs in the presence of charged organic bases.

The evaluation of the character of the bases and the effect of p*H* and the nature and concentration of other inorganic anions are presented.

Canadian Journal of Chemistry, 49, 173 (1971)

N-heterocyclic azodyes have been used in the analytical chemistry of heavy and noble metals because of their great sensitivity and better selectivity when compared with isocyclic azodyes. The derivatives of thiazolylazophenols have often been preferred because of their easier preparation (1, 2). For extractive applications, reagents with one —OH group have been primarily utilized because they form uncharged complexes. Although the derivatives of resorcinol (*i.e.*, 4-(2-thiazolylazo)-resorcinol (TAR) and 4-(2-pyridylazo)-resorcinol (PAR)) have been employed widely as chelatometric indicators because of their ability to form colored complexes with many metal ions, they have not been used in extraction procedures. The reason for this is the charge of the complexes which results from the preferential dissociation of the —OH group on the resorcinol in the position *para* to the azo group. An exception is palladium, which has been extracted with PAR (3, 4) and TAR (5) using ethyl acetate or isoamyl alcohol as solvents. Pd–PAR or Pd–TAR 1:1 chelate complexes were extracted from sulfuric acid medium.

In the present work attention is focused on the extractive-photometric investigation of some heavy metal chelates of TAR with a view toward further electrophoretical studies of these charged complexes.

Experimental

Solutions and Reagents

Aqueous stock solutions of the metal ions Cu^{2+}, Ni^{2+}, Co^{2+}, Cd^{2+}, Zn^{2+}, Pb^{2+}, Fe^{2+}, and Mn^{2+} were prepared and if necessary a small amount of hydrochloric or sulfuric acid was added to prevent hydrolysis. Stock solutions of tetramethylammonium iodide (Me_4NI), tetra-*n*-propylammonium bromide (Pr_4NBr), tetra-*n*-butylammonium iodide (Bu_4NI), tetra-*n*-hexylammonium bromide (Hex_4NBr), tetra-*n*-hexylammonium iodide (Hex_4NI), tetra-*n*-heptylammonium chloride (Hep_4NCl), ethylhexadecyldimethylammonium bromide ($EtHdMe_2NBr$), trimethylphenylammonium chloride (Me_3PhNCl), 1,3-diphenylguanidine (DPG) (all Eastman Organic Chemicals), tetraphenylarsonium chloride (Ph_4AsCl), tri-*n*-octylamine (TOA) (both Aldrich), tri-*n*-butylamine (TBA) (British Drug Houses), cetylpyridinium chloride (CPCl) (Fisher Scientific), and 2,9-dimethyl-1,10-phenanthroline (DMphen) (Frederick Smith Chem.) were prepared from weighed amounts dissolved in benzene, chloroform, methylisobutyl-ketone (MIBK), isoamyl alcohol (IAOL), or water. TAR (Aldrich) was dissolved in 0.05 *M* ammonium hydroxide solution. Chloroacetate, acetate, borate, and ammonia – ammonium chloride buffers were used over the p*H* range 1.9 to 10; the concentration of the inorganic solutions of the water phase was always 0.03 *M* except for the study of the dependency of the equilibrium ratio of the metals on the analytical concentration of the interfering inorganic anions. All chemicals and reagents used were of analytical reagent grade quality.

Apparatus

Transmission spectra were measured with a Bausch and Lomb Spectronic 505 recording spectrophotometer in the visible region using 1 cm glass cuvettes. The atomic absorption spectrophotometer (Perkin–Elmer Model 290) with Cd, Co–Cr–Cu–Mn–Ni, and Zn–Ca hollow cathodes was used for the measurement of the metal concentrations in water and organic phases. For p*H* measurements of the aqueous phase a Radiometer p*H* meter 28 (Denmark) was used.

Procedure

Four to five ml of water phase containing $5 \times 10^{-5} - 5 \times 10^{-4}$ *M* solution of the metal ion, a solution of $5 \times 10^{-4} - 5 \times 10^{-3}$ *M* TAR, buffer solution, and masking agents were shaken with an equal volume of organic solvent containing $1 \times 10^{-4} - 1 \times 10^{-2}$ *M* organic base. To establish equilibrium these systems were shaken for 2–3.5 h in test tubes with ground glass stoppers in a homemade rotator, using 1.5 turns/s. This time

[1]On leave from the University of Brno, Czechoslovakia.
[2]To whom correspondence is to be addressed.

interval was sufficient to establish equilibrium in all systems. After separating the layers, an aliquot part was taken from the organic phase for spectrophotometric measurements, or from both phases for atomic absorption measurements. The concentration of the metals present in each liquid phase was determined with the use of calibration curves.

The distribution of TAR alone between benzene or IAOL and aqueous buffer solutions was studied spectrophotometrically as described above. A definite volume of a solution of 0.12 *M* NaOH was added to an aliquot of the water phase (or organic phase after evaporation to dryness) so that TAR (= H_2A) was completely transformed to the anionic form A^{2-}. Its concentration was measured against a water blank, using suitable calibration curves.

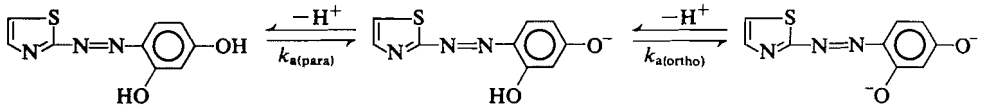
Results and Discussion

The distribution of TAR

The acid dissociation constants of TAR were determined spectrophotometrically to be $pk_{a(para)} = 6.23$ and $pk_{a(ortho)} = 9.44$ (6) according to the equations below

$$k_{a(para)} = \frac{[H^+_{para}][HA^-]}{[H_2A]} = 10^{-6.23} \quad k_{a(ortho)} = \frac{[H^+_{ortho}][A^{2-}]}{[HA^-]} = 10^{-9.44}$$

Thus the —OH group in para position to the azo group is more acidic



and since it does not participate directly in the formation of the metal chelate it must be responsible for the negative charge of the complex in neutral and alkaline media. The solubility of the reagent is probably better in a more polar organic solvent; the experimental results obtained by the authors show the value[3] of $Q_{H_2A} = [H_2A]_0/[H_2A]$ to be 19.8 in the system benzene – 0.03 *M* aqueous buffer solution and 1211 in the buffer – isoamyl alcohol system.

The distribution of TAR between aqueous buffer solution and benzene given by eqs. 1 and 2

[1] $$q_{H_2A} = \frac{[H_2A]_0}{[H_2A] + [HA^-] + [A^{2-}]}$$

or

[2] $$q_{H_2A} = -\frac{Q_{H_2A}[H^+]^2}{[H^+]^2 + k_{a(para)}[H^+] + k_{a(para)}k_{a(ortho)}}$$

and the theoretical distribution curve calculated according to eq. 2 is shown in Fig. 1. Experimental values obtained by spectrophotometric measurements agree well with the theoretical values.

The Extraction of Cd(II)–TAR Complexes

Assuming that the highest coordination number of Cd(II) is six and A^{2-} is a tridentate ligand, we can postulate that 1:1 CdA and 1:2 CdA_2^{2-} complexes are formed. Although the CdA complex is neutral, it is normally poorly extractable because of the presence of water molecules which can occupy free coordination sites on the metal. The extraction of such a complex is, however, possible when the coordinated water is replaced by a suitable organic reagent or organic solvent. For the extraction of the CdA_2^{2-} complex, on the other hand, the major problem is the elimination of the negative charge. This can be achieved with the addition of a suitable organic cation, which results in the formation of an extractable ion association complex.

The cadmium ion was chosen for an investigation of both types of extractable complexes (A and B) because of the good sensitivity of this metal when using atomic absorption spectrophotometry for determination.

[3]The equilibrium concentration of the compound X in the organic phase is expressed as $[X]_0$ and that in the water phase as [X].

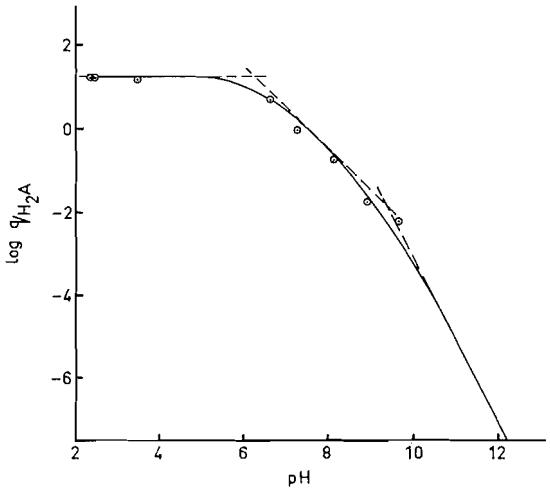

FIG. 1. Effect of pH of the water phase on the distribution of H_2A between benzene and 0.03 M buffer solutions. The curve represents calculated values, the intersection of broken lines represents theoretical values of $pk_{a(para)}$ and $pk_{a(ortho)}$; ○ are experimental points.

(A) A quantitative description of the extraction of cadmium when using DMphen as a suitable uncharged organic base can be made with the assumption of the following distribution equilibria

[3] $$Cd^{2+} + H_2A \rightleftharpoons CdA + 2H^+ \qquad K_1 = -\frac{[CdA][H^+]^2}{[Cd^{2+}][H_2A]}$$

[4] $$Cd^{2+} + 2H_2A \rightleftharpoons CdA_2^{2-} + 4H^+ \qquad K_2 = \frac{[CdA_2^{2-}][H^+]^4}{[Cd^{2+}][H_2A]^2}$$

[5] $$CdA + DMphen \rightleftarrows CdA(DMphen) \qquad k_{ad1} = \frac{[CdA(DMphen)]}{[CdA][DMphen]}$$

The number of coordinated water molecules in the CdA complex is neglected.

[6] $$CdA(DMphen) \rightleftarrows \{CdA(DMphen)\}_0 \qquad Q_{CdA(DMphen)} = \frac{[CdA(DMphen)]_0}{[CdA(DMphen)]}$$

[7] $$Cd^{2+} + y DMphen \rightleftarrows Cd(DMphen)_y^{2+} \qquad k_{ad2} = \frac{[Cd(DMphen)_y]}{[Cd^{2+}][DMphen]^y}$$

For the extraction of cadmium as a CdA(DMphen) complex the distribution of Cd is given as

[8] $$q_{Cd} = \frac{[CdA(DMphen)]_0}{[Cd^{2+}] + [CdA] + [CdA_2^{2-}] + [CdA(DMphen)] + [Cd(DMphen)_y^{2+}]}$$

where $y = 1$–3. Then

[9] $$q_{Cd} = \frac{Q_{CdA(DMphen)} k_{ad1} K_1 [DMphen][H_2A]}{[H^+]^2\{1 + \frac{[H_2A]K_1}{[H^+]^2}(1 + [DMphen]k_{ad1}) + \frac{[H_2A]^2 K_2}{[H^+]^4} + k_{ad2}[DMphen]^y\}}$$

Typical extraction curves for the dependency of the log equilibrium ratio of Cd ($= q_{Cd}$) on pH are shown in Fig. 2. It can be seen that log q_{Cd} values increase with a slope of 2.0 ∓ 0.2 in the low pH range, then pass through a maximum and decrease with a slope of -1.7 ∓ 0.3 with higher pH values. Each interval of the value of the slope of the pH-extraction curve depends on the predominant species in the water phase and can be described by the term in brackets in the denomi-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

nator of eqs. 8 and 9, *e.g.* $Cd^{2+} \rightarrow CdA(DMphen) \rightarrow CdA_2^{2-}$. The extraction maximum on the curve is equal to the maximum of the concentration of the CdA(DMphen) species; it can also be observed in the same p*H* region when the system Cd^{2+}–TAR is used with IAOL as an organic phase without DMphen (see Fig. 2). On the other hand, when benzene is present as organic phase without DMphen, the extraction of Cd is negligible in all the p*H* region ($\log q_{Cd} < -2.5$). This fact indicates that the complex CdA is probably hydrated and non-extractable into benzene. Taking into account that the water molecules can be replaced by the relatively polar IAOL molecules, we can assume the extractable complex to be $CdA(IAOL)_r$.

The formation of the $Cd(DMphen)_y^{2+}$ species also plays an important role, and the same effect can be observed as described recently by Hamilton and Freiser (7). First the extraction of Cd is observed to increase with an increase in DMphen concentration. At a concrete concentration level the extraction curve shifts to the right because of a formation of the unextractable $Cd(DMphen)_2^{2+}$ and $Cd(DMphen)_3^{2+}$ complexes. As a consequence, the last term in the lower part of eq. 9 cannot be neglected.

(*B*) When ionic associates are formed as a result of the presence of a charged organic base, the following equilibria can be formulated (K_{as} = association constant, Q = partition coefficient)

[10] $$B^+ + X^- \rightleftarrows (B^+, X^-) \qquad K_{as,BX} = \frac{[(B^+, X^-)]}{[B^+][X^-]}$$

[11] $$(B^+, X^-) \rightleftarrows (B^+, X^-)_0 \qquad Q_{BX} = \frac{[(B^+, X^-)]_0}{[(B^+, X^-)]}$$

X^- is the inorganic anion present in the water phase.

[12] $$2B^+ + CdA_2^{2-} \rightleftarrows (2B^+, CdA_2^{2-}) \qquad K_{as,BCdA} = \frac{[(2B^+, CdA_2^{2-})]}{[B^+]^2[CdA_2^{2-}]}$$

[13] $$(2B^+, CdA_2^{2-}) \rightleftarrows (2B^+, CdA_2^{2-})_0 \qquad Q_{BCdA} = \frac{[(2B^+, CdA_2^{2-})]_0}{[(2B^+, CdA_2^{2-})]}$$

Then the distribution of Cd in the presence of charged organic base is given by

[14] $$q_{Cd} = \frac{[(2B^+, CdA_2^{2-})]_0}{[Cd^{2+}] + [CdA] + [CdA_2^{2-}]}$$

assuming that the concentration of the ionic associates in the water phase can be neglected (*e.g.* the value of Q_{BCdA} is very high).

From the equilibria mentioned above, the following equation for the distribution of cadmium can be written

[15] $$q_{Cd} = \frac{Q_{BCdA} K_{as,BCdA} K_{as,BX}^{-2} Q_{BX}^{-2} K_2 [(B, X)]_0^2 [H_2A]^2 [H^+]^{-4} [X^-]^{-2}}{1 + K_1[H_2A][H^+]^{-2} + K_2[H_2A]^2[H^+]^{-4}}$$

Equation 15 does not take into account the possible formation of Cd–X complexes which could take place at higher concentrations of X^-; it does, however, indicate that q_{Cd} is proportional to $[(B^+, X^-)]_0^2$ and to $[X^-]^{-2}$ when the p*H* of the water phase remains constant.

The Effect of Composition and Concentration of Organic Bases on the Extraction of Some M^{II}–TAR Complexes

In general, the extraction of ionic pairs is favored when the solvent molecules of the extracting agent and the oppositely charged part of the complex are similar in character; this results in a higher value of $Q_{BCdA} \times K_{as,BCdA}$. Various types of organic bases were examined and the values of equilibrium ratios of Cd, Co, and Ni when using 1×10^{-2} *M* solutions of organic bases in benzene, isoamyl alcohol, or MIBK are presented in Table 1.

Comparing the character of the bases investigated, we can conclude that the extraction of Cd, Co, and Ni improves with an increase in chain length of the alkyl group in the alkylammonium base. Best results are obtained with the systems Hep_4NCl–benzene and CPCl–IAOL. The use of ternary amines (TOA, TBA) and also

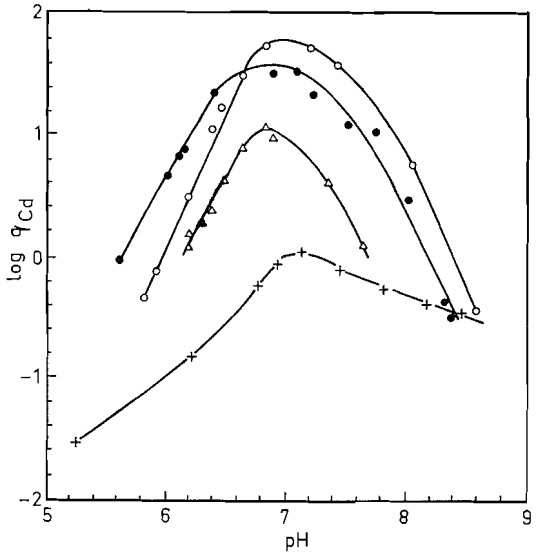

FIG. 2. Effect of p*H* of the water phase on the distribution of cadmium between solution of DMphen in benzene and IAOL only and 0.03 *M* water buffer solution. $c_{H_2A} = 1 \times 10^{-3}$ *M*; $c_{Cd} = 1 \times 10^{-4}$ *M*; c_{DMphen}: ○, 1×10^{-3} *M*; ●, 1×10^{-4} *M*; △, 2.5×10^{-5} *M*; +, IAOL only, without DMphen.

DPG is not satisfactory because of their inability to form charged cations in alkaline medium. The dependence between log q_{Cd} and the analytical concentration of the base is presented in Fig. 3. The limiting values of the slopes for the straight plots are $+2.0 \mp 0.2$ in all cases. Thus the dependence between q_{Cd} and $[(B,X)]_0$ from eq. 15 is valid and complexes of the type ($2B^+$, CdA_2^{2-}) are extracted in all systems.

The Effect of the Nature and Concentration of Inorganic Anions

It is known that the nature and concentration of inorganic anions influence the extractability of ionic pairs because of their different hydration (8). A competitive extraction according to eqs. 10 and 11 can take place, resulting in a decrease of free base in the system.

The influence of the analytical concentration of some inorganic anions on the extractability of Cd, when using a 1×10^{-2} *M* solution of CPCl in IAOL, is shown in Fig. 4. The limiting value of the slopes of these curves is equal to -2.0 ∓ 0.2 for SCN^-, ClO_4^-, and I^-. The good agreement between the theoretical and the experimental values of the slopes can be explained by the low hydration numbers of these anions (9), *e.g.* by the relatively constant distance between anion and cation in the extractable ionic pair. On the other hand, the hydration of the other anions investigated is not negligible and consequently the conditions for their extraction as ionic pairs are more complicated. Similar observations have been made with a Cd–TAR benzene chloride system as described in the following section.

The Effect of the Analytical Concentration of TAR

The dependence between log q_{Cd} and log c_{H_2A} in natural water phase is shown in Fig. 5. The slope of the straight line is 2.0 ∓ 0.1 in accordance with eq. 15, because at a constant p*H* of the water phase, c_{H_2A} is directly proportional to $[H_2A]$.

The Effect of pH of the Water Phase

As shown in Fig. 6, the pH–extraction curves have different characteristics for the CPCl–IAOL and Hep_4NCl–benzene systems. The first one is in quantitative agreement with eq. 15 after subtraction of the corresponding portion for the extractable cadmium in the system Cd–H_2A–IAOL only (blank curve). The extractability of the second system is practically independent of pH due to the formation of a competitive extractable anionic chloro complex.

The explanation of these phenomena probably depends on an evaluation of the association and equilibrium constants according to eqs. 10 and 11. The magnitude of these constants on the other hand evidently depends on the dielectric constants of the solvents, on the size and charge of the species formed, and on the ionic strength of the water phase (10). The behavior of the other bivalent heavy metals is different; only zinc interferes seriously as can be seen in Table 2.

Conclusions

The systems studied in this work can be utilized in analytical chemistry depending on the nature

of the water phase. Cadmium can be separated directly from acidic water solutions by extraction with solutions of suitable tetraalkylammonium salts in benzene. When TAR is used in alkaline water phase medium, the group of bivalent heavy metals or especially soluble amine complexes can be extracted preferentially as ion association complexes and determined in the organic phase with the aid of suitable instrumental methods.

^{18}O Transfer in the System Thiosulfate–Sulfite–Water: an Example of a Set of Consecutive Reversible First Order Rate Processes

R. H. Betts and S. Libich
Department of Chemistry, University of Manitoba, Winnipeg 19, Manitoba

Received June 30, 1970

The rate and mechanism of transfer of oxygen between thiosulfate ion and water, in the presence of sulfite, has been investigated with ^{18}O-enriched $Na_2S_2O_3$. The principal path, for the conditions examined, is via sulfur atom transfer between sulfite and thiosulfate, accompanied by oxygen atom transfer between sulfite and the solvent water. The latter path is suppressed at high p*H*, and oxygen transfer from thiosulfate proceeds to the sulfite stage only. At intermediate p*H*, the two processes have comparable rates, and the kinetics show the behavior expected for a system of consecutive, reversible first order processes. Under these conditions sulfite is observed to behave as a true intermediate, first accumulating ^{18}O from thiosulfate, and then releasing it to the solvent water.

Canadian Journal of Chemistry, 49, 180 (1971)

Introduction

The isotopic exchange reaction of sulfur in the aqueous system sulfite–thiosulfate was examined some years ago by Ames and Willard (1). The outer sulfur of thiosulfate is transferred to sulfite at a measurable rate, the reaction being first order in both sulfite and thiosulfate, and zero order with respect to hydrogen ion. It will at once be evident that transfer of the outer S from thiosulfate converts the donor ion to sulfite, and the acceptor ion to thiosulfate. In effect this is equivalent to transfer of oxygen from one species to the other. More recently, oxygen transfer between water and thiosulfate has been examined over a limited range of temperature and p*H* (2). The reaction is observable, but slow *e.g.*, half-time of 20–30 h at p*H* 6.0, and at a temperature of 80 °C. In view of the known S atom transfer process [1], addition of sulfite would be expected to provide an alternate path for transfer of oxygen between thiosulfate and water, provided that the sulfite–water oxygen exchange process [2] is reasonably rapid

[1] $$*OSS + SO \rightarrow *OS + SSO$$

[2] $$*OS + H_2O \rightarrow OS + H_2O*$$

(OSS represents thiosulfate and SO the appropriate sulfite species). The authors of ref. 2 have found no evidence of this coupled path, in that addition of 0.01 *M* sulfite to 0.1 *M* ^{18}O-thiosulfate produced no noticeable acceleration of oxygen transfer. They suggested that the apparent lack of catalysis by sulfite was due to the slowness of the sulfite–H_2O exchange reaction. However, a recent study of the kinetics of the sulfite–water exchange in this laboratory (3) shows that for the conditions of temperature and p*H* used in (2), oxygen exchange between these latter species is very rapid, and indeed the oxygen in H_2O and sulfite would be always at isotopic equilibrium for the time scale (hours) used in ref. 2.

To resolve this discrepancy, we have studied the kinetics of oxygen transfer in the system thiosulfate–sulfite–water, using ^{18}O-labelled thiosulfate, over the p*H* region from 3 to 13, and for sulfite–thiosulfate ratios from 0.75 to 4.0. The results confirm that the sulfur atom transfer process (reaction 1) provides an important route for interchange of oxygen between thiosulfate and water. As is outlined more fully below, the results at appropriate p*H* values provide a most interesting illustration of a system of reversible, consecutive first order rate processes. Such systems have been examined theoretically a number of times, but to the best of our knowledge, no actual chemical systems of this kind have been described heretofore.

Experimental

Enriched water (1.6 atom%, ^{18}O obtained from Yeda Research and Development Co., Ltd.) was redistilled from alkaline permanganate. Water of normal isotopic composition used in our experiments was doubly distilled. Sodium sulfite was anhydrous certified A.C.S. Fisher. All other chemicals were of reagent grade, and used without further purification. ^{18}O-enriched sodium thiosulfate was prepared from sodium sulfite and sulfur according to the method of Hargreaves and Dunningham (4). A mixture of sodium sulfite, ^{18}O-labelled water, and sulfur in a molar ratio of $\sim$1:5:1.5 (excess sulfur was used) was heated at approximately 80 °C for 60 h. Sulfite rapidly reaches isotopic equilibrium with the labelled water and reacts with sulfur to form $Na_2S_2O_3 \cdot 5H_2O$. This material is a liquid above 48 °C, in which the other materials present are insoluble. It was filtered through a sintered glass filter at 50 °C, and the separated liquid $Na_2S_2O_3 \cdot 5H_2O$ dehydrated under vacuum at 90–100 °C. Iodometric

For personal use only.

analysis of the product indicated it to be 99% $Na_2S_2O_3$ and less than 1% Na_2SO_3. The isotopic oxygen composition was found to be 1.24 atom% ^{18}O. This labelled material was used without further purification.

Kinetic runs were done in the following way. The water was freed of dissolved oxygen by bubbling with argon (Matheson H.P.) before adding sulfite, to prevent the oxidation of the latter. Then concentrated HCl or NaOH was added as required to obtain the desired p*H*, and ^{18}O-$Na_2S_2O_3$ was then added. This solution was then placed in a water bath held at 50.3 °C, the temperature used for all experiments. In some experiments, the p*H* measurements were made at room temperature on duplicate solutions made up with unlabelled anhydrous sodium thiosulfate, while in other experiments the labelled solutions were used directly. A Model 801 Orion p*H* meter was used.

At timed intervals, 1–2 ml aliquots were removed, the p*H* adjusted to 11–12, and sulfite was precipitated and centrifuged down as $SrSO_3$ by addition of an aqueous solution of $SrCl_2$. The remaining solution was adjusted to p*H* 4.7 with acetate, and thiosulfate recovered by adding excess 0.5 *M* Cu(II) tetrapyridine acetate solution. This reagent ($CuPy_4Ac_2$) is made simply by adding excess pyridine to a solution of Cu(II) acetate. Cu(II) oxidizes thiosulfate to tetrathionate and the latter precipitates with excess $CuPy_4Ac_2$ as $CuPy_4S_4O_6$ (5). This precipitate filters readily, and when washed with ether or acetone gives an anhydrous product. Blank experiments with ^{18}O-labelled water showed that this procedure for isolating thiosulfate from solution caused not more than 3% induced exchange of the oxygen in the salt with the solvent oxygen.

In some experiments, thiosulfate was recovered as BaS_2O_3 precipitate after the sulfite had been removed as $SrSO_3$. The BaS_2O_3 precipitate, however, proved difficult to handle, since precipitation was very slow; often requiring addition of alcohol to encourage precipitation. Moreover, this salt is difficult to dehydrate.

The isotopic composition of the sulfite, tetrathionate, or thiosulfate was determined using the method of Shakhashiri and Gordon (6), in which the oxygen of the salt is converted to CO_2 by heating it with AgCN under vacuum for 2 h at 500 °C. The CO_2 thus formed was purified by sublimation from an *n*-pentane slush bath (−130 °C) to a bulb cooled in liquid nitrogen.

Isotopic analysis of CO_2 was done with a Varian-Mat GD-150 isotope ratio mass spectrometer. The relative abundance of ^{18}O in each sample was measured directly as a so-called *P*-factor on this instrument, defined as the ratio of abundance of carbon dioxide of mass 46 to that for masses 44 + 45.

Results and Discussion

In an aqueous solution of thiosulfate and sulfite, there are several possibilities of ^{18}O exchange among the various species. The direct exchange of ^{18}O between thiosulfate and water has been shown to be quite slow (2) and for the experimental conditions and times used here this possibility can be neglected. The remaining ^{18}O exchange possibilities can be represented by eqs. 1 and 2 above, with corresponding exchange rates R_1 and R_2. Now if thiosulfate only is labelled with ^{18}O initially, then one has a system of two consecutive reversible first order reactions with respect to ^{18}O exchange.

The following definitions are required. $x = [S_2O_2O^{*2-}], y = [SO_2O^{*2-}], z = [H_2O^*], X = 3[S_2O_3^{2-}]$, $Y = 3[SO_3^{2-}]$, and $Z = [H_2O]$; where x, y, and z represent the molar concentrations of the ^{18}O-labelled species. Because the ^{18}O level was low ($\sim 1\%$), doubly labelled oxyanions can be neglected. The quantities X, Y, and Z represent the concentration of ^{16}O in g-atoms l^{-1} of the indicated species.

Noting that for each sulfur atom transferred at a rate R_1, there are three oxygen atoms transferred (see footnote to Table 1), the rates of ^{18}O transfer are readily shown to be given by eqs. 3–5

$$[3] \quad \frac{dx}{dt} = R_1 \frac{y}{Y} - R_1 \frac{x}{X}$$

$$[4] \quad \frac{dy}{dt} = R_1 \frac{x}{X} - R_1 \frac{y}{Y} - R_2 \frac{y}{Y} + R_2 \frac{z}{Z}$$

$$[5] \quad \frac{dz}{dt} = R_2 \frac{y}{Y} - R_2 \frac{z}{Z}$$

It is convenient to recast eqs. 3–5 in terms of the corresponding experimental *P*-factors, defined as follows

$$P_x = k \frac{x}{X},$$

$$P_y = k \frac{y}{Y}$$

and

$$P_z = k \frac{z}{Z}$$

(The term k in these definitions is a proportionality constant, the same for each definition, which allows for the fact that the *P*-factor is only a relative and not an absolute measure of the corresponding $^{18}O/^{16}O$ ratio. It allows *e.g.*, for instrumental calibration, and for the statistical factor of 2 involved in ^{18}O assay via CO_2 mass spectrometry. It is cancelled out in the following differential equations, and also out of the *F* values following eq. 13.) Substituting appropriately for x, y, and z in eqs. 3–5, one has

$$[6] \quad \frac{dP_x}{dt} = \frac{R_1}{X}(P_y - P_x)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$[7] \quad \frac{dP_y}{dt} = \frac{R_1}{Y}(P_x - P_y) - \frac{R_2}{Y}(P_y - P_z)$$

$$[8] \quad \frac{dP_z}{dt} = \frac{R_2}{Z}(P_y - P_z)$$

The general solution of such a set of coupled rate equations has been given in the literature (7–12). The two methods of solving such coupled rate equations are: (*a*) converting these equations into second order differential equations of a single component and solving the resulting second order equation by standard methods, refs. 7–9, or (*b*) the above set of coupled differential equations can be solved in closed form, refs. 10–12. We have used the second method and specifically followed the procedure given in ref. 12 because equations for P_x, P_y, and P_z can be obtained conveniently by this method.

The general solution of eqs. 6–8 can therefore be written simply as

$$[9] \quad P_i = A_i' e^{-\lambda_1 t} + A_i'' e^{-\lambda_2 t} + A_3$$

where P_i represents P_x, P_y, or P_z as appropriate; A_i' and A_i'' are constants of integration satisfying initial conditions and $A_3 = P_\infty$ (the equilibrium isotopic ratio in all components at infinite time (eq. 17 below). λ_1 and λ_2 are the same for P_x, P_y, or P_z and can be given in terms of the reaction rates R_1 and R_2 and of the concentrations of the components X, Y, and Z as given by eqs. 10 and 11.

$$[10] \quad \lambda_1 = \frac{1}{2}\left\{\frac{R_1}{X} + \frac{R_1 + R_2}{Y} + \frac{R_2}{Z} + \left[\left(\frac{R_1}{X} + \frac{R_1 + R_2}{Y} + \frac{R_2}{Z}\right)^2 - 4R_1R_2\left(\frac{X + Y + Z}{XYZ}\right)\right]^{1/2}\right\}$$

$$[11] \quad \lambda_2 = \frac{1}{2}\left\{\frac{R_1}{X} + \frac{R_1 + R_2}{Y} + \frac{R_2}{Z} - \left[\left(\frac{R_1}{X} + \frac{R_1 + R_2}{Y} + \frac{R_2}{Z}\right)^2 - 4R_1R_2\left(\frac{X + Y + Z}{XYZ}\right)\right]^{1/2}\right\}$$

Equations 9–11 describe the variation of the isotopic ratios in thiosulfate, sulfite, and water as a function of time. Because water is overwhelmingly the main species, its isotopic composition is not a sensitive indicator of the exchange process and so was not measured.

The kinetics of reactions 1 and 2 have been studied previously (1, 3). Reaction 1 has a first order dependence on thiosulfate and sulfite, and zero order dependence on $[H^+]$, whereas reaction 2 has a first order dependence on sulfite, and is second order in $[H^+]$. Clearly there is available a greater degree of experimental control on R_2 than on R_1, since the former can be varied by many orders of magnitude, with respect to R_1, simply by alteration of the p*H*. Experimental measurements were made in the p*H* region 2.75 to 13, with the results up to p*H* 9.6 summarized in Table 1.

It is convenient and useful to consider all the results in four groups, distinguished by the p*H* region. Each of these groups will now be discussed separately for sulfite and thiosulfate concentrations of the order of 0.5 *M*.

Case 1

In the p*H* range 5 to 10 the exchange of oxygens between water and sulfite is extremely rapid so that $R_2 \gg R_1$. Therefore only the rate of oxygen atom transfer between thiosulfate and water is experimentally measurable by our method. Sulfite acts as a catalyst to exchange oxygen atoms between thiosulfate and water at a rate governed by the sulfur atom transfer between thiosulfate and sulfite as measured by Ames and Willard (1). Sulfite and water form a common pool of oxygen atoms which exchange with the oxygen atoms of thiosulfate. In this region of p*H* the sulfite is in ^{18}O isotopic equilibrium with water so $P_y = P_z$ at all times. Since no ^{18}O is lost from the system the following relation holds for infinite time

$$[12] \quad P_\infty(X + Y + Z) = XP_x + (Y + Z)P_y$$

Equation 12 can be used to eliminate P_y from eq. 6, and the resulting equation can be integrated directly to give

$$[13] \quad \ln\left[\frac{P_x + P_\infty}{P_{x_0} - P_\infty}\right] = -R_1\frac{X + Y + Z}{X(Y + Z)}t$$

Here, P_{x_0} is the isotopic ratio in thiosulfate at zero time; P_x is the isotopic ratio in thiosulfate at time t; and P_∞ is the isotopic ratio in thiosulfate or in any of the other components at infinite time. In terms of the *P*-factors, the fraction exchanged, *F*, can be defined as

$$F = (P_{x_0} - P_x)/(P_{x_0} - P_\infty)$$

hence

$$(P_x - P_\infty)/(P_{x_0} - P_\infty) = (1-F)$$

*Thiosulfate recovered as $CuPy_2S_4O_6$.
†Thiosulfate recovered as BaS_2O_3.
‡Note higher ionic strength for these experiments. ($R_1 = 3k_1[SO_3^{2-}][S_2O_3^{2-}]$. k_1 in ref. 1 is given in terms of S atom transfer; for each such event, 3 oxygen atoms, in effect, transfer.

and eq. 13 is in the form of a conventional McKay relation (13). Equation 13 is also identical to an equation derived by Takaishi (7) for exchange processes involving an intermediate complex.

Plots of log $(1 - F)$ *vs.* time show linear behavior as illustrated in Fig. 1 for run No. 1 in Table 1. From the slopes of such plots, R_1 has been determined. Using the kinetic equation determined by Ames and Willard given by [14]

$$[14] \qquad R_1 = 3\,k_1\,[S_2O_3^{2-}]\,[SO_3^{2-}]$$

values of k_1 shown in Table 1 have been calculated. As a comparison the rate constant k_1 calculated from the data of Ames and Willard is 3.44×10^{-4} $l\,m^{-1}$ s^{-1} at 50 °C and for ionic strength of 2.0. Evidently the sulfur atom transfer process accounts very well for the interchange of oxygen between thiosulfate and water over this region of pH.

Case 2

At a p$H > 11$, oxygen exchange between sulfite and water is effectively stopped (3). The only oxygen exchange is between thiosulfate and sulfite, via S atom transfer. The McKay equation (13) for ^{18}O exchange between these two species is given by eq. 15

$$[15] \qquad \ln \frac{P_x - P_\infty}{P_{x_0} - P_\infty} = -R_1 \frac{X + Y}{XY}\,t$$

where P_x and P_{x_0} have the same definition as in case 1 but P_∞ now refers to the ^{18}O isotopic equilibrium between *thiosulfate and sulfite only*, as given by eq. 16

$$[16] \qquad P_\infty = \frac{XP_{x_0} + YP_{y_0}}{(X + Y)}$$

A plot of log $(1 - F)$ *vs.* time for an experiment done at pH 13 is illustrated in Fig. 2. The good linearity of this plot is proof that oxygen in H_2O is not involved in any way. From the slope of this plot, R_1 was calculated as 5.75×10^{-5} g-atoms oxygen l^{-1} s^{-1}. This is in good agreement with the data of Table 1, in which the thiosulfate exchange with water was catalyzed by sulfite, and R_1 was calculated from eq. 13. Evidently sulfur atom transfer is still the main process responsible for oxygen exchange. The insensitivity of this process to pH is to be expected from the work of Ames and Willard (1).

Case 3

In the pH range 10 to 11 both R_1 and R_2 are within one or two orders of magnitude of each other. Thiosulfate and sulfite are exchanging oxygen atoms at a rate R_1 and sulfite is simultaneously exchanging oxygen atoms with water at a rate R_2. Since the ^{18}O isotopic label begins in thiosulfate, the ^{18}O exchange in this system can best be described as two consecutive reversible first order reactions represented by eqs. 1 and 2. The analytical solution of these equations has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

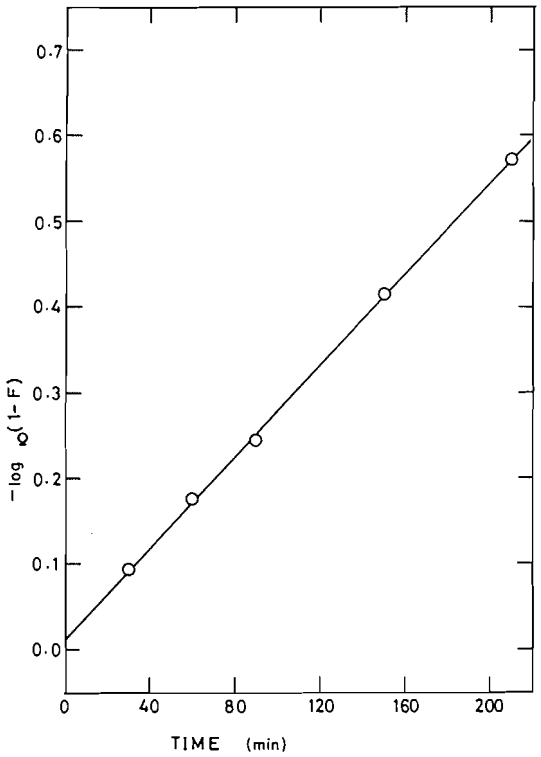

FIG. 1. Fraction of ^{18}O exchange between thiosulfate and water catalyzed by sulfite at pH = 9.6 (see eq. 13).

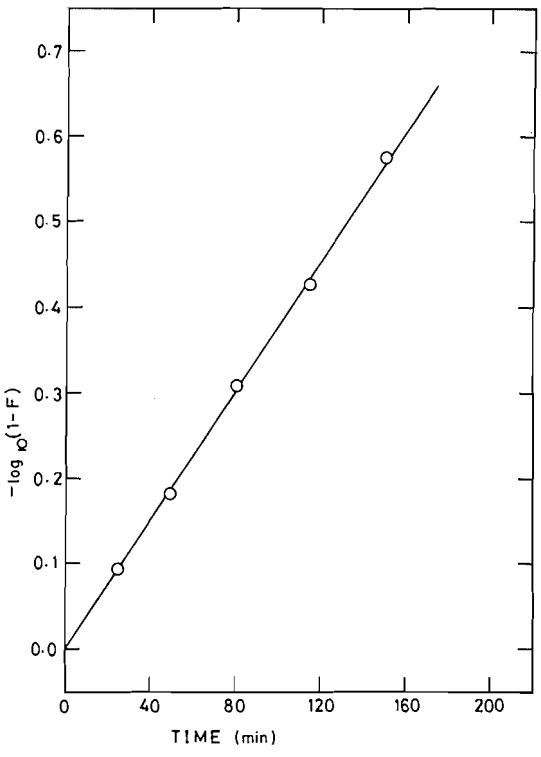

FIG. 2. Fraction of ^{18}O exchange between thiosulfate and sulfite at pH 13 (see eq. 15), 0.2 M $S_2O_3^{2-}$, 0.5 M SO_3^{2-}.

already been discussed and the general solution is given by eq. 9.

A graphical method can be used to evaluate λ_1, λ_2, A_x', and A_x'' in eq. 9, provided that R_1 and R_2 are sufficiently different so that λ_1 and λ_2 will differ by at least an order of magnitude. If $(P_x - P_\infty)$ is plotted against time on semi-log paper, then at sufficiently long times the curve should become a straight line, the exponential term with the smaller λ factor in eq. 9 being the main component at long times. The slope of this line segment will give the value of the smaller of the two λ's. If this line segment is extrapolated back to zero time and the ordinates of all points on this extrapolated line are now subtracted from the ordinates of the corresponding points on the original curve, and the resulting values replotted as before *vs.* time, a straight line should result corresponding to the other exponential term in eq. 9. The slopes of these two resolved lines give λ_1 and λ_2 and the intercepts give the pre-exponential factors, A_x' and A_x''. From this information R_1 and R_2 can be calculated. The data for $(P_y - P_\infty)$ can be treated in a similar way, and should give the same set of values for λ_1 and λ_2, and appropriate values for A_y' and A_y''.

To indicate the validity of this analysis, an experiment was done at pH 10.8, $[S_2O_3^{2-}] = [SO_3^{2-}] = 0.5$ M, a condition for which R_2 is expected to be less than R_1, but not zero. The ^{18}O level in both thiosulfate and sulfite was determined experimentally as a function of time, *i.e.*, values of P_x and P_y were obtained. (The quantity P_z (^{18}O level in H_2O) was not followed, because as indicated earlier, this quantity does not change appreciably during the experiment.) Experimental values of P_x and P_y are shown in Fig. 3. In this figure, the upper result shows the fall in level of ^{18}O in thiosulfate as the reaction proceeds. The lower curve shows very clearly the corresponding initial rise in ^{18}O abundance in sulfite. A transient equilibrium is reached, as expected, followed by a decrease as the sulfite–water exchange proceeds towards isotopic equilibrium.

Plots of $(P_x - P_\infty)$ and $(P_y - P_\infty)$, on a logarithmic scale, *vs.* time, are shown in Fig. 4, together with resolution of the curves into straight

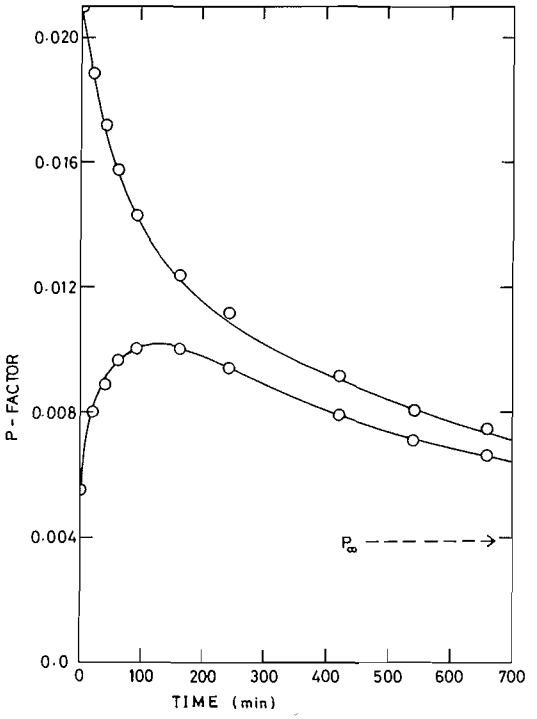

FIG. 3. Variation of ^{18}O in thiosulfate (upper curve) and sulfite (lower curve) as a function of time at pH 10.8. Open circles are experimental points and the lines are drawn from eqs. 18 and 19.

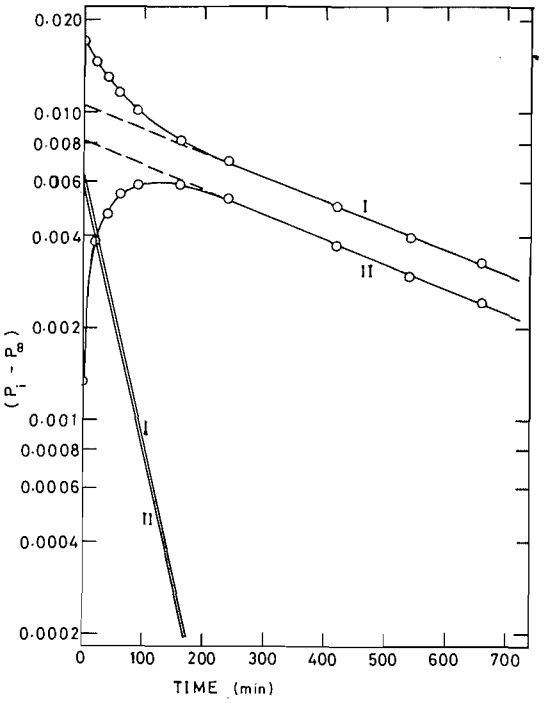

FIG. 4. *I*, Data from measurement of ^{18}O content of thiosulfate; *II*, ^{18}O content of sulfite. The corresponding straight line portions show the resolution of the two exponential terms (see text).

line components corresponding to the individual exponential terms comprising the curves as described above. The two sets of data lead to consistent values for λ_1 and λ_2, namely $\lambda_1 = 0.0193\ \text{min}^{-1}$, $\lambda_2 = 0.00182\ \text{min}^{-1}$, from the $(P_x - P_\infty)$ results, and $\lambda_1 = 0.0195\ \text{min}^{-1}$ $\lambda_2 \approx 0.00186\ \text{min}^{-1}$ from the $(P_y - P_\infty)$ results. The quantities A_i' and A_i'' have been determined from the intercepts of the straight lines in Fig. 4 P_∞ was calculated from eq. 17.

$$[17] \qquad P_\infty = \frac{XP_{x_0} + YP_{y_0} + ZP_{z_0}}{X + Y + Z}$$

where P_{x_0} was the initial isotopic ratio in the thiosulfate at the start of the experiment and P_{y_0} and P_{x_0} are isotopic ratios for naturally occurring sulfite and water. The equations for variation of P_x and P_y as a function of time under our experimental conditions become

$$[18] \quad P_x = 0.0042 + 0.0065\, e^{-0.0194t} + 0.0106\, e^{-0.00184t}$$

$$[19] \quad P_y = 0.0042 - 0.0060\, e^{-0.0194t} + 0.0082\, e^{-0.00184t}$$

Values of λ and t are in consistent units of min^{-1} and min, respectively.

In Fig. 3 the open circles represent experimental values whereas the solid lines are drawn from eqs. 18 and 19. The fit is very satisfactory.

From the average values of λ_1 and λ_2 determined in Fig. 4 and given above, R_1 and R_2 can be calculated from eqs. 20 and 21

$$[20] \qquad \lambda_1 + \lambda_2 = \frac{R_1}{X} + \frac{R_1}{Y} + \frac{R_2}{Y} + \frac{R_2}{Z}$$

and

$$[21] \qquad \lambda_1\lambda_2 = R_1R_2\,\frac{X + Y + Z}{XYZ}$$

from which $R_1 = 2.13 \times 10^{-4}$ g-atoms oxygen $l^{-1}\ s^{-1}$ and $R_2 = 1.00 \times 10^{-4}$ g-atoms oxygen $l^{-1}\ s^{-1}$. From this value of R_1, k_1 (eq. 14) has been calculated as 2.82×10^{-4} l $\text{mole}^{-1}\ s^{-1}$ which agrees with the values in Table 1 for similar thiosulfate and sulfite concentrations.

The value of R_2 (the rate of the sulfite–water exchange) derived in this analysis is not directly comparable to the data for this quantity from

ref. 3 because of the large differences in the experimental conditions (ionic strength, sulfite concentration) between the two sets of results. Our best estimate of R_2 from ref. 3, extrapolated to the present conditions, is $\sim 1.4 \times 10^{-5}$ g-atom oxygen l^{-1} s^{-1}, in not unreasonable agreement with the value reported above.

Case 4

In the acid region (pH < 4) thiosulfate by itself becomes increasingly unstable (14). However, in the presence of sulfite which in this pH region is mainly in the forms bisulfite and sulfurous acid (sulfur dioxide), the thiosulfate is stabilized and no sulfur appears even after several hours. In the absence of sulfite, precipitation of sulfur occurs within seconds. The unexpected stability of the thiosulfate in this acid medium may be related to the process

$$[22] \quad H^+ + HSO_3^- + S_2O_3^{2-} \rightleftharpoons SO_2 \cdot S_2O_3^{2-} + H_2O$$

Spectroscopic evidence for the complex $SO_2 \cdot S_2O_3^{2-}$ has been found by Battaglia and Miller (15). Addition of thiosulfate to sulfite in a sufficiently acid medium produces a yellow color in the solution and this is thought to be due to the molecular complex shown in eq. 22.

The rate of oxygen atom transfer between thiosulfate and water is clearly accelerated at low pH, as is shown by run No. 18 in Table 1 made at a pH of 2.75. The value of k_1 is 6.46×10^{-4} l m^{-1} s^{-1} and this is 3 times greater than for equivalent runs at higher pH. This acceleration at low pH may be due to direct exchange between thiosulfate and water; Pryor and Tonellato (2) indicate that this process is accelerated by a decrease in pH. Alternatively, the sulfur atom transfer process may show some slight dependence on pH; the work of Ames and Willard (1) did not go below pH 4.5. Also thiosulfate may decompose and the sulfur produced may react with the sulfite thus producing thiosulfate with an ^{18}O isotopic ratio equal to that of the water with which the sulfite is in equilibrium. Radioactive sulfur exchange measurements between sulfite and thiosulfate in acid medium are required to check for the presence of the latter processes.

Conclusion

Evidently the sulfur atom transfer process of Ames and Willard (1) has an important role in the kinetics of oxygen transfer between thiosulfate and sulfite. The subsequent oxygen transfer from sulfite to water then occurs, depending on the pH of the system. The kinetics of the overall process are as predicted from independent studies of the two separate systems. Because of the differing kinetic orders of the two parts of the system, with respect to $[H^+]$, the overall kinetics can be varied at will. At each end of the pH range, the usual first order kinetics of simple isotopic exchange reactions is observed, while in the mid-region, one has two consecutive processes occurring at not dissimilar rates. This leads to the reversible consecutive first order behavior illustrated in Figs. 3 and 4.

We are unable to state with precision the exact reason for the disagreement between this work and that in ref. 2, inasmuch as there are some numerical inconsistencies in the earlier work. We would suggest, however, that the conditions chosen there (low concentration of sulfite relative to thiosulfate) were not such as to allow the S atom transfer process to be clearly identified in the presence of the concurrent direct exchange of oxygen between water and thiosulfate.

The Radiolysis of Gaseous DCl[1,2]

D. K. JARDINE AND D. A. ARMSTRONG

AND

A. W. BOYD AND C. WILLIS
Physical Chemistry Branch, Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario

Received August 26, 1970

The value of $G(D_2)$ from the radiolysis of gaseous DCl is 7.4 ± 0.3 at dose rates of 10^{15} and 10^{27} eV g^{-1} s^{-1}. The yield of hydrogen (D_2, H_2, or HD) from electron reactions and the unscavengeable yield are, within experimental error, the same as in HCl. However, fewer thermal hydrogen atoms are formed in primary processes and a greater proportion of the electrons produce clustered negative ions ($(DCl)^-_{(c)}$) than in HCl. The magnitude of $k_{D+DCl}/k_{D+Cl_2} = 2.9 \times 10^{-3}$ at 288 °K is a factor of three smaller than k_{H+HCl}/k_{H+Cl_2} at the same temperature.

Introduction

The effects of isotopic substitution on the primary radiolysis yields and on the ion and radical reactions are of considerable interest. For studying these effects the system used should be one in which the fundamental radiolytic processes are well known and understood. Gaseous hydrogen chloride is such a system. The use of SF_6 and chlorine as scavengers for electrons and hydrogen atoms has led to determinations of the yields of these species and to the mechanism for radiolysis (1). Both the yields and the mechanism have been confirmed by irradiations at very high dose rates (2).

This paper is a report of the experimental values for the yields of electrons and thermal deuterium atoms obtained in the radiolysis of DCl with the above scavengers using both high and low dose rates. The significance of these yields with respect to the primary processes occurring in DCl and HCl are not discussed in the present paper but will be presented in a subsequent publication.

Experimental

The apparatus and techniques were the same as those previously described. The Febetron 705 pulsed electron accelerator at Chalk River Nuclear Laboratories was used for the high dose rate irradiations (2). Dosimetry was based on the nitrogen yields from N_2O with $G(N_2)$ taken as 12.4 (3). The dose in DCl was calculated from the ratio of electron stopping powers of DCl and N_2O. Low dose rate irradiations were carried out with a 120 kVp Phillips X-ray machine at the University of Calgary as in the earlier work with HCl (1). In this case dosimetry was based on the hydrogen yields from HCl. The dose rate per mole in DCl was taken as identical to that in HCl under the same conditions.

The deuterium chloride was guaranteed 99% minimum purity as supplied by Merck, Sharp and Dohme of Montreal. It was preirradiated and sublimed at −125 °C before use. All irradiation cells and vacuum lines were treated with DCl for at least 24 h prior to the radiolysis experiments. The Cl_2 and SF_6 were freed of permanent gases before use.

The isotopic composition of the product gas from the Febetron irradiations was determined with a C.E.C. 21-610 mass spectrometer. It averaged 93 ± 3% deuterium. Radiolysis of a 50:50 mixture of HCl and DCl indicated an enrichment by a factor of two in the H content of the product hydrogen (*i.e.* D_2, H_2, or HD). Hence it appears that the DCl content of the starting material is in the range 95 to 98% and there is no significant contamination of the DCl. The doses in the Febetron irradiations were 1.6 Mrads, in the X-ray irradiations 1–20 krads.

Results

Radiolysis in the Absence of Scavengers

Four determinations of the hydrogen yield from the X-radiolysis of DCl at ~600 Torr were made at 273 and 296 °K. The mean value, which is taken as $G(D_2)$, was 7.4 ± 0.2. The mean value of 12 determinations in the Febetron radiolysis at 288 °K and 1200 Torr was 7.5 ± 0.4. As in the radiolysis of HCl (2) the hydrogen yield is unaffected by the change from the X-ray dose rate (~10^{15} eV g^{-1} s^{-1}) to the much larger Febetron dose rate (~10^{27} eV g^{-1} s^{-1}).

[1]AECL No. 3754.

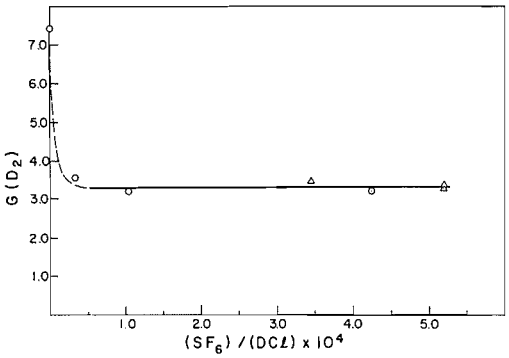

FIG. 1. The effect of SF_6 on the yield of D_2 in the radiolysis of DCl. ○, Febetron radiolysis at 10^{27} eV g^{-1} s^{-1}, 1200 Torr, and 290 ± 3 °K. △, X-radiolysis at 10^{15} eV g^{-1} s^{-1}, 600 Torr, and 290 ± 3 °K.

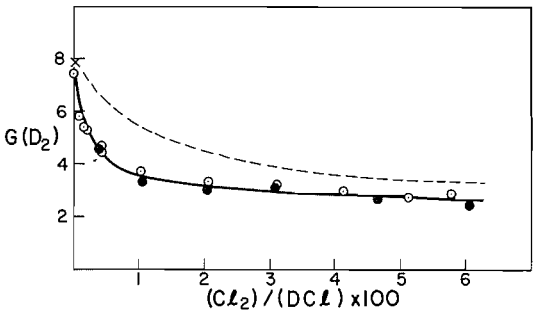

FIG. 2. The effect of Cl_2 on the yield of D_2 in the Febetron radiolysis of DCl at 1200 Torr and 288 °K. ○, 10^{27} eV g^{-1} s^{-1}; ⊙, 5×10^{26} eV g^{-1} s^{-1}; ---, results with HCl (2).

Effect of SF_6

Figure 1 shows the plateau yield obtained in the presence of SF_6. Values are included for irradiations at both high and low dose rates. The net reduction in $G(D_2)$ is 4.1. Within the experimental error of ±0.2 molecule per 100 eV, this is equal to the value of $G_{ionization} = G_e = 4.0 \pm 0.1$ calculated from W for DCl. The latter quantity is identical to W for HCl (= 25.0 ± 0.4 eV (4)).

Effects of Chlorine

The effects of chlorine were studied under three different sets of conditions: (*a*) Febetron radiolysis at 288 °K, (*b*) X-radiolysis at 273 °K, and (*c*) X-radiolysis at 196 °K. The results are presented in Figs. 2, 3, and 4, respectively. The dashed lines show the effects of Cl_2 in HCl under similar conditions. Comparative data for the radiolysis of HCl are included (1, 2). The G values for $(Cl_2)/(DCl)$ ratios below 3×10^{-5} at 196 °K were obtained from the slopes of hydrogen concentration *vs.* dose plots for the radiolysis of DCl, which initially contained no chlorine. These G values are shown on the left hand side of Fig. 4, which has an expanded scale. The other data on this figure and the values in Figs. 2 and 3 were derived by irradiating synthetic mixtures of Cl_2 and DCl.

Discussion

Previous studies (1, 2, 5) have shown that the important primary reactions in irradiated gaseous HCl are as follows

[1] $$HCl \rightsquigarrow HCl^+ + e \qquad (G_{ionization} = 4.0 \pm 0.1 = G_e)$$

[2] $$HCl^+ + HCl \rightarrow H_2Cl^+ + Cl$$

[3] $$e + HCl \xrightarrow{[3b]} (HCl)^-_{(c)} \xrightarrow{[6]} H \text{ (or } H_2 \text{ directly)} \quad (G(HCl)^-_{(c)} = 2.5)$$
$$e + HCl \xrightarrow{[3c]} H \quad (G_\beta = 1.5) \quad (G_\gamma = 1.8) \quad G_{\beta+\gamma} = 3.3$$
$$G_{H'} = 5.8 \pm 0.2 \quad (= \text{Total scavengeable yield of } H_2) = G_e + G_\gamma$$

[4] $$HCl \rightsquigarrow Cl + H$$

[5] $$HCl \rightsquigarrow Cl + H \qquad G_{H''} = 2.2 \pm 0.2 \ (= \text{Unscavengeable yield of } H_2)$$

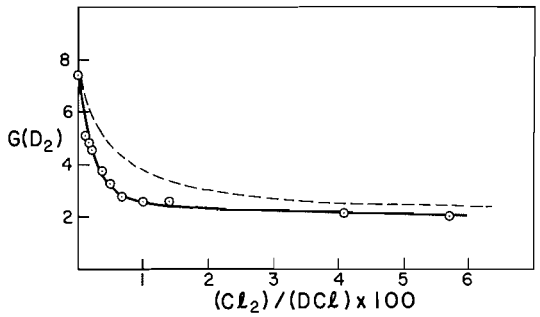

FIG. 3. The effect of Cl_2 on the yield of D_2 in the X-radiolysis of DCl at 600 Torr and 273 °K. Dose Rate 10^{15} eV g^{-1} s^{-1}. ---, results with HCl (1).

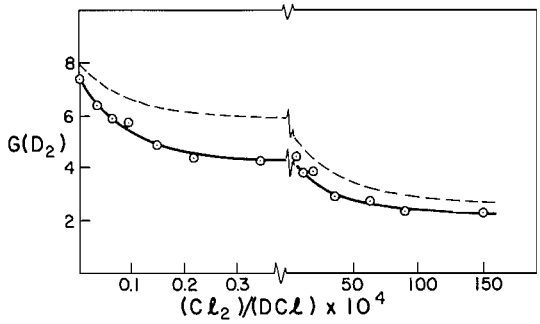

FIG. 4. The effect of Cl_2 on the yield of D_2 in the X-radiolysis of DCl at 400 Torr and 196 °K. Dose rate 10^{15} eV g^{-1} s^{-1}. ---, results with HCl (1).

Reactions 4 and 5 are dissociative excitation giving either thermal hydrogen atoms or unscavengeable (hot) hydrogen atoms (H). All the unscavengeable hydrogen atoms result from [5] with a yield of $G_{H''} = 2.2 \pm 0.2$ but reaction 4 contributes only part, *i.e.*, $G_\gamma = 1.8$, of the total thermal hydrogen atom yield.

The ionic reactions are complex. The capture of thermal electrons (reaction 3) can be explained in terms of the following reactions (5, 6)[3]

$$[3a] \qquad e + 2\,HCl \rightleftarrows (HCl)_2^{-*}$$

$$[3b] \qquad (HCl)_2^{-*} + HCl \rightarrow (HCl)_2^{-} + HCl$$

$$[3c] \qquad (HCl)_2^{-*} + HCl \rightarrow H + Cl^- \cdot 2HCl$$

On the basis of high pressure mass spectral data for ions in other polar gases, it has been assumed that H_2Cl^+, Cl^-, and $(HCl)_2^-$ all become clustered. This is indicated by the subscript (c). The clustered $(HCl)_2^-$ ion, *i.e.* $(HCl)^-_{(c)}$ has a lifetime $> 2 \times 10^{-7}$ s with respect to reaction 6 (2)

$$[6] \qquad (HCl)^-_{(c)} \rightarrow H + HCl_2^-{}_{(c)} \text{ or } H_2 + Cl_2^-{}_{(c)}$$

at room temperature, so this reaction occurs at the X-ray dose rate where the mean ion combination lifetime is ~ 10 ms. As shown, its yield is $G(HCl)^-_{(c)} = 2.5$. At the Febetron dose rate the ion combination lifetime is less than 10 ns (2). Chemical evidence (2) shows that under these conditions $(HCl)^-_{(c)}$ forms thermal H atoms in reaction 7

$$[7] \qquad H_2Cl^+_{(c)} + (HCl)^-_{(c)} \rightarrow H + xHCl$$

In the absence of hydrogen atom scavengers all thermal hydrogen atoms, H, undergo reaction 8

$$[8] \qquad H + HCl \rightarrow H_2 + Cl$$

leading to a total hydrogen yield of $G(H_2) = G(HCl)^-_c + G_\beta + G_\gamma + G_{H''} = 2.5 + 1.5 + 1.8 + 2.2 = 8.0 \pm 0.3$. The yield $G_{H''}$ of unscavengeable hydrogen has been attributed to reactions of hot hydrogen atoms, H, formed in reaction 5. Molecular chlorine is produced in reaction 9

$$[9] \qquad Cl + Cl + M \rightarrow Cl_2 + M$$

In the remainder of this paper DCl reactions are indicated by inserting D after the number of the corresponding HCl reaction.

Effect of SF_6

The net reduction in $G(D_2)$ caused by SF_6 is equal to G_e and is the same as the reduction of $G(H_2)$ from HCl (4.0 ± 0.1 molecules per 100 eV). Thus it is clear that in both systems the net stoichiometry *one electron → one molecule of hydrogen* is maintained.

Effects of Chlorine

Figure 5 shows a reciprocal plot of the data from the chlorine experiments in the Febetron radiolysis at 288 °K based on a competition between Cl_2 and DCl for the scavengeable hydrogen forming species. The total yield of these, $G_{D'}$, given by the intercept of the reciprocal plot is 5.0.

Subtraction from the total Febetron yield $G(D_2) = 7.5$ gives a value of 2.5 for the unscavengeable yield, $G_{D''}$. The values of $G_{D''}$ derived from the high chlorine concentrations in Figs. 3 and 4 are 2.0 and 2.2, respectively, for

[3] * denotes an undeactivated complex.

TABLE 1. Radiolysis yields from DCl and HCl

	DCl	HCl
G(total product)	7.4	8.0
$G_{\text{Ionization}} = G_e$ (from W)	4.0	4.0
Product yield from electrons	4.1	4.0
Total scavengeable yield	$G_{D'} = 5.2$	$G_{H'} = 5.8$
Unscavengeable yield	$G_{D''} = 2.2$	$G_{H''} = 2.2$
Yield of scavengeable negative ion	$G_{(DCl)_{(c)}^-} = 3.1$	$G_{(HCl)_{(c)}^-} = 2.5$
Yield of thermal H atoms		
(*a*) From reaction 3*c*	$G_{\beta D} = 0.9$	$G_{\beta} = 1.5$
(*b*) From reaction 4	$G_{\gamma D} = 1.2$	$G_{\gamma} = 1.8$
Rate constant ratios	$(k_{D+DCl}/k_{D+Cl_2})_{290\ °K} = 2.9 \times 10^{-3}$	$(k_{H+HCl}/k_{H+Cl_2})_{290\ °K} = 1.07 \times 10^{-2}$
	$(k_{3bD}/k_{3cD})_{196\ °K} = 3.4$	$(k_{3b}/k_{3c})_{196\ °K} = 1.7$
	$(k_{6D}/k_{11D})_{196\ °K} = 6 \times 10^{-5}$	$(k_6/k_{11})_{196\ °K} = 8 \times 10^{-5}$

*G_e has an uncertainty of ± 0.1 per 100 eV. All other yields have a relative uncertainty of 0.2 per 100 eV.

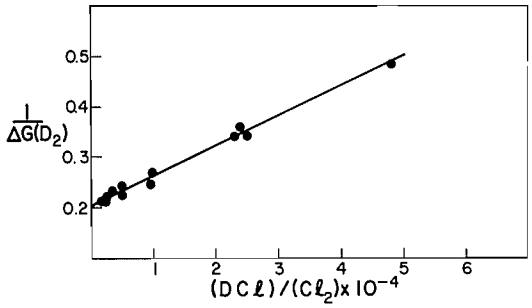

FIG. 5. Reciprocal plot of the reduction in the D_2 yield in DCl–Cl_2 mixtures at a dose rate of 10^{27} eV g^{-1} s^{-1} at 288 °K.

X-irradiations, where the total yield $G(D_2) = 7.4$. From the three results we take $G_{D''} = 2.2$ and $G_{D'} = 5.2$, each with an uncertainty of ± 0.3. $G_{\gamma D}$ can be derived from the yield $G_{D'}$ $(= G_e + G_{\gamma D})$ giving $G_{\gamma D} = 1.2$. These yields are compared with the corresponding yields for HCl in Table 1.

If it is assumed that in the Febetron irradiations chlorine and DCl are competing only for thermal D atoms, *viz.*

[8D] $\quad D + DCl \rightarrow D_2 + Cl$

[10D] $\quad D + Cl_2 \rightarrow DCl + Cl$

then k_{8D}/k_{10D} can be shown from the slope and intercept of the reciprocal plot in Fig. 5 to be 2.9×10^{-3} at 288 °K. This is in excellent agreement with $2.8_7 \times 10^{-3}$ calculated from the expression

$$\frac{k_{D+DCl}}{k_{D+Cl_2}} = \frac{1}{12.9} \exp\left(-\frac{1887 \text{ cal mol}^{-1}}{RT}\right)$$

This expression was derived by Wood and White (7) from the experimentally determined temperature dependence of k_{H+HCl}/k_{H+Cl_2}, using transition state theory. It is not likely to be seriously in error, and the good agreement provides strong evidence that at Febetron dose rates chlorine scavenges only thermal D atoms. This observation parallels that for HCl (2). It means that under Febetron conditions all electrons form thermal deuterium atoms and is taken as evidence for reaction 7D

[7D] $\quad D_2Cl^+_{(c)} + (DCl)^-_{(c)} \rightarrow D + x DCl$

The total yield of thermal D atoms $G_{D'}$ is thus equal to G_e plus the yield of thermal deuterium atoms $G_{\gamma D}$ formed directly in reaction 4D. The yield of the latter, 1.2, is significantly less than $G_{\gamma} = 1.8$ in HCl. This is in fact the main source of the difference in total product yields between the two gases, and it will be considered in a later paper on primary processes.

The results in Fig. 4 show that the scavenging of chlorine in the X-radiolysis at 196 °K is composite as was the case for HCl (1) under these conditions. The initial reduction to a plateau at $G(D_2) = 4.3$ is attributed to the scavenging of the negative ion $(DCl)^-_{(c)}$ formed in DCl reactions which are analogous to [3*a*] and [3*b*].

[3*a*D] $\quad e + 2DCl \rightarrow (DCl)_2^-{}^*$

[3*b*D] $\quad (DCl)_2^-{}^* + DCl \rightarrow (DCl)_2^- + DCl$

As in HCl this postulated intermediate must either form product

[6D] $\quad (DCl)^-_{(c)} \rightarrow D + (DCl_2)^-_{(c)}$ or $D_2 + Cl_2^-{}_{(c)}$

$\quad\quad + DCl \downarrow$

$\quad\quad D_2$

or can be scavenged by chlorine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[11D] $(DCl)^-_{(c)} + Cl_2 \rightarrow Cl_2^-{}_{(c)}$ or $Cl + Cl^-_{(c)}$

A competition treatment of the data in the left hand side of Fig. 4 gives $k_{6D}/k_{11D} \sim 6 \times 10^{-5}$ at 196 °K as opposed to 8×10^{-5} for k_6/k_{11} at the same temperature

[11] $(HCl)^-_{(c)} + Cl_2 \rightarrow Cl_2^-{}_{(c)}$ or $Cl + Cl^-_{(c)}$

The yield of $(DCl)^-_{(c)}$, 3.1, is the total hydrogen yield less the yield of 4.3 from the first plateau of Fig. 4. This is larger than the yield of $(HCl)^-_{(c)}$, 2.5. The fact that isotopic substitution favors reaction 3*b* over 3*c* is probably due to the greater strength of the DCl bond, which has to be broken in forming Cl^- ($D_{DCl} = 103$ kcal mole^{-1} *vs.* $D_{HCl} = 102$ kcal mole^{-1} (8)), thus slowing down [3*c*].

The results for chlorine at 273 °K do not clearly fall into two distinct scavenging regions, but they cannot be interpreted purely in terms of a competition for D atoms. An analysis of the kind conducted for HCl (1) was not attempted. However, the data do indicate a value of about 10^{-3} for k_{6D}/k_{11D} at this temperature. Hence, k_{6D}, like k_6, must have an activation energy of ~ 5 kcal mole^{-1} (1).

The Electronic Spectra of Tetragonal Chromium(III) Complexes

M. KEETON, B. FA-CHUN CHOU, AND A. B. P. LEVER
The Department of Chemistry, York University, Downsview, Ontario

Received April 30, 1970

Methods for processing the electronic spectra of tetragonal chromium(III) complexes are briefly reviewed. New criteria for assigning the spectra of these complexes are introduced and the data processed to yield a series of crystal field and molecular orbital parameters. The validity of these are discussed with particular reference to the apparent π bond contribution in the chromium ligand bonds. It is concluded that the bonding is better described in ionic rather than covalent terms.

Introduction

There has been considerable interest recently (1–9) in the study of the electronic spectra of tetragonal complexes with a $^{n}B_{1g}$ (in D_{4h}) ground term, ($^{n}A_{2g}$ in O_h). In particular, studies have been made of a wide series of chromium(III) (1–6) and nickel(II) (1, 7–9) complexes. This paper concerns itself primarily with the methods available to interpret the spectra of tetragonal chromium(III) complexes in terms of chemically useful parameters.

Calculation

Three basic approaches are available.

(*i*) Crystal field theory (2) which parametrizes the data in terms of the radial integrals *Dq*, *Ds*, and *Dt* and the interelectronic repulsion parameter *B*(2). *Dq* may be further factored into the in-plane crystal field strength Dq_{xy} and the out-of-plane, or axial, field strength Dq_z. This is a four variable approach and there are generally four observable d–d transitions, thus a complete solution is possible but cannot be readily checked. Knowledge of the in-plane and out-of-plane field strengths is very convenient (1).

(*ii*) A strong field approach which parametrizes the data in terms of the one electron energy separation of the d orbitals (1). This is also a four parameter theory, *viz.* Δ_1 = splitting of the t_{2g} level, Δ_2 = separation of the d_{xy} and $d_{x^2-y^2}$ orbitals (also equal to $10Dq_{xy}$), and Δ_3 = splitting of the e_g level, and the repulsion parameter *B*.

Approaches (*i*) and (*ii*) may be directly related by the relationships already published (1), but are not strictly homomorphous because there are constraints placed upon the values of the radial integrals by the crystal field theory, whilst no such constraints are placed upon the one electron splitting energies.

(*iii*) Various semi-empirical molecular orbital approaches have been applied. Some years ago McClure (10) discussed the splitting of the octahedral d levels by the distortion in terms of the parameters dσ and dπ, describing the differences in the σ and π bonding of the ligands, respectively. More recently the orbital angular overlap model (11–16) has been tentatively applied (1) to these systems. This treatment utilizes five parameters, $e_{\sigma L}'$, $e_{\pi L}'$, $e_{\sigma Z}'$, $e_{\pi Z}'$, and *B* (for a complex with ligands L and Z). This is inconvenient when there are only four observables, unless one of these parameters may be set to zero (as can frequently occur) or can be independently determined. These overlap parameters are directly related to the McClure parameters by the equations (1)

$$d\sigma = (3/4)(e_{\sigma Z}' - e_{\sigma L}') \text{ and } d\pi = e_{\pi Z}' - e_{\pi L}'$$

If these parameters are chemically significant, they can provide valuable insight into the nature of the chemical bond in these non-cubic systems. Further sophistication is possible, *e.g.* *B* could be factored into B_{xy} and B_z, but in the absence of further independent data, such an analysis would not be profitable.

Given an assignment of the spectrum, any or all of the above parameters may generally be determined. However, an unambiguous assignment is rarely possible. Several approaches to the problem of assignment have been made.

Four transitions are generally observed, arising from the lifting of the degeneracy of the orbital triplets (in octahedral symmetry), *viz.*

$$\nu_1\ {}^4E_g^a \leftarrow {}^4B_{1g}$$
$$\nu_2\ {}^4B_{2g} \leftarrow {}^4B_{1g}$$
$$\nu_3\ {}^4E_g^b \leftarrow {}^4B_{1g}$$
$$\nu_4\ {}^4A_{2g}^a \leftarrow {}^4B_{1g}$$

where the numerals 1–4 do not necessarily imply

order of increasing energy. ν_1 and ν_2 derive from the $^4T_{2g}$ level in O_h symmetry, whilst ν_3 and ν_4 derive from $^4T_{1g}$(F). Transitions to the components $^4E_g{}^c$ and $^4A_{2g}{}^b$ derived from $^4T_{1g}$(P) occur at much higher energies (around 40 000 – 45 000 cm^{-1}) and are rarely observed.

The transition ν_2 is equal to $10Dq_{xy}$ and is approximately constant in a series of complexes CrL_4Z_2 when L is kept constant and Z is varied. It can, therefore, be easily identified in the spectrum. The separation between ν_1 and ν_2 is, to first order, $35/4Dt$ and Dt is related to the in-plane and out-of-plane field strengths via (17)

$$[1] \qquad Dt = (4/7)(Dq_{xy} - Dq_z)$$

Since the first order energy of ν_1 is $10Dq - (35/4)Dt$, and the sign of Dt is generally identifiable through expression 1, assignment of ν_1 to the band on the low or high energy side of ν_2 (according to whether the in-plane field is greater than or less than the out-of-plane field strength, respectively) is generally unambiguous. The inclusion of off-diagonal terms into the energy through configurational interaction between the various E_g levels will very rarely invert this sequence (2). Thus we are left with a decision regarding assignment of the two high energy bands to $A_{2g}{}^a$ and $E_g{}^b$.

A number of approaches to this problem have been proposed. Perumareddi (2) generally requires that k ($= Ds/Dt$) is positive although he points out that negative values of k cannot be ruled out. Positive values of k lead to the energy order $^4E_g{}^b > {}^4A_{2g}{}^a$ (if Dt is positive which is the case for all compounds under consideration here). There is no theoretically justifiable reason to assume that k is always positive, and indeed, negative values have now been unambiguously observed (5, 6). Dubicki and Martin (4) deduce the signs of $d\sigma$ and $d\pi$ through consideration of the chemical nature of the ligands concerned, and thereby can in most, but not all, cases, arrive at an unambiguous assignment.

Here we do not put any constraints on the signs of the parameters (except perhaps for Dt, whose sign is almost invariably unequivocal) but merely require that the parameters obtained for a series of closely related complexes be internally consistent. Thus the calculations are carried out for both possible assignments and the results compared for consistency.

Ideally single crystal polarized spectra or magnetic circular dichroism spectra should be obtained to unequivocally identify the transitions. In fact two polarized light studies have been reported (5, 18) and these provide a firm basis for the final assignments.

A first order calculation ignoring any configurational interaction between the E_g or between the A_{2g} states has been shown to be inadequate, yielding misleading results for most parameters (1). Earlier (1) we had proposed including configurational interaction between the two lowest E_g levels ($E_g{}^a$ and $E_g{}^b$) but ignoring interaction with $E_g{}^c$, (and also ignoring the interaction of $A_{2g}{}^a$ with $A_{2g}{}^b$) since these were felt to be of too high an energy to interfere. Comparison of those results with the data reported here utilizing the secular determinants (1, 2), which take into account all configurational interaction within the E_g and A_{2g} sets, reveals that this last approximation is also inadequate for most parameters. It is sufficient to evaluate Dq_z very accurately, but provides misleading values of most other parameters and in particular grossly underestimates B. Thus all the data reported here are derived from the complete configuration interaction matrices.

A computer program was written to solve the matrices for all the parameters (using the interrelationships previously reported (1)) for both possible assignments, I, $E_g{}^b > A_{2g}{}^a$, II, $E_g{}^b < A_{2g}{}^a$. The final parameters were used to recalculate the input energies and the difference between the input and output energies printed as a measure of the exactness of the fit. In virtually all cases a perfect fit was achievable. *A good fit cannot be taken as evidence of a correct assignment.*

In order to distinguish one assignment from the other, a parameter is needed which is sensitive to the choice of assignment, and for whose value and sign we have a chemically intuitive grasp. The parameter $d\pi$, and $e_{\pi L}{}'$ derived therefrom, fulfils these criteria. In order to use the five-parameter theory with only four observables, we have written $e_{\pi en}{}'$ and $e_{\pi NH_3}{}'$ as zero, since the amines do not possess any orbitals capable of a π interaction with the chromium ion.

Table 1 lists the orbital angular overlap parameters $e_{\sigma L}{}'$ and $e_{\pi L}{}'$ calculated via both assignments for the complexes under discussion. Since the assignments of the $Cren_2Cl_2{}^+$ and $Cren_2F_2{}^+$ spectra are known from single crystal polarized spectra (5, 18) these assignments (italicized in the table) are assumed to be correct and are used as the basis for discussion. Note that these

*Assumed assignments in italics are known to be correct from single crystal polarized spectra studies (5, 18).

complexes are assigned in the reverse sense to one another. Assignment I is preferred for the bromide complex since Br^- is expected to be a better π donor than the Cl^- ion, but should surely be more similar to the latter than to F^-. Moreover assignment II requires Br^- to be a better σ donor than Cl^- towards chromium(III), which in view of the hardness of this metal ion is not expected (4).

In the case of the hydroxyl complex, $Cren_2(OH)_2^+$, assignment I is immediately eliminated since it is inconceivable that the hydroxyl ion be a π acceptor to chromium(III) (negative $e_{\pi Z}'$), assignment II is therefore accepted; this implies that the hydroxyl group is a slightly better π donor towards chromium(III) than the bromide ion, which is not too unreasonable (but see below). Assignment II then follows for the aquo complex $Cren_2(H_2O)_2^{3+}$, since the π characteristics of H_2O and OH (in view of polarization by the Cr(III) ion) are surely not so disparate that assignment I could be accepted. Assignment II for the $Cr(NH_3)_4F_2^+$ species follows by comparison with the ethylenediamine fluoride complex. The reverse assignment yields a negative value for $e_{\pi F}'$ inconsistent with the ethylenediamine fluoride data.

In the case of the aquo-fluoride, none of the orbital angular overlap parameters can be written as zero, so one must be assumed. We arbitrarily choose to assume that $e_{\pi(H_2O)}' = 1370$ cm^{-1} as derived above (Table 1). The parameters derived from assignment II are then more consistent with previous data than those from assignment I (this predicts very low values for both e_F' parameters). Note that had assignment I for $Cren_2(H_2O)_2^{3+}$ been accepted and the much lower value of $e_{\pi(H_2O)}'$ been used in the case of the aquo-fluoride, both assignments would give inconsistent and low values of the e_F' parameters. Additional support for the correctness of assignment II for the aquo-fluoride follows from the observation of a band near 37 000 cm^{-1} in its spectrum (19). Assignment II predicts (Table 3) the components of the $^4T_{1g}$(P) term (in O_h symmetry) to lie near 37 000 cm^{-1}, whilst assignment I predicts them to lie above 38 000 cm^{-1}.

Comparison of our assignments with those of Dubicki and Martin (4), who, as indicated above, used different criteria for assignment, show agreement for the assignments of $Cren_2Cl_2^+$, $Cren_2F_2^+$, and $Cr(H_2O)_4F_2^+$. Their treatment, however, failed to unequivocally assign the spectra of $Cren_2Br_2^+$ and $Cren_2(H_2O)_2^{3+}$. There is also agreement with the previous assignment (6) for $Cr(NH_3)_4F_2^+$. The assignments quoted here supersede those presented earlier (1) which are, in part, in error.

The parameters calculated from the data (Table 2) assuming these assignments are shown in Table 3.

*The data were obtained from the references indicated. The energies for the $^4A_{2g}{}^b$ and $^4E_g{}^c$ transitions, indicated in italics, are calculated from the parameters in Table 2. They are generally too high in energy to be observed. Note however that $Cr(H_2O)_4F_2{}^+$ does (19) have a band at 37 000 cm^{-1} in agreement with calculation. The parameters in Table 3 fit these transition energies exactly.
†This band was not observed. We assume it on the basis that the crystal field strength of water in $Cr(H_2O)_6{}^{3+}$ is 1740 cm^{-1}.

Before discussing these results and their chemical significance, it is worth considering the probable errors which may be present in these parameter values.

In utilizing the equations for this system one makes the implicit assumption that the band energies employed represent electronic transition energies. In fact they are known to be vibronic in origin. In consequence the actual electronic energies will differ from observed energies by the vibrational component; in addition the neglect of spin–orbit coupling will cause additional error. Moreover, the bands are not always sharp so that estimation of the true band energy from the experimental spectrum may involve some error (which, however, may be minimized by use of low temperature data). These errors will influence the values of the final parameters and in order to estimate these errors a calculation of the data for $Cren_2Cl_2{}^+$ was made in which all the input energies were allowed to vary, individually, or in concert, by ± 200 cm^{-1}. The following data ensued from the 81 resulting calculations: *Ds*, 175–333, mean 254 cm^{-1}; *Dt*, 461–553, mean 509; $e_{\sigma Cl}{}'$, 5341–5761, mean 5556; $e_{\sigma en}{}'$, 7277–7400, mean 7339; $d\pi$, 660–1105, mean 891; $d\sigma$, -1147–-1509, mean -1334; Dq_z, 1252–1372, mean 1310; *B*, 619–726, mean 670; Δ_1, -1320–-2205, mean -1780; Δ_3, 3059–4024, mean 3557, cm^{-1}.

In the case of $d\pi$ the two extreme values, 660 and 1105 cm^{-1}, were isolated solutions, the other 79 roots lying within 19% of the mean.

These results, and similar data with other sets of input energies, suggest that the smaller parameters may be in error by some 10%, perhaps more in the case of *Ds* and $d\pi(\Delta_1)$ and any parameters with very small values. The larger molecular orbital parameters may be in error by several hundred wavenumbers, but this only represents an error of some 5%. The confidence in a given parameter value may be improved by consideration of a series of related complexes and by measurement of a given complex in different physical states. Where possible this is done here. Of course error is undoubtedly introduced by the simplicity of the basic assumptions made for this treatment (*e.g.* exclusion of overlap with the ligands) and the absolute value of any parameter should not be regarded too seriously. However, it may be hoped that the relative variations in a parameter from one ligand to another do have real chemical significance.

Bearing this in mind, the variation of the parameter $e_{\pi L}{}'$ may be written

[2] $\quad en < Cl^- \leqslant Br^- < OH^- \simeq H_2O < F^-$

and the variation in $e_{\sigma L}{}'$

[3] $\quad Br^- \simeq Cl^- < en \simeq H_2O \simeq OH^- < F^-$

These series are similar to those presented by Glerup and Schäffer (6) except that they find that OH^- and F^- are interchanged in both series. These authors based their series on the spectra of the complexes $Cr(NH_3)_4X_2{}^+$ but have not reported detailed calculations.

The internal consistency of the data is exemplified by noting that parameters obtained for a given ligand in one complex are essentially unaltered in other complexes with the same ligand, within the limits of the errors discussed above. For example, the value of Dq_z, which incidentally is comparatively insensitive to small errors in the input energies, for the fluoride ion is precisely the same in the three fluoro complexes studied.

It is evident that chromium(III) interacts much more strongly with oxygen ligands and the fluoride ion than it does with the amines or the heavier halogens. This indicates strong class *A*

*Assumed. The parameters are defined in the text. The parameters given here reproduce exactly the transition energies quoted in Table 3. Using an alternate source of data for the first two compounds (4) yields $e_{\pi F}' = 2159$ and $e_{\pi Cl}' = 740$ cm^{-1}. Δ_1 the splitting of the t_{2g} level (in O_h symmetry) is positive when the xz, yz pair of orbitals lies lower than xy. Δ_3 the splitting of the e_g level (in O_h symmetry) is positive when the z^2 orbital lies lower than $x^2 - y^2$. Note that the definition (1) of Ds and Dt differs in sign from the definitions used by some other authors (2, 4, 5). Assignment I, $^4E_g^b > {}^4A_{2g}^a$; II, $^4E_g^b < {}^4A_{2g}^a$.

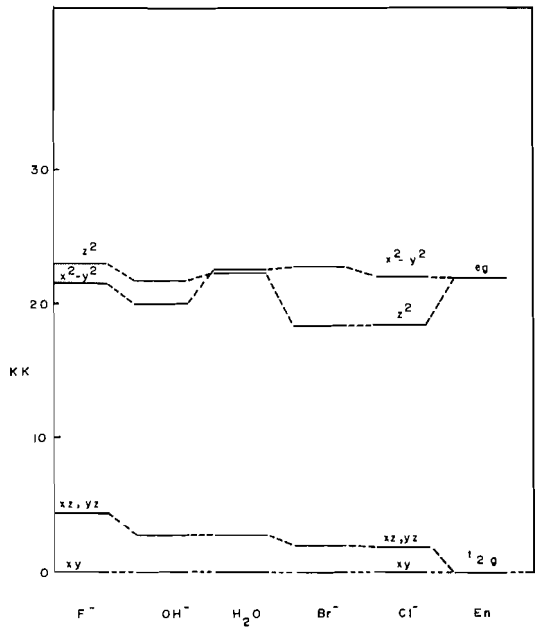

FIG. 1. One electron d orbital energy levels in the complexes $Cren_2X_2^{n+}$, where X = F, Cl, Br, OH, H_2O, or X_2 = en.

behavior for the ion as expected. The high position of the F^- ion in the σ bonding series should not, therefore, be too surprising. Its high position in the π bonding series is however puzzling at first sight.

To clarify this point a plot was made (Fig. 1) of the splitting of the $t_{2g}(\Delta_1)$ and $e_g(\Delta_3)$ levels (in O_h symmetry) by the tetragonal field. The splitting of the t_{2g} level arises purely as a consequence of the difference in π bond capability between the two ligands, whilst the splitting of the e_g set reflects the differences in σ bonding (1). The energy of the d_{xy} orbital was arbitrarily set at zero in all complexes since its energy, to first order, should be unaffected by changes in the axial ligand. It is clear from Fig. 1 there is a general trend that as the splitting of the t_{2g} level decreases (left to right) the splitting of the e_g level also decreases and changes sign in the center of the diagram. This diagram reinforces the view evident from the series 2 and 3 that the strongly σ bonding ligands are also the strongly π bonding ligands.

These data need not necessarily be interpreted in terms of a covalent metal–ligand interaction; indeed an ionic interaction seems more credible. If a ligand were bound strongly to the chromium atom through a covalent σ bond, its effective charge would be made so positive that it is unlikely it could simultaneously function as a good π donor. In other words transfer of charge to the chromium atom through a σ mechanism will inhibit transfer to charge *in the same direction* by a π mechanism. On the other hand this apparent behavior would be expected if the bonding is essentially ionic. Polarization of the ligand by the chromium(III) ion can take place leading to a splitting of the chromium d orbitals which could be described via crystal field theory. The ligand σ electrons and the ligand π electrons may each be considered to repel chromium d electrons (20). The latter would be less effective than the former since the distance of the ligand π orbitals from the origin (chromium atom) will be greater than for the ligand σ orbitals. In the tetragonal situation a splitting of the e_g and t_{2g} levels will occur as a consequence of the differences in the σ and π charge localizations in the two ligands. Such a description reproduces qualitatively the results presented here; indeed one can go further by predicting that the smallest ligand, F^-, will give the largest splitting of $\Delta_1(t_{2g})$ simply because it is closest to the metal. This is seen to be the case.

Thus although the semi-empirical molecular orbital parameters might infer that the fluoride ion, and to a lesser extent the hydroxyl ion and water, are involved in strong π bonding to the chromium atom, (5) this is probably not the case. The energy parameters are probably quite correct within the errors described above, but their interpretation must be treated with caution. These data have been used (6) to more quantitatively set up a two-dimensional spectrochemical series, first described by McClure (10), which would simultaneously demonstrate the σ and π characteristics of a given ligand. Whilst such a diagram can be physically constructed using dσ and dπ values (or Δ_1 and Δ_3 (6)), the conclusion from this work must be that these parameters do not necessarily infer anything about the extent of σ or π *covalent* interaction.

This is not to exclude the possibility of chromium(III) forming strong covalent bonds to a ligand. With perhaps the cyanide ion it may do so. Unfortunately a *trans* dicyanide chromium tetraammine complex has not yet been synthesized. The existence of *cis* dicyanide derivatives, however, may reflect the presence of covalent π bonding.

A recent comparison of the electron spin

resonance (e.s.r.) spectra of the CrF_6^{3-} and $Cr(CN)_6^{3-}$ ions (21) provides support for these studies by concluding that whilst both the CN and F ligands contribute π orbital density to the description of the molecular orbital primarily involving the metal t_{2g} orbitals, no overlap is necessary in the fluoride case to reproduce the e.s.r. parameters, whilst overlap is required in the case of cyanide. In other words the bonding is ionic. Similar conclusions have been reached in the e.s.r. studies of other fluoro complexes of the first row transition metals (20), where ionic π contributions have been apparent.

The data and sources thereof are given in Table 2. They were processed in part with an IBM 360/50 computer and in part by a CDC 6400 computer.

Method of Calculation

The data were analyzed by a program which processed them by the following general procedure. The energies were solved for *Dq*, *Ds*, *Dt*, and *B* using first order equations, *i.e.* neglecting configurational interaction. Since these are linear (1) the solutions are trivial. These first order parameters were then inserted back into the calculation and used to solve the secular determinants, inclusive of configurational interaction (22), for the transition energy roots. These roots were compared with the input transition energies, and an absolute standard deviation calculated. Each of the input parameters was then individually incremented and the calculation iterated to minimize the absolute standard deviation.

Given time and sufficiently small increments a perfect fit to the data could generally be obtained. This procedure was facilitated by the fact that it was not usually necessary to increment 10 *Dq* since it was a direct observable from the spectrum ($^4B_{2g} \leftarrow {}^4B_{1g}$ transition energy). Moreover the range of possible values for *B* is quite small (region 500–800 cm^{-1}). Other techniques for solution of the secular determinants were tried, but this appeared to be the most economic in computer time. This procedure is more reliable than a possibly shorter but more involved minimum seeking routine in that provided the increments in the parameters are small (*i.e.* less than 50 cm^{-1}) convergence into false minima is avoided.

The program which computed the errors in the parameters followed the same routine. However, in view of the very large number of calculations involved (81 for one set of input energies), the parameters were not iterated to a perfect fit. Instead the parameters were printed when the absolute standard deviation of output transition energies from the input energies was less than 100 cm^{-1}.

We are indebted to the National Research Council of Canada for financial assistance and to Dr. Bryan Hollebone for useful discussions.

La réaction des nitrilotriacétates métalliques avec la proline

J. Israeli et J. R. Cayouette
Département de Chimie, Université de Moncton, Moncton, New Brunswick

Reçu le 9 juillet 1970

On a calculé à partir des courbes de titrages pH métriques les constantes de formation des complexes mixtes resultant de la réaction des nitrilotriacétates métalliques avec la proline. Les constantes de formation des complexes mixtes suivent la série de Irving–Williams.

La réaction de formation des complexes mixtes est une réaction exothermique; on en a déterminé l'enthalpie et l'entropie. La grande diminution d'entropie qui accompagne la formation des complexes mixtes de cuivre(II) a été interpretée par l'effet Jahn–Teller.

Introduction

La réaction des nitrilotriacétates métalliques avec des coordinats bidentés a été observée pour la première fois dans ce laboratoire (1); nous avons également étudié d'une façon systématique la formation des complexes mixtes qui resultent de la réaction des nitrilotriacétates métalliques avec les acides aminés (2–4). Des études similaires ont été rapportées récemment par d'autres chercheurs (5–8).

Comme suite à nos recherches antérieures, nous avons étudié dans ce travail la réaction des nitrilotriacétates métalliques avec la proline, acide aminé contenant un groupement amine secondaire cyclisé. Petit-Ramel et Pâris (9, 10) a rapporté l'existence du cuivre(II) – glycinate-prolinate et il semble que ce soit le seul complexe mixte contenant la proline que l'on connaisse.

Partie expérimentale

Une force ionique de 0.1 M a été maintenue constante à l'aide du nitrate de potassium. Par conséquent toutes les constantes que nous utilisons dans ce travail sont des constantes de concentration et se rapportent à cette force ionique.

Le pH a été mesuré avec l'aide d'un pH mètre "Radiometer Model 26" qui a été calibré avec des solutions tampons ayant des pH connus à différentes températures. La concentration des protons a été calculé par la formule $a_{H^+} = C_{H^+} f$ et pour l'évaluation de f on a utilisé la formule de Davies (11).

Résultats

On a titré à l'aide de la soude un mélange équimoléculaire de nitrate métallique ($Me(NO_3)_2$) de nitrilotriacétate disodique (HX^{2-}) et de proline (LH). La Fig. 1 reproduit de titrages réalisés à une température de 25 °C.

Soit "a" le nombre de moles de soude ajouté par mole de métal. La Fig. 1 montre l'existence

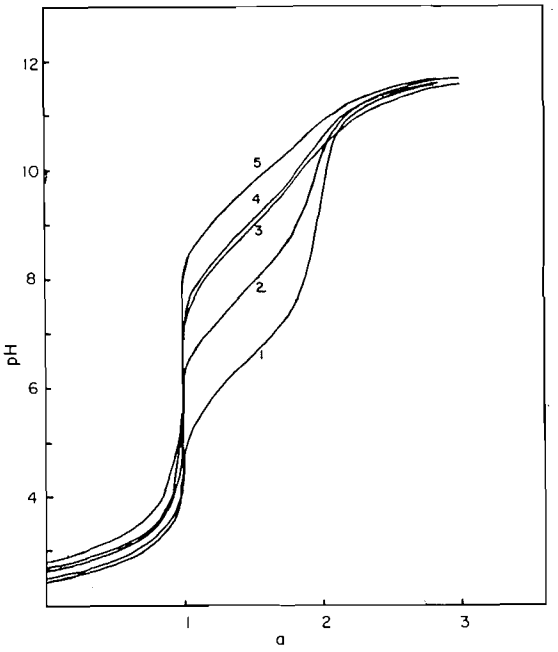

Fig. 1. Titrage par la soude d'un mélange équimoléculaire de nitrate métallique 0.01 M en présence du nitrilotriacétate disodique 0.01 M et de proline 0.01 M à une force ionique de 0.1 M KNO_3 et à la température de 25 °C. Le nombre de moles de soude ajouté par mole de métal est dénoté par "a". *1*, Me = Cu; *2*, Me = Ni; *3*, Me = Zn; *4*, Me = Co; *5*, Me = Cd.

de deux points d'inflexion situés respectivement à $a = 1$ et à $a = 2$.

Jusqu'à $a = 1$, il se forme le nitrilotriacétate métallique MeX^-, et entre $a = 1$ et $a = 2$, il se forme le complexe mixte suivant la réaction

$$[1] \qquad MeX^- + LH \rightarrow MeXL^{2-} + H^+$$

Pour calculer la constante de formation K_f du complexe mixte, on a utilisé les points expérimentaux situés entre $a = 1$ et $a = 2$ et pour

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

cette région nous avons employé les équations suivantes qui ont été démontré auparavant (2–4)

$$[2] \quad (\mathrm{L}) = \frac{(2-a)C_{\mathrm{Me}} + (\mathrm{OH}^-) - (\mathrm{H}^+)}{(\mathrm{H}^+)/K_a}$$

$$[3] \quad K_f(\mathrm{L}) + 1 = \frac{C_{\mathrm{Me}}}{(\mathrm{L})\left\{1 + \frac{(\mathrm{H}^+)}{K_a}\right\}} = y$$

Dans ces formules, K_a est la constante de dissociation de la proline.

On voit donc qu'un graphique de y en fonction de (L) doit donner une droite de pente égale à K_f, et dont l'ordonnée à l'origine est 1. Dans toutes nos expériences, nous avons vérifié cette formule, et on a toujours obtenu une ordonnée à l'origine égale à 1. Les travaux furent effectués à des concentrations initiales $C_{\mathrm{Me}} = C_{\mathrm{HX}} = C_{\mathrm{HL}}$ variant de 0.02 à 0.001 M.

Dans le Tableau 1, on donne le pK_a de la proline à différentes températures.

Dans le Tableau 2, on donne le logarithme de la constante de formation des complexes mixtes à différentes températures, comme l'enthalpie et l'entropie de la réaction de formation des complexes mixtes.

L'enthalpie de la réaction de formation des complexes mixtes a été calculée en multipliant par R la pente de la droite représantant $\ln K_f = f(1/T)$.

Pour calculer l'entropie Jones (12) a recommandé d'utiliser la relation

$$(\partial \Delta G^0/\partial T)_P = -\Delta S^0$$

Pour cuivre – nitrilotriacétate-prolinate on a fait un graphique de $-\Delta G^0 = f(T)$ et on a obtenu une droite dont la pente est égale a ΔS^0. L'energie libre a été calculé par la formule

$$\Delta G^0 = -RT \ln K$$

Dans le cas du Ni(II), Zn(II), Co(II) et Cd(II), il était impossible d'utiliser cette méthode pour calculer l'entropie parce que l'intervalle de variation de ΔG^0 est du même ordre de grandeur que l'erreur expérimentale de ΔG. Par conséquent pour ces cas, on a calculé à chaque température l'entropie à partir de la relation $\Delta G^0 = \Delta H^0 - T\Delta S^0$, et la valeur moyenne est donnée dans le Tableau 2. Comme l'a indiqué Jones (12), ces valeurs d'entropies, obtenues par cette méthode pour Ni, Co, Zn, Cd, sont moins précises.

TABLEAU 1. pK_a de la proline à différentes températures et à μ = 0.1 M KNO_3

t (°C)	pK_a
15	10.64±0.01
25	10.41±0.01
50	9.86±0.01
70	9.39±0.01

Auparavant (1) nous avons déterminé les constantes de formation des complexes mixtes qui résultent de la réaction des nitrilotriacétates métalliques avec la glycine à une force ionique 0.5 M KNO_3. Hopgood et Angelici (6) a redéterminé ces constantes à une force ionique 0.07 M KNO_3.

Dans ce travail nous avons redéterminé ces constantes à 25 °C et à une force ionique 0.1 M KNO_3 Dans ces conditions pour la glycine pK_a = 9.54 ± 0.01. Le Tableau 3 rassemble nos résultats.

Discussion

Les constantes de formation des complexes mixtes contenant la proline, suivent la série de Irving–Williams (13) et on peut les placer dans l'ordre

Cu > Ni > Zn > Co > Cd

La réaction conduisant à la formation des complexes mixtes est une réaction exothermique et les enthalpies de la réaction suivent le même ordre que les constantes de stabilité.

La réaction de formation du complexe mixte de cuivre est plus exothermique que la réaction de formation du complexe mixte de nickel. D'après Yatsimirskii (14) ceci indique que pour le cuivre il y a une grande stabilisation par l'effet Jahn–Teller. De ce fait, les groupements axiaux liés au métal central s'éloignent de celui-ci, et par conséquent ces groupements peuvent être solvatés par le solvant. Le processus de solvatation des groupements axiaux conduit à une diminution de l'entropie de la réaction. D'après les valeurs du Tableau 2, on voit que pour le cuivre l'entropie de la réaction de formation du complexe mixte est assez négative (−12 u.e./mole).

Une phénomène semblable a été rapporté par Nancollas (8) pour la réaction de formation du complexe mixte cuivre(II) – éthylènediaminediacétate – éthylènediamine à partir de l'éthylène-

TABLEAU 3. Constantes de formation des complexes mixtes résultant de la réaction des nitrilotriacétates métalliques avec la glycine à 25 °C et à $\mu = 0.1\ M\ KNO_3$

Métal	log K_f
Cu(II)	5.26±0.02
Ni(II)	4.41±0.04
Zn(II)	3.59±0.05
Co(II)	3.38±0.05
Cd(II)	3.05±0.05
Mn(II)	1.80±0.10

diamine et cuivre(II) – éthylènediaminediacétate. Nancollas a suggéré que la formation du complexe mixte est accompagnée par la libération de deux groupements carboxyliques et par leur solvatation simultanée.

Dans le cas des complexes mixtes contenant la proline, il est difficile de savoir si les deux groupements carboxyliques proviennent de nitrilotriacétate seulement, ou si un carboxyle provient du nitrilotriacétate et l'autre de la proline.

Si K_f(proline) dénote la constante de formation des complexes mixtes contenant la proline et si K_f(glycine) dénote la constante de formation des complexes mixtes contenant la glycine, on peut écrire pour eux la relation linéaire suivante

$$\log K_f(\text{proline}) = 1.5 \log K_f(\text{glycine}) - 1.5$$

Les complexes mixtes contenant la proline sont plus stables que les complexes mixtes contenant la glycine, car la stabilité des complexes mixtes augmente avec la basicité du coordinat.

Dimethylgermanium Dinitrate

D. POTTS AND A. WALKER
Department of Chemistry, Scarborough College, University of Toronto, 1265 Military Trail, West Hill, Ontario
Received July 20, 1970

Dimethylgermanium dinitrate has been prepared by the reaction of dimethylgermanium dichloride and nitrogen pentoxide in carbon tetrachloride. The properties of this compound have been investigated and compared with those of other known Group IVA alkyl nitrates. The vibrational spectra show that the nitrato groups are covalently bound to the germanium in a unidentate manner. Ultraviolet spectra and conductivity measurements indicate that the compound behaves as a 1:2 electrolyte in water and dimethyl sulfoxide but is a non-electrolyte in methyl cyanide, nitromethane, and ethyl acetate. The complexes $Me_2Ge(NO_3)_2 \cdot py$ and $Me_2Ge(NO_3)_2 \cdot 2,2'dipy$ have been prepared and the infrared spectra of these compounds indicate considerable weakening of the germanium–nitrato bonds.

Canadian Journal of Chemistry, 49, 202 (1971)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Following our work on $Et_2Pb(NO_3)_2$ (1) and $MeSn(NO_3)_3$ (2), it was of interest to us to investigate the organo-nitrate chemistry of germanium, since the only organogermanium nitrate known to date is trimethylgermanium nitrate (3), and this compound has not been characterized completely.

We first attempted to prepare dimethylgermanium dinitrate by the reaction of liquid dinitrogen tetroxide on tetramethylgermanium in ethyl acetate, since this was the synthetic route used in the preparation of $Et_2Pb(NO_3)_2$ (1) and $Me_2Sn(NO_3)_2$ (4). After removal of solvent and excess tetroxide, the product was always an oil, probably a mixture of the mono and dinitrato species. Our work on $MeSn(NO_3)_3$ (2) suggested that dimethylgermanium dinitrate might be obtained by reacting the dichloride analogue with either dinitrogen tetroxide or dinitrogen pentoxide in carbon tetrachloride. The reaction using dinitrogen tetroxide did give the required product but the reaction was slow and the yield poor. The reaction with dinitrogen pentoxide, however, proceeded smoothly yielding white needle-like crystals of dimethylgermanium dinitrate which, after filtration and washing with cold carbon tetrachloride, were easily purified by sublimation in vacuo at 60 °C.

This paper discusses some of the chemical and physical properties of dimethylgermanium dinitrate, particularly those useful for comparison with other Group IVA alkyl nitrato complexes.

Results and Discussion

Dimethylgermanium dinitrate is a stable white crystalline solid, in contrast to the methylgermanium halides and trimethylgermanium nitrate, all of which are liquids at room temperature. Like the tin analogue (4), it is very hygroscopic, but it is more volatile than $Me_2Sn(NO_3)_2$, subliming rapidly at 60 °C/10^{-2} mm. The compound is readily soluble in water and many polar organic solvents and, like $Sn(NO_3)_4$ (5) and $MeSn(NO_3)_3$ (2) but in contrast to $Me_2Sn(NO_3)_2$ (4), is appreciably soluble in some non-polar organic solvents such as chloroform and carbon tetrachloride. These solubility properties support the spectroscopic evidence of highly covalent nitrato groups in dimethylgermanium dinitrate. The lack of reactivity of the compound towards diethyl ether, acetone, and Nujol is consistent with Raman spectroscopic evidence of unidentate nitrate groups (5). When heated gently in air the compound melts liberating dinitrogen tetroxide; but when heated strongly it explodes, leaving a white residue.

Vibrational Spectra

The observed infrared and Raman bands together with suggested assignments are presented in Table 1. The appearance of Raman bands in the 1300 cm^{-1} region and the fact that the Raman band in the 1600 cm^{-1} region is very weak is characteristic of the pattern observed for all compounds known to contain unidentate nitrate groups, and quite unlike that observed for those compounds containing known symmetrically bidentate nitrate groups (6). Consequently the nitrate bands are assigned in accordance with Addison and Logan (7) assuming a unidentate nitrato structure. The Ge—CH_3 vibrational modes are assigned following Griffiths (8).

The splitting of the bands in the 1300 and 900 cm^{-1} regions is undoubtedly due to vibrational coupling of the two nitrato groups, as was

*s = strong, m = medium, w = weak, v = very, sh = shoulder, sp = sharp.

observed for diethyllead dinitrate (1) and dimethyltin dinitrate (4), and is consistent with a pseudo tetrahedral structure for $Me_2Ge(NO_3)_2$. The two germanium–carbon stretching frequencies required for such a structure are also observed. The asymmetric NO_2 stretching frequency is not split, but as this band is rather broad, the two expected bands may not be sufficiently resolved.

The strong bands at 394 cm^{-1} infrared (i.r.) and 370 cm^{-1} Raman (R) are assigned to Ge—O stretching modes.

The bands at 247 cm^{-1} (i.r.) and 248 cm^{-1} (R) are too high to be assigned to GeC_2 bending vibrations (8), and are thus conditionally assigned to Ge—O bending and torsion modes. The fact that the asymmetric and symmetric Ge—C stretching modes occur at somewhat higher frequencies as compared to the analogous bands for Me_2GeCl_2 (8) indicates that the germanium is more electropositive in the nitrato compound.

Ultraviolet Spectra

The ultraviolet spectra of solutions of dimethylgermanium dinitrate in water and dimethyl sulfoxide are shown in Fig. 1. The observed peak at 302.5 mμ (ε = 14.35) for the aqueous solution corresponds to the dissociation of the molecule yielding two nitrate ions in solution (9). In contrast to $Me_2Sn(NO_3)_2$ (4) and $Et_2Pb(NO_3)_2$ (1), the aqueous solution of $Me_2Ge(NO_3)_2$ did not change upon boiling. The spectrum of the dimethyl sulfoxide solution has a peak at 312.5 mμ (ε = 9.75) and this is also consistent with the presence of two nitrate ions per mole (9). Again in contrast to the tin and lead analogues, this solution was found to be stable with respect to time.

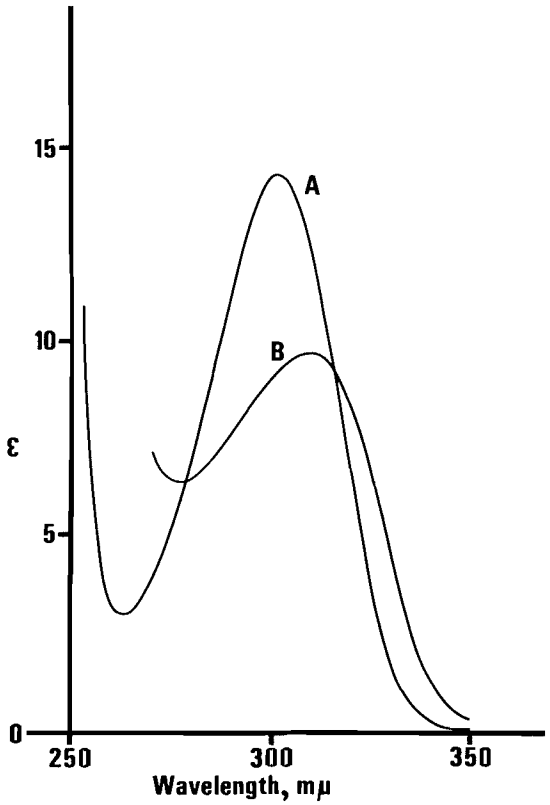

FIG. 1. Ultraviolet spectra of solutions of dimethylgermanium dinitrate at 25 °C. *A*, water; *B*, dimethyl sulfoxide.

Figure 2 shows the ultraviolet solution spectra of dimethylgermanium dinitrate in methyl cyanide, ethyl acetate, and methanol. The spectra are typical of those obtained for solutions of many covalent metal nitrates in these solvents, indicating considerable metal-nitrate interaction (9). They are in general the same as those obtained for $Me_2Sn(NO_3)_2$ (4), and for fresh solutions of $Et_2Pb(NO_3)_2$ (1), although the extinction coefficients are somewhat lower in the present case. The peak maxima occur at 270.0 mμ in all three solvents, and the extinction coefficients are 14.56, 18.02, and 16.18 in methyl

cyanide, ethyl acetate, and methanol, respectively. These solutions were stable with respect both to time and refluxing.

Conductivities

The molar conductivities of dimethylgermanium dinitrate in water, dimethyl sulfoxide, methanol, methyl cyanide, and nitromethane are listed in Table 2. The low conductivity of methyl cyanide and nitromethane solutions indicate that $Me_2Ge(NO_3)_2$ is virtually a non-electrolyte in these solvents (10). The molar conductivities of aqueous solutions greatly exceed the expected value for a 1:2 electrolyte (*ca.* 240 ohm^{-1} cm^2 at 0.001 *M*) (4). These solutions are very acidic and the high conductivities are attributed to hydrolysis similar to that found for dimethyltin dinitrate (4). However, the conductivity values for the germanium solutions are much higher than those found for tin, the latter having a molar conductivity of 403 ohm^{-1} cm^2 at 0.001 *M* (4). This result is consistent with the greater acidity of the Me_2Ge^{2+} ion. By comparison it was found that the Et_2Pb^{2+} ion is only hydrolyzed in hot aqueous solutions (1). The conductivities of dimethyl sulfoxide solutions are very similar to those obtained for $Me_2Sn(NO_3)_2$ (4) and indicate that $Me_2Ge(NO_3)_2$ is a 1:2 electrolyte in this solvent. The values obtained in methanol show concentration dependence typical of weak electrolyte behavior. Therefore while in very dilute solutions (0.001 *M*) the conductivity indicates some degree of ionization ($AgNO_3$ in MeOH has a molar conductivity of 94.20 ohm^{-1} cm^2 at a concentration of 0.00168 *M* (11)), at the concentration used for the u.v. spectrum (0.0412 *M*) considerable association is evident.

Molecular Weight

The molecular weight of $Me_2Ge(NO_3)_2$ was determined cryoscopically in nitrobenzene and found to be 238.6 (theoretical monomeric value = 226.7).

Pyridine and 2,2'-Dipyridyl Complexes

The two adducts $Me_2Ge(NO_3)_2$·py and $Me_2Ge(NO_3)_2$·dipy were obtained as white precipitates from chloroform solutions containing $Me_2Ge(NO_3)_2$ and excess ligand. Since the six coordinate dipyridyl adduct is formed readily, it is interesting that only a mono adduct is formed between $Me_2Ge(NO_3)_2$ and pyridine. Present work in this laboratory has shown that

595 w, sh	a	Sym. Ge—C stretching
363 m, br	375 w	Ge—O stretching

*s = strong, m = medium, w = weak, br = broad, sh = shoulder, sp = sharp, a = obscured by ligand absorption.

$Me_2Sn(NO_3)_2$ forms the analogous complexes $Me_2Sn(NO_3)_2 \cdot py$ and $Me_2Sn(NO_3)_2 \cdot dipy$. Pyridine and 2,2′-dipyridyl adducts with Group IVA alkyl nitrates are presently being studied in detail. The pyridine adduct is very hygroscopic, whereas the dipyridyl adduct is only slightly hygroscopic.

The principal infrared bands and their assignments for the two complexes are presented in Table 3. By comparison with similar chloro complexes the bands due to pyridine and dipyridyl were clearly identified and are not included in the table. The lower values for the splitting between the asymmetric and symmetric NO_2 stretching frequencies and the higher values for the N—O stretching frequencies as compared to $Me_2Ge(NO_3)_2$, indicate that the metal–nitrate bonds are much weaker in both adducts. The somewhat lower values for the Ge—O stretches in the adducts also indicate weaker metal–nitrate interaction.

Experimental

Dimethylgermanium Dinitrate

Dinitrogen pentoxide was prepared by a gas phase reaction between dinitrogen tetroxide and ozone. Dimethylgermanium dichloride (6.6 g) was added to a solution of dinitrogen pentoxide (13.5 g) dissolved in carbon tetrachloride (60 ml). The dichloride dissolved immediately in the reaction mixture and after stirring for ½ h white crystals were precipitated from the solution. The mixture was stirred for 24 h and the crystals were separated by filtration. After sublimation in vacuo at 60 °C, pure $Me_2Ge(NO_3)_2$ (5.3 g) was obtained as a white crystalline solid. Extreme care was taken to exclude moisture throughout the entire procedure.

Anal. Calcd. for $Me_2Ge(NO_3)_2$: C, 10.6; NO_3^-, 54.7; Ge, 32.02. Found: C, 10.1; NO_3^-, 54.0; Ge, 32.58.

$Me_2Ge(NO_3)_2py$

Pyridine (5.0 ml, 0.062 mol) in chloroform (5 ml) was added to a solution containing dimethylgermanium dinitrate (1.05 g, 0.00463 mol) in chloroform (10 ml). A white precipitate was formed immediately, accompanied by the evolution of heat. After cooling, the precipitate was filtered and washed twice with dry petroleum ether. Moisture was again carefully excluded from the apparatus. The pyridine adduct obtained (1.15 g) was a white powdery solid.

Anal. Calcd. for $Me_2Ge(NO_3)_2py$: C, 27.49; NO_3^-, 40.55; Ge, 23.74. Found: C, 27.08; NO_3^-, 40.64; Ge, 23.33.

$Me_2Ge(NO_3)_2dipy$

2,2′-Dipyridyl (0.922 g, 0.00591 mol) dissolved in chloroform (5 ml) was added to a solution of $Me_2Ge(NO_3)_2$ (0.528 g, 0.00233 mol) in chloroform (10 ml). The white precipitate, which formed immediately, was filtered and washed first with dry chloroform and then with dry petroleum ether. The yield of the white powdery solid was 0.66 g.

Anal. Calcd. for $Me_2Ge(NO_3)_2dipy$: C, 37.64; H, 3.69; N, 14.64. Found: C, 37.48; H, 3.84; N, 14.53.

For the compounds $Me_2Ge(NO_3)_2$ and $Me_2Ge(NO_3)_2py$, nitrate was determined gravimetrically as nitron nitrate, germanium was determined gravimetrically as GeO_2 using the technique employed by Rochow (12), and carbon was determined by the Van Slyke wet oxidation method. Due to the extreme difficulty found in oxidizing the carbon in these compounds, it was necessary to mix 1.5 g KIO_3 with the sample before the addition of the Van Slyke oxidation mixture. All other analyses were carried out by microanalytical laboratories. Pyridine was dried by allowing it to sit 24 h over calcium hydride followed by distillation onto molecular sieves. Other solvents were dried by standard techniques.

Infrared spectra were recorded using a Beckman I.R. 12 spectrophotometer. Spectra of $Me_2Ge(NO_3)_2$ were taken in carbon tetrachloride and carbon disulfide using variable path length cells with silver chloride windows. Far infrared spectra (200–400 cm^{-1}) were taken in carbon tetrachloride using 0.1 mm polyethylene liquid

For personal use only.

cells. All other spectra were obtained with Nujol or halocarbon mulls using KRS-5 plates.

Raman spectra were determined on the solid phase using a Spex monochromator and the red line of a krypton laser.

Ultraviolet spectra were recorded using a Cary #14 spectrophotometer using fused silica cells and dried spectroscopic solvents.

Conductivities were recorded with a Beckman model RC-18 bridge system, and a cell following the design of Greiner (13).

Nitrogen Bridged Osmium–Ruthenium Complexes

CLIVE M. ELSON, J. GULENS, AND JOHN A. PAGE
Department of Chemistry, Queen's University, Kingston, Ontario
Received August 14, 1970

The formation of $[(H_2O)(NH_3)_4Ru—N_2—Os(NH_3)_5]^{4+}$ by the reaction of *cis*-$Ru(NH_3)_4(H_2O)_2^{2+}$ and $Os(NH_3)_5N_2^{2+}$ has been studied over the range 15–45 °C. The reaction followed second order kinetics with $k_f = 1.2 \times 10^{-1}\ M^{-1}\ s^{-1}$ at 25.0 °C and $E_a = 16.8 \pm 0.1$ kcal/mole. Measurement of equilibrium concentrations gave $K_{eq} = 4 \times 10^3\ M^{-1}$ at 25.0 °C.

The (4+) dimer was stable but removal of the excess *cis*-$Ru(NH_3)_4(H_2O)_2^{2+}$ reactant by oxidation at −0.10 V was followed by dimer decomposition. The breakup obeyed simple first order kinetics with $k_r = 2.9 \times 10^{-5}\ s^{-1}$ at 25.0 °C.

Oxidation of the (4+) dimer at +0.10 V gave a stable (5+) dimer. Removal of the excess $Os(NH_3)_5N_2^{2+}$ reactant at +0.30 V was followed by decomposition of the (5+) dimer giving $Os(NH_3)_5N_2^{2+}$ and $Ru^{III}(NH_3)_4X_2$. The decomposition again obeyed first order kinetics with $k_1 = 1.5 \times 10^{-5}\ s^{-1}$ at 25.0 °C. The (5+) dimer has an intervalence – transfer absorption band at 755 nm and is characterized as $[X(NH_3)_4Ru^{III}—N_2—Os^{II}(NH_3)_5]^{5+}$.

The studies were carried out in an aqueous H_2SO_4–K_2SO_4 electrolyte of p*H* 3.3, $\mu = 0.30$.

Canadian Journal of Chemistry, 49, 207 (1971)

Introduction

The formation of the binuclear complex, $[(NH_3)_5Ru—N_2—Ru(NH_3)_5]^{4+}$ in which the nitrogen group bridges the two metal atoms was first reported by Taube and co-workers (1). An analogous dimeric ruthenium(II) aquo-tetraammine (2) and a mixed ruthenium(II) pentaammine aquo-tetraammine species (3) are now known and the kinetics and energetics of formation of these complexes have been studied (3).

The nitrogen bridged binuclear osmium(II) pentaammine complex is not known. However, Allen and Stevens have prepared the unsymmetrical complexes, $[(NH_3)_5Ru—N_2—Os(NH_3)_5]^{4+}$ and $[(NH_3)_5Ru—N_2—Os(NH_3)_5]^{5+}$ (4). In this paper we report on the characterization and kinetics of formation and decomposition of the related nitrogen bridged osmium pentaammine – ruthenium aquo-tetraammine complexes.

Experimental

The experimental methods, apparatus, and the preparation of the *cis*-$Ru(NH_3)_4Cl_2 \cdot Cl$ have been previously described (3). The near-infrared spectra were recorded on a Cary 14 spectrophotometer. The reactions were carried out in an aqueous K_2SO_4–H_2SO_2 electrolyte ($\mu = 0.30$, pH = 3.3 at 25 °C). The potentials reported (V) are in volts relative to a saturated potassium chloride calomel electrode.

The $Os(NH_3)_5N_2 \cdot Cl_2$ was prepared from $(NH_4)_2OsCl_6$ (Engelhard Os-40) by the method of Allen and Stevens (5). The purity of the product was established spectrophotometrically using Taube's value of the extinction coefficient ($\varepsilon = 2.5 \times 10^4$ at 208 mm) (6). The initial product was found to be only 60–70% $Os(NH_3)_5N_2 \cdot Cl_2$, but this was increased to 85–90% by a second reflux with hydrazine hydrate. The purity was also established by coulometry (7); the $Os(NH_3)_5N_2^{2+}$ underwent a clean oxidation at +0.32 V ($n = 1.0 \pm 0.1$) on Pt in a 0.08 *M* $MeSO_3H$ electrolyte. The extinction coefficients actually used in this work are reported in Table 1.

Results

(1) $[(H_2O)(NH_3)_4Ru—N_2—Os(NH_3)_5]^{4+}$

The reactant, *cis*-$Ru(NH_3)_4(H_2O)_2^{2+}$ (A), was prepared by controlled potential electrolysis of weighed amounts of *cis*-$Ru(NH_3)_4Cl_2 \cdot Cl$ on a Hg cathode at −0.50 V under Ar. The reaction was initiated by the addition of $Os(NH_3)_5N_2 \cdot Cl_2$(M) to the Ru(II) solution. The Hg electrode was kept at its reducing potential and the Ar atmosphere maintained throughout the subsequent reaction; the background current remained negligible.

The initial concentration of M was determined spectrophotometrically. With time, an absorbance peak developed at 257 nm while the peak at 208 nm (due to M) decreased. A well defined isosbestic point appeared at 227 nm. The peak at 257 nm is assigned to the complex $[(H_2O)(NH_3)_4Ru—N_2—Os(NH_3)_5]^{4+}$ (D(4+)) having both metals in the +2 oxidation state: *i.e.* D(2,2). The reaction can be represented by

$$A + M \xrightarrow{k_f} D(4+)$$

The concentration of M was followed by the decrease in absorbance at 208 nm allowing for the contribution of the product. The second

TABLE 2. Rate constants for (4+) dimer formation

Temperature (°C)	C_A^0 ($M \times 10^3$)	C_M^0 ($M \times 10^3$)	k_f (M^{-1} s^{-1} × 10)	Number of points	Reaction time (min)	Correlation coefficient
14.9	1.88	0.565	0.48_0	21	101	1.000
16.7	1.48	0.526	0.53_3	14	66	1.000
25.0	0.951	0.638	1.2_5	10	48	0.998
25.0	1.01	0.536	1.2_0	15	56	1.000
35.1	0.893	0.531	3.1_2	15	37	0.993
39.6	0.425	0.285	4.7_4	10	20	0.997
45.2	0.410	0.310	7.5_4	5	10	0.979

order rate constant was evaluated by least square fits on plots of

$$(C_A^0 - C_M^0)^{-1} \times \ln[C_M^0(C_A^0 - C_M^0 + C_M)/C_A^0 C_M]$$

vs. time and the results, over a range of temperatures, are tabulated in Table 2. The plots were linear over the stated reaction times, although at the higher temperatures a negative curvature was observed at longer times as the back reaction became significant. The rate of reaction was demonstrated to be dependent on the initial concentrations of both A and M. A good Arrhenius plot was obtained and gave, by least squares fitting, $E_a = 16.8 \pm 0.1$ kcal/mole and $\Delta S^{\ddagger} = -6 \pm 0.5$ e.u.

One kinetic run at 25.0 °C was allowed to proceed for 30 h under the stated conditions. After approximately 17 h the concentrations of M and D(4+) stabilized; past this point from 17 to 30 h there was a small decrease (~3%) in the absorbances at 208 and 257 nm. The concentrations of M and D(4+) were calculated from simultaneous equations for the absorbance at the two wavelengths, and assuming equilibrium at 17 h gave

$$K_{eq} = \frac{C_{D(4+)}}{C_A \cdot C_M} = \frac{C_{D(4+)}}{(C_A^0 - C_{D(4+)})(C_M)} = 4.2 \times 10^3\ M^{-1}$$

The decomposition of the dimer was followed in another series of experiments. The reaction was allowed to proceed as before, but when an appreciable concentration of dimer had been formed the reaction was reversed by switching the electrode potential to −0.10 V. This potential will oxidize the excess A to *cis*-ruthenium(III) tetraammine (3) but is not sufficiently oxidizing to attack either nitrogen species

$$D(4+) \xrightarrow{k_r} A + M$$

$$A \xrightarrow[-0.10\ V]{-e} Ru(III)$$

The electrode was maintained at −0.10 V after the excess Ru(II) had been oxidized and past this point the absorbance at 257 nm decreased and that at 208 nm increased. A well defined isosbestic point was observed at 227 nm. The concentrations of M and D(4+) were calculated from the simultaneous equations at the two wavelengths; the sum of their calculated

TABLE 3. Rate constants for dimer decomposition at 25 °C

Dimer	C_M^0 ($M \times 10^3$)	C_D^0 ($M \times 10^3$)	k_r ($s^{-1} \times 10^5$)	Number of points	Reaction time (min)	Correlation coefficient
(4+)	0.249	0.315	2.9_0	19	140	0.999
	0.214	0.336	2.9_2	17	180	0.999
(5+)	—	0.281	1.5_1	22	480	1.000

concentrations was constant throughout the run. The first order rate constant for the decomposition was evaluated by plotting ln ($C_{D(4+)}$) *vs.* time. The plots were linear for the time studied; this represented the decomposition of approximately 30% of the initial (4+) dimer. The values of k_r are given in Table 3.

If the equilibrium constant for the formation of the (4+) dimer is calculated as the ratio of k_f to k_r, then at 25 °C

$$K_{eq} = \frac{k_f}{k_r} = \frac{1.2 \times 10^{-1}\ M^{-1}\ s^{-1}}{2.9 \times 10^{-5}\ s^{-1}} = 4.1 \times 10^3\ M^{-1}$$

This value agrees closely with that obtained from the assumed equilibrium concentrations.

(2) $[(H_2O)(NH_3)_4Ru—N_2—Os(NH_3)_5]^{5+}$

Further electrolysis of the solution containing the (4+) dimer, M and Ru(III) using a Pt electrode at +0.10 V under Ar gave a clean oxidation of the dimer. The oxidation consumed 1.0 faraday per mole based on the initial concentration of dimer, and was accompanied by a decrease in absorbance and a shift in the maximum from 257 to 246 nm. The reaction was reversible and the (4+) dimer could be quantitatively regenerated at a Hg electrode at −0.15 V, a more reducing potential. The reaction can be represented as

$$\underset{D(4+)}{[(H_2O)(NH_3)_4Ru—N_2—Os(NH_3)_5]^{4+}} \underset{+e\ -0.15\ V}{\overset{-e\ +0.10\ V}{\rightleftharpoons}} \underset{D(5+)}{[(H_2O)(NH_3)_4Ru—N_2—Os(NH_3)_5]^{5+}}$$

However, the coulometry does not indicate the distribution of oxidation states in the (5+) dimer. It is possible that the aquo group on the ruthenium may be replaced by a SO_4^{2-} or HSO_4^- from the electrolyte if the ruthenium is in the (3+) state. The (5+) dimer also exhibited an absorbance maximum at 755 nm ($\varepsilon \sim 2 \times 10^3$).

The decomposition of the (5+) dimer was also examined. The solution containing the (5+) dimer, M and Ru(III) was further oxidized using the Pt electrode at +0.30 V, under Ar. This potential will oxidize M to an Os(III) species (7). Upon "completion" of the electrolysis the working electrode was disconnected. From this point, it was observed that the absorbance at 246 nm decreased while that at 208 nm increased. A well defined isosbestic was obtained at 224 nm. The reaction can be represented

$$D(5+) \underset{Ar}{\overset{k_r'}{\rightarrow}} M + Ru(III)$$

so that the (5+) dimer decomposes to $Os(NH_3)_5N_2^{2+}$ and *cis*-$Ru^{III}(NH_3)_4X_2$. The first order rate constant was evaluated by plotting ln ($C_{D(5+)}$) *vs.* time and the plot was linear over 30% decomposition of the (5+) dimer. The sum of the concentrations of D(5+) and M was constant over the time studied. The value of k_r' is given in Table 3.

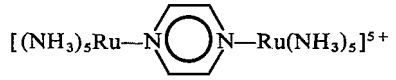
Attempts to prepare the (5+) dimer by direct reactions were unsuccessful. The pairs of reactants, *cis*-$Ru^{III}(NH_3)_4X_2$ with $Os(NH_3)_5N_2^{2+}$, and $Os(NH_3)_5(H_2O)^{3+}$ with *cis*-$Ru(NH_3)_4(H_2O)N_2^{2+}$ were mixed together in the 0.08 *M* $MeSO_3H$ electrolyte, but there was not any detectable increase in absorbance at 246 nm on prolonged standing at room temperature.

Discussion

The $Os(NH_3)_5N_2^{2+}$ nucleophile and *cis*-$Ru(NH_3)_4(H_2O)_2^{2+}$ substrate have been shown to react with overall second order kinetics to produce the (4+) dimer. The kinetics can be interpreted in terms of a displacement mechanism (S_N2) or a dissociative mechanism (S_N1) with the implications stated previously (3) still applying. The rate of reaction at 25.0 °C of the $Os(NH_3)_5N_2^{2+}$ nucleophile with the substrate ($1.2 \times 10^{-1}\ M^{-1}\ s^{-1}$) was found to be about twice as fast as those previously reported (3) for the nucleophiles $Ru(NH_3)_5N_2^{2+}$ ($0.68 \times 10^{-1}\ M^{-1}\ s^{-1}$) and *cis*-$Ru(NH_3)_4(H_2O)N_2^{2+}$ ($0.72 \times 10^{-1}\ M^{-1}\ s^{-1}$) with the same substrate. The activation energies and entropies of activation are of the same order for all three nucleophiles.

The increased nucleophilicity of the nitrogen group bound to osmium can be explained by the stronger π-donating ability of Os(II) compared to that of Ru(II).

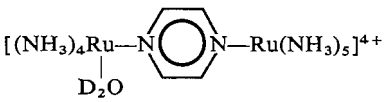
The one electron oxidation of the (4+) dimer to produce a stable species that can be reversibly reduced, indicates the (5+) species is still a simple dimer. The band at 246 nm of the (5+) dimer is assigned to the charge-transfer absorption $t_{2g} \rightarrow \pi^*$. The lower energy absorption at 755 nm can be interpreted as a heteronuclear intervalence-transfer absorption (IT) (3,2) $\rightarrow$ (2,3)* (8) where the "odd" electron in the 5+ complex preferentially resides on one of the metals. This is analogous to the arguments of Creutz and Taube (9) who have reported that



exhibits an IT band at 1570 nm. However, the observed decomposition of the (5+) dimer to give only Os(II) and Ru(III) species is not conclusive proof that the odd electron in the dimer resides exclusively on the Os center; the localization could take place in the decomposition step.

An attempt was made to locate the "odd" electron by an anation experiment. The (4+) and (5+) dimers of the osmium pentaammine with both the tetraammine and pentaammine of ruthenium were prepared in a non-complexing 0.08 *M* $MeSO_3H$ electrolyte. Both of the (4+) dimers exhibited absorbance peaks at 257 nm. The $[(H_2O)(NH_3)_4Ru—N_2—Os(NH_3)_5]^{5+}$ exhibited peaks at 246 and 770 nm, and the $[(NH_3)_5Ru—N_2—Os(NH_3)_5]^{5+}$ at 246 and 758 nm. Anation of the (5+) dimers by a 1000 fold excess of Cl^- shifted the peak of the (5+) dimer of the ruthenium tetraammine to 803 nm, and the peak of the (5+) dimer of the ruthenium pentaammine to 775 nm. There was not any appreciable shift (< 2 nm) in the higher energy band of either dimer.

The greater shift of the near-infrared band of the (5+) dimer of the ruthenium tetraammine can be ascribed to a Cl^- substitution of the aquo group on the ruthenium (9). This suggests that in the (5+) dimer there is a ruthenium(III) center, since the tendency of non π-acceptor ligands to substitute on a ruthenium(II) center is small (10). In a similar case Taube and Creutz have shown (9) that in 2 *M* NaCl, the (D_2O) group of



is substituted only after oxidation of the tetraammine center to ruthenium(III).

Therefore, in the sulfate electrolyte, the (5+) dimer is presumably $[X(NH_3)_4Ru^{III}—N_2—Os^{II}(NH_3)_5]$.

The authors are greatly indebted to Dr. A. D. Allen and J. R. Stevens for their part in this work. A fellowship (C.M.E.) from the Province of Ontario and both a scholarship (J.G.) and grant from the National Research Council of Canada are gratefully acknowledged.

Application of Paramagnetic Shift Reagents in Nuclear Magnetic Resonance Studies of Complex Alcohols and Amines[1]

ELAINE GILLIES,[2] W. A. SZAREK, AND M. C. BAIRD
Department of Chemistry, Queen's University, Kingston, Ontario

Received June 9, 1970

The effects of Co(acetylacetonate)$_2$, Ni(acetylacetonate)$_2$, and Cu(ethyl acetoacetate)$_2$ on the nuclear magnetic resonance spectra of a variety of alcohols and amines have been studied. Changes are produced in the spectra, which are useful for assigning the signals.

Canadian Journal of Chemistry, 49, 211 (1971)

Introduction

The effects of paramagnetic transition metal ions on chemical shifts in ^{1}H nuclear magnetic resonance (n.m.r.) spectra have been the subject of intensive study for about ten years. In cases where there are no chemical interactions, the resonance positions of the protons in solution are shifted to higher fields by the magnetic fields resulting from the presence of the paramagnetic ions. This susceptibility shift is given (2) by the expression

$$[1]\quad \Delta\nu = \left[\chi - \chi_0 - \frac{\chi_0(d_0 - d_s)}{m}\right]\frac{2\pi\nu_0 m}{3}$$

where $\Delta\nu$ is the change in chemical shift from the diamagnetic position, χ is the mass susceptibility of the paramagnetic compound, χ_0 is the mass susceptibility of the solvent, d_0 is the density of the solvent, d_s is the density of the solution, m is the mass of the paramagnetic compound in 1 ml of solution, and ν_0 is the probe frequency of the spectrometer. Evans (2) has described a procedure, based on eq. 1, for determining the paramagnetic susceptibilities of transition metal compounds.

In cases where an organic molecule coordinates to a paramagnetic transition metal ion, the n.m.r. spectrum is usually dominated by electron spin – nuclear spin interactions.[3] The Fermi contact shift arises when unpaired electron spin density is delocalized from the metal ion into the molecular orbitals of the coordinated ligand. The result is that the n.m.r. spectra of paramagnetic complexes often show much larger variations in the shielding of the different hydrogen nuclei than is normally found for diamagnetic molecules. The magnitude of the contact shift, $\Delta\nu_i$, is given by the equation

$$[2]\quad \frac{\Delta\nu_i}{\nu_0} = -A_i\frac{\gamma_e}{\gamma_N}\frac{g\beta S(S+1)}{3kT}$$

where ν_0 is the probe frequency of the spectrometer, A_i is the isotropic electron spin – nuclear spin coupling constant, usually observed in electronic spin resonance (e.s.r.) spectra, γ_e and γ_N are the gyromagnetic ratios of the electron and nucleus, respectively, g is the Landé factor, β is the Bohr magneton, and S is the total electron spin. In cases where proton contact shifts occur as a consequence of electron delocalization into a ligand π-molecular orbital, A_i is proportional to the π-electron spin density of the ith carbon atom, and contact shift data are very useful in elucidating the nature of metal–ligand bonding and mechanisms of spin delocalization (4).

In cases where the g tensor of the metal complex is not isotropic, dipolar interactions between the magnetic dipoles of the unpaired electrons and those of the nuclear spins occur. The resulting pseudocontact shifts depend only on the geometry of the molecule and do not involve covalent metal–ligand interactions. Pseudocontact data have been used in ion-pair formation and solvation studies (5).

As mentioned above, the ^{1}H n.m.r. spectra of many paramagnetic molecules cover a much larger range than do those of diamagnetic molecules, resonance frequencies often being 100–200 p.p.m. from the diamagnetic positions. Where the electronic relaxation times are favorable, reasonably narrow line widths occur, and the spectra of complex molecules can often be interpreted on a first-order basis.

Recently a number of publications have appeared describing attempts to use paramagnetic

ions to simplify and aid in the interpretation of the ^1H n.m.r. spectra of complex organic molecules. On the basis of contact shifts induced by $NiBr_2 \cdot 3H_2O$, Zaev *et al.* (6) have suggested assignments in the ^1H n.m.r. spectra of several substituted pyrazoles. Changes induced by metal ions in the n.m.r. spectra of biologically important molecules such as lysozyme (7) and cholesterol (8) have also been noted, although few definite assignments could be made in either case. We are engaged in a systematic investigation of the possible uses of a number of paramagnetic transition metal complexes in the simplification and interpretation of the n.m.r. spectra of complex organic molecules such as carbohydrates. In order to establish a firm basis for investigations of complex molecules, we have studied in detail the effect of $Co(acac)_2$ (acac = acetylacetonate) on the n.m.r. spectra of solutions of a wide variety of compounds containing hydroxyl groups. Some results have already been communicated (1); we now report full details of our work to date.[4]

Experimental

The compounds $Co(acac)_2$ (9), $Ni(acac)_2$ (10), and Cu(ethyl acetoacetate)$_2$ (11) were prepared as described in the literature. The violet-red cobalt compound is stable in the solid state, but oxidizes slowly in solution to give orange Co(III) compounds; thus only freshly prepared solutions of $Co(acac)_2$ were used. Most of the organic compounds were purchased from commercial sources, and were not purified unless their n.m.r. spectra indicated the presence of impurities.

The general procedure followed was to observe the n.m.r. spectra of the hydroxyl compound in $CDCl_3$ in the presence of varying concentrations of $Co(acac)_2$. The solutions of the hydroxyl compounds varied in concentration from 0.2 to 1 *M*, with preference being given to the higher concentration, although in any one set of measurements the concentration was kept constant. The concentration of the metal complexes varied from 1×10^{-6} to 0.3 *M*, depending on the effect on the spectrum. The spectra were measured on Varian T-60 and A-60 spectrometers with tetramethylsilane (TMS) as both internal and external standard.

Results

Solutions of $Co(acac)_2$ in $CDCl_3$ are pale pink in color; addition of alcohols does not change the color noticeably. For 1*M* ethanol solutions containing cobalt concentrations of greater than about 0.005 *M*, the susceptibility shifts (*i.e.* the difference between the internal and external TMS references) are measurable and increase linearly with increasing cobalt concentration up to at least 0.3 *M* $Co(acac)_2$. This relationship is to be expected if the magnetic properties of the cobalt complex do not change over the concentration range studied, and thus it seems likely that the nature of the cobalt species remains unchanged.

On adding increasing amounts of $Co(acac)_2$ to a solution of a saturated alcohol in $CDCl_3$, quite drastic and systematic changes take place in the n.m.r. spectrum, both in the chemical shifts and in the line widths. These changes are illustrated in Fig. 1, which shows the effects that $Co(acac)_2$, in the concentration range 0.010 to 0.152 *M*, has on a 1*M* solution of ethanol in $CDCl_3$. It can be seen that the hydroxyl resonance broadens and moves upfield beyond the internal TMS line at quite low cobalt concentrations. The methylene lines, on the other hand, broaden and lose their resolution to the same extent only at higher concentrations of $Co(acac)_2$, moving downfield at a slower rate as well. The methyl triplet, although obviously affected more than the internal TMS line, broadens the least of the ethanol resonances, moving slightly upfield only at relatively high cobalt concentrations. The extent of the susceptibility shift is indicated by the external TMS lines imposed on the spectra.

The effects described above were observed in almost all of the examples of saturated alcohols. Only the magnitude and the direction of the hydroxyl resonances varied unpredictably; deuterated samples were used whenever necessary, to avoid ambiguities. Unfortunately, only the resonances due to α-CH_n groups appear to change their chemical shifts to any great extent, thereby making only their identification possible; β- and γ-CH_n resonances generally shift very little (20–30 Hz), and to higher field. We have found, however, that the line broadening effect *is* attenuated along a saturated organic molecule. This broadening, which may be attributed to the proximity of the unpaired electrons on the cobalt ion, has the effect of destroying the fine structure of the α-CH_n resonance and changing it to a broad, featureless band at such low cobalt concentrations that the spectrum of the rest of the molecule is still quite well resolved. As the cobalt concentration is increased, the β-CH_n resonance loses its fine structure, then the γ-CH_n resonance, and so on.

[4]Since submitting this manuscript, a report appeared on another shift reagent [tris(dipivalomethanato) europium] for use in nuclear magnetic resonance spectroscopy; see ref. 19.

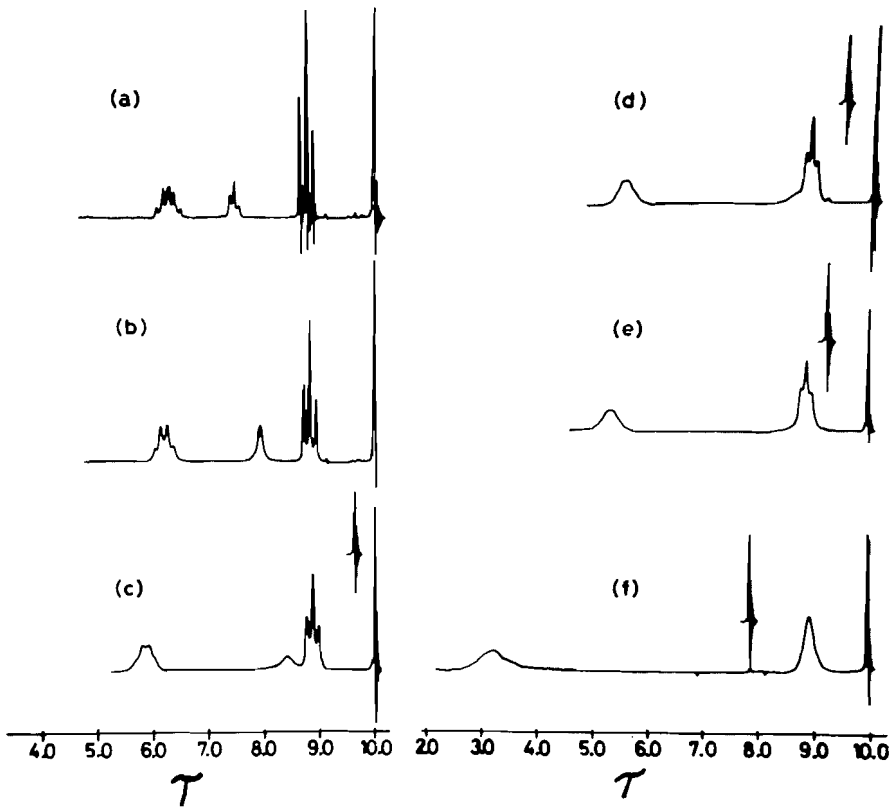

FIG. 1. Perturbation of the nuclear magnetic resonance spectrum of ethanol (1*M* in $CDCl_3$) by $Co(acac)_2$. Concentrations of $Co(acac)_2$: (*a*) 0, (*b*) 0.010 *M*, (*c*) 0.0276 *M*, (*d*) 0.0404 *M*, (*e*) 0.0512 *M*, and (*f*) 0.152 *M*. The susceptibility shift is indicated by the external tetramethylsilane lines imposed on the spectra.

A number of alcohols have been studied as described above, and it appears that there is a correlation between the structure of the alcohol and the contact shift of the α-CH_n group as the concentration of $Co(acac)_2$ is increased. Our results are summarized in Fig. 2, in which the chemical shift change ($\Delta\nu$) of the α-CH_n resonances of a series of alcohol solutions 1 *M* in $CDCl_3$ is plotted against the concentration of $Co(acac)_2$. It can be seen that the straight-chain alcohols shift the fastest, while isopropyl alcohol and *sec*-butyl alcohol, which have methyl groups on the α-carbon atom, shift the slowest. Isobutyl alcohol, which has branching at the β-carbon atom, is intermediate. In all of these cases the α-CH_n resonance lies in the region τ6–7, and is readily distinguished from the other aliphatic proton lines at higher fields. The latter resonances, in all cases, retain their fine structure up to at least 0.05 *M* $Co(acac)_2$, at which concentration the α-CH_n resonances are invariably a broad, featureless band. The chemical shifts of the β-, γ-, etc. CH_n resonances do not change significantly relative to internal tetramethylsilane, presumably because of a lack of Fermi contact interactions, and nothing apparently can be gained from inspection of this part of the spectrum.

The trends noted above are followed by a number of polyfunctional alcohols. In cases such as 2-methoxyethanol, 2-(2-ethoxyethoxy)-ethanol, ethylene glycol, 1,3- and 1,4-butanediol, 2-hydroxymethyltetrahydrofuran, and 2-hydroxymethyltetrahydropyran, the presence of more than one oxygen atom causes considerable overlap of the proton resonances. On addition of $Co(acac)_2$ to solutions of these compounds, resonances corresponding in intensity to the number of α-CH protons present shifted downfield in each case.

Allyl alcohol, benzyl alcohol, and phenol exhibited behavior quite different from the simple aliphatic compounds. In all three cases there were rapid shifts both upfield and downfield.

As a check on the influence of other functional

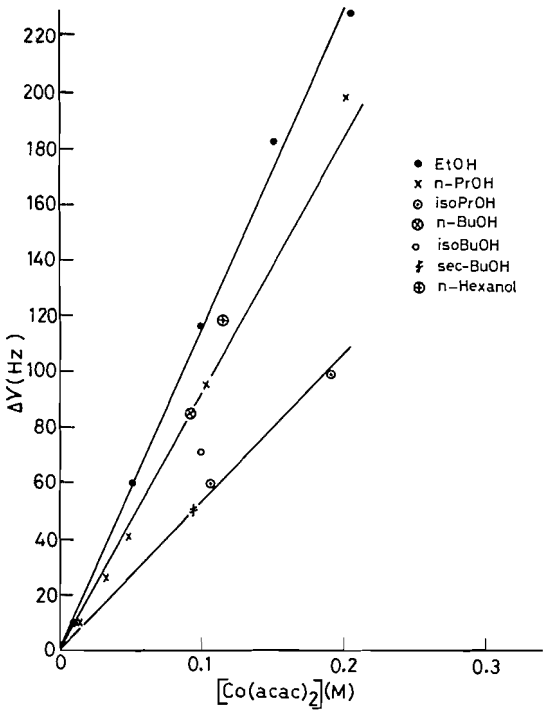

FIG. 2. Dependence of the change in chemical shift ($\Delta\nu$) of the α-CH_n resonances of saturated alcohols (1 *M* in $CDCl_3$) on the concentration of $Co(acac)_2$.

groups, we have also run the n.m.r. spectra of $CDCl_3$ solutions of dimethyl sulfoxide, ethyl methyl ketone, diethyl ether, tetrahydrofuran, 1,4-dioxane, 1,3,5-trioxane, 1,2-dimethoxyethane, and diglyme in the presence of $Co(acac)_2$. Although some of the oxygen donors form yellow solutions with $Co(acac)_2$, in all cases the lines shift to somewhat higher field and remain relatively narrow. Thus these functional groups should not affect the influence that $Co(acac)_2$ has on the spectra of compounds containing hydroxyl groups. Solutions of $Co(acac)_2$ and ethyl sulfide turn deep orange, suggesting a chemical reaction; the solutions remain paramagnetic, although there appears to be little effect on the n.m.r. spectra, either on the line widths or the chemical shifts.

Amines, however, behave very similarly to alcohols. On adding $Co(acac)_2$ to a solution of triethylamine, the methylene quartet moves downfield and loses its fine structure at about the same rate as does that of ethanol. The methylene quartet of diethylamine moves downfield even faster. Obviously amino groups will interfere with any investigations of compounds containing hydroxyl groups, and the influence of $Co(acac)_2$ on the ^1H n.m.r. spectra of amines is being examined further.

The effects of some other paramagnetic complexes on the n.m.r. spectra of amines and hydroxylic compounds were also investigated. Contact shifts with $Ni(acac)_2$ are approximately as large as with $Co(acac)_2$, although β-CH_n resonances tend to move slightly downfield rather than upfield. Line broadening is much more noticeable with $Ni(acac)_2$, however, with the result that loss of resolution of fine structure is much more pronounced.

No contact shifts were observed using Cu(ethyl acetoacetate)$_2$ either with alcohols or amines. In the case of ethanol, at least, the line broadening effects are much greater than those with $Co(acac)_2$. In the case of amines, the attenuation of the line broadening by the copper compound is rather remarkable. The presence of 5.6×10^{-3} *M* Cu(ethyl acetoacetate)$_2$ in a 1 *M* solution of triethylamine causes complete loss of resolution of the methylene quartet, leaving a broad band. The methyl resonance, on the other hand, is still a very well-resolved triplet. The effect of the copper compound on diethylamine is even more drastic and is illustrated in Fig. 3. The presence of only 3×10^{-5} *M* copper completely destroys the methylene resolution, although the methyl triplet is virtually unaffected and still exhibits ringing. When the copper concentration is raised to 6.2×10^{-4} *M*, the methylene resonance has virtually disappeared into the baseline, a change which is complete when the copper concentration is 3.4×10^{-3} *M*, although the methyl resonance is still an easily recognized triplet.

Discussion

In the presence of a Lewis base, the cobalt and nickel acetylacetonates exist as the labile monomers *trans*-$M(acac)_2L_2$ (M = Co, Ni; L = Lewis base) (12).

$$[3] \qquad M(acac)_2 + 2L \rightleftharpoons M(acac)_2L_2$$

Since the exchange of ligands L between complexed and uncomplexed sites is rapid on the n.m.r. time scale, the spectra are time-averaged, the various proton resonances being shifted from their normal diamagnetic values by an amount which is proportional to the concentration of the paramagnetic compound. Thus as $Co(acac)_2$ is added to a solution of a potential ligand, in this

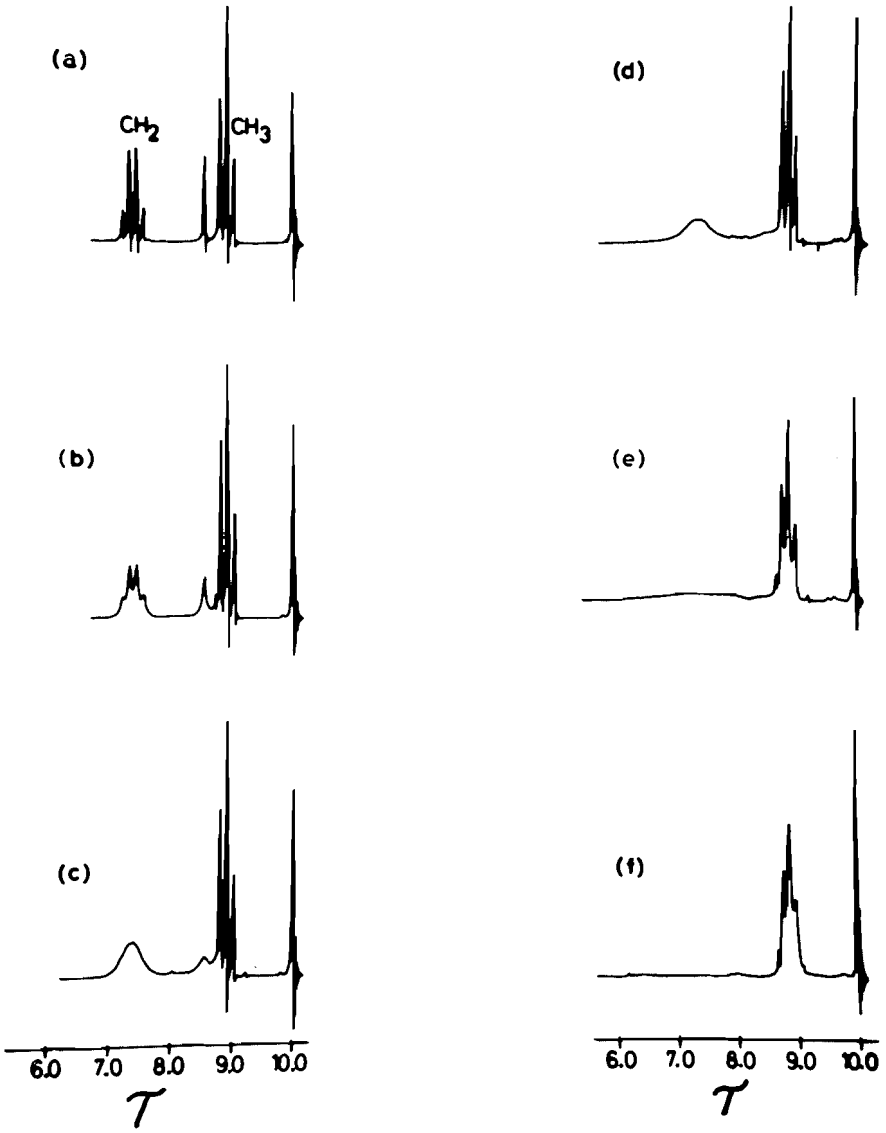

FIG. 3. Perturbation of the nuclear magnetic resonance spectrum of diethylamine (1 M in $CHCl_3$) by Cu(ethyl acetoacetate)$_2$. Concentrations of Cu(ethyl acetoacetate)$_2$: (*a*) 0, (*b*) ~ 6.0×10^{-6} M, (*c*) ~ 3.0×10^{-5} M, (*d*) ~ 6.2×10^{-5} M, (*e*) 6.2×10^{-4} M, and (*f*) 3.4×10^{-3} M.

work an alcohol, the proton resonances of L shift towards the resonance positions of the complex $Co(acac)_2L_2$. A number of reports have been published on the ^1H n.m.r. spectra of the complexes $Co(acac)_2L_2$ and $Ni(acac)_2L_2$ where L is pyridine (13), piperidine (13), α-, β-, and γ-picolines (13), aryl phosphines, arsines, amines, sulfides, halides, and isonitriles (14), substituted anilines (15), substituted pyridine *N*-oxides (16, 17) and quinoline *N*-oxides (18). No contact shifts were observed with bromobenzene, tris-*o*-tolylphosphine, triphenylarsine, triphenylamine, benzonitrile, and diphenyl sulfide (13). Contact shift data have been generally interpreted in terms of spin delocalization from the metal to the ligands L and it has been found that, as expected, both σ- and π-delocalization mechanisms can operate.

The correlation of the contact shift of the α-CH_n group of the saturated alcohols with structure (Fig. 2) is probably a result of steric interactions. It is seen that the contact shift is approximately the same for all the straight-chain alcohols, but is decreased somewhat when an alkyl substituent is on the β-carbon atom and decreased still further when substitution occurs on the α-carbon atom. The substituents probably have the effect of destabilizing the metal–ligand bond, thereby shifting the equilibrium of eq. 3 to the left. Since the observed contact shift is a weighted average of the chemical shifts of free and complexed L, a decrease in equilibrium constant will lead to smaller contact shifts.

Our results with compounds containing other functional groups as potential Lewis bases suggest that only amines will interfere. Although some of the ethers undoubtedly interact with $Co(acac)_2$, only slight shifts to higher field appear to occur. Ether linkages two or three carbon atoms away from a hydroxyl group may lead to chelation, but we have no evidence for such behavior at present.

The relatively large contact shifts with amines are probably a result of the much greater basicity of amines as compared with alcohols. Thus the equilibrium in eq. 3 will lie farther to the right, resulting in a greater proportion of the ligand being complexed and hence a larger contact shift. The difference between di- and triethylamine is probably a result of steric factors, although a great deal of work with nitrogen donors remains to be done. The effect of Cu(ethyl acetoacetate)$_2$ on the methylene resonance of diethylamine is quite remarkable, and work is now in progress to see if the result is general for secondary amines. It may be that different metal complexes will be specific for different functional groups.

The authors thank the National Research Council of Canada for financial support of this research and Mr. T. B. Grindley for carrying out some of the preliminary work.

The Heats of Solution and Related Thermodynamic Properties of Sodium Chlorate in Water and Water–Dioxane Mixtures

A. N. CAMPBELL AND O. BHATNAGAR[1]

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received August 17, 1970

The heats of solution of sodium chlorate in water, and in several water–dioxane mixtures, have been determined experimentally at concentrations of salt ranging from 0.01 molal to saturation. For the dilute region, a direct method was used but for the concentrated range the method was that of diluting the saturated solution. The free energy decreases due to dilution have been calculated from previously determined activity coefficients. Using these data, the entropy changes have been evaluated.

The graph of heat of solution *vs.* concentration of sodium chlorate passes through a minimum for the solutions more concentrated in dioxane, but not for water and weak dioxane mixtures. A tentative explanation of this is offered.

Canadian Journal of Chemistry, 49, 217 (1971)

The present paper is a continuation of the work on the electrical and thermodynamic properties of solutions of sodium chlorate and of lithium chlorate in water and in water–dioxane mixtures, which has been carried out in this laboratory over the last few years (1). In a recent paper (2) Campbell and Oliver reported the mean molal activity coefficients of sodium chlorate and of lithium chlorate in water, in 44.5 wt. % dioxane–water and in 64.5 wt. % dioxane–water. In the present work we have determined the heats of solution of $NaClO_3$ over the entire solubility range in water and in various water–dioxane mixtures, including those solvent mixtures, for which we had previously determined the activity coefficients.

These data have enabled us to determine the excess free energy and entropy of solution. A comparison of these thermodynamic data for the various solutions illustrates the effect of varying dielectric constant on the excess free energy and entropy of solution.

Experimental

Purity of Chemicals

The methods of purification have been described previously (2). The purified dioxane had a refractive index of $n_D^{25} = 1.4203$ and a density of 1.0283 g/cc. The accepted literature values are $n_D^{25} = 1.42025$ (3) and $d = 1.02804$ (4). The water, obtained by passage through an ion-exchange column, had a specific conductance of 2×10^{-7} mhos/cm.

Heats of Solution

The heats of solution were determined by two different methods, one applied to the dilute range and the other to the concentrated range. The heats of solution in the dilute range were determined in an apparatus which is represented in Fig. 1. Heats of solution in the concentrated range were determined as heats of dilution of the saturated solution, using an apparatus previously described (5). Such results are dependent for their accuracy upon the reliance which can be placed upon the

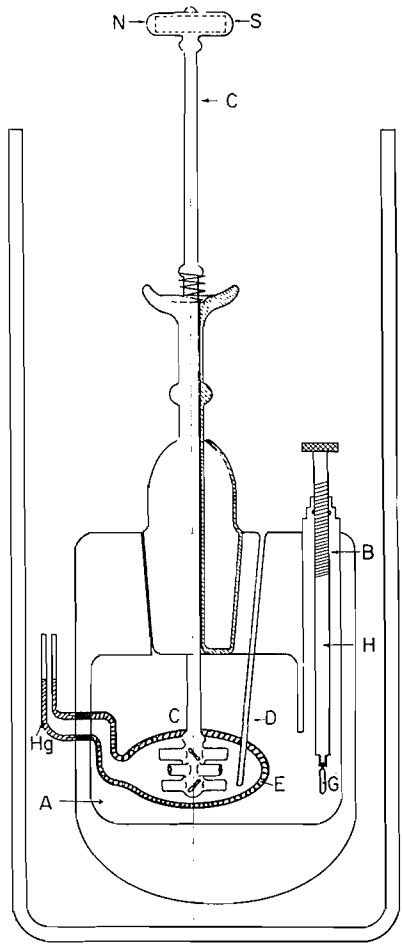

FIG. 1. Double-walled glass calorimeter.

[1]Postdoctorate Fellow.

direct determination of heat of solution in, say, 1 *m* solution. We found that our results by both methods lay on one smooth curve.

The calorimeter used for direct determination (Fig. 1) consists of a double-walled glass vessel of total capacity about 80 cc. The space between the inner and outer walls is evacuated and silvered. The inner compartment is divided into two parts, A and B. Part A is fitted with standard taper joint and a silvered glass stopper, which carries an exit tube housing the magnetic stirrer, C. The blades of the stirrer are bent in such a way as to create a whirlpool around the stirrer, which sucks solid salt into this area very quickly, ensuring quick solution of the salt. Compartment A also carries a thermistor well, D, for temperature sensing. The heating element, E, consists of platinum wire (resistance = 2 ohms approximately) and is sealed into a glass tube. Compartment B contains an ampoule, G, and a crushing device, H, consisting of a teflon screw. The ampoules are made from 6 mm Pyrex tubing, blown to 1 cm diameter, and 5 cm long. The ampoules are sealed under vacuum and attached to the teflon screw with polyethylene tubing. Screwing down the crushing device causes the ampoule to break.

The accuracy of the calorimeter was tested by determining the heat of reaction of THAM (tris(hydroxymethylamino) methane) with 0.1 *N* HCl. We obtained a value of 7136 ± 22 cal/mole, slightly higher than the reported value of 7104 cal/mole (6). We claim an overall accuracy of 1% for our results.

Results

The direct experimental results are reproduced in Table 1, which gives the direct heats of solution, heats of dilution, and derived heats of solution, as functions of molality and of $m^{1/2}$.

The derived thermodynamic quantities were obtained as follows. Campbell and Oliver (2) have reported the activity coefficients of $NaClO_3$ in water, in 44.5% dioxane and in 64.5% dioxane – water mixtures. They found that the mean molal activity coefficients could be represented by the equation

$$[1] \quad \ln\gamma = -Sm^{1/2} + Bm + Cm^{3/2} - Dm^2$$

where γ is the mean molal activity coefficient of the solute, S is the Debye–Hückel limiting slope, and B, C, and D are adjustable constants. The latter were evaluated from the experimental data, as described by Campbell and Oliver (2). In the absence of experimental work leading to γ values in the dilute region, we used the above equation to calculate γ in the dilute region. The activity coefficients were then used to calculate the excess free energy decrease of solution and from this the entropy change or $T\Delta S$ values, in the usual way. These values are reproduced in Table 2. The limiting or standard heats of solution ΔH^0, were obtained by plotting experimental ΔH's of solution against $m^{1/2}$ and extrapolating to $m = 0$. The results are expressed graphically in Fig. 2. Since sodium chlorate is insoluble in pure dioxane, experimental measurements were impossible but a reasonable value of ΔH^0 for pure dioxane was obtained from the so-called heat of transfer (ΔH_{trans}). This represents the difference between the heat of solution ΔH^0 in pure water and in a given dioxane–water solvent. The heats of transfer were evaluated for dioxane–water mixtures and these were plotted against the dielectric constant of the mixture. From this plot the value of ΔH_{trans} from water to pure dioxane was found to be 4660 cal/mole from which the ΔH^0 value for pure dioxane results as 620 cal/mole. The values of ΔH^0 for the mixed solvents, obtained in the above way, are also to be found in Table 2.

Discussion

Foz and Colomina (7) report a ΔH^0 value of 5.29 kcal/mole, as against our value of 5.28 kcal/mole. In obtaining their ΔH^0 value, however, Foz and Colomina plotted experimental ΔH values against m, the molality. A better procedure, and that adopted by us, is to plot ΔH against $m^{1/2}$. When the data of Foz and Colomina are treated in this way, a result of $\Delta H^0 = 5.40$ kcal/mole is obtained, a value somewhat higher than ours. The results of Foz and Colomina are higher than ours.

The plots of ΔH *vs.* $m^{1/2}$ are straight lines for pure water and for 44.5% dioxane but 50.0, 64.5, and 70.0% dioxane – water mixtures give curves passing through a minimum, and this minimum becomes more pronounced with increasing dioxane content, that is, with lower dielectric constant. According to theory, in the absence of ionic association, the experimental plot should lie above the limiting slope but this behavior is only observed with pure water as solvent. In all the dioxane–water mixtures, the experimental curves lie below the limiting slope, the deviation being more pronounced with increasing dioxane content, that is, with decreasing dielectric constant. Ionic association of course increases in the lower dielectric constant media.

Figure 3 is a plot of ΔH, ΔG, and $T\Delta S$ *vs.* m, for water and for two mixed solvents. The values of limiting ΔH and $T\Delta S$ decrease with decreasing dielectric constant but the value of the free energy

change increases. The lower values of ΔH^0 may be accounted for on the supposition that, as the content of dioxane increases, fewer hydrogen bonds, per mole of solvent, are broken.

The fact that a minimum occurs in the ΔH plot on three of the five curves, *viz.*, those for 50.0, 64.5, and 70.0% dioxane, may possibly be due to dioxane playing the major role in solvating the ions in the dilute region, while the process is reversed as the concentration of salt increases, the solvation then being principally a water solvation. The curves for the concentrated (salt) range are similar to those in water and 44.5% dioxane, where, presumably, the solvation is principally hydration. At first sight, this explanation seems unlikely, in view of the lower dielectric

constant of pure dioxane. Hyne (8), however, has shown that the addition of electrolyte to dioxane–water mixtures greatly increases the micro dielectric constant above its bulk value. However this may be, one can hardly avoid the conclusion from purely arithmetical considerations that dioxane solvation (low value of ΔH) must predominate in solutions low in salt, if the dioxane content is greater than 44.5%.

We thank our glass-blower, Mr. Bryn Easterbrook, for construction of the apparatus as well as helpful suggestions for its design.

A Technique for Determining Proton Chemical Shifts arising from Ring Current Effects: the Conformations of Triply Ortho-substituted Diphenyl Ethers[1]

J. J. BERGMAN AND W. D. CHANDLER
Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan

AND

R. Y. MOIR
Department of Chemistry, Queen's University, Kingston, Ontario

Received July 22, 1970

A double-difference technique, making it possible to obtain that part of proton chemical shifts that originates in the shielding by the second ring in diphenyl compounds, is discussed. Evidence in support of the theory comes from the chemical shifts of aromatic ring protons in a family of triply ortho-substituted diphenyl ethers. The conformations of these ethers appear to be independent of the ortho-substituent, X ($X \neq H$), and the COC angle is shown to be approximately 120°.

Canadian Journal of Chemistry, 49, 225 (1971)

Studies of aromatic conformation rely heavily upon the magnetic anisotropy of the benzene ring. Separation of this effect from the others that influence the chemical shift of proton magnetic resonance (p.m.r.) signals has been difficult, and most of the previous studies (*e.g.*, ref. 1) have been content with qualitative or empirical evaluations. This paper describes a method for determining the "other ring" contribution quantitatively for diphenyl ethers.

In a previous paper (1) it was shown by nuclear magnetic resonance (n.m.r.) spectral analysis that triply ortho-substituted diphenyl ethers derived from metameconine (**1***a–c*) adopt the asymmetric, "H_a-inside" conformation as their principal conformation (Fig. 1). This conclusion was inferred from the observation that the n.m.r. signal from H_a occurs 0.27 to 0.38 p.p.m. to higher field in the diphenyl ethers than in the corresponding anisoles (**2***a–c*). At the same time, the signals from H_b and H_c are 0.13 to 0.18 and 0.067 to 0.20 p.p.m. to higher and lower field respectively when a similar comparison is made. H_a and H_b must see more of the ring current-induced shielding field of the metameconine ring than does H_c and the "H_a-inside" conformation of Fig. 1 accounts for this fact nicely. It was shown in the same paper that the two ortho-hydrogens of **1***d* are magnetically equivalent, indicating that the two "H-inside" conformations are exchanged at such a rate that the average lifetime is less than the lifetime of proton spin states.

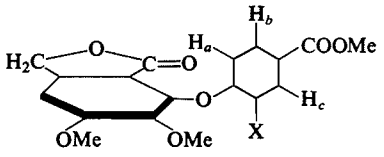

FIG. 1. "H_a-inside" conformation of triply ortho-substituted diphenyl ethers derived from metameconine.

was done in the previous work, since the "other-ring" shielding is highly conformation dependent. The conformation, or geometrical relationship of the two rings, can, except for the carbon–oxygen bond lengths, be described in terms of three angular parameters. These are the COC bond angle and the two angles defining the rotation of each ring relative to the plane containing the COC bond. Every conformation will fix the geometric relation of H_a, H_b, and H_c to the other ring and, by the use of some appropriate model (2–5), the "other-ring" shielding at these protons could be calculated. If, at the same time, there were a method of extracting the "other-ring" shielding for each of H_a, H_b, and H_c from their chemical shifts, these experimental values could be related to the calculated ones and the average conformation deduced. There would be three equations, one for each of the three protons, to calculate the three unknown angles. In practice, such a procedure would be difficult for two reasons: (*i*) the "other-ring" shielding must be averaged over weighted values of the angles as the n.m.r. spectrum is obtained for a mobile system. Doing this averaging could be a formidable task unless reasonable guesses were made as to the limits to be imposed on the angles; (*ii*) the total chemical shift is dependent upon a number of factors, the magnetic anisotropy of the second ring being only one of them.

The next section describes a method of extracting the "other-ring" effects from experimental chemical shifts.

First-order, Double-difference Method

The discussion is restricted to the determination of "other-ring" effects for protons of triply ortho-substituted diphenyl ethers such as **1***a*–**1***c*. Our method requires that the related disubstituted ether (**1***d*) and anisoles (**2***a*–**2***d*) be available for comparison.

Let $\delta_{DX}{}^j$ be the chemical shift observed for the *j*th ring proton (H_a, H_b, or H_c) in a diphenyl ether such as **1***a*–**1***c*, *i.e.* with X not hydrogen. The simplest possible theory would be that this chemical shift could be thought of as made up of independent contributions from: (*i*) the substituent X, $\delta_X{}^j$, (*ii*) the rest of the molecule but not including "other-ring" shielding, $\delta_D{}^j$, and (*iii*) the "other-ring" shielding, $\delta_{\omega X}{}^j$, which depends on conformation. Thus,

$$\delta_{DX}{}^j = \delta_X{}^j + \delta_D{}^j + \delta_{\omega X}{}^j$$

In practice this model was found to work well enough to inspire confidence in the approach, but considerable improvement was obtained by the introduction of a parameter $\delta_{D,X}{}^j$, which expresses the fact that the contributions of D and X are not quite independent. With this term added the working equation is [1].

$$[1] \qquad \delta_{DX}{}^j = \delta_D{}^j + \delta_X{}^j + \delta_{D,X}{}^j + \delta_{\omega X}{}^j$$

As shown later this very simple model satisfied several experimental tests. For the anisoles such as **2***a*–**2***c*

$$[2] \qquad \delta_{AX}{}^j = \delta_A{}^j + \delta_X{}^j + \delta_{A,X}{}^j$$

where $\delta_{AX}{}^j$ is the chemical shift of the *j*th proton in the appropriately substituted anisole. Subtracting [2] from [1] for the same X and *j* gives

$$[3] \quad \delta_{DX}{}^j - \delta_{AX}{}^j = (\delta_D{}^j - \delta_A{}^j) + (\delta_{D,X}{}^j - \delta_{A,X}{}^j) + \delta_{\omega X}{}^j$$

When X = H (**1***d* and **2***d*) eq. 3 becomes

$$[4] \quad \delta_{DH}{}^j - \delta_{AH}{}^j = (\delta_D{}^j - \delta_A{}^j) + (\delta_{D,H}{}^j - \delta_{A,H}{}^j) + \delta_{\omega H}{}^j$$

The difference between [3] and [4] gives the double-difference eq. 5.

$$[5] \quad \Delta_X{}^j \equiv (\delta_{DX}{}^j - \delta_{AX}{}^j) - (\delta_{DH}{}^j - \delta_{AH}{}^j) = (\delta_{D,X}{}^j - \delta_{A,X}{}^j) - (\delta_{D,H}{}^j - \delta_{A,H}{}^j) + (\delta_{\omega X}{}^j - \delta_{\omega H}{}^j)$$

Were it not for the two non-linear terms, $\Delta_X{}^j$ would be a direct experimental measure of the difference in "other-ring" shielding for diphenyl ethers with X = H and X ≠ H, and if the assumption were made that $\delta_{\omega X}{}^j$ is independent of the substituent X, then eq. 5 would predict $\Delta_X{}^j$ to be a constant throughout a given family. Although the number of compounds in family **1** was limited, the observation (1) that $\Delta_X{}^j$ varies with X far beyond experimental error suggests that $\delta_{\omega X}{}^j$ is not substituent independent, or that the non-linear terms are important or both.

Equation 5 may be further simplified if use is made of the separability postulate.[2] The interaction shifts are written as

$$[6] \qquad \delta_{Y,Z}{}^j = I_Y{}^j I_Z{}^j$$

[2]A discussion of this postulate is given by Leffler and Grunwald (6) under the theory of extrathermodynamic relationships.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the product of separate parameters for each part, provided that the interaction is small or has a direction that remains approximately constant for the family to be compared. Then eq. 5 becomes

$$[7]\quad \Delta_X{}^j = (I_D{}^j I_X{}^j - I_A{}^j I_X{}^j) - (I_D{}^j I_H{}^j - I_A{}^j I_H{}^j) + (\delta_{\omega X}{}^j - \delta_{\omega H}{}^j)$$

$$[8]\quad \Delta_X{}^j = (I_X{}^j - I_H{}^j)(I_D{}^j - I_A{}^j) + (\delta_{\omega X}{}^j - \delta_{\omega H}{}^j)$$

The use of [8] is made difficult by the two X-dependent terms on the right side. However, if $\delta_{\omega X}{}^j$ were independent of X (X ≠ H), a plot of $\Delta_X{}^j$ *vs.* $I_X{}^j - I_H{}^j$ would result in a straight line whose intercept on the $\Delta_X{}^j$ axis would be the desired $\delta_{\omega X}{}^j - \delta_{\omega H}{}^j$ for a mythical diphenyl ether with the same conformation as the other ethers (X ≠ H) but for which the electronic properties of X would be the same as those of H. The problem with this analysis is that the interaction parameters $I_X{}^j$ are not known.

There have been attempts to correlate the chemical shifts of aromatic protons with substituent parameters such as Hammett's σ values (7), and *d* values of Martin and Dailey (8), and *Q* values (9–11).[3] Since all of these parameters have been used to explain non-additive chemical shifts with some success, it is not unreasonable to assume that the $I_X{}^j$ parameters might be related in some way to them. If a linear relationship were to hold, the following equations would be obtained.

$$[9]\quad \Delta_X{}^a = A(d_m{}^X - d_m{}^H) + (\delta_{\omega X}{}^a - \delta_{\omega H}{}^a)$$
$$\Delta_X{}^a = B(\sigma_m{}^X - \sigma_m{}^H) + (\delta_{\omega X}{}^a - \delta_{\omega H}{}^a)$$

$$[10]\quad \Delta_X{}^b = C(d_p{}^X - d_p{}^H) + (\delta_{\omega X}{}^b - \delta_{\omega H}{}^b)$$
$$\Delta_X{}^b = D(\sigma_p{}^X - \sigma_p{}^H) + (\delta_{\omega X}{}^b - \delta_{\omega H}{}^b)$$

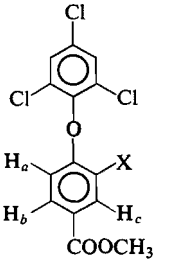
$$[11]\quad \Delta_X{}^c = F(d_o{}^X - d_o{}^H) + (\delta_{\omega X}{}^c - \delta_{\omega H}{}^c)$$
$$\Delta_X{}^c = G(Q^X - Q^H) + (\delta_{\omega X}{}^c - \delta_{\omega H}{}^c)$$

where *A*, *B*, *C*, *D*, *E*, *F*, and *G* are all constants. Since the σ, *d*, and *Q* parameters are known or can be calculated, an experimental way is open to test the double-difference theory and its underlying assumptions and, at the same time, to obtain "other-ring" shielding data.

[3]W. B. Smith, private communication. For purposes of this work the *Q* values for NH_2 and NO_2 were taken to be −0.7 and 6.3, respectively (11).

Results

To test the method outlined above a new series of triply ortho-substituted diphenyl ethers (**3**) was prepared. This particular series was chosen because (*i*) it was easier to synthesize than the corresponding metameconine series (**1**) and (*ii*) the two trichlorophenyl ring protons are equivalent, can easily be identified, and their signal does not interfere with the *ABC* pattern of the other three aromatic protons.



3

3*a*: X = NO_2; **3***b*: X = NH_2
3*c*: X = I; **3***d*: X = H
3*e*: X = OCH_3; **3***f*: X = Cl
3*g*: X = CN

The n.m.r. spectrum of each ether was taken along with that of the corresponding anisole (**2**) at ambient temperature. In all cases concentration effects were minimized. To insure accuracy of the chemical shift data, the aromatic region of each spectrum was reproduced to within ±0.2 Hz by an *ABC* or *AA'BB'* calculation. The experimental values for $\Delta_X{}^j$ are given in Table 1.

An excellent linear, least-squares correlation was obtained from a plot[4] of $\Delta_X{}^b$ against σ_p (Fig. 2), with a standard deviation of 0.005 p.p.m.

TABLE 1. $\Delta_X{}^j$ values for the diphenyl ether series **3***

X	$\Delta_X{}^a$ (p.p.m.)†	$\Delta_X{}^b$ (p.p.m.)†	$\Delta_X{}^c$ (p.p.m.)†
NO_2	−0.419‡	−0.107†	0.165
NH_2	−0.408	−0.167	0.118
I	−0.398	−0.140	0.097
CN	−0.375	−0.110	0.128
Cl	−0.402	−0.132	0.112
OCH_3	−0.382	−0.143	0.132

*In solution in chloroform-*d*.
†The estimated experimental error is ±0.007 p.p.m.
‡The δ values were measured relative to tetramethylsilane so as to increase as the applied magnetic field decreases. The negative sign indicates that H_a and H_b are more shielded in the diphenyl ether than in the corresponding anisole.

[4]σ values have been taken from reviews by Jaffé (12) and Ritchie and Sager (13).

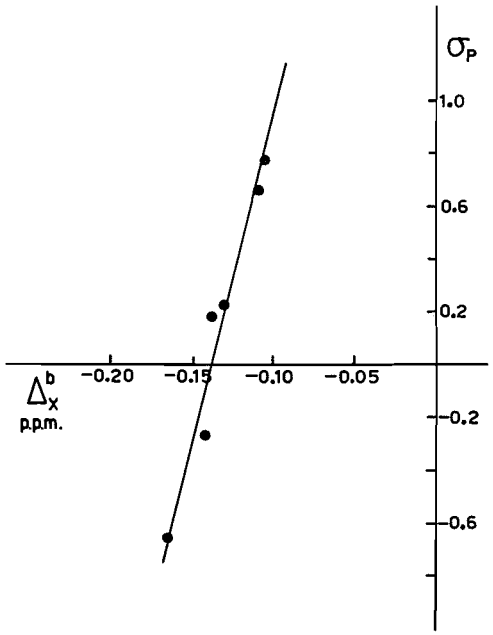


FIG. 2. Plot of $\Delta_X{}^b$ *vs.* σ_p.

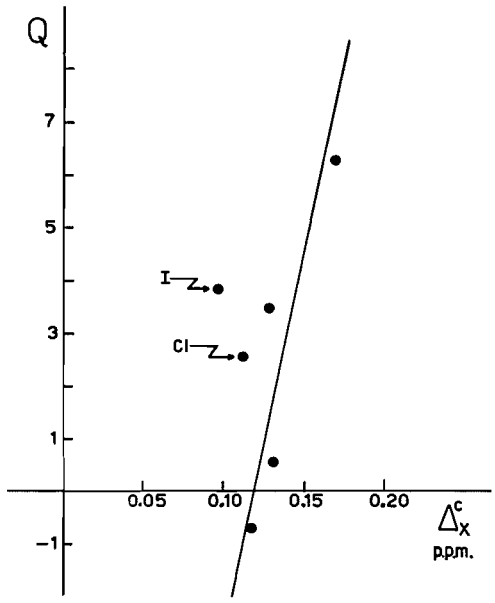

FIG. 3. Plot of $\Delta_X{}^c$ *vs.* Q.

and a correlation coefficient of 0.97. Using $\sigma_p{}^H = 0.00$ and the equation for the line ($\Delta_X{}^b = -0.149 + 0.0395\sigma_p{}^X$), $\delta_{\omega X}{}^b - \delta_{\omega H}{}^b$ was calculated to be -0.140 ± 0.002 p.p.m., well within the estimated experimental error. By comparison, the average value, $\bar{\Delta}_X{}^b$, for the six compounds studied is -0.133 p.p.m. with a standard deviation of 0.020 p.p.m. As expected, the correlation between $\Delta_X{}^b$ and d_p was equally good, since d_p and σ_p themselves correlate well (8). It would seem that there is an experimental justification for the approach used for H_b.

There is a poorer correlation between $\Delta_X{}^c$ and Q (Fig. 3) or d_o with the points for X = I and X = Cl deviating from the best straight line drawn for the other four substituents by 0.03 to 0.05 p.p.m. Without these two points the standard deviation is 0.010 p.p.m. and the correlation coefficient is 0.89. Using the known value for Q^H, $\delta_{\omega X}{}^c - \delta_{\omega H}{}^c$ was calculated to be 0.135 ± 0.003 p.p.m., again within experimental error. With all six points included, the standard deviation increased to 0.018 p.p.m. while $\delta_{\omega X}{}^c - \delta_{\omega H}{}^c$ was 0.123 ± 0.008 p.p.m. The average value for the six compounds is 0.125 p.p.m. with a standard deviation of 0.023 p.p.m. The inability of substituent parameters to account for the chemical shifts of protons ortho to I and, to a lesser extent, to Cl, is well known (7, 8). However, the present deviation of 0.05 p.p.m. is lower than that observed by these single-difference techniques. In light of the earlier work on substituent parameters, it is surprising that the CN group does not also cause a large deviation.

$\Delta_X{}^a$ does not correlate with either σ_m (Fig. 4) or d_m within experimental error although there is a trend of $\Delta_X{}^a$ becoming slightly less negative with decreasing σ_m and with increasing d_m. The standard deviation from a straight line is 0.018 p.p.m. with a correlation coefficient of 0.06. By comparison, the average value $\bar{\Delta}_X{}^a = -0.396$ p.p.m. with a standard deviation of 0.017 p.p.m. It is this average value that will be used in subsequent discussion of $\delta_{\omega X}{}^a - \delta_{\omega H}{}^a$.

It is understandable that $\Delta_X{}^a$ would give such poor correlation with substituent parameters as H_a, because of its proximity to the trichlorophenyl ring, would be most affected by deviations from an X-independent conformation; small variations would be less significant for H_b and H_c. In addition, d_m and σ_m vary over a smaller range than do the corresponding ortho and para parameters used for the six substituents. Considering the inherent errors in the substituent parameters and the reasonably small variations in the $\Delta_X{}^j$ values, it is satisfying that the correlations for H_b and H_c are as good as they are.

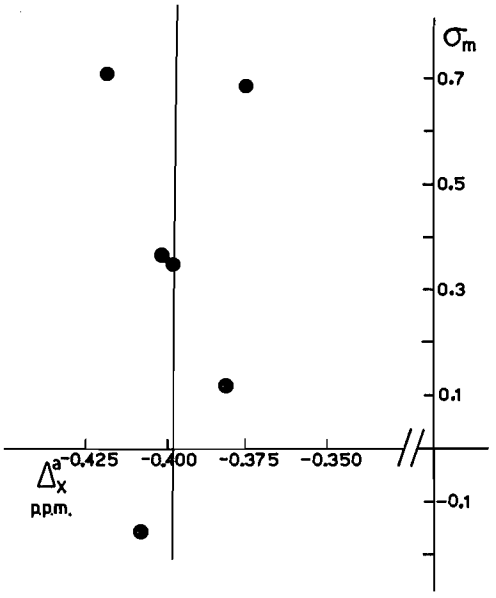

FIG. 4. Plot of $\Delta_X{}^a$ *vs.* σ_m.

Further evidence in favor of the theory can be obtained from a more explicit consideration of the conformations involved. If each diphenyl ether in series **3** (X ≠ H) adopts only the "H_a-inside" conformation[5] then

$$[12] \qquad \delta_{\omega X}{}^j = \lambda_0{}^j$$

where $\lambda_0{}^j$ is the "other-ring" shielding in that conformation, assuming that the COC bond angle and other parameters do not vary with X. To account for the equivalency of H_a and X, and H_b and H_c when X = H where $\lambda_\pi{}^j$ is the "other-

$$[13] \qquad \delta_{\omega H}{}^j = (\lambda_0{}^j + \lambda_\pi{}^j)/2$$

ring" shielding for the jth proton in the "H_a-outside" conformation (the ring has been rotated through 180°). At this level of approximation

$$[14] \qquad \delta_{\omega X}{}^j - \delta_{\omega H}{}^j = (\lambda_0{}^j - \lambda_\pi{}^j)/2$$

Since H_b and H_c would exchange places in a rotation of the X-containing ring through 180°, $\lambda_0{}^b = \lambda_\pi{}^c$ and $\lambda_\pi{}^b = \lambda_0{}^c$. Therefore,

$$[15] \quad \delta_{\omega X}{}^b - \delta_{\omega H}{}^b = (\lambda_0{}^b - \lambda_\pi{}^b)/2 = (\lambda_\pi{}^c - \lambda_0{}^c)/2 = -(\delta_{\omega X}{}^c - \delta_{\omega H}{}^c)$$

[5]Evidence from variable temperature n.m.r. studies (to be presented in a later paper) indicates this assumption is valid.

The experimental data show that the relationship expressed by [15] is observed, as $\delta_{\omega X}{}^c - \delta_{\omega H}{}^c = 0.135 \pm 0.003$ p.p.m. and $\delta_{\omega X}{}^b - \delta_{\omega H}{}^b = -0.140 \pm 0.002$ p.p.m. Thus the model has passed an important test that is independent of any particular theory for the source of the magnetic anisotropy in aromatic rings.

The data obtained for series **3** indicate that the double-difference technique works well and that the assumption that the ether conformation is independent of X is a reasonable one.

Determination of Conformation

The three angular parameters θ, φ, and ψ necessary to fix the conformation of a diphenyl ether can be defined as follows: θ is the COC bond angle, φ is the angle the ring containing H_a, H_b, and H_c makes with the COC plane, and ψ is the angle the trichlorophenyl ring (the "other-ring") makes with the plane perpendicular to the COC plane but containing the CO bond. Such a definition means that when the molecule is in the "H_a-inside" conformation (Fig. 1), both φ and ψ are zero. The signs of φ and ψ are set as being positive for counterclockwise rotation when viewed along the respective CO bonds toward the oxygen.

If z_j and ρ_j are the coordinates defining the distance of H_j above the plane of the trichlorophenyl ring and the distance in the plane of the ring from its center, respectively (Fig. 5), then it is a straightforward matter to derive expressions for these coordinates in terms of the three angular parameters.

Although it represents an oversimplification, it is, nonetheless, instructive to see what happens if both φ and ψ are set equal to zero ("H_a-inside" conformation). In such a conformation, the shielding at H_a and H_b becomes a maximum. Using the appropriate calculated values of ρ and

TABLE 2. "Other-ring" shielding values calculated for the "H_a-inside" conformation*

θ	λ_0^a (p.p.m.)	λ_0^b (p.p.m.)	λ_0^c (p.p.m.)
110	−2.722	−0.358	0.038
115	−2.026	−0.284	0.047
120	−1.500	−0.222	0.056
130	−0.811	−0.126	0.067

*$\phi = \psi = 0$. See Fig. 1.

z, and the ring current shielding tables of Johnson and Bovey (4) the "other-ring" shielding shift has been calculated for each ring proton. These values, which are presented in Table 2 for four different θ's, are the λ_0^j used in eqs. 12 to 15 (the subscript 0 means that $\phi = 0$). For purposes of obtaining this datum, the CO length, L, was taken to be 1.28 Å, the value found by Toussaint (14) for 4,4′-dibromodiphenyl ether. Tables supplied by Farnum and Wilcox (5) gave similar values for λ_0^j although they are larger in magnitude by 10 to 20% than those obtained using the tables of Johnson and Bovey.

Since $\delta_{\omega X}^j - \delta_{\omega H}^j$ would be $(\lambda_0^j - \lambda_\pi^j)/2$ for the "H_a-inside" conformation (from eq. 14), these have been calculated for the same COC angles and are shown in Table 3.

On the basis of a pure "H_a-inside" conformation, the three calculated values for $\delta_{\omega X}^j - \delta_{\omega H}^j$ are not internally consistent for any COC angle, θ, when compared with the experimental ones (−0.396, −0.140, and 0.135 p.p.m.). For example, if the experimental and calculated values for $\delta_{\omega X}^b - \delta_{\omega H}^b$ or $\delta_{\omega X}^c - \delta_{\omega H}^c$ are matched, θ would have to be in the neighborhood of 120°. At this angle, the calculated $\delta_{\omega X}^a - \delta_{\omega H}^a$ is more than twice the experimental −0.396 p.p.m. Common sense suggests that the actual conformation must account for librations in the angles φ and ψ even if H_a is "inside". How large these librations should be and how the infinite number of conformations generated by them should be averaged to give an average value of $\delta_{\omega X}^j - \delta_{\omega H}^j$ is difficult to judge.[6] However, the use of equations for z and ρ and tables of ring shielding parameters shows that as φ and ψ increase from zero, the shielding drops off far more rapidly for H_a than for either H_b or H_c. For example, with $\theta = 120°$, if $\phi = \psi = 15°$, $\delta_{\omega X}^j - \delta_{\omega H}^j$ would be −0.46, −0.12, and 0.12 p.p.m. for $j = a$, b, and c, respectively. This assumes that when X = H, the two "H-inside" conformations with $\phi = 15$ and 165° are still equally probable to account for magnetic equivalence. Thus it is quite reasonable to have $\theta = 120°$ and $\delta_{\omega X}^j - \delta_{\omega H}^j = -0.40$, −0.14, and 0.14 p.p.m. provided that ϕ_{av} and ψ_{av} are sufficiently large.[7]

TABLE 3. $(\lambda_0^j - \lambda_\pi^j)/2$ calculated for the "H_a-inside" conformation*

θ	$(\lambda_0^a - \lambda_\pi^a)/2$ (p.p.m.)†	$(\lambda_0^b - \lambda_\pi^b)/2$ (p.p.m.)	$(\lambda_0^c - \lambda_\pi^c)/2$ (p.p.m.)
110	−1.454	−0.198	0.198
115	−1.107	−0.165	0.165
120	−0.844	−0.139	0.139
130	−0.500	−0.096	0.096

*$\phi = \psi = 0$. See Fig. 1.
†λ_π^a is approximately 0.190 p.p.m. regardless of the value of θ.

Although no estimates of the COC bond angle have been made previously for diphenyl ethers as highly substituted as those used in this study, Toussaint (14) estimated the angle in solid 4,4′-dibromodiphenyl ether to be 123° by X-ray studies and Leonard and Sutton (15) obtained a value of 116 ± 4° for diphenyl ether itself from dipole moment studies. The present work suggests an angle not larger than 120° but probably greater than 115°, surprisingly in good agreement with the literature when one considers the simplicity of the model used.

Besides the previously mentioned simplifications, the ring current picture is itself a classical model and may not adequately give a three-dimensional representation of the associated magnetic field. The π-current is undoubtedly more dispersed than the two currents separated by 1.28 Å in the Johnson–Bovey model (the Farnum–Wilcox, double torroidal-shell model predicts a slightly larger value for θ). How substituents such as three chlorines affect the ring current is, of course, unknown but the possibility of the effect being substantial cannot be ruled out.

Finally, although a specific series of diphenyl ethers was studied, any group of diphenyl com-

[6]Work is presently underway on computer averaging of the possible conformations to obtain better estimates of $\delta_{\omega X}^j - \delta_{\omega H}^j$ to compare with the experimental values.

[7]$\delta_{\omega X}^a - \delta_{\omega H}^a$ can be made equal to −0.40 p.p.m ($\theta = 120°$) if the conformation is taken to be 70% pure "H_a-inside" and 30% "H_a-outside". However, $\delta_{\omega X}^b - \delta_{\omega H}^b$ would then be −0.05 p.p.m., a value far too low to be acceptable. Also see footnote 5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

pounds could have been used provided that a corresponding group of monophenyls was also available. An extension to benzophenones, diphenylmethanes, and diphenyl sulfides is presently underway.

Experimental

All nuclear magnetic resonance (n.m.r.) data reported were recorded using a Varian A-60-A spectrometer on a scale of 100 Hz sweep width, calibrated by means of a side-band method. All the lines in the aromatic 3- and 4-proton region were reproduced to within ±0.2 Hz by means of *ABC* or *AA'BB'* calculations done by means of the computer. $\Delta_X{}^J$ values were obtained as follows: the aromatic proton chemical shifts were measured on the corrected 100 Hz sweep width relative to a generated side-band of tetramethylsilane as an internal standard (2% *v/v*) and the four appropriate shifts were used to calculate $\Delta_X{}^J$. Because tetramethylsilane was used as the standard for shift measurements, negative values of $\Delta_X{}^J$ indicate that the *j*th proton was more shielded in the diphenyl ether than in the corresponding anisole. All the compounds were dissolved in chloroform-*d* at a concentration less than 9 mg/0.5 ml. No concentration effects were noticed provided the concentration was kept below this value. In many cases no concentration effects were noticed at all.

Melting points were determined on a Kofler, micro hot stage apparatus and are reported uncorrected.

The preparation and properties of the following have been described previously (1, 17): methyl 4-methoxy-3-nitrobenzoate (**2***a*); methyl 3-amino-4-methoxybenzoate (**2***b*); methyl 3-iodo-4-methoxybenzoate (**2***c*); methyl 4-methoxybenzoate (**2***d*); methyl 3,4-dimethoxybenzoate (**2***e*); 2-(4′-carbomethoxy-2′-nitrophenoxy)-1,3,5-trichlorobenzene (**3***a*); 2-(2′-amino-4′-carbomethoxyphenoxy)-1,3,5-trichlorobenzene (**3***b*); 2-(4′-carbomethoxy-2′-iodophenoxy)-1,3,5-trichlorobenzene (**3***c*); 2-(4′-carbomethoxyphenoxy)-1,3,5-trichlorobenzene (**3***d*); 2-(4′-carbomethoxy-2′-methoxyphenoxy)-1,3,5-trichlorobenzene (**3***e*).

Methyl 3-Chloro-4-methoxybenzoate (2f)

3-Chloro-4-hydroxybenzoic acid (0.5 g, m.p. 170–172°) was dissolved in 2 *N* aqueous sodium hydroxide (20 ml) and dimethyl sulfate (5 ml) was added. Additional base was added as needed to maintain a basic solution. The solution was allowed to stand overnight before being acidified with dilute hydrochloric acid to produce 3-chloro-4-methoxybenzoic acid (0.48 g), m.p. 114–115° (uncorrected). The methylated acid was refluxed for 10 h with methanol (30 ml), methyl iodide (3.0 ml), potassium carbonate (0.6 g), and a little water. Dilution of the solution with water gave the crude product (0.4 g) which was recrystallized from ligroin (b.p. 100–115°) as long white needles, m.p. 94–95° (uncorrected). A literature value of 94–95° is reported for this compound (16).

Methyl 3-Cyano-4-methoxybenzoate (2g)

Methyl 3-amino-4-methoxybenzoate (3.6 g) was dissolved in 6 *N* hydrochloric acid. After the solution had been cooled to below 5°, sodium nitrite (1.5 g) was added in small amounts with stirring. A solution of cuprous cyanide was prepared as follows: To a solution of copper sulfate (6.25 g) and sodium chloride (1.62 g) in hot water (20 ml), a solution of sodium bisulfite (1.32 g) and sodium hydroxide (1.75 g) in water (10 ml) was added. The precipitated cuprous chloride was filtered, washed well with absolute ethanol and ether, and was suspended in water (20 ml). Sodium cyanide (3.25 g) in water (5 ml) was added and the resulting solution cooled to 5°. Toluene (50 ml) was poured on top of the cuprous chloride solution before the cold diazonium salt solution, previously brought to neutral by the addition of sodium carbonate, was added slowly and with vigorous stirring. An immediate reaction occurred to yield an orange-red coloration. When addition was complete, the mixture was kept in ice for 0.5 h and then was left at room temperature for an additional 12 h. The toluene was evaporated and the dark residue collected (4.3 g). This material was recrystallized twice from ligroin (b.p. 100–115°), was sublimed and the sublimate was recrystallized from ligroin as a slightly yellow product, m.p. 125–126° (uncorrected). The infrared spectrum showed a peak due to CN stretching.

Anal. Calcd. for $C_{10}H_9NO_3$: C, 62.82; H, 4.74; N, 7.33. Found: C, 62.43, 62.75; H, 4.55, 4.53; N, 7.91, 7.63.

2-(4′-Carbomethoxy-2′-chlorophenoxy)-1,3,5-trichlorobenzene (3f)

(*a*) 2-(4′-Carbomethoxy-2′-iodophenoxy)-1,3,5-trichlorobenzene (5.0 g) was refluxed with cuprous chloride (1.0 g, prepared as outlined under preparation of **2***g*) in dimethylformamide (50 ml) for 12 h. The mixture was poured into an aqueous solution of acidic ferric chloride. Although the viscous oil that formed would not solidify, it was collected by decanting the water solution and was crystallized from hot ethanol (95%) as dark crystals (1.12 g). Two more crystallizations from ethanol (95%) gave white crystals, m.p. 97–99°. An n.m.r. spectrum of this sample showed the presence of a small amount of the iodo starting material. The analytical sample was prepared by crystallizing the material from petroleum ether (b.p. 37–50°), ligroin (b.p. 100–115°), aqueous ethanol and diethyl ether – petroleum ether (1:1), m.p. 97–100° but the iodo impurity could not be removed completely this way.

Anal. Calcd. for $C_{14}H_8O_3Cl_4$: C, 45.94; H, 2.20; Cl, 38.74. Found: C, 44.62, 44.77; H, 2.05, 1.97; Cl, 36.96, 37.28. This analysis indicates about 8–9% of the iodo starting material.

The n.m.r. data reported for this compound were obtained from the analytical sample.

(*b*) 2-(2′-Amino-4′-carbomethoxyphenoxy)-1,3,5-trichlorobenzene (5.9 g) was dissolved in glacial acetic acid (40 ml). This solution was added slowly to a second solution of sodium nitrite (1.38 g) in sulfuric acid (20 ml) with the temperature kept below 35°. After 2 h the mixture was added to a solution of cuprous chloride (8.0 g, prepared as outlined under preparation of **2***g*) in hydrochloric acid (10 ml). Frothing occurred initially but after 2 h the reaction subsided. Dilution with water produced a gummy residue which was dissolved in hot ethanol and

filtered, and the filtrate cooled to produce an oil. The oil could be crystallized from methanol only with much difficulty. Two further crystallizations from methanol yielded yellowish crystals, m.p. 96–99°. The infrared spectrum was essentially identical to that of the product produced by method (*a*) although there were traces of some impurity. The yield by this method was so low as to make it impractical to use it as a preparative procedure.

2-(4′-Carbomethoxy-2′-cyanophenoxy)-1,3,5-trichlorobenzene (3g)

2-(4′-Carbomethoxy-2′-iodophenoxy)-1,3,5-trichlorobenzene (5.0 g) was refluxed for 4 h with cuprous cyanide (1.11 g) in dimethylformamide (50 ml). The mixture was poured into a solution of ferric chloride (6.0 g) in dilute hydrochloric acid (50 ml). A gum was formed initially but this soon solidified. One recrystallization from ethanol (95%) gave long brown prisms (2.4 g), m.p. 126–128° (uncorrected), whose infrared spectrum showed absorption due to CN stretching. A further recrystallization from ethanol gave the analytical sample, m.p. 129–130° (uncorrected).

The Triplet State of Borazine

W. F. YOUNG, F. GREIN, J. PASSMORE, AND I. UNGER
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received August 5, 1970

An attempt has been made to experimentally locate the triplet state of borazine. Borazine vapor was added to benzene vapor excited at 2580 Å. Borazine vapor has no effect on the first excited singlet state of benzene but does strongly quench the triplet state. A comparison of the experimental findings with theoretical predictions has been carried out.

Introduction

The borazine molecule is remarkably similar to the benzene molecule. However, while there exists a considerable amount of literature dealing with the photochemistry of benzene (1–4), very little is known about the photochemical behavior of borazine (5). Borazine begins to absorb at about 2000 Å (6) and excitation in this region does not lead to dissociation (7) or emission, although the excited species may undergo certain reactions, such as deuterium exchange (5), which do not involve ring cleavage.

Theory predicts the triplet state of borazine to be at about 130 kcal. To date no experimental data have been forthcoming to substantiate this point. This communication describes an attempt to experimentally locate the triplet state of borazine.

Experimental

Materials

Biacetyl, from Aldrich Chemical Company, was stored in a blackened bulb and was purified by bulb-to-bulb distillation *in vacuo*. Fluorometric grade benzene from Hartman-Leddon Company was used without further purification. Borazine was prepared and purified according to the method of Hohnstedt and Haworth (8), but at lower yields. The purity of the product was estimated at about 98% from its infrared spectrum and vapor phase chromatography. The ultraviolet spectrum of up to 50 Torr of borazine was obtained by use of a Jarrell-Ash one meter 15° Robin Vacuum U.V. dual beam spectrophotometer. Above 2000 Å the spectrum was completely featureless (9). Below 2000 Å the spectrum was similar to that reported in the literature (6). All materials were thoroughly degassed before use.

Equipment

The high vacuum system employed was grease and mercury free equipped with Hoke packless metal diaphragm valves. Pressures were measured by means of a spiral gauge obtained from the National Research Council of Canada (NRCC) in Ottawa. The cell was a flow-through cuvette type, 1 cm × 1 cm × 4.5 cm. Samples in this cell were mixed by means of a circulating pump obtained from NRCC; all experiments were carried out at room temperature (27 °C). A modified Aminco-Bowman spectrofluorometer (spf.) was used for all emission measurements. Details about the spf. have been described previously (10).

When mixtures containing borazine, at pressures exceeding 30 Torr, and biacetyl were allowed to stay in the system for a short while ($\simeq$30 min), a heavy material was deposited on the walls of the vacuum line and some uncondensable gas was produced. These phenomena were observed with or without exposure to light. In order to minimize such effects fresh samples were always used with mixing, recording of the emission being performed as rapidly as possible ($\simeq$5 min).

Theoretical

Several s.c.f.–c.i. (self-consistent-field configuration-interaction) calculations, based on the Pariser–Parr–Pople (P.P.P.) approximation, have been reported in the literature. The results of Perkins and Wall (11) and Chalvet, Daudel, and Kaufman (12) are reproduced in Table 1. Chalvet *et al.* performed several sets of computations, differing in the choice of parameters. Only the set which is in best agreement with the observed u.v.-absorption spectrum has been selected for inclusion in Table 1. In rows 3 and 4 of Table 1 we report two representative sets of results from computations done in this laboratory. Details will be published elsewhere. In both cases the parameters were chosen according to P.P.P. methods with further adjustments to yield about 6.5 and 7.2 eV for the singlet transitions from the ground state to the $^1A_2'$ and $^1E'$ states of borazine, respectively. In the first case (row 3), the starting π-electron charges were taken to be one unit for both boron and nitrogen; in the second case (row 4), the starting charges for boron were zero, for nitrogen two units (uncharged model). It was found easier to work with the uncharged model, which also gave ionization energies in reasonable agreement with

TABLE 1. Electronic transition energies (in eV) from ground state of borazine

the observed one (11.5 eV calculated *vs.* 10.3 eV observed).

Of main interest are the calculated energies of the lowest triplet state. According to Table 1 they lie between 5.57 and 6.58 eV. Our calculations favor a value of 5.6 to 5.7 eV, or about 130 kcal/mole. In no case could a triplet excitation energy below 5.5 eV, or 127 kcal/mole, be obtained.

It may be noted in passing that our calculations place the excited $^1A_1'$ state above the $^1E'$ state. Similarly, one of the ^3A states comes out much higher in energy than the $^3E'$ state.

Results and Discussion

Essentially two types of experiments were carried out. (*a*) The effect of increasing pressures of borazine on the relative quantum yield of fluorescence of benzene excited at 2580 Å (band pass 40 Å) and hence the singlet yield was monitored. Table 2 summarizes the results, basically borazine has no effect on the first excited state of benzene. (*b*) The effect of borazine on the relative triplet quantum yield of benzene, excited at 2580 Å, was examined. Since benzene does not exhibit any phosphorescent emission in the gas phase the sensitized emission of biacetyl technique (13) was used to monitor the triplet yield of benzene. Borazine strongly quenches the triplet state of benzene, and $1/\Phi_s$ (the reciprocal of the relative sensitized emission yield of biacetyl) *vs.* borazine obeys a linear relationship (see Fig. 1). In order to be sure that the above phenomenon is not some sort of artifact due to the possible reaction between biacetyl and borazine, the effect of borazine on biacetyl excited at 4360 and 3650 Å was examined, the results are given in Fig. 2. Borazine has no effect on the emission yield of biacetyl excited directly at 4360 Å and increases the emission yield of biacetyl excited at 3650 Å. The above observations indicate that borazine has much the same effect as other vibrational quenchers have on the photochemical behavior of biacetyl (2, 14).

These experimental findings indicate that the triplet state of borazine lies at an energy not higher than 112 kcal, which is the maximum energy a benzene triplet would have if inter-

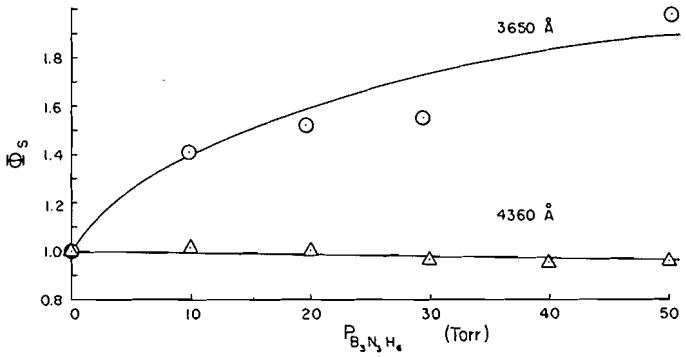

FIG. 2. The effect of borazine on the relative emission yield of 9.1 Torr of biacetyl excited directly at 3650 and 4360 Å.

system crossing, in that molecule, occurs from upper vibrational levels of the singlet. A kinetic scheme consistent with the experimental observations is given below. This scheme is by no means complete; however, since at 2580 Å, 80% of the benzene molecules which have absorbed light either fluoresce or crossover to the triplet state (15), the scheme should account for most of the major processes.

$$[1a] \quad B + h\nu \rightarrow B^s$$

$$[1] \quad B^s \rightarrow B + h\nu_f$$

$$[2] \quad B^s \rightarrow B^t$$

$$[3] \quad B^t + BiA \rightarrow BiA^t$$

$$[4] \quad B^t + BN \rightarrow BN^t + B$$

$$[5] \quad BiA^t \rightarrow BiA + h\nu_p$$

$$[6] \quad BiA^t \rightarrow BiA$$

$$[7] \quad BN^t \rightarrow BN$$

In the above scheme, B, BiA, and BN represent benzene, biacetyl, and borazine respectively, s denotes a molecule in the singlet state and t a molecule in the triplet state. Fluorescent emission is represented by $h\nu_f$ while phosphorescent emission is denoted by $h\nu_p$. Application of the steady state treatment to this scheme yields

$$[8] \quad \frac{1}{\Phi_s} = \frac{(k_5 + k_6)(k_1 + k_2)(k_3[\mathrm{BiA}] + k_4[\mathrm{BN}])}{k_5 k_3 k_2 [\mathrm{BiA}]}$$

Since the biacetyl pressure was held constant in all experiments eq. 8 predicts that a plot $1/\Phi_s$ *vs.* [BN] should be linear and is confirmed experimentally.

The data also indicate that the lifetime of the borazine triplet must be considerably shorter than the lifetime of the benzene triplet. If this were not the case then borazine triplets, having been formed in reaction 4, could transfer energy to biacetyl by a reaction such as

$$[9] \quad BN^t + BiA \rightarrow BiA^t + BN$$

and one would not observe any quenching of the sensitized emission of biacetyl which is contrary to the experimental observations.

The authors are grateful to the National Research Council of Canada for financial support.

Fluorinated Carbohydrates. Part VIII. Studies of Some 3-Deoxy-3-fluoro-D-pyranosyl Fluorides[1]

L. D. HALL AND R. N. JOHNSON[2]
Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

AND

A. B. FOSTER AND J. H. WESTWOOD
Chester Beatty Research Institute, Institute of Cancer Research; Royal Cancer Hospital, Fulham Road, London, S.W.3, Great Britain

Received August 26, 1970

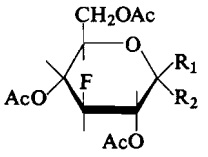
Detailed analyses have been made of the ^1H and ^{19}F n.m.r. spectra of the α- and β-anomers of 2,4,6-tri-*O*-acetyl-3-deoxy-3-fluoro-D-glucopyranosyl fluoride and of 2,4-di-*O*-acetyl-3-deoxy-3-fluoro-β-D-xylopyranosyl fluoride. The $^4J_{F,F}$ couplings demonstrate a stereospecific dependence with $^4J_{a,a} = +10.4$, $^4J_{a,e} = +1.0$, and $^4J_{e,e} = -3.0$ Hz.

Canadian Journal of Chemistry, 49, 236 (1971)

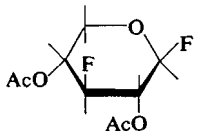
Introduction

In the previous paper of this series we utilized (1) a series of 2-deoxy-2-fluoro-D-hexopyranosyl fluorides as model systems to determine the angular dependence of vicinal (^3J) ^{19}F–^{19}F couplings. We now describe a parallel investigation which enables us to comment on the stereospecific dependencies of long-range (^4J), ^{19}F–^{19}F couplings.

The derivatives chosen were the α- (**1**) and β-anomers (**2**) of 2,4,6-tri-*O*-acetyl-3-deoxy-3-fluoro-D-glucopyranosyl fluoride and 2,4-di-*O*-acetyl-3-deoxy-3-fluoro-β-D-xylopyranosyl fluoride (**3**) which were prepared by standard procedures (see Experimental).



1 $R_1 = H$; $R_2 = F$
2 $R_1 = F$; $R_2 = H$

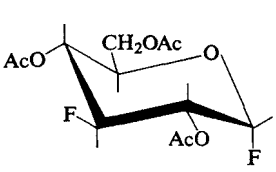


3

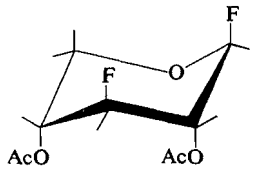
Results and Discussion

The ^1H n.m.r. spectra of derivatives **1–3** were analyzed in the usual fashion, using ^1H–{^{19}F} decoupling experiments to confirm the source and magnitude of the individual ^{19}F–^1H coupling constants. The resultant data are summarized in Tables 1 and 2.

The ^1H–^1H and ^{19}F–^1H couplings of the α-D-*gluco*-derivative (**1**) are all consistent with the anticipation that this derivative should favor the $^4C_1$ (D) conformation **A**. The data for the



A



B

corresponding β-anomer (**2**) also accord reasonably well with the $^4C_1$ (D) conformation, although the values of $J_{2,3}$ and $J_{3,4}$ are smaller than the corresponding values for **1**. Possibly the strong "anomeric effect" (2) of the fluorine substituent at C-1 results (3) in local flattening of the pyranose ring in the O_5—C_1—C_2 region; it seems somewhat unlikely that this derivative is undergoing an overall conformational inversion to the $^1C_4$ (D) conformation because the value of $J_{4,5a}$ is identical to that of the α-anomer (**1**).

In accord with expectation (3), the data for the β-D-*xylo* derivative (**3**) indicate that this derivative favors almost exclusively the $^1C_4$ (D) conformation **B**. That the vicinal ^1H–^1H couplings of **3** are all somewhat smaller than those previously reported (3) for 2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl fluoride may indicate that **3** has a somewhat higher preference for the $^1C_4$ (D) conformation; however, the change in the elec-

[1]This paper also constitutes Part XI of a series from U.B.C. entitled "Studies of Specifically Fluorinated Carbohydrates".

tronegativity of the C-3 substituent cannot be discounted.

The magnitudes of the ^4J, ^{19}F–^{19}F couplings were readily obtained from the ^{19}F spectra, using noise-modulated ^{19}F–{^1H} decoupling (4) to eliminate all the proton couplings.

Attempts were made to determine the signs of the ^{19}F–^{19}F couplings by experiments based (5) on the well known, selective irradiation method (6). A radiofrequency field was placed in the near vicinity of one of the fluorine resonances and its effects on the ^1H resonances followed as a function of the separation between the decoupling frequency and the fluorine resonance frequency. The extent of collapse of individual splittings depends not only on the magnitudes, but also on the signs of the individual splittings.

It proved possible to follow unequivocally the selective collapses observed in the ^1H spectra of both the α-D-*gluco* (**1**) and the β-D-*xylo* (**3**) derivatives. In the former case, the $^4J_{F,F}$ coupling proved to have the same sign as the F_1–H_1 and F_3–H_1 couplings and is thus *absolutely positive* in sign (7, 1). For compound **3** the $^4J_{F,F}$ coupling had the same sign as the F_3–H_{5_a} coupling and is thus also *absolutely positive* in sign (1). It proved

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

more difficult to follow the experiments made with the β-D-*gluco* derivative (**2**), but the spectra obtained were most readily interpreted on the basis of an *absolutely negative* sign for the $^4J_{Fe,Fe}$ coupling, or, more specifically, for the F_1–F_3 coupling opposite in sign to the F_3–H_2 coupling.

While this study was in progress Abraham (8) reported an analysis of the $^4J_{F,F}$ couplings of perfluorinated cyclohexanes and propanes. His conclusions are summarized in Table 3, together with the couplings obtained from derivatives **1**–**3**. It is noteworthy that even though the absolute magnitudes of couplings of the fluoro-sugars are different from those reported by Abraham, the *relative* magnitudes in the two series are identical. In particular, the "1,3-diaxial" relationship appears to lead to the largest couplings. It is evident that the magnitude of a $^4J_{F,F}$ coupling is dependent on the relative orientations of the fluorine substituents and of the nature of nearby substituents. Since the diaxial arrangement of the two fluorine substituents leads to a positive coupling whereas the diequatorial relationship leads to a negative coupling, it is likely that some molecular geometries may lead to near-zero $^4J_{F,F}$ couplings. Until further details of these dependencies are available, it would seem unwise to use $^4J_{F,F}$ as the sole basis for conformational or configurational assignments. For example, the $^4J_{Fe,Fe}$ coupling of Abraham (8) and the $^4J_{Fa,Fa}$ coupling of this investigation have almost the same absolute magnitude. That it is mandatory to determine the sign of such ^4J couplings is exemplified by the opposite sign of these couplings.

The heteronuclear decoupling experiments described above automatically provided evidence concerning the signs of several of the ^1H–^1H and ^{19}F–^1H couplings. These signs are listed in Table 2; all of them are in accord with previous determinations (1, 9, 10).

Experimental

The n.m.r. experiments were performed with a modified (4) Varian HA-100 instrument, following previously established procedures.

Melting points are uncorrected. Optical rotations were determined on ~1% solutions in chloroform using a Perkin–Elmer 141 polarimeter. The t.l.c. was performed on Kieselgel (Merck) 7731 and detection with concentrated sulfuric acid. Column chromatography was effected on Kieselgel 7734. Light petroleum refers to the fraction b.p. 40–60°.

2,4-Di-O-acetyl-3-deoxy-3-fluoro-β-D-*xylopyranosyl Fluoride (3)*

3-Deoxy-3-fluoro-D-xylose (11) was treated with pyridine – acetic anhydride in the usual way to give a product which, after elution from Kieselgel with ether – light petroleum (b.p. 40–60°) (1:1), was shown to be a mixture of 1,2,4-tri-*O*-acetyl-3-deoxy-3-fluoro-α- and β-D-xylopyranoses on the basis of n.m.r. data ($CDCl_3$): α-anomer, H-1, triplet, τ 3.74 ($J_{1,2} \sim 4$, $J_{F,3} \sim 4$ Hz); β-anomer, H-1, doublet, τ 4.29 ($J_{1,2} \sim 7$ Hz). The α,β-mixture crystallized from ethanol – light petroleum to give material of m.p. 90–100°.

A solution of the α,β-mixture (753 mg) in a 45% solution (6 ml) of hydrogen bromide in glacial acetic acid was kept at room temperature for 1 h. Examination by t.l.c. (ether – light petroleum, 1:1) showed that no starting material remained but also indicated that the product apparently had decomposed on the silica plate. For this reason, after removal of solvents at *ca.* 30°/1–3 mm, the crude xylosyl bromide was not purified by chromatography on silica. However, the n.m.r. spectrum ($CDCl_3$), which showed only one anomeric proton signal (triplet, τ 3.30, $J_{1,2} \sim 4$, $J_{F,1} \sim 4$ Hz), was consistent with the anticipated structure 2,4-di-*O*-acetyl-3-deoxy-3-fluoro-α-D-xylopyranosyl bromide.

The crude bromide (700 mg) was dissolved in dry acetonitrile (10 ml) and stirred with silver monofluoride (1.2 g) at room temperature for 1 h, with the exclusion of light. The t.l.c. (ether – light petroleum, 1:1) then showed one major and traces of minor products. The filtered mixture was then concentrated in the presence of a small amount of Kieselgel and the residue was added to the top of a column of Kieselgel. Elution with ether – light petroleum (1:1) gave the major product (300 mg, 46% overall yield) which was crystallized from chloroform – light petroleum (b.p. 60–80°) to give the title compound **3**, m.p. 58°, $[\alpha]_D^{20}$ −67°.

Anal. Calcd. for $C_9H_{12}F_2O_5$: C, 45.4; H, 5.05; F, 16.0. Found: C, 45.4; H, 5.1; F, 15.9.

2,4,6-Tri-O-acetyl-3-deoxy-3-fluoro-α-D-*glucopyranosyl Fluoride (1)*

Anhydrous hydrogen fluoride (20 ml) was poured on to a mixture of 1,2,4,6-tetra-*O*-acetyl-3-deoxy-3-fluoro-α- and β-D-glucopyranoses (2 g) (obtained by treatment of 3-deoxy-3-fluoro-D-glucose with pyridine – acetic anhydride in the usual manner). The solution was stored for 20 min at *ca.* −10° and then at room temperature for 10 min. After pouring into a well-stirred water–chloroform mixture, the chloroform solution was neutralized with saturated aqueous sodium hydrogen carbonate, dried ($MgSO_4$), and concentrated. Examination of the residue by t.l.c. (ether – light petroleum, 2:1) showed four components. Elution of the mixture from Kieselgel

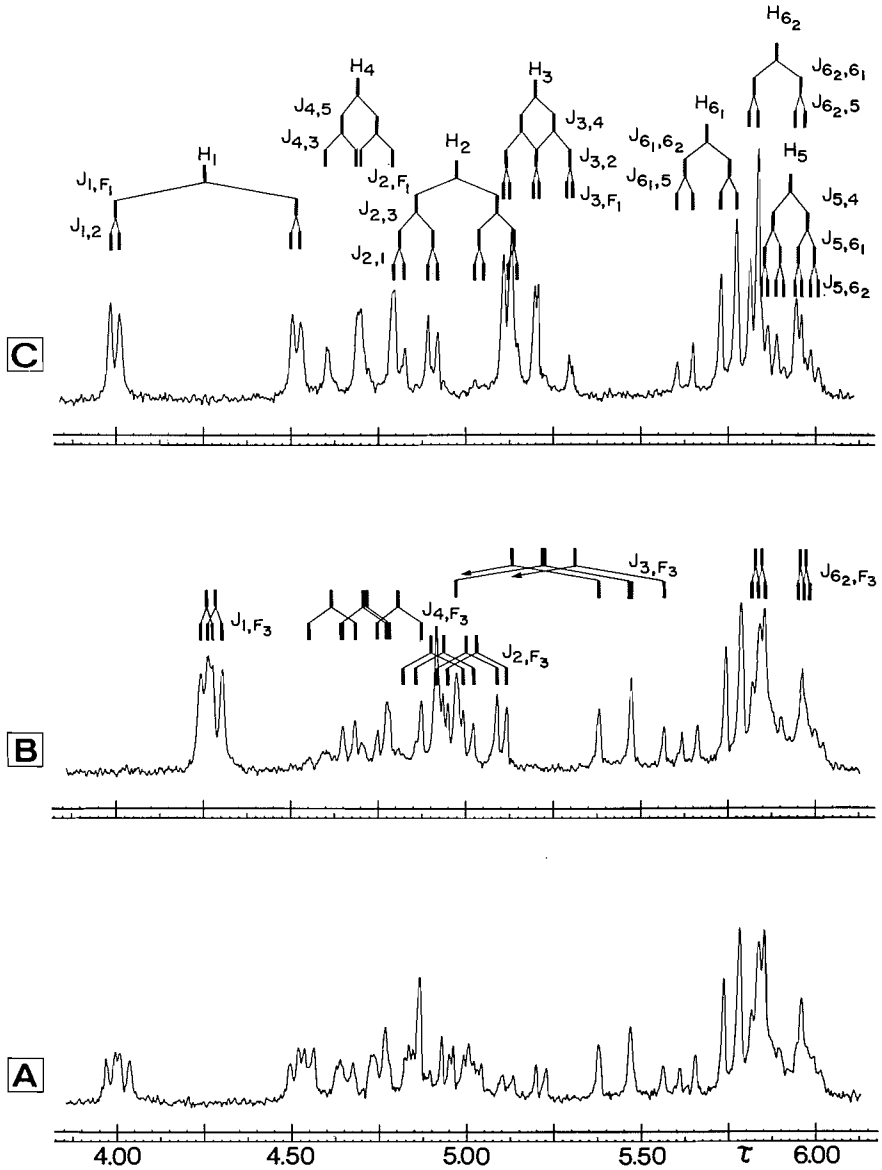

FIG. 1. Partial ^{1}H n.m.r. spectra (100 MHz) of 2,4,6-tri-*O*-acetyl-3-deoxy-3-fluoro-α-D-glucopyranosyl fluoride (**1**) in $CDCl_3$:$CFCl_3$:TMS (60:25:15) solution. A, Normal spectrum B, spectrum with simultaneous irradiation at the F-1 resonance frequency (94 079 960.0 Hz). C, spectrum with simultaneous irradiation at the F-3 resonance frequency (94 075 160.0 Hz). A diagrammatic representation of the first-order assignment is given.

with the same solvent mixture gave the title compound **1** (673 mg, 38%), b.p. 155–165° (bath)/0.1 mm, $[\alpha]_D^{23}$ +76°.

Anal. Calcd. for $C_{12}H_{16}F_2O_7$: C, 46.4; H, 5.2; F, 12.3. Found: C, 46.4; H, 5.4; F, 12.1.

2,4,6-Tetra-O-acetyl-3-deoxy-3-fluoro-β-D-*glucopyranosyl Fluoride (2)*

A solution of 1,2,4,6-tetra-*O*-acetyl-3-deoxy-3-fluoro-α-D-glucopyranose (**10**) (1.1 g) in a 45% solution (4 ml) of hydrogen bromide in acetic acid was stored at room temperature, and monitored by t.l.c. (ether – light petroleum, 1:1). After 90 min, no starting material remained and a major product (R_F *ca.* 0.6) was detected. The solution was evaporated at <40°/0.5 mm and final traces of solvent were removed by distillation of toluene from the residue which was then eluted from Kieselgel with ether – light petroleum (1:1). The major, chro-

matographically homogeneous product (850 mg, 73%) failed to crystallize and slowly decomposed at room temperature. The n.m.r. spectrum was consistent with the structure 2,4,6-tri-*O*-acetyl-3-deoxy-3-fluoro-α-D-glucopyranosyl bromide. The splitting of the signal for H-1 (triplet, $J_{1,2} \sim 4$, $J_{F,1} \sim 4$ Hz; *cf.* $J_{F,1} \sim 4$ Hz for 1,2,4,6-tetra-*O*-acetyl-3-deoxy-3-fluoro-α-D-glucopyranose) was indicative of the α-configuration.

To a stirred solution of freshly prepared glycosyl bromide (850 mg) in dry acetonitrile (2 ml) was added silver monofluoride (1.5 g). After 1 h, the solution was filtered, concentrated under diminished pressure, and the residue was eluted from Kieselgel with benzene–ether (9:1). The major product (550 mg, 77%) was recrystallized from ethanol – light petroleum to give the title compound, m.p. 79.5–80°, $[\alpha]_D^{25}$ +6°.

Anal. Calcd. for $C_{12}H_{16}F_2O_7$: C, 46.5; H, 5.2; F, 12.3. Found: C, 46.4; H, 5.2; F, 12.7.

Spectral Assignments and Analyses

The assignments of the spectra were based on matching of multiplet spacings and were confirmed by ^1H–{^{19}F} heteronuclear spin-decoupling experiments. A typical example is shown in Fig. 1.

Distinction between the resonances of H-5$_e$ and -5$_a$ of the β-D-*xylo* derivative **3** was based primarily on the magnitude of the coupling between H-3 and *one* of the H-5 protons, assigned thereby as H-5$_e$. Further evidence in support of this assignment can be derived from a comparison of the H-5$_e$ and -5$_a$ shifts of **3** (τ 6.28 and 5.69, respectively) with the corresponding shifts of those of 2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl fluoride (τ 6.26 and 5.72).

It is a pleasure for one of us (L.D.H.) to thank the National Research Council of Canada for their generous financial support. This investigation was also supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council of Great Britain and the Cancer Research Campaign (formerly the British Empire Cancer Campaign for Research), and from N.A.T.O., grant No. 352.

Fulvenes have long aroused interest because of their natural occurrence, distinct chemical behavior, and bright colors (1–5). In this note we wish to report new syntheses of some 6-hydroxyfulvene derivatives. Compounds of this type are useful intermediates in the synthesis of several nonbenzenoid cyclic conjugated systems (3, 6).

We describe the preparation of 2,3-dicarboxy-, 2-carboxy-3-carbomethoxy-, and 2,3-dicarbomethoxy-4,6-dimethyl-6-hydroxyfulvenes (**3***a–c*) and of 2-carbomethoxy-4,6-dimethyl-6-hydroxyfulvene (**3***d*). All four compounds (**3***a–d*) were prepared by acid-catalyzed rearrangement of the bromolactonic acid **2***a* or its methyl ester **2***b*, while **3***c* was also prepared by acid-catalyzed rearrangement of the oxaquadricyclane **4**. The experimental conditions and yields are summarized in Table 1.

Compound **2***a* was prepared by bromination of the Diels–Alder *exo* adduct **1** of 2,5-dimethylfuran and maleic anhydride in aqueous base, as described by Woodward and Baer and Zefirov *et al.* (7). The latter group have found that **2***a* in the presence of H_2SO_4 in methanolic 2,4-dinitrophenylhydrazine rearranges to give the 2,4-dinitrophenylhydrazone derivative of the keto form of **3***c*. We have found that the bromolactonic acid **2***a* rearranges in the presence of HBr or H_2SO_4 in $CHCl_3$ to give an almost quantitative yield of the fulvene **3***a*, while its monomethyl ester **2***b* undergoes a similar rearrangement to yield **3***b*. Even more remarkable is the spontaneous conversion of **2***a* (or **2***b*) to **3***a* (or **3***b*) *in the solid state*. Crystals of **2***a* (or **2***b*) evolve hydrogen bromide over a period of two to three months at room temperature eventually ending up as green crystals of **3***a* (or **3***b*). The conversion is complete in about 3 weeks if crystals of **2***a* (or **2***b*) are kept in an atmosphere saturated with HBr. The above rearrangements undoubtedly proceed by initial protonation of the lactone carbonyl followed by a concerted intramolecular rearrangement with elimination of HBr to give the cyclopentadiene skeleton (see Scheme 1). Enolization then yields the substituted 6-hydroxyfulvene The stability of the latter is due to the ability of the substituents to form a strong hydrogen bonded network.

TABLE 1. Products obtained after 24 h at room temperature

Starting material	Acid/solvent	Products (%)				
		2*b*	**3***a*	**3***b*	**3***c*	**3***d*
2*a*	$HBr/CHCl_3$		95			
2*a*	$H_2SO_4/CHCl_3$		77			
2*a*	HBr/CH_3OH				47	34
2*a*	H_2SO_4/CH_3OH	90				
	excess H_2SO_4/CH_3OH	20			60	20
2*b*	$HBr/CHCl_3$	95				
2*b*	$H_2SO_4/CHCl_3$			60		
2*b*	HBr/CH_3OH				95	
2*b*	H_2SO_4/CH_3OH	85				
	excess H_2SO_4/CH_3OH				90	
2*a*	HBr/MeOH/0°/40 h				32	12
	HBr/MeOH/60°/18 h				20	30
4	H_2SO_4/CH_2Cl_2/25°/20 m				37	

The elimination of HBr does not appear to be rate determining since the conversion of **2***a* to **3***a* is not accelerated by pyridine. Moreover, rearrangement (in the solid state) of **2***a* occurs much more readily than that of **2***b*; intramolecular protonation of the lactone carbonyl can only occur in **2***a* indicating that this step is important in initiating reaction.

If the bromolactonic ester **2***b* was treated with excess HBr or H_2SO_4 in *methanol* rather than $CHCl_3$, rearrangement was accompanied by

[1]Issued as NRCC No. 11599.

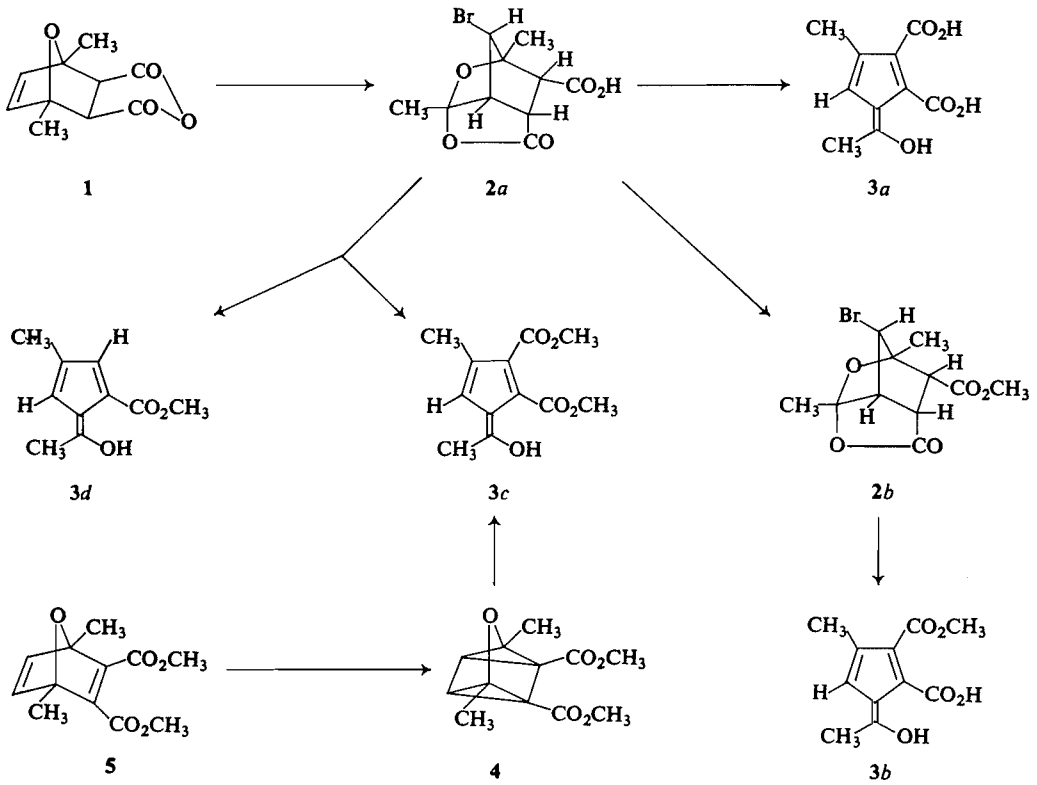
[3]NRCC Postdoctorate Fellow, 1964–1965.



esterification to give the fulvene diester **3c**. In the case of **2a**, however, this change in solvent resulted in its conversion to **3d** as well as **3c**. The ratio of these products was temperature dependent, an increase in temperature favoring the formation of **3d** (see Table 1). Conversion of **2a** to **3d** occurs by the decarboxylative elimination process shown in Scheme 2.

The fulvene diester **3c** has also been obtained (37%) by acid-catalyzed cleavage and rearrangement of the oxaquadricyclane **4**. Prinzbach and Vogel have recently reported that this same conversion is promoted by CuCl, and that some substituted oxaquadricyclanes may be isomerized thermally to 6-hydroxyfulvenes (8).

Structures of 3a–d

The structures of the fulvenes **3a–d** were elucidated on the basis of their analytical and spectral data (see Experimental and Table 2). All four compounds show i.r. absorptions for very strongly hydrogen-bonded hydroxyl and also for bonded carboxy or carbomethoxy carbonyl groups as expected of 6-hydroxyfulvenes with carbonyl substituents at C-2 (3, 9–12). Their u.v. spectra are compatible with fulvene structures (1, 2).

The p.m.r. spectra (Table 2) of **3a**, *b*, and *c* show characteristic signals (quartets) for a single fulvene ring proton coupled to the protons of an allylic methyl group. In addition each shows

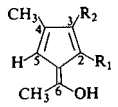
*The compound had the following general structure:



†In tetrahydrofuran-d_8.
‡b = broad, s = singlet, d = doublet, m = multiplet.
§In $CDCl_3$.

a singlet for the methyl group at C-6 with a chemical shift in agreement with those reported (10, 13–16) for methyl groups in a similar environment. Enolic hydroxyl groups at C-6 in fulvenes carrying a carbonyl substituent at C-2 are known to form very strong hydrogen bonds. The hydrogen-bonded hydroxyl protons have characteristically low chemical shifts, *e.g.* −8.87 τ (8–10, 13, 16, 17). In **3***c* the signal for this proton appears at −5.70 τ, while in **3***a* and *b* it appears at −9.71 τ!

The p.m.r. spectrum of **3***d* (Table 2) shows characteristic signals for carbomethoxy, allylic methyl, C-6 methyl, and enolic hydroxyl, as well as for *two* fulvene ring protons. The proton at C-5 appears as a sextet, being coupled to both the allylic methyl hydrogens (J = 1.1 Hz) and to the proton at C-3 ($J_{3,5}$ = 2.3 Hz). The value of $J_{3,5}$ is consistent with values previously reported for 2,4-couplings in similarly substituted fulvenes (10). Supporting evidence for the structure of **3***d* was obtained from its mass spectrum. Loss of methanol from the parent ion (*m/e* 180 → 148) is a characteristic of 2-carbomethoxyfulvenes (10). (A similar loss of methanol was observed in the spectrum of **3***c*.) The i.r. absorption for a hydrogen-bonded carbonyl at 1626 cm^{-1} confirms that the carbomethoxy and enolic hydroxyl groups have the steric relationship shown in **3***d*. The evidence cited above indicates that these compounds (**3***a–d*) exist predominantly in solution in enolic form, a finding in accord with those obtained previously (*cf.* 3, 9, 17) for similar systems possessing a carbonyl substituent at C-2.

We had hoped that this procedure might offer a general route to the 6-hydroxyfulvene system. However the method is subject to certain limitations, the chief of these being (*a*) that it requires the formation of a bromolactonic derivative of type **2**, and (*b*) that the strongly acidic nature of the reaction mixture may cause decomposition of the starting material or reaction product. These difficulties have been overcome by the development of a general, photochemical synthesis of 6-hydroxyfulvenes from adducts of type **5**; this will be the subject of a future communication.

Experimental

The u.v. spectra were determined using a Beckman DK-2 ratio recording spectrophotometer and i.r. spectra with Perkin–Elmer 237 or 521 spectrometers. The p.m.r. spectra were recorded using a Varian A-60A spectrometer, with tetramethylsilane as internal standard.

The bromolactonic acid **2***a* and its methyl ester **2***b* were prepared according to the methods of Woodward and Baer and Zefirov *et al.* (7). The oxaquadricyclane **4** was prepared from the appropriate Diels–Alder adduct under conditions similar to those reported by Prinzbach *et al.* (18).

2,3-Dicarboxy-4,6-dimethyl-6-hydroxyfulvene (3a)

(i) By Reaction of 2a with HBr in $CHCl_3$

The bromolactonic acid, **2***a*, (2.91 g, 0.01 mol) was suspended in 10 ml or dissolved in 30 ml alcohol-free $CHCl_3$. The suspension or solution was saturated with HBr and allowed to stand overnight at room temperature. The green solid product was filtered and washed with a small amount of $CHCl_3$. Crystallization from a large volume of benzene gave yellow prisms (2.0 g, 95%), m.p. 128–129°. The i.r. spectrum (KBr) showed absorptions for bonded hydroxyl (broad band centered at 3000 cm^{-1}) and carboxyl carbonyl (medium intensity band at 1650 cm^{-1}) groups; $\lambda\lambda_{max}$ (EtOH): 243 (ε 11 500), 332 (ε 12 100), 384 mμ (ε 5500); $\lambda\lambda_{max}$ ($CHCl_3$): 342 (ε 11 200), 390 mμ (ε 4200).

Anal. Calcd. for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80; O, 38.06. Found: C, 57.40; H, 4.98; O, 37.60.

(ii) By Reaction of 2a with H_2SO_4 in $CHCl_3$

Compound **2***a* (500 mg) was stirred with a 30% excess of concentrated H_2SO_4 (235 mg) in alcohol-free $CHCl_3$ (10 ml) overnight at room temperature. The product (276 mg, 77%) which was filtered and washed with H_2O and $CHCl_3$, was identical to that isolated in (*i*) above.

(iii) Solid State

The elimination of HBr from **2***a* took place also in the solid state, conversion to **3***a* being complete in about 2 months. If the solid compound was allowed to stand in an atmosphere of HBr the reaction was complete in 3–4 weeks.

2-Carboxy-3-carbomethoxy-4,6-dimethyl-6-hydroxyfulvene (3b)

(i) By Reaction of 2b with HBr in $CHCl_3$

Compound **2***b* (3.05 g, 0.01 mol) was dissolved in alcohol-free $CHCl_3$ (15 ml) and the solution saturated with HBr and allowed to stand overnight at room temperature. The fulvene **3***b*, (1.7 g, 76%) crystallized from solution. Crystallization from benzene gave greenish prisms, m.p. 97–98°. Compound **3***b* shows no OH stretching absorption when examined as a dilute (0.005 *M*) solution in CCl_4. However, after replacement of exchangeable hydrogens with deuterium, the hydrogen-bonded OH groups were observed as an OD stretching vibration at 2334 cm^{-1}. The carbonyl region (KBr) was complex with an envelope rather than well-defined bands; $\lambda\lambda_{max}$ (EtOH): 255 (ε 12 200), 332 mμ (ε 17 000); $\lambda\lambda_{max}$ ($CHCl_3$): 343 (ε 16 700), 392 mμ (ε 5600).

Anal. Calcd. for $C_{11}H_{12}O_5$ (mol. wt. 224): C, 58.92; H, 5.40; O, 35.68. Found (224 (osmometer)): C, 59.07; H, 5.33; O, 35.74.

(ii) By Reaction of 2b with H_2SO_4 in $CHCl_3$

Treatment of **2***b* (896 mg) with a 100% excess of concentrated H_2SO_4 (800 mg) in $CHCl_3$ (10 ml) for 24 h at room temperature caused 60% conversion to **3***b*.

Reaction in the solid state was complete in about 3 months.

2,3-Dicarbomethoxy-4,6-dimethyl-6-hydroxyfulvene (3c)

(i) By Reaction of 2b with HBr or H_2SO_4 in CH_3OH

Compound **2***b* (200 mg) was dissolved in CH_3OH (8 ml) and the solution saturated with HBr and allowed to stand overnight at room temperature. The yellow–green solution was then poured into $CHCl_3$ and washed with H_2O. Drying and evaporation gave **3***c* as a yellow oil (164 mg, 95%).

Compound **2***b* (450 mg) was dissolved in CH_3OH (10 ml) and a 12-mol excess of concentrated H_2SO_4 (2.0 g) added. The mixture was stirred overnight at room temperature, then worked-up as above to give a yellow oil (318 mg, 90%). In the presence of lower concentrations of H_2SO_4 conversion to **3***c* was slow. Compound **3***c* was obtained as a yellow oil, $n_D^{25} = 1.5713$. Molecular ion mass: Calcd. for $C_{12}H_{14}O_5$, 238. Found: *m/e* 238. Characteristic i.r. absorptions (liq. film): broad band centered at 2950 (bonded OH), 1726 (non-bonded C=O), 1618 cm^{-1} (bonded C=O); $\lambda\lambda_{max}$ (EtOH): 247 (ε 9400), 327 mμ (ε 10 400); $\lambda\lambda_{max}$ ($CHCl_3$): 323 (ε 7650), 379 mμ (ε 3500).

Compound **3***c* was also obtained together with **3***d* by reaction of **2***a* with HBr or H_2SO_4 in CH_3OH (see below).

(ii) By Reaction of the Oxaquadricyclane 4 with H_2SO_4

Compound **4** (2.40 g) was dissolved in CH_2Cl_2 (100 ml) and concentrated H_2SO_4 (500 mg) added to the stirred, ice-cold solution, which immediately darkened in color. After stirring at room temperature for 20 min the mixture was poured into ice water. After drying, evaporation from the organic layer gave a dark brown residue (2.51 g). Chromatography on silicic acid ($CHCl_3$ as eluant) gave **3***c* as a bright yellow oil (892 mg, 37%) identical in all respects to the product isolated above.

2-Carbomethoxy-4,6-dimethyl-6-hydroxyfulvene (3d)

(*i*) Compound **2***a* (4.0 g) was dissolved in CH_3OH (25 ml) and the ice-cold solution saturated with HBr. The mixture was allowed to stand at room temperature overnight, and was then poured into $CHCl_3$ and washed with H_2O. Drying and evaporation of the organic layer gave an orange–red oil. Preparative t.l.c. (silica gel G, $CHCl_3$ as eluant) gave two yellow materials, with R_f values of 0.35 and 0.8. The fraction of R_f 0.8 afforded **3***d* as a bright yellow oil (851 mg, 34%) which solidified on cooling, m.p. 16–17°. Molecular ion mass: Calcd. for $C_{10}H_{12}O_3$, 180. Found: *m/e* 180. Characteristic i.r. absorptions (liq. film): broad band centered at 2900 (bonded OH), 1626 cm^{-1} (bonded C=O); $\lambda\lambda_{max}$ (EtOH): 237 (ε 16 600), 314 (ε 10 950), 373 mμ (ε 5200); $\lambda\lambda_{max}$ ($CHCl_3$): 317 (ε 11 500), 376 mμ (ε 5400).

The fraction of R_f 0.35 gave the fulvene diester **3***c* as a yellow oil (1.54 g, 47%), identified by p.m.r.

(*ii*) Compound **2***a* (500 mg) was dissolved in CH_3OH (10 ml) and a large excess (2.2 g) of concentrated H_2SO_4 added. The mixture was stirred overnight at room temperature. After work-up as in (*i*) above, a yellow–orange oil was obtained, p.m.r. analysis of which showed approximately 20% conversion to **3***d*, with *ca.* 20% **2***b* and 60% **3***c*.

In the presence of lower concentrations of H_2SO_4 the conversions to **3***c* and *d* were slower, **2***b* being the major product.

(iii) Effect of Temperature

Samples (500 mg) of **2***a* were dissolved in CH_3OH (15 ml). The solutions were then saturated with HBr (*i*) at 0°, with ice-cooling, and (*ii*) at reflux temperature (60°). The reactions were carried out at these temperatures and were then worked-up as above and the products separated by preparative t.l.c. The yields obtained are given in Table 1.

We wish to thank Mrs. M. G. Flack and J. van Ingen for technical assistance and D. J. Embree for recording the mass spectra.

Spiroalkylation of some Homophthalimides and Oxindoles with 1-Bromo-2-chloroethane

D. E. HORNING, G. LACASSE, AND J. M. MUCHOWSKI[1]
Bristol Laboratories of Canada, Candiac, Quebec

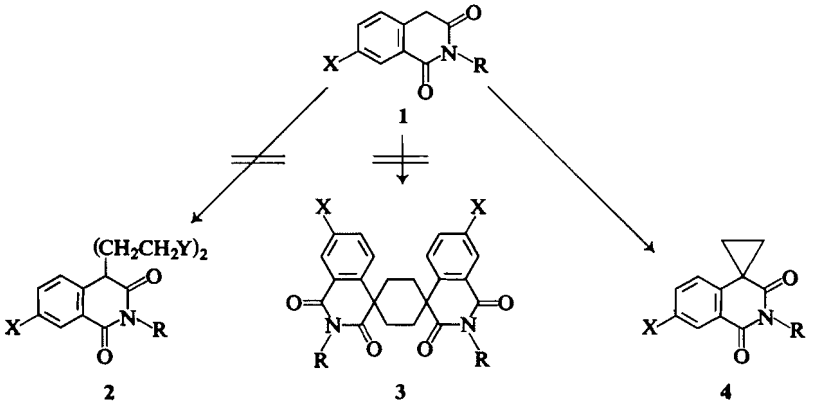
Received August 6, 1970

The base-induced alkylation of 4-unsubstituted homophthalimides with 1-bromo-2-chloroethane produced the spirocyclopropane compounds **4**. The structures of these compounds were supported by their spectral properties and by their susceptibility towards cleavage of the three-membered ring with secondary amines.

Under similar conditions, 3-unsubstituted oxindoles also yielded spirocyclopropane compounds **7**, but 4-hydroxycarbostyril gave the 4-*O*-alkylated compound **8** instead.

Canadian Journal of Chemistry, 49, 246 (1971)

In connection with another problem, it was found necessary to prepare 4,4-disubstituted homophthalimides of type **2** (Y = Cl, Br; X = H, Cl). Since Fournier and Decombe (1) had reported that the triethylamine-induced alkylation of homophthalimides (**1**, R = H, alkyl, aryl) with 1,2-dibromoethane afforded the spiro compounds **3**, we attempted to avoid this reaction pathway by operating under conditions which would be expected to favor the formation of **2**. When a dimethyl formamide (DMF) solution of 2-methylhomophthalimide (**1**, R = CH_3; X = H) containing potassium carbonate or sodium hydride was treated with a large excess of 1-bromo-2-chloroethane, a halogen free compound with the same m.p. as that reported for **3** (R = CH_3; X = H) was produced (Table 2). The n.m.r. spectrum (Figs. 1 and 3) was completely inconsistent with this structure and uniquely compatible with that of the spiro cyclopropane **4** (R = CH_3; X = H) (see Scheme 1). The four-proton multiplet centered at δ 1.85 (Fig. 3 and Table 1) was of the AA′BB′ type with a pattern very similar to that observed for the methylene hydrogens of 1-phenylcyclopropane-1-carboxylic acid (2). The low field multiplet at δ 8.17 (Fig. 1) was assigned to H-8 of the aromatic ring which had been deshielded by the adjacent carbonyl group. The chemical shift of this proton was almost the same as that observed (δ 8.08) for the analogous proton in the starting material and essentially identical to that of H-8 in 2,4,4-trimethylhomophthalimide (δ 8.16, Fig. 2). The absorption at δ 6.74 (Fig. 1) was attributed to H-5 on the expectation that a proton situated above the plane of a cyclopropane ring would experience shielding relative to its "normal" position (3). This characteristic upfield shift (Δ > 20 Hz in comparison to the analogous proton in 2-methylhomophthalimide



SCHEME 1

[1]To whom enquiries concerning this paper should be addressed.

TABLE 1. Chemical shifts and coupling constants for the cyclopropane hydrogens of 2-methyl-4,4-dimethylenehomophthalimide in Hz

H_A*	H_B	L†	N	K	M	J_{gem}	J_{trans}	J_A‡	J_B
95.7	126.5	±11.75§	3.58	19.80	±0.2	−4.1§	7.7	10.0	9.8

*H_A and H_B were assigned arbitrarily to the high and the low field portions of the spectrum, respectively. We are currently examining this system for the presence of a n.O.e. between H-5 and the adjacent cyclopropane protons. If a positive effect is observed, an unambiguous assignment of the A and B protons will be possible (see ref. 13 for example). See NOTE ADDED IN PROOF below.

†For the significance of the terms K, L, M, N, etc. see ref. 2.

‡$J_A = J_{AA'} : J_B = J_{BB'}$.

§All but one of the calculated and observed transition energies agreed to within ±0.2 Hz. The calculated position for line no. 4 was 0.5 Hz on the low field side of the measured value. Since transitions 3, 4, and 7 appeared as a singlet with w_H = 1.6 Hz, it was not possible to gauge the significance of this discrepancy. For the calculated spectrum and coupling constants L was taken as a negative and M as a positive quantity. See ref. 2 for details.

NOTE ADDED IN PROOF: Irradiation of the low field half of the cyclopropane absorption did not significantly affect the integrated intensity of any of the aromatic protons. In contrast, saturation of the high field portion of the cyclopropane resonance resulted in a 16% increase in the integrated intensity of the δ 6.74 multiplet (*i.e.* H-5, see Fig. 1). Therefore H_A can now be unambiguously assigned to the two cyclopropane hydrogens directed toward the aromatic ring, in agreement with our original arbitrary assignment (see footnote†, Table 3).

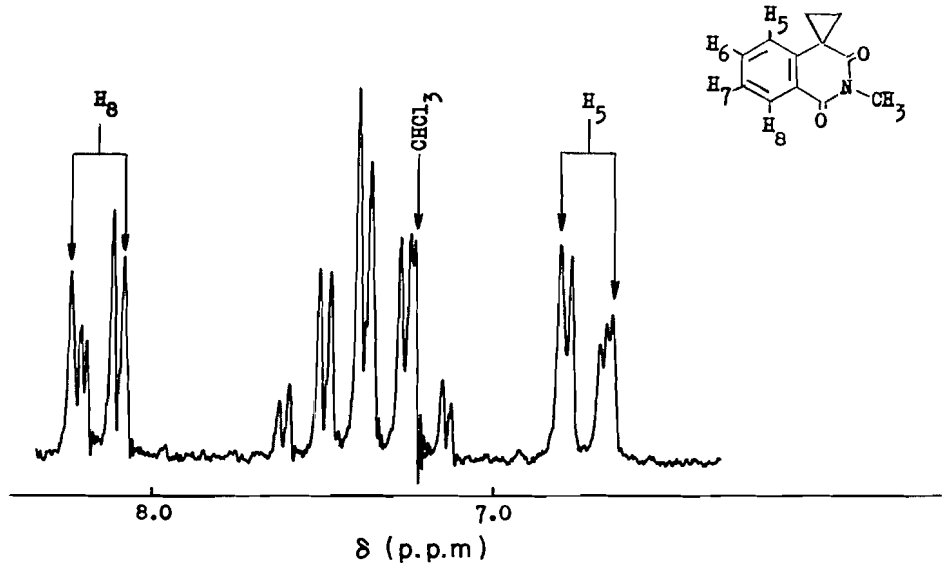


FIG. 1. The n.m.r. spectrum of the aromatic protons of 2-methyl-4,4-dimethylenehomophthalimide.

or in 2,4,4-trimethylhomophthalimide) which has recently been recorded for similarly constituted systems without comment (4), was even more clearly observed (Δ = 29 Hz) for the 7-chloro derivative of **4** (R = CH_3; X = Cl, see Figs. 4 and 5).

In addition to the n.m.r. and i.r.[2] spectral properties and the correct elemental analysis and molecular weight (Rast), the structure of **4** (R = CH_3; X = H) was supported by its reactions with secondary amines. As a cyclopropane-bearing carbanion stabilizing substituents, the ring cleavage of this compound was anticipated (6) and demonstrated to be especially facile. An excess of dimethylamine in DMF (65°) rapidly produced the air sensitive amine ***5a*** (Scheme 2) which was characterized as its stable hydrobromide salt. Its structure was substantiated by its elemental analysis and spectral characteristics. In particular, the n.m.r. spectrum of the free base had a broad (w_H = 13 Hz, probably due to slow exchange) absorption centered at δ 3.96 due to the single proton at C-4, which was rapidly exchanged with deuterium oxide. Neither the salt nor the free base showed any evidence of an i.r. absorption in the 3100–3650

[2]The spirocyclic homophthalimides described herein (Table 2) possessed a medium intensity absorption at 1708 ± 10 cm^{-1} and a strong band at 1665 ± 5 cm^{-1}; all of the other homophthalimides possessed similar absorptions at 1673 ± 10 and 1719 ± 10 cm^{-1}. Hall and Zbinden (5) reported absorptions at 1728 ± 1 and 1672 ± 4 cm^{-1} for two six-membered imides.

cm^{-1} region. On standing in air, the base was transformed in part to the hydroxy compound **6***a*. The presence of an hydroxyl moiety was indicated by a broad band at 3270 cm^{-1} in the i.r. spectrum of the hydrobromide salt, and a diffuse (w_H = 40 Hz) absorption easily exchangeable with D_2O centered at δ 5.98 in the n.m.r. spectrum of the free base. The hydroxy compound **6***a* is the product which would be expected from reduction of an hydroperoxide by a tertiary amine (7). 1-Dimethylamino-3-phenyloxindole has been reported to undergo an analogous aerial oxidation (8). Scission of the cyclopropane ring was also accomplished with refluxing piperidine,

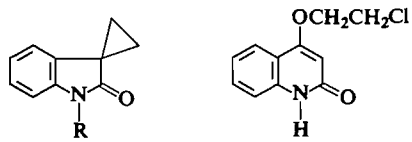
SCHEME 2

and the base thus obtained (**5***b*) was also rapidly oxidized by air to the hydroxy compound **6***b*. The *N*-ethyl compound (**4**, R = C_2H_5; X = H) underwent the same cleavage reaction with secondary amines, but the products were not fully characterized.

The base-promoted alkylation of several other homophthalimides with 1-bromo-2-chloroethane also yielded compounds to which cyclopropane structures were assigned (Table 2) principally on the basis of the similarity of their n.m.r. spectra (Table 3) to that of **4** (R = CH_3; X = H). Two members of this group (**4**, R = H, C_6H_5; X = H; see Table 2) also had melting points which were close to those reported (1) for the alleged spiro compounds (**3**, R = H, C_6H_5; X = H). On the basis of the observations described herein, it is highly probable that all of these latter structures will have to be revised.

The alkylation reaction was extendable to oxindole and 1-methyloxindole. The products (**7***a*, *b*)[3] were assigned the spiro cyclopropane structures **7** mainly by analogy, since, in this case, the n.m.r. spectra were much less definitive than observed in the homophthalimide series. Although the cyclopropane hydrogens still appeared as an AA'BB' pattern, the upfield shift of the adjacent aromatic proton (H-4) was no longer observed. This latter effect was presumably a consequence of the increased tilting of the plane of the cyclopropane ring away from the adjacent Ar—H bond. An attempt to cycloalkylate 4-hydroxycarbostyril in the usual manner gave instead only 4-(2-chloroethoxy)carbostyril (**8**), the structure of which was readily apparent from its elemental analysis and spectral properties (see Tables 2 and 3).



7
a R = CH_2CH_2Cl
b R = CH_3

8

[3]The cycloalkylation of the oxindole compounds could only be effected with sodium hydride as the base. Under these conditions oxindole did not lend itself to selective *C*-alkylation, therefore the reaction was carried out in a manner such that only **7***a* was produced (excess sodium hydride).

Experimental

The melting points were recorded in a Gallenkamp melting point apparatus and are not corrected. The i.r. spectra were measured as solutions in chloroform or solid dispersions in mineral oil with a Perkin–Elmer 237-B grating spectrophotometer or a Unicam SP-200G i.r. spectrophotometer.

Homophthalic acid was purchased from the Aldrich Chemical Co. and oxindole and *N*-methyloxindole were prepared by catalytic reduction of the corresponding isatins (9).

Preparation of the Homophthalimides (1)

The following general procedures were found to be more reproducible and to give products of better purity than the usual literature methods (*e.g.*, 10, 11).

(a) Low Boiling Amines (Water Soluble)

Homophthalic acid (0.1 mol), was dissolved with stirring in a solution of the primary amine (1.0 mol) in *ca.* 150 ml of water; brief heating was sometimes necessary to obtain a clear solution. The solution was evaporated to dryness *in vacuo* and 250 ml of xylene was added to the residue. The vigorously stirred mixture was heated under reflux while the water was collected and periodically removed from an attached Dean–Stark apparatus. When the evolution of water had ceased (reaction periods ≤ 18 h), the solvent was removed *in vacuo* and the residue was crystallized from the appropriate solvent.

2-Methyl-7-chlorohomophthalimide was obtained in this way in 76% yield (pure), m.p. 116–118°.

Anal. Calcd. for $C_{10}H_8NO_2Cl$: C, 57.29; H, 3.84; N, 6.68. Found: C, 57.34; H, 3.91; N, 6.71.

(b) High Boiling and/or Water Insoluble Amines

Homophthalic acid (0.1 mol) was added with vigorous stirring to a solution of the amine (0.4 mol) in 250 ml of xylene. The mixture was heated at reflux temperature

with separation of water as above. The work up procedure was the same as that described above.

The pure yields of the homophthalimides obtained by methods *a* and *b* ranged from 70–90%. The melting points and other physical properties of these compounds agreed with the literature values.

General Conditions for the Cycloalkylation Reaction

(a) Sodium Hydride as the Base

A 55% dispersion of sodium hydride in mineral oil (50 mmol)[4] was washed free of the carrier with hexane and layered with 100 ml of dry DMF. The mixture was stirred at 0° in a nitrogen atmosphere while the solid homophthalimide or oxindole (25 mmol) was added portionwise. When the evolution of gas had become slow, 1-bromo-2-chloroethane (250 mmol) was added dropwise at 0° at a rate such that excessive foaming was avoided (*ca.* 1/2 h). The cooling bath was removed, and stirring at room temperature under a slight positive pressure of nitrogen was continued for 12–24 h. The deeply colored solution was poured into a large volume of water and the product was extracted into benzene. The extract was washed well with water, dried over sodium sulfate, and evaporated *in vacuo*. The spirocyclic homophthalimides were usually obtained crystalline and were then recrystallized from a suitable solvent. The oxindoles gave oils from which the desired spiro compound was isolated by column chromatography on neutral alumina (Fluka, activity II).

(i) 1-Methyloxindole gave an oil (*ca.* 2 g from a 10 mmol scale reaction) which was chromatographed on 100 g of alumina (packed in benzene) using methylene chloride as the eluant. The first 100 ml of the eluate was discarded, the next 130 ml contained the product which was then further purified by crystallization.

(ii) The reaction with oxindole also gave an oil (2.4 g from a 15 mmol scale reaction). The product was obtained from the mixture by dry column chromatography (12) on 200 g of alumina using chloroform as the eluant (50 ml fractions). The product was found in fractions 2–7.

(b) Potassium Carbonate as the Base

To a stirred mixture of the homophthalimide (50 mmol) and potassium carbonate (90–100 mmol) in 100 ml of dry DMF was added 500 mmol of 1-bromo-2-chloroethane. The mixture was stirred at room temperature under a positive pressure of nitrogen for 18–48 h. The deeply colored mixture was poured into water and extracted with benzene [ethyl acetate for **4** (R = H = X)] and after the usual manipulations the crude product was purified by crystallization. In the case of **4** (R = C_6H_5; X = H) it was necessary to isolate the product by chromatography of the mixture on alumina (30 g/g of substrate) using chloroform as the eluant.

*Ring Cleavage of **4** (R = CH_3, X = H) with Secondary Amines*

(a) Dimethylamine

Nitrogen was bubbled through 50 ml of DMF, contained in a pressure bottle, for 10 min and then dimethylamine was passed into the solvent until 9.0 g (200 mmol) had been absorbed. The cyclopropane (2.00 g) was added, the bottle was sealed and placed in an oil bath at 65°. After 1.5 h the solution was cooled to room temperature and nitrogen was passed through the solvent to remove the dimethylamine (*ca.* 10 min). The solution was concentrated to 15 ml at 60°/20 mm and the resultant was diluted with 15 ml of water and 10 ml of 48% hydrobromic acid. The solution was concentrated to about 5 ml *in vacuo* and then it was diluted with water and made basic with sodium carbonate solution (200 g/l). The mixture was extracted with dichloromethane, the extract was dried over sodium sulfate and evaporated *in vacuo* (eventually at 60°/0.01 mm). All operations on the free base were performed as rapidly as possible to minimize aerial oxidation. The oil (1.693 g) was converted to its hydrobromide salt in ether and this was crystallized from acetonitrile. The first crop (945 mg) of crystalline material was fairly pure **5***a* (m.p. 196–200°). Addition of ether (to turbidity) to the mother liquor gave 1.05 g of a mixture (m.p. 170–200°) which was fractionally crystallized from acetonitrile. The mixture was thus separated into a small amount (128 mg) of the very insoluble 4-hydroxy compound **6***a* (m.p. 227–230°) and 436 mg (200–205°) of the more soluble **5***a*.

Three recrystallizations of the lower melting salt from acetonitrile gave pure **5***a*, m.p. 203–205°.

Anal. Calcd. for $C_{14}H_{18}N_2O_2 \cdot HBr$: C, 51.40; H, 5.85; N, 8.55. Found: C, 51.17; H, 5.93; N, 8.54.

The i.r. spectrum (Nujol mull) of the salt had absorptions at 2700 (br), 2605, 2480, 1717, and 1675 cm^{-1}.

The n.m.r. spectrum of the free base ($CDCl_3$) had singlets at δ 2.03 (*N*-dimethyl group) and 3.29 (ring *N*-methyl) and multiplets centered at δ 2.23 (four methylene protons), 3.96 (methine proton at C-5, w_H = 13 Hz), 7.44 (H-5 to -7) and 8.13 (H-8). The absorption at δ 3.96 was easily exchanged with D_2O.

The high melting salt was thrice recrystallized from acetonitrile, but the m.p. (227–230°) remained unchanged. This material (**6***a*) could be obtained in much larger amounts if **5***a* was left (as the free base) in an open vessel for 2–3 days. Only **6***a* could be isolated (as the insoluble hydrobromide salt) from the mixture thus obtained.

Anal. Calcd. for $C_{14}H_{18}N_2O_3 \cdot HBr$: C, 48.99; H, 5.58; N, 8.16. Found: C, 48.93; H, 5.60; N, 8.25.

The i.r. spectrum (Nujol mull) of the salt of **6***a* had absorptions at 3270, 2670 (br), 2460 (br), 1725, and 1675 cm^{-1}.

The n.m.r. spectrum ($CDCl_3$) of the free base had singlets at δ 2.33 (*N*-dimethyl group), 3.34 (ring *N*-methyl), and 5.98 (OH; w_H = 40 Hz), and complex multiplets centered at δ 2.17 (four methylene protons), 7.58 (H-5 to -7) and 8.14 (H-8).

(b) Piperidine

Piperidine (20 ml) was deoxygenated as before, then 2.00 g of the cyclopropyl compound was added and the solution was heated at reflux temperature (nitrogen atmosphere for 1/2 h. The work-up procedure was the same as that described above but no precautions were taken to minimize exposure to air. The mixture of bases (2.10 g) was separated by fractional crystallization of the hydrobromide salts from acetonitrile. The less soluble higher melting (the various crops had melting points which ranged from 255 to 268°) fractions (total of 988 mg) contained mainly the product of aerial oxidation (*i.e.* **6***b*). The lower melting (melting points ranged from 205–209°), more soluble fractions consisted of fairly pure **6***a* (total of 837 mg).

[4]Sodium hydride (75 mmol) was used for oxindole.

After three crystallizations from acetonitrile the higher melting material (*6b*) had m.p. 271–272°.

Anal. Calcd. for $C_{17}H_{22}N_2O_3 \cdot HBr$: C, 53.27; H, 6.05; N, 7.31. Found: C, 53.06; H, 6.04; N, 7.33.

The i.r. spectrum (Nujol mull) had bands at 3370, 2725, 2660, 2550, 1725, and 1674 cm^{-1}.

The more soluble salt (*6a*) was crystallized once from acetonitrile and twice from 2-propanol. The m.p. was then 207–209°.

Anal. Calcd. for $C_{17}H_{22}N_2O_2 \cdot HBr$: C, 55.59; H, 6.31; N, 7.63. Found: C, 55.30; H, 6.34; N, 7.54.

The i.r. spectrum (Nujol mull) had absorptions at 2660 (br), 2560, 1718, and 1677 cm^{-1}.

The Overhauser effect was measured with a Varian HA-100 spectrometer by Dr. H. J. Koch and Mr. R. Simoneau at the Department of Chemistry, McGill University, Montreal, Quebec. We thank Professor A. S. Perlin for making the service available to us.

Effects of Centrifugal Distortion and Nuclear Quadrupole Coupling in the Microwave Spectrum of Vinyl Chloride

M. C. L. GERRY

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received August 31, 1970

Both *a*- and *b*-type rotational transitions have been measured up to $J = 30$ for the two most abundant isotopic species of vinyl chloride, in the frequency region 8–18 GHz. These have enabled refinement of the rotational and chlorine nuclear quadrupole coupling constants, and evaluation of all first order centrifugal distortion constants. From the quadrupole coupling constants it is concluded that the field gradient around the C—Cl bond is somewhat more symmetric than previously reported. A comparison is made between the centrifugal distortion constants obtained from the microwave spectrum and those calculated using infrared data.

Canadian Journal of Chemistry, 49, 255 (1971)

Introduction

Several aspects of the microwave spectrum of vinyl chloride have appeared previously. In the first study (1) nuclear quadrupole coupling was observed and measured for the first time in the rotational spectrum of an asymmetric rotor. Subsequently Kivelson, Wilson, and Lide (K.W.L.) (2) observed low J *a*-type R branches of several isotopic species, which yielded internuclear parameters, more accurate chlorine nuclear quadrupole coupling constants, and the molecular dipole moment. More recently Savariraj (3) measured some low J *a*-type and *b*-type transitions, and after accounting partially for centrifugal distortion, obtained a value for the rotational constant A in the ground vibrational state.

This article presents the assignment and measurement of a large number of *a*- and *b*-type transitions to high values for J for the two most abundant isotopic species. Using these transitions the rotational and nuclear quadrupole coupling constants have been refined, enabling some further structural information to be obtained. Also, good values for all first order centrifugal distortion constants have been obtained, permitting comparison with those calculated from a force field obtained solely from vibrational data.

Experimental

Transitions were measured in the frequency region 8–18 GHz, using a 100 kHz Stark modulated spectrometer having a 10 ft X-band cell. The spectrometer was of conventional design, except that the source was a phase stabilized Hewlett-Packard 8400B Microwave Spectroscopy Source. This source permitted broad banded frequency sweeps with chart presentation of absorption lines, which considerably eased initial searches for transitions. For accurate measurements the source, phase stabilized, was swept manually through the absorption lines. All measurements were made at room temperature at sample pressures of 1–10 μ. The sample was obtained from the Matheson Company and used without further purification.

Observed Spectrum and Assignment

Initially the rigid rotor spectrum of vinyl chloride, with transitions split by nuclear quadrupole coupling, was predicted using previously published rotational and nuclear quadrupole coupling constants (2, 3). After a general search for transitions over the complete frequency range studied, the prediction enabled several previously unreported low J transitions to be identified easily. Using these transitions in turn, and the methods of analysis given in the following sections, refined rotational and quadrupole coupling constants and preliminary centrifugal distortion constants were obtained; these gave further predictions of higher J transitions. Several of these were identified after detailed investigation of the appropriate frequency regions, and yielded improved distortion constants, as well as satisfactory predictions and assignments up to $J = 30$. The quadrupole coupling patterns confirmed all assignments.

The observed frequencies and their assignments, hypothetical unsplit frequencies, transition frequencies calculated using the measured rotational and centrifugal distortion constants, and the distortion corrections are given in Tables 1 and 2 for $CH_2CH^{35}Cl$ and $CH_2CH^{37}Cl$, respectively. The average deviations for observed and calculated frequencies are 0.03 MHz for $CH_2CH^{35}Cl$ and 0.04 MHz for $CH_2CH^{37}Cl$.

Nuclear Quadrupole Coupling

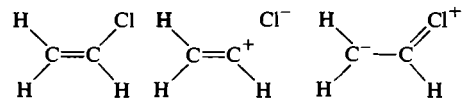
The nuclear quadrupole energy of an asymmetric rotor having one quadrupolar nucleus may be written to first order as (4)

$$[1]\quad E_Q = \frac{f(I,J,F)}{J(J+1)}\chi_{aa} \times [3\langle P_a^2\rangle - J(J+1) + (\langle P_a^2\rangle - W)\eta/b_p]$$

where $f(I,J,F)$ is Casimir's function (5); b_p is Wang's asymmetry parameter; $W = W(b_p)$ is the Wang reduced energy; $\langle P_a^2\rangle$ is the average value of the square of the angular momentum about the a-principal inertial axis. If χ_{gg} is the component of the quadrupole coupling tensor along the g-principal inertial axis, η is defined by $\eta\chi_{aa} = \chi_{bb} - \chi_{cc}$. A least squares fit was made to χ_{aa} and $\eta\chi_{aa}$ in this equation using all resolved groups having $J \leqslant 25$ for both isotopic species. The results are shown in Table 3. It is seen that the values for χ_{aa} are in excellent agreement with earlier values (2), whereas the values for η are rather different. Nevertheless, the ratio $\chi_{cc}(^{35}Cl)/\chi_{cc}(^{37}Cl) = 1.2649 \pm 0.0042$;[1] this agrees well with the ratio of the quadrupole moments of the two isotopes (1.2688), as is expected for a planar molecule.

With the assumption that one principal axis of the chlorine quadrupole tensor coincides with the C—Cl bond, and using the structural data of K.W.L. (2), the coupling constants were transformed from the inertial axis system to the principal axis system (z parallel to the C—Cl bond, y perpendicular to the molecular plane). The principal values of the quadrupole coupling tensor thus obtained are $\chi_{xx} = 38.37$ MHz, $\chi_{yy} = 31.52$ MHz, and $\chi_{zz} = -69.89$ MHz. These values are somewhat different from those obtained previously (2); in particular the difference $\chi_{xx} - \chi_{yy} = 6.85$ MHz is rather less.

The three main contributing resonance structures of vinyl chloride are probably



1 2 3

Goldstein (6) has shown that the difference $\chi_{xx} - \chi_{yy}$ is related to the number of electrons lost from chlorine as a result of double bonding, δ, with $\delta = (\chi_{xx} - \chi_{yy})/164.6$. In turn δ may be

[1]All errors reported are for confidence limits of 95%.

regarded as approximately defining the double bond character, or the fractional contribution of **3**. In the present case $\delta \sim 0.04$, indicating a rather smaller contribution of **3** than 0.06 given previously. Using well known methods (5) structures **1** and **2** were found to have fractional contributions 0.73 and 0.23, respectively. In view of the approximations made in these calculations, most notably the neglect of overlap, these values must be regarded as very approximate.

Rotational Constants and Centrifugal Distortion

The first order energy expression for a semi-rigid asymmetric rotor may be written as (7)

$$[2] \qquad E = E_R + E_D$$

$$[3] \qquad E_R = \tfrac{1}{2}(B + C)J(J + 1) + [A - \tfrac{1}{2}(B + C)]\,W(b_p)$$

[4] $$E_D = \tfrac{1}{4} \sum_{\alpha,\beta} \tau'_{\alpha\alpha\beta\beta} \langle P_\alpha^2 P_\beta^2 \rangle$$

Here E_R is the rigid rotor energy and E_D is the first order centrifugal distortion correction. In eq. 4 the coefficients $\tau'_{\alpha\alpha\beta\beta}$ are related to the centrifugal distortion constants by $\tau'_{\alpha\alpha\alpha\alpha} = \tau_{\alpha\alpha\alpha\alpha}$ and $\tau'_{\alpha\alpha\beta\beta} = \tau_{\alpha\alpha\beta\beta} + 2\tau_{\alpha\beta\alpha\beta}$; α and β can be a, b, or c. Expressions for the average values of the angular momentum operators in the rigid asymmetric rotor basis have been given elsewhere (8, 9).

Although nine distinct coefficients appear in eq. 4, at most only five combinations of these can be evaluated to first order from a rotational spectrum (9). For the particular case of a planar molecule like vinyl chloride, relations exist (10) which enable this number to be reduced to four.[2] A least squares fit of the spectrum was made to three rotational constants and the four centrifugal distortion constants τ_{aaaa}, τ_{bbbb}, τ_{aabb}, τ_{abab}. Linear variations of the rotational constants were allowed. No attempt was made to include second order or P^6 terms. It has been shown, however, that good distortion constants are obtainable using the first order expression if the analysis excludes high J transitions (10). This procedure has been adopted in the present case, and the analysis has included transitions with $J \leq 25$.

Table 4 gives the ground state rotational constants and centrifugal distortion constants for both isotopic species. The rotational constants obtained are in good agreement with those of earlier work (2, 3). The centrifugal distortion constants are similar for both isotopic species, and differ substantially from those given previously (3). As a check the analysis were carried out using transitions with $J \leq 20$; the results agreed with those of Table 4 within experimental error.

The centrifugal distortion constants can be calculated from the inverse force constant matrix using the following equation (11)

[5] $$\tau_{\alpha\beta\gamma\delta} = -\frac{A\Delta}{I_{\beta\beta} I_{\gamma\gamma}} R \sum_{i,j} (J^\circ_{\alpha\beta})_i (F^{-1})_{ij} (J^\circ_{\gamma\delta})_j$$

The quantities $(J^\circ_{\alpha\beta})_i = (\partial I_{\alpha\beta}/\partial S_i)_0$ are the partial derivatives of the components of the inertia tensor with respect to the ith internal coordinate. A, Δ are rotational constants in MHz; $I_{\beta\beta}$, $I_{\gamma\gamma}$ are principal moments of inertia in a.m.u. Å^2; $R = 2h \times 10^{17}$ with h in erg s. If the derivatives have units of a.m.u. Å and a.m.u. Å^2 rad^{-1} for a stretch and a bend, respectively, and the force constants have units of mdyn Å^{-1}, mdyn Å rad^{-2}, and mdyn rad^{-1} for a stretch, a bend and a stretch bend interaction, respectively, then the $\tau_{\alpha\beta\gamma\delta}$ are in MHz.

El-Sabban and Zwolinski (12) have recently published a set of force constants using vibrational data from the normal isotopic species and the seven deuterated species. It is interesting to compare centrifugal distortion constants calculated from their results with those obtained experimentally. In their analysis they used a valence force field where the in-plane internal coordinates were the changes in the five bond distances and the four X—C=C angles, with X being Cl or H, and the out-of-plane coordinates were roughly a CH_2 wag, a CHCl wag, and a C=C twist. The derivatives of the components of the inertia tensor with respect to these coordi-

[2]Strictly these relations are valid for a rigid planar body, and thus require the use of equilibrium rotational constants. Since these are not available, the ground state rotational constants A and B were used, and the rotational constant C adjusted to make the inertial defect identically zero.

TABLE 5. Comparison of observed and calculated centrifugal distortion constants (MHz) of $CH_2CH^{35}Cl$

Parameter	Observed	Calculated	
		Using all force constants	Using diagonal force constants
τ_{aaaa}	−4.868	−5.10	−3.86
τ_{bbbb}	−0.01649	−0.0174	−0.0152
τ_{aabb}	0.1474	0.158	0.128
τ_{abab}	−0.04840	−0.0537	−0.0461

nates were obtained according to the methods of Kivelson and Wilson (11). Only the derivatives with respect to the in-plane coordinates were found to be non-zero. Using these derivatives the centrifugal distortion constants for CH_2-$CH^{35}Cl$ were evaluated using all the force constants of El-Sabban and Zwolinski, and also using only the diagonal force constants. The values obtained are compared with the experimental values in Table 5.

The agreement between the observed values and those calculated using all the force constants is fairly good. The agreement when the diagonal force constants are used is in general rather worse, though clearly a good approximation is obtained. Evidently the distortion constants are much more sensitive to the diagonal than to the off diagonal elements, with the latter having a comparatively minor effect, though giving better values. One should, however, be careful in drawing any conclusions from the improved agreement when all the force constants are used, for there are still discrepancies between the observed and calculated values. Some of the interaction constants, notably those between C=C stretching and both C—Cl stretching and C=C—Cl bending, were unobtainable in the normal coordinate treatment, and could well affect the centrifugal distortion constants.

5,6-Dehydrolupanine, a New Alkaloid, and Lupanine from *Thermopsis rhombifolia* (Nutt.) Richards

Y. D. Cho and R. O. Martin

Department of Biochemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received February 23, 1970[1]

In addition to the alkaloids originally reported in flowering plants of *T. rhombifolia*, lupanine (**3**) and a new major alkaloid were isolated from 6 week old plants. This new alkaloid has been characterized as 5,6-dehydrolupanine (**7**).

Canadian Journal of Chemistry, 49, 265 (1971)

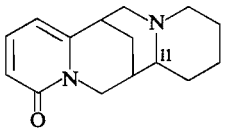
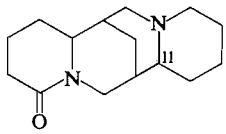
Introduction

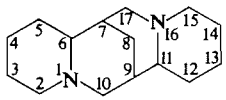
In their original investigation of the alkaloids of *T. rhombifolia*, using dried flowering plants, Manske and Marion (1) reported the presence of the pyridone bases cytisine, *N*-methylcytisine, anagyrine (rhombinine) (**1**), thermopsine (**2**), and rhombifoline. There has been no report of the occurrence in this species of either lupanine (**3**) or sparteine (**4**), reported widespread in other thermopsis species (2, 3).



1 (11 R)
2 (11 S)



3 (11 R)
6 (11 S)



4

The most widely accepted view concerning the biosynthesis of these alkaloids is that sparteine, formed from lysine via cadaverine, is oxidized to lupanine which in turn may be further oxidized to the pyridone base anagyrine (4, 5). Though never discussed this latter conversion presumably occurs via an intermediate dehydrolupanine. Interestingly, in contrast to several dehydrolupanines (C=C in C or D ring)[2] accessible through chemical methods (6–8), the only such natural compounds reported are a dehydrolupanine from *Lupinus albus* (9) to which, however, no assignment has been made of the position of unsaturation (10) and a reportedly different dehydrolupanine from *L. perennis* L. (11).

As an integral part of our studies on the biosynthesis of these alkaloids from $^{14}CO_2$, we examined the alkaloid extracts of fresh plants from 1–10 weeks of age by means of t.l.c. and g.l.c. By 5 weeks of age an alkaloid, designated as BNC-1, whose g.l.c. behavior differed from that of any of the known alkaloids previously reported in this species, was evident. Analysis of these extracts, at various time intervals after pulse labelling of 5–7 week old plants with $^{14}CO_2$, by g.l.c.–combustion – continuous counting and t.l.c.–autoradiography as described previously for our work with the *Conium* alkaloids (12), showed **3** to be the earliest labelled alkaloid, followed by BNC-1 and then **1**. This "chronology" of appearance of ^{14}C in these bases suggested BNC-1 might be the expected, though never proposed dehydrolupanine, intermediate between **1** and **3**, thus deserving of further investigation. Also the surprising finding of what appeared to be lupanine as the earliest formed alkaloid made confirmation of its occurrence an identity by chemical means desirable.

Discussion

An examination of the basic extract of fresh 6 week old plants of *T. rhombifolia* by t.l.c., g.l.c., and mass spectrometry of individual g.l.c. fractions confirmed the presence of the five quinolizidine alkaloids originally reported in dried flowering plants. In addition, traces of lupanine (**3**), and a new major constituent, having distinctive g.l.c. behavior (Fig. 1) were isolated.

This latter compound called BNC-1 gave a mass fragmentation pattern (Fig. 2B) remarkably similar to that reported for aphyllidine (**5**) (13)

[1]Revision received September 9, 1970.

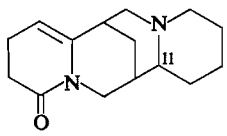
5



7

and its molecular formula, $C_{15}H_{22}N_2O$. However, its mild catalytic hydrogenation gave **3** ($C_{15}H_{24}N_2O$) as the sole reduction product which was readily distinguishable by its mass spectrum from isolupanine (**6**), as well as the isomeric 10-oxo-sparteine (aphylline), epiaphylline, and 17-oxo-sparteine (13), showed it to be a dehydrolupanine. The problem to be resolved then, was the location of the double bond, the C-11 position being excluded because **6** would have been the expected reduction product (6). Comparison with a sample of authentic 11,12-dehydrolupanine showed BNC-1 to clearly differ in its t.l.c. behavior (Table 1), u.v. spectrum, and sensitivity to air oxidation. The failure of formic acid to reduce BNC-1 could not, owing to the low basicity of the lactam nitrogen (14), rule out the double bond being within the lactam ring at C-5.

The u.v. spectrum of BNC-1 (λ_{max} 250 mμ, $\log_\varepsilon$ 3.8) was similar to that of **5** (15) and indicative of the vinyl amide grouping as in **7**. Such a grouping was further suggested by the i.r. spectrum, which exhibited a strong ν_{max} at 1635 cm^{-1} ($\nu_{C=O}$), only slightly higher than for **5**, and between that of **3** (1622 cm^{-1}) and the corresponding pyridone, **1** (1652 cm^{-1}) (16).

A single olefinic proton (symmetrical 1H triplet, τ 5.10, $J \simeq 4$ Hz), at the low end of the range expected for the vinyl amine grouping (17), was present in the n.m.r. spectrum of BNC-1 but not in that of **3**. In addition, the signal (1H doublet, τ 5.6, $J \simeq 13$ Hz) arising from the strongly deshielded equatorial proton of the geminal pair at C-10 (*peri* to the C=O group) in **5** (18, 19), was somewhat more shielded in BNC-1 (1H doublet, τ 6.00, $J \simeq 12$ Hz). An even stronger shielding effect has been observed on the chemical shift of the analogous pair of protons at C-2 (*peri* to the C=O group) in aphyllidine. This pair is equivalent (2H singlet, τ 6.34 (19)), and has been attributed to a deformation of the A ring by the double bond thus displacing these protons relative to the anisotropic magnetic field of the carbonyl group. It is doubtful that any long range interaction from a double bond in the D ring could account for this effect on these protons in either **5** or **7**.

The apparent ease of hydrolysis of BNC-1 (>10×) compared to **3**, is consistent with a strain producing ring deformation expected from the introduction of a double bond into the C-5 position, evident from a molecular model of **7**. This should be contrasted to the lack of appreciable difference in stability between **5**, and its dihydroderivative, aphylline, both of which hydrolyze with difficulty compared to even **3** (20). This ease of hydrolysis accounted for its variable and often poor recovery from plants in early studies. In fact more recently, BNC-1 has been found to exceed the concentration of *N*-methylcytisine in plants 5–6 weeks of age.

Having located the unsaturation between C-5 and -6 in ring A, **7**, its pronounced effect on altering the mass fragmentation of the parent lupanine skeleton can be rationalized by two considerations. First, the double bond at C-5 greatly reduces the possibility of the two cleavage reactions between C-6 and -7, considered to lead to the two major fragments at *m/e* 136 and 149 in the spectrum of **3** (13). This has been clearly observed when comparing the mass spectrum of **5** (*m/e* 98 (base peak) and 136, RA 10%) with its dihydroderivative, aphylline (*m/e* 136 (base peak) and 98, RA 45%) (13). Second, the lowering of the ability of N-1 to stabilize a positive charge, resulting from the interaction of its lone pair of electrons with the adjacent p-orbitals of the carbonyl and olefinic groups, would have the effect that the major center of charge localization would be expected on N-16, favoring the formation of the major fragment at *m/e* 98 ($C_6H_{12}N^+$) by either of two paths analogous to those occurring with **5** (13) or **1** (21).

On the basis of this cumulative evidence we therefore assigned to alkaloid BNC-1 the structure of 5,6-dehydrolupanine (2-oxo-5,6-dehydrosparteine) (**7**), which in addition to being the "missing link" between anagyrine and lupanine, both also present in this particular species, is the first fully characterized naturally occurring dehydrolupanine.

Given the hydrolytic instability of this compound it is unlikely it would have been recovered by most isolation procedures commonly used, without the special precautions now described. Also its occurrence in quantity only in young plants at a particular stage of development, means it would not be noticed in most alkaloid studies, which utilize older, flowering, and frequently dried plants. Of interest is our failure to detect any isolupanine although the corresponding pyridone, thermopsine, is present. Likewise the apparent absence of sparteine from this species is not an isolated instance in this genus (3) in which it has been reported widespread (2) and should be compared to its rare occurrence in the closely related genus *Baptisia* (22).

Experimental

All solvents were reagent grade, redistilled through a 70 cm column filled with glass helices.

Chromatographic and Spectroscopic Methods

Thin Layer Chromatography

The t.l.c. was carried out using three systems: (A) silica gel G (E. Merck) developed with chloroform/methanol/-concentrated ammonia 90:9:1 (v/v/v); (B) aluminum oxide, basic (Woelm binderless) developed with benzene/-acetone/methanol (34:3:3 (v/v/v); (C) cellulose (Machery Nagel, MN pulver 300) developed with *n*-butanol/concentrated HCl/water 70:7.5:13.5 (v/v/v). Tanks were lined with filter paper. Chromatograms, air dried for 1 h were viewed under u.v. light to locate pyridone alkaloids, then sprayed with iodoplatinate reagent (23) to visualize all alkaloid areas.

Gas–Liquid Chromatography

The g.l.c. was carried out using an F & M (Hewlett Packard Corp.) Model 400 gas chromatograph, equipped with an exit splitter and a single hydrogen flame detector. Columns were U-shaped pyrex glass tubes (1.3 m × 4 mm i.d.) filled with Chromosorb W (AW, DMCS treated, 70–80 mesh) coated with 10% QF-1 by the filtration method of Horning *et al.* (24) and conditioned for 48 h at 240°. The injector was held at 230°; the column, initially at 140°, 5 min after injection of the sample was programmed at a rate of 2°/min to a maximum of 230°; He flow 40 ml/min. Other columns utilized were 5% XE-60 (22) and 5% SE-30. Collection of individual effluent peaks for spectroscopic examination, rechromatography, etc. was achieved by inserting clean capillary tubes (10 × 1.8 mm o.d.) into the exit port. To determine the extent of liquid phase "bleeding" which might contaminate the collected compound, a generous blank was collected from the g.l.c. from 1 min prior to expected peak emergence to 1 min past the usual peak end, which was then introduced as a sample into the mass spectrometer. A maximum column temperature of 210° was not exceeded when collecting compounds for mass spectra. A more detailed description of these chromatographic and collection methods, applied to a wider range of lupin alkaloids, will be presented elsewhere (25).

Spectroscopic Methods

All integer mass spectra were recorded at 70 eV, using an AEI M.S. 12 instrument. Samples contained in capillary tubes were directly inserted by means of a probe into the ion source. High resolution mass spectra were kindly carried out by Prof. A. M. Hogg of the Department of Chemistry, University of Alberta, Edmonton, Alberta. The u.v. absorption spectra, on samples collected from g.l.c. in preweighed capillaries, and eluted with 95% ethanol, were determined using a Cary model 14 instrument. The i.r. spectra were determined in dry $CHCl_3$, using a Beckman IR-8 instrument. The n.m.r. spectra were determined in $CDCl_3$ with tetramethylsilane as an internal reference, using a Varian HA 100 instrument.

Reference Compounds

The chromatographic behavior of the following compounds, homogeneous on all three t.l.c. systems and on g.l.c. (QF-1 and SE-30 columns) are summarized in Table 1. All gave mass spectra in agreement with those previously published (13, 21) and were free of any extraneous fragments above the molecular ion. The mass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

spectra of the free base forms were identical, before and after g.l.c., and differed from the salt form mainly by exhibiting a more abundant molecular ion.[3]

Commercial cytisine, thermopsine, lupanine perchlorate, and sparteine sulfate (converted to monoperchlorate salt) were recrystallized to give melting points in agreement with literature values (1, 27). Anagyrine hydrobromide, a gift of Prof. T. J. Mabry, Department of Chemistry, University of Texas, had g.l.c. behavior as previously reported (22). Lupinine, a gift of Prof. E. Wenkert, Department of Chemistry, Indiana University, had a satisfactory melting point. *N*-Methylcytisine, a gift of the S. B. Penick Co., showed g.l.c. behavior relative to cytisine as previously reported (22) and was purified by that means.

Isolupanine was synthesized in 60% yield by catalytic reduction of thermopsine (28) and purified by g.l.c. Its mass spectrum was very similar to lupanine: *m/e* 136 (base peak); 149, RA 60%, but with a more abundant molecular ion, *m/e* 248, RA 90%. Rhombifoline was synthesized in 70% yield from cytisine and but-3-enyl bromide (29) and purified by t.l.c. (system A), then by g.l.c. Mass spectra (M^+) *m/e* 244.1572 calculated for $C_{15}H_{20}N_2O$, 244.1576; base peak, *m/e* 58. Lupaninic acid was prepared in 90% yield by hydrolysis of lupanine and purified by preparative paper chromatography (30). 11,12-Dehydrolupanine was synthesized in quantitative yield (t.l.c.) by mercuric acetate oxidation of lupanine and isolated as the acetate salt (pale yellow gum) (6); λ_{max} (shoulder 235 nm). Due to the nature of the sample, accurate weight determination necessary for extinction coefficient calculation was not possible. The free base was too sensitive to air oxidation to prepare a suitable sample for g.l.c., or mass spectrometry. Catalytic reduction in glacial acetic acid over PtO_2, 25°, atmospheric pressure for 1 h gave >90% of a product identical with isolupanine on t.l.c.

Isolation and Characterization of Plant Alkaloids

Extraction

Five hundred grams of freshly harvested, 6 week old plants of *T. rhombifolia*, grown from locally collected seeds in a controlled environment chamber, were extracted immediately. Whole plants washed free of vermiculite were homogenized for 5 min in 4 l of 1% HCl in 95% ethanol and allowed to stand overnight at 5°. The filtered extract was evaporated to near dryness *in vacuo* at 20–25°. The dark green residue was suspended in water, filtered, alkalinized to p*H* 11–12 with cold 10 *N* NaOH, and extracted 3× with 1.5 volumes of CH_2Cl_2. The combined CH_2Cl_2 extracts were extracted 3× with equal volumes of 0.25 *N* HCl. The combined aqueous acid extract was cooled to 5°, alkalinized to p*H* 11 with cold 10 *N* NaOH and extracted 3× with 1.5 volumes of CH_2Cl_2. The pooled CH_2Cl_2 extract was dried over anhydrous Na_2SO_4 and the solvent removed *in vacuo* at 20°. The pale yellow total alkaloid residue, 25 mg, was redissolved in 1 ml of methanol and stored under nitrogen at 0°. Recovery as determined by g.l.c. peak areas of all the reference alkaloids by this scheme was greater than 90%, as indicated by a pilot extraction of a mixture of known amounts of each alkaloid. It was necessary to keep the aqueous extracts cold during p*H* changes owing to the hydrolytic instability of alkaloid BNC-1.

Identification and Estimation of Alkaloids

The g.l.c. of aliquot portions of the total alkaloid extract indicated the presence of at least six components (see Fig. 1) whose relative percentages were estimated from their respective peak areas (Table 1). The t.l.c. on system A revealed the presence of at least five components. Tentative identifications, made following co-chromatography with reference compounds, indicated the presence of all the compounds previously reported (1) and in addition the earliest component to be eluted from the g.l.c., designated as BNC-1 (before *N*-methylcytisine) which did not correspond to any standard available. The chromatographic behavior of all the plant alkaloids and reference compounds is summarized in Table 1. Confirmation of identity and purity of each g.l.c. peak was made by comparison of mass fragmentation patterns of individual components (20–50 μg), collected from the g.l.c. with those of authentic reference compounds collected in the same way. In all cases "clean" spectra were obtained identical to the appropriate standard with the exception of the early portion of the cytisine peak which had mass fragments at *m/e* 248, 149, and 136, none of which are present in the spectra of cytisine and in a ratio of 6:6:10, characteristic of lupanine.

Lupanine

To confirm the presence of lupanine, 10% of the total alkaloid extract was chromatographed (preparative) on system A, the region above *N*-methylcytisine eluted with methanol and injected into the g.l.c. In addition to alkaloids BNC-1, rhombifoline, thermopsine and anagyrine, a small peak (4–5% relative to thermopsine) corresponding to lupanine was detectable, which when collected gave a mass spectrum identical to that for lupanine (see Fig. 2A). No sign of sparteine was seen on the preparative chromatograms.

Alkaloid BNC-1

The earliest component to be eluted from the g.l.c., after collection, appeared unchanged on reinjection onto the same column and homogeneous on XE60 and SE30 columns and on all three t.l.c. systems. By repeated collection of this component from successive injections of aliquot portions of 2/3 of the total alkaloid extract into the g.l.c., 2–3 mg of a colorless liquid was obtained. Its mass spectrum is shown in Fig. 2B; M^+ at *m/e* 246 and base peak at *m/e* 98. Precise mass analysis of the peaks at *m/e* 246 (M^+) and 98 showed them to have the following compositions: (M^+) measured 246.1733; calcd. 246.1732 for $C_{15}H_{22}N_2O$; *m/e* 98 measured 98.0974; calculated 98.0970 for $C_6H_{12}N$; λ_{max}(EtOH) 250 nm (log ε 3.8); λ_{max} 2920 and 2840 (m) (methylene CH) and 1635 cm^{-1} (s) ($\nu_{C=O}$). The n.m.r.: τ 5.1 t (1H, J = 4 Hz), 6.00 d (1H, J = 12 Hz).

Catalytic Hydrogenation of BNC-1

A slow stream of hydrogen was passed through a

[3]The mass spectra of rhombifoline, isolupanine, and thermopsine, not previously reported, will be published elsewhere in digital and bar graph form together with those of the above and a number of related compounds (26).

solution of 0.5 mg of BNC-1 in 1.5 ml ethanol over 0.1 mg of 5% Pd/C at room temperature and atmospheric pressure. The catalyst was removed by filtration and the solvent removed *in vacuo* below 30°. The residue, redissolved in methanol and analyzed by g.l.c. and three t.l.c. systems, contained only a single product corresponding to lupanine, with no sign of the easily distinguished starting material for isolupanine. The mass spectrum of a sample collected from g.l.c., compared with that of a parallel sample of authentic lupanine, confirmed lupanine as the sole reduction product. The absence of extraneous peaks confirmed the purity of the original BNC-1 sample.

Attempted Formic Acid Reduction of BNC-1

To 490 μg (2μmol) of BNC-1 in a capillary tube (g.l.c. collection) 4 μmol of 97% formic acid was added. The tube after heat sealing was incubated at 65° for 2 h. The tubes were cooled, the contents washed out with water, made alkaline with cold 10% NaOH, and extracted into CH_2Cl_2. Aliquot portions of the CH_2Cl_2 extract, after volume reduction were analyzed by g.l.c. and on three t.l.c. systems which showed only unchanged starting material to be present.

Acid Hydrolysis of BNC-1 and Lupanine

Hydrolysis of BNC-1, its hydrogenation product, and lupanine were carried out directly in capillary tubes containing 125 μg (0.5 μmol) of each compound collected from g.l.c. by introducing 20 μl of 0.5 *N* HCl (10 μmol), heat sealing the tubes, and incubating at 60° for 1 h. The tubes were opened and the contents analyzed directly by t.l.c. in systems A and C. In addition to the starting compounds only a single product of lower R_f was detected in each case. The hydrolysis product of lupanine and reduced BNC-1 had R_f values identical with lupaninic acid, whereas that of BNC-1 was of even lower R_f in system C. (See Table 1.) The degree of hydrolysis, estimated from relative spot areas was 60% for BNC-1 and 5% for its hydrogenation product and lupanine.

We thank Mr. T. Mazurek of the Prairie Regional Laboratory, National Research Council of Canada for the n.m.r. spectra and the National and Medical Research Councils of Canada for their support of this work.

Nucleophilic Substitution on S_4N_4. Reactions with Benzylamines

YUKIHIKO SASAKI AND FREDRIC P. OLSEN
Department of Chemistry, McMaster University, Hamilton, Ontario

Received May 29, 1970

Reactions of benzylamines with tetrasulfur tetranitride lead to benzylidenimine polysulfides, ammonia, *N*-benzylidene benzylamines, and some free sulfur. The stoichiometric equation has been established. The reaction is quite sensitive to structural changes and appears limited to ring substituted benzylamines. The benzylidenimine polysulfides undergo thermal decomposition to sulfur and triphenyl-*s*-triazine and react with benzylamine to give benzylammonium polysulfides, ammonia, and *N*-benzylidene benzylamine. The benzylammonium polysulfides decompose in air to sulfur, hydrogen sulfide, and benzylammonium thiosulfate.

Canadian Journal of Chemistry, 49, 271 (1971)

Tetrasulfur tetranitride is quite reactive toward nucleophilic substitution. Reactions with phosphines (1–3), Grignard reagents (4, 5), ammonia (6, 7), amines (8), cyanide ion (1), and diazomethanes (9) have been reported. Although the products differ considerably from one reaction to another, they generally arise from attack of the nucleophile on sulfur with destruction of the sulfur nitrogen ring system. Formulas of products from a few of these reactions are supported by both elemental analysis and molecular weight determinations, but for some only an elemental analysis is reported; in a few cases there is neither. Seldom is the structure of the product unambiguously determined with both. Overall stoichiometries have only rarely been investigated and, not surprisingly, a composite picture of nucleophilic substitution on tetrasulfur tetranitride has not emerged.

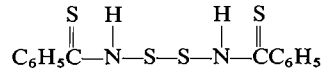
Closely related nucleophiles often appear to behave differently. Although ammonia (6, 7) is reported to give an ammoniate of composition $S_2N_2 \cdot NH_3$, generally formulated as $H_2N—S—\overset{-}{N}—\overset{+}{S}=NH$, secondary amines are reported to give thiobisamines. Thus, dimethylamine gave bisdimethylamine monosulfide and piperidine gave bispiperidine monosulfide (8). Benzylamine on the other hand was reported by Schenck (8) to give ammonia, sulfur, and triphenyl-*s*-triazine when reacted on a steam bath but the thioamide of thiobenzoic acid, **1**, at room temperature. The stoichiometry given in eq. 1 was proposed. A material identical to **1** was subsequently

[1] $6C_6H_5CH_2NH_2 + 3S_4N_4 \rightarrow$

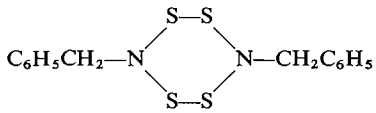
$$6C_6H_5—\overset{\overset{S}{\|}}{C}—N=S + 8NH_3 + 2N_2$$

1

isolated from the reaction of sulfur with benzylamine in the presence of lead(II) oxide (10). Based on a molecular weight determination, structure **1** was discarded in favor of **2** or possibly **3**. An authentic sample of **3** subsequently pre-



2



3

pared from benzylamine and sulfurmonochloride, however, had different properties (11). The structure of Schenck's material remains in doubt (11*b*). A reaction between tetrasulfur tetranitride and phenylhydrazine was reported to lead to sulfur, nitrogen, and ammonia. The stoichiometry given in eq. 2 was proposed although benzene was not isolated.

[2] $12C_6H_5NHNH_2 + 3S_4N_4 \rightarrow$

$$12S + 8NH_3 + 12C_6H_6 + 14N_2$$

The work described herein was undertaken with the aims of clarifying the structure of the benzylamine tetrasulfur tetranitride product, of establishing the overall stoichiometry for the reaction, and of determining if this reaction was applicable to other primary amines or to phenylhydrazine.

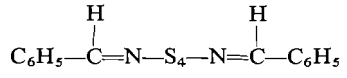
Results and Discussion

Characterization of Products

When tetrasulfur tetranitride and benzylamine were mixed as described by Schenck (8) [about 1 mol of tetrasulfur tetranitride to 7 mol of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

amine], an exothermic reaction was observed. This was accompanied by several color changes and the evolution of ammonia. Yellow needles which appeared to be identical to the material described by Schenck were obtained on washing the product with ice cold methanol and constituted the major crystalline product. The elemental analysis corresponded quite closely to the composition $(C_7H_6NS_2)_x$, and the molecular weight (osmometric in benzene) showed x to be 2 in agreement with Levi's observations (10) on the material isolated from the reaction of sulfur with benzylamine in the presence of lead(II) oxide. The properties of this yellow solid were, however, inconsistent with both of Levi's proposed structures, **2** and **3**, and also with **1**. It should have been formulated as benzylidenimine tetrasulfide, **4**, based on the following evidence.



4

The n.m.r. spectrum, Fig. 1, showed a sharp singlet at -7.87 p.p.m. and a multiplet at -7.05 to -7.48 p.p.m. Integration indicated one proton for the singlet and five protons for the multiplet (phenyl group). This eliminated structures **1** and **3** but did not rule out **2** although it would be rather surprising to have found such a sharp singlet for a thioamide proton (usually at least 0.5 p.p.m. wide). The i.r. spectrum showed no N—H stretching absorption (nothing above 3100 cm^{-1}) thus eliminating **2**. There was, however, a weak band at 1630 cm^{-1} assignable to a C=N stretch, *i.e.* structure **4**.

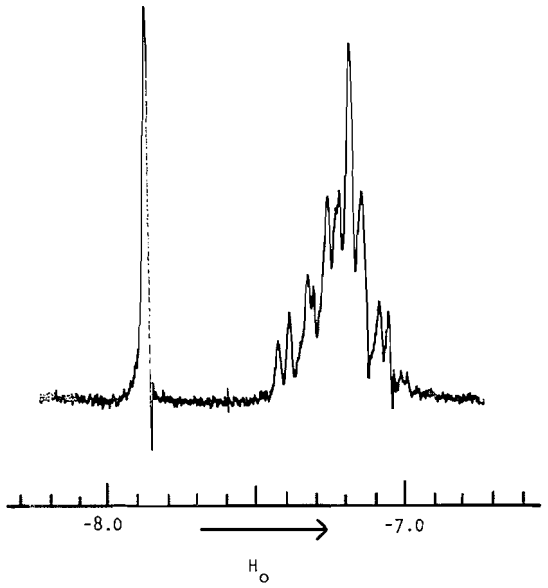


FIG. 1. The n.m.r. spectrum of benzylidenimine tetrasulfide.

Furthermore, two analogous compounds were isolated from the same reaction mixture whose n.m.r. spectra were quite similar to **4**. They both had one sharp singlet of area one downfield from a phenyl multiplet of area five. Elemental analyses and molecular weights along with n.m.r. confirmed that these compounds had the same organic component as **4** but that three and two sulfur atoms replaced the four in **4**. Table 1 lists n.m.r. chemical shifts in various known compounds with a benzylidenimine group. The benzylidenic protons in these compounds lie between -7.73 and -8.61 p.p.m. The chemical shifts of the low field singlets for the three compounds isolated from the reaction of tetrasulfur tetranitride with benzylamine, Table 2, also lie in this region. Thus, the chemical shifts are in good agreement with the benzylidenimine structure. The last compound in Table 2, an analogous monosulfide prepared from *p*-chlorobenzylamine and tetrasulfur tetranitride, is of particular interest. Its n.m.r. spectrum is very similar to that of **4** with a sharp singlet downfield of the phenyl multiplet (areas 1:4). The elemental analysis showed only one sulfur atom per two nitrogen atoms. With a molecular weight near 322, the n.m.r. spectrum requires this compound to have equivalent organic components. There is only one possible symmetrical structure with one sulfur which satisfies all of the requirements: *p*-chlorobenzylidenimine monosulfide. The similarity in n.m.r. spectra then requires similar structures for the other materials. Pyrolysis of benzylidenimine tetrasulfide to elemental sulfur, benzonitrile, and triphenyl-*s*-triazine also supports structure **4**.

A similar arylimine disulfide (but disubstituted on both benzylidene carbons) has been previously prepared (14) by reaction of sulfur monochloride with the phenyl magnesium bromide – benzonitrile adduct. The assignment of structure was based mainly on chemical evidence including the method of synthesis and the observed hydrolysis to benzophenoneimine hydrochloride and sulfur monochloride with concentrated hydrochloric acid.

Stoichiometry of the Reaction

Schenck's (8) proposed reaction, corrected to the benzylidenimine tetrasulfide structure, is given in eq. 3. When a five-fold excess of acid

[3] $S_4N_4 + 2C_6H_5CH_2NH_2 \rightarrow N_2 + C_6H_5CH{=}N{-}S_x{-}N{=}CHC_6H_5 + (4 - x)S + 2NH_3$

(5 HCl/S_4N_4) was used to trap the ammonia, the acid solution was basic at the end of the reaction. More than 5 mol of ammonia per mol of nitride was evolved rather than the 2 required by eq. 3. Formation of benzylidenimine tetrasulfide from benzylamine represents oxidation; taking nitrogen to retain its −3 oxidation state in ammonia, sulfur must be reduced. The change in formal oxidation state for sulfur is from +3 in S_4N_4 to $+\frac{1}{2}$ in benzylidenimine tetrasulfide, a change of $2\frac{1}{2}\,e^-$/sulfur, or $10\,e^-/S_4N_4$. Oxidation of benzylamine represents a $2\,e^-$ change or $4\,e^-$/benzylidenimine tetrasulfide. An additional $6\,e^-$ oxidation product is required. Schenck's scheme used the conversion of two nitrogen atoms of S_4N_4 to elemental nitrogen for this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

purpose. It seems quite likely from the large quantity of ammonia evolved, however, that *all* of the nitrogen of S_4N_4 goes to ammonia. Since 80–85% of the sulfur has been accounted for already, the additional oxidized product must arise from the benzylamine. Column chromatography gave this product, *N*-benzylidene benzylamine. The latter is formally derivable from benzylamine by a $2\,e^-$ oxidation to benzylidenimine and subsequent elimination of ammonia between this product and benzylamine. Thus, 3 mol of *N*-benzylidene benzylamine would be required to account for the missing $6\,e^-$ oxidation. One might then formulate the overall reaction as eq. 4 where the three *N*-benzylidene

[4] $$S_4N_4 + 8C_6H_5CH_2NH_2 \rightarrow C_6H_5CH{=}N{-}S_x{-}N{=}CHC_6H_5 + 7NH_3 + 3C_6H_5CH{=}N{-}CH_2C_6H_5 + (4 - x)S$$

benzylamines are needed to complete the reduction of sulfur. Four moles of ammonia would arise from the four nitrogens of the nitride and the remaining three would result from formation of the 3 mol of *N*-benzylidene benzylamine. This equation was tested by reacting benzylamine and tetrasulfur tetranitride in an 8:1 molar ratio and attempting quantitative isolation of all products. The coefficients from eq. 4 (1:8:1:7:3) were found experimentally to be 1.0:8.0:1.0:6.8:2.8. The stoichiometry given in eq. 4 was therefore quite closely approximated. With a large excess of benzylamine (22:1 molar ratio), benzylidenimine polysulfides were not obtained. The yield of *N*-benzylidene benzylamine increased considerably, and an orange solid identified as benzylammonium polysulfide was obtained in addition to a small amount of benzylammonium thiosulfate. These products were also observed when benzylidenimine polysulfides were reacted with benzylamine. With less than 8 mol of amine per mol of nitride, eq. 4 was still observed, but the quantity of arylimine polysulfides produced decreased in proportion to the quantity of amine used. When the 8:1 stoichiometric reaction was followed by n.m.r. spectroscopy, the final products were found to be present along with the starting materials even in the very early stages of the reaction (5 min). The concentration of the final products increased, and the concentration of the reactants decreased as time passed; the reaction was completed in about 15 h at room temperature. No peaks were observed at any time other than those corresponding to products and reactants, and notwithstanding several color changes, it appears unlikely that any *long-lived* intermediates are present between the starting tetrasulfur tetranitride and benzylidenimine polysulfides. Therefore, the reaction as represented by eq. 4 describes the course of nucleophilic substitution on tetrasulfur tetranitride by benzylamine and offers a synthetic route to arylimine polysulfides with mono substituted α-carbons.[1] The mechanism is not clear, but all of the nitrogen of the tetrasulfur tetranitride goes to ammonia, and the nucleophile becomes bound only to sulfur. Clearly several steps are required with an early step being partially ionic since the reaction is at least ten fold slower in non polar solvents (see next section). The reaction might be better thought of as a redox process than as a nucleophilic substitution.

Synthetic Application

Since the reaction as run was heterogeneous and would not be useful for solid amines, the effect of various solvents was investigated. Benzene resulted in a very slow reaction (if any); only unreacted starting materials were present after 24 h. Acetone resulted in rapid consumption of tetrasulfur tetranitride and amine; however, this appeared to be a Willgerodt–Kindler reaction (15, 16).[2] Several amine solvents were found to give benzylidenimine polysulfides, but the yields were lower than in the absence of solvent. Yields of benzylidenimine polysulfides were 52% in dimethylformamide, 60% in pyridine, and 91% in triethylamine compared to the quantitative reaction observed in the absence of these solvents. Triethylamine, therefore, appears usable when necessary but offers no advantage over the *neat* reaction. Both *p*-methoxy and *p*-chlorobenzylamine were found to undergo a reaction analogous to eq. 4. With the former, the sulfur containing species were *p,p'*-dimethoxybenzylidenimine tetrasulfide in 77% yield and the apparent trisulfide in about 5% yield. The yield of *N*-(*p*-methoxybenzylidene)*p*-methoxybenzylamine was quantitative. With *p*-chlorobenzylamine the yield of polysulfides and of *N*-(*p*-chlorobenzylidene)-

[1]See however following paper.

[2]Although tetrasulfur tetranitride has not previously been examined as a sulfur source under Willgerodt-Kindler conditions, its reactivity in this sense is probably not too surprising (17).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

p-chlorobenzylamine was 79%, and some mono sulfide was isolated along with the tetrasulfide. An additional 14% of elemental sulfur was also obtained. Free sulfur could arise by decomposition of the tetrasulfide to the observed monosulfide or by decomposition of some precursor. *p*-Nitrobenzylamine gave approximately 48% of elemental sulfur and no other tractable product. The *p*-nitro group is most likely involved directly in a competing reaction[3] of some sort since both *p*-chloro and *p*-methoxybenzylamines gave acceptable yields of aryliminepolysulfides. α-Methylbenzylamine did not lead to an analogous arylimine polysulfide while allylamine resulted in an apparent polymer. The reaction is therefore quite sensitive to small structural changes, and its synthetic usefulness appears limited to the reactions of ring substituted benzylamines.

With phenylhydrazine (8:1 molar ratio) the products were diphenyl disulfide, diphenyl monosulfide, elemental sulfur, and ammonia. In this reaction approximately 2 mol of ammonia per mol of tetrasulfur tetranitride were evolved. Thus, nitrogen gas must have been formed directly from tetrasulfur tetranitride to complete reduction of the sulfur. Had a reaction analogous to that with benzylamine occurred to give $C_6H_5N{=}N{-}S_x{-}N{=}NC_6H_5$, followed by breakdown of this product to the observed phenylsulfides and nitrogen, 7 mol of ammonia per mol of tetrasulfur tetranitride should still have been evolved. The phenylhydrazine reaction is therefore quite different from that with benzylamine and appears best formulated as in eq. 5. The yield of diphenyl-

$$[5]\quad S_4N_4 + 2C_6H_5\overset{\displaystyle H}{\underset{|}{N}}{-}NH_2 \rightarrow 2NH_3 + C_6H_5S_xC_6H_5 + 3N_2 + (4-x)S$$

polysulfides isolated in the presence of triethylamine based on eq. 5 was 74% (55% disulfide and 19% monosulfide). Here also the nucleophile becomes bonded only to sulfur, but the nitrogen is obtained in a different oxidation state than in the benzylamine reaction.

Reactions of Benzylidenimine Tetrasulfide

A mass spectrum of benzylidenimine tetrasulfide failed to show the parent peak. Instead, fragments such as S_x^+ ($x = 1$–8) and $C_6H_5CN^+$ were observed. The sulfur species with $x > 4$ must come from thermal decomposition and subsequent reactions rather than fragmentation, and the whole mass spectrum therefore probably represents pyrolysis products. Schenck (8) reported triphenyl-*s*-triazine as a product from the reaction of tetrasulfur tetranitride with benzylamine at steam bath temperature. Levi (10) was unable to reproduce this work in refluxing benzene. Consequently, the thermal decomposition of benzylidenimine tetrasulfide was investigated. Benzylidenimine tetrasulfide, heated to 105 °C (just above the m.p.) *in vacuo*, gave triphenyl-*s*-triazine, hydrogen sulfide, elemental sulfur, and benzonitrile as the main products along with a basic gas presumed to be ammonia. Thus, the main decomposition is described by eq. 6. The yield of sulfur based on eq. 6 was 82%,

$$[6]\quad C_6H_5CH{=}N{-}S_4{-}N{=}CHC_6H_5 \rightarrow H_2S + 2/x(C_6H_5CN)_x + 3S$$

and 67% of the total nitrogen was isolated in the form of either triphenyl-*s*-triazine or benzonitrile. Ammonia must arise from another reaction in competition with eq. 6. This decomposition was not observed in refluxing benzene and appeared to occur only at or above the m.p.

Photolysis of benzylidenimine tetrasulfide resulted in decomposition to lower polysulfides and elemental sulfur as shown in eq. 7. Benzyl-

$$[7]\quad C_6H_5CH{=}N{-}S_4{-}N{=}CHC_6H_5 \xrightarrow{h\nu} C_6H_5CH{=}N{-}S_{4-x}{-}N{=}CHC_6H_5 + xS \quad (x = 1\text{–}3)$$

idenimine monosulfide is very likely produced in this reaction. Although not isolated and fully characterized, the presence of this material is fairly certain from n.m.r. spectra (benzylidenimine type proton at −8.61 p.p.m.) and t.l.c. (R_f of 0.24, color observed when sprayed with silver nitrate solution was nearly identical to the other three benzylidenimine polysulfides and developed at the same rate) of the photolysis mixture.

Since benzylidenimine tetrasulfide was not isolated from tetrasulfur tetranitride in the presence of excess benzylamine, the reaction of the polysulfide with benzylamine was investigated. Benzylidenimine tetrasulfide reacted readily with benzylamine to give a deep reddish solution. Addition of anhydrous ether precipitated an orange solid which resembled the benzylammonium hexasulfide prepared by Levi (19) from sulfur, benzylamine, and hydrogen sulfide.

[3]See for example ref. 18.

Its n.m.r. spectrum supported this structure. A sample left in the air for a few days decomposed slowly with the evolution of hydrogen sulfide to sulfur and benzylammonium thiosulfate. The thiosulfate presumably arose by air oxidation of either the polysulfide or of one of its intermediate hydrolysis products. Thiosulfates have been previously isolated from sulfur with butylamine and from sulfur with ethylenediamine (20). In these cases the thiosulfates were thought to form concurrently with, rather than from, the polysulfides. Our results demonstrate that in the benzylamine system thiosulfates are a simple air oxidation/hydrolysis product of the benzylammonium polysulfides.

When a sample of benzylammonium polysulfide was dissolved in methanol, it decomposed quite rapidly to hydrogen sulfide, benzylamine and sulfur. The molar ratio of benzylamine to sulfur was 1:3.2 requiring an average sulfur chain length between 7 and 8. Levi's designation (19) of a similar material as a *hexa*sulfide was based on this type of quantitative decomposition to hydrogen sulfide, sulfur, and benzylamine.[4] Similar orange solids were prepared by Levi's (19) method and were also found to result from the reaction of either sulfur or heptasulfurimide with benzylamine. Heptasulfurimide has been previously (21) found to react with a large number of amines. In the case of propylamine, Richter (21) was able to demonstrate the presence of the propylammonium cation in solution although the anion was not identified. Our results would suggest that the anion was a polysulfide or possibly a thiosulfate if the solutions were not kept free of air. (Reactions between sulfur and benzylamine form the basis of the following paper.)

Sulfur chain lengths obtained by analysis of the products from the sulfur–amine, heptasulfurimide–amine, and benzylidenimine tetrasulfide – amine routes tended to vary from one preparation to another. In general, values ranged between 6 and 7 although values as high as 8–9 were occasionally obtained. Several samples of these materials were subjected to pyrolysis and in all cases gave hydrogen sulfide, sulfur, thiobenzamide, 3,5-diphenyl-1,2,4-thiadiazole, and dibenzyl polysulfides. Occasionally, 1,2-diphenyl ethane or *N*-benzylthiobenzamide was also isolated. The ratio of these materials tended to vary from one benzylammonium polysulfide preparation to another with sulfur rich species (free sulfur and dibenzylpolysulfides) predominating by a greater amount compared to sulfur-poor species (diphenylethane, *N*-benzylthiobenzamide, and 3,5-diphenyl-1,2,4-thiadiazole) in those cases where analysis suggested longer sulfur chains. While we cannot be certain that the starting material is free of *uncombined* sulfur in all cases, we favor a variable chain length polysulfide formulation with an average sulfur chain length of between 6 and 7 being most common for the product from the sulfur–benzylamine route in the absence of added hydrogen sulfide and also from the benzylidenimine polysulfide – benzylamine route. The polysulfides when heated with excess benzylamine gave *N*-benzylthiobenzamide. This material has also been obtained in high yield by heating sulfur in benzylamine directly (22). Its formation by heating polysulfides in benzylamine could well arise indirectly by this route, *i.e.*, decomposition to hydrogen sulfide, benzylamine, and free sulfur and subsequent reactions of the latter.

Spectra of Benzylidenimine Polysulfides

The chemical shift in the proton n.m.r. spectra of the methylene group in alkyl polysulfides, $RCH_2S_xCH_2R$, has been reported to be quite sensitive to sulfur chain length (23, 24). For dimethyl-di-*t*-butyl- and dibenzylpolysulfides the absorption moves to lower field as the number of sulfur atoms in the chain increases while for methyl chloro polysulfides, CH_3S_xCl, the methyl absorption moves to higher field as the number of sulfurs increases (23, 24). The difference in chemical shifts between two members of a series generally tended to become smaller as the sulfur chain length increased in all series although the tetra- and pentasulfides appeared closer than expected in the methyl series. For the unsubstituted benzylidenimine polysulfides, the chemical shifts of the benzylidene protons (Table 2) did not vary with sulfur chain length in a consistent manner. The tetrasulfide was at highest field,

[4]Elemental analysis leading to percent composition does not distinguish between a benzylammonium polysulfide (chain length 6–7) and a benzylammonium hydrogen sulfide (with a chain length of 3–3.5); however, a polysulfide on thermal decomposition would lead to hydrogen sulfide and benzylamine in molar ratios of 1:2 while a benzylammonium hydrogensulfide would give these materials in a 1:1 molar ratio. Levi's (19) observed values of 1:1.97 and 1:2.07 eliminate this latter possibility.

followed by the disulfide, the trisulfide, and at lowest field the (presumed) monosulfide. It is apparent that estimating sulfur chain lengths from relative chemical shifts alone is dangerous where these shifts have not been independently established by some other method. The R_f values (Table 2) appear to be a better criterion for this purpose. These increase monotonously as the number of sulfurs increase in all cases.

The i.r. spectra of the benzylidenimine polysulfides were complex; however, all showed weak absorption between 1640 and 1670 cm^{-1} as well as fairly strong absorption between 850–865 cm^{-1}. These regions, summarized in Table 2, represent C=N and N—S stretching frequencies. The intensity of the C=N absorption is known to be quite variable (25). Oximes generally give very weak C=N stretching absorptions.[5] For all benzylidenimine polysulfides prepared, the C=N stretching absorptions were observed to be weak. The sulfur–nitrogen stretching frequencies have been found (27) to be related to the sulfur–nitrogen bond lengths by the empirical eq. 8,

$$[8] \qquad r_{NS} = 0.0483\mu_{NS} + 1.099$$

where μ_{NS} = i.r. stretch in μ; r_{NS} = bond length. The sulfur–nitrogen bond lengths estimated from this equation are fairly constant at 1.66 Å for all of the imines prepared. This is somewhat shorter than the normal single bond length of 1.76 Å found in sulfamic acid (28) or the single bond covalent radii sum of 1.74 Å (29) but is longer than the N—S bond in tetrasulfur tetranitride (1.62 Å) (30). These data suggest that the N—S bond in the benzylidenimine polysulfides has at least some double bond character. The bond order is estimated as about 1.5 from the empirical relationship between i.r. stretching frequency and bond order given by Chapman and Waddington (31). If these empirical relationships hold for the benzylidenimine polysulfides, the suggested increase in bond order could be interpreted as evidence for $d\pi$–$p\pi$ double bonding between the Schiff's base and the adjacent sulfur.

Ultraviolet absorption spectra for the unsubstituted benzylidenimine polysulfides are shown in Fig. 2. The tetrasulfide showed three maxima at 243 ($\varepsilon = 1.8 \times 10^4$), 303 ($\varepsilon = 2.3 \times 10^4$), and 333 m$\mu$ ($\varepsilon = 1.0 \times 10^4$). The trisulfide showed only two obvious maxima at 242 ($\varepsilon = 1.3 \times 10^4$) and 309 m$\mu$ ($\varepsilon = 2.4 \times 10^4$) while the disulfide had maxima at 294 ($\varepsilon = 2.8 \times 10^4$) and 304 m$\mu$ ($\varepsilon = 2.9 \times 10^4$). These spectra do not closely resemble those of either typical alkyl polysulfides (32, 33) or typical Schiff's bases (34). Judging from the increase in extinction coefficients in the 300 mμ region for the

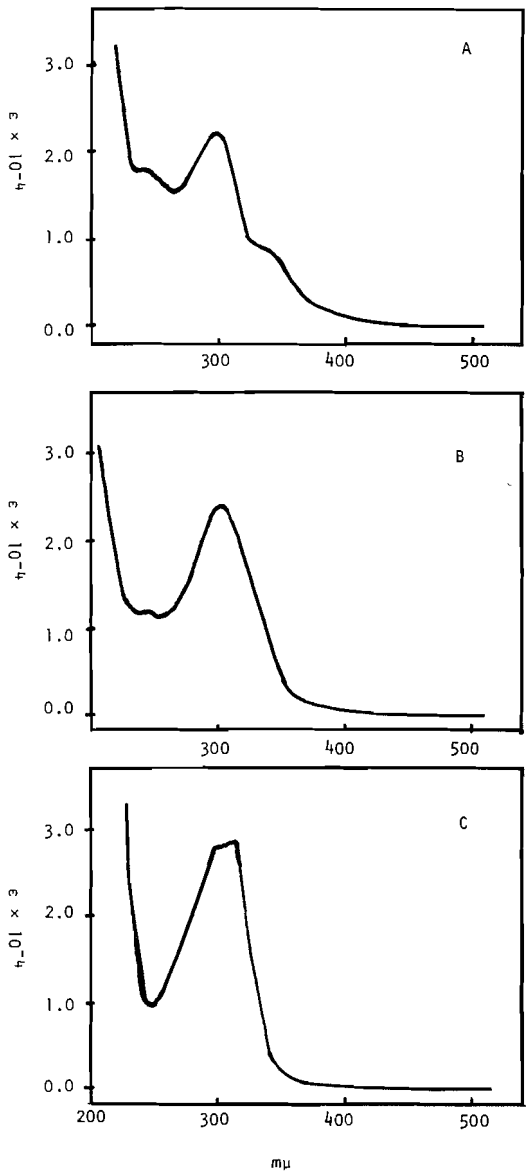

FIG. 2. Electronic absorption spectra of benzylidenimine polysulfides in methanol; (A) tetrasulfide; (B) trisulfide; (C) disulfide.

[5]Acetophenoneoxime shows a C=N stretching absorption whose molar extinction coefficient is almost 1/20 the value in the corresponding Schiff's base (26).

For personal use only.

lower sulfides, it appears likely that three absorptions occur in each compound becoming more clearly separated as the sulfur chain length increases. It does not seem profitable to speculate on the probable origin of these transitions at this time.

Experimental

General

Melting points were obtained on a Thomas Hoover capillary melting point apparatus and are uncorrected. Proton n.m.r. spectra were recorded on a Varian Model T-60 spectrometer and are relative to internal tetramethyl silane. Elemental analyses were performed by Schwarzkopf Microanalytic Laboratories, Woodside, New York. Molecular weight measurements were carried out on a Mechrolab Model 301A Vapor Pressure Osmometer with dibenzyl disulfide as reference and benzene as solvent. The i.r. spectra were recorded on a Beckman IR5 spectrometer and u.v. spectra on a Cary Model 14 using methanol as solvent. The dry box was a Vacuum Atmospheres Corporation Dry Lab Model HE-43 equipped with Dry Train Model HE-93B. The t.l.c.'s were obtained on 0.1 mm air dried silica gel plates using carbon disulfide or methylene chloride as eluent and sulfur as a reference. Chromatography grade silica gel (100–200 mesh) was used for column chromatography keeping the weight of absorbent to that of the mixture near 50:1.

Materials

Tetrasulfur tetranitride was prepared from sulfur monochloride and ammonia as previously described (35). Recrystallization from benzene afforded pure material of m.p. 178 °C dec. *p*-Nitrobenzylamine was prepared from potassium phthalimide and *p*-nitrobenzylbromide as previously described (36, 37). Its n.m.r. spectrum in deuterochloroform showed three absorptions: −1.72 p.p.m. (broad singlet, 2.2 H, $—NH_2$), −4.05 p.p.m. (singlet, 2.0 H, $—CH_2—$), and −7.36 to −8.34 p.p.m. (multiplet, 4.1 H, $—C_6H_4—$). The m.p. of the hydrochloride salt was 249–250 °C [lit. 250 (38) and 256 °C (39)]. Solvents used for chromatography were U.S.P. grade, and sulfur was "precipitated" grade. Other materials were reagent grade and were used without further purification.

Reactions of Sulfur with Benzylamine; Identification of Products

Tetrasulfur tetranitride (1.99 g, 10.8 mmol) was placed in a 100 ml three-necked flask with a magnetic stirring bar. A rubber serum stopper was placed at one of the necks and another was connected to a cylinder of dry nitrogen. The third neck was connected to a gas washing bottle containing 50.0 mg equiv of hydrochloric acid in about 250 ml of water. Benzylamine was degassed under vacuum, and 8.0 ml (73 mmol) was introduced through the rubber serum stopper by syringe. The reaction was stirred at room temperature while a continuous flow of nitrogen was maintained through the apparatus. The tetrasulfur tetranitride dissolved in the benzylamine to give an orange solution which gradually changed to dark green and after 30 min to yellow-brown. These color changes were accompanied by evolution of heat and ammonia, the latter continuing for at least 5 h. After 14 h the reaction mixture solidified to a yellow chunk. At this point the hydrochloric acid solution was found to be basic. The reaction mixture was separated by chromatography. Hexane eluted about 20 mg of sulfur identified by its m.p. and R_f value. Pure benzylidenimine tetrasulfide (about 2.5 g), obtained from the column by elution with 13% benzene in hexane, was recrystallized from hot methanol to give yellow needles of m.p. 100.5–102 °C.

Anal. Calcd. for $C_{14}H_{12}N_2S_4$ (mol. wt.: 336): C, 49.97; H, 3.59; N, 8.32; S, 38.11. Found (332): C, 49.54; H, 3.67; N, 8.70; S, 37.70.

Benzylidenimine tri- and disulfides were also eluted by 13% benzene in hexane but were not cleanly separated on the column. Appropriate enriched fractions were combined and were further purified by fractional recrystallization from methanol. The trisulfide (about 200 mg) gave white needles of m.p. 125–126 °C.

Anal. Calcd. for $C_{14}H_{12}N_2S_3$ (mol. wt.: 304): C, 55.23; H, 3.97; N, 9.20; S, 31.59. Found (306): C, 55.07; H, 4.12; N, 8.98; S, 32.04.

The disulfide (about 400 mg) was recrystallized from methanol to give nearly colorless white needles of m.p. 100–100.5 °C.

Anal. Calcd. for $C_{14}H_{12}N_2S_2$ (mol. wt.: 272): C, 61.74; H, 4.44; N, 10.28; S, 23.54. Found (271): C, 61.16; H, 4.20; N, 10.41; S, 23.74.

Elution with 20% ether in benzene gave *N*-benzylidene benzylamine (about 1.9 g) as an oil with a b.p. near 105 °C at 0.1 mm Hg. The n.m.r. and i.r. spectra were identical to those of an authentic sample prepared from benzylamine and benzaldehyde (40). Benzaldehyde (about 2.0 g) was eluted by 40% ether in benzene and was identified by comparison of its n.m.r. and i.r. spectra with those of an authentic sample. A quantity of benzylamine was obtained from the column on elution with 50% methanol in ether. Since an n.m.r. spectrum of the crude reaction mixture prior to chromatography did not indicate the presence of either benzylamine or benzaldehyde, these materials must form by hydrolysis of *N*-benzylidene benzylamine on the column.

Quantitative Reaction at a Molar Ratio of 1:8

The reaction was repeated as above using 922 mg (5.01 mmol) of tetrasulfur tetranitride and 4.4 ml (40.3 mmol) of benzylamine. The gas washing bottle contained 50.0 mg equiv of hydrochloric acid. After 20 h of stirring the hydrochloric acid was diluted to 500 ml. A 25.0 ml aliquot required 8.20 ml of 0.100 *N* sodium hydroxide solution for neutralization. The products were separated by washing with ice cold methanol to give 1.21 g of benzylidenimine tetrasulfide contaminated with small amounts of sulfur and benzylidenimine tri- and disulfides. The methanol was removed *in vacuo* to give 3.26 g of oil. The t.l.c. indicated this oil to be mainly *N*-benzylidene benzylamine with a small amount of benzylidenimine tetrasulfide. An n.m.r. spectrum gave the molar ratio of these two as 9.1 to 1.0. Total yields of products were therefore: ammonia, 33.6 mmol; *N*-benzylidene benzylamine, 2.74 g (14.0 mmol); sulfur and benzylidenimine polysulfides together expressed as tetrasulfide, 1.73 g (5.15 mmol).

Excess Benzylamine

Tetrasulfur tetranitride (500 mg, 2.72 mmol) and 6.4 ml of benzylamine (59 mmol) were stirred under a dry nitrogen atmosphere. The solution went through the orange and green stages, became orange and then blood red. After 24 h it was reddish brown and quite viscous. Upon addition of anhydrous ether a reddish solution containing an orange solid was obtained; some hydrogen sulfide was evolved. The orange solid was filtered, and the red ether solution was evaporated to give 5.75 g of material which when chromatographed yielded *N*-benzylidene benzylamine (1.78 g), sulfur (130 mg), benzaldehyde (1.95 g), benzylammonium thiosulfate (210 mg), and a quantity of benzylamine. The orange solid melted with decomposition at 90–97 °C in an evacuated sealed tube and decomposed continuously in air with evolution of hydrogen sulfide. After several days in air it was a mixture of sulfur and a white solid which after recrystallization from methanol had a m.p. of 173–174 °C. This material in aqueous solution gave a white precipitate with lead acetate; with silver nitrate it gave a yellowish precipitate which soon turned brown; with barium chloride it gave a white precipitate which was soluble in dilute hydrochloric acid but not in acetic acid; it readily discolored permanganate and was therefore identified as a thiosulfate. The n.m.r. spectrum in deuterium oxide showed three peaks consistent in chemical shift and areas with those expected for the phenyl, ammonium (exchanging with water), and methylene peaks of a benzylammonium ion. Its i.r. spectrum showed a strong NH stretch at 3280 cm^{-1}. Calcd. for benzylammonium thiosulfate 8.80% N, found 8.53% N.

Reactions with p-Chlorobenzylamine; Identification of Products

Tetrasulfur tetranitride (533 mg, 2.90 mmol) and 2 ml of *p*-chlorobenzylamine (16 mmol) were reacted as above. After 24 h the thick yellow paste was separated by chromatography. Hexane eluted about 70 mg of sulfur. Elution with 20% benzene in hexane gave about 570 mg of *p*-chlorobenzylidenimine tetrasulfide which was recrystallized from methanol to give yellow needles of m.p. 114.5–116 °C.

Anal. Calcd. for $C_{14}H_{10}N_2S_4Cl_2$ (mol. wt.: 405): C, 41.48; H, 2.49; N, 6.91; Cl, 17.49; S, 31.64. Found (395): C, 41.56; H, 2.65; N, 6.91; Cl, 17.38; S, 31.80.

p-Chlorobenzylidenimine monosulfide (about 240 mg) was eluted by 50% benzene in hexane and after recrystallization from methanol gave yellow needles of m.p. 146.2–146.8 °C.

Anal. Calcd. for $C_{14}H_{10}N_2SCl_2$ (mol. wt.: 309): C, 54.38; H, 3.26; N, 9.06; Cl, 22.93; S, 10.37. Found (322): C, 54.15; H, 3.25; N, 9.56; Cl, 22.86; S, 10.88.

N-(*p*-Chlorobenzylidene)-*p*-chlorobenzylamine was eluted by 100% benzene and was recrystallized from methanol to give thin white plates of m.p. 62–65 °C.

Anal. Calcd. for $C_{14}H_{11}NCl_2$ (mol. wt.: 264): C, 63.66; H, 4.20; N, 5.30; Cl, 26.84. Found (281): C, 63.57; H, 4.18; N, 5.31; Cl, 26.58.

At Molar Ratio of 1:8

When 344 mg (1.87 mmol) of tetrasulfur tetranitride was reacted with 2.11 g (14.9 mmol) of *p*-chlorobenzylamine, the products obtained were sulfur, 33 mg (1.03 mmol), *p*-chlorobenzylidenimine tetrasulfide, 598 mg (1.48 mmol), and *N*-(*p*-chlorobenzylidene)-*p*-chlorobenzylamine, 1.17 g (4.43 mmol). *p*-Chlorobenzylidenimine monosulfide was found in only trace amounts along with two other materials which appeared to be the di- and trisulfides based on their R_f values of 0.38 and 0.30 *vs.* 0.49 and 0.25 for the tetra- and monosulfides, respectively.

Reactions with p-Methoxybenzylamine; Identification of Products

Tetrasulfur tetranitride (542 mg, 2.94 mmol) and 2.0 ml (16 mmol) of *p*-methoxybenzylamine were reacted as above. After 24 h the solidified product was washed with ice cold methanol to give 710 mg (1.79 mmol) of *p*-methoxybenzylidenimine tetrasulfide which on recrystallization from absolute ethanol gave yellow plates of m.p. 112–113 °C.

Anal. Calcd. for $C_{16}H_{16}N_2S_4O_2$ (mol. wt.: 396): C, 48.46; H, 4.07; N, 7.06; S, 32.34. Found (391): C, 48.59; H, 4.24; N, 7.10; S, 32.66.

The methanol solution was concentrated, and the products were dissolved in chloroform from which 93 mg of a white solid of m.p. 230 °C precipitated. This material was identified as *p*-methoxybenzylammonium thiosulfate based on n.m.r. and chemical analyses as described for benzylammonium thiosulfate. The remaining yellow oil was purified by column chromatography to give an additional 140 mg of *p*-methoxybenzylidenimine tetrasulfide (eluted by 5% ether in benzene), 620 mg of anisaldehyde (eluted by 100% ether) identified by comparison of its n.m.r. and i.r. spectra with those of an authentic sample, and *p*-methoxybenzylamine (eluted by 80% methanol in ether) which was identified by its n.m.r. spectrum.

At Molar Ratio of 1:8

When 2.00 g (10.8 mmol) of tetrasulfur tetranitride was reacted with 10.9 ml (87 mmol) of *p*-methoxybenzylamine and the product was washed with ice cold methanol, 3.13 g of *p*-methoxybenzylidenimine tetrasulfide remained. Upon cooling to about −20 °C, 372 mg of a yellow solid precipitated. This material was a roughly equal mixture of *p*-methoxybenzylidenimine tetrasulfide and a new *p*-methoxybenzylidenimine polysulfide of $R_f = 0.68$ *vs.* 0.73 for the tetrasulfide. Attempted recrystallization of this material led to a mixture of these two materials with a third, *p*-methoxybenzylidenimine polysulfide. The original solvent from which these solids were obtained was removed *in vacuo* to give 8.45 g of oil. A part of this material when chromatographed gave mainly anisaldehyde and *p*-methoxybenzylamine. The n.m.r. spectrum before chromatography did not show any aldehyde, however. When the balance was distilled under reduced pressure, a yellow oil was obtained at 175–180 °C and 0.1 mm Hg which crystallized to a solid of m.p. 36.5–37.5 °C, lit. (41) 37–38 °C for *N*-(*p*-methoxybenzylidene)-*p*-methoxybenzylamine. The n.m.r. spectrum (a singlet at −3.62, 3.0 H, CH_3O—; a broad singlet at −4.58, 4.1 H, —CH_2—; a multiplet at −6.58 to −7.80, 4.1 H, —C_6H_4—; and a broad singlet at −8.10 p.p.m., 1.0 H, H—C=N) was consistent with that expected for this material. Total yields were therefore

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

3.32 g (8.37 mmol) of *p*-methoxybenzylidenimine tetrasulfide, 180 mg (0.49 mmol) of *p*-methoxybenzylidenimine trisulfide[6] and 8.45 g (33.1 mmol) of *N*-(*p*-methoxybenzylidene)-*p*-methoxybenzylamine.

p-Nitrobenzylamine

Tetrasulfur tetranitride (500 mg, 2.72 mmol) was reacted as above with 2.0 g (13 mmol) of *p*-nitrobenzylamine. The reaction mixture became very viscous, and 2 ml of dimethylformamide (the minimum amount to allow the mixture to be stirred) was added. After 12 h the product, a very viscous dark brown gum, was dissolved in hot methanol. From this solution 166 mg of elemental sulfur (5.19 mg atoms) precipitated. The mother liquor contained a viscous tar whose n.m.r. spectrum showed no peaks downfield from the phenyl multiplet. Characterization of this material was not undertaken.

d,l-α-Methylbenzylamine

Tetrasulfur tetranitride (656 mg, 3.56 mmol) was reacted as above with 2 ml of α-methylbenzylamine (16 mmol). The reaction mixture became brownish red, and a basic gas was evolved. After stirring for 24 h, the viscous product was dissolved in methanol and cooled to 0 °C whereupon 160 mg (5.0 mg atoms) of sulfur precipitated. Attempted chromatographic separation led to a number of fractions of viscous dark brown materials but none had the singlet methyl peak required for a benzylidenimine type of product. Distillation, recrystallization and preparative scale t.l.c. failed to give tractable, single component products.

Allylamine

Tetrasulfur tetranitride (501 mg, 2.72 mmol) was reacted as above with allylamine (2 ml, 27 mmol). Ammonia was evolved fairly rapidly, and the color passed through orange to dark brown; after 6 h it had become very viscous. The excess allylamine was removed *in vacuo* leaving a dark brown tar which was insoluble in ether, benzene, hexane, and alcohol. This was assumed to be polymeric and was not further characterized.

Phenylhydrazine

Tetrasulfur tetranitride, 514 mg (2.80 mmol), was placed in a flask equipped as in the benzylamine reaction and cooled to 0 °C. The gas washing bottle contained 7.00 mg equiv of hydrochloric acid in about 70 ml of water. Phenylhydrazine (2.15 g, 19.9 mmol) was added to the flask and immediately solidified. On warming to about 20 °C it remelted, and the temperature of the exothermic reaction which ensued was maintained below 25 °C by periodic cooling. The solution became orange, then brilliant yellow-orange, and eventually yellow. After 6 h gas evolution had ceased. After 12 h the reaction was stopped, and the solution in the acid trap was diluted to 100 ml. A 50 ml aliquot required 4.45 ml of 0.075 *N* potassium hydroxide solution for neutralization. The products were separated by column chromatography. Hexane eluted 221 mg (6.90 mg atoms) of elemental sulfur. Elution with 15% benzene in hexane gave 196 mg of a white solid which was recrystallized from methanol to give diphenyl disulfide of m.p. 59–60 °C, lit. (42) 60–61 °C, and molecular weight by mass spectrum of 218 (Calcd. for $C_{12}H_{10}S_2$, 218). The n.m.r. and i.r. spectra were identical to those of authentic diphenyldisulfide. Elution with 20% benzene in hexane gave 122 mg of diphenyl monosulfide as a colorless oil. The mass spectrum showed an apparent molecular ion of mass 186 (Calcd. for $C_{12}H_{10}S$, 186). The n.m.r. and i.r. spectra were identical to those of the authentic material. Elution with more polar solvents gave considerable amounts of multicomponent mixtures of viscous red materials which were not characterized. A similar reaction of 504 mg (2.74 mmol) of tetrasulfur tetranitride and 2 ml (20.4 mmol) of phenylhydrazine in 5 ml of triethylamine for 30 h at 0 °C with work-up as above led to 95 mg (2.97 mg atoms) of elemental sulfur, 326 mg (1.49 mmol) of diphenyl disulfide, and 99 mg (0.53 mmol) of diphenyl monosulfide

Pyrolysis of Benzylidenimine Tetrasulfide

Benzylidenimine tetrasulfide (711 mg, 2.12 mmol) was placed in a 100 ml flask, evacuated to 7×10^{-4} mm Hg, sealed, and heated in an oil bath to 105 °C. As the solid fused, some gas evolution was observed, and an oil boiled off and condensed on the walls of the flask above the oil bath level. After 7 h the mixture was cooled, the flask was opened, and a basic gas was detected by p*H* paper. Hydrogen sulfide was also detected by wet lead acetate paper. The non-volatile products were separated by column chromatography. Pure hexane eluted 222 mg (6.6 mg atoms) of elemental sulfur. Elution with 13% benzene in hexane gave 45 mg of unreacted benzylidenimine tetrasulfide (0.13 mmol). Elution with 20% benzene in hexane gave 234 mg (0.76 mmol) of triphenyl-*s*-triazine (R_f 0.14, silica gel – carbon disulfide with sulfur = 0.80). Recrystallization from a hexane–benzene mixture gave colorless needles of m.p. 234.5–235 °C [lit. (43) 235–235.4 °C]. The i.r. spectrum of this material was identical to that of authentic triphenyl-*s*-triazine (43). A 1:1 mixture of benzene and hexane eluted 59 mg (0.57 mmol) of benzonitrile identified by comparison of its i.r. and n.m.r. spectra with those of an authentic sample.

Benzylidenimine Tetrasulfide with Excess Benzylamine

Benzylidenimine tetrasulfide (510 mg, 1.52 mmol) was dissolved in 2.71 g (25 mmol) of benzylamine under a dry nitrogen atmosphere and stirred for 24 h.[7] The reaction mixture was placed in a dry box and anhydrous ether was introduced into the reaction mixture and stirred well. An orange solid precipitated which was filtered and washed with ether. This solid decomposed in air with the evolution of hydrogen sulfide and melted at 93–96 °C dec. in an evacuated sealed tube. Nitrogen analysis gave 6.67%. Calcd. for $C_{14}H_{10}N_2S_6$, 6.85 and for $C_{14}H_{10}N_2S_7$, 6.37%. An n.m.r. spectrum in dry dimethyl-d_6-sulfoxide showed three peaks: −3.96 (singlet, 1.7 H, $—CH_2—$), −6.32 (broad singlet, 3.4 H, $—NH_3$) and

[6]The assignment of this material as the trisulfide rests on the R_f value and on the decomposition to tetrasulfide and a new material, probably the disulfide. Disproportionation of unsubstituted benzylidenimine trisulfide to di- and tetrasulfides was observed when samples were left in solution for long periods of time.

[7]A reaction run without a dry nitrogen atmosphere led to benzylammonium thiosulfate.

−7.00 p.p.m. (broad singlet, 5.0 H, C_6H_5—). The filtrate was concentrated to give an oily material. This was separated by column chromatography to give 55 mg of sulfur (1.7 mg atoms), 425 mg (2.2 mmol) of *N*-benzylidene benzylamine, 310 mg (2.9 mmol) of benzaldehyde, and a substantial quantity of benzylamine. A sample of the orange solid was placed in an evacuated sealed tube (weight not recorded) in the dry box and heated to 170–180 °C for 12 h. A strong odor of hydrogen sulfide (confirmed by wet lead acetate paper) was noted when the tube was cooled and opened. The non-volatile products were separated by column chromatography. Hexane eluted 73 mg (2.3 mg atoms) of elemental sulfur. Elution by 20–40% benzene in hexane gave 120 mg (about 0.4 mmol) of dibenzyl-polysulfides with sulfur chain lengths of 2–6 inclusive.[8] Elution with benzene gave 66 mg (0.27 mmol) of 3,5-diphenyl-1,2,3-thiadiazole which after recrystallization from ethanol had a m.p. of 89–90 °C [lit. (44) 89–90 °C]. This was further identified by mixed m.p. (undepressed) and comparison of its i.r. and n.m.r. spectra with those of an authentic sample prepared from thiobenzamide and iodine (44). Ether eluted 37 mg (0.16 mmol) of *N*-benzylthiobenzamide of m.p. 85 °C [lit. (45) 84–85 °C]. This was identified by mixed m.p. (undepressed) and comparison of its i.r. and n.m.r. spectra with those of the authentic material prepared from sulfur and benzylamine (45). Elution with 30% methanol in ether gave 72 mg (0.53 mmol) of thiobenzamide which was recrystallized from benzene to give a m.p. of 113–114 °C [lit. (46) 115–116 °C]. The mixed m.p. with an authentic sample prepared from benzonitrile and hydrogen sulfide (46, 47) was undepressed, and the i.r. and n.m.r. spectra were identical.

A sample of benzylammonium hexasulfide was prepared from benzylamine, sulfur, and hydrogen sulfide as previously described (19). It melted at 96 °C in an evacuated sealed tube and was an orange solid which decomposed slowly in air with evolution of hydrogen sulfide to give eventually elemental sulfur and benzylammonium thiosulfate. The n.m.r. spectrum of this material was virtually superimposable on that of the material obtained from the benzylidenimine tetrasulfide reaction.

Benzylamine with Sulfur

Benzylamine (5 ml, 45.8 mmol) was added to 1.08 g (33.8 mg atoms) of sulfur, and the mixture was stirred for 24 h under a nitrogen atmosphere. Anhydrous ether was added and stirred well. An orange solid remained undissolved (1.94 g) which melted at 93–94 °C in an evacuated sealed tube. Nitrogen analysis gave 6.54% (*i.e.*, between a hexa- and heptasulfide).

A sample was subjected to a Soxhlet extraction with anhydrous ether in the dry box for 24 h and was found to be completely decomposed into sulfur, benzylamine, and (presumably) hydrogen sulfide. A sample left in air evolved hydrogen sulfide and became a yellowish solid. This was dissolved in methanol to leave some elemental sulfur. The methanol solution was found to contain mainly benzylammonium thiosulfate. Another sample added to methanol evolved hydrogen sulfide and deposited 344 mg (10.7 mg atoms) of sulfur. The methanol solution contained 357 mg (3.3 mmol) of benzylamine. A sample (not weighed) was heated for 12 h at 170–180 °C in an evacuated sealed tube. The products obtained on chromatography were: sulfur, 188 mg (5.9 mg atoms); 1,2-diphenylethane, 74 mg (0.41 mmol); dibenzylpolysulfides (a mixture of tri-, tetra-, penta- and hexasulfides), 88 mg (about 0.35 mmol);[8] 3,5-diphenyl-1,2,3-thiadiazole, 127 mg (0.53 mmol); and thiobenzamide, 40 mg (0.29 mmol).

A sample of the benzylammonium polysulfide (568 mg) was dissolved in 8 ml of benzylamine and refluxed for 3 h during which time the dark reddish brown color slowly changed to pale yellow, and vigorous hydrogen sulfide evolution was observed. The reaction mixture was dissolved in hot hexane, and upon cooling 600 mg (2.7 mmol) of *N*-benzylthiobenzamide of m.p. 86 °C was obtained.

Heptasulfurimide with Benzylamine

Benzylamine (4.2 ml, 38.6 mmol) was added to 1.00 g (4.18 mmol) of heptasulfurimide under a dry nitrogen atmosphere. The solution immediately became blue and after a few minutes dull green and then reddish. After 10 h the dark red solution was placed in the dry box, and an aliquot was removed and heated in a free flame until it boiled. The red color became pale yellow and evolution of hydrogen sulfide was observed. After cooling it solidified and was recrystallized from hexane to give *N*-benzylthiobenzamide of m.p. 84 °C. The remainder was stirred with anhydrous ether in the dry box. About 400 mg of an orange solid precipitated. This was filtered and washed with anhydrous ether to give a material of m.p. 95–97 °C dec. Nitrogen analysis gave 5.82%; calculated for benzylammonium *octa*sulfide, 6.06 and for the *nona*sulfide, 5.67%. This material, in contrast to the previous samples, was not stable even in the dry box; it slowly became dark brown and looked "wet". In air it decomposed with the evolution of hydrogen sulfide to give sulfur and benzylammonium thiosulfate. A sample (not weighed) was pyrolyzed in an evacuated sealed tube as before and gave: sulfur, 174 mg (5.4 mg atoms); dibenzylpolysulfides (a mixture of di-, tetra- and pentasulfides), 214 mg (0.86 mmol);[8] 3,5-diphenyl-1,2,3-thiadiazole, 127 mg (0.53 mmol); and thiobenzamide, 40 mg (0.29 mmol).

This work was carried out under a grant from the National Research Council of Canada.

Reactions of Benzylamine with Sulfur

YUKIHIKO SASAKI AND FREDRIC P. OLSEN
Department of Chemistry, McMaster University, Hamilton, Ontario
Received May 29, 1970

A five-step sequence has been established for the room temperature reaction of sulfur with benzylamine. Benzylamine polysulfides and benzylidenimine polysulfides occur as interconverting intermediates in this system. The final products are benzylammonium polysulfides, ammonia, and *N*-benzylidene benzylamine.

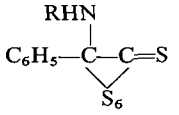
Primary amines have been successfully employed in the Willgerodt–Kindler reaction (1, 2) where, in addition to the usual products, they can lead to novel types of compounds. Thus, acetophenone at elevated temperatures gives thioamides (1, 2) but at room temperature (in the presence of 0.25 g atoms of sulfur per mol of ketone) gives a Schiff's base (3). When the quantity of sulfur is increased, the yield of Schiff's base decreases, and at a sulfur to ketone ratio of 8:1 the heterocyclic compound 8-alkylamino-8-phenyl-1,2,3,4,5,6-hexathiocane-7-thione (**1**) results (4, 5). Primary amines are



1

known to catalyze various reactions of sulfur with organic substrates. Aniline, for example, shows an accelerating effect on the rate of vulcanization of natural rubbers (6–8). Mercaptans, unreactive toward elemental sulfur at low temperatures, readily evolve hydrogen sulfide in the presence of butylamine (9, 10) providing a convenient route to alkyl disulfides. By adjusting the molar ratio of mercaptan to sulfur, the sulfur chain length in the product can be changed fairly selectively up to the tetrasulfide (10). *n*-Butyl- and other amines may function as catalysts in the dehydrogenation of heterocyclic compounds with elemental sulfur (11, 12).

The mechanism of the Willgerodt–Kindler reaction remains unclear, notwithstanding a considerable amount of work. Most of the proposed mechanisms (1, 2, 9, 13–17) have considered the first step to be attack either by the amine at the carbonyl carbon or by sulfur at the α-carbon to the carbonyl group. This step is generally thought to be followed by migration of the functional group or groups along the carbon chain with eventual irreversible oxidation at the end of the chain giving the final product. These mechanisms remain rather speculative, and none has considered the possibility of any reaction between sulfur and the amine. More detailed information about the interaction of sulfur with amines, a reaction which is known to occur even at room temperature (18, 19), appears vital to any understanding of the Willgerodt–Kindler reaction and the various other reactions involving amines as catalysts in sulfur reactions. The work described herein was undertaken with the aim of establishing the nature of the room temperature reactions between sulfur and benzylamine.

Results and Discussion

A Proposed Reaction Scheme

Purified tertiary amines have been demonstrated to be inert to sulfur under normal conditions (18, 20, 21) but to give trialkylammonium polysulfides when hydrogen sulfide is added (22). Primary and secondary amines also lead to alkylammonium polysulfides with hydrogen sulfide and sulfur (22) although here the same products result even in the absence of added hydrogen sulfide (23, 24). Levi (25) has proposed reactions 1 and 2 to account for these observations.

[1] $2R_2NH + S_{y+1} \rightarrow R_2N{-}S_y{-}NR_2 + H_2S$

[2] $H_2S + (x-1)S + 2R_2NH \rightarrow (R_2NH_2^+)_2S_x^{2-}$

Spectroscopic and conductometric measurements (18) have confirmed the presence of alkylammonium polysulfides in both the primary and secondary amine systems. The e.s.r. data have been interpreted (26) in terms of polythiobisamines, and these materials have been isolated from several secondary amine – sulfur reactions car-

For personal use only.

ried out in the presence of a hydrogen sulfide scavenger (25, 27). It therefore seems reasonable to assume that since primary amines form polysulfide ions, they should also form polythiobisamines. The product isolated from benzylamine (the only primary amine reported to lead to a well-defined product) and sulfur in the presence of lead(II) oxide was not the benzylamine polysulfide, however, but rather its oxidation product, benzylidenimine tetrasulfide (28, 29).

Benzylamine *di*sulfide was consequently prepared and evaluated as a possible intermediate in this reaction. This material decomposed quite readily when exposed to small amounts of benzylamine at room temperature. Even in the absence of base it was stable for only a few hours. After an induction period (5–5½ h with no change), it underwent fairly rapid (~1 h) autocatalytic decomposition. The products of these decompositions were *N*-benzylidene benzylamine and ammonia along with smaller amounts of benzylidenimine tetrasulfide, benzylammonium polysulfides, and sulfur. When the autocatalytic decomposition was monitored by n.m.r., benzylamine and benzylidenimine tetrasulfide were observed to form, to increase to a maximum concentration, and then to decrease in amount as the concentration of *N*-benzylidene benzylamine increased. The ratio of benzylamine to benzylidenimine tetrasulfide formed in the early stages was near 4:1. These results suggested a base catalyzed redox type disproportionation of benzylamine disulfide as per eq. 3. The benzylamine produced would be expected to catalyze further decomposition of the benzylamine disulfide leading to the observed autocatalysis. As described in the preceding paper (29), benzylidenimine tetrasulfide reacts with benzylamine to give benzylammonium polysulfides, *N*-benzylidene benzylamine, and ammonia. This reaction would occur as the concentration of benzylidenimine tetrasulfide and benzylamine increased during the decomposition and would thus account for the observed products. Since benzylidenimine tetrasulfide was obtained from the decomposition of benzylamine *di*sulfide, benzylamine polysulfides could be intermediates in the reaction of benzylamine with sulfur. When sulfur, benzylamine disulfide, or benzylidenimine tetrasulfide was dissolved in an excess of benzylamine, a reddish-brown solution formed, and ammonia was evolved. From all of these solutions benzylammonium polysulfides and *N*-benzylidene benzylamine were isolated. Thus, these possible intermediates all lead to the same final products.

[3] $$3C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_2—\overset{H}{\underset{|}{N}}CH_2C_6H_5 \rightarrow 4C_6H_5CH_2NH_2 + C_6H_5\overset{H}{\underset{|}{C}}{=}N—S_4—N{=}\overset{H}{\underset{|}{C}}C_6H_5 + 2S$$

Equations 4 to 8 are consequently proposed to account for the benzylamine-sulfur system[1] where [6] is base catalyzed and [7] is catalyzed by sulfide ion. The latter point seems justified since only small amounts of *N*-benzylidene benzylamine and ammonia were produced from benzylidenimine tetrasulfide and benzylamine in the presence of lead(II) oxide, a sulfide ion scavenger.

[4] $$(a+1)S + 2C_6H_5CH_2NH_2 \rightleftharpoons H_2S + C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_a—\overset{H}{\underset{|}{N}}CH_2C_6H_5$$

[5] $$H_2S + (x-1)S + 2C_6H_5CH_2NH_2 \rightarrow (C_6H_5CH_2NH_3^+)_2S_x^{2-}$$

[6] $$3C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_a—\overset{H}{\underset{|}{N}}CH_2C_6H_5 \rightarrow 4C_6H_5CH_2NH_2 + C_6H_5CH{=}N—S_b—N{=}CHC_6H_5 + (3a-b)S$$

[7] $$C_6H_5CH{=}N—S_b—N{=}CHC_6H_5 + 2C_6H_5CH_2NH_2 \rightleftharpoons 2C_6H_5CH{=}NH + C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_b—\overset{H}{\underset{|}{N}}CH_2C_6H_5$$

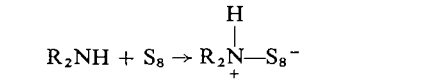
[8] $$C_6H_5CH{=}NH + C_6H_5CH_2NH_2 \rightarrow NH_3 + C_6H_5CH{=}N—CH_2C_6H_5$$

In [4], benzylamine reacts with sulfur to give a benzylamine polysulfide and hydrogen sulfide. This is written as an equilibrium since tetraalkylamine polysulfides are known (30) to react with hydrogen sulfide to give amines and elemental sulfur. In eq. 5, the hydrogen sulfide formed in [4] reacts with more sulfur and benzylamine to give benzylammonium polysulfides (one of the final products). Both eqs. 4 and 5 are based on analogy with Levi's (25) work on secondary amines. Davis and Nakshbendi (18)

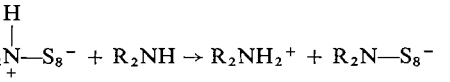
[1]In eqs. 4–8 *a*, *b*, and *x* represent the number of sulfur atoms in the various polysulfide chains; *b* is generally 4 and less commonly 3, 2, or 1; *x* is generally 6–7; no estimate for *a* is available.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

have proposed an alternative mechanism (reactions 9 and 10) for the initial steps in the interaction of sulfur with a secondary amine which does not involve free hydrogen sulfide. The primary amine analogue of **2** could well be present



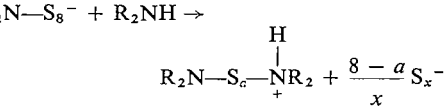
[9] $R_2NH + S_8 \rightarrow R_2\overset{+}{N}(H)—S_8^-$



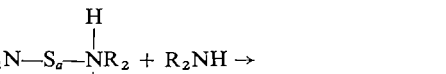
[10] $R_2\overset{+}{N}(H)—S_8^- + R_2NH \rightarrow R_2NH_2^+ + R_2N—S_8^-$

2

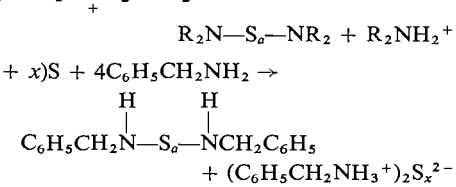
in our system as an intermediate which could react with more amine to give benzylamine polysulfide and alkylammonium polysulfides as per eqs. 11 and 12. The sum of eqs. 9 to 12, given by [13], is the same as the sum of [4] and [5].



[11][2] $R_2N—S_8^- + R_2NH \rightarrow R_2N—S_a—\overset{+}{N}(H)R_2 + \frac{8-a}{x}S_x^{-2}$

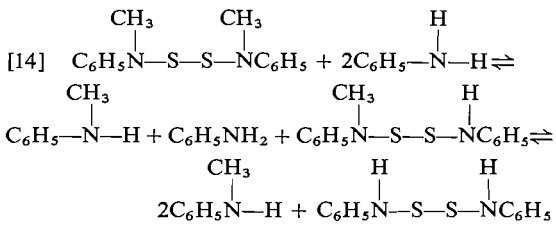


[12] $R_2N—S_a—\overset{+}{N}(H)R_2 + R_2NH \rightarrow R_2N—S_a—NR_2 + R_2NH_2^+$



[13] $(a + x)S + 4C_6H_5CH_2NH_2 \rightarrow C_6H_5CH_2\overset{H}{N}—S_a—\overset{H}{N}CH_2C_6H_5 + (C_6H_5CH_2NH_3^+)_2S_x^{2-}$

For simplicity only, since it is not possible to distinguish between these two mechanisms on the basis of the work described here, the scheme will be based on eqs. 4 and 5. It should be emphasized, however, that eqs. 9–12 offer an equally good alternative to [4] and [5] (see also reference 31). In eq. 6, the benzylamine polysulfides formed in [4] are proposed to decompose to benzylamine, sulfur, and benzylidenimine polysulfides as observed experimentally for benzylamine *di*sulfide. Since sulfur and benzylamine are produced in this step, eqs. 4–6 will be repeated. In eq. 7, the benzylidenimine polysulfides produced in [6] are proposed to react with benzylamine in the presence of sulfide ion to give benzylamine polysulfides and benzylidenimine. Exchange of one amine for another has been previously observed in alkylamine polysulfides. Thus, when *N*-methylaniline disulfide is mixed with aniline or when aniline disulfide is mixed with *N*-methylaniline, exchange occurs quite rapidly at room temperature[3] to give the five species shown in eq. 14. By analogy, exchange of imine for amine in the presence of the excess benzylamine is



[14] $C_6H_5\overset{CH_3}{N}—S—S—\overset{CH_3}{N}C_6H_5 + 2C_6H_5—\overset{H}{N}—H \rightleftharpoons C_6H_5—\overset{CH_3}{N}—H + C_6H_5NH_2 + C_6H_5\overset{CH_3}{N}—S—S—\overset{H}{N}C_6H_5 \rightleftharpoons 2C_6H_5\overset{CH_3}{N}—H + C_6H_5\overset{H}{N}—S—S—\overset{H}{N}C_6H_5$

expected to occur here with the benzylidenimine polysulfides. The benzylidenimine proposed as a product in this exchange is known (32) and is quite reactive toward nucleophiles. It has been previously proposed (33) to react with benzylamine to give *N*-benzylidene benzylamine and ammonia as per [8]. Catalysis by sulfide ion as proposed in eq. 7 appears to be fairly common in sulfur-amine reactions (20, 21). Since benzylamine polysulfides are produced in [7], all steps will be repeated until all the sulfur is converted to benzylammonium polysulfides or all the benzylamine is converted to *N*-benzylidene benzylamine and ammonia. The proposed scheme is obviously complex with benzylamine polysulfides and benzylidenimine polysulfides involved in a cyclical catalytic sense. The interrelationship between the various compounds is shown in Fig. 1.

Quantitative Assessment of the Proposed Reaction Scheme

The proposed scheme described by Fig. 1 (reactions 4–8) accounts for the observed products using intermediates which are known independently to lead to these products. Each of the steps is based on analogy with a known reaction in a similar system. The intricate relationship between the compounds makes it impossible, however, to study any one step independently of the others. Nevertheless, a number of quantitative predictions can be derived from this scheme which are subject to experimental test. Before deriving these predic-

[2]From the charge balance it is apparent that $(8 - a)/x$ must equal 1 in this particular equation (*i.e.*, $a + x = 8$).

tions, three useful relationships are noted. First, all hydrogen sulfide formed in the presence of benzylamine (since hydrogen sulfide is formed only from benzylamine, it cannot be formed in the absence of benzylamine) goes immediately to benzylammonium polysulfides. Therefore, in the absence of a sulfide scavenger, eqs. 4 and 5 may always be combined (added) to eliminate hydrogen sulfide as in [13]. Second, since benzylidenimine was neither isolated nor detected, it must react with benzylamine fairly rapidly compared to the various other reactions in the system. Here again, benzylidenimine is formed only from benzylamine and hence cannot be formed in the absence of benzylamine (alternatively and equally good, equilibrium [7] may lie fairly far to the left). Equations 7 and 8 may consequently be combined to eliminate benzylidenimine (twice [8] added to [7]) to give [15]. Finally, it should be noted that the benzylamine polysulfides formed in [7] have

[15] $$C_6H_5CH{=}N{-}S_b{-}N{=}CHC_6H_5 + 4C_6H_5CH_2NH_2 \rightarrow C_6H_5CH_2\overset{H}{\underset{|}{N}}{-}S_b{-}\overset{H}{\underset{|}{N}}CH_2C_6H_5 + 2NH_3 + 2C_6H_5CH{=}NCH_2C_6H_5$$

a different sulfur chain length than those formed in [4]. Since the chain length is variable in both places, this does not pose a chemical problem. However, the combination of equations is very much simpler if these two materials can be related. Equation 16 is postulated for this purpose. This equation is solely a computational

[16] $$C_6H_5CH_2\overset{H}{\underset{|}{N}}{-}S_b{-}\overset{H}{\underset{|}{N}}CH_2C_6H_5 \rightarrow C_6H_5CH_2\overset{H}{\underset{|}{N}}{-}S_a{-}\overset{H}{\underset{|}{N}}CH_2C_6H_5 + (b-a)S$$

artifact and need not reflect a real chemical process. Indeed, free sulfur could be formed or consumed in eqs. 6 or 7. It could also be formed by decomposition of (or consumed by addition to) either benzylamine polysulfides or benzylidenimine polysulfides or by any combination of these four processes. The result is the same and is accounted for by [16].

Stoichiometry of the Overall Reaction of Sulfur with an Excess of Benzylamine

An overall equation for the reaction of sulfur with excess benzylamine may be obtained by

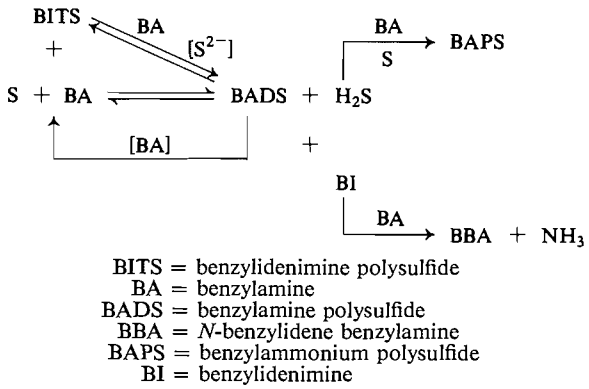

FIG. 1. Reaction of sulfur with benzylamine.

combining eqs. 4 through 8 to eliminate all intermediates. Benzylamine polysulfides may be eliminated by adding eq. 6 to three times [13] to give [17]. The benzylidenimine polysulfides may

[17] $$(3x+b)S + 8C_6H_5CH_2NH_2 \rightarrow C_6H_5CH{=}N{-}S_b{-}N{=}CHC_6H_5 + 3(C_6H_5CH_2NH_3^+)_2S_x^{2-}$$

now be eliminated from [17] by the following procedure. First, eq. 15 is combined with [16] to correct the sulfur chain lengths and then (after multiplying by three) combined with [6] to give (after dividing by a common factor of 2) [18]. Equation 18 when combined with [17] gives

[18] $$C_6H_5CH{=}N{-}S_b{-}N{=}CHC_6H_5 + 4C_6H_5CH_2NH_2 \rightarrow 3NH_3 + 3C_6H_5CH{=}NCH_2C_6H_5 + bS$$

(after dividing by $3x$) the predicted overall stoichiometric reaction, [19]. The quantities of

[19] $$S + \frac{4}{x}C_6H_5CH_2NH_2 \rightarrow \frac{1}{x}C_6H_5CH{=}NCH_2C_6H_5 + \frac{1}{x}NH_3 + \frac{1}{x}(C_6H_5CH_2NH_3^+)_2S_x^{2-}$$

benzylamine, *N*-benzylidene benzylamine, ammonia, and benzylammonium polysulfide required to react with or formed from one gram atom of sulfur are functions of x, the number of sulfurs in the benzylammonium polysulfide chain. Since this is known (29) to be between 6 and 7, an "acceptable range" for each coefficient is predicted. A known quantity of sulfur was therefore reacted with a *known excess* of benzylamine. The ammonia evolved was collected in an acid trap and determined by back titration. The

$x = 7$	0.150	—	0.143

*± 5% of value shown.

benzylammonium polysulfides were precipitated by addition of ether, dried, and weighed. The total combined weight of *N*-benzylidene benzylamine and residual benzylamine was determined, and the molar ratio of these two materials was obtained by integration of an n.m.r. spectrum to give the absolute quantities of *N*-benzylidene benzylamine formed and of benzylamine consumed. Thus, each of the four coefficients in [19] is experimentally measurable. Table 1 compares the experimental values with those calculated for $x = 6$ and 7. The results for all four materials are in quite good agreement with those predicted based on eq. 19.

Reaction of Sulfur with Benzylamine in the Presence of a Sulfide Scavenger

Steps 4 and 6 together should be subject to examination independently of the others by adding a sulfide scavenger to suppress the sulfide catalyzed reaction 7. Combination of [4] and [6] (three times [4] added to [6]) gives the stoichiometric eq. 20 where the hydrogen sulfide produced is removed by the lead oxide to give lead sulfide and water rather than reacting as per [5]. When

[20] $$(b + 3)S + 2C_6H_5CH_2NH_2 \rightarrow C_6H_5\overset{H}{\overset{|}{C}}{=}N{-}S_b{-}N{=}\overset{H}{\overset{|}{C}}C_6H_5 + 3H_2S$$

sulfur and benzylamine were allowed to react in triethylamine in the molar ratio of 7 to 2 (*i.e.*, $b = 4$), the yield of benzylidenimine polysulfides isolated was 90 ± 2% based on [20]. The products consisted of benzylidenimine tetra-, tri-, di-, and monosulfides in molar ratios of approximately 16:2:2:1. The balance of the starting material was converted to *N*-benzylidene benzylamine along with some benzylidenimine benzylamine sulfide (the unsymmetrical mixed amine imine monosulfide). The same reaction in benzene gave a similar yield and distribution of products, but the reaction time was almost ten fold longer. When the benzylamine to sulfur ratio was increased, the average sulfur content of the benzylidenimine polysulfides formed decreased, and the total yield of polysulfides based on [20] decreased somewhat. The decrease appeared to be due to incomplete blocking of reaction 7 since *N*-benzylidene benzylamine formation was increased considerably as was the quantity of benzylidenimine benzylamine monosulfide. The latter is most likely an intermediate in the exchange reaction as shown in eq. 21. Thus,

[21] $$C_6H_5\overset{H}{\overset{|}{C}}{=}N{-}S_b{-}N{=}\overset{H}{\overset{|}{C}}C_6H_5 + C_6H_5CH_2NH_2 \rightleftarrows C_6H_5\overset{H}{\overset{|}{C}}{=}N{-}S_b{-}\overset{H}{\overset{|}{N}}CH_2C_6H_5 + C_6H_5CH{=}NH$$

eq. 20 appears to remain valid. Changing the molar ratio of sulfur to benzylamine leads mainly to variation in the numerical value of *b*.

Reactions of Benzylidenimine Tetrasulfide with Excess Benzylamine

This situation is nearly covered by eq. 18 above. The *b*S formed in [18] should react in the presence of the excess benzylamine according to [19]. Adding [18] to [19] multiplied by *b* eliminates the sulfur to give [22]. Since the starting material is the tetrasulfide, $b = 4$ and the overall stoichiometric eq. 23 results. The coefficients based

[22] $$C_6H_5CH{=}N{-}S_b{-}N{=}CHC_6H_5 + \frac{4(b + x)}{x}C_6H_5CH_2NH_2 \rightarrow \frac{b}{x}(C_6H_5CH_2NH_3^+)_2S_x^{2-} + \frac{3x + b}{x}(C_6H_5CH{=}N{-}CH_2C_6H_5 + NH_3)$$

[23] $$C_6H_5CH{=}N{-}S_4{-}N{=}HCC_6H_5 + \frac{(16 + 4x)}{x}C_6H_5CH_2NH_2 \rightarrow \frac{4}{x}(C_6H_5CH_2NH_3^+)_2S_x^{2-} + \frac{4 + 3x}{x}[NH_3 + C_6H_5CH{=}N{-}CH_2C_6H_5]$$

on the reaction of 1 mol of benzylidenimine tetrasulfide with excess amine are determined by the average sulfur chain length of the benzylammonium polysulfide produced. The products

Ammonia	3.37	3.67	3.58

*±5% of values shown.

were separated as described for the reaction of sulfur with excess amine. Table 2 shows the experimental coefficients for *N*-benzylidene benzylamine, ammonia, benzylammonium polysulfide, and benzylamine along with those predicted from eq. 23 for $x = 6$ and 7. These results show eq. 23 to provide a good quantitative description of the experimental facts.

Benzylidenimine tetrasulfide exposed to benzylamine in the presence of lead(II) oxide gave only equilibration of the sulfur chain length as well as small amounts of several benzylidenimine benzylamine polysulfides again presumably via reaction 21.

Autocatalytic Decomposition of Benzylamine Disulfide

In the autocatalytic decomposition of benzylamine disulfide, the final products are *N*-benzylidene benzylamine and ammonia along with smaller quantities of benzylammonium polysulfides, benzylidenimine tetrasulfide, and elemental sulfur. Two assumptions are inherent in the derivation of the previous equations. Equations 4–8 must of course hold, and there must be an excess of benzylamine (not necessary for [20] only). In the decomposition of benzylamine disulfide, benzylidenimine polysulfides, and sulfur are produced in the presence of a *limited amount* of benzylamine. Since the latter reacts with both of the former, it is necessary to consider the relative rates of the two processes, a factor which is not relevant to the previous derivations. Two limiting cases can be imagined: (*i*) where benzylamine reacts with sulfur very much faster than with benzylidenimine polysulfides, and (*ii*) where benzylidenimine polysulfides react much faster than sulfur.

Case (i) Following decomposition according to [6], the reaction of $(3a - b)$ sulfurs with 4 benzylamines according to [13] must be considered. For the values of a, b, and x relevant to this case ($a = 2$ since the starting material is the disulfide, $b \sim 4$ and $x = 6$–7), it is apparent that $3a - b < a + x$. Therefore, reaction 13 is limited by the quantity of sulfur present and not by the quantity of benzylamine. Multiplying [13] by $(3a - b)/(a + x)$ and adding this result to [6] eliminates the sulfur and leads to [24].

$$[24]\quad \frac{3x+b}{a+x}\,C_6H_5CH_2\overset{H}{\underset{|}{N}}\!-S_a-\overset{H}{\underset{|}{N}}CH_2C_6H_5 \rightarrow C_6H_5CH{=}N-S_b-N{=}CHC_6H_5 + \frac{4x-8a+4b}{a+x}\,C_6H_5CH_2NH_2 + \frac{3a-b}{a+x}\,(C_6H_5CH_2NH_3^+)_2S_x^{2-}$$

The remaining benzylamine will now react with the benzylidenimine polysulfides. This should be according to [15]. However, it is first necessary to correct for the differing sulfur chain lengths, *i.e.*, eq. 15 is added to [16] to give [25].

$$[25]\quad C_6H_5CH{=}N-S_b-N{=}CHC_6H_5 + 4C_6H_5CH_2NH_2 \rightarrow C_6H_5CH_2\overset{H}{\underset{|}{N}}\!-S_a-\overset{H}{\underset{|}{N}}CH_2C_6H_5 + (b-a)S + 2NH_3 + 2C_6H_5CH{=}NCH_2C_6H_5$$

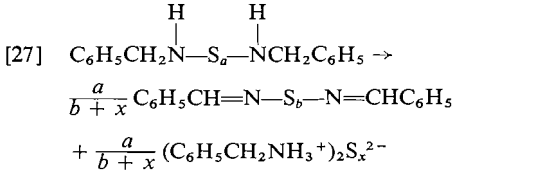
However, this equation is not consistent with the assumption that reaction of sulfur with benzylamine is rapid. Since sulfur is formed in the presence of benzylamine, eq. 25 must be modified to allow for reaction of the sulfur with benzylamine. This can be done by multiplying [13] by $(b - a)/(a + x)$ and then adding [25]. The result, [26], now gives the fate of the remaining benzylamine present in [24].

$$[26]\quad C_6H_5CH{=}N-S_b-N{=}CHC_6H_5 + \frac{4(x+b)}{a+x}\,C_6H_5CH_2NH_2 \rightarrow 2(NH_3 + C_6H_5CH{=}NCH_2C_6H_5) + \frac{x+b}{a+x}\,C_6H_5CH_2\overset{H}{\underset{|}{N}}\!-S_a-\overset{H}{\underset{|}{N}}CH_2C_6H_5 + \frac{b-a}{a+x}\,(C_6H_5CH_2NH_3^+)_2S_x^{2-}$$

Equations 26 and 24 may now be combined to eliminate benzylamine by multiplying [26] by $(x - 2a + b)/(x + b)$ and adding this to [24] to

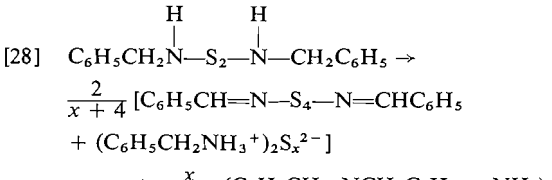
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

give (after dividing out a common factor of 2) eq. 27. Since the starting material is the disulfide,



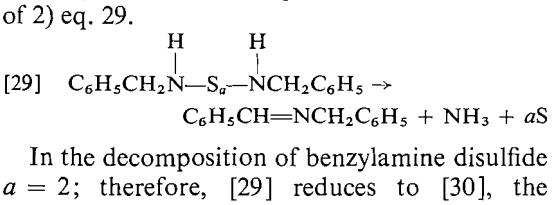
[27] $C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_a—\overset{H}{\underset{|}{N}}CH_2C_6H_5 \rightarrow$
$\frac{a}{b+x}C_6H_5CH{=}N—S_b—N{=}CHC_6H_5$
$+ \frac{a}{b+x}(C_6H_5CH_2NH_3^+)_2S_x^{2-}$
$+ \frac{x-2a+b}{b+x}(NH_3 + C_6H_5CH{=}NCH_2C_6H_5)$

$a = 2$, and since only benzylidenimine tetrasulfide was observed experimentally among the products in this reaction, $b = 4$. Substituting these for a and b in [27] gives [28] as the predicted overall stoichiometric reaction for case (*i*).



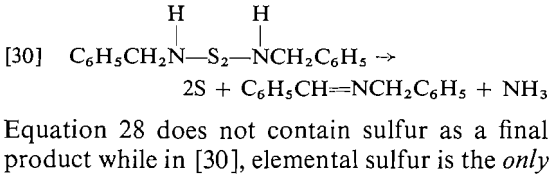
[28] $C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_2—\overset{H}{\underset{|}{N}}—CH_2C_6H_5 \rightarrow$
$\frac{2}{x+4}[C_6H_5CH{=}N—S_4—N{=}CHC_6H_5$
$+ (C_6H_5CH_2NH_3^+)_2S_x^{2-}]$
$+ \frac{x}{x+4}(C_6H_5CH{=}NCH_2C_6H_5 + NH_3)$

Case (ii) Returning to eq. 6, the benzylamine produced now reacts exclusively with the benzylidenimine polysulfides according to [15]. The latter must be modified (added to [16]) to correct the sulfur chain length and may then be added to [6] to give (after dividing out a common factor of 2) eq. 29.



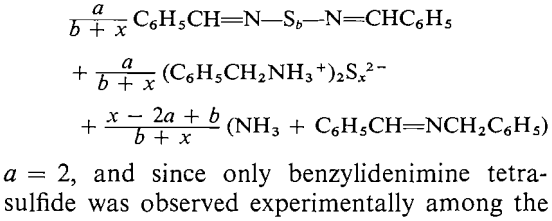
[29] $C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_a—\overset{H}{\underset{|}{N}}CH_2C_6H_5 \rightarrow$
$C_6H_5CH{=}NCH_2C_6H_5 + NH_3 + aS$

In the decomposition of benzylamine disulfide $a = 2$; therefore, [29] reduces to [30], the predicted stoichiometric equation for this case.



[30] $C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_2—\overset{H}{\underset{|}{N}}CH_2C_6H_5 \rightarrow$
$2S + C_6H_5CH{=}NCH_2C_6H_5 + NH_3$

Equation 28 does not contain sulfur as a final product while in [30], elemental sulfur is the *only* sulfur-containing species. Experimentally, 38% of all the sulfur present went to elemental sulfur. Therefore neither of these two limiting cases holds. The intermediate case may be approximated by combining eqs. 28 and 30 and taking the fraction of sulfur obtained as a product (f_S = mg atoms of elemental sulfur produced/total mg atoms of sulfur present in all forms) as a measure of the relative importance of these two extreme cases (*i.e.*, f_S[30] added to $(1 - f_S)$[28]) as in [31]. Equation 31 predicts the ratio of benzylidenimine tetrasulfide to benzylammonium polysulfide as well as the ratio of benzylidenimine



[31] $C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_2—\overset{H}{\underset{|}{N}}CH_2C_6H_5 \rightarrow 2f_SS$
$+ \frac{2(1-f_S)}{x+4}[C_6H_5CH{=}N—S_4—N{=}CHC_6H_5$
$+ (C_6H_5CH_2NH_3^+)_2S_x^{2-}]$
$+ \frac{x+4f_S}{x+4}(C_6H_5CH{=}NCH_2C_6H_5 + NH_3)$

benzylamine to ammonia to be 1:1. Experimentally these two ratios were found to be 0.99 ± 0.05 and 1.02 ± 0.05 in excellent agreement with [31]. The ratio of *N*-benzylidene benzylamine *plus* ammonia to benzylammonium polysulfide *plus* benzylidenimine tetrasulfide is predicted by [31] to be $(x + 4f_S)/2(1 - f_S)$. Since experimentally $f_S = 0.38$, this ratio should be 6.1 for $x = 6$ and 6.9 for $x = 7$. The experimental value was $\sim 10 \pm 3$. The probable error is quite large, but the agreement appears acceptable.[4]

p-Methoxybenzylidenimine Tetrasulfide with Amine

Two kinds of *N*-benzylidene benzylamines are expected as products from the reaction of *p*-methoxybenzylidenimine tetrasulfide with unsubstituted benzylamine according to eqs. 4–8. When eq. 7 is written for the reaction of *p*-methoxybenzylidenimine polysulfide with unsubstituted benzylamine and added to twice [8] (*p*-methoxybenzylidenimine reacting with unsubstituted benzylamine), the result is [32]. All

[32] $CH_3OC_6H_4CH{=}N—S_b—N{=}CHC_6H_4OCH_3$
$+ 4C_6H_5CH_2NH_2 \rightarrow$
$2CH_3OC_6H_4CH{=}NCH_2C_6H_5$
$+ 2NH_3 + C_6H_5CH_2\overset{H}{\underset{|}{N}}—S_b—\overset{H}{\underset{|}{N}}CH_2C_6H_5$

the *p*-methoxy substituent has now been converted to final products and the newly formed unsubstituted benzylamine polysulfides decompose via [6]. After correcting for the sulfur chain

[4]The 38% of sulfur isolated is apt to be too low rather than too high since sulfur has some solubility in *N*-benzylidene benzylamine. If the quantity of sulfur isolated were to be increased (as it probably should be) by only a few milligrams, the agreement would improve considerably.

length in [6] by adding three times [16], three times [32] may be added leading to the situation shown in [33]. Since there is an excess of benzyl-

[33] $3CH_3OC_6H_4CH{=}N{-}S_b{-}N{=}CHC_6H_4OCH_3 + 8C_6H_5CH_2NH_2 \rightarrow C_6H_5CH{=}N{-}S_b{-}N{=}CHC_6H_5 + 2bS + 6NH_3 + 6CH_3OC_6H_4CH{=}NCH_2C_6H_5$

amine, the sulfur in [33] reacts as per [19], and the benzylidenimine polysulfides as per [23]. Adding eq. 22 to 33 and this in turn to $2b$ times eq. 19 gives (after dividing out a common factor of 3) the predicted overall stoichiometric equation as in [34]. Since the starting material is the tetra-

[34] $CH_3OC_6H_4CH{=}N{-}S_b{-}N{=}CHC_6H_4OCH_3 + \frac{4(b+x)}{x} C_6H_5CH_2NH_2 \rightarrow \frac{b}{x}(C_6H_5CH_2NH_3^+)_2S_x^{2-} + \frac{3x+b}{x} NH_3 + \frac{x+b}{x} C_6H_5CH{=}NCH_2C_6H_5 + 2CH_3OC_6H_4CH{=}NCH_2C_6H_5$

sulfide, $b = 4$, and [34] reduces to [35].

[35] $CH_3OC_6H_4CH{=}N{-}S_4{-}N{=}CHC_6H_4OCH_3 + \frac{(16+4x)}{x} C_6H_5CH_2NH_2 \rightarrow 2CH_3OC_6H_4CH{=}NCH_2C_6H_5 + \frac{4+x}{x} C_6H_5CH{=}NCH_2C_6H_5 + \frac{4+3x}{x} NH_3 + \frac{4}{x}(C_6H_5CH_2NH_3^+)_2S_x^{2-}$

The ratio of *N*-(*p*-methoxybenzylidenimine) benzylamine to *N*-benzylidenimine benzylamine should be $2:[(4+x)/x]$ or 1.20 to 1.27 where $x = 6$ to 7. The products, obtained after removal of the benzylammonium polysulfides, were hydrolyzed with dilute hydrochloric acid. As required by eq. 35 the benzylammonium polysulfides and *all* of the benzylamine formed by hydrolysis of the *N*-benzylidene benzylamine were unsubstituted; *all* of the *p*-methoxy substituent was present in the aldehydes formed from the *N*-benzylidene benzylamines. Not all of the aldehyde was substituted however; the ratio of anisaldehyde to benzaldehyde was 1.29 ± 0.10 in excellent agreement with that predicted in eq. 35.

Conclusions

Using a polysulfide chain length of 6–7 as established independently (29) for the benzylammonium polysulfides, all aspects of each of the five eqs. 19, 20, 23, 31, and 35, derived from the proposed scheme (reactions 4–8), have been quantitatively confirmed experimentally. The reaction scheme with a benzylidenimine polysulfide – benzylamine polysulfide "cycle" is therefore considered to provide a satisfactory explanation of the reactions of sulfur with benzylamine. Although the scheme has been established only for benzylamine, it nevertheless seems reasonable to expect that other primary amines might follow a similar overall reaction sequence. It has been previously shown (23, 24) that sulfur with a few primary amines, such as butylamine and ethylenediamine, gives alkylammonium polysulfides. Since sulfur is reduced by these amines, the amines must be oxidized, presumably to either the alkylamine polysulfides, alkylidenimine polysulfides, or Schiff's bases.

A detailed mechanistic interpretation cannot be formulated for each of the steps (eqs. 4–8) at this time but an early step is probably ionic since the rate of formation of benzylidenimine tetrasulfide from benzylamine and sulfur in the presence of the sulfide scavenger was considerably faster in polar solvents than in non-polar solvents. Step 5 is obviously ionic as is the analogous step 9 in the Davis (18) mechanism. The observed base catalysis in step 6 most probably involves the weakly acidic N—H protons. This is consistent with the isolation (25, 27) of tetraalkylamine polysulfides from sulfur and secondary amines where the absence of a second N—H would block step 6. The autocatalytic decomposition of benzylamine disulfide which produced a limited amount of benzylamine in addition to sulfur and benzylidenimine polysulfides provides some indication of the relative rates of steps 4 and 7 (because these appear to be equilibria, steps 5, 6, and 8 may also contribute, however) since the latter two materials compete for the limited amount of benzylamine formed. Apparently, step 4 (along with 5 and 6) is about 50% faster than 7 (along with 8). The final step, 8, is very likely a reversible nucleophilic addition of benzylamine to the imine carbon followed by a proton shift and elimination of ammonia.

The reaction of primary amines with sulfur in the presence of lead(II) oxide has some potential synthetic importance in the preparation of imine polysulfides. Sulfur is obviously a more convenient starting material than tetrasulfur tetranitride (29). The reaction conditions are quite

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

mild, and the rate is reasonably rapid. If this synthesis is applicable to other primary amines, it could provide a convenient route for the conversion of primary amines to aldehydes or ketones which could be readily obtained by hydrolysis of the imine polysulfides.

Experimental

Instrumentation, solvents and chromatography were as previously described (29).

Benzylamine Disulfide

Freshly distilled sulfur monochloride (1.9 ml, 23.6 mmol) in 100 ml of anhydrous ether was added dropwise to 10.0 ml (91.7 mmol) of benzylamine in 500 ml of anhydrous ether in a 1 l three-necked flask equipped with a stirrer and calcium chloride drying tube. A white precipitate of benzylammonium chloride formed rapidly and was separated by filtration. The solvent was removed *in vacuo* to give a pale yellow, creamy oil. This oil was dissolved in hexane at 30–40 °C and on cooling to ice temperature precipitated a white solid. Further recrystallization from pentane gave pure benzylamine disulfide of m.p. 52.5–53 °C.

Anal. Calcd. for $C_{14}H_{16}N_2S_2$ (mol. wt.: 276): C, 60.83; H, 5.83; N, 10.13; S, 23.20. Found (270): C, 60.93; H, 5.53; N, 9.94; S, 23.42.

Evaporation of the mother liquor gave 3.0 g of oil whose n.m.r. spectrum indicated the presence of benzylamine disulfide, *N*-benzylidene benzylamine, and other unidentified materials.

The n.m.r. spectrum of benzylamine disulfide showed absorptions at −2.75 (broad, —NH), −4.09 (singlet, —CH_2—), and −7.05 p.p.m. (singlet, phenyl-) with relative areas of 1.00:1.91:4.92, respectively. The i.r. spectrum showed N—H stretching at 3334 cm^{-1} and S—N stretching at 850 cm^{-1}. An R_f value could not be obtained since the material decomposed on the silica gel plate. Pure benzylamine disulfide kept under vacuum in a drying apparatus at room temperature for 5–6 h decomposed to a mixture of benzylidenimine polysulfides, *N*-benzylidene benzylamine, and sulfur. It could be stored at −20 °C for several weeks, but decomposition eventually began even at this temperature. The impure material could be kept for a much longer period. When benzylamine disulfide was heated in a m.p. capillary to 75 °C and cooled, the oil solidified and remelted at 53 °C. When it was heated above 100 °C, however, decomposition occurred with evolution of gas. A t.l.c. of the decomposition product showed sulfur, benzylidenimine tetra-, tri-, and disulfides, and *N*-benzylidene benzylamine.

The course of the room temperature decomposition of benzylamine disulfide was monitored by n.m.r. spectroscopy. Approximately 260 mg of pure material was stirred under a nitrogen atmosphere. Periodically a 25–30 mg aliquot was withdrawn, dissolved in 0.5 ml of deuterochloroform and an n.m.r. spectrum was taken. After 3 h no change was apparent. After 5 h some benzylamine was visible (about 5%). After 6 h approximately 85% of the disulfide remained. After an additional ½ h (total elapsed time: 6½ h) nearly 95% of the disulfide was decomposed, and benzylamine and benzylidenimine tetrasulfide were prominent in molar ratios of approximately 4:1. A small amount of *N*-benzylidene benzylamine was also observable at this time. After 8 h the n.m.r. showed mainly *N*-benzylidene benzylamine, small amounts of benzylidenimine tetrasulfide and the benzylammonium cation (presumably the polysulfides). A spectrum after 13 h was unchanged from that at 8 h.

Benzylidenimine Benzylamine Monosulfide

Sulfur (984 mg, 30.7 mg atoms), lead(II) oxide (9.10 g, 40.7 mmol), and 10 ml of benzene were placed in a 100 ml three-necked flask equipped with a water condenser, a serum rubber stopper, a cylinder of dry nitrogen gas, and an outlet to a gas washing bottle with about 250 ml of aqueous hydrochloric acid solution (containing 50.0 mg equiv of acid). The benzylamine used was degassed under vacuum, and 3.4 ml (31.2 mmol) was introduced through the serum stopper by syringe. The reaction mixture was stirred for about 20 h with a continuous slow flow of dry nitrogen. The acid solution was diluted to 500 ml, and a 5.00 ml aliquot required 4.53 ml of 0.100 *N* sodium hydroxide for neutralization. Ammonia (4.7 mmol) had therefore been evolved. The lead sulfide was removed by filtration and was thoroughly washed with ether and benzene. The combined solvents were removed, the remaining oil was weighed, and an n.m.r. spectrum integrated. This led to the following distribution of materials: benzylidenimine tetrasulfide, 910 mg (2.7 mmol); benzylidenimine disulfide, 260 mg (1.0 mmol); benzylidenimine benzylamine monosulfide, 700 mg (2.9 mmol); *N*-benzylidene benzylamine, 1.12 g (5.7 mmol); and unreacted benzylamine, 100 mg (0.9 mmol). These data rest on the assumed structure of benzylidenimine benzylamine monosulfide. This material was isolated, and its structure was confirmed as follows. The crude oil was taken up in about 50 ml of methanol and chilled. Benzylidenimine tetrasulfide precipitated (850 mg) and was discarded. Then, 260 mg of benzylidenimine disulfide (contaminated with some tetrasulfide) precipitated in several successive fractions which were collected and discarded. After several days at −20 °C, 350 mg of a white crystalline material precipitated. This material was recrystallized from methanol to give benzylidenimine benzylamine monosulfide of m.p. 58.5–59 °C.

Anal. Calcd. for $C_{14}H_{14}N_2S$ (mol. wt.: 242): C, 69.39; H, 5.82; N, 11.56; S, 13.23. Found (249): C, 69.6; H, 5.30; N, 11.74; S, 13.65.

An n.m.r. spectrum in carbon tetrachloride showed four absorptions: a singlet at −7.77 (1.0 H, benzylidene proton), a multiplet at −7.07 to −7.67 (10.2 H, phenyl rings), a doublet at −4.30 (2.0 H, J = 5.5 c.p.s., methylene protons), and a broad triplet at −3.66 p.p.m. (1.0 H, proton on nitrogen). The i.r. spectrum in carbon tetrachloride showed bands assignable to N—H stretching at 3360 cm^{-1}, C=N stretching at 1645 cm^{-1}, and S—N stretching at 853 cm^{-1}. The R_f value on silica gel with carbon disulfide as eluent was 0.15 *vs.* 0.80 for sulfur. This material was also formed when benzylidenimine tetrasulfide and benzylamine were mixed in the presence of lead(II) oxide. For example, 1.00 g (2.98 mmol) of benzylidenimine tetrasulfide stirred for 5 h with 3.9 ml (35.7 mmol) of benzylamine and 2.71 g (12.2 mmol) of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

lead(II) oxide in 15 ml of benzene led on chromatography to: 37 mg (1.2 mg atom) of sulfur, 170 mg (0.51 mmol) of benzylidenimine tetrasulfide, 110 mg (0.37 mmol) of benzylidenimine trisulfide, 90 mg (0.33 mmol) of benzylidenimine disulfide, 25 mg (0.10 mmol) of benzylidenimine benzylamine sulfide, 75 mg of two other unsymmetrical amine–imine polysulfides which were not fully characterized, and 480 mg (2.5 mmol) of *N*-benzylidene benzylamine. Ammonia (2.4 mmol) was evolved.

Quantitative Experiments; Sulfur with Excess Benzylamine

Sulfur (640 mg, 20.0 mg atoms) was placed in a three-necked flask equipped with a stirrer, gas washing bottle, nitrogen inlet, and rubber serum stopper. The gas washing bottle contained 7.50 mg equiv of hydrochloric acid. Benzylamine (2.90 g, 27.1 mmol) was introduced through the serum stopper, and the flask was stirred at room temperature under a slow continuous flow of nitrogen. After 4 h the reaction was complete, and anhydrous ether was added. The mixture was stirred for 2 h, and the orange solid which precipitated was filtered and washed with anhydrous ether. When this solid was dried in air, evolution of hydrogen sulfide was observed. When the solid was free of ether, it weighed approximately 960 ± 30 mg. The weight was not accurate due to continuous decomposition with evolution of hydrogen sulfide, about 35 mg weight loss per 20 min. The m.p. was 90–96 °C dec. in an evacuated sealed tube. After 2 days in air, it had decomposed into sulfur and benzylammonium thiosulfate. The combined ether extract was evaporated under reduced pressure at about 35–40 °C to give 2.42 g of oil containing benzylamine, *N*-benzylidene benzylamine, and benzylammonium polysulfide. The integrated n.m.r. spectrum led to the following distribution of products: benzylamine, 1.47 g (therefore 1.43 g, 13.4 mmol, consumed); *N*-benzylidenebenzylamine, 640 mg (3.26 mmol); benzylammonium polysulfides, 1.31 g (total; 3.22–2.98 mmol for $x = 6$ and 7, respectively). The acid solution in the gas washing bottle was diluted to 500 ml, and a 50.0 ml aliquot required 4.50 ml of 0.100 *N* sodium hydroxide solution for neutralization. Therefore, 3.00 mg equiv of ammonia were evolved.

Sulfur and Benzylamine in the Presence of a Sulfide Scavenger

Sulfur (1.03 g, 32.2 mg atoms), 3.49 g (15.6 mmol) of lead(II) oxide, 1 ml (9.17 mmol) of benzylamine, and 10 ml of triethylamine were stirred together under a dry nitrogen atmosphere at room temperature. Within 2 h the reaction mixture had become quite black. After 24 h it was filtered, and the lead sulfide was washed thoroughly with ether and benzene. The combined filtrate was concentrated to give 1.41 g of solid. This was dissolved in carbon disulfide, and its n.m.r. spectrum was recorded. Integration gave the relative amounts of the five components (whose identities were verified by t.l.c.) and led to the following data: benzylidenimine tetrasulfide, 1.06 g (3.16 mmol); benzylidenimine trisulfide, 0.11 g (0.37 mmol); benzylidenimine disulfide, 0.11 g (0.41 mmol); benzylidenimine monosulfide,[5] 0.043 g (0.18 mmol); *N*-benzylidene benzylamine, 0.080 g (0.41 mmol). An analogous reaction in benzene using identical quantities required 1 week for complete reaction of the sulfur and led to the following data: tetrasulfide, 1.13 g (3.36 mmol); trisulfide, 0.14 g (0.46 mmol); disulfide, 0.027 g (0.10 mmol); monosulfide,[5] 0.071 g (0.30 mmol); *N*-benzylidene benzylamine, 0.125 g (0.64 mmol).

A similar reaction with 1.02 g (31.9 mg atoms) of sulfur, 7.53 g (33.8 mmol) of lead oxide, and 2.2 ml (20.1 mmol) of benzylamine in 3 ml of benzene led to the data below: tetrasulfide, 0.26 g (0.77 mmol); trisulfide, 0.12 g (0.39 mmol); disulfide, 0.59 g (2.2 mmol); benzylidenimine benzylamine monosulfide, 0.34 g (1.4 mmol); and *N*-benzylidene benzylamine, 0.95 g (4.9 mmol).

Benzylidenimine Tetrasulfide with Excess Benzylamine

Benzylidenimine tetrasulfide (1.02 g, 3.03 mmol) was placed in a 100 ml three-necked flask equipped as described above. The gas washing bottle contained 15.00 mg equiv of hydrochloric acid. Benzylamine (6.6 ml, 60.5 mmol) was introduced through the serum stopper. After 6 h the reaction was complete. The acid solution was diluted to 500 ml, and a 50.0 ml aliquot required 4.82 ml of 0.100 *N* sodium hydroxide solution for neutralization. Therefore, 10.2 mg equiv of ammonia were evolved. The reaction mixture was diluted with 50 ml of anhydrous ether, and the orange solid which precipitated was filtered and washed with anhydrous ether. The combined ether solutions were concentrated *in vacuo* at 40–50 °C to give 6.41 g of oil containing only *N*-benzylidene benzylamine and unreacted benzylamine. The weight and integrated n.m.r. spectrum indicated the amounts of these two products to be: benzylamine, 4.32 g (therefore 2.15 g, 20.2 mmol, consumed) and *N*-benzylidene benzylamine, 2.10 g (10.8 mmol).

Decomposition of Benzylamine Disulfide

Benzylamine disulfide (248 mg, 0.90 mmol) was stirred under a slow flow of nitrogen gas. The outlet was connected to a gas washing bottle containing 1.00 mg equiv of aqueous hydrochloric acid. The white solid changed slowly to a yellow oil which contained a solid. The precipitate was filtered and washed with small amounts of anhydrous ether to give 22 mg (0.69 mg atoms) of elemental sulfur. The solvent was removed *in vacuo* to give 196 mg of an oil whose n.m.r. spectrum showed three materials: benzylidenimine tetrasulfide, *N*-benzylidene benzylamine, and benzylammonium ion (presumably the polysulfide) in molar ratios of 2.0:20.5:2.0, respectively. From these data the yields of products were calculated to be:[6] benzylidenimine tetrasulfide, 24 mg (0.071 mmol); *N*-benzylidene benzylamine, 142 mg (0.73 mmol); benzylammonium polysulfide, 31 mg (0.071 mmol). The acid solution was diluted to 500 ml, and a 200 ml aliquot required 1.14 ml of 0.100 *N* sodium hydroxide for neutralization. Therefore, 0.715 mmol of ammonia was evolved.

p-Methoxybenzylidenimine Tetrasulfide

p-Methoxybenzylidenimine tetrasulfide was prepared from *p*-methoxybenzylamine and tetrasulfur tetranitride as previously described (29). After recrystallization from methanol it had a m.p. of 112–113 °C. A 734 mg (1.85 mmol) sample was placed in a 100 ml round-bottom flask with a magnetic stirring bar, and 1.4 ml (12.8 mmol)

[5]Not fully characterized, see ref. 29.

[6]Benzylammonium polysulfide was assumed to be the heptasulfide. These numbers do not change more than 5% if the hexa- or octasulfide is assumed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of benzylamine was added. The reaction mixture was stirred under a nitrogen atmosphere for 5 h whereupon a t.l.c. showed the absence of *p*-methoxybenzylidenimine tetrasulfide. About 60 ml of anhydrous ether was introduced into the reaction mixture and stirred for 1 h. An orange solid precipitated from the yellowish solution which was filtered and washed with anhydrous ether. It melted at 95–97 °C dec. and, when kept in the air for a few days, decomposed to sulfur and a thiosulfate with the evolution of hydrogen sulfide. An n.m.r. spectrum of the thiosulfate taken in deuterium oxide showed three absorptions corresponding to a benzyl CH_2 group, an NH_3^+ group, and a phenyl complex. No absorption corresponding to a *p*-methoxy methyl group was detected. The orange solid was, therefore, unsubstituted benzylammonium polysulfide. The combined ether extracts were concentrated *in vacuo*, and the n.m.r. spectrum of the resulting oil showed a complicated phenyl region between −6.85 and −8.04 p.p.m., a broad NH_2 peak at −1.87 p.p.m., a methoxy methyl group at −3.47 p.p.m., the CH_2 of benzylamine at −3.87 p.p.m., an unresolved CH_2 doublet for mixed *N*-benzylidene benzylamine at −4.74 p.p.m., and the unresolved CH triplets for mixed *N*-benzylidene benzylamine at −8.21 p.p.m. This mixture was refluxed for 4 h with 50 ml of 5% hydrochloric acid. After cooling the mixture was extracted with ether (ether extract I). The aqueous layer was neutralized with base and extracted with ether (ether extract II). Ether extract II was dried and concentrated to give a large quantity of oil. The n.m.r. spectrum of this material, taken in deuterochloroform, showed only benzylamine. No trace of a methoxy methyl group could be detected. Ether extract I was dried and the ether removed *in vacuo* to give an oil whose n.m.r. spectrum showed two aldehyde peaks: anisaldehyde at −9.87 p.p.m. and benzaldehyde at −10.00 p.p.m. as well as the *p*-methoxy methyl absorption at −3.74 p.p.m. and a complex phenyl region. The ratio of the two aldehyde peaks, anisaldehyde to benzaldehyde, was approximately 1.5 to 1. However, the ratio increased with the time of evaporation (of the ether) presumably due to selective loss of the more volatile benzaldehyde. A more accurate ratio was obtained from the n.m.r. spectrum of the crude reaction mixture (before hydrolysis). Integration of the combined overlapping CH_2 peaks for the two kinds of *N*-benzylidene benzylamines at −4.74 p.p.m. relative to the methoxy methyl peak at −3.47 p.p.m. gave 40.3:34.0. The relative amount of the *p*-methoxy derivative was therefore 1/3 of 34.0 or 11.3, and the total relative amount of both kinds of Schiff's bases was 1/2 of 40.3 or 20.1. The relative amount of the unsubstituted material was therefore 20.1 less 11.3 or 8.8. The ratio of *p*-methoxy substituted to unsubstituted *N*-benzylidene benzylamine was therefore 11.3/8.8 or 1.29 ± 0.10.

This work was carried out under a grant from the National Research Council of Canada.

Oxydation lente du cétène en phase gazeuse. I. Réaction à "hautes températures"

PIERRE MICHAUD[1] ET CYRIAS OUELLET
Département de Chimie, Université Laval, Québec 10, Québec

Reçu le 30 juin 1970

La combustion lente du cétène en phase gazeuse a été étudiée en régime statique dans un réacteur en Vycor de 30 × 4 cm, pour différents mélanges cétène–oxygène entre 280 et 500 °C à partir d'une pression totale de 20 mm Hg. Continuant les travaux de Barnard et Kirschner, nous avons mis en évidence deux domaines de combustion lente. Ce premier article présente les résultats cinétiques et analytiques relatifs au domaine des "hautes températures" (380–500 °C). La réaction est autocatalytique, l'énergie globale d'activation est de l'ordre de quelques kilocalories par mole. Les principaux produits sont le monoxyde de carbone, le formaldéhyde, l'eau, et l'anhydride carbonique. On ne décèle pas d'éthylène. Nous proposons un schéma réactionnel en chaînes, dans lequel le formaldéhyde est l'agent de ramification dégénérée:

$$CH_2O + O_2 = HCOOH + O$$
$$O + CH_2O = \cdot CHO + \cdot OH$$

The slow combustion of ketene in the gas phase was studied by the static method in a 30 × 4 cm Vycor cylinder between 280 and 500 °C at pressures above 20 mm Hg. Extending the work of Barnard and Kirschner, we have established the existence of two types of slow combustion of ketene corresponding to two temperature ranges. In this first paper, we describe the kinetic and analytical results obtained in the higher temperature range (380–500 °C). The reaction is autocatalytic and shows a low temperature coefficient corresponding to a few kilocalories per mole. The main products are carbon monoxide, formaldehyde, water, and carbon dioxide. No ethylene was detected. We suggest a chain reaction in which formaldehyde is the intermediate responsible for degenerate branching:

$$CH_2O + O_2 = HCOOH + O$$
$$O + CH_2O = \cdot CHO + \cdot OH$$

Canadian Journal of Chemistry, 49, 294 (1971)

Introduction

Comme le constate Salooja (1), le cétène intervient souvent comme produit intermédiaire dans la combustion de nombreux dérivés oxygénés d'hydrocarbures. Par exemple, dans le cas de l'oxydation lente de l'acétone à 498 °C, l'initiation $CH_3—CO—CH_3 + O_2 = \dot{C}H_2—CO—CH_3 + \cdot HO_2$ est suivie par la décomposition du radical $\dot{C}H_2—CO—CH_3$ instable à cette température $\dot{C}H_2—CO—\dot{C}H_3 = CH_2CO + \cdot CH_3$, le cétène étant ensuite lui-même consommé par l'oxygène (2). Le seul travail au sujet de la combustion lente du cétène est celui de Barnard et Kirschner (3) qui ont surtout étudié la réaction à haute température (475 °C); ces auteurs trouvent que les principaux produits de combustion sont le monooxyde de carbone, le formaldéhyde, l'eau, et l'anhydride carbonique, et proposent un schéma cinétique de réactions en chaînes propagées par les radicaux $\cdot OH$ et $\cdot HO_2$, l'agent de ramification étant le formaldéhyde $CH_2O + O_2 = \cdot CHO + \cdot HO_2$. Dans un travail préliminaire, nous avons déterminé la limite inférieure d'explosion, les limites de flammes froides uniques et multiples, et la limite inférieure de combustion lente pour des mélanges stoechiométriques cétène–oxygène ($CH_2CO:O_2 = 1:2$) (4). Nous présentons les résultats cinétiques et analytiques relatifs à la combustion lente du cétène dans le domaine des "hautes températures" ($\theta > 380$ °C) en complétant les résultats de Barnard et Kirschner et dans le domaine des "basses températures" ($\theta < 350$ °C) qui n'a pas été décrit par ces auteurs. Nous proposons des schémas cinétiques qui expliquent la plupart de nos résultats expérimentaux.

Méthode expérimentale

(A) Appareillage

La combustion du cétène est étudiée par la méthode statique, dans un cylindre de Vycor (30 cm × 4 cm) maintenu à une température constante (± 1 °C); le seul traitement préalable du réacteur est un lavage à l'acide nitrique concentré suivi d'un rinçage soigneux à l'eau distillée. Tout le montage adjacent au réacteur est muni de robinets en Teflon Delmar et chauffé à une température d'environ 100 °C, pour éviter toute condensation ou polymérisation. La réaction est suivie par enregistrement de la variation de pression mesurée par une jauge magnétique (Pace Engineering Co.) et par le prélèvement d'échantillons à différents temps en vue de l'analyse.

(B) Gaz employés

Le cétène est préparé selon la méthode de Fisher *et al.* (5), par pyrolyse de l'anhydride acétique 99% + 3 (Matheson, Coleman et Bell) sur un ruban de chromel A porté à 500 °C, et sous une pression de 500 mm Hg. Après distillation fractionnée et purification, le cétène est conservé dans une ampoule à l'obscurité et à −196 °C pour éviter toute polymérisation. La pureté du cétène a été contrôlée en comparant le spectre i.r. de notre produit à celui publié par Drayton et Thompson (6), et par c.p.g. sur une colonne de célite modifiée par 20% de dinonylphtalate; il ne contient en particulier pas de traces d'éthylène et autres hydrocarbures, les impuretés principales (< 0.3%) étant l'acide et l'anhydride acétiques. Nous utilisons de l'oxygène médical 99.6% + 3 (Ohio). Le formaldéhyde est préparé par chauffage modéré du paraformaldéhyde.

(C) Analyse

Après un certain temps de réaction, les produits de combustion sont détendus dans un ballon d'analyse de 250 cm^3 préalablement évacué et sont analysés par c.p.g. (chromatographe F/M, modèle 700, modifié pour l'introduction des gaz, muni de détecteurs à conductivité thermique et ionisation de flamme). Le monoxyde de carbone, le méthane, l'oxygène résiduel et l'hydrogène sont analysés sur une colonne de tamis moléculaire 5A à 25 °C, l'anhydride carbonique sur une colonne de gel de silice à 60 °C et le cétène sur une colonne de célite modifiée par 20% de dinonylphtalate à 25 °C. Les autres produits de combustion (eau, méthanol, acétaldéhyde, et acétone) sont analysés sur une colonne de brique pilée modifiée par 20% de carbowax 400 à 50 °C, ou de célite modifiée par 20% de diglycérol à 100 °C. Les acides, le formaldéhyde et les peroxydes sont piégés à −80 °C dans une ampoule amovible contenant 10 cm^3 d'eau distillée: les acides sont titrés par une solution de soude *N*/100 sous atmosphère d'azote, en présence de phénolphtaléine; le formaldéhyde est mesuré par la méthode spectrophotométrique de Bricker et Johnson (7) et les peroxydes sont dosés par la méthode iodométrique de Cullis et Newitt (8).

Résultats

(A) Résultats cinétiques

Les variations de pression en fonction du temps (ΔP *vs.* t) ont été enregistrées pour différents mélanges cétène–oxygène ($0.5 \leq CH_2CO:O_2 \leq 2$) entre les températures de 280 et 500 °C et à partir d'une pression totale de 20 mm Hg. Pour obtenir des résultats reproductibles, il est nécessaire de "passiver" le réacteur par une série d'expériences préliminaires et d'employer un protocole standard de manipulation; la reproductibilité est de l'ordre de 5% à 420 °C, étant beaucoup plus difficile à obtenir à basse température (vers 300 °C). Après une période d'induction plus ou moins longue pendant laquelle ΔP est nulle, la pression augmente suivant une courbe en "S" caractéristique (fig. 1). Nous avons défini sur ces enregistrements manométriques quatre principaux paramètres cinétiques: ΔP_∞ = augmentation maximum de pression (mm Hg); P_0 = pression totale à $t = 0$; $(dP/dt)_{max}$ = vitesse maximum de la réaction (mm Hg/s); t_{max} = temps auquel la vitesse maximum est atteinte (s); ϕ = constante d'accélération (s^{-1}), exprimant l'accélération initiale exponentielle de la pression.

Jusqu'à $t = t_{max}$, la pression croît suivant $\Delta P = Ne^{\phi t}$, où N est une constante. L'augmentation maximum de pression est proportionnelle à la pression initiale ($\Delta P_\infty = \alpha.P_0$); le coefficient α passe par un maximum pour un rapport $CH_2CO:O_2$ voisin de l'unité et il varie en fonction des pressions partielles du cétène et de l'oxygène de la façon représentée sur la fig. 2. L'ordre global (relatif à P_0) et les ordres par rapport à CH_2CO et à O_2 sont donnés au tableau 1 et sont en bon accord avec ceux déterminés par Barnard et Kirschner à 475 °C.

Le tableau 2 présente des valeurs de $(dP/dt)_{max}$, de t_{max}, et de ϕ pour quelques réactions à différentes températures. On en tire des valeurs de l'énergie d'activation apparente qui varient un peu selon le paramètre utilisé pour les calculer (tableau 3), mais qui permettent quand même de

TABLEAU 2. Influence de la température sur les paramètres de vitesse. Mélange 1 $CH_2CO : 2\ O_2$. $P_0 = 59$ mm Hg

θ (°C)	$(dP/dt)_{max}$ (mm Hg/s)	t_{max} (s)	ϕ (s^{-1})
497	0.95	6.5	0.87
452	0.80	13.8	0.52
420	0.74	23.2	0.34
388	0.65	39.5	0.24
340	0.40	132.	0.10
330	0.14	214.	0.05

tirer une conclusion d'ensemble: la réaction est affectée d'un coefficient de température petit aux températures supérieures, tel que l'ont déjà constaté Barnard et Kirschner, mais grand aux températures inférieures. La transition, qui se situe vers 370 °C, induit à penser qu'on a affaire à des mécanismes différents.

L'addition d'hélium abaisse très légèrement la vitesse de la réaction, alors que le ralentissement est beaucoup plus marqué si le rapport surface/volume du réacteur augmente. La surface du réacteur exerce des effets importants et en particulier des revêtements de chlorure de potassium et d'oxyde de plomb inhibent fortement la combustion lente.

(B) Résultats analytiques

Les principaux produits de la combustion lente à 420 °C sont le monoxyde de carbone, le formaldéhyde, l'eau, et l'anhydride carbonique, accompagnés de traces de méthane, d'hydrogène, de méthanol, d'acide acétique, d'acétaldéhyde, et de peroxyde d'hydrogène (fig. 3) qui sont essentiellement les produits trouvés par Barnard et Kirschner (3). L'augmentation ΔP de la pression est une bonne mesure de l'avancement de la réaction, sauf pendant la période d'induction où

TABLEAU 3. Energies d'activation apparentes d'après trois paramètres. Mélange 1 $CH_2CO : 2\ O_2$. $P_0 = 59$ mm Hg

	Energie d'activation (kcal $mole^{-1}$)	
Paramètre	370–500 °C	300–360 °C
$(dP/dt)_{max}$	4.3±0.3	42.0±2.0
t_{max}	16.0±0.3	32.0±1.0
ϕ	10.8±0.6	40.0±2.0

le cétène et l'oxygène sont consommés pour donner principalement du formaldéhyde. Les bilans sont satisfaisants surtout lorsque la réaction est bien avancée (tableau 4). La fig. 4 indique comment varient les pressions finales des réactifs et des produits principaux avec le rapport $CH_2CO:O_2$, la pression totale étant constante.

Le résultat le plus caractéristique est relatif au formaldéhyde; sa pression varie parallèlement à la vitesse dP/dt de la réaction et suit au début de la combustion la même croissance exponentielle que $\Delta P = Ne^{\phi t}$, la constante d'accélération étant égale à $3.4 \times 10^{-1}\ s^{-1}$ à 420 °C. L'addition de formaldéhyde à l'instant initial, en quantité égale à la concentration maximum, supprime totalement la période d'induction, la combustion débutant avec la vitesse maximum (fig. 5), alors que l'addition au temps t_{max} et après celui-ci n'a pas d'influence. La pression maximum de formaldéhyde croît linéairement avec la pression initiale de cétène $(P_{CH_2O})_{max} = 0.32\ P_{CH_2CO}$ et diminue très légèrement avec celle d'oxygène. On voit au tableau 5 que la vitesse maximum de la réaction et la concentration maximum de formaldéhyde varient parallèlement l'une à l'autre entre 420, et 500 °C. Le facteur de température relatif à $(CH_2O)_{max}$ est de 4.6 ± 0.3 kcal $mole^{-1}$.

Nous avons déduit des résultats analytiques les énergies globales d'activation relatives aux vitesses de consommation du cétène et d'oxygène et à la vitesse de formation du monoxyde de carbone, soit respectivement 5.1, 6.0, et 5.2 kcal/mole.

Discussion

La transition que nous observons vers une température de 370 °C (tableaux 2 et 3), indique certainement le passage d'un mécanisme de combustion à "hautes températures" (380–500 °C), à un mécanisme à basses températures (280–350 °C). Cette transition est confirmée par

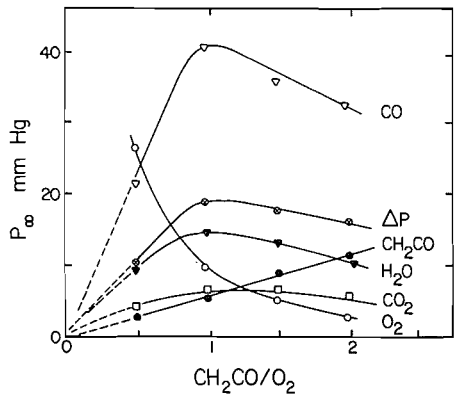

FIG. 4. A 420 °C et 59 mm Hg, influence du rapport CH_2CO/O_2 sur les valeurs finales de ΔP et des pressions partielles.

l'étude du diagramme d'explosion (4); la pression P_c et la température T_c sur la limite d'explosion obéissent à la relation $\ln P_c = A/T_c + B$, qui est représentée par un couple de deux droites qui se coupent pour $\theta = 375$ °C, et d'autre part, la température de 370 °C correspond à la pression minimum du lobe de flamme froide unique (9).

Tous les résultats que nous avons décrits indiquent que la combustion lente du cétène est une réaction en chaînes ramifiées probablement dégénérées:

(*a*) La réaction débute après une période d'induction, l'augmentation consécutive de pression étant exponentielle jusqu'au temps t_{max}.

(*b*) Nous avons observé des flammes froides et l'analyse un peu avant le passage de la flamme

420	0.88	7.6
388	0.83	6.7

montre que le formaldéhyde est alors en concentration importante (9).

(*c*) La concentration en formaldéhyde varie parallèlement à la vitesse de la réaction et son addition à l'instant initial en quantité égale à sa concentration maximum supprime totalement la période d'induction (fig. 5).

(*d*) Les paramètres cinétiques dépendent d'une fonction compliquée des concentrations en cétène et en oxygène, la constante d'accélération $\phi = 3.4 \times 10^{-1}\ s^{-1}$ étant de l'ordre de celle associée à une réaction en chaînes ramifiées.

Trois modes d'initiation semblent a priori possibles. Le premier est la réaction invoquée dans la pyrolyse ou la photolyse du cétène (éq. 1).

[1] $$CH_2CO = :CH_2 + CO$$
$$\Delta H_1 = 77 \pm 3 \text{ kcal/mole}$$
avec $\Delta H_f^0(CH_2CO) = -14.8$ kcal/mole,
$\Delta H_f^0(CO) = -26.4$ kcal/mole,
et $\Delta H_f^0(:CH_2) = 88 \pm 3$ kcal/mole (10)

Non seulement cette réaction est fortement endothermique, mais les radicaux $:CH_2$ qu'elle produit peuvent réagir non seulement avec l'oxygène, mais aussi avec le cétène pour donner de l'éthylène (11). Or, on n'a pu déceler aucune trace d'éthylène entre 250 et 500 °C. Le second mode d'initiation (éq. 2) possible est:

[2] $$CH_2CO + O_2 = \cdot CHCO + HO_2^{\cdot}$$
$$\Delta H_2 = 59 \pm 3 \text{ kcal/mole}$$

ΔH_2 a été calculée en supposant que D^0 ($\cdot CH{=}CO$) = $D^0(CH_2{=}CO)$ = 77 ± 3 kcal/mole et en prenant ΔH_f^0 ($:\!CH$) = 142 kcal/mole (10). Le radical ·CHCO a été postulé par Young (12) et plus récemment par Becker *et al.* (13) dans l'étude spectroscopique des flammes du système $\cdot H + O_2 + CH_2CO$.

Le troisième mode d'initiation possible est l'addition d'oxygène sur la double liaison du cétène, processus semblable à celui invoqué dans le cas de la combustion des hydrocarbures éthyléniques (14). Dans cette réaction (éq. 3)

[3] $CH_2CO + O_2 \rightarrow$

$$\begin{pmatrix} CH_2{-}C{=}O \\ | \quad\quad | \\ O{-}{-}O \end{pmatrix} \rightarrow CH_2O + CO_2 \quad [a]$$
$$\rightarrow \cdot OH + \cdot CHO + CO \quad [b]$$

la formation du superoxide est probablement exothermique. Cet intermédiaire peut se décomposer en $CH_2O + CO_2$ comme en [3*a*], ce qui correspondrait à la formation de très petites

		ΔH kcal/mole

SCHÉMA 1

quantités de ces substances durant la période d'induction avec une exothermicité d'environ -107 kcal/mole très suffisante pour donner du formaldéhyde excité (20) comme il s'en produit dans les flammes froides. On peut concevoir que le transfert de cette énergie crée les premiers centres actifs radicalaires, mais on ne saurait distinguer expérimentalement cette alternative de la réaction 3*b* que nous proposons pour l'initiation. Cette réaction a, sur les réactions 1 et 2, l'avantage d'être affectée d'une faible endothermicité, $\Delta H_{3b} = 4 \pm 2$ kcal/mole, ce qui permet de supposer que son énergie d'activation globale est nettement inférieure à celles des deux autres.

Les radicaux ·OH produits dans l'initiation peuvent propager deux chaînes. L'une d'elles, [4], [5], et [6], rend compte de l'accumulation de formaldéhyde et de monoxyde de carbone dans les premiers temps de la réaction; l'autre, par les réactions 7 et 8, indique un mode de formation de l'eau et un rôle possible du radical ·CHCO. Cependant, lorsque la concentration de formaldéhyde sera suffisamment élevée, l'attaque de cette espèce par les radicaux ·OH provenant de la ramification constituera le mode de propagation le plus important [10], [11], et [5].

Pour expliquer la formation des produits principaux, nous proposons donc le schéma 1.

Si l'on tient compte de ce que le formaldéhyde s'oxyde suivant la réaction globale $CH_2O + 1/2\ O_2 = CO + H_2O$ (15), la somme de cette réaction et des réactions d'initiation [3] et de propagation P_1 et P_2 est compatible avec nos résultats analytiques, puisqu'elle conduit à

$$4\ CH_2CO + 3.5\ O_2 = 2\ CH_2O + 5\ CO + 2\ H_2O + CO_2$$

ce qui correspond à $P_{CO} = 2\ \Delta P$, $P_{H_2O} = 0.8\ \Delta P$, et $P_{CO_2} = 0.4\ \Delta P$, alors que nos analyses nous ont donné respectivement $P_{CO} = 2\ \Delta P$, $P_{H_2O} = 1\ \Delta P$, et $P_{CO_2} = 0.4\ \Delta P$.

Pour ce qui est de la ramification, le formaldéhyde, formé par les réactions 4, 6, et 16, est le seul produit qui réunit tous les critères d'agent de ramification dégénérée. La faible énergie d'activation à l'époque où la vitesse est maximum indique déjà que la réaction de ramification doit être affectée d'une énergie d'activation peu élevée. Cette énergie peut être calculée à partir de nos données (4, 9) sur la limite inférieure d'explosion. On sait que dans le cas d'une explosion en chaînes avec rupture sur une paroi efficace la pression P_c à la limite inférieure, obéit à la loi

$$P_c \propto e^{E_r/2RT}$$

E_r étant l'énergie d'activation de la ramification

SCHEMA 2

(16). Nous avons trouvé (9) que notre limite obéit à la relation

$$[14] \qquad \ln P_c = A/T_c + B$$

et que $A = 1470 \pm 20$ °K, ce qui conduit à $E_r = 5.9 \pm 0.1$ kcal/mole. Nous ne pouvons retenir la réaction de ramification habituellement invoquée:

$$[15] \qquad CH_2O + O_2 = \cdot CHO + HO_2^{\bullet}$$

dont l'énergie d'activation est égale à au moins 32 kcal/mole (17) en phase gazeuse et à au moins la moitié de cette valeur dans l'hypothèse où la réaction aurait lieu sur la paroi. C'est pourquoi nous proposons le mécanisme de ramification de Knox et Norrish (18), soit les réactions 9 et 10, la première s'effectuant suivant [9*a*] et [9*b*].

$$[9a] \qquad \cdot CHO + O_2 = HCO_2^{\bullet} + :O$$

$$[9b] \qquad HCO_2 + CH_2O = HCOOH + \cdot CHO$$

Ce processus de ramification est compatible avec une énergie d'activation de 6 kcal/mole. Cette hypothèse a été récemment reprise par Yang et Gray (19) dans une théorie expliquant les phénomènes d'explosion et de flammes froides. En particulier la réaction 16 affectée d'une exothermicité $\Delta H_{16} = -99$ kcal/mole serait suffisante pour porter le formaldéhyde à l'état excité (20) dans les flammes froides du cétène.

$$[16] \quad CH_2CO + :O = \begin{pmatrix} CH_2—CO \\ \diagdown\ \diagup \\ O \end{pmatrix} = CH_2O + CO$$

Pour éviter de faire appel à des atomes d'oxygène libres, on pourrait remplacer la réaction 9 par

$$CH_2O + O_2 = [P] = \cdot H + CO_2 + \cdot OH$$

où [P] serait un intermédiaire peroxydique hypothétique. Cette réaction est exothermique par environ 5 kcal/mole.

La terminaison des chaînes, compte-tenu des effets de surface observés, est sans doute hétérogène et, parmi les radicaux, $HO_2^{\bullet}$ est le plus susceptible de se détruire sur la paroi, en particulier recouverte de chlorure de potassium ou d'oxyde de plomb (21).

Parmi les produits mineurs, nous avons décelé à 420 °C, de petites quantités de méthane, de méthanol, d'hydrogène, d'acide acétique, d'acétaldéhyde, et de peroxyde d'hydrogène. Il est probable que les réactions du schéma 2 interviennent dans la formation de ces composés.

A cette température élevée, les radicaux méthyle ont une bonne chance (22) d'abstraire un hydrogène selon [18], réaction concurrencée par leur réaction avec l'oxygène pour former le radical peroxydique qui se décompose en formaldéhyde et radical hydroxyle. Une partie des atomes d'hydrogène réagissant en [22] provient vraisemblablement de la décomposition de radicaux $\cdot CHO$ et $HO_2^{\bullet}$. Nous avons mesuré (9) la vitesse de la réaction du cétène avec l'eau [23] à 360 °C. Quant au peroxyde d'hydrogène, il ne peut pas jouer un rôle important comme agent de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ramification, car sa décomposition homogène est beaucoup plus lente que sa destruction sur la paroi à la température de nos expériences (23).

Nous avons traité notre schéma cinétique par l'approximation des états quasi-stationnaires, en analysant d'abord le début de la combustion pendant la période d'induction et ensuite la réaction au temps t_{max} où la vitesse est maximum.

Première étape: période d'induction

Il se forme principalement du formaldéhyde et du monoxyde de carbone, ces formations faisant intervenir surtout les réactions d'initiation [3] et de propagation P_1 [4], [5], et [6]. On suppose que la vitesse de consommation du formaldéhyde est contrôlée par celle de la ramification représentée par la somme des réactions 9 et 10, soit

[26] $2\,CH_2O + O_2 = HCOOH + \cdot CHO + \cdot OH$

pour simplifier la notation. Le paramètre qui décrit le mieux l'évolution de la réaction durant cette période est la constante d'accélération ϕ qui exprime la croissance exponentielle de la pression et de la concentration de formaldéhyde. L'approximation des états quasi-stationnaires, soit

$$d[\cdot OH]/dt = d[\cdot CHO]/dt = d[HO_2^{\bullet}]/dt = 0$$

avec $d[CH_2O]/dt \neq 0$, puisque le formaldéhyde s'accumule durant cette période, conduit à la relation

$$[27] \qquad [CH_2O] = \frac{n_0}{a_{26}}(e^{\phi t} - 1)$$

où n_0 = taux de la réaction d'initiation, $a_{26} = k_{26}[O_2]$, et

$$\phi \text{ (théorique)} \propto k_6 k_{26} k_{13}^{-1} [CH_2CO][O_2]$$

Nous retrouvons le fait que la croissance de la concentration du formaldéhyde est exponentielle et nous devons pouvoir identifier cette constante ϕ (théorique) à la constante d'accélération expérimentale ϕ. Nous trouvons effectivement que ϕ dépend des pressions partielles de cétène et d'oxygène suivant des ordres voisins de l'unité (tableau 1). L'énergie globale d'activation relative à ϕ doit être égale à $E_6 + E_{26} - E_{13} = 10.8 \pm 0.6$ kcal/mole (tableau 3). Rappelons que l'énergie d'activation de la ramification telle que déterminée d'après la limite inférieure d'explosion est $E_{26} \simeq 6$ kcal/mole. Comme $E_{13} \sim 0$, nous obtenons $E_6 = 4.8 \pm 0.6$ kcal/mole, valeur plausible puisque $\Delta H_6 = -35 \pm 2$ kcal/mole.

Deuxième étape: calcul de la concentration maximum de formaldéhyde et de la vitesse maximum de consommation du cétène au temps t_{max}

Au temps t_{max}, nous ne pouvons plus négliger la propagation P_2 ni la consommation du formaldéhyde par les radicaux $\cdot OH$ et $HO_2^{\bullet}$ dans les réactions 11 et 12. Au maximum de vitesse, le taux de production de centres actifs par la réaction d'initiation est négligeable par rapport au taux de leur production par la réaction de ramification, la seule dont il faut tenir compte. En faisant cette simplification, on trouve, pour la concentration maximum du formaldéhyde

$$[28] \quad [CH_2O]_{max} \propto \left[\frac{k_4\,k_6}{k_{11}k_{12}}\right]^{1/2} [CH_2CO],$$

et pour la vitesse maximum de consommation du cétène

$$[29] \quad -\frac{d}{dt}[CH_2CO]_{max} \propto \frac{k_6 k_{26}}{k_{13}}\left(\frac{k_4 k_6}{k_{11}k_{12}}\right)^{1/2}[CH_2CO]^2[O_2]$$

Nous retrouvons le fait expérimental que la pression maximum atteinte par le formaldéhyde est proportionnelle à la pression du cétène dans le mélange initial mais ne dépend pas de celle de l'oxygène. L'expression [29] est en accord avec l'ordre global de 3 par rapport à la vitesse maximum trouvé expérimentalement (tableau 1) et avec le fait que l'ordre partiel est plus grand par rapport au cétène que par rapport à l'oxygène.

Nous avons vu que $E_6 = 5$ kcal/mole et $E_{26} \simeq 6$ kcal/mole et il va de soi que $E_{13} \sim 0$. En appliquant la relation empirique de Polanyi, $E \simeq 11.5 - 0.25\ |\Delta H|$, nous obtenons les valeurs approximatives $E_{11} = 3.5$ et $E_{12} = 10.5$ kcal/mole. L'énergie globale d'activation relative à $(P_{CH_2O})_{max}$ doit s'identifier à $\frac{1}{2}(E_4 + E_6 - E_{11} - E_{12}) = 4.5$ kcal/mole en excellent accord avec la valeur expérimentale de 4.3 kcal/mole, si l'on fait $E_4 = 18$ kcal/mole. Avec cette même valeur de E_4, l'énergie globale d'activation par rapport à la vitesse maximum de consommation du cétène est $(E_6 + E_{26} - E_{13}) + \frac{1}{2}(E_4 + E_6 - E_{11} - E_{12}) = 15.5$ kcal/mole, valeur qui est forte par rapport à celle de 5 kcal/mole mesurée,

mais qui reste dans l'intervalle des valeurs inscrites au tableau 3.

Oxydation lente du cétène en phase gazeuse. II. Réaction à "basses températures"

PIERRE MICHAUD[1] ET CYRIAS OUELLET
Département de Chimie, Université Laval, Québec 10, Québec

Reçu le 30 juin 1970

Nous avons étudié la combustion lente du cétène entre 280 et 350 °C. La différence fondamentale avec la combustion lente de "hautes températures" est la présence de peroxydes (surtout d'hydroperoxydes) et l'absence de méthane. Les produits principaux: formaldéhyde, monoxyde de carbone, eau, et anhydride carbonique demeurent les mêmes. Nous proposons un schéma en chaînes ramifiées par la décomposition homogène: $CH_3OOH = CH_3O\cdot + \cdot OH$.

The slow combustion of ketene was investigated in the low-temperature range 280–350 °C. It differs from the reaction at higher temperatures chiefly by the presence of peroxides (mostly hydroperoxides) and the absence of methane. The main products: formaldehyde, carbon monoxide, water, and carbon dioxide are the same in both cases. A reaction scheme is proposed, which involves degenerate branching through the decomposition of methyl hydroperoxide: $CH_3OOH = CH_3O\cdot + \cdot OH$.

Canadian Journal of Chemistry, 49, 303 (1971)

Introduction

Dans la partie I (Oxydation lente du cétène en phase gazeuse: réaction à "hautes températures" (1)), nous avons mis en évidence un domaine de combustion lente de "basses températures" 280 °C < θ < 350 °C. Cet article décrit les résultats cinétiques et analytiques relatifs à cette région.

Méthode expérimentale

L'appareil et la préparation du cétène ont été décrits dans la partie I: en particulier, la combustion est étudiée dans le même réacteur de Vycor. La différence fondamentale entre les deux domaines de combustion lente est la présence à basses températures de peroxydes parmi les produits de combustion. Ceux-ci ont été dosés par la méthode de Cullis et Newitt (2) qui permet de déterminer quantitativement les peracides, le peroxyde d'hydrogène et les hydroperoxydes. Cette méthode nous a indiqué qu'environ 90% des peroxydes sont des hydroperoxydes, 10% des peracides et H_2O_2.

Résultats

(A) Résultats cinétiques

La reproductibilité est plus difficile à obtenir qu'à "hautes températures", principalement pour les longues périodes d'induction. Les enregistrements sont des courbes en "S", sauf certaines variations singulières, pour lesquelles l'accélération initiale exponentielle est suivie par un arrêt apparent de la combustion par consommation de la totalité de l'oxygène (fig. 1). Il ne peut s'agir de flammes froides, puisque celles-ci sont toujours suivies par une montée consécutive de la pression (3) mais peut-être du "pic d'arrêt" mis en évidence par Lucquin (4); ce phénomène ne s'observe que pour des mélanges riches en cétène ($CH_2CO:O_2 > 1.1$) et dans un intervalle de températures relativement restreint (autour de 300 °C).

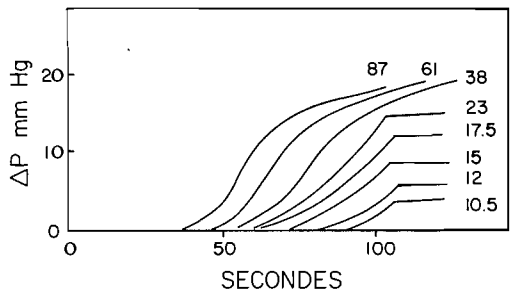

FIG. 1. Enregistrements manométriques à 330 °C pour différentes pressions initiales $P_0(O_2)$ inscrites sur les courbes, la pression initiale de cétène étant $P_0(CH_2CO)$ = 38 mm Hg dans tous les cas.

Les paramètres cinétiques ΔP_∞, $(dp/dt)_{max}$, t_{max}, et ϕ (définis dans partie I), ont été étudiés en fonction de la pression totale P_0 et des pressions partielles de cétène et d'oxygène. ΔP_∞ est proportionnel à P_0, ($\Delta P_\infty = \alpha \cdot P_0$), le coefficient α passant par un maximum pour $CH_2CO:O_2 \geqslant 1:1$. Les ordres globaux et partiels sont différents à 330 °C de ceux calculés à 420 °C et sont inscrits dans le tableau 1.

(B) Résultats analytiques

Nous avons analysé en détail les produits de la combustion lente d'un mélange stoechiométrique cétène–oxygène à 330 °C (fig. 2). Les bilans sont satisfaisants surtout lorsque la réac-

278	67.0	68.5	98.0	38.5	35.1
380	67.2	70.7	101.3	40.7	36.6

tion est bien avancée (tableau 2). Les pressions partielles de cétène et d'oxygène décroissent linéairement avec l'augmentation ΔP de la pression à partir de la fin de la période d'induction (fig. 3), ce qui permet de prendre dp/dt comme mesure de la vitesse de la réaction. Les principaux produits de combustion sont les mêmes qu'à 420 °C, la différence principale étant la présence de peroxydes (surtout des hydroperoxydes), l'absence de méthane et la présence de traces d'acétone. La formation de méthanol est plus importante qu'à 420 °C. Le formaldéhyde atteint très vite une pression stationnaire de l'ordre de 8 mm Hg et son addition à l'instant initial n'a pas d'effet sur la vitesse de la combustion, contrairement à son influence à 420 °C.

Discussion

Les résultats cinétiques et analytiques indiquent que la combustion du cétène à 300 °C est une réaction en chaînes ramifiées. L'intermédiaire responsable de la ramification ne semble pas être le formaldéhyde puisque sa concentration demeure stationnaire jusqu'au moment où le cétène a été entièrement consommé (fig. 2). De plus l'addition de formaldéhyde n'affecte ni la période d'induction, ni la vitesse maximum de la réaction. Les longues périodes d'induction que nous obtenons (de l'ordre de centaines de secondes), ainsi que la région de détonation mise en évidence sur le diagramme d'explosion (3),

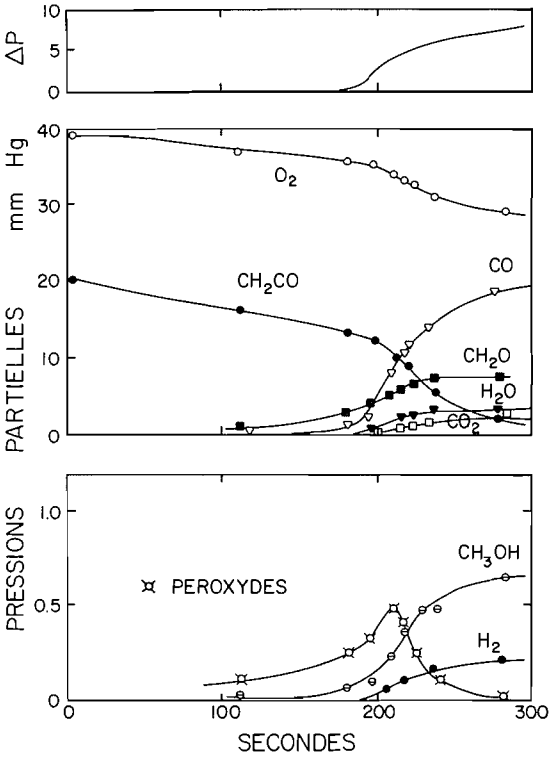

FIG. 2. Evolution de la pression et de la composition durant l'oxydation lente à 330 °C d'un mélange 1 CH_2CO:2 O_2 de pression initiale 59 mm Hg.

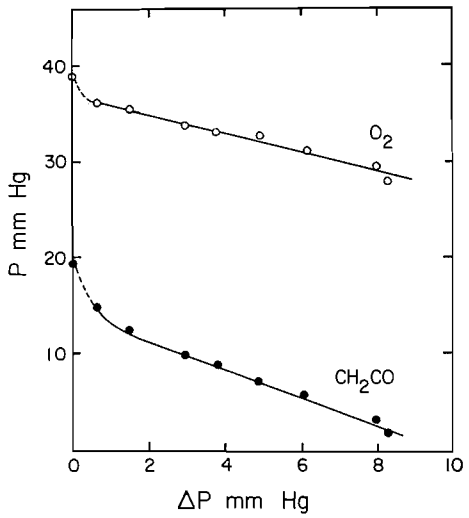

FIG. 3. Consommation des réactifs en fonction de ΔP comme mesure de l'avancement de la réaction à 330 °C d'un mélange 1 CH_2CO:2 O_2 de pression initiale 59 Hg mm.

doivent être associées à la formation de peroxydes. Le temps de vie moyen de l'agent de ramification est approximativement égal à $1/\phi$, ϕ étant la constante d'accélération: à 330 °C, $\phi = 0.048\ s^{-1}$, d'où un temps de vie de 21 s. Norrish (5) a montré que le temps de vie moyen est égal au rapport de la concentration stationnaire de l'intermédiaire à sa vitesse maximum de formation; la concentration maximum de peroxydes est de 0.6 mm Hg, leur vitesse de formation 0.023 mm Hg/s, d'où un temps de vie de 26 s en bon accord avec la valeur déterminée précédemment. Parmi les peroxydes, nous avons identifié H_2O_2, des peracides et surtout des hydroperoxydes (90%). Le H_2O_2 en très faible concentration ne semble pas être l'agent de ramification car sa vitesse de décomposition homogène est faible à une température de l'ordre de 300 °C, et sa décomposition thermique à des températures inférieures à 400 °C est surtout hétérogène (6, 7). Les peracides pouvant être présents (acides performique et peracétique) ont des temps de vie de l'ordre de 10^{-1} à 10^{-2} s à 330 °C (8), et la valeur que nous avons calculée (21–26 s) est de l'ordre du temps de vie d'un hydroperoxyde (9). Fisher et Tipper (10) trouvent que le temps de vie de l'hydroperoxyde de méthyle est de 30 s à 395 °C, Barnard et Honeyman (11) trouvent 75 s à 284 °C.

Ces considérations, en plus de l'absence de méthane et de la concentration plus élevée de méthanol à 330 °C, nous suggèrent que CH_3OOH est l'agent de ramification probable à cette température:

[32] $CH_3OOH \rightarrow CH_3O\cdot + \cdot OH$

[17] $\cdot OH + CH_2CO \rightarrow CH_3\cdot + CO_2$

suivie par l'oxydation des radicaux $\cdot CH_3$

[30] $\cdot CH_3 + O_2 + M = CH_3O_2\cdot + M$

[31] $CH_3O_2\cdot + CH_2CO = CH_3OOH + \cdot CHCO$

les radicaux $CH_3O_2\cdot$ ayant à 330 °C un temps de vie suffisamment long pour abstraire un atome d'hydrogène (12). La ramification homogène [32] contrôlant la vitesse de la combustion, en particulier au maximum de vitesse, l'énergie globale d'activation de 42 ± 2 kcal/mole (mesurée comme la variation de $(dp/dt)_{max}$ avec $1/T$) est en accord avec la valeur de $E_{30} = 38.5$ kcal $mole^{-1}$ déterminée par Barnard et Cohen (12).

Rappelons que, dans le domaine de hautes températures, c'est le formaldéhyde qui est l'agent de ramification. La combustion lente du cétène est donc une réaction qui passe d'un mécanisme aldéhydique à un mécanisme peroxydique par un changement modéré de la température.

L'analyse du schéma réactionnel complet est très compliquée, et nous proposons une suite de réactions qui s'applique raisonnablement bien au début de la réaction, en faisant les remarques suivantes:

(1) Les produits principaux sont dans la phase initiale le formaldéhyde, le monoxyde de carbone et les peroxydes (CH_3OOH), l'eau et l'anhydride carbonique s'accumulant relativement tard.

(2) La formation de H_2O_2 est plus importante qu'à 420 °C et la terminaison homogène [33].

Le schéma réactionnel est le schéma 1:[2]

		$\Delta H°$ kcal/mole
[3*a*]	$CH_2CO + O_2 = \begin{matrix} CH_2—C^{O} \\ \vert \quad \vert \\ O \quad —O \end{matrix} \rightarrow CH_2O + CO_2$	−107
[3*b*]	$\rightarrow \cdot CHO + \cdot OH + CO$	4 ± 2
[4]	Propagation $CH_2CO + \cdot OH \rightarrow CH_2O + \cdot CHO$	−16 ± 2
[5]	P_1 $\cdot CHO + O_2 \rightarrow CO + \cdot HO_2$	−27 ± 4
[6]	$CH_2CO + \cdot HO_2 \rightarrow CH_2O + CO + \cdot OH$	−35 ± 2
[17]	Propagation $CH_2CO + \cdot OH \rightarrow \cdot CH_3 + CO_2$	−56 ± 1
[30]	P_3 $\cdot CH_3 + O_2 + M \rightarrow CH_3O_2\cdot + M$	−27 ± 1
[31]	$\cdot CH_3O_2 + CH_2CO \rightarrow CH_3OOH + \cdot CHCO$	7 ± 3
[8]	$\cdot CHCO + O_2 \rightarrow 2CO + \cdot OH$	−82 ± 3
[32]	Ramification $CH_3OOH \rightarrow CH_3O\cdot + \cdot OH$	−40 ± 1
[33]	Terminaison $HO_2\cdot + HO_2\cdot \rightarrow H_2O_2 + O_2$	−43 ± 1

Schéma 1

[2]Les numéros des réactions font suite à ceux de l'article précédent (1).

L'approximation des états quasi-stationnaires et des considérations cinétiques nous conduisent (13) à

$$[CH_3OOH]^{1/2} = \frac{k_6 \cdot k_{17}[CH_2CO]}{k_4 \cdot (k_{32}k_{33})^{1/2}} (1 - e^{-k_{32}t/2})$$

Ce résultat présente l'intérêt de prévoir l'allure de la formation du peroxyde en fonction du temps, et permet d'évaluer approximativement la constante k_{32}. D'après nos résultats analytiques (tableau 2), il faut un temps de 210 s pour que la concentration des peroxydes atteigne les 9/10 de leur concentration maximum, d'où

$$\frac{k_{32}}{2} \cdot 210 \sim 2.1 \text{ et } k_{32} \sim 2.10^{-2}\ s^{-1}$$

Cette valeur est en accord avec la détermination de Barnard et Cohen (12) qui trouvent

$$k_{32} = 4.3 \times 10^{12}\ e^{\cdot -38500/RT}$$

pour la décomposition homogène de CH_3OOH, soit $\sim 4 \times 10^{-2}$ à 330 °C.

Ce travail a été financé par une subvention du Conseil National de Recherches du Canada, et l'un de nous (P.M.) remercie le gouvernement canadien pour l'attribution d'une bourse.

Alkaloids of *Tabernaemontana psychotrifolia* H.B.K.

R. H. BURNELL AND J. D. MEDINA
Département de chimie, Université Laval, Québec, Québec
Received June 23, 1970

A new alkaloid $C_{20}H_{24}N_2O$ (taberpsychine) obtained from Venezuelan *T. psychotrifolia* is shown to have structure **5**. The Hofmann degradation products of taberpsychine and its dihydro derivative are discussed. Two other bases isolated are affinine and 16-epi-vobasinic acid, the latter for the first time as a natural product.

Canadian Journal of Chemistry, 49, 307 (1971)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Extraction of *Tabernaemontana psychotrifolia* H.B.K.[1] yielded three principal alkaloids but the abundance of the major base taberpsychine, $C_{20}H_{24}N_2O$, and the fact that it could not be readily placed in a "skeletal" group by mass spectrometry made it the principal area of interest.

The u.v. spectrum of taberpsychine shows absorption typical of an indole moiety, with no substituents other than the "normal" ones at position 2 and 3. The i.r. spectrum confirms the presence of the aromatic nucleus and of the indolic NH, but the absence of absorption due to hydroxyl or carbonyl groups fails to provide information concerning the nature of the oxygen atom present. Since neither acetylation nor mild oxidation reactions produced any change in the molecule, the oxygen atom was, by exclusion, assumed to be ethereal.

The n.m.r. spectrum affords evidence about the remainder of the molecule, including the functionality of the second nitrogen atom. A broad quartet at 5.38 δ (J = 6.5 Hz) integrating for one proton, accompanied by a doublet of doublets for three protons at 1.68 δ (J = 6.5 and 2.0 Hz respectively) is evidence for an ethylidene side chain. Decoupling experiments (Fig. 1) left no doubt about this and at the same time localized the origin of the small coupling observed in the methyl signal and also of the broadening of the quartet for the olefinic proton. Irradiating the methyl signal, the broad lower field part (H in Fig. 1) of an AB quartet (3.60 and 2.93 δ, J = 14 Hz) becomes a sharp doublet; while irradiating this broad doublet (3.60 δ) the disappearance of the small splitting of the methyl group signal is observed (this also sharpens the quartet for the olefinic proton). This AB quartet is found in a region typical for protons at carbon atoms adjacent to nitrogen, permitting the placing of the ethylidene side chain in the sequence shown in **1**, with the methylene group adjacent to the basic nitrogen atom responsible for the AB quartet discussed above. A singlet at 2.53 δ integrating for three protons must be assigned to a methyl group on the basic nitrogen (since the indolic nitrogen bears no substituent). The spectrum also confirms the presence of four aromatic protons (4H multiplet 7.07–7.66 δ) and the indolic NH (singlet 8.42 δ).

Another feature in the n.m.r. spectrum is a pair of doublets at 5.13 δ (J = 10 and 2 Hz) integrating for one proton. The signal is only ascribable to a proton adjacent both to an aromatic moiety and an oxygen atom. The splitting pattern suggests that it is also adjacent to a methylene.

Zinc dust distillation of taberpsychine, following a small scale method described by Biemann and Spiteller (1) coupled with gas-chromatographic analysis of the volatile distillate showed the major product to be 3-ethylpyridine (direct comparison in the gas chromatograph with an authentic sample and n.m.r. spectrometry of the material recovered). The product could only *be formed from the part of the molecule containing the basic nitrogen* and since the analogous pyridinium ion is observed as one of the major peaks in the fragmentation in the mass spectrum (122 m/e) the basic nitrogen atom is located in a six-membered ring.

Hydrogenation of taberpsychine afforded a dihydro derivative, $C_{20}H_{26}N_2O$, in which the ethylidene side chain was no longer present as shown by the n.m.r. spectrum, while a signal due to a methyl group on a saturated carbon appeared as a triplet at 0.98 δ (J = 7 Hz).

[1]The identification was made by, and a herbareum specimen is filed at, the Botanical Gardens, Caracas, Venezuela.

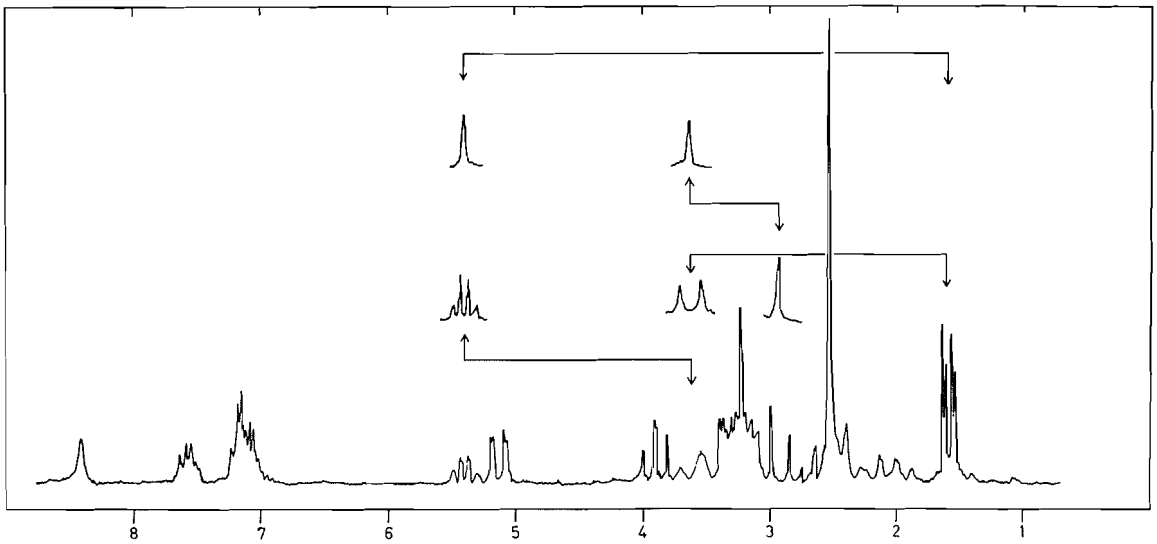

FIG. 1. The n.m.r. spectrum (100 MHz) of taberpsychine in deuteriochloroform (TMS = 0 p.p.m.). Double irradiations are indicated by the double headed arrows.

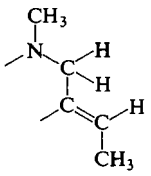
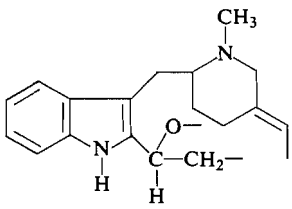


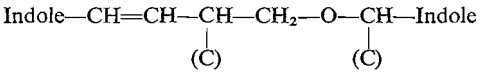
1



2

The methiodide of the dihydro derivative undergoes Hofmann degradation with potassium tertiobutoxide to give a major product, $C_{21}H_{28}N_2O$, whose u.v. spectrum indicates the presence of a double bond conjugated to the indole chromophore (2, 3). The presence of this new double bond is corroborated by the n.m.r. spectrum of the dihydrotaberpsychine-methine, in which one finds the signals for two olefinic protons at 6.69 (doublet J = 12 Hz) and 5.55 δ (doublet of doublets J = 12 and 8 Hz) as the low field AB part of an ABX system (see Fig. 2). The fact that the double bond introduced during this reaction is conjugated with the aromatic moiety and the assumption of a very likely tryptamine biogenesis allows the linkage of the two units as shown in partial structure **2** and also places the oxygen atom on the carbon attached to position 2 of the indolic portion. A methylene group can be placed adjacent to the carbon bearing the oxygen atom on the basis of the pattern for the proton adjacent to both the aromatic residue and oxygen (doublet of doublets J = 10 and 2 Hz).

Spin decoupling experiments (Fig. 2) on dihydrotaberpsychine-methine provided information concerning the missing linkage of the oxygen atom. In effect, it demonstrated that the X part (1H) of the ABX system involving the vinyl protons introduced by the degradation, is also coupled to an A′B′ system (doublet 4.21 δ, J = 11 Hz and triplet 3.79 δ, J = 11 Hz) appearing in a region typical for protons adjacent to oxygen. The Hofmann product must therefore contain the sequence:



and this observation is only compatible with the partial structure for the methine shown by **3**.

The molecular formula of the base indicates a pentacyclic structure. The additional ring must involve the methylene group shown and only one point of attachment remains (at the starred carbon) since the nature and number of protons at all other positions has been demonstrated in the discussion above, thus the complete structure for the major Hofmann product is given as **4** in which the configuration of the *C*-ethyl residue must be as shown, arising from hydrogen addition to the more exposed face of the molecule, and hence the

6

structure of taberpsychine is **5** which is compatible with all spectral data.[2]

A minor product from the Hofmann degradation of dihydrotaberpsychine methiodide was also isolated although it could not be induced to crystallize. The n.m.r. spectrum shows a pair of doublets (4.98 and 5.63 δ, J = 1 Hz) typical of a terminal methylene group, which together with the preceding evidence permitted the formulation of the material as structure **6**.

Once the structure of taberpsychine had been elucidated, the result obtained from the Hofmann degradation performed on the methiodide of taberpsychine itself could be rationalized, whereas before a rather complex n.m.r. spectrum had rendered its interpretation difficult. This degradation, effected using the same conditions as for the dihydro compound already discussed, af-

[2]After our preliminary report on taberpsychine (P. R. Benoin *et al.* (6)) we were informed that the alkaloid anhydrovobasindiol had been ascribed the same structure (M. Hesse, personal communication). In a subsequent publication (J. J. Dugan *et al.* (7)) the two alkaloids are shown to be identical.

forded a major product, $C_{21}H_{26}N_2O$, whose u.v. spectrum shows the presence of a conjugated diene in addition to the original indole residue. The n.m.r. spectrum of this taberpsychine-methine shows a complex (5H) pattern in the region where the absorption for olefinic protons is expected (see Fig. 3). The pattern is further complicated by the presence in the same area, of the absorption due to the C-3 proton adjacent to the aromatic ring and the oxygen atom. The product obtained by hydrogenation of the methine showed two saturated *C*-methyl signals in the n.m.r. spectrum hence the conjugated diene could only be formed by elimination of one of the protons in the methyl group and migration of the double bond to open the piperidine ring, leaving the nitrogen attached to the eight-membered ring. The structure of this degradation product was assigned as shown in **7**. A very minor product of this Hofmann degradation was observed by t.l.c. but could not be isolated. This is probably the isomer of the diene as depicted in **8**.

The problem of the stereochemistry of taberpsychine is almost reduced to a question of absolute stereochemistry, since once the configuration at one of the asymmetric centers is fixed, the closing of the rings determines the configuration at the other centers. Thus the alkaloid has either the stereochemistry shown in structure **4** or its complete mirror image. The vinylogous Hofmann degradation of taberpsychine methiodide to give the diene **7** is understandable since the two activated "benzylic" protons at C-6 are not suitably disposed to allow facile *trans*-elimination. Examination of molecular models of taberpsychine suggests that the hydrogenation of the exocyclic double bond would be specifically from that face of the molecule which would lead to an equatorial ethyl group as in **10***a*. Hydrogenation from the other face, which should give the axial ethyl residue (as in **10***b*) is seriously hindered by the eight-membered ring and the aromatic system. The results of the Hofmann degradation of the methiodide of the dihydrotaberpsychine **10***a* show that the predominant reaction involves the elimination of one of the protons at C-6 adjacent to the indole ring. It would be difficult to rationalize this observation on the basis of structure **10***b* where the equatorial hydrogen substituent, introduced by hydrogenation, is stereochemically well situated for a *trans*-elimination.[3]

Another alkaloid obtained from *T. psychotrifolia* analyzed for $C_{20}H_{24}N_2O_2$ and its particular u.v. spectrum [λ_{max} 224 (10 000) and 318 (12 000)] permitted its classification as an α-acyl indole.

The i.r. spectrum confirms the presence of the

[3]We realize that the structural elucidation of taberpsychine is based almost entirely on spectral evidence. Although we had a large amount of alkaloid available for degradative studies, some 40 different experiments aimed at the isolation of other degradation products failed (J. D. Medina (8)).

For personal use only.

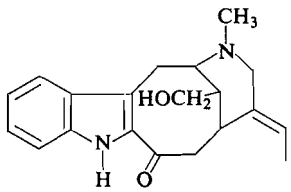
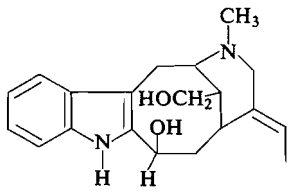
carbonyl group (strong band 1650 cm^{-1}) as well as that of the aromatic moiety and the indolic NH. This spectrum also shows the presence of a hydroxyl group. The n.m.r. spectrum was difficult to perform due to the only slight solubility of the base in most organic solvents, but the problem was partly solved by the use of a hot saturated chloroform solution. The spectrum showed the presence of a methyl group attached to the basic nitrogen (singlet 2.53 δ) and of a methyl group on a tri-substituted double bond (1H quartet 5.40 δ, $J = 6$ Hz and 3H triplets 1.68 δ, $J = 6$ Hz).

Acetylation of the base with acetic anhydride in pyridine at room temperature gives a monoacetate (molecular weight by mass spectrometry 366) and while this product is rather unstable it could be characterized spectrally. The i.r. spectrum proves that it is an *O*-acetyl derivative (peaks at 1745 and 1235 cm^{-1}) and the n.m.r. spectrum reveals that the acetyl methyl is unusually shielded (3H singlet 1.77 δ). The most useful information, however, is given by the mass spectra since that of the base itself shows two major peaks at 152 and 122 *m/e* while in the acetate one finds a new peak at 194 *m/e* (42 mass units from 152 *m/e*).



11

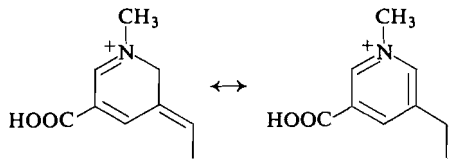


12

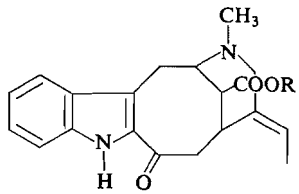
The structure proposed, which is justified by the mass spectrum is identical with that proposed for affinine **11**, (4) and although the physical constants given in the literature for the latter were misleading, the base is in fact affinine and this was confirmed by reduction by sodium borohydride to vobasinediol **12**.

That the stereochemistry at C-16 is as shown can be readily seen from the extreme shielding of the acetyl methyl (3H singlet 1.77 δ) observed in the n.m.r. spectrum of the *O*-acetyl derivative. In vobasine, the same shielding is observed for the methyl of the ester group, this appearing at 2.63 δ.

A third alkaloid, $C_{20}H_{22}N_2O_3$, is a high melting compound (m.p. 295° dec.) only sparingly soluble in most organic solvents which suggested it to be a salt. However, no anion was detectable pointing to an internal salt or amino acid. The u.v. spectrum of the base [λ_{max} 238 (13 100) and 316 (20 000) mμ] is that of an α-acyl indole and the i.r. spectrum presents two very typical bands in the region for carbonyl groups. One of them at 1650 cm^{-1} is assigned, in agreement with the u.v. spectrum, to a keto group on C-3 conjugated to the indole moiety and the other at 1610 cm^{-1}, a very strong band which is only compatible with a carboxylate carbonyl. The n.m.r. spectrum (performed in 2% D_2SO_4 in D_2O solution) shows the presence of an *N*-methyl group (3H singlet at 3.00 δ, displaced to lower field due to the quaternization of the basic nitrogen) and of an exocyclic ethylidene chain (1H quartet 5.93 δ and 3H doublet 1.68 δ, $J = 7$ Hz) in addition to the absorption expected from the indolic residue.



13



14

a R = H
b R = CH_3

The mass spectrum of the base presents its principal peak at 122 *m/e*, very typical fragmentation in the mass spectrometric degradation of vobasine-like alkaloids. Another important peak is that at 166 *m/e* (44 mass units = COO from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

122) which coupled to the evidence for the presence of an acidic residue in the molecule, leads to the conclusion that the latter is attached to the six-membered ring producing the pyridinium ion **13** in the fragmentation.

Based on this evidence the alkaloid was assigned structure **14***a*, which is that of 16-epi-vobasinic acid previously prepared by Renner (5) but never before reported as a natural product. All spectral data are in agreement with this structure, including the fragmentation in the mass spectrum.

Confirmation for the structure is provided by methylation of the base by prolonged treatment with diazomethane. The i.r. spectrum of the product obtained shows the absorption typical of esters (1740 cm^{-1}), while the n.m.r. spectrum shows it is a methyl ester (3H singlet 3.53 δ). The position of the absorption for the methyl group of the ester in the spectrum determines the stereochemistry at C-16, as being epimeric to that in vobasine where the same absorption shows the methyl group of the ester to be very shielded (3H singlet 2.63 δ) presumably because it lies immediately above the electronic cloud of the aromatic ring.

The methylated derivative **14***b* presents the same physical properties, and the i.r., n.m.r., and mass spectra are identical with those of *16-epi-vobasine* given in the literature (5).

Experimental

Melting points are uncorrected. Unless otherwise stated, the conditions and instruments employed for the various spectra were as follows: u.v., ethanol solutions (ε in parentheses); i.r., KBr pellets, Beckmann I.R.4; n.m.r., deuteriochloroform solutions with tetramethylsilane protons taken as 0 p.p.m., Varian A 60; mass spectra, AEI MS-9 and Varian M-66 spectrometers.

Extraction and Isolation of the Alkaloids

The ground trunk bark (6.5 kg) was extracted with methanol, until the alcoholic extract gave a negative reaction with Vassler's reagent. Evaporated to dryness this extract yielded a brown tar, which was triturated five times with 200 ml fractions of 2% hydrochloric acid. The acidic solution was then continuously extracted with chloroform to separate non-basic materials. From this chloroform, after concentration and cooling, was obtained the soluble hydrochloride of *taberpsychine* (6.627 g).

The aqueous solution was then basified with ammonia and again continuously extracted with chloroform. The chloroform containing the basic material yielded, on cooling, a black powder (1.505 g) which was filtered, redissolved in 2% hydrochloric acid, and extracted once with chloroform. This chloroform was discarded and the aqueous solution neutralized with ammonia then extracted with chloroform four times. The chloroform was taken to dryness and the white amorphous *16-epi-vobasinic* acid (454 mg) was obtained.

The chloroform solution containing the bases was evaporated to dryness to give a semi-solid tar (61 g; total crude bases: 68.08 g). Part of the crude bases (10 g) was dissolved in acetone–ethanol and on slow evaporation a fine precipitate was obtained. Filtered and washed with cold acetone, it resulted in a mixture of 16-epi-vobasinic acid and affinine (300 mg). Both materials are virtually insoluble in all solvents, but affinine is slightly soluble in hot methanol and so the mixture was separated by boiling the solid in methanol and filtering while hot. Affinine (180 mg) precipitated from the methanol solution as an amorphous solid.

Another portion of the crude base (25 g) was submitted to a countercurrent distribution with acetate buffer, p*H* 3.4 (25 ml), using chloroform as stationary phase (25 ml), for a total of 50 transfers.

Fractions 1 to 7 (10 g) contained only neutral material and were not investigated further. Fractions 18 to 40 (12.7 g) yielded taberpsychine. Fractions 41 to 50 (1.22 g) yielded affinine.

Taberpsychine

The base was recrystallized from acetone and sublimed for analysis, m.p. 208° (dec.), $[\alpha]_D$ −243°; λ_{max} 222 (33 100), 272 (sh. 6500), 280 (7500), and 286 mμ (6650); ν_{max} 3241 (NH), 2747 (*N*-methyl), 744 and 728 cm^{-1} (aromatic).

The n.m.r. spectrum δ: 1H singlet 8.42 (NH); 4H multiplet 7.07–7.66 (aromatic); 1H broad quartet 5.38, J = 6.5 Hz, and 3H doublet of doublets, J = 6.5 and 2.0 Hz (ethylidene side chain); 3H singlet 2.53 (*N*-methyl); 1H doublet of doublets 5.13, J = 10 and 2 Hz (C_3—H); 2H AB quartet 2.93 and 3.60, J = 14 Hz (C-21 methylene). Mass spectrum: 308.1849 (M^+; $C_{20}H_{24}N_2O$ requires 308.1887), 293, 279, 154, 130, 122, 121, 108, 107 *m/e*.

3-Ethyl Pyridine from Taberpsychine

Sublimed taberpsychine (194 mg) was mixed with dried zinc dust (1 g) and heated in a sealed tube at 280° for 3 h. A yellow distillate obtained in the cooler part of the tube protruding from the block was dissolved in methanol and analyzed in the gas chromatograph [Apiezon L 10%]. The spectrum shows two peaks (3:1 ratio) with retention times of 6 and 12.5 min respectively at a column temperature of 130° and increasing at the rate of 1°/min, which were identified by direct comparison as corresponding to 3-ethyl pyridine and 3-methyl-5-ethyl pyridine respectively. The major fraction was recovered and dissolved in deuterated chloroform. The n.m.r. spectrum δ : 2H multiplet 8.27–8.47 (H-2 and -6); 1H broad doublet 7.40, J = 8 Hz (H-4); 1H quartet 7.03 and 7.13 J = 8 Hz (H-5); 2H quartet 2.62, J = 7 Hz, and 3H triplet 1.22, J = 7 Hz (ethyl chain).

Dihydrotaberpsychine

Taberpsychine (1.210 g) was dissolved in ethanol (100 ml) and platinum oxide (500 mg) added together with glacial acetic acid (10 ml). After shaking for 50 h in an atmosphere of hydrogen (50 p.s.i.), the catalyst was filtered off and the alcoholic solution evaporated to dryness under reduced pressure. The resulting brown foam was redissolved in 2% hydrochloric acid, basified with ammonia, and extracted four times with chloroform which was evaporated to dryness. The product (1.150 g) was dissolved in acetone and the dihydrotaberpsychine obtained as white crystals, m.p. 191–193°; λ_{max} 223 (34 100), 277 (sh. 9000), 284 (9800), and 293 (8300) mμ; ν_{max} 3271 (indole NH), 2788 (*N*-methyl), 745 and 726 aromatic cm^{-1}

The n.m.r. spectrum δ : 4H multiplet 7.00–7.80 (aromatic); 1H doublet of doublets 5.12, J = 10 and 2 Hz (C_3—H); 3H singlet 2.53 (*N*-methyl); 3H triplet 0.98, J = 7 Hz (methyl in saturated ethyl side chain). Mass spectrum: 310 (M^+), 295 (M-15), 279 (M-31), 265, 251, 195, 180, 170, 168, 155 *m/e*. (M^{++}), 144, 138, 130, 124, 122, 108 *m/e*.

Anal. Calcd. for $C_{20}H_{26}N_2O$: C, 77.4; H, 8.4; N, 9.0; O, 5.2. Found: C, 77.2; H, 8.4; N, 8.9; O, 5.4.

Dihydrotaberpsychine Methiodide

Dihydrotaberpsychine (650 mg) was dissolved in acetone (15 ml) and methyl iodide (2.5 ml) was added to the warm solution. The mixture was boiled for 5 min and then allowed to cool. The amorphous dihydrotaberpsychine methiodide obtained was recrystallized from acetone, m.p. 255–258° (dec.); λ_{max} 221 (55 200), 275 (sh. 10 900), 284 (11 700), and 292 (10 400) mμ.

Anal. Calcd. for $C_{21}H_{29}N_2OI$: C, 55.8; H, 6.5; N, 6.2; O, 3.5; I, 28.1. Found: C, 55.7; H, 6.5; N, 6.3; O, 3.6; I, 28.3.

Dihydrotaberpsychine-methine

Dihydrotaberpsychine methiodide (550 mg) was suspended in *tert*-butyl alcohol (15 ml) and a solution (25 ml) of potassium (1 g) in *tert*-butyl alcohol added slowly. The mixture was refluxed for 24 h, then evaporated to dryness under reduced pressure, the residue was redissolved in water and the aqueous solution extracted four times with chloroform. The dihydrotaberpsychine-methine (418 mg) was obtained as a pale yellow foam which was crystallized from acetone and sublimed for analysis, m.p. 153–155°; λ_{max} 229.5 (38 500), 271 (12 000), 284 (11 400), and 294 (sh. 9000) mμ; ν_{max} 3250 (indole NH), 2820 and 2760 (*N*-methyl), 745 and 730 (aromatic) cm^{-1}.

The n.m.r. spectrum δ : 1H singlet 8.84 (indole NH); 4H multiplet 7.00–7.64 (aromatic); 1H doublet 6.69, J = 12 Hz (C_6—H) and 1H doublet of doublets 5.55, J = 12 and 8 Hz (C_5—H), both being the low field portion of an ABX system; 1H doublet of doublets 4.84, J = 12 and 2Hz (C_3—H); AB part of a second ABX system; 1H doublet 4.21, J = 11 Hz and 1H triplet 3.79, J = 11 Hz (methylene adjacent to oxygen in the oxide ring); 6H singlet 2.20 (*N*-dimethyl); 3H triplet 0.87, J = 7 Hz (methyl on saturated ethyl side chain). Mass spectrum: 324 (M^+), 310, 295, 280, 266, 194, 185, 180, 169, 168, 162 (M^{2+}), 156, 137, 130, 124, 58 *m/e*. Mol. wt. by mass spectrometry: 324.2175. $C_{21}H_{28}N_2O$ requires: 324.2202.

A minor product which could not be induced to crystallize was identified by means of its n.m.r. spectrum as the other isomer of dihydrotaberpsychine-methine (structure **6**). The n.m.r. spectrum δ : principal feature was a pair of doublets at 4.97 and 5.63, J = 2 Hz due to a terminal methylene.

Hydrogenation of Dihydrotaberpsychine-methine

Dihydrotaberpsychine-methine (400 mg) was dissolved in ethanol (50 ml), platinum oxide (150 mg) and glacial acetic acid (15 ml) were added, and the mixture left hydrogenating for 24 h (50 p.s.i.). The reaction mixture was then filtered and evaporated to dryness under reduced pressure. The residue was dissolved in water, basified with ammonia, and extracted with chloroform yielding a yellow foam (340 mg). This foam was dissolved in acetone and the crystalline derivative obtained was recrystallized from the same solvent, m.p. 184–186°; λ_{max} 224.5 (46 000), 279 (sh. 11 050), 285 (12 000), and 293 (10 300) mμ; ν_{max} 3250 (indole NH), 2750 (*N*-methyl) and 740 (aromatic) cm^{-1}.

The n.m.r. spectrum δ : 1H broad singlet 9.23 (indole NH); 4H multiplet 6.92–7.73 (aromatic); 1H broad doublet 5.10, J = 10 Hz (C_3—H); 6H singlet 2.20 (*N*-methyls); 3H triplet 0.85, J = 7 Hz (methyl in saturated ethyl side chain). Mass spectrum: 326.2362 (M^+; $C_{21}H_{30}N_2O$ requires: 326.2358), 282, 281, 268, 226, 225, 180, 168, 156, 144, 130 *m/e*.

A minor product was observed by t.l.c. but could not be isolated. This is probably the other isomer formed in small quantity.

Hydrogenation of Taberpsychine-methine

Taberpsychine-methine (429 mg) was dissolved in ethanol (50 ml) containing acetic acid. Platinum oxide (200 mg) was added and the mixture shaken for 18 h under hydrogen (50 p.s.i.). The solution was then filtered, evaporated to dryness under reduced pressure, and the residue redissolved in water, basified with ammonia, and extracted with ether. The ether was evaporated to dryness and a white foam (400 mg) was obtained. The tetrahydro compound was crystallized from acetone–ether and sublimed, m.p. 153–155°; λ_{max} 225 (29 300), 278 (7500). 284.5 (8100), and 293 (7050) mμ; ν_{max} 3250 (indole NH), 2766 (*N*-methyl), 740 and 730 (aromatic) cm^{-1}.

The n.m.r. spectrum δ : 1H broad singlet 8.82 (indole NH); 4H multiplet 6.97–7.73 (aromatic); 1H broad doublet 5.12, $J = 10$ Hz (C_3—H); 6H singlet 2.35 (*N*-methyls); 3H triplet 1.25, $J = 9$ Hz, and 3H doublet 0.93, $J = 6$ Hz (saturated methyls).

Anal. Calcd. for $C_{21}H_{30}N_2O$: C, 77.3; H, 9.3; N, 8.6; O, 4.9. Found: C, 77.2; H, 9.3; N, 8.3; O, 4.9.

Affinine

The very insoluble base was recrystallized from a large volume of ethanol and sublimed for analysis, m.p. 273–275° (dec.); λ_{max} 236 (sh. 13 200) and 320 (13 400) mμ; ν_{max} 3150 (broad, NH and OH), 2800 (*N*-methyl), 1650 (3-keto), 740 (aromatic) cm^{-1}.

The n.m.r. spectrum δ : 1H broad singlet 9.80 (indole NH); 4H multiplet 7.00–7.83 (aromatic); 1H broad quartet 5.40, $J = 6$ Hz, and 3H broad doublet 1.68, $J = 6$ Hz (ethylidene side chain); 3H sharp singlet 2.53 (*N*-methyl). Mass spectrum: 324 (M^+), 293 (M-CH_2OH), 158, 152, 122, 108 *m/e*.

Anal. Calcd. for $C_{20}H_{24}N_2O_2$: C, 74.0; H, 7.5; N, 8.6; O, 9.9. Found: C, 73.8; H, 7.5; N, 8.5; O, 10.0.

Affinine Acetate

Affinine (150 mg) was dissolved in pyridine (5 ml) and an excess of acetic anhydride (1 ml) added. The mixture was left standing overnight at room temperature. Methanol was then added to hydrolyze the excess anhydride and the solution evaporated to dryness under reduced pressure. The residue was redissolved in water, basified with ammonia, and the aqueous solution extracted with chloroform. The product is very unstable and decomposes while in solution, so crystallization was not possible. However i.r., n.m.r., and mass spectra indicate that it is indeed monoacetate of the base; λ_{max} (qualitative) 223 (shoulder), 237 (shoulder), and 319 mμ; ν_{max} 3300 (indole NH), 1745 and 1235 (O-acetyl), 1650 (3-keto), 1575 and 740 (aromatic) cm^{-1}.

The n.m.r. spectrum δ : 1H singlet 9.80 (indole NH); 4H multiplet 7.00–7.84 (aromatic); 1H broad quartet 5.40, $J = 6$ Hz and 3H doublet 1.67, $J = 6$ Hz (ethylidene side chain); 3H singlet 2.53 (*N*-methyl); 3H singlet 1.77 (*O*-acetyl). Mass spectrum: 366 (M^+), 306 (M-acetic acid), 293 (M-CH_3COOCH_2), 263, 194, 158, 122 *m/e*.

Vobasinediol (from Affinine)

Affinine (110 mg) was suspended in absolute methanol (25 ml), an excess of sodium borohydride (100 mg) was added, and the mixture left standing overnight at room temperature. Water (200 ml) was then added and the aqueous solution extracted with ether. After evaporation to a small volume, colorless needles of vobasinediol (100 mg) were obtained and sublimed for analysis, m.p. 244–245° (dec.), $[\alpha]_D$ −60° (methanol); λ_{max} 224 (21 600), 283 (6100), and 291 (5400) mμ; ν_{max} 3300 (NH and OH), 2280 (*N*-methyl), 740 (aromatic) cm^{-1}.

The n.m.r. spectrum δ : 1H singlet 9.75 (indole NH); 4H multiplet 6.90–7.62 (aromatic); 1H broad quartet 5.47, $J = 7$ Hz and 3H broad doublet 1.68, $J = 7$ Hz (ethylidene side chain); 1H broad doublet 5.27, $J = 6$ Hz C_3—H); 3H singlet 2.43 (*N*-methyl). Mass spectrum: 326 (M^+), 308 (M-H_2O), 293 (M-H_2O-15), 277 (M-H_2O-CH_2-OH), 183, 180, 154, 152, 136, 130, 122 *m/e*.

Anal. Calcd. for $C_{20}H_{26}N_2O_2$: C, 73.6; H, 8.0; N, 8.6; O, 9.8. Found: C, 73.6; H, 8.0; N, 8.4; O, 9.7.

16-epi-Vobasinic Acid

The base was recrystallized several times from large volumes of hot ethanol, m.p. 295° (dec.); λ_{max} 238 (13 100) and 316 (20 000) mμ; ν_{max} 3105 (indole NH), 1650 (3-keto), 1610 (carboxylate), and 753 (aromatic) cm^{-1}.

The n.m.r. spectrum δ : (in 2% D_2SO_4/D_2O solution) 4H multiplet 6.88–7.77 (aromatic); 1H broad quartet 5.93, $J = 7$ Hz and 3H broad doublet 1.68, $J = 7$ Hz (exocyclic ethylidene); 3H singlet 3.00 (*N*-methyl on quaternary nitrogen. Mass spectrum: 338 (M^+), 293 (M-COOH), 180, 166, 158, 122 *m/e*.

Anal. Calcd. for $C_{20}H_{22}N_2O_3$: C, 71.0; H, 6.6; N, 8.3; O, 14.2. Found: C, 70.8; H, 6.6; N, 8.0; O, 14.4.

16-epi-Vobasine (from 16-epi-Vobasinic Acid)

16-epi-Vobasinic acid (200 mg) was suspended in dry methanol (20 ml) and ethereal diazomethane solution (20 ml) added. The mixture was refluxed overnight on a water bath. The solution was then evaporated to dryness and redissolved in ether. 16-epi-Vobasine (190 mg) crystallized on slow evaporation and was recrystallized from ether, m.p. 185–187°; λ_{max} 237 (10 550) and 320 (12 000) mμ; ν_{max} 3300 (indole NH), 2750 (*N*-methyl), 1740 (methyl ester), 1645 (3-keto) and (aromatic) cm^{-1}.

The n.m.r. spectrum δ : 1H broad singlet 9.57 (indole NH); 4H multiplet 7.00–7.83 (aromatic); 1H broad quartet 5.51, $J = 7$ Hz and 3H broad doublet 1.73, $J = 7$ Hz (exocyclic ethylidene); 3H singlet 3.53 (methyl ester); 3H singlet 2.52 (*N*-methyl). Mass spectrum: 352 (M^+), 293 (M-$COOCH_3$), 180, 166, 158, 122 *m/e*.

Anal. Calcd. for $C_{21}H_{24}N_2O_3$: C, 71.6; H, 6.9; N, 8.0; O, 13.6. Found: C, 71.5; H, 6.8; N, 8.0; O, 13.6.

Kinetics of Thermal Decomposition of Aqueous Perchloric Acid

M. Patricia Henderson, Viola I. Miasek, and T. W. Swaddle[1]
Department of Chemistry, The University of Calgary, Calgary 44, Alberta

Received August 27, 1970

Thermal decomposition of 1.1–6.6 *m* aqueous perchloric acid at 295–322° yields oxygen, chlorine, and a small quantity of hydrochloric acid. The initial rates of decomposition have been measured, using a perchlorate ion activity electrode, and show 3.5 order dependence on the stoichiometric perchloric acid concentration; the corresponding rate coefficient and activation energy at 300.0° are $3.1 \times 10^{-7}\ m^{-2.5}\ s^{-1}$ and 84 kcal $mole^{-1}$, respectively. The order of reaction with respect to time is less than 3.5 and depends upon the initial perchloric acid concentration; this effect is due to acceleration of the decomposition by the reaction products, notably chloride ion. It is suggested that the rate-determining step in the decomposition of aqueous perchloric acid is the reaction of two undissociated $HClO_4$ molecules to give H_2O, ClO_3, and ClO_4.

Perchloric acid is used extensively in physical studies of phenomena in aqueous solution, since it is the strongest of the common acids and also because its anion has remarkably little tendency to form complexes with metal ions. The aqueous acid is, however, thermodynamically unstable ($\Delta G^0 = -26.3$ kcal/$mole^{-1}$ at 25° for the hypothetical 1 *m* solution (1)) with respect to decomposition to oxygen, chlorine, and water, and it is clear that the kinetics of this decomposition must be known if the acid is to be used in extending studies of aqueous electrolyte solutions to high temperatures.

Accordingly, the present study was designed primarily to provide empirical rate data on the decomposition of aqueous perchloric acid as a function of temperature, and over a concentration range which would include the commonly-chosen "swamping electrolyte" values, 1–6 *m*. A literature search for such information was unsuccessful, although it has been reported (2) that no chlorine, DOCl, $DClO_2$, or $DClO_3$ can be detected spectroscopically in 1 *m* $DClO_4$ after several days in a titanium vessel with sapphire windows at 250°. On the other hand, the decomposition of 83–100% $HClO_4$ has received considerable attention (3–8), as has the decomposition of $HClO_4$ vapor (9–12).

Experimental

All the stock chemicals used in this study were "Baker Analyzed" reagent grade, with the exception of ammonium nitrate (Matheson, Coleman and Bell) and sodium nitrate (Fisher Certified reagent). The perchloric acid (72%) was used without further purification; the experimental results were independent of the manufacturer's batch. Lithium perchlorate trihydrate was made from lithium carbonate and perchloric acid. Distilled water was passed through Barnstead deionizer and organic removal cartridges before use. Red mercuric oxide was used as the primary standard in acidimetry. Spectrophotometric measurements were made using a Cary Model 15 spectrometer.

The pressure vessels used consisted of a cylindrical body (2.54 cm i.d. × 4.60 cm o.d.) of ATL-40 commercially pure titanium, 0.2% palladium alloy (Atlas Titanium, Welland, Ontario), with a plug of the same material, such that the cavity volume was 62.0 cm^3. The seal between plug and body was effected with a Teflon gasket contained between two Ti–0.2%Pd rings, after the manner of Gill and Marshall (13). Retaining pressure was applied to the plug through a bearing ring which transmitted the thrust of six bolts located in the top of the externally-fitted stainless-steel screw cap.

The Ti–0.2%Pd alloy was selected because of its high resistance to attack by chlorine in the presence of water, together with its low susceptibility to crevice corrosion (which is a particularly serious hazard where Teflon gaskets are used and where chloride ion may be present) (14). However, it was found that 6 *m* $HClO_4$ attacked the metal appreciably at 300°, with the production of an orange solution containing titanium, evidently in the form of the familiar Ti(IV)–peroxy complexes. Accordingly, the vessels were fitted with silica liners with loosely-fitting caps, for the purpose of kinetic studies involving $HClO_4$ at high temperatures; attack of the titanium by the gaseous reaction products was then negligible except when chloride ion was added in large amounts to the $HClO_4$, in which case very high chlorine pressures were developed and some $TiCl_4$ fumes were observed on opening the vessels. The volume occupied by the silica liner and its cap was 14.2 cm^3, and the capacity of the liner was about 30 ml.

Thermostating of the pressure vessels was achieved with a Blue M Conwate CW-160HF-1 forced-convection oven. The reaction temperature was measured with an iron–constantan thermocouple in conjunction with a Leeds–Northrup 742523-All potentiometer. A Thermoelectric Icell provided the cold-junction reference temperature (0.00 to 0.05°), and the hot junction was en-

closed in a thin-walled Pyrex sheath and immersed in Dow-Corning 560 silicone fluid contained in a dummy pressure vessel. The thermocouple was standardized frequently, either against a platinum resistance thermometer traceable to N.B.S., or against Fisher T-421 Ther-Metric fusion-point standards (notably anthraquinone, triple point 284.59 ± 0.05°).

With correct positioning of the pressure vessels in the oven and adequate stability of the room temperature, the reaction temperatures were constant within ±0.2° or better in the course of a kinetic experiment; where larger temperature uncertainties are stated, these reflect differences in the absolute value of the thermoregulator set-point from one set of experiments to another.

A Lauda NS-HT thermostat bath was used for calibrations against the platinum resistance thermometer, and for some experiments involving sampling of the gaseous reaction products. The latter employed the same pressure vessels but with the usual plug replaced by one having a long stem protruding 10 cm beyond the pressure vessel cap. This plug, of Ti–0.2% Pd alloy, had a narrow axial bore which led to a stainless-steel high-pressure valve; the upper part of the plug stem extended out of the bath and was cooled with circulating water so as to protect the valve from corrosion. However, decomposition of the best available bath oils (Lauda Ultratherm 330S Circulating Fluid, and Dow Corning 560 Silicone Fluid) was so extensive when operating at 300° that the NS-HT bath could be used only for a few brief experiments and calibrations.

In a typical kinetic run, 20.0 ml aliquots of perchloric acid solution, of which both the hydrogen-ion and perchlorate contents had been measured, were placed in the silica liners, capped, and sealed in the pressure vessels under a nitrogen atmosphere. The vessels were placed in the overheated oven, so that the oven and vessel temperatures converged more rapidly upon the set-point. Thermal equilibrium was achieved in less than 50 min even at 322°, but the reaction time was reckoned from the time at which the monitored dummy vessel was within 5° of the set-point (in effect, 35–40 min after insertion of the vessels). After a chosen reaction time, a vessel would be removed from the oven and chilled rapidly with cold water. The vessels were opened cautiously in the hood, the compressed gaseous products (chlorine and oxygen) being allowed to dissipate before removal of the screw-cap, and the contents of the liner and the condensate in the pressure vessel were transferred quantitatively to 50 ml graduated flasks and made to the mark with water.

After dilution so that $0.01\ M < [ClO_4^-] < 0.10\ M$, the ionic strength was adjusted to 1.0 M with sodium nitrate, and the pH was made to about 5 with the minimum amount of concentrated NaOH solution, added with a syringe burette. The perchlorate ion concentration was then determined with an Orion 92-81 perchlorate ion activity electrode in conjunction with a Beckman Research Model pH Meter and an Orion 90-02 double junction reference electrode in which the outer chamber was filled with 10% NH_4NO_3 solution.

The sample was thermostated (20.5 ± 0.1°) and gently stirred magnetically while reading the electromotive force (e.m.f.); most of the dissolved chlorine escaped to the air, and in any event did not affect the electrode response. The e.m.f. reading was converted to perchlorate ion concentration using a calibration curve which had been set up in the same way with five standard $HClO_4$ solutions spanning the range 0.01–0.10 M; plots of e.m.f. *vs.* log $[ClO_4^-]$ were invariably linear to a high degree, but a fresh calibration curve was necessary for each set of measurements. The stoichiometric perchlorate concentration so determined was accurate to ±2.0% or better, but other factors such as leakage of gases during the kinetic runs could have introduced greater uncertainties. In general, triplicate kinetic measurements agreed to within ±3.0%. Concentrations were measured on the molar scale, for convenience, and subsequently converted (where possible) to the molal scale, using the density data of Markham (15) as adapted by Robertson (16).

Hydrogen ion concentrations were measured in a similar way, prior to pH adjustment, using a Beckman Futura 39311 glass electrode.

Potentiometric titration of perchlorate with tetraphenylarsonium chloride (17) was also tried, using the Gran method (18), but the procedure was no more accurate and much less convenient than the direct-reading method, and in any event standardization of the arsonium salt solution is necessary.

The chloride ion contents of some samples were determined using an Ag/AgCl electrode, although the residual chlorine in the solution affected the electrode response. Nevertheless, it was established that chloride ion was not a major reaction product; such HCl as was present in the solutions at 20° probably came from reactions 1 and 2.

$$[1] \qquad Cl_2 + H_2O \rightleftharpoons HOCl + H^+ + Cl^-$$

$$[2] \qquad 2HOCl \rightarrow 2HCl + O_2$$

Attempts were made to follow the decomposition of $HClO_4$ by iodometric titration of the chlorine produced, but the reproducibility of the results was poor and the yields of chlorine were less than those expected on the basis of the corresponding perchlorate concentrations. These inconsistencies arose partly from the hydrolysis of chlorine to HOCl and HCl, but mainly from leakage of gases from the reaction vessel on chilling, which often lead to gasket failure. There was no evidence of high-temperature leakage in any of the experiments referred to in this report.

Results

Reaction Products

The absence of chlorine gas, and the absence of a detectable increase in $[Cl^-]$ or a decrease in $[H^+]$ or $[ClO_4^-]$, showed that 4 m $HClO_4$ does not undergo significant thermal decomposition in 13 h at 250°; at 300°, however, much chlorine was produced in the same time. The absorption spectrum of the latter solution showed a pronounced maximum at 325 mμ which is characteristic of aqueous chlorine (19), but the absence of other features in this region of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

spectrum indicated that ClO_2, ClO_2^-, and $HClO_2$ were not present in significant amounts (20).

Chloride ion was present in the decomposed $HClO_4$ solutions to the extent of 4% or less of the total chlorine in the decomposition products. This can be accounted for in terms of equilibrium 1, which is rather rapidly established at room temperature and for which the equilibrium quotient is $4 \times 10^{-4}\ M^2$ at 25° (21). Reaction 1 is endothermic ($\Delta H^0 = 5.06$ kcal mole^{-1}) at 25°, but the data of Connick and Chia (21) suggest $\Delta C_p^0 = -95$ cal deg^{-1} mole^{-1} at 25°, and, if this does not change greatly with temperature, it can be argued that equilibrium 1 will lie even further to the left at 300°. Thus, the chloride concentrations at 300° will remain rather small, despite the high pressures of chlorine gas developed in $HClO_4$ decompositions.

The direct vapor-phase hydrolysis of chlorine to HCl and oxygen is not favored thermodynamically at 300° (22, 23). However, HCl and O_2 may be the main products of aqueous $HClO_4$ decomposition at the critical temperature (24).

In the decomposition of pure aqueous $HClO_4$, the decrease in perchlorate ion content to a stoichiometric concentration c was invariably accompanied by a corresponding decrease in the hydrogen ion concentration to an amount exceeding c but not greater than 1.06 c. The slight excess of $[H^+]$ over $[ClO_4^-]$ is evidently a consequence of reactions 1 and 2, and it was therefore necessary to follow the progress of the decomposition of aqueous $HClO_4$ by analyzing for the stoichiometric perchlorate concentration, c. It is, however, clear that the overall stoichiometry of decomposition is

$$[3] \qquad 4H^+ + 4ClO_4^- \rightleftharpoons 2H_2O + 2Cl_2 + 7O_2$$

Kinetics of Decomposition of Aqueous Perchloric Acid

Preliminary results obtained at 300° showed that the *apparent* order of reaction with respect to *time* was dependent upon the initial concentration of c_0 of the perchloric acid. Thus, the perchlorate concentrations plotted against time in Fig. 1 refer to $c_0 = 6.61\ m$ and require an order of 2.6 in stoichiometric perchloric acid with respect to time, while the corresponding order is 1.5 when $c_0 = 2.26\ m$ (as is illustrated by the typical linear plot of $c^{-0.5}$ *vs.* time in Fig. 2). Similarly, at 306°, the apparent order with respect to time was 2.0 for $c_0 = 3.60\ m$, and at all temperatures studied the order was 1.5 when $c_0 = 2.26\ m$. These apparent orders of reaction are purely empirical and do not necessarily have any theoretical significance; they do, however, represent the experimental data adequately to at least 80% completion of reaction.

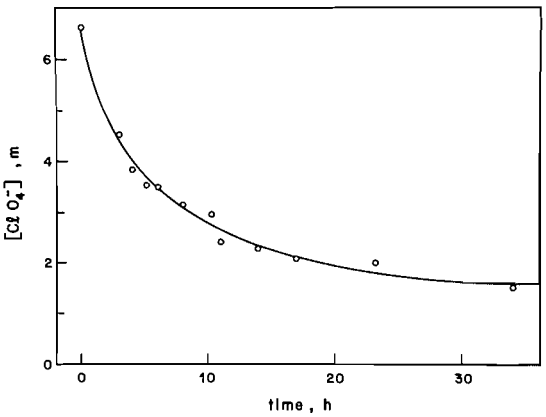

FIG. 1. Decomposition of 6.61 m perchloric acid at 300.0°.

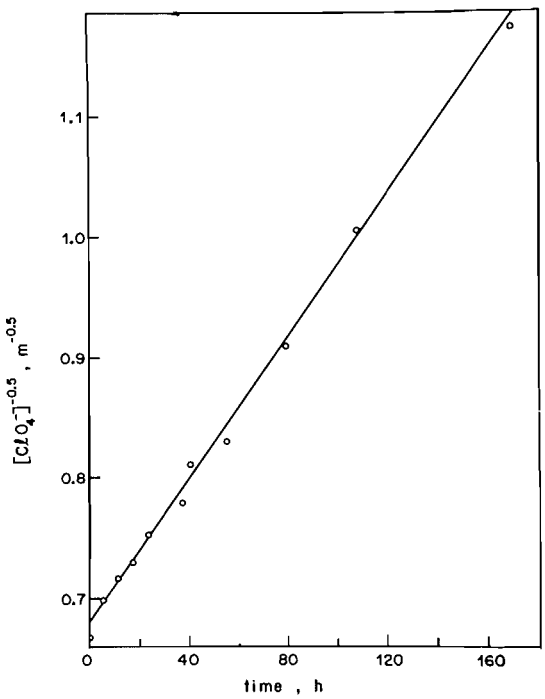

FIG. 2. Apparent 1.5-order kinetics of decomposition of 2.26 m perchloric acid at 300.0°.

TABLE 1. Initial rates of decomposition of aqueous perchloric acid

c_0, m	Temperature (°C)	$-dc/dt$ (m s^{-1}) as $c \rightarrow c_0$
6.61	300.0	2.2×10^{-4}
5.06	300.0	8.7×10^{-5}
3.59	300.0	2.3×10^{-5}
2.26	300.0	5.6×10^{-6}
1.09	300.0	5.3×10^{-7}
4.63	306.5	1.7×10^{-4}
3.60	306.0	5.1×10^{-5}
2.26	306.0	9.8×10^{-6}
1.02	306.5	1.1×10^{-6}

These results are typical of reactions in which the products cause acceleration of the reaction rate (25), and it is therefore necessary to determine the *true* order of the initial decomposition reaction (*i.e.*, the order with respect to *concentration*) by graphical estimation of the initial rate of decomposition, $-dc_0/dt$, as a function of the initial perchloric acid concentration c_0. The estimation of initial rates is subject to rather large uncertainties, as will be obvious from Fig. 1 (this being a worse case than most), but log–log plots of the data of Table 1 show very clearly that the order of reaction is 3.50 ± 0.05, at 300 and 306° at least

$$[4] \qquad -dc/dt = k_{3.5}c^{3.5}$$

where $k_{3.5}$ has the weighted mean values of 3.1×10^{-7} $m^{-2.5}$ s^{-1} at 300° and 5.7×10^{-7} $m^{-2.5}$ s^{-1} at 306.0°, the error limits being ±10% in either case.

In view of the difficulty of determining the initial rates of decomposition with sufficient accuracy from the sharply curved plots of c *vs.* time, the activation energy E was calculated using the *apparent* (1.5-order) rate coefficients for a fixed initial molality (2.26 m) of the acid. It is immaterial, for this purpose, that the apparent order with respect to time has no theoretical validity. We can write

$$[5] \qquad \ln(-dc_0/dt) = \ln k' + n' \ln c_0 = \ln k + n \ln c_0$$

where n and n' are the true and apparent reaction orders, and k and k' are the corresponding rate coefficients, respectively. Then,

$$[6] \qquad \ln k = (n' - n) \ln c_0 + \ln k' = \text{constant} + \ln k'$$

so that a plot of $\ln k'$ against $1/T$ will have the same slope as the Arrhenius plot for the true reaction order, so long as n' is independent of temperature and represents the data accurately.

Values of $k'_{1.5}$ over a 27° range of temperature are listed in Table 2. These, and all other data given in this article (except where otherwise stated), refer to 20.0 ml samples with a gas space of 27.8 cm^3 at 20°. Strictly speaking, a correction should be applied to the molalities measured at 20° for water removed into the vapor phase at high temperatures. This cannot be done with great accuracy, since the vapor pressure of water in aqueous $HClO_4$ at high temperatures is not accurately known, but we have assumed that it is the same fraction of the vapor pressure of pure water at high temperatures (26) as at 25° (27) and we have calculated the increase Δm in molality expected for 2.26 m $HClO_4$ at high temperatures, due allowance being made for the decrease in vapor volume brought about by expansion of the liquid phase (26). Estimates of Δm are listed in column 3 of Table 2; it will be seen that Δm is barely outside the experimental error, and accordingly we have chosen to ignore it except in column 4 of Table 2. The latter data show that the activation energy E for the thermal decomposition of dilute aqueous perchloric acid is $84._2$ kcal mole^{-1}, with a possible uncertainty of ±2 kcal mole^{-1}. The $k'_{1.5}$ data are reproduced by eq. 7 to within the experimental error

$$[7] \qquad \log_{10} k'_{1.5} = 26.37 - (18\,400/T)$$

The above analysis assumes that the decomposition of $HClO_4$ occurs in the solution, and not the vapor, phase. This supposition was shown to be correct by partially decomposing 15, 20, and 25 ml aliquots of 2.26 m $HClO_4$ at 306.0° for identical periods of time. The vapor spaces in the three vessels would be 26.3, 19.2, and 12.0 cm^3, and the relative rates of disappearance

of $HClO_4$ should therefore have been about 1.4:1.0:0.6 if decomposition of $HClO_4$ vapor, in equilibrium with the dissolved acid, were the main contributor to the reaction rate (the negligible $HClO_4$ content of the condensate formed outside the liner proved that most of the $HClO_4$ remains in solution even at 322°). In fact, the reaction rates were rather similar and actually showed the opposite trend, if any at all (*e.g.*, after 90.8 h, the perchlorate concentrations remaining in the 20 and 25 ml samples were 0.507 and 0.490 *m*, respectively).

Addition of broken silica glass, such that the area of silica in contact with the solutions was more than doubled, produced no significant changes in the percentage decompositions per given time interval, within the experimental error. Thus, in 35.3 h, at 306.0°, 15 ml of 2.26 *m* $HClO_4$ decomposed to 1.26 *m* in the presence of about 5 ml crushed silica, while the corresponding figure for 20 ml of the same acid without added silica was 1.25 *m*; similarly, after 73.0 h, the corresponding data were 0.65 and 0.69 *m*. It may therefore be concluded that the reaction is a homogeneous one, in solution.

Thus far, the reaction order has been expressed in terms of the stoichiometric $HClO_4$ concentration; if the acid is completely dissociated, however, this order will represent the sum of the orders with respect to $[ClO_4^-]$ and $[H^+]$. The reaction rate is directly proportional to the hydrogen-ion concentration raised to some power, since 2.26 *m* $LiClO_4$ underwent no decomposition (within the limits of detection) under conditions which brought about more than 50% decomposition of 2.26 *m* $HClO_4$.

The results of series of experiments at 300.0° and roughly constant ionic strength ($[H^+] + [Li^+] = [ClO_4^-] = 2.2\ m$) are summarized in Table 3 in terms of extrapolated initial perchlorate decomposition rates. A plot of log $(-dc_0/dt)$ *vs.* log $[H^+]_0$ indicates an order of 1.2 (or 1.17 ± 0.06) with respect to hydrogen ion.

In order to check the order of reaction with respect to perchlorate ion directly, or to learn how the $HClO_4$ decomposition rate responds to changes in the ionic strength, one must find an inert, non-basic, anionic substitute for perchlorate ion with a low tendency to ion-pairing, so that the ionic strength or the acidity can be maintained at will. Of the common anions, only the hydrogen sulfate ion, HSO_4^-, behaves as a univalent, non-basic, non-acidic ion between 300 and 400° (28), and a solution, 2 *M* in $LiClO_4$ and 3 *M* in $NaHSO_4$ at 20°, showed no decomposition after 55 h at 294.5°.

*$[H^+] + [Li^+] = [ClO_4^-] \approx 2.2\ m$.

The effect of added $NaHSO_4$ on the rate of decomposition of 2 *M* (20°) $HClO_4$ is illustrated by the data of Table 4, which show that a modest but definite "medium" or "ionic strength" effect causes the rate of $HClO_4$ decomposition to decrease as the electrolyte concentration increases.

Semi-quantitative experiments, in which the extent of decomposition of 3.5 *m* $HClO_4$ at 300.0° was compared with that of 2.26 *m* $HClO_4$/1.2 *m* $H[HSO_4]$ mixture, and 6.61 *m* $HClO_4$ with 2.26 *m* $HClO_4$/4.3 *m* $H[HSO_4]$, confirmed that the true order of reaction with respect to perchlorate ion was roughly 2 at these concentrations of electrolytes.

When lithium chloride was added to the $HClO_4$ before thermal decomposition, greatly increased yields of chlorine were obtained, and much H^+ and Cl^- were consumed. The rate of loss of perchlorate was accelerated by the addition of moderate amounts of chloride. The decomposition of 2 *M* (25°) $HClO_4$ at 294.5° in 23.3 h showed the same general features as the data for 55 h listed in Table 5.

It should be noted, from Table 5, that the decrease $\Delta[H^+]$ in hydrogen-ion concentration equals the sum of $\Delta[ClO_4^-]$ and $\Delta[Cl^-]$, within the experimental uncertainty. The apparent near-

constancy of $\Delta[ClO_4^-]$ in the presence of added chloride is presumably fortuitous; acceleration by chloride is evidently compensated for by reductions in the reaction rate caused by the rapid exhaustion of the hydrogen ion content. The effect of chloride ion requires the presence of hydrogen ion, since it was found that 2 *M* (25°) $LiClO_4$ containing 2 *M* (25°) LiCl underwent no detectable loss of perchlorate or evolution of chlorine in 55 h at 294.5°.

Discussion

The initial rate of decomposition of dilute aqueous $HClO_4$ decreases approximately threefold for each 10° decrease in temperature, and approximately ten-fold for each halving of the initial concentration of $HClO_4$. These large effects are reflections of the unusually high activation energy (84 kcal $mole^{-1}$) and order of reaction (3.5) with respect to the substrate. Since the initial rate of decomposition of 1 *m* $HClO_4$ is small (5×10^{-7} *m* s^{-1}) at 300°, it can be stated that the rate is negligibly small for 1 *m* $HClO_4$ at 250° and for the 0.2 *m* acid at 300°, as far as experiments of about a day's duration are concerned. Perchloric acid may therefore have considerable utility in physico-chemical studies of high temperature aqueous solutions, although direct attack by $HClO_4$ on oxidizable solute species such as transition-metal ions may limit its applicability.

The observed non-integral orders of reaction with respect to hydrogen ion (about 1.2) and perchlorate ion (by difference, about 2.3) prevent the unambiguous assignment of a reaction mechanism. The reaction was found to be somewhat retarded by high concentrations of inert electrolyte ($NaHSO_4$), and so the overall molecularity of reaction with respect to the stoichiometric $HClO_4$ concentration is probably 4. The orders of reaction with respect to H^+ and ClO_4^- separately are each greater than 1, and it is probable that the molecularity is 2 with respect to each of these species. The "ionic strength" concept, used in deriving the order in H^+, may not be reliable at these high temperatures, at which the product of the solvent dielectric constant and the absolute temperature has less than half its room temperature value; this is particularly unsatisfactory since the substrate ($HClO_4$) comprised most or all of the electrolyte present in many of the experiments. There is also the possibility that the perchloric acid is appreciably associated near 300°.

However, if we assume that the molecularities with respect to H^+ and ClO_4^- are both 2, then the stoichiometric mechanism is probably

$$[8] \qquad H^+ + ClO_4^- \overset{K}{\rightleftharpoons} HClO_4$$

$$[9] \qquad 2HClO_4 \xrightarrow{\text{slow}} \text{intermediates} \xrightarrow{\text{fast}} H_2O + Cl_2 + \tfrac{7}{2}O_2$$

Values of the association constant *K* of $HClO_4$ are not accurately known even for temperatures below 100°; the available estimates are conflicting (27, 29), but it seems that not more than 1% of the $HClO_4$ in the solutions used in the present study could be associated at 25°. Reaction 8 is likely to be endothermic with a positive molal heat capacity change, so that association could be extensive in the temperature range of interest (295–322°). However, for the much weaker acid HCl, *K* is only about 30 m^{-1} at 306° (30), while sulfuric acid (which, as $H[HSO_4]$, is a close analogue of $H[ClO_4]$) is recognized (28) to behave as a strong uni-univalent electrolyte between 300 and 400°. It therefore seems reasonable to assume that only a small fraction of the $HClO_4$ is associated at 295–322°, so that the mechanism of reactions 8 and 9 would give rise to a fourth-order rate law.

The nature of reaction 9 is a matter for speculation, since we detected no intermediates. The reversible condensation of two $HClO_4$ molecules to give water and the relatively unstable anhydride Cl_2O_7 has been suggested (3, 4, 6, 7) for the decomposition of 83–100% $HClO_4$, but Pearson (31) considers this improbable, and besides it is scarcely likely to be relevant to dilute aqueous $HClO_4$.

The rate of homogeneous pyrolysis of $HClO_4$ vapor is first order in molecular $HClO_4$, and has an activation energy of 45.1 kcal mole^{-1}, which is close to the HO—ClO_3 bond energy of 48.3 kcal mole^{-1} (9); in contrast, the H—$OClO_3$ bond energy is 112 kcal mole^{-1} (32), and the O—ClO_3H energy is over 105 kcal mole^{-1} (5). It is therefore highly probable that reaction 10 is the rate-determining step in the homogeneous gas-phase pyrolysis of $HClO_4$.

[10] $$HClO_4 \rightarrow HO\cdot + \cdot ClO_3$$

This is supported by Fisher's demonstration (11) that ClO is a major reaction intermediate, along with some ClO_2; these probably originate from ClO_3 and ClO_4. The rapid reactions following [10] are probably [11] through [16].

[11] $$HClO_4 + \cdot OH \rightarrow H_2O + ClO_4\cdot$$

[12] $$ClO_4\cdot \rightarrow ClO_2 + O_2$$

[13] $$ClO_2 \rightarrow Cl\cdot + O_2$$

[14] $$2Cl\cdot \rightarrow Cl_2$$

[15] $$\cdot ClO_3 \rightarrow \cdot ClO + O_2$$

[16] $$2\cdot ClO \rightarrow Cl_2 + O_2$$

In contrast to the gas-phase reaction, the decomposition of dilute aqueous $HClO_4$ appears to be bimolecular in undissociated $HClO_4$, and we therefore propose that the rate-determining step in solution involves association of two $HClO_4$ molecules through interaction of their strong —$O^{\delta-}H^{\delta+}$ dipoles. The resulting geometry will be favorable to the elimination of H_2O and the formation of the fragments $\cdot ClO_3$ and $\cdot ClO_4$ (reaction 17) which would subsequently decompose rapidly to oxygen and chlorine via reactions 12 through 16.

[17] $$O_3Cl—OH + H—OClO_3 \xrightarrow{\text{slow}} ClO_4\cdot + \cdot ClO_3 + H_2O$$

It will be seen that this is the same as the probable gas-phase mechanism outlined above, except that the sequential reactions 10 and 11 have coalesced into a single synchronous step. It also resembles the condensation mechanism favored by Zinoviev *et al.* (3, 4, 6, 7), except that independent ClO_3 and ClO_4 fragments are the products of the initial step, rather than Cl_2O_7.

If the H—OH bond energy is taken to be 117 kcal mole^{-1}, then the minimal activation energy for step 17 in the gas phase is 43 kcal mole^{-1}; in solution, the polar molecule $HClO_4$ would be further stabilized relative to the products of step 17, so that the activation energy for this step may be 50 kcal mole^{-1} or more. The enthalpy change of reaction 8 at about 300° can only be guessed at, but it will almost certainly be quite endothermic, and, by analogy with HCl (for which ΔH^0 is about 17 kcal mole^{-1} (30) for association of the aqueous acid), we can anticipate that $10 < \Delta H^0 < 25$ kcal mole^{-1}. Hence, for a mechanism in which reaction 8 (taken *twice*) is followed by the rate-determining step 17, we can expect an overall activation energy greater than 70 and perhaps as much as 100 kcal mole^{-1}; the observed value is 84 kcal mole^{-1}.

The addition of chloride ion to aqueous perchloric acid must reduce the free H^+ concentration at high temperatures by forming molecular HCl (30), yet it is observed that the decomposition of $HClO_4$ is actually faster when chloride is added. Evidently, a direct reaction can occur between HCl and ClO_4^- (or possibly $HClO_4$). The data of Table 5 show that, if enough chloride is present, three moles of chloride are consumed for each mole of perchlorate decomposed. The stoichiometry of the chloride-dependent pathway is therefore,

[18] $$4H^+ + 3Cl^- + ClO_4^- = 2Cl_2 + 2H_2O + O_2$$

It will be noted that, regardless of what fraction of the decomposition goes by reaction 18, the change in hydrogen ion concentration, $\Delta[H^+]$, is given by eq. 19, which is verified by the data of Table 5.

[19] $$\Delta[H^+] = \Delta[Cl^-] + \Delta[ClO_4^-]$$

Reaction 18 is best accounted for by the mechanistic sequence [20]–[23], which, like the gas-phase pyrolysis scheme of Fisher (11), involves the rapid decomposition of ClO_3 to ClO and oxygen. Other plausible mechanisms which do not involve this step give the wrong overall stoichiometry. Reaction 23 will be complex.

$$[20]\quad H^+ + HCl + ClO_4^- \xrightarrow{\text{slow}} Cl^\cdot + H_2O + {}^\cdot ClO_3$$

$$[21]\quad 2Cl^\cdot \xrightarrow{\text{fast}} Cl_2$$

$$[22]\quad ClO_3^\cdot \xrightarrow{\text{fast}} ClO^\cdot + O_2$$

$$[23]\quad ClO^\cdot + 2HCl \xrightarrow{\text{fast}} H_2O + \tfrac{3}{2}Cl_2$$

The observed acceleration of the decomposition of pure aqueous $HClO_4$ by its own decomposition products (specifically Cl_2) can be attributed, at least in part, to the production of small amounts of chloride by reactions 1 and 2. It might be noted that bromide (33) and iodide (34) ions both can cause reduction of aqueous $HClO_4$ at temperatures as low as 100–135°.

Reactions of Some Allylic and Propargylic Halides with Nucleophiles Analogous to Those Present in Proteins and Nucleic Acids

J. Bryan Jones and David W. Hysert[1]

Lash Miller Chemical Laboratories, Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received June 12, 1970

The relative alkylating capabilities of crotyl chloride, allyl bromide, and 1-bromo-2-butyne with respect to compounds containing thiol, imidazole, primary amino, and methylthio functions representative of those present in cysteine, histidine, lysine and methionine residues have been studied using 2-bromoacetophenone as the reference alkylating agent.

Canadian Journal of Chemistry, 49, 325 (1971)

The use of reagents capable of effecting chemical modifications of proteins (including enzymes and immunoglobulins) and nucleic acids has proven of great value in recent years (1–5). However, although the spectrum of modifications which can now be achieved is quite broad it is clear that there remains considerable scope for improving the functional group- and stereospecificity (or selectivity) of such reagents.

In this regard we have initiated a programme designed to explore and evaluate the feasibility of incorporating *cis*- and/or *trans*-ethylenic and acetylenic bonds into alkylating functions in order to exploit their unique geometrical properties with respect to specific and stereochemically controlled protein or nucleic acid modifications.[2]

The types of compounds considered first were among the simplest which could be chosen, *viz.* those containing one ethylenic or acetylenic bond only. Although most of the alkylating groups which had already proven useful (1–5) would be expected to be quite reactive when attached to simple unsaturated carrier moieties of this kind, it was decided initially to evaluate the hitherto biologically untried alkylating agents of the allylic and propargylic halide types.

The compounds selected as being representative of allylic and propargylic halides were crotyl bromide (**1**), crotyl chloride (**2**), allyl bromide (**3**), and 1-bromo-2-butyne (**4**). 2-Bromoacetophenone (**5**) was also included in the survey for comparison purposes and as a reference reagent whose utility and rates of reaction with certain protein nucleophiles had been established previously (2). The protein nucleophiles which should be most susceptible to alkylation by the above reagents under conditions of physiological p*H* are cysteine thiol, histidine imidazole, lysine ε-amino, and methionine methylthio groups. However, since in previous related studies, difficulties in isolating and identifying products had arisen when appropriate amino acid derivatives models had been used, it was decided to carry out the first experiments using even simpler model compounds containing functions analogous to those of the amino acids of interest in order to simplify the structural analyses involved. In addition, on the basis of past experience (7, 8) it was felt that delineation of the range of reactions to be expected and the provision of p.m.r. spectra for reference purposes would prove invaluable in the design and analyses of the subsequent amino acid and protein alkylation experiments. The model compounds chosen[3] were, respectively, α-toluene thiol (**6**), imidazole (**7***a*), and *N*-methylimidazole (**7***b*),[4] benzylamine (**8**) and benzyl methyl sulfide (**9**).

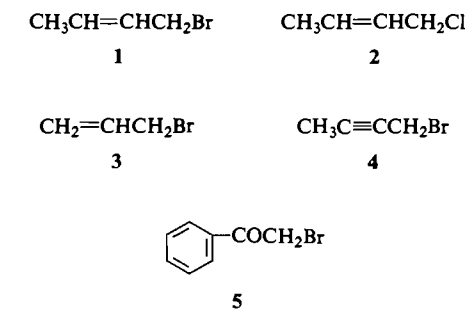
The guanidinium group of arginine (pK_a 11.6–12.1 (1)) was also considered, using guanidine (**10**) as the model, even though *in vivo* it is always largely protonated and thus retains very little nucleophilic character. However, it was felt that by using a suitably constructed bridge, *exo*-arginine residues on appropriate proteins might

[1]Abstracted in part from the M.Sc. thesis of D. W. H., University of Toronto, Toronto, Ontario, 1968.

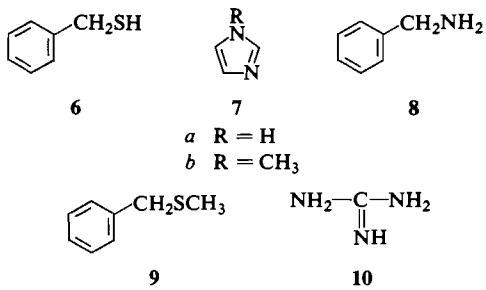
[2]The potential of the geometry of the acetylenic bond with respect to the design of enzyme probes has recently been recognized independently by Latif and Kaiser (6).

[3]The factors considered in choosing these model nucleophiles included the similarity of their pK_a's to the corresponding *in vivo* group, and the ease with which the p.m.r. spectra of the possible products could be interpreted (7, 8).

[4]*N*-methylimidazole also provided a model for the guanine residues of DNA and RNA since compounds capable of effecting its *N*-alkylation should also react with N-7 of guanine (7).



be brought into close enough proximity with an alkylating function for any unfavorable rate of the alkylation reaction to be counterbalanced sufficiently for significant modification to be achieved. That such a possibility was not unreasonable was substantiated by the successful active site and other arginine modifications reported recently (3) using dicarbonyl reagents.[5]



All of the compounds **1**–**10** were available commercially except for 1-bromo-2-butyne which was readily prepared by bromination of 2-butyn-1-ol. Unfortunately, after the investigation had been under way for some time it became necessary to discontinue the studies on crotyl bromide (**1**) since its tendency to isomerize to a mixture containing 15% of 3-bromo-1-butene at equilibrium (9) precluded the collection of any reproducible data. Attention was therefore concentrated on a comparison of the relative alkylating abilities of crotyl chloride (**2**), allyl bromide (**3**), 1-bromo-2-butyne (**4**), and 2-bromoacetophenone (**5**). No attempt was made at this preliminary stage to separate the *cis* and *trans* isomers present in the commercial crotyl chloride since both isomers have been shown to undergo nucleophilic substitution at approximately the same rates (10).

The experimental procedures followed were relatively straightforward and most of the reactions studied proceeded as expected and do not warrant individual discussion. Accordingly the relevant data for the reactions of crotyl chloride, allyl bromide, 1-bromo-2-butyne, and 2-bromoacetophenone with α-toluenethiol, imidazole, *N*-methylimidazole, benzylamine, and benzyl methyl sulfide have been summarized in Chart 1 and Table 1. As Table 1 shows, no attempt was made at this stage to carry out the reactions in aqueous media approximating more closely the expected *in vivo* conditions in order to avoid the complications which would undoubtedly have arisen from competitive hydrolysis of the alkylating agents (11).

The alkylations of α-toluenethiol all proceeded very smoothly in the presence of 1 equiv of base to give easily isolable products in high yields. Further alkylation of the sulfide products **11***a*–*d* to give sulfonium salts did not occur under the mild reaction conditions employed.

The reactions with imidazole (**7***a*) and *N*-methylimidazole (**7***b*) were rather more difficult to control owing to the ease with which the primary alkylation products **12** reacted with a second mole of alkylating agent to give the bisalkylated salts **13**. The mono-alkylated products were relatively easily isolated and characterized; in contrast, compounds **13** and **14** were much less tractable and proved no exception to the general rule that doubly alkylated imidazolium salt derivatives are difficult to purify (12–15). In fact owing to the extremely deliquescent natures of the series of salts **13** and **14** only the 2-bromoacetophenone products **13***d* and **14***d* could be satisfactorily isolated and characterized and the structural assignments of **13***a*–*c* and **14***a*–*c* were made mainly on the basis of their p.m.r. spectra. The purest samples of the imidazolium salts **13***a*–*c* were obtained by the appropriate alkylation of the corresponding mono-alkylated compounds **12***a*–*c*.

The benzylamine reactions presented no problems and each of the mono- and bisalkylated derivatives were isolated without difficulty. However, since the phenacyl compounds **15***d* and **16***d* were known to be unstable as the free

[5]These reactions occur most readily at p*H* 8–9 and an initial nucleophilic attack of a carbonyl group by the guanidinium moiety is implicit in such modifications.

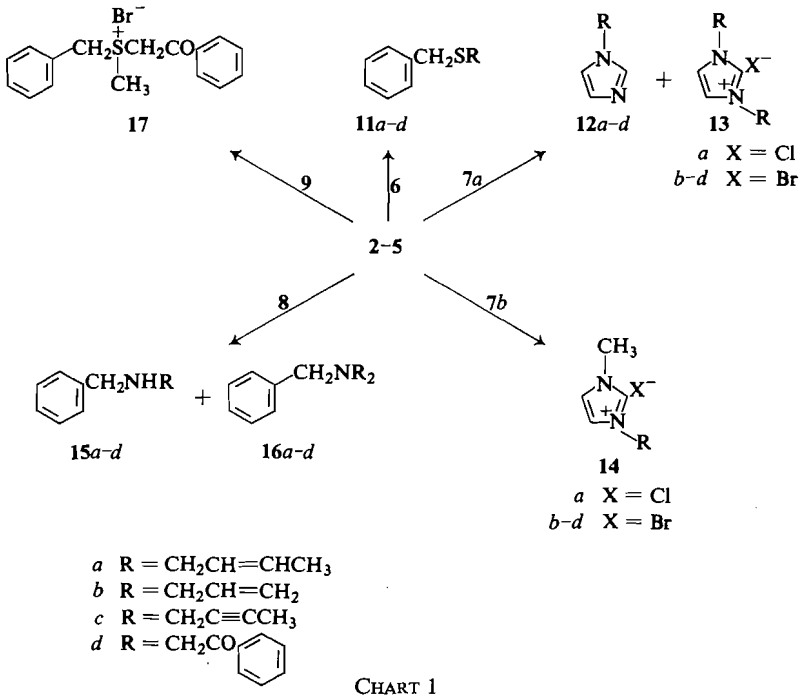

CHART 1

bases (16) they were isolated as the hydrobromide salts.

Although as expected from its ability to alkylate the α-chymotryptic methionine 195 residue (2), 2-bromoacetophenone reacted smoothly with benzyl methyl sulfide (**9**) to give the corresponding sulfonium salt **17**, no such products could be isolated upon treatment of **9** with crotyl chloride, allyl bromide or 1-bromo-2-butyne under reaction conditions varying from mild (organic solvents, 25°) to vigorous (neat reactants, sealed tube, 150°). The inaccessibility of the latter compounds is perhaps not surprising in view of the well documented instability of simple sulfonium salts in general (17) and of unsaturated derivatives in particular (18) and in retrospect it appears that benzyl methyl sulfide was not a suitable choice as a model for the methionine *S*-methyl group.[6]

The reasons for including the guanidinium group in this survey have been outlined earlier and in order to provide an estimate of the difficulties which might be expected with the current series of alkylating agents the reaction of the most reactive of them, 2-bromoacetophenone, with the model nucleophile guanidine was studied as a function of p*H*.[7] In aqueous methanol no reaction occurred until a p*H* of 11 was approached and at p*H* 11.7 at 25° rapid, multiple (ten products by t.l.c.), reactions occurred. However, on lowering the reaction temperature to 0° a crystalline product was isolated and from the melting behavior and the spectroscopic properties of the material it was concluded that the product was the result of base-catalyzed Darzens condensation of 2-bromoacetophenone. On recrystallization of the mixture from ethanol under equilibrating conditions, the higher melting, thermodynamically more stable, *cis* (21) isomer, m.p. 154–155.5°, of 4-bromo-2,3-epoxy-3-phenylbutyrophenone was obtained exclusively. Since no reaction of guanidine with 2-bromoacetophenone could be induced at p*H*

[6]This view is substantiated by the subsequent observations that the *S*-methyl group of *N*-acetylmethionine is readily alkylated by both allyl bromide, 1-bromo-2-butyne, and 2-bromoacetophenone (19).

[7]Very few guanidine alkylations have been reported in the literature and for most of these vigorous reaction conditions were found to be necessary. However, recently it has been demonstrated that using suitably reactive reagents, such as 5-chloro-3-methyl-4-nitro-2-pyrazoline, alkylation of guanidine is facile under very mild conditions (20).

Benzyl methyl sulfide (*9*)	Crotyl chloride	Varied	—
	Allyl bromide	,,	—
	1-Bromo-2-butyne	,,	—
	2-Bromoacetophenone [1.0]	Benzene or aqueous acetone (25°)	**17** (51%)

*All yields quoted are absolute and have not been corrected for any recovered starting materials.
†Yield estimated by p.m.r.

values below those at which the latter began to undergo the self-condensation reaction no further studies on guanidine were carried out.

From the preparative reactions summarized in Table 1 the relative reactivities of the alkylating agents **2**–**5** with each of the model compounds **6**, **7***a*, **7***b*, and **8** appeared to be in the order 2-bromoacetophenone ≫ allyl bromide > 1-bromo-2-butyne ≫ crotyl chloride.

Summary and Conclusions

The data obtained indicate that, although chloro compounds probably react too slowly to be of much value, allylic and propargylic bromides (and presumably iodides) are of potential value for alkylating cysteine sulfhydryl, histidine imidazole, and lysine amino groups. In addition differences between the rates of reaction of functional groups such as those of the bromides **3** and **4** and the bromomethylketone **5** may enable selective or sequential *in vivo* modifications to be achieved.

Further structural, rate of reaction, and p*H* dependence studies on the above and more conjugated alkylating agents with amino acid derivatives, and on polyunsaturated bifunctional reagents as probes for proteins and nucleic acids are in progress.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The g.l.c. analyses were performed on an F and M 400 chromatograph fitted with glass columns containing 3.8% SE-30 or 1% NPGS on Diatoport S. The t.l.c. was carried out on Silica gel G with chloroform – methanol – ammonium hydroxide (90:15:1, v/v/v) as the developing solvent and using iodine vapor visualization. The various spectral data reported were obtained on Varian A-60 and HA-100, Perkin–Elmer 237B and 350, MS-902 or CEC 21-490, and Unicam SP 800 instruments. Tetramethylsilane was used as the internal reference for all p.m.r. spectra. All reactions were monitored by t.l.c. or g.l.c. and solvent evaporations were effected by rotary evaporation.

Materials

1-Bromo-2-butyne was prepared in 54% yield from but-2-yn-1-ol (Columbia Organic Chemicals) by the method of Ashworth *et al.* (22). All other required compounds were purchased from Fisher or Aldrich and each was repurified by fractional (including spinning band) distillation or recrystallization until the physical properties *viz.* m.p. or b.p. (and when necessary, refractive index), t.l.c., g.l.c., i.r., and p.m.r. spectra, indicated the absence of impurities.

Alkylation of α-Toluenethiol (6)[8]

(a) With Crotyl Chloride (2)

Crotyl chloride (1.81 g, 20 mmol) was added dropwise at 25° to a stirred solution of α-toluenethiol (2.48 g, 20 mmol) in methanol (30 ml) containing 10 *N* aqueous sodium hydroxide (2ml, 20 mmol). After 24 h the reaction mixture was diluted with ether (100 ml) and the precipitated sodium chloride removed by filtration. The ethereal filtrate was washed with saturated aqueous sodium chloride (50 ml), then dried ($MgSO_4$), and evaporated. Fractional distillation of the residual oil gave benzyl crotyl sulfide (**11***a*, 3.09 g, 87%), b.p. 86°/0.5 Torr (lit. (23) b.p. 137–139°/18 Torr); p.m.r. ($CDCl_3$) δ 1.64–1.74 (3H, m, CH_3C=), 2.94–3.06 (2H, m, SCH_2C=), 3.64 (2H, s, $C_6H_5CH_2S$), 5.42–5.62 (2H, m, —CH=CH—), and 7.32 p.p.m. (5H, s, C_6H_5).

(b) With Allyl Bromide (3)

From 1 molecular equiv each of allyl bromide and α-toluenethiol under the above conditions for 1 h was obtained in 77% yield allyl benzyl sulfide (**11***b*), b.p. 117–118°/14 Torr (lit. (24) b.p. 115–116°/14 Torr); p.m.r. ($CDCl_3$) δ 2.95 (2H, d of q, J = 1.7 Hz, SCH_2CH=CH_2), 3.58 (2H, s, $C_6H_5CH_2S$), 4.9–5.7 (3H, m, CH=CH_2), and 7.26 p.p.m. (5H, m, C_6H_5).

(c) With 1-Bromo-2-butyne (4)

One molecular equivalent each of 1-bromo-2-butyne and α-toluenethiol for 10 h yielded 78% of benzyl but-2-ynyl sulfide (**11***c*), b.p. 82–83°/0.1 Torr; u.v. (CH_3OH) 267 (ε 204) and 261 (ε 321) nm; p.m.r. ($CDCl_3$) δ 1.82 (3H, t, J = 2 Hz, CH_3C≡), 3.03 (2H, q, J = 2 Hz, ≡CCH_2S), 3.81 (2H, s, $C_6H_5CH_2S$), and 7.2–7.4 p.p.m. (5H, m, C_6H_5).

Anal. Calcd. for $C_{11}H_{12}S$: C, 74.94; H, 6.86; S, 18.19. Found: C, 74.98; H, 6.76; S, 18.20.

(d) With 2-Bromoacetophenone (5)

Equimolar amounts of 2-bromoacetophenone, α-toluenethiol, and triethylamine were mixed in ether at 0° to give, after work-up, 2-(benzylthiol)acetophenone (**11***d*, quantitative yield), plates from ethanol, m.p. 88.5–90° (lit. (25) m.p. 89°); p.m.r. ($CDCl_3$), δ 3.66 (2H, s, $C_6H_5CH_2S$), 3.75 (2H, s, SCH_2CO), 7.26–7.64 (8H, m, aromatic), and 7.92–8.04 p.p.m. (2H, d of d, J = 2.7 Hz, ortho aromatic protons).

Alkylations of Imidazole (7a)

As indicated by Table 1 the alkylations of imidazole were carried out in methanol solutions with varying molar proportions of reagents, and both in the presence and absence of sodium bicarbonate. The conditions outlined below for the crotyl chloride reactions[8] are representative of those used to prepare the reference samples of the individual products used in the analyses summarized in Table 1.

[8]Since the alkylation procedures are similar within each series of reactions only the crotyl chloride reaction is fully described for any nucleophile. The total data obtained are summarized in Table 1. The p.m.r. data are reported in full for each product since the chemical shift values and splitting patterns observed were sufficiently characteristic to be of value during subsequent analyses of the products of reactions of amino acids and proteins. When not recorded, i.r. and u.v. data were as expected.

(a) With Crotyl Chloride (2)

Crotyl chloride (3.2 g, 35 mmol) in methanol (35 ml) was added dropwise with stirring during 3.5 h to a refluxing mixture of imidazole (11.9 g, 175 mmol) and sodium bicarbonate (2.95 g, 35 mmol) in methanol (35 ml). Following further heating under reflux for 24 h the reaction mixture was evaporated and the residue dissolved in water (60 ml) and extracted with chloroform (3 × 20 ml). The chloroform extract was washed with saturated aqueous sodium chloride (25 ml), then dried ($MgSO_4$), and evaporated. Fractional distillation of the oil obtained yielded *N*-crotylimidazole (**12***a*, 2.55 g), b.p. 52–54°/0.15 Torr; p.m.r. (CCl_4) δ 1.65–1.82 (3H, m, CH═CHC*H*$_3$), 4.38–4.58 (2H, m, NC*H*$_2$CH═), 5.57–5.63 (2H, m, CH$_2$C*H*═C*H*CH$_3$), 6.77 (1H, t, J = 1 Hz, CH═C*H*NCH$_2$), 6.87 (1H, s, C*H*═CHNCH$_2$), and 7.26 p.p.m. (1H, s, N═C*H*—N).

Anal. Calcd. for $C_7H_{10}N_2$: C, 68.81; H, 8,25; N, 22.94. Found: C, 69.17; H, 8.14; N, 22.97.

Subsequent reaction of *N*-crotylimidazole (1.0 g, 9 mmol) with crotyl chloride (0.82 g, 9 mmol) at 60° for 1 h gave *N,N'*-dicrotylimidazolium chloride (**13***a*, 94% by p.m.r.[9]); p.m.r. (DMSO-d_6) δ 1.5–1.8 (6H, m, CH═CH-C*H*$_3$), 4.5–4.8 (4H, m, NC*H*$_2$CH═), 5.2–5.7 (4H, m, CH$_2$C*H*═C*H*CH$_3$), 7.25 (2H, d, J = 1 Hz, $\overset{+}{N}$CH═C-*H*N), and 9.78 p.p.m., (1H, broad s, $\overset{+}{N}$C*H*N).

(b) With Allyl Bromide (3)

Allyl bromide (1 equiv), imidazole (5 equiv), and sodium bicarbonate (1 equiv) in methanol at 25° for 4 days yielded *N*-allylimidazole (**12***b*, 96%), b.p. 40–42°/0.1 Torr; p.m.r. ($CDCl_3$) δ 4.5 (2H, d of t, J = 6.1 Hz, NC*H*$_2$CH═), 5.0–6.2 (3H, m, C*H*═C*H*$_2$), 6.90 (1H, t, J = 1 Hz, NCH═C*H*NCH$_2$), 7.05 (1H, d, J = 1 Hz, NC*H*═CHNCH$_2$), and 7.47 p.p.m. (1H, s, N═C*H*N); mass spectrum *m/e* (relative intensity) 108 P (51), 41 (100).

Anal. Calcd. for $C_6H_8N_2$: C, 66.64; H, 7.46; N, 25.91. Found: C, 66.42; H, 7.78; N, 25.74.

From *N*-allylimidazole (1 equiv) and allyl bromide (1 equiv) in methanol at 25° for 1 week was obtained 88% of *N,N'*-diallylimidazolium bromide[9] (**13***b*), p.m.r., (DMSO-d_6) δ 5.12 (4H, d of t, J = 6.1 Hz, $\overset{+}{N}$C*H*$_2$CH═), 5.31–5.56 (4H, m, CH$_2$CH═C*H*$_2$), 5.98–6.42 (2H, m, CH$_2$C*H*═CH$_2$), 8.09 (2H, d, J = 2 Hz, $\overset{+}{N}$C*H*═C*H*N), and 9.78 p.p.m. (1H, t, J = 2 Hz, $\overset{+}{N}$═CHN).

(c) With 1-Bromo-2-butyne (4)

1-Bromo-2-butyne (1 equiv), imidazole (5 equiv), and sodium bicarbonate (1 equiv) in methanol at 25° for 4 days afforded *N*-(but-2-ynyl)imidazole (**12***c*, 83%) b.p. 59–59.5°/0.1 Torr; p.m.r. ($CDCl_3$) δ 1.81 (3H, t, J = 2 Hz, C*H*$_3$C≡), 4.65 (2H, q, J = 2 Hz, NC*H*$_2$C≡), 7.04 (1 H, t, J = 1 Hz, NCH═C*H*NCH$_2$), 7.07 (1 H, d, J = 1 Hz, NC*H*═CHNCH$_2$) and 7.59 p.p.m. (1H, s, N═C*H*N); mass spectrum *m/e* (relative intensity) 120 P (100).

Anal. Calcd. for $C_7H_8N_2$: C, 69.98; H, 6.71; N, 23.32. Found: C, 69.66; H, 6.66; N, 23.24.

One equivalent each of *N*-(but-2-ynyl)imidazole and 1-bromo-2-butyne in methanol at 25° for 1 week yielded 94% of *N,N'*-di(but-2-ynyl)imidazolium bromide (**13***c*),[9] p.m.r. (DMSO-d_6) δ 1.89 (6H, t, J = 3 Hz, CH$_3$C≡), 5.32 (4H, q, J = 3 Hz, $\overset{+}{N}$C*H*$_2$C≡), 7.99 (2H, d, J = 2 Hz, $\overset{+}{N}$C*H*═C*H*N), and 9.75 p.p.m. (1H, t, J = 2 Hz, $\overset{+}{N}$═C*H*N).

(d) With 2-Bromoacetophenone (5)

2-Bromoacetophenone (1 equiv) and imidazole (10 equiv) alone in methanol at 25° for 20 h gave (following sodium bicarbonate treatment during work-up) *N*-(2-oxo-2-phenylethyl)imidazole (**12***d*, 94%), spars from benzene m.p. 119–120°; p.m.r. ($CDCl_3$) δ 5.38 (2H, s, C$_6$H$_5$COC*H*$_2$N), 6.95 (1H, t, J = 1 Hz, NCH═C*H*-NCH$_2$), 7.14 (1H, s, NC*H*═CHNCH$_2$), 7.4–7.7 (4H, m, meta and para aromatic and N═C*H*—N), and 8.03 p.p.m. (2H, d of d, J = 2.8 Hz, ortho aromatic). Mass spectrum *m/e* (relative intensity) 186 P (20) and 104 (100).

Anal. Calcd. for $C_{11}H_{10}N_2O$: C, 70.95; H, 5.41; N, 15.05. Found: C, 71.13; H, 5.32; N, 14.87.

N,N'-Di(2-oxo-2-phenylethyl)imidazolium bromide (**13***d*) was obtained in 59% yield from the reaction of equimolar proportions of 2-bromoacetophenone and imidazole in methanol at 25° for 24 h. Following sodium bicarbonate treatment during the work-up procedure, it was obtained as needles (from ethanol) m.p. 258–259°, p.m.r. (DMSO-d_6), δ 6.31 (4H, s, $\overset{+}{N}$C*H*$_2$CO), 7.70–7.86 (6H, m, meta and para aromatic), 7.93 (2H, d, J = 1 Hz, $\overset{+}{N}$C*H*═C*H*N), 8.13, 8.21 (4H, 2d, J = 1 Hz, ortho aromatic), and 9.30 p.p.m. (1H, t, J = 1 Hz, $\overset{+}{N}$═C*H*N).

Anal. Calcd. for $C_{19}H_{17}N_2O_2Br$: C, 59.23; H, 4.45; N, 7.27; Br, 20.74. Found: C, 59.48; H, 4.64; N, 7.15; Br, 20.82.

Alkylations of N-Methylimidazole (7b)

(a) With Crotyl Chloride (2)

A solution of *N*-methylimidazole (2.0 g, 24 mmol) and crotyl chloride (2.20 g, 24 mmol) in methanol (25 ml) was heated under reflux for 11 h. Evaporation of the solvent yielded quantitatively *N*-crotyl-*N'*-methylimidazolium chloride (**14***a*) as a deliquescent[9] solid, p.m.r. (DMSO-d_6) δ 1.6–1.9 (3H, m, CH═CHC*H*$_3$), 3.98 (3H, s, $\overset{+}{N}$—C*H*$_3$), 4.8–5.1 (2H, m, $\overset{+}{N}$C*H*$_2$CH═CHCH$_3$), 5.6–6.2 (2H, m, C*H*═C*H*CH$_3$), 8.0 (2H, d, J = 1Hz, $\overset{+}{N}$C*H*═C*H*N), and 9.84 p.p.m. (1H, broad s, $\overset{+}{N}$═C*H*N).

(b) With Allyl Bromide (3)

Equimolar allyl bromide and *N*-methylimidazole in methanol at 25° for 7 days gave *N*-allyl-*N'*-methylimidazolium bromide (**14***b*) as a low melting deliquescent, solid (89%),[9] p.m.r. (DMSO-d_6) δ 4.0 (3H, s, C*H*$_3\overset{+}{N}$), 5.05 (2H, d of t, J = 6. 1 Hz, $\overset{+}{N}$C*H*$_2$CH═CH$_2$), 5.28–5.53 (2H, m, CH═C*H*$_2$), 5.95–6.36 (1H, m, CH$_2$C*H*═CH$_2$), 8.01 (2H, d, J = 2 Hz, $\overset{+}{N}$C*H*═C*H*N), and 9.64 p.p.m. (1H, broad s, $\overset{+}{N}$═C*H*N).

[9]Owing to the extremely deliquescent properties of the bisalkylated imidazolium salts and of the alkylated *N*-methylimidazole derivatives (**12–15**) no further purification of this compound was possible.

For personal use only.

(c) With 1-Bromo-2-butyne (4)

One equivalent each of 1-bromo-2-butyne and *N*-methylimidazole in methanol at 25° for 7 days afforded a 91% yield of the low melting, deliquescent, *N*-(but-2-ynyl)-*N'*-methylimidazolium bromide (**14***c*), p.m.r. (DMSO-d_6) δ 1.91 (3H, t, J = 3 Hz, $\overset{+}{N}CH_2C{\equiv}CCH_3$), 3.98 (3H, s, $CH_3\overset{+}{N}$), 5.31 (2H, q, J = 3 Hz, $\overset{+}{N}CH_2C{\equiv}CCH_3$), 7.96 (2H, d, J = 2 Hz, $\overset{+}{N}CH{=}CH\overset{+}{N}$), and 9.62 p.p.m. (1H, broad s, $\overset{+}{N}{=}CH\overset{+}{N}$).

(d) With 2-Bromoacetophenone (5)

2-Bromoacetophenone (1 equiv) and *N*-methylimidazole (1 equiv) were reacted in methanol solution at 25° for 6 h. *N*-Methyl-*N'*-(2-oxo-2-phenylethyl)imidazolium bromide (**14***d*) was obtained in 98% yield as prisms from acetonitrile/tetrahydrofuran, m.p. 153–154° (lit. (26) m.p. 153–155°), p.m.r. (DMSO-d_6) δ 4.0 (3H, s, $CH_3\overset{+}{N}$), 6.31 (2H, s, $\overset{+}{N}CH_2CO$), 7.59–8.00 (5H, m, meta and para aromatic and $\overset{+}{N}CH{=}CH\overset{+}{N}$), 8.15 (2H, d of d, J = 6.1 Hz, ortho aromatic), and 9.4 p.p.m. (1H, s, $\overset{+}{N}{=}CH\overset{+}{N}$).

Alkylations of Benzylamine

(a) With Crotyl Chloride (2)

Crotyl chloride (9.06 g, 0.1 mol) and benzylamine (10.7 g, 0.1 mol) were dissolved in methanol (50 ml) and the solution was heated at 60° for 4 days. Following solvent evaporation, the residue was dissolved in aqueous sodium hydroxide (10% w/v, 100 ml) and the resulting solution was extracted with ether (3 × 75 ml). The combined ether extract was washed with saturated aqueous sodium chloride (50 ml), dried ($MgSO_4$), and evaporated. Fractional (spinning band) distillation of the residual oil gave *N*-crotylbenzylamine (**15***a*, 2.4 g), b.p. 81°/1.5 Torr (lit. (27) b.p. 95°/12 Torr), p.m.r. ($CDCl_3$) δ 1.27 (1H, s, N*H*), 1.5–1.7 (3H, m, =CH—CH_3), 3.1–3.3 (2H, m, NCH_2CH=), 3.72 (2H, s, $C_6H_5CH_2N$), 5.5–5.7 (2H, m, —C*H*=C*H*—), and 7.30 p.p.m. (5H, s, C_6H_5).

The pot residue was dissolved in ether (35 ml) and was then treated with aqueous sodium hydroxide (10% w/v, 50 ml) and benzenesulfonylchloride (2.5 g) (to remove any remaining primary or secondary amino compounds) and the ethereal solution was separated and washed with aqueous sodium hydroxide solution (10% w/v, 5 × 25 ml). The organic layer was then extracted with aqueous hydrochloric acid (3 × 25 ml) and the acid solution was washed with ether (25 ml) and was then brought to p*H* 12 with solid sodium hydroxide. Extraction with ether (3 × 25 ml), followed by evaporation of the dried ($MgSO_4$) ether solution and fractional distillation yielded *N,N'*-dicrotylbenzylamine (**16***a*, 3.8 g), b.p. 75°/0.1 Torr, p.m.r. ($CDCl_3$), δ 1.5–1.7 (6H, m, =CHCH_3), 2.9–3.1 (4H, m, NCH_2CH=), 3.47 (2H, d, J = 2 Hz, $C_6H_5CH_2N$), 5.4–5.6 (4H, m, —C*H*=C*H*—), and 7.1–7.4 (5H, m, C_6H_5); mass spectrum *m/e* (relative intensity), 215 P (24) and 91 (100).

Anal. Calcd. for $C_{15}H_{21}N$: C, 83.66; H, 9.83; N, 6.51. Found: C, 83.73; H, 9.70; N, 6.77.

(b) With Allyl Bromide (3)

A solution containing equimolar amounts of allyl bromide and benzylamine in ether was kept at 25° for 5 days and was then filtered to remove benzylamine hydrochloride. Treatment of the filtrate with dry HCl gave *N*-allylbenzylamine (**15***b*, 36%) as its hydrochloride salt, needles from ethanol–ether, m.p. 144–145° (lit. (28) m.p. 143–144°); the free base had b.p. 63°/0.75 Torr (lit. (28) b.p. 70–79°/5.5 Torr), p.m.r. ($CDCl_3$) δ 1.32 (1H, s, N*H*), 3.19 (2H, d of t, J = 6.1 Hz, NCH_2CH=CH), 3.7 (2H, s, $C_6H_5CH_2N$), 5.0–5.3 (2H, m, CH=CH_2), 5.7–6.1 (1H, m, C*H*=CH_2), and 7.28 p.p.m. (5H, m, C_6H_5).

The ether filtrate from the original reaction was worked-up as for the crotyl chloride reaction (except that the Hinsberg sulfonation step was omitted) and yielded (after spinning band fractionation) 37% of *N,N'*-diallylbenzylamine (**16***b*), b.p. 73°/1.0 Torr (lit. (29) b.p. 89°/4 Torr); p.m.r. ($CDCl_3$) δ 3.06 (4H, d of t, J = 6.1 Hz, NCH_2CH=), 3.55 (2H, s, $C_6H_5CH_2N$), 5.0–5.3 (4H, m, CH=CH_2), 5.7–6.1 (2H, m, C*H*=CH_2) and 7.2–7.4 (5H, m, C_6H_5).

(c) With 1-Bromo-2-butyne (4)

The mono-(**15***c*) and bis-(**16***c*) alkylated products were obtained directly from the first fractional (spinning band) distillation of the mixture obtained from the reaction of 1-bromo-2-butyne (1 equiv) and benzylamine (1 equiv) in ether at 25° for 5 days. *N*-(But-2-ynyl) benzylamine (27%) had b.p. 89–90°/1.2 Torr; p.m.r. ($CDCl_3$) δ 1.4 (1H, s, N*H*), 1.77 (3H t, J = 2 Hz, ≡CCH_3), 3.31 (2H, q, J = 2 Hz, NCH_2C≡), 3.8 (2H, s, $C_6H_5CH_2N$), and 7.2–7.4 p.p.m. (5H, m, C_6H_5).

Anal. Calcd. for $C_{11}H_{13}N$: C, 82.97; H, 8.23; N, 8.80. Found: C, 82.88; H, 8.25; N, 8.84.

N,N'-Di(but-2-ynyl)benzylamine (43%) had b.p. 99°/0.17 Torr; p.m.r. ($CDCl_3$) δ 1.81 (6H, t, J = 2 Hz, ≡CCH_3), 3.33 (4H, q, J = 2 Hz, NCH_2C≡), 3.76 (2H, s, $C_6H_5CH_2N$), and 7.2–7.5 p.p.m. (5H, m, C_6H_5), mass spectrum *m/e* (relative intensity) 211 P (4) and 43 (100).

Anal. Calcd. for $C_{15}H_{17}N$: C, 85.26; H, 8.11; N, 6.63. Found: C, 84.79; H, 7.98; N, 6.95.

(d) With 2-Bromoacetophenone (5)

From 2-bromoacetophenone (1 equiv) and benzylamine (1 equiv) in methanol at 25° for 10 h, the hydrobromide of *N,N'*-di(2-oxo-2-phenylethyl)benzylamine (**16***d*) was obtained directly by filtration in 54% yield. It formed fine prisms from ethanol m.p. 197–198° (lit. (30) m.p. 196–197°); p.m.r. (DMSO-d_6) δ 4.58 (2H, s, $C_6H_5CH_2\overset{+}{N}$), 5.14 (4H, s, $\overset{+}{N}CH_2CO$), 7.29–7.83 (1H, m, aromatic), 7.93 (2H, d, J = 1 Hz, ortho aromatic), and 8.01 p.p.m. (2H, d, J = 1 Hz, ortho aromatic).

Anal. Calcd. for $C_{23}H_{22}NO_2Br$: C, 65.10; H, 4.99; N, 3.30; Br, 18.84. Found: C, 64.92; H, 5.24; N, 3.35; Br, 18.70.

The original filtrate was evaporated and the residue dissolved in hot aqueous hydrobromic acid (p*H* 4, 70 ml). On cooling, the filtered solution yielded 8% of the hydrobromide of *N*-(2-oxo-2-phenylethyl)benzylamine (**15***d*), fine needles from aqueous ethanol, m.p. 201–202° (lit. (30) m.p. 201–202°); p.m.r. (DMSO-d_6) δ 4.28 (2H, s, $C_6H_5CH_2\overset{+}{N}$), 4.89 (2H, s, $\overset{+}{N}CH_2CO$), 7.41–7.88 (8H, m, aromatic), 8.05 (1H, d, J = 1 Hz, ortho aromatic), and 8.13 p.p.m. (1H, d, J = 1 Hz, ortho aromatic).

Anal. Calcd. for $C_{15}H_{16}NOBr$: C, 58.83; H, 5.21; N, 4.58; Br, 26.10. Found: C, 59.04; H, 5.42; N, 4.57; Br, 26.27.

Alkylation of Benzyl Methyl Sulfide (9)

Attempted alkylations with (*a*) crotyl chloride, (*b*) allyl bromide, and (*c*) 1-bromo-2-butyne under a variety of conditions were unsuccessful.

(d) With 2-Bromoacetophenone (5)

Benzyl methyl sulfide (2.1 g, 15 mmol) and 2-bromoacetophenone (3.0 g, 15 mmol) were dissolved in benzene (10 ml) and after keeping the mixture for 4 days at 7°, the solid produced was filtered off, and washed with acetone. Recrystallization from methanol/2-propanol gave fine needles of benzyl-(2-oxo-2-phenylethyl)methyl sulfonium bromide (17, 2.6 g), m.p. 118–119° (lit. (31) m.p. 118°); p.m.r. (CF_3COOH) δ 3.03 (3H, s, $CH_3\overset{+}{S}$), 4.88 (2H, s, $C_6H_5CH_2\overset{+}{S}$), 5.29 (2H, s, $C_6H_5COCH_2\overset{+}{S}$), and 7.4–8.2 p.p.m. (10H, m, C_6H_5).

Attempted Alkylation of Guanidine with 2-Bromoacetophenone

Aqueous sodium hydroxide (1 ml of 10 *N*, 10 mmol) was added to a suspension of guanidine hydrochloride (0.96 g, 10 mmol) in methanol (15 ml) at 0° and the mixture was then filtered to remove sodium chloride. 2-Bromoacetophenone (2 g, 10 mmol) in cooled (0°) methanol (10 ml) was then added to the stirred filtrate and after keeping for 6 h at 0°, the reaction mixture was filtered. The crystalline solid (0.43 g) obtained was shown by p.m.r. (see Discussion) to consist of a mixture of *cis*- and *trans*-4-bromo-2,3-epoxy-3-phenylbutyrophenone. Three recrystallizations from ethanol afforded the pure *cis*-isomer as spars, m.p. 154–155° (lit. (21) m.p. 160–161°); i.r. (KBr) 1679 (CO), 1227 (C—C) and 919 cm^{-1} (C—C); p.m.r. (DMSO-d_6), δ 3.9 (1H, d, J = 11 Hz, $BrCH_A$), 4.75 (1H, d, J = 11 Hz, $BrCH_B$), 5.1 (1H, s, $OCHCO$), and 7.18–8.0 p.p.m. (10H, m, C_6H_5); mass spectrum *m/e* (relative intensity) 316 P (4) and 223 (100).

Anal.[10] Calcd. for $C_{16}H_{13}O_2Br$: C, 60.58; H, 4.13; Br, 25.20. Found: C, 60.61; H, 4.41; Br, 25.15.

Guanidine hydrobromide was recovered from the reaction mixture in 74% yield.

We thank the National Research Council of Canada and the National Cancer Institute of Canada for their generous support and for the award (to D.W.H.) of an NRCC Science Scholarship.

The Mass Spectrometry of *para*-Substituted Benzyl Nitrates

P. J. SMITH[1]
Department of Chemistry, Bishop's University, Lennoxville, Quebec

Received[2] August 5, 1969

The mass spectra of several *para*-substituted benzyl nitrates have been measured at 70 and 15 eV. The major fragmentation pathways have been established using deuterium labelling and measurement of metastable peaks. The formation of the *para*.$Y.C_6H_4.CH_2O^+$ ions from the parent ions approximately correlate with the Hammett sigma constants. A hydrogen–deuterium isotope effect of approximately 1.8 was found for the loss of hydrogen (deuterium) from the $C_6H_5CHDO^+$ ion at 10 eV.

Canadian Journal of Chemistry, **49**, 333 (1971)

Introduction

A detailed study of the mass spectra of aliphatic organic nitrate esters has recently been reported (1, 2). No observable parent ion was found for any of the straight-chain esters up to ten carbon atoms. The major fragments were found to arise from cleavage of the carbon–carbon bond adjacent to the nitrate group to give an *m/e* 76 peak ($CH_2ONO_2^+$), from fission of the carbon–oxygen bond leading exclusively to the RCH_2^+ ion, and from cleavage of the oxygen–nitrogen bond to give an *m/e* 46 peak (NO_2^+). There was no observable fragment ion corresponding to oxygen–nitrogen bond rupture leading to the RCH_2O^+ ion. The principal cleavages of an *n*-alkyl nitrate are summarized in reaction 1.

$$[1]\quad RCH_2^+ \overset{b}{\leftarrow} [R\overset{a}{-}CH_2\overset{b}{-}O\overset{c}{-}NO_2]^{\ddagger} \overset{c}{\rightarrow} NO_2^+ \; m/e\ 46$$
$$\downarrow a$$
$$CH_2ONO_2^+ \; m/e\ 76$$

Results and Discussion

The present study was carried out on a series of *para*-substituted benzyl nitrates with the aim of establishing and comparing their fragmentation patterns with those of the aliphatic compounds. The nitrate esters were synthesized as described in the Experimental Section and all were shown to be thermally stable at the operating conditions of the mass spectrometer. The spectra were determined at both 70 and 15 eV for the *p*-CH_3, *p*-H, *p*-Cl, and *p*-CF_3 compounds and the major fragments are shown in Table 1. The benzyl nitrates, unlike the aliphatic esters, all exhibit a fairly intense parent ion, particularly at the lower ionization voltage. The major fragmentation pathways lead to the $P - 46$ ion (loss of nitrite), $P - 62$ ion (loss of nitrate), and the $p.Y.C_6H_4^+$ and $C_6H_5^+$ ions.

The fragmentation process of oxygen–nitrogen bond rupture leading to loss of nitrite from the parent ion and the formation of the $P - 46$ ions, reaction 2, unlike that of the aliphatic compounds where no $P - 46$ peak was observed, is a favored pathway for the decomposition of the benzyl

$$[2]\quad p.Y.C_6H_4.CH_2ONO_2^{\ddagger} \rightarrow p.Y.C_6H_4.CH_2O^+ + NO_2^{\cdot}$$

nitrate esters. This process, in fact, leads to the base peak in the mass spectrum of the *p*-trifluoromethyl compound determined at 15 eV. The corresponding α-d_2 esters, $p.Y.C_6H_4.CD_2ONO_2$, fragmented also to the $P - 46$ ions, $p.Y.C_6H_4.CD_2O^+$.

The decomposition of the $P - 46$ ions, p-$Y.C_6H_4.CH_2O^+$, is of some interest. For all the compounds studied, both undeuterated and α-dideuterated, peaks were observed in the mass spectra corresponding to the loss of one H (or D) from the $p.Y.C_6H_4CH_2(D_2)O^+$ ion to give the benzaldehyde-like $P - 47$ (or $P - 48$) ion which subsequently loses another H (or D) to give a $P - 48$ (or $P - 50$) peak. These processes are represented in reaction 3. The $p.Y.C_6H_4.C{\equiv}O^+$

$$[3]\quad p.Y.C_6H_4.CH_2(D_2)O^+ \xrightarrow{-H\ (or\ D)} p.Y.C_6H_4.CH(D)O^+ \xrightarrow{-H\ (or\ D)} p.Y.C_6H_4.C{\equiv}O^+$$

[1]Present address: Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan.

[2]Revision received August 31, 1970.

*Peaks having an abundance of 1% or greater relative to the base peak as given in the Table.

ions were produced in all cases by the preferential loss of the α-hydrogens from the $P - 46$ ions since the $p.Y.C_6H_4.CD_2O^+$ ions decomposed by the loss of two and four mass units to give the $p.Y.C_6H_4.C{\equiv}O^+$ ions with no loss of a hydrogen radical being observed.[3] Both $C_6H_5CH_2O^+$ and $C_6H_5CD_2O^+$ led to the ion, $C_6H_5C{\equiv}O^+$, at *m/e* 105 which decomposed to $C_6H_5^+$ by the loss of carbon monoxide as evidenced by the metastable peak at 56.5 (105 → 77).

Another decomposition pathway for the $p.Y.C_6H_4.CH_2O^+$ ions is confirmed by metastable peaks in the spectra of benzyl nitrate and its α-d_2 analogue. This route is similar to that proposed by Shannon (4) for the decomposition

[3]Eliel *et al.* (3) obtained a similar result in a study of the formation of the $C_6H_5CO^+$ ion from benzyl alcohol.

m/e 107 *m/e* 79 Phenyl ion, *m/e* 77

of benzyl alcohol and is represented in reaction 4 for the $C_6H_5CH_2O^+$ ion.

The loss of carbon monoxide from the $C_7H_7O^+$ ion, *m/e* 107, to give *m/e* 79 is confirmed by the observation of a metastable peak at 58.3 (107 → 79). Similarly, the $C_6H_5CD_2O^+$ ion loses CO to give a peak at *m/e* 81, $m^* = 60.3$ (109 → 81). The $C_6H_7^+$ ion, *m/e* 79, loses two hydrogen atoms to give the phenyl ion, $C_6H_5^+$, as confirmed by a metastable peak at 75.1 (79 → 77). The corresponding deuterated ion, $C_6H_5D_2$, *m/e* 81, loses one deuterium[4] to give *m/e* 79, $m^* = 77.1$ (81 → 79). The $C_6H_5D^+$ ion, *m/e* 79, subsequently decomposes to *m/e* 77, the base peak in the spectrum, $m^* = 75.1$ (79 → 77).

The phenyl ion,[5] *m/e* 77, derived from both the undeuterated and deuterated benzyl nitrate lost C_2H_2 to give *m/e* 51, $m^* = 33.8$ (77 → 51), indicating that deuterium was not scrambled into the ring during the fragmentation processes although it must be considered that the statistical factor, which favors loss of H over D, might lead to a very weak metastable ion corresponding to the loss of C_2HD.[6]

The formation of the $p.Y.C_6H_4^+$ ions can occur by two pathways other than that represented in reaction 3 for the decomposition of the $p.Y.C_6H_4.CH_2O^+$ ions. Firstly, the neutral formaldehyde molecule can be lost from the $p.Y.C_6H_4.CH_2O^+$ ions, reaction 5

[5] $p.Y.C_6H_4.CH_2O^+ \rightarrow p.Y.C_6H_4^+ + CH_2{=}O$

and secondly, the cleavage of the carbon–carbon bond adjacent to the nitrate function[7] leads also to the $p.Y.C_6H_4^+$ ions, reaction 6.

[6] $p.Y.C_6H_4.CH_2ONO_2^{\ddagger} \rightarrow p.Y.C_6H_4^+ + {}^{\cdot}CH_2ONO_2$

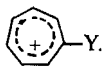
Metastable peaks, corresponding to these two processes, did not appear in the spectra of benzyl nitrate and its α-d_2 analogue.

The "benzyl" ion, $p.Y.C_6H_4.CH_2^+$, a significant ion in the spectra of all the compounds studied, is produced by cleavage of the carbon–oxygen bond, reaction 7.

[7] $p.Y.C_6H_4.CH_2ONO_2^{\ddagger} \rightarrow p.Y.C_6H_4.CH_2^+ + NO_3$

In no case was a peak observed at *m/e* 62 corresponding to the NO_3^+ ion in agreement with the results obtained from the aliphatic nitrate ester study. For all the compounds, the α-d_2 analogues gave peaks corresponding to the $p.Y.C_6H_4CD_2^+$ ions and as well $C_6H_5CHDONO_2$ fragmented to the *m/e* 92 ion, $C_6H_5CHD^+$.

The spectrum of $C_6H_5CH_2ONO_2$ revealed a strong metastable peak at 46.4 (91 → 65) corresponding to the loss of acetylene from the "benzyl" ion. Similarly, $C_6H_5CD_2ONO_2$ gave two weak metastable peaks; one at 46.8 (93 → 66) corresponding to the loss of C_2HD from $C_6H_5CD_2^+$ and the other at 48.3 (93 → 67), resulting from the loss of C_2H_2. These results suggest that deuterium is scrambled in the "benzyl" ion via the tropylium ion (5), and that the benzyl ions, $p.Y.C_6H_4.CH_2^+$ can best be represented by the structure



The fragmentation process, illustrated in reaction 2, was studied with the view of determining whether a hydrogen–deuterium isotope effect exists for the loss of hydrogen from the $C_6H_5CHDO^+$ ion, reaction 8. The mass spectrum

[8] $C_6H_5CHDONO_2^{\ddagger} \rightarrow C_6H_5CHDO^+ \xrightarrow{k^H} C_6H_5CDO^+$, $C_6H_5CDO^+ \xrightarrow{k^D} C_6H_5CHO^+$

of $C_6H_5CHDONO_2$ was obtained at low ionization voltage (10 eV, nominal) in order to minimize

[4] A peak at *m/e* 80 corresponding to the loss of a hydrogen from $C_6H_5D_2^+$ is not observed.

[5] The stability of this ion is indicated by the fact that it is a major fragment (Table 1) even for the *para*-substituted compounds where loss of *para*-substituent is necessary for its formation.

[6] Benzyl nitrate α-d_1 gave $C_6H_5CHDO^+$ ion, *m/e* 108, which lost CO to give *m/e* 80 which also decomposed to the phenyl ion, *m/e* 77.

[7] In no case was a peak observed at *m/e* 76 corresponding to the $CH_2ONO_2^+$ ion, which is a prominent ion in the spectra of the aliphatic nitrates (1).

subsequent fragmentation from the above ions and, in fact, only the four ions represented above appeared in the mass spectrum. The isotope effect[8] was measured using the ratio of peak heights for $C_6H_5CDO^+$ and $C_6H_5CHO^+$ ions after appropriate corrections for ^{13}C. The value for k^H/k^D was determined to be approximately 1.8 and is somewhat less than that found for *N*-methyl-3-cyano-1,4-dihydropyridine-4-*d*, 7.85 at 11.2 eV (6).

An interpretation of the magnitude of the isotope effect obtained in the present study, however, is difficult since the origin of an isotope effect obtained from electron bombardment reactions is somewhat obscure (6). It is suggested that a study of the possible effect of *para*-substituent on the magnitude of the hydrogen–deuterium isotope effect[9] might shed some light on the factors which contribute to the isotope effects encountered in mass spectral fragmentations.

The elegant technique of kinetic substituent effects (7–11) has recently been used for the assignment of ion structures and for the detailed elucidation of fragmentation pathways. Consequently, it was decided to investigate the effect of *para*-substituents on the fragmentation of the parent ion of the nitrate esters to the $p.Y.C_6H_4.CH_2O^+$ ions at both 70 and 15 eV. The results are shown in Table 2 where Z is defined as $[P - NO_2]^+/[P]^+$ and Z_0 refers to the unsubstituted compound.

Since the substituent is retained, and consequently a correlation of Z values with rates is not expected (10), an approximate Hammett plot is obtained when log Z/Z_0 is plotted against Hammett's sigma values, Fig. 1. It is possible that part of the apparent rate reduction by electron-donating substituents could be due to the accompanying reduction in ionization potentials

TABLE 2. Relative intensities for the loss of $NO_2^\cdot$ from *para*-substituted benzyl nitrates at 70 and 15 eV

para-Substituent	Z/Z_0 for loss of $NO_2^\cdot$	
	70 eV	15 eV
CH_3	1.2	1.2
H	1.0	1.0
Cl	1.5	1.3
CF_3	4.8	4.3

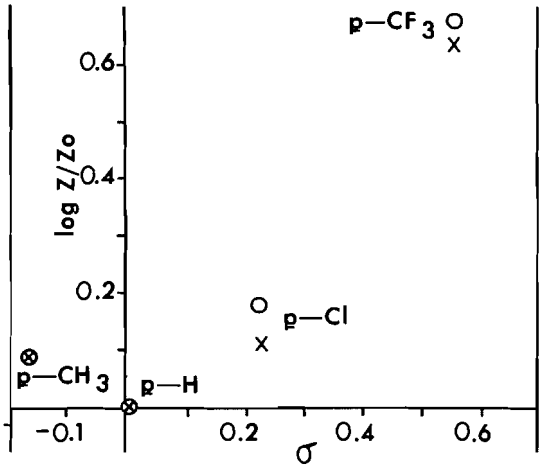

FIG. 1. log Z/Z_0 *vs.* σ constants for fragmentation of $p.Y.C_6H_4.CH_2ONO_2$ ions to $p.Y.C_6H_4.CH_2O^+$ ions; ×, 70 eV; ○, 15 eV.

(12) producing a larger fraction of molecular ions with less than the activation energy for dissociation, thus decreasing the Z values (see ref. 13 for a critical review on the correlation of substituents with rates). This effect would be very important at low voltage. The approximate constancy of the Z/Z_0 ratios in Table 2, however, for changes in ionization voltage from 70 to 15 eV, indicates that at least in part the fragmentation process is aided by electron-withdrawing substituents. It is expected that the Hammett correlation would improve at ionization voltages near the appearance potential where decomposition of the $p.Y.C_6H_4CH_2O^+$ ions is negligible.

Experimental

Materials

Benzyl Nitrate

This was prepared from benzyl chloride and silver nitrate in acetonitrile (14). The product, purified by fractional distillation from silver nitrate and calcium carbonate, was obtained in 60% yield, b.p. 62–62.5°/1 mm (ref. 14, b.p. 45°/0.5 mm).

[8]The possibility of scrambling in the $C_6H_5CHDO^+$ ion exists with deuterium being incorporated into the ring. That scrambling is probably unimportant is shown from the spectrum of $C_6H_5CD_2ONO_2$ where a peak corresponding to the loss of hydrogen from the $C_6H_5CD_2O^+$ ion is not observed. Furthermore, both benzyl nitrate and benzyl nitrate α-d_2 gave $C_6H_5C{\equiv}O^+$ which decomposed to *m/e* 77, $C_6H_5^+$, since both compounds gave a metastable peak at 56.5 (105 → 77).

[9]A. N. Bourns and P. J. Smith (results to be published) found that k^H/k^D varied with *para*-substituent for the reaction of 2-arylethylammonium salts with ethoxide ion in ethanol at 40°; $k^H/k^D = 4.15$ for *p*-CF_3 and 2.64 for *p*-OMe.

p-Methylbenzyl Nitrate

This was prepared from *p*-methylbenzyl bromide and silver nitrate by the same procedure used for benzyl nitrate (14). The product was obtained in 42% yield, b.p. 72.0–73.5°/1 mm (ref. 15, 78°/0.6 mm).

p-Chlorobenzyl Nitrate

This was prepared from *p*-chlorobenzyl chloride and silver nitrate by the same procedure used for benzyl nitrate (14). The product was obtained in 75% yield, b.p. 107–107.1°/8 mm.

Anal.[10] Calcd. for $C_7H_6ClNO_3$; C, 44.82; H, 3.22. Found: C, 44.76; H, 3.25.

p-Trifluoromethylbenzyl Nitrate

This was prepared from *p*-trifluoromethylbenzyl bromide[11] and silver nitrate by the same procedure used for benzyl nitrate (14). The product was obtained in 57% yield, b.p. 83.5–84°/2.5 mm.

Anal. Calcd. for $C_8H_6O_3NF_3$; C, 43.45; H, 2.73; F, 25.78. Found: C, 43.37; H, 2.58; F, 25.73.

Benzyl Nitrate α-d_2

This compound was prepared using the procedure described by Buncel and Bourns (14). Benzyl α-d_2 alcohol was synthesized and found to be better than 99% $C_6H_5CD_2OH$ by nuclear magnetic resonance (n.m.r.) analysis. Benzyl nitrate α-d_2 was prepared from the above alcohol in two steps, b.p. 45°/0.5 mm (ref. 14, b.p. 45°/0.5 mm). Benzyl nitrate α-d_2 was shown to be better than 99% deuterated in the benzylic position by n.m.r. analysis.

Benzyl Nitrate α-d_1

This compound was prepared using the procedure described by Buncel and Bourns (14). Benzyl α-d_1 alcohol was prepared by reduction of purified benzaldehyde with lithium aluminum deuteride and was shown to contain 1.02 hydrogens in the benzylic position by n.m.r. analysis. Benzyl nitrate α-d_1 was prepared from this alcohol in two steps, b.p. 45°/0.5 mm (ref. 14, b.p. 45°/0.5 mm). Benzyl nitrate α-d_1 was shown to have 1.01 hydrogens in the benzylic position by n.m.r. analysis.

p-Methylbenzyl Nitrate α-d_2

This compound was prepared using the procedure described by Buncel and Bourns (14). *p*-Methylbenzyl alcohol α-d_2 was synthesized and shown to be completely deuterated at the benzylic position by n.m.r. analysis. *p*-Methylbenzyl nitrate α-d_2 was prepared from the above alcohol in two steps, b.p. 72.5–73.0/1 mm (ref. 15, 78°/0.6 mm). This nitrate ester was shown to be better than 99% deuterated in the benzylic position by n.m.r. analysis.

p-Trifluoromethylbenzyl Nitrate α-d_2

This compound was prepared by the procedure described by Buncel and Bourns (14). *p*-Trifluoromethylbenzyl alcohol α-d_2 was synthesized and shown to be completely deuterated at the benzylic position by n.m.r. analysis. *p*-Trifluoromethylbenzyl nitrate α-d_2 was prepared from the above alcohol in two steps, b.p. 83.8–84°/2.5 mm. This compound was shown by n.m.r. analysis to be better than 99% deuterated in the benzylic position.

Mass Spectra

Most mass spectra were obtained with a Consolidated Electrodynamics Corp. Model 21-104 mass spectrometer. The samples were introduced by a CEC all glass inlet system, at 60°, into the source maintained at 90°. The spectra were recorded at 70 and 15 eV at an ionization current of 10 μA. The metastable spectra were run on an MS-12 mass spectrometer with these samples introduced directly into the source at 80°. The spectra were run at an accelerating voltage of 8 kV and an ionization voltage of 70 eV and ionization current of 10 μA.

Test of the Thermal Stability of the Organic Nitrate Esters

The fragmentation patterns of all the compounds studied did not vary on changes of inlet and source temperatures of 30° from those reported above. In addition, a sample of each of the esters studied was heated at 100° for 30 min in an evacuated sealed tube and no change in its n.m.r. and mass spectra was found.

The author would like to thank Mrs. Carol Pollock who synthesized several of the undeuterated nitrate esters. Financial support from the National Research Council of Canada is gratefully acknowledged.

Applications of Quantum Chemistry. I. Energetics and Bonding in Conjugated Free Radical Chains[1]

N. C. BAIRD
Department of Chemistry, University of Western Ontario, London, Ontario
Received August 28, 1970

The heats of formation at 25 °C and the equilibrium carbon–carbon bond lengths are calculated by the neglect of nonbonded differential overlap molecular orbital theory for a series of conjugated, acyclic free radicals containing from one to nine unsaturated carbon atoms. The total bonding energies in the radicals exceed the values expected from polyene bond terms by 5–9 kcal/mol, depending on the length and branching of the chain.

Canadian Journal of Chemistry, 49, 338 (1971)

Introduction

Although considerable experimental difficulties are associated with the determination of thermodynamic properties of free radicals, the potential utility of such information continues to spur considerable research in this field. Heats of formation (ΔH_f) of hydrocarbon free radicals are useful (*1*) in deducing the nature of the bonding in open-shell systems, (*2*) in calculations of the rates of homolytic gas-phase reactions (*1*), and (*3*) in the estimation of the energies of twisted triplet states of polyenes (2), etc.

Recently, Dewar *et al.* (3) have shown that accurate ΔH_f's for hydrocarbon free radicals can be calculated using the same molecular orbital theories which have proven so successful in reproducing the ΔH_f's of closed-shell organic molecules. In this paper, a π electron s.c.f.-l.c.a.o.-m.o. method is used to explore the thermochemistry and bonding in acyclic, conjugated free radicals containing from one to nine sp^2-hybridized carbon atoms.

Method of Calculation

The molecular orbital theory employed herein is a variant of the n.n.d.o. (neglect of nonbonded differential overlap) method reported previously (4). The bonding energy and the equilibrium bond lengths in each free radical are evaluated by deducing the optimum set of π electron molecular orbitals via the "half-electron" procedure (3); the total bonding energy associated with the carbon–carbon and the carbon–hydrogen single bonds is evaluated empirically from Morse functions (4).

[1]Research supported by the National Research Council of Canada.

The n.n.d.o. theory used here differs from that previously reported only in several of the semi-empirical parameter values; the new version yields more accurate energies and geometries than did the old:

(*i*) The equilibrium $C(sp^2)$–$C(sp^2)$ single bond energy is taken as 88.8 (rather than 88.0) kcal/mol.

(*ii*) The two-center component β (in eV) of the resonance integral between carbon atoms separated by distance R (in Å) is now

$$\beta = -105.202/\exp(1.985R)$$

(*iii*) The bond lengths R are made self-consistent with the simple bond order matrix **P** (no overlap populations included) by

$$R = 1.496 - 0.2021\mathbf{P}$$

In all cases, *initial* bond lengths of 1.4 Å and idealized bond angles of 120° were assumed.

Results and Discussion

The calculated heats of formation for eight conjugated free radicals are listed in the fourth column of Table 1. The agreement between the calculated and experimental ΔH_f's is excellent (within 2 kcal/mol) for the three radicals, methyl,[2] allyl, and pentadienyl, for which measurements are available. In the case of the branched free radicals (**4**, **6**, and **7**), there exists steric interactions between hydrogen atoms separated by three carbon–carbon bonds of the same type that destabilize *cis*-butadiene by 2 kcal/mol

[2]Note that the ΔH_f of CH_3 (along with those of ethylene, *trans*-butadiene, benzene, naphthalene, and anthracene) was used to fit the parameters. The r.m.s. error in the ΔH_f is reduced from 1.4 to 0.5 kcal/mol for this series by use of the new parameterization.

TABLE 1. Thermochemistry at 25 °C of free radicals (kcal/mole)

Radical	Source	ΔH_f of radical: Experimental	Calculated	Adjusted*	ΔH_f†	ΔH‡

*ΔH_f's of 4, 6, and 7 corrected for steric interactions. See text for details.
†From ref. 7 unless indicated otherwise.
‡ΔH for the reaction RH → R + H, where ΔH_f(H) = 52.1 kcal/mol.
§See ref. 8.
‖See ref. 9.
¶Extrapolated from the ΔH_f's (see note † above) of the series ethylene, *trans*-butadiene, propene, 2-methylbutadiene, and 1-*trans*-3-pentadiene.

relative to the *trans* conformation (5). Since such effects are not included in the present molecular orbital treatment, an empirical correction of the above magnitude has been applied where applicable (column five of Table 1). Given the calculated ΔH_f's in Table 1, the C—H and C—C bond dissociation enthalpies in a wide variety of closed-shell hydrocarbons can be determined, provided the ΔH_f of the latter is known or can be estimated. As an example of this application, the heats of reaction from various reactants (column 2 of Table 1) to the conjugated radicals are listed in the last column of Table 1.

The trends in the theoretical ΔH_f's (Table 1) and in the calculated bond lengths (Table 2) yield an interesting insight into the bonding in conjugated free radicals. The change in the ΔH_f when an additional double bond is joined to an unbranched radical increases with chain length, and eventually converges to the value of $\sim$ 14 kcal/mol found in closed-shell polyenes

$$\Delta\Delta H_f(C_3 - C_1) = 8.9 \text{ kcal/mol}$$
$$\Delta\Delta H_f(C_5 - C_3) = 11.4 \text{ kcal/mol}$$
$$\Delta\Delta H_f(C_7 - C_5) = 13.2 \text{ kcal/mol}$$
$$\Delta\Delta H_f(C_9 - C_7) = 13.8 \text{ kcal/mol}$$

Thus the unbranched radicals having three, five, seven, and nine carbon atoms are stabilized by 5.1, 7.7, 8.5, and 8.7 kcal/mol relative to the *effective* double and single bond energies operative in polyenes. Combining the stabilization in allyl with the known single-bond rotation barrier of $\sim$ 5 kcal/mol in *trans*-butadiene (6) leads to the prediction that the barrier to rotation about a carbon–carbon bond of $\sim$ 10 kcal/mol in the allyl free radical.

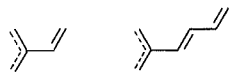
	5–6	1.368
	3–7′	1.370
8	1–2	1.351
	2–3	1.452
	3–4	1.378
	4–5	1.416

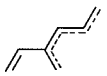
*In branched radicals, the carbon atoms are numbered starting from the left of the diagram in Table 1 and along the all *trans* backbone. The primed numbers refer to atoms branched off this backbone.

The calculated bond distances in the unbranched radicals further emphasize the decreasing importance of additional electron delocalization in the longer chains. There is a marked tendency for the terminal bonds to acquire full polyene "double bond" character and for the penultimate bonds polyene "single bond" character; for example the C_9 free radical is well represented by the single structure

The extent of bond alternation is more pronounced in the radicals **4** and **6** which are both branched at the 2 position. The bonding in these systems simulates that of an allyl radical joined at its "inactive" middle carbon to ethylene and to butadiene, respectively, by a polyene-like single bond, since the bond distances are well characterized by the structures



This interpretation is supported by the energetics of the free radicals, since the increases in the ΔH_f upon adding two and four carbon atoms to allyl in this manner are calculated as +14.0 and +27.8 kcal/mol, respectively, which are essentially identical to the values calculated for addition of double bonds to ethylene of +14 and +28 kcal/mol. Similarly, the bond lengths in the seven-carbon radical branched at the 3-position simulate those of a polyene unit joined at an inactive position of the pentadienyl radical



The calculated energy for this system is, however, almost 1 kcal/mol greater than expected for this structure.

Chemistry of the Aminochromes. Part XIV. Noradrenochrome[1,2]

W. S. POWELL[3,4] AND R. A. HEACOCK[5,6]
Department of Biochemistry, Faculty of Medicine, Laval University, Quebec 10, Quebec

Received July 30, 1970

The preparation, in pure crystalline form, of noradrenochrome and its monosemicarbazone, together with some of their more important properties is described.

Canadian Journal of Chemistry, 49, 341 (1971)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

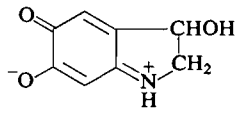
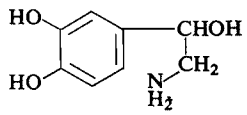
Despite the fact that adrenochrome, the important red quinonoid oxidation product of adrenaline, has been known in crystalline form since 1937 (1), noradrenochrome (**1**), the corresponding aminochrome (*cf.* refs. 2, 3) obtained from noradrenaline (**2**), has not been fully characterized in the solid state. The properties of solutions containing variable amounts of **1** prepared by the oxidation of solutions of **2** have been described fairly extensively (*cf.* refs. 2, 3). These solutions may also have contained other substances, such as unchanged **2** and its initial, uncyclized oxidation product, noradrenaline quinone (4, 5). Noradrenochrome (**1**) has been obtained as "red rings on the side of the flask" after solutions containing **1**, prepared by the oxidation of **2** with silver oxide in acetonitrile (6), were concentrated to dryness *in vacuo*. However, the preparation of crystalline **1** has not yet been reported. This note describes the preparation, characterization, and properties of this interesting oxidation product of noradrenaline (**2**).

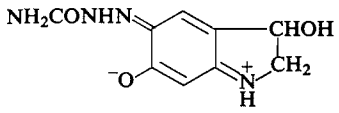
Noradrenochrome (**1**) can be obtained as a deep reddish-violet crystalline solid on careful concentration, at low temperatures, of its solutions in methanol, prepared by oxidation of suspensions of **2** (free base) by silver oxide. Extreme care must be taken to remove all traces of silver from the solutions containing **1** prior to their concentration. This has been achieved by filtration of the solution, firstly through a bed of anhydrous sodium sulfate (*cf.* 7) and



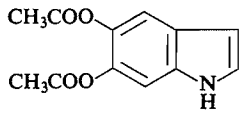
1



2



3



4

secondly through a Dowex-1 (Cl^-) resin bed (*cf.* 8). There appeared to be no advantage in centrifuging the solution (*cf.* 9) prior to crystallization of the aminochrome.

A crystalline derivative of **1**, the monosemicarbazone **3**, has been prepared directly from the aminochrome. This compound has not previously been described in the literature. The aminochrome monosemicarbazones have considerable importance in medicine as haemostatic agents (*cf.* refs. 3, 10).

Noradrenochrome (**2**) can be easily reduced in aqueous solution by ascorbic acid (*cf.* refs. 2, 3) to 5,6-dihydroxyindole, which can readily be isolated as its diacetyl derivative (*i.e.* **4**).

Experimental

The melting points were determined on either a Leitz Hot-Stage instrument or a Fisher–Johns apparatus and are uncorrected. The i.r., u.v., n.m.r., and mass spectra were determined on Perkin–Elmer model 237, Bausch and Lomb 505, Varian A-60-A, and Dupont/C.E.C. 21-110B instruments respectively.

Noradrenochrome (1)

Freshly prepared silver oxide (22.5 g) was added to a suspension of L-noradrenaline base (5 g, Schuchardt) in

dry methanol (500 ml) at 32°. The reaction mixture was vigorously shaken for 6 min at this temperature (it was possible to maintain the temperature at 32° without external heating due to the mildly exothermic nature of the reaction), after which time it was filtered firstly through an anhydrous sodium sulfate bed (height = 2 cm; diameter = 11 cm) and secondly through a Dowex-1 × 8 (Cl^-) resin[7] bed (height = 3 cm; diameter = 10 cm). The filtrate was concentrated below 20° *in vacuo* to small bulk (*ca.* 30 ml), until crystals began to form in the solution. Noradrenochrome was obtained in dark reddish-violet needles [150 mg (3%); totally decomposed without melting by 105°] on filtration of the solution; $\lambda_{max}(H_2O)$ nm(ε): 217(22 350), 293(8580), 488(3190); ν_{max}(KBr): 3320 (sh), 3120, 1676, 1663, 1622, 1580, 1530 cm^{-1}.

Anal. Calcd. for $C_8H_7NO_3$: C, 58.18; H, 4.24; N, 8.48. Found: C, 58.39; H, 4.08; N, 8.56.

Noradrenochrome Monosemicarbazone (3)

Semicarbazide hydrochloride (27 mg) in acetate buffer (1.5 ml) at p*H* 5 was added to a stirred solution of noradrenochrome (20 mg) in water (1.5 ml). The crude monosemicarbazone (15 mg) was obtained in brownish-orange needles after the solution had been allowed to stand at room temperature for 1.5 h. Pure noradrenochrome monosemicarbazone [9 mg (34%); totally decomposed without melting by 221°] was obtained in fine orange needles after recrystallization of the crude product from water; λ_{max}(0.1 *N* HCl): nm(ε): 373(29 000); $\lambda_{max}(H_2O)$ nm(ε): 440(sh), 351(27 000); λ_{max}(0.1 *N* NaOH) nm(ε): 441 mμ (27 700).

Anal. Calcd. for $C_9H_{10}N_4O_3$: C, 48.65; H, 4.54; N, 25.22. Found: C, 48.84; H, 4.46; N, 25.03.

Reduction of Noradrenochrome (1) by Ascorbic Acid (cf. 11); Preparation of 5,6-Diacetoxyindole (4)

Ascorbic acid (400 mg) was added to a mixture of noradrenochrome (75 mg) in water (5 ml) and peroxide-free ether (15 ml). The system was vigorously shaken until the red color was totally discharged (about 1 min). The ether phase was removed and dried (Na_2SO_4) and a mixture of acetic anhydride (2 ml) and dry pyridine (2 ml) added. After removal of the ether *in vacuo* the reaction mixture was allowed to stand at room temperature for 2 h, and was then evaporated to dryness *in vacuo*. The residue was dissolved in CH_2Cl_2 (15 ml) and washed in turn with the following reagents: 0.1 *N* HCl (15 ml), saturated aqueous sodium bicarbonate (3 × 15 ml), and water (2 × 15 ml). The CH_2Cl_2 solution was dried (Na_2SO_4) and on evaporation to dryness gave a white crystalline solid (47 mg), which gave 5,6-diacetoxyindole [38 mg (36%), m.p. 139–142°] on recrystallization from heptane containing a small quantity of benzene, lit. m.p. 139–140° (12), 130–133° (13). The n.m.r., τ($CDCl_3$): 1.6 (broad s, *N*—H), 2.74 (s, H_4), 2.96 (s, H_7), 3.08 (t, H_2), 3.70 (t, H_3), 7.73 (s, CH_3). After shaking with D_2O the peak at τ 1.6 disappeared and the triplets at τ 3.08 and 3.70 collapsed to doublets ($J_{2,3}$ = 2.7 Hz).[8] Mass spectrum: $M^{+\cdot}$ 233.0684 ± .0007; Calcd. for $C_{12}H_{11}NO_4$ 233.06881.

The authors wish to express their thanks to Dr. L. Babineau (Department of Biochemistry, Faculty of Medicine, Laval University) for providing the necessary space and facilities in his laboratories to enable this research to have been carried out. The n.m.r. spectrum was obtained by courtesy of Dr. R. Burnell (Department of Chemistry, Faculty of Science, Laval University). The mass spectrum was recorded by Mr. D. Embree (A.R.L.).

Hydrocarbon Complexes of Iron Carbonyls Formed Photochemically in Argon Matrices at 17 K

M. J. NEWLANDS AND J. F. OGILVIE
Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received August 5, 1970

Irradiation of pentacarbonyliron with ethene in an argon matrix gives $(C_2H_4)Fe(CO)_4$, while ethyne reacts with the carbonyl under similar conditions to give a complex of 1-buten-3-yne.

Canadian Journal of Chemistry, 49, 343 (1971)

Matrix isolation coupled with absorption spectrometry has recently been shown to be a convenient method for the study of photochemical reactions of transition metal carbonyl derivatives (1). Products were detected which could not be prepared by standard thermal methods.

Further studies with ethene and normal and deuterated ethyne have now been carried out. A mixture of the hydrocarbon and pentacarbonyliron in an argon matrix (proportions ~10:1:100) at 17 K has been subjected to photolysis by radiation from a mercury lamp filtered to exclude wavelengths < 312 nm and between 417 and 676 nm.

Reaction of ethene with pentacarbonyliron during irradiation produces carbon monoxide and a monoalkene complex, $(C_2H_4)Fe(CO)_4$, a compound previously prepared by a high-pressure reaction (2).

A comparison of the important new bands in the vibrational spectrum (Perkin–Elmer 225, CsI optics), with the fundamental wave numbers previously reported appears in Table 1. Further irradiation leads to new bands, such as 1490 and 1218 cm^{-1}, which may indicate loss of further carbon monoxide from the alkene complex.

*Masked by remaining ethene.

Reactions of ethyne with iron carbonyls yield complex mixtures of products under conventional conditions (3). In the present experiments, spectrometric changes during photolysis indicate production of 1-buten-3-yne, which complexes with the iron via the alkyne group only. The principal evidence for this comes from new bands for $C_2H_2(C_2D_2)$ at 1709 (1560), co-ordinated C≡C vibration (4); 1547 (1462), uncoordinated C=C (5); 912 (796), methylene wag of vinyl group (5); and 672 (531) cm^{-1}, CH bending vibration of C≡CH group which is presumably no longer linear. Dimerization of ethyne to 1-buten-3-yne in the presence of copper(I) salts was discovered by Nieuwland *et al.* about 1930 (6), but the present work appears to have provided the first evidence for a complex of 1-buten-3-yne with a metal other than copper. Photolysis of ethyne itself, either gaseous or solid, requiring light of wavelength < 257 nm, produces 1-buten-3-yne as a minor by-product and then only under special conditions (7).

Photochemistry of Steroid 4-en-3-one 11α-Nitrites. A Novel Synthesis of A-Nor-B-homo Steroids

HANS REIMANN AND OLGA Z. SARRE
Schering Corporation, Bloomfield, New Jersey 07003

Received September 25, 1970

Photolysis of some 11α-hydroxysteroid 4-en-3-one nitrites afforded 1-oximinosteroid 4-en-3-ones and 9*a*-methyl-B(9*a*)-homo-A-norsteroid 3(5),9*a*-dien-2-ones. Chemical and physical evidence for the latter, as well as a plausible mechanism for the transformation, is presented.

La photolyse de quelques nitrites dérivés d'hydroxy-11α oxo-3 Δ^4-stéroides a fourni des oximino-1 oxo-3 Δ^4-stéroides et des oxo-2 $\Delta^{3(5),9}$ méthyl-9*a* B(9*a*)-homo A-norstéroides. Des preuves physiques et chimiques de la nature de ces derniers composés ainsi qu'un mécanisme plausible pour cette transformation sont aussi présentés.

Canadian Journal of Chemistry, **49**, 344 (1971)

Since the original publication by Barton and coworkers (1), the photolysis of organic nitrites has provided many interesting and sometimes unexpected transformation products (2). In general, the Barton reaction in the steroid series has been directed to the functionalization of axial angular methyl groups, starting with suitably oriented nitrite esters. It appeared, however, that it should be possible to involve a ring methylene group in hydrogen abstraction by an alkoxy radical, generated from an equatorial nitrite group located so as to permit the formation of a six-membered transition state. This communication reports the photolysis of nitrite esters of some 11α-hydroxysteroid 4-en-3-ones, resulting in attack at C-1.[1]

Irradiation of 11α-hydroxy-4-pregnene-3,20-dione nitrite (**1***a*, obtained as a gum from the free alcohol by reaction with nitrosyl chloride in pyridine) in toluene afforded two major products. One of these was identified as the expected product of the Barton reaction, 11α-hydroxy-1-oximino-4-pregnene-3,20-dione (**2***a*),[2] m.p. 238–240° dec.; $[\alpha]_D$ +3.5° (chloroform); λ_{max}(MeOH) 238 nm (ε 12 900); λ_{max}(NaOH) 365 nm; λ(Nujol) 2.80, 3.04, 5.88, 6.02, 6.18, 10.5 μ; δ 0.67 (s, 18-H_3), 1.51 (s, 19-H_3), 2.12 (s, 21-H_3), 5.90 (broad s, 4-H) p.p.m.[3] The second major product was assigned structure **3***a* (R = H), 11α-hydroxy-9*a*-methyl-B(9*a*)-homo-A-nor-3(5),9*a*-pregnadien-2-one, on the basis of its physical and spectroscopic properties as well as chemical transformations.[4] Compound **3***a* (R = H) (m.p. 170–171°; $[\alpha]_D$ −220°; λ_{max}(MeOH) 306 nm (ε 17 900); λ(Nujol) 2.95, 5.90, 6.03, 6.43 μ) contained no nitrogen and analyzed well for $C_{21}H_{28}O_3$. The molecular formula was supported by the mass spectrum, molecular ion at *m/e* 328 and a prominent peak due to loss of H_2O at *m/e* 310. The n.m.r. spectrum was interpretable on the basis of the assigned structure, δ 0.71 (s, 18-H_3), 2.01 (s, 19-H_3), 2.17 (s, 21-H_3), 2.94 (s, 1-H_2), 4.17 (t of d, J = 10 and 5 Hz, 11β-H), 5.91 (broad s, 3-H) p.p.m. The compound was purified via its acetate (**3***a*, R = $COCH_3$), m.p. 168–170°; $[\alpha]_D$ −186° (chloroform); λ_{max}(MeOH) 303 nm (ε 17 500); λ(Nujol) 5.75, 5.86, 5.98, 6.03, 6.40, 8.0 μ; mass spectrum, no molecular ion, but prominent peak at *m/e* 310;

[1] *cf.* The reaction of 11α-hydroxysteroids with lead tetraacetate (3). The photolysis of an 11α-nitrite in a ring A saturated triterpene was recently used in the synthesis of β-amyrin (4).

[2] All new crystalline compounds gave satisfactory analytical values. Physical measurements were performed under the direction of Dr. M. Yudis. The n.m.r. spectra were recorded in deuteriochloroform solution with TMS as internal standard. Rotations were measured in dioxane unless otherwise noted.

[3] The chemistry of 1-oximino-steroid 4-en-3-ones such as **2***a* will be reported elsewhere.

[4] The 9*a*-methyl-B(9*a*)-homo-A-nor-3(5), 9*a*-dien-2-one steroid system has very recently been described as the product of a complex reaction sequence (5).

δ 0.76 (s, 18-H_3), 1.73 (s, 19-H_3), 2.03 (s, acetate), 2.15 (s, 21-H_3), 2.94 (s, 1-H_2), 5.96 (s, 3-H) p.p.m., from which it was readily regenerated by saponification with potassium hydroxide in aqueous methanol. Attempts to dehydrate the alcohol **3***a* (R = H) under a variety of conditions were unsuccessful; however, the acetate **3***a* (R = $COCH_3$) readily underwent pyrolytic elimination in mineral oil at about 350° to afford the 3(5),9*a*,9(11)-trien-2-one (**4**), m.p. 145–146°; $[\alpha]_D$ +57°; λ_{max}(MeOH) 215 (ε 6200), 233–238 (ε 6500), 314 nm (ε 18 300); λ(Nujol) 5.85, 5.92, 6.07, 6.37 μ; mass spectrum, molecular ion *m/e* 310; δ 0.68 (s, 18-H_3), 2.01 (s, 19-H_3), 2.15 (s, 21-H_3), 2.98 (s, 1-H_2), ~5.80 (m, 11-H), 5.92 (s, 3-H) p.p.m. Compound **4** on hydrogenation with palladium on calcium carbonate in benzene consumed 2 mol of hydrogen, giving the conjugated cyclopentenone derivative (**5**), m.p. 175–176°; λ_{max}(MeOH) 236 nm (ε 16 000); λ(Nujol) 5.85, 5.89 (sh), 6.22 μ; δ 0.65 (s, 18-H_3), 0.70 (d, J = ~7 Hz, 19-H_3), 2.11 (s, 21-H_3), 5.91 (m, 3-H) p.p.m. The stereochemistry of **5** at C-9, -9*a*, and -10 has not been established; it is presumed that hydrogenation from the α-face may be preferred.

The photolysis of an 11α-nitrite was also carried out, *inter alia*, in the 17α-methyltestosterone series. The requisite starting material, 11α,17β-dihydroxy-17α-methyl-4-androsten-3-one 17-acetate 11-nitrite (**1***b*, R′ = $COCH_3$), m.p. 143–144° dec.; $[\alpha]_D$ +27°; λ_{max}(MeOH) 239 nm (ε 18 200); λ(Nujol) 5.78, 5.98, 6.13, 6.22, 7.87, 7.95 μ, was prepared from 11α-hydroxy-17α-methyltestosterone by diacetylation, selective hydrolysis at C-11, and reaction with nitrosyl chloride. Irradiation of **1***b* (R′ = $COCH_3$) afforded the 1-oxime (**2***b*, R′ = $COCH_3$), m.p. 258–259° dec.; $[\alpha]_D$ −125°; λ_{max}(MeOH) 239 nm (ε 13 800), λ_{max}(NaOH) 365 nm; λ($CHCl_3$) 2.81, 3.0, 5.80, 5.97, 6.20, 7.9 μ, and the A-nor-B-homo compound (**3***b*, R = H, R′ = $COCH_3$), m.p. 259–262° dec.; $[\alpha]_D$ −285°; λ_{max}(MeOH) 307 nm (ε 17 300); λ(Nujol) 3.01, 5.75, 5.95, 6.10, 6.38, 7.9, 8.0 μ, as the major products. Acetylation of **3***b* (R = H, R′ = $COCH_3$) gave the 11,17-diacetate (**3***b*, R = R′ = $COCH_3$), m.p. 180–181°; λ_{max}(MeOH) 218 (ε 7000), 303 nm (ε 17 500); λ(Nujol) 5.76, 5.92, 6.10, 6.40, 8.0 μ, while saponification afforded the diol (**3***b*, R = R′ = H), m.p. 232–233° dec.; $[\alpha]_D$ −311°; λ_{max}(MeOH) 216 (ε 6900), 308 nm (ε 17 200); λ(Nujol) 3.0 (broad), 6.00, 6.10, 6.42 μ, which was converted to the 11-acetate (**3***b*, R = $COCH_3$, R′ = H), m.p. 186–190°; λ_{max}(MeOH) 218 (ε 7800), 304 nm (ε 17 000); λ(Nujol) 2.91, 5.76, 5.96, 6.37, 8.0 μ.

The products of the photolysis may be rationalized on the basis of the C-1 radical **A**, which may combine with NO to yield the 1-oxime **2**, or alternatively proceed to the A-nor-B-homo compound **3** via the C-4 radical **B** by loss of the C-1 hydrogen with cleavage of the C_5—C_{10} bond.

Infrared Studies of Water in Crystalline Hydrates: $LiI.3H_2O$[1]

GEORGE BRINK[2] AND MICHAEL FALK

Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received September 14, 1970

The infrared spectra of undeuterated and partially deuterated $LiI.3H_2O$ were recorded between 4000 and 1000 cm^{-1}. The splitting of the fundamentals of isotopically dilute HDO indicates that the water molecules are distorted and form one strong, linear OH...I^- hydrogen bond and one weak, non-linear hydrogen bond. The non-equivalence of the two hydrogens of the water molecule disagrees with the space group $P6_3mc$-C_{6v}^4 for this hydrate, proposed on the basis of X-ray diffraction studies. It is concluded that the space group, including hydrogens, is one of lower symmetry, $P6_3$-C_6^6. The gradual broadening and convergence of the HDO fundamentals at increasing temperature is explained by increasing librational motion of the water molecules.

Canadian Journal of Chemistry, 49, 347 (1971)

Introduction

The crystal structure of $LiI.3H_2O$ was examined in 1928 by Hendricks, who reported a hexagonal unit cell with $a = 7.45$ Å and $c = 5.45$ Å, two formula units per unit cell and space group $P6_3mc$-C_{6v}^4 (1). West re-examined the structure in 1934, confirmed the space group, and derived approximate atomic coordinates for iodine, oxygen, and lithium (2). According to West the structure of $LiI.3H_2O$, like that of $LiClO_4.3H_2O$, has the space group $P6_3mc$ (2). In both hydrates the water oxygens (O_w) lie on planes of symmetry, and are coordinated to two lithium cations and, through hydrogen bonds, to two anions.

In the case of $LiClO_4.3H_2O$ the basic structure proposed by West has been confirmed. The proton positions have been located and the presence of weak hydrogen bonds established by Raman spectroscopy (3), nuclear magnetic resonance (4), neutron diffraction (5, 6), and infrared spectroscopy (7). The structure of $LiI.3H_2O$, on the other hand, does not appear to have been further studied in the past 36 years and the proton positions are unknown. As a part of our research program on the infrared spectra and structure of water in crystalline hydrates (7–9), we have now investigated $LiI.3H_2O$.

[1]NRCC No. 11 633.

[2]NRCC Postdoctorate Fellow, 1968–1970.

Experimental

$LiI.3H_2O$ was obtained from Alpha Inorganics, Beverley, Mass. Because of the plasticity and lack of cleavage of this hydrate, it is not possible to grind it and the usual techniques of sample preparation employing Nujol mulls and KBr pellets cannot be used. Instead, thin films of $LiI.3H_2O$ on CaF_2 plates were used, prepared as follows: a drop of a nearly saturated solution of LiI in H_2O or in a mixture of H_2O and D_2O, heated to about 35°, was placed between two warm CaF_2 plates,[3] forming a capillary film. The plates were allowed to cool to room temperature, then slid apart, producing a thin film of saturated solution on each plate. Gentle evaporation of such films under a stream of dry nitrogen in a room maintained at about 20% relative humidity produced clear polycrystalline films of $LiI.3H_2O$. The films had a melting point of 75.4°, in good agreement with the literature value of 75.5° (10). At higher humidities the crystals deliquesced rapidly. At lower humidities (*e.g.* over concentrated H_2SO_4) the crystals were dehydrated to lower hydrates.[4]

[3]AgCl plates could not be used because they are attacked by aqueous LiI.

[4]We have obtained the spectra of the lower hydrates by controlled dehydration of the trihydrate. The dihydrate was obtained by exposing the trihydrate films to a partial vacuum of about 0.01 mm Hg for 20 min. The observed melting point was 77.9° [$LiI.2H_2O$, m.p. 78° (10)]. The main absorption bands of the dihydrate above 1000 cm^{-1} (the transmission cut-off of the CaF_2 plate) are: OH stretching at 3390 and 3470 cm^{-1}, HOH bending at 1604 cm^{-1} with a shoulder at 1620 cm^{-1}, and its overtone $2\nu_2$ at 3219 cm^{-1}. When the films were exposed to a vacuum of about 0.001 mm Hg, a spectrum of what may be the monohydrate was obtained: OH stretching at 3480 and 3412 cm^{-1}, HOH bending at 1612 cm^{-1}, $2\nu_2$ overtone at 3210 cm^{-1}. The above spectra were recorded at room temperature.

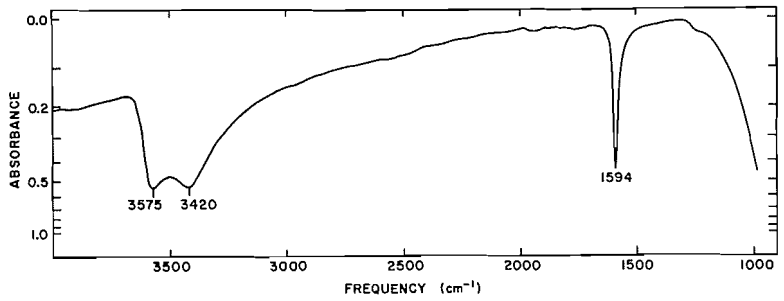

FIG. 1. Spectrum of undeuterated $LiI.3H_2O$ on a CaF_2 substrate at room temperature.

Isotopically dilute HDO was used in this study since it has a far simpler vibrational spectrum than H_2O or D_2O and hence is preferable in structural studies (11–13). The D:H ratios in the hydrate were taken to be twice the ratio of the area of the OD stretching band to the area of the OH stretching band in the spectrum of the parent solution (14, 15). The HDO concentration was about 6%, assuming a random distribution of H and D. It was not practical to work with lower HDO concentrations in view of the extremely thin films used.

Spectra were recorded on a Perkin–Elmer model 521 spectrophotometer, as described in ref. 7. In low-temperature experiments, the hydrate films were protected from dehydration by a thin film of Nujol or halocarbon oil.

Results

The spectrum of undeuterated $LiI.3H_2O$ at room temperature is shown in Fig. 1. The bands at 3575 and 3420 cm^{-1} are due to OH stretching. The band at 1594 cm^{-1} is due to HOH bending. The small band near 1250 cm^{-1} is probably due to the overtone of the librational frequencies near 625 cm^{-1}, which are not accessible because of the absorption of the CaF_2 window. At $-175°$ the OH stretching bands are better resolved and occur at 3586 and 3409 cm^{-1}; the HOH bending is at 1590 cm^{-1} and its overtone, $2\nu_2$, at 3170 cm^{-1}.

Figure 2 shows the bands due to OD stretching and HOD bending fundamentals of isotopically dilute HDO in $LiI.3H_2O$ in the temperature range $+25$ to $-175°$. At low temperatures both fundamentals give rise to doublets, separated by 110 cm^{-1} for OD stretching and 20 cm^{-1} for HOD bending. Increasing temperature causes a gradual broadening and convergence of the doublets. At room temperature the two OD stretching bands are still separated by about 60 cm^{-1} while the two components of the HOD bending are no longer resolved.

Discussion

Site Symmetry of H_2O and the Space Group of $LiI.3H_2O$

West (2) placed the oxygen atom, O_w, of the water molecule of $LiI.3H_2O$ in the 6(*c*) equipoint, which has the symmetry m-C_s (16). The six water molecules must then be equivalent; this is confirmed by the single HOH bending fundamental in Fig. 1. The two hydrogen atoms of the water molecule are unlikely to lie *on* the mirror plane passing through O_w, Li′, and Li″, as this would lead to a planar four-fold coordination about the water oxygen. The expected, approximately tetrahedral coordination places the hydrogen atoms *off* the mirror plane, as shown by the dotted lines in Fig. 3*B*, and renders them equivalent by symmetry.

The splitting of the HDO fundamentals shows, however, that the water molecules are distorted and their two hydrogens non-equivalent (8, 17). The infrared spectra thus suggest that the planes of symmetry are in fact absent, as far as the hydrogen positions are concerned. Therefore, the space group of $LiI.3H_2O$ *including hydrogens* is not $P6_3mc$-$C_{6v}{}^4$, but one of lower symmetry, $P6_3$-$C_6{}^6$.

Hydrogen Bonding in $LiClO_4.3H_2O$ and in $LiI.3H_2O$

In $LiClO_4.3H_2O$, the O . . . O_w. . . O angle is 125° (2), only 16° wider than the usual H—O_w—H angle of about 109° in crystals. Neutron diffraction studies (5, 6) have shown that the two O_w—H bonds assume symmetric orientations with respect to the Li′—O_w—Li″ plane. This leads to two equivalent hydrogen bonds, O_w—H′. . . O′ and O_w—H″. . . O″, which are slightly non-linear, the O—H . . . O angle being about 160° (Fig. 3*A*). The absence of splitting of the HDO fundamentals in the infrared spectrum

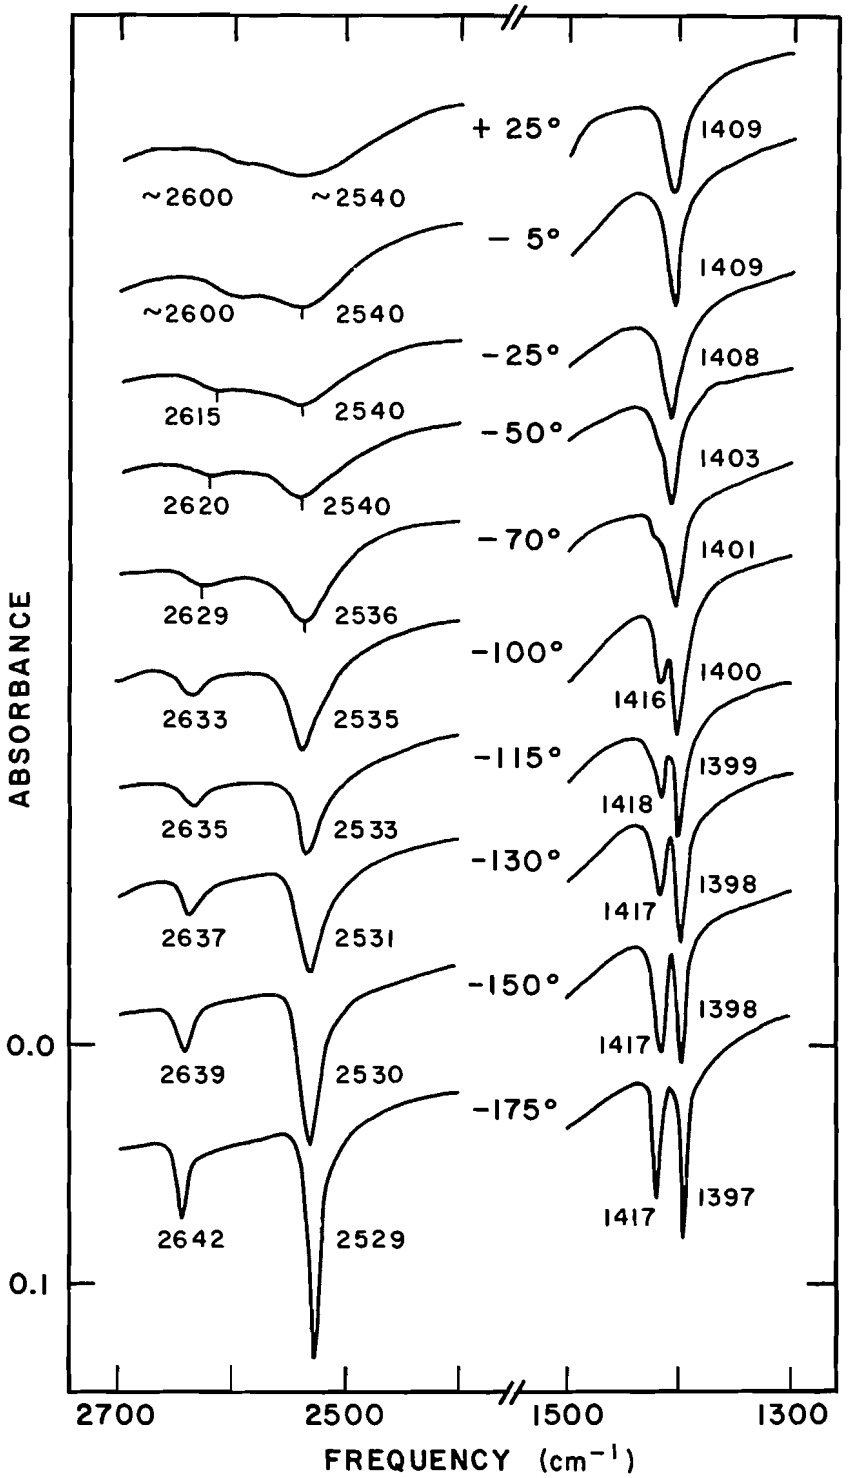

FIG. 2. Spectrum of partially deuterated LiI.3H$_2$O (H:D = 97:3) in the OD stretching and HOD bending regions at various temperatures.

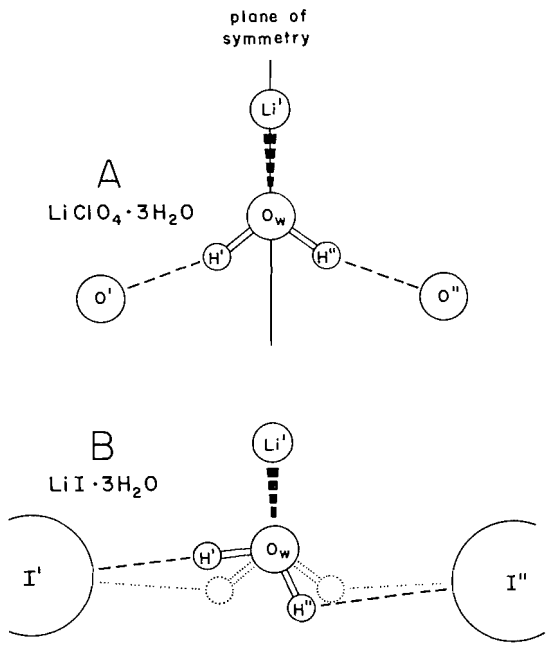

FIG. 3. The environment of the water molecule in $LiClO_4.3H_2O$ and $LiI.3H_2O$, viewed down the six-fold axis which passes through Li′ and Li″ (eclipsed). Heavy atom positions are from West (2); hydrogen atom positions are discussed in the text.

of this hydrate is a particularly sensitive confirmation of the equivalence of O_wH' and O_wH'' (7).

In $LiI.3H_2O$, if we accept West's coordinates for the heavy atoms (2), the I′. . . O_w. . . I″ angle is about 169°, much wider than the usual H—O_w—H angle of 109°. If the O_w—H bonds of the water molecules were oriented symmetrically with respect to the Li′—O_w—Li″ plane, as in $LiClO_4.3H_2O$, the angles O_w—H′. . .I′ and O_w—H″. . . I″ would be 140° and the two hydrogen bonds highly non-linear (Fig. 3*B*, dotted lines). Alternatively, the water molecules may be oriented in such a way as to form two unequal OH . . . I hydrogen bonds. In the extreme case, one bond would be linear and the other extremely non-linear, with an OH . . . I angle of about 103°, as shown by full lines in Fig. 3*B*. There are two equivalent ways in which a water molecule can achieve this configuration: the linear bond may be formed with either I′ or with I″.

The splitting of the HDO fundamentals in partially deuterated $LiI.3H_2O$ shows that in this hydrate, in contrast to $LiClO_4.3H_2O$, the orientation of least energy is asymmetric. At the lowest temperature, −175°, the water molecules appear to adopt the extreme configuration of Fig. 3*B*. The OD stretching frequency of 2529 cm^{-1} corresponds to a relatively strong hydrogen bond, which must be nearly linear, while the frequncy of 2642 cm^{-1} corresponds to an extremely weak bond, which must be non-linear. The two possible asymmetric orientations are of equal energy and are separated by a small potential maximum; they probably occur statistically throughout the crystal. At low temperatures, when only the lower librational energy levels are occupied, each water molecule has one strongly bonded and one weakly bonded OH group. With increasing temperature the higher energy levels of the libration of the water molecule about the axis parallel to the six-fold axis of the crystal become increasingly occupied. This libration will tend to bend and thus weaken the stronger OH . . . I bond and at the same time straighten and thus strengthen the weaker OH . . . I bond. The resulting gradual reorientation causes the observed shifting together and broadening of the HDO doublets. Librational levels which lie above the central maximum of the double-well potential correspond to states in which the water molecule is *on the average* symmetrically oriented. Thus, at sufficiently high temperatures a coalescence of the HDO doublets may be expected. This coalescence does not occur for the OD stretching fundamental of partially deuterated $LiI.3H_2O$, but appears to arise for partially deuterated $Ba(ClO_4)_2.3H_2O$ and $NaClO_4.H_2O$, for both of which the split HDO fundamentals merge into a single broad band before the dehydration temperature is reached (7).

Electron Spin Resonance Study of Surface Defects of Silica Gel Formed by Gas Discharges[1]

K. HUKUDA[2] AND Y. AMENOMIYA
Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received July 27, 1970

Surface defects of silica gel formed by a microwave electric discharge in a stream of oxygen and of nitrogen have been studied by means of electron spin resonance (e.s.r.) spectroscopy. The magnetic center is identified as a hole trapped by a surface oxygen atom which is formed by the removal of a hydrogen atom from a hydroxyl group. The principal values of the **g**-tensor were found to be $\mathbf{g}_{xx} = 2.037$, $\mathbf{g}_{yy} = 2.008$, and $\mathbf{g}_{zz} = 2.002$, respectively, where the direction of x-axis was taken along the O—Si bond. The center has a weak hyperfine interaction with a hydrogen nucleus of an adjacent hydroxyl group. The hyperfine splitting is 15 Oe.

Canadian Journal of Chemistry, 49, 352 (1971)

Introduction

Since the early work of Kazanskii *et al.* (1) on hydrogen atoms trapped on the surface of silica gel, a number of attempts have been made to detect e.s.r. signals of atoms and free radicals adsorbed on solid surfaces. This type of work provides useful information on the structure of solid surfaces which aids our understanding of the catalytic activity of solids. Recently, particular interest has been shown in e.s.r. signals with three different components of **g**-tensor (we call this kind of center a three-**g**-value center hereafter). Kasai (2) reported a set of principal **g**-values, 2.0046, 2.0090, and 2.057, for O_2^- on barium zeolite, and 2.0016, 2.0066, and 2.113 for O_2^- on sodium zeolite. Wang and Lunsford observed similar spectra on various kinds of alkaline earth zeolites (3). Iyengar *et al.* obtained a set of **g**-values, 1.980, 2.002, and 2.024, on rutile (4) and attributed this signal to O_2^+ species. However, Iyengar and Kellerman later revised their earlier assignment to a species containing nitrogen and oxygen (5). In the present work e.s.r. measurements of three-**g**-value centers which are formed on the surface of silica gel by a microwave electric discharge in a stream of gas have been made in an attempt to obtain information on the surface properties of oxide catalysts.

Experimental

The silica gel which was used was obtained by grinding Cab-O-sil M-5 with water. The gel was dried in an oven overnight at 110 °C, and finally calcined in air for 3 h at 600 °C. The silica gel thus prepared was crushed and screened to 28–32 mesh. About 30 mg of the powder was placed at the bottom of a U-shaped discharge tube such as shown in Fig. 1. After evacuation, oxygen or nitrogen gas was permitted to flow through the tube at a flow rate of about 0.0002 mol/min at a pressure of 2 Torr. The discharge cavity shown in the same figure was fed with an incident microwave power of 60 W at 2450 MHz from a Microtron 200 generator (Electro-medical Supplies Ltd.). After operation of the discharge for 500 s, the tube was evacuated at room temperature and about 4 Torr of helium was admitted in order to shorten the time required for changing the sample temperature. The silica gel was then dropped into the bottom of the quartz tube (Fig. 1) for e.s.r. measurement. A Varian X-band spectrometer was used with a rectangular TE_{012} sample cavity. The temperature of measurement was varied from −196 to 127 °C.

A deuterated silica gel which was used for comparison purposes was prepared by contacting silica gel which had been previously evacuated for 10 min at 800 °C, with the saturated vapor of D_2O for several days at room temperature.

Results and Discussion

Figure 2 shows typical e.s.r. spectra obtained at various temperatures after discharge in the oxygen stream at room temperature. The shape of the spectrum is sensitive to the temperature of measurement (sample temperature), as is clear from Fig. 2. At any given temperature, however, the spectrum was reproduced with a somewhat reduced intensity after a heating-and-cooling cycle. The discharge in the nitrogen stream gave similar results to those shown in Fig. 2, indicating that the formation of centers did not require the presence of oxygen in the gas phase. Since the same spectrum was obtained independent of which gas was used, most of the present experiments were carried out with an oxygen stream.

When the sample was heated above room temperature after the discharge, the intensity of the spectrum measured at liquid nitrogen temperature decreased without changing its shape, as mentioned above. Figure 3 shows the first-order plot of the intensity against time. The figure indicates that there are two different processes involved in the decay of the centers, and the activation energies were found to be 11.3 kcal/mol for the faster and 13.2 kcal/mol for the slower decay, respectively.

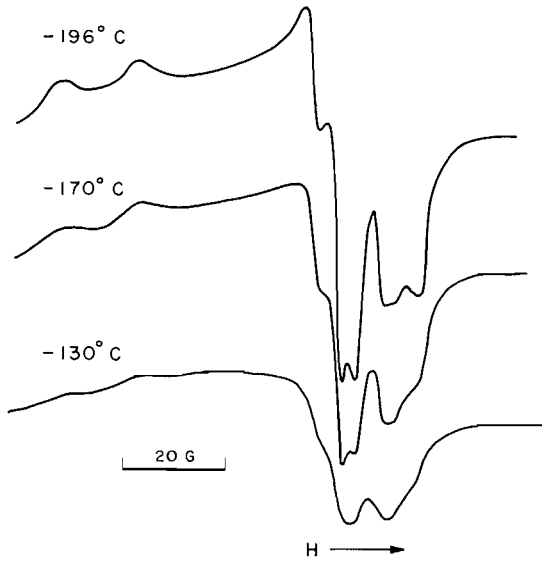

FIG. 2. Typical e.s.r. spectra obtained at various temperatures. Discharge was carried out in O_2 stream at room temperature.

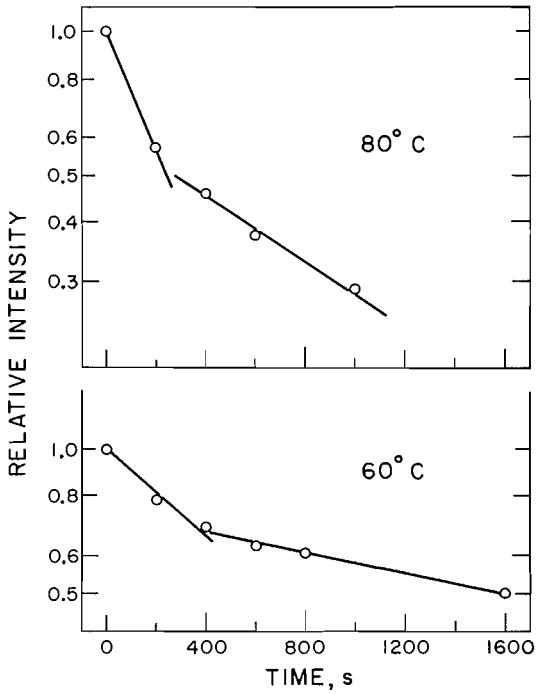

FIG. 3. Variation of spectral intensity with time.

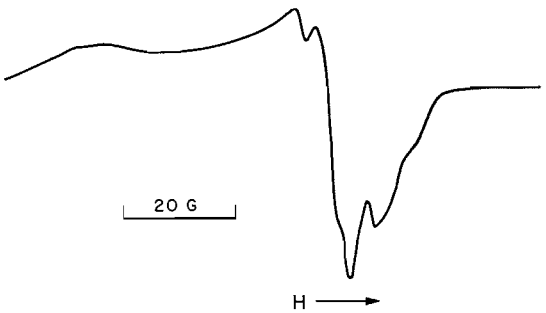

FIG. 4. Spectrum of deuterated silica gel obtained at −196 °C.

A spectrum obtained with the deuterated sample is shown in Fig. 4. It is apparent that the shape of the spectrum is different from that of the undeuterated sample shown in Fig. 2. In particular, the two small peaks of the undeuterated sample appearing at low magnetic field became a single broad peak when the sample was deuterated. This fact suggests that there is a hyperfine interaction with a hydrogen nucleus existing on an adjacent site, and the spectrum of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

undeuterated sample consists of two hyperfine components. It is reasonable that the hyperfine components should not be separated for the deuterated silica gel, since the spin of deuterium nucleus is 1 and the magnetic moment is 3.25 times smaller than that of the proton. In addition, the deuterated sample would not have been fully deuterated, so that the peak appearing at low magnetic field is very broad as a result of the superposition of hyperfine components of both H and D atoms. If this is the case, the splitting of the two peaks in the undeuterated sample should remain unchanged even if the measurement is made at a different microwave frequency. On the other hand, the splitting should be proportional to the frequency, if the two components are due to two kinds of centers with different **g**-values. Measurements were therefore made with a Q-band spectrometer, whose frequency was about 4 times larger than that of the X-band, and it was found that the two small peaks became a single broad peak with a half-width of 37 Oe. The results may be explained as follows. The magnetic centers are formed on the silica gel surface which has far more defects compared to the bulk of the solid. The existence of various crystal surfaces in the solid results in the formation of several kinds of surface sites with different crystal field environments, causing a spread of **g**-values and broadening of the peak. The effect of broadening should be greatest for the peak at the lowest magnetic field where the difference in **g**-value from that of free spin is largest. Since the line broadening due to the distribution of **g**-values is magnified in the higher frequency measurement, the two peaks in the X-band spectrum would become a single unresolved peak in the Q-band spectrum. From the Q-band spectrum the distribution range of the largest principal component of the **g**-tensor was roughly estimated to be 2.039 to 2.035.

As already mentioned, the present results indicate that the e.s.r. spectrum obtained with the undeuterated silica gel has two hyperfine components as a result of interaction with a hydrogen nucleus in a neighboring hydroxyl group. It also seems reasonable to assume that there are in addition magnetic centers which are not in close proximity with hydroxyl groups and which therefore give similar signals but without interaction with protons. In other words, the observed spectrum consists of three elementary spectra, two hyperfine components and the other without the interaction. Using the shape function $g(H)$ of an elementary spectrum, the shape function $f(H)$ of the observed spectrum is expressed as

$$f(H) = g(H - \tfrac{1}{2}\Delta H) + g(H + \tfrac{1}{2}\Delta H) + \alpha g(H)$$

where ΔH is the hyperfine splitting and α is a coefficient determined from the population ratio between interacting and non-interacting centers. ΔH was determined as 15 Oe from the separation of the two small peaks appearing at low magnetic field (Fig. 2). With this value for ΔH and taking 0.5 as α and also assuming the elementary spectrum as shown in Fig. 5(*a*), a simulated spectrum is obtained as shown by the solid line in Fig. 5(*b*) where the observed spectrum is also indicated by a broken line. Although some parts of the simulated spectrum differ from the observed one, the agreement is considered satisfactory, particularly with regard to the position of peaks. We could get better agreement if we added another spectrum with an axially symmetric **g**-tensor and adjusted the value of α. However, this is too

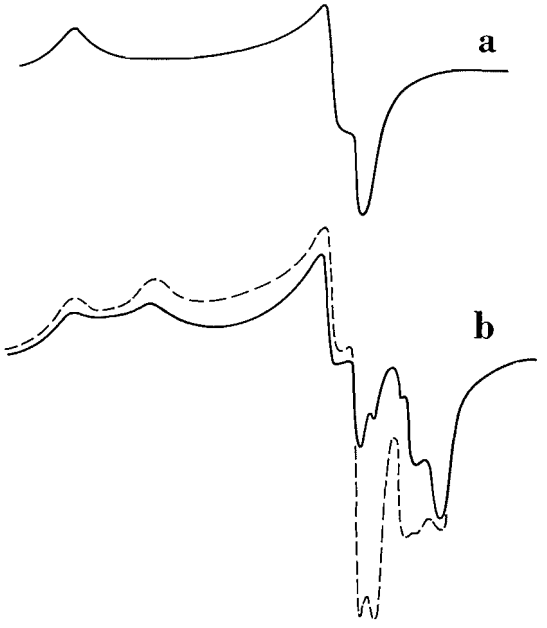

FIG. 5. Comparison of simulated spectrum with observed one. (*a*) Elementary spectrum, (*b*) simulated spectrum (solid curve), and observed spectrum (broken curve).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

speculative at this stage. $\alpha = 0.5$ used in the simulation means that only 25% of total magnetic centers lack a hydroxyl group in their neighboring sites. This is not unreasonable for the present silica gel which was not dehydrated at high temperatures. In conclusion, it seems certain that the magnetic centers formed by the discharge have a **g**-tensor with three different principal values. The **g**-values of the centers were $\mathbf{g}_{xx} = 2.037$, $\mathbf{g}_{yy} = 2.008$, and $\mathbf{g}_{zz} = 2.002$, respectively, and the hyperfine splitting was 15 Oe as already mentioned.

The **g**-tensor obtained above is close to that of the O_2^+ species trapped in alkali halide crystals (6). Similar spectra were observed on the surface of alkaline earth zeolites (3) and the center was identified as adsorbed O_2^-. In the present study, however, both O_2^+ and O_2^- are ruled out because the center could be formed by a nitrogen gas discharge with almost the same efficiency as by an oxygen gas discharge. The present **g**-values are also close to those obtained with hydroxyl radicals in solid ice (7). However, hydroxyl radical is stable only at low temperatures (8–10), and it is unlikely that these radicals are trapped stably on solid surface at such a high temperature as employed in the present experiments (room temperature). Moreover, the hyperfine splitting obtained here is almost a half of that reported on the hydroxyl radical.

The e.s.r. signal at -196 °C disappeared when the sample was heated at temperatures above 100 °C for several minutes. It reappeared if the sample was subjected to a discharge again, but its intensity became very weak after the procedure was repeated two or three times. It was necessary to expose the silica gel to saturated water vapor for several days to recover the signal intensity. This fact indicates that the existence of hydroxyl groups on the surface is essential to the formation of the centers. It is therefore postulated that hydrogen atoms are removed from hydroxyl groups during a discharge, thus producing on the surface $\mathrm{O{-}\overset{|}{\underset{|}{Si}}{-}}$ with a trapped hole on the oxygen.

We can roughly estimate the **g**-values for this particular center by a similar method to that employed by Kurita and Gordy (11) for $\mathrm{S{-}\overset{|}{\underset{|}{C}}{-}}$ radicals. For the calculation of **g**-shift,

$$\Delta\mathbf{g}_{vv} = -\sum_i 2\lambda\langle\psi_0|L_v|\psi_i\rangle\langle\psi_i|L_v|\psi_0\rangle/(E_i - E_0)$$

it is assumed that the hole is in the π orbital of oxygen as ground state, and that one of the sp_2 hybrids forms a σ bonding orbital with Si. It is further assumed that the energy of the state in which the hole exists in the bonding σ orbital is very high. Taking the x-axis along the O—Si bond and the z-axis perpendicular to the sp_2 hybrid plane, the **g**-shifts from the free electron value are obtained as

$$\Delta\mathbf{g}_{xx} = -2\lambda/\Delta E$$

$$\Delta\mathbf{g}_{yy} = -2\lambda/3\Delta E$$

$$\Delta\mathbf{g}_{zz} = 0$$

where λ is the spin–orbit coupling constant of oxygen and ΔE is the energy difference between the ground state and the excited state in which the hole is in one of the nonbonding sp_2 hybrids. The ratio of $\Delta\mathbf{g}_{xx}/\Delta\mathbf{g}_{yy}$ is about 3 from the above calculation, while the observed ratio is 5.8. With $\lambda = -150\ \mathrm{cm}^{-1}$ and the observed value of $\Delta\mathbf{g}_{xx} = 0.035$, ΔE is calculated to be $8.6 \times 10^3\ \mathrm{cm}^{-1}$. Further deductions will not be made because the above model is an oversimplified one and also no value of ΔE is available for comparison. The model is, however, consistent with the observation that the center has one large principal value of the **g**-tensor and two smaller values close to the **g**-value of the free electron and the value of ΔE calculated is thought to be a reasonable order of magnitude.

The hyperfine splitting of 15 Oe may appear to be small compared with that of other compounds containing hydrogen. However, this value means that the fractional occupancy of the hole on the hydrogen s orbital is about 3%, which is considered to be a reasonable value if we assume a hydrogen bond between the center and an adjacent hydroxyl group. Coulson and Danielsson calculated the contribution of a covalent structure to such bonding to be several percent (12). Further experimental evidence is, however, needed to confirm this point.

The authors wish to express their sincere thanks to Dr. C. V. Stager of McMaster University, Hamilton for the measurements which he kindly made with a Q-band

spectrometer. Thanks are also due to Drs. K. F. Preston and J. R. Morton of these laboratories for the use of the e.s.r. spectrometer and for the loan of vacuum facilities.

Free Radicals by Mass Spectrometry. XLIII. Ionization Potentials and Ionic Heats of Formation for Vinyl, Allyl, and Benzyl Radicals[1]

F. P. LOSSING
Division of Chemistry, National Research Council of Canada, Ottawa, Canada

Received August 27, 1970

Using an energy-resolved electron beam, ionization potentials for the following free radicals have been measured: vinyl 8.95 V, allyl 8.07 V, benzyl 7.27 V. For vinyl and allyl ions new measurements of thresholds for dissociative ionization give $\Delta H_f(C_2H_3^+) = 266$ kcal/mol and $\Delta H_f(C_3H_5^+) = 226$ kcal/mol, leading to neutral radical heats of formation $\Delta H_f(C_2H_3) = 59.6$ kcal/mol and $\Delta H_f(C_3H_5) = 40$ kcal/mol. The data for benzyl radical and ion give ΔH_f(benzyl cation) = 213 kcal/mol.

Introduction

The ionization potential values available for vinyl, allyl, and benzyl free radicals were measured some years ago, using conventional mass spectrometer ion sources. It is now well-known that, as a result of low resolution in energy, ionization thresholds determined in this way are generally higher than the adiabatic IP by 0.1–0.7 V, the error becoming larger with unfavorable Franck–Condon factors in the threshold ionization region. Recent electron impact measurements, either by the Retarding Potential Difference (RPD) method or by the use of true energy-resolved electron beams, are in satisfactory agreement with the more precise results obtainable by photoionization (PI) or photoelectron spectroscopy. The results of a recent study (1) of the ionization potentials of C_1–C_4 alkyl radicals, using an energy-resolved electron beam from a two-stage double-hemispherical energy selector, show that good agreement now holds among the IP values for these radicals as measured by the RPD method, photoionization, and monoenergetic electron impact, even in cases where the ionization efficiency curves in the threshold region are decidedly non-linear. The present work reports new IP values for vinyl, allyl, and benzyl radicals using a monoenergetic electron beam with an energy width at half-height of about 0.07 V.

For vinyl and allyl radicals, appearance potentials for formation of the corresponding $C_2H_3^+$ and $C_3H_5^+$ ions in dissociative ionization of suitable compounds have also been obtained. Heats of formation of the ionic and neutral species have been derived, and compared with available literature data. The situation is more complicated for benzyl ion, since $C_7H_7^+$ ions formed by dissociative ionization processes have almost certainly the tropylium ion structure (2, 3).

Experimental

The measurements were carried out using the electron energy selector, ionization chamber, ion extractor, and quadrupole mass filter previously described (4). Radicals were produced in sufficient concentrations by pyrolysis of suitable compounds (see below) at pressures of about 10^{-3} Torr in a fused-silica capillary furnace (5). Performance characteristics of this apparatus for some simple molecules (6) and radicals (1, 7) have been reported previously.

Results and Discussion

Vinyl Radical and Ion

In earlier measurements on vinyl radical (8) the radical was produced by the pyrolysis of methylvinyl mercury. In the present work the radicals were obtained more conveniently and in somewhat better yield from the pyrolysis of divinylsulfone.

[1] $(CH_2{=}CH)_2SO_2 \rightarrow 2\,CH_2{=}\dot{C}H + SO_2$

Some C_2H_2 and C_2H_4 were also formed by secondary reactions. Contributions from these species to the *m/e* 27 peak were shown to be negligible with electron energies in the range used for measuring the threshold ionization of C_2H_3 radical.

A typical threshold ionization curve for C_2H_3 radical is shown in Fig. 1, along with that for krypton added to the gas stream for calibration of the energy scale. This curve appears to exhibit one or more short linear sections, possibly corresponding to vibrational levels of the $C_2H_3^+$ ion.

[1]NRCC No. 11 667.

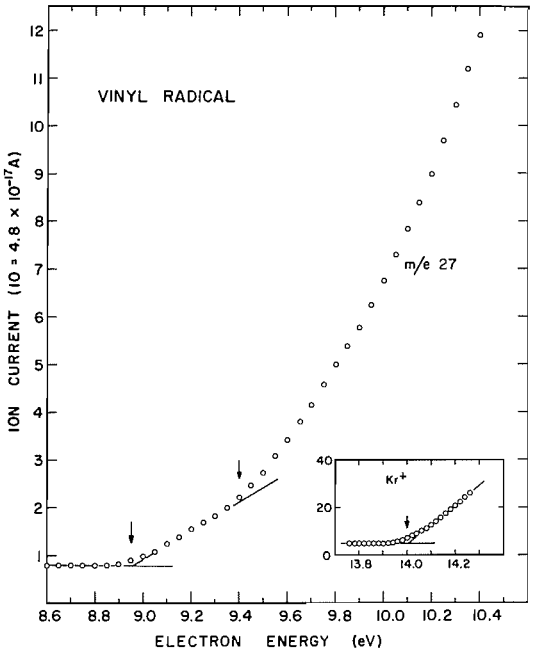

FIG. 1. Threshold ionization curve for vinyl radical produced by pyrolysis of divinyl sulfone.

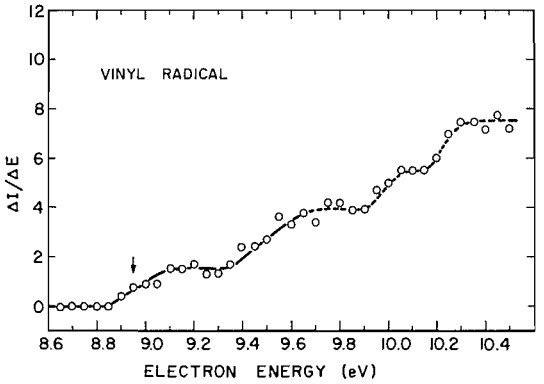

FIG. 2. First differential curve for vinyl radical ionization. The arrow marks the ionization potential obtained from Fig. 1.

The reality or otherwise of this structure may be judged from Fig. 2, which gives the first derivative of the data points of Fig. 1. No smoothing was employed. Extrapolation of the first "linear" segment of Fig. 1 gives 8.95 V for the ionization potential of C_2H_3 radical. An upward break at around 9.4 V appears to correspond to the earlier values of 9.35–9.45 V obtained for IP(C_2H_3) using conventional ion sources (8, 9). Owing to lack of energy resolution in the earlier measurements, the lowest segment of the curve was not observed. It is difficult to say whether the present result represents the true adiabatic IP, or whether it should be considered merely an upper limit. From Fig. 1 it appears improbable that the curve extends below 8.95 V but this possibility cannot be entirely ruled out.

There appears to be no other literature value, either experimental or theoretical, for this ionization potential aside from the earlier low resolution results cited above. It may be noted for comparison that this value for the ionization potential of vinyl is 0.9 V lower than that of CH_3 radical (9.84 V) and about 0.6 V higher than that of C_2H_5 radical (8.38 V) (1). Current theoretical treatments for ionization energies of radicals appear to be insufficiently reliable to enable an estimate for IP(C_2H_3) to be made.

Three recent measurements of the photoionization threshold for the dissociative process

[2] $$C_2H_4 + h\nu \rightarrow C_2H_3^+ + H + e$$

have been made, giving the appearance potential AP($C_2H_3^+$) as 13.80 V (10), 13.37 ± 0.03 V (11), and 13.25 ± 0.05 V (12). It seems probable that the lowest value is to be preferred. From standard heat of formation data this value gives $\Delta H_f(C_2H_3^+) = 266$ kcal/mol. The reason for the difficulty in measuring this threshold, even by the usually precise PI method, is the low probability for $C_2H_3^+$ ion formation near the energy threshold, resulting from the competing process

[3] $$C_2H_4 + h\nu \rightarrow C_2H_2^+ + H_2 + e$$

for which the appearance potential is slightly lower (10, 12). Earlier electron impact values for AP($C_2H_3^+$) are in the range 14.00–14.06 V using a conventional ion source (8, 13) and 14.10 ± 0.15 V using RPD electron impact (14). In view of this difficulty no attempt was made to remeasure this appearance potential in the present work. As an alternative, the appearance potentials for $C_2H_3^+$ ion formation from vinyl chloride and vinyl bromide were examined. The curves found for $C_2H_3^+$ ion formation from these compounds exhibited a feature not observed for other fragment ions examined so far with this apparatus. As can be seen in Fig. 3, the ionization efficiency curve for $C_2H_3^+$ production showed a "tail" of low $C_2H_3^+$ yield, having a nearly linear form, followed by an abrupt upward break corresponding to a sudden large increase in $C_2H_3^+$ yield. Comparison with the shape of the krypton standard curve indicates that this break is at

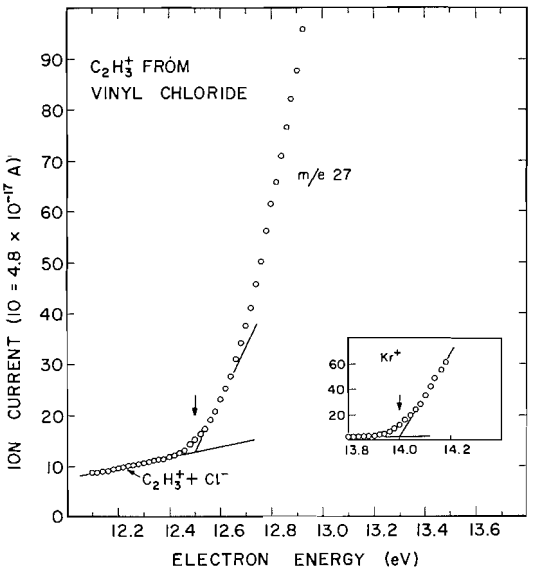

FIG. 3. Appearance potential curve for formation of $C_2H_3^+$ ion from vinyl chloride. The arrow marks the onset for the production of $C_2H_3^+$ and neutral Cl atom.

about 12.5 V. It seems probable that the "tail" can be associated with the ion pair process

[4] $$C_2H_3Cl + e \rightarrow C_2H_3^+ + Cl^- + e$$

and that the upward break corresponds to the threshold for the process

[5] $$C_2H_3Cl + e \rightarrow C_2H_3^+ + Cl + 2e$$

with this assumption, $AP(C_2H_3^+) = 12.5$ V gives $\Delta H_f(C_2H_3^+) = 268$ kcal/mol. A curve of nearly identical form was obtained for vinyl bromide, with an upward break at 11.9 V, corresponding to $\Delta H_f(C_2H_3^+) = 266$ kcal/mol. These results are in good agreement with the photoionization value (12) of $\Delta H_f(C_2H_3^+) = 265.9$ kcal/mol. No definite value could be obtained for the onset of the "tail" portion of the $C_2H_3^+$ curves, owing to the low probability for this process and the uncertainty as to the true shape of its ion yield curve.

From $\Delta H_f(C_2H_3^+) = 266$ kcal/mol and $IP(C_2H_3) = 8.95$ V one gets $\Delta H_f(C_2H_3) = 59.6$ kcal/mol, corresponding to a bond dissociation energy $D(C_2H_3—H) = 99.2$ kcal/mol. Aside from the earlier electron impact work, which is based on erroneously high values for $AP(C_2H_3^+)$ and $IP(C_2H_3)$, experimental data for this bond are rather sparse. A pyrolytic study of divinyl mercury using the toluene carrier technique gave $D(C_2H_3—H) \sim 102.5$ kcal/mol (15, 16) with a rather large uncertainty. From unpublished results on the reaction of HI with vinyl iodide, Golden and Benson (17) deduced $D(C_2H_3—H) \geqslant 108 \pm 2$ kcal/mol, corresponding to $\Delta H_f(C_2H_3) \geqslant 68.4$ kcal/mol. Assuming the value of $\Delta H_f(C_2H_3^+) = 266$ kcal/mol to be correct, this heat of formation for C_2H_3 would require $IP(C_2H_3)$ to be $\leqslant 8.57$ V, about 0.4 V lower than the presently reported value. This discrepancy is large enough to raise the question as to whether the $C_2H_3^+$ ion formed at the dissociation threshold for ethylene and vinyl halides has some other minimum energy configuration differing substantially from the "vinyl" structure.

Allyl Radical and Ion

A good yield of allyl radical was obtained by the pyrolysis of allylmethyl nitrite, prepared from a sample of 3-butene-1-ol. A threshold ionization curve for allyl radical is given in Fig. 4. The curve exhibits one or perhaps two breaks above the threshold, which is at 8.07 V with a probable uncertainty of about ± 0.03 V. A first differential curve for these data points is given in Fig. 5, which shows clearly a second "step" at 8.22 V and just possibly a third at about 8.45 V. Earlier

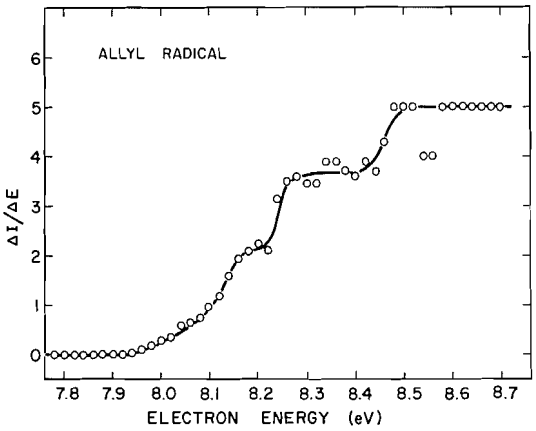

FIG. 5. First differential curve for allyl radical ionization, showing two and possibly three "steps".

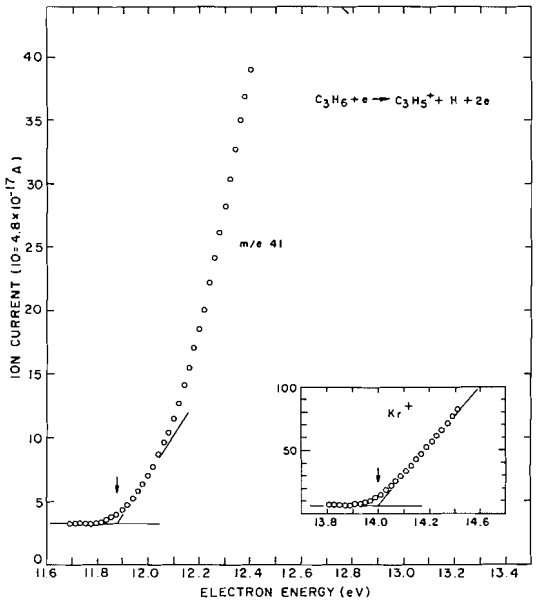

FIG. 6. Threshold curve for formation of $C_3H_5^+$ ion from propylene. Curves for $C_3H_5^+$ formation from 1- and 2-butene were of the same form.

measurements of 8.16 V (18) and 8.15 V (9) for IP(allyl) using conventional ion sources presumably correspond approximately to an unresolved maximum Franck–Condon factor at an energy of about 8.2 V. With some reservations, one can assign the onset at 8.07 V to the adiabatic IP. The presence of another "segment" below this value looks improbable but cannot be entirely ruled out.

The appearance potentials for $C_3H_5^+$ fragment ion from propylene, 1- and 2-butene were also measured. The efficiency curves were all of the apparently structureless type shown in Fig. 6. The estimated thresholds are given in Table 1, along with some earlier values measured by conventional methods (19) and by a second differential ionization method (20). No photon impact or RPD electron impact values for $C_3H_5^+$ appear to have been published. From standard heats of formation these appearance potentials lead to $\Delta H_f(C_3H_5^+) = 226$ kcal/mol with a probable uncertainty of 1 or 2 kcal/mol. Subtracting IP(allyl) = 8.07 V gives ΔH_f(allyl) = 40 ± 2 kcal/mol, in reasonable agreement with recent measurements by kinetic methods of 41 ± 1 kcal/mol (17, 21). Appearance potential data for $C_3H_5^+$, as collected in a recent compilation (22), give a wide range of values of $\Delta H_f(C_3H_5^+)$, from 216 to more than 260 kcal/mol. This indicates that although *m/e* 41 is a relatively abundant ion in the mass spectra of many hydrocarbons and allyl derivatives, its formation is not a particularly simple process (23).

Benzyl Radical and Ion

A reasonably good yield of benzyl radical was obtained by the pyrolysis of benzylmethyl nitrite at moderate furnace temperatures (24)

$$C_6H_5CH_2CH_2ONO \rightarrow C_6H_5CH_2CH_2\dot{O} + NO$$

$$C_6H_5CH_2CH_2\dot{O} \rightarrow C_6H_5\dot{C}H_2 + CH_2O$$

The threshold ionization curve for benzyl radical (Fig. 7) was strongly curved, and showed no evident structure over the first 2.5 V portion. In the absence of any linear or quasi-linear section at the onset, an extrapolation to a well-defined threshold cannot be made. A comparison of the curved foot in the inset of Fig. 7 with the curvature of the foot of the krypton standard curve, resulting from the 0.07 V energy half-width, indicates that the onset of the benzyl curve cannot be lower

TABLE 1. Appearance potentials for $C_3H_5^+$ ion formation

Compound	AP (V)	$\Delta H_f(C_3H_5^+)$ (kcal/mol)	Previous AP (V)
Propylene	11.88	226.8	12.11[a]
1-Butene	11.28	226.1	11.73[a], 11.4[b]
2-Butene	11.33	225.6	11.60[a]

[a]Reference 19.
[b]Reference 20.

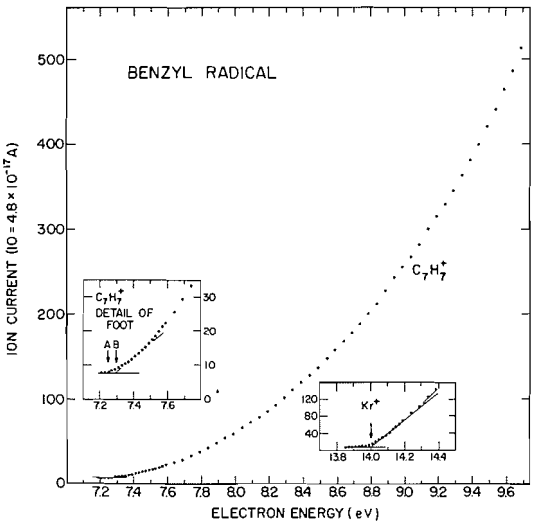

FIG. 7. Threshold ionization curve for benzyl radical, produced by pyrolysis of benzylmethyl nitrite. Points *A* and *B* are estimated lower and upper limits for the onset of ionization.

than point *A* (7.25 V) nor higher than point *B* (7.30 V). The best way to express this result is as the limit IP(benzyl) $\leqslant 7.27 \pm 0.03$ V. This is appreciably lower than the value of 7.76 V obtained earlier by electron impact in a conventional ion source; evidently the curvature of the foot of the benzyl curve was seriously underestimated in the earlier measurement. There is, however, an unresolved discrepancy between the present value, and a value of 7.63 ± 0.02 obtained by photoionization (25, 26). There seems no reason to suspect in either experiment that isomerization of benzyl radicals to tolyl or cycloheptatrienyl radicals, which are less stable than benzyl, has occurred. In any case, the IP of cycloheptatrienyl, 6.237 V (26, 27) is much lower than either of the experimental values for benzyl. The ionization potential of tolyl radical, $CH_3C_6H_4$, is probably not too different from that of toluene[2] and consequently too high to be a source of confusion in these experiments. The possibility of a real difference between the electron and photon impact experiments does exist, although it is rather unlikely. Ionization of benzyl radical by electron impact could conceivably occur through formation of a discrete excited neutral state, which then rearranges and ejects an electron to form tropylium ion.

[2]Compare, for instance IP(phenyl) and IP(benzene) (ref. 22).

$$C_6H_5CH_2 + e \rightarrow C_6H_5CH_2^* + e$$

$$C_6H_5CH_2^* \rightarrow C_7H_7^+ \text{ (tropylium)} + e$$

Formation of the excited state $C_6H_5CH_2^*$ by photon impact could be spin-forbidden, making this mechanism inoperative or improbable for photoionization.

It is of interest in this respect, particularly in view of the well-known isomerization (2, 3)

[6] $$\text{benzyl}^+ \rightarrow \text{tropylium}^+$$

to calculate heats of formation for these two ionic species from the current data. Taking IP(cycloheptatrienyl) = 6.24 V (26, 27), $D(C_7H_7—C_7H_7)$ in ditropenyl = 1.85 ± 0.05 V (26), and ΔH_f(ditropenyl) = 94.6 kcal/mol (28), one obtains ΔH_f(cyclo-$C_7H_7^+$) = 212 kcal/mol. A slightly lower value for $\Delta H_f(C_7H_7^+)$, 209 kcal/mol, has been suggested from a measurement of the enthalpy of dissociation of bitropenyl (29). Taking ΔH_f(benzyl) = 45 kcal/mol (16) and IP(benzyl) = 7.27 V, one obtains $\Delta H_f(C_6H_5CH_2^+)$ = 213 kcal/mol. On this basis, reaction 6 is thermoneutral or only slightly exothermic. This result is surprising in view of the universality of this reaction for benzyl ion and its analogs (3), and tends to support the possibility that the present electron impact IP for benzyl is too low because of some rearrangement as suggested above.

X-Ray Induced Polymerization of Gaseous Vinyl Chloride. Effect of Additives

JACQUES GROSSOLEIL AND JAN A. HERMAN
Department of Chemistry, Laval University, Quebec, Quebec

Received August 17, 1970

The X-ray induced polymerization in the gas phase of pure vinyl chloride and of its mixtures with O_2, NO, SF_6, NH_3, CH_3NH_2, H_2O, HCl, and C_2H_2 were examined. About 75% of the polymerization proceeds via a radical mechanism. The experiments indicate that most of the additives are deactivating chain transfer agents. Gel permeation chromatography showed that the polymer is activated by X-ray absorption during the time it takes to fall to the bottom of the irradiation cell, and forms a branched polymer.

Introduction

It is generally accepted that the radiation-induced polymerization of gaseous vinyl chloride is an example of a radical mechanism (1, 2). Our previous work (3) on the X-ray induced polymerization of vinyl chloride, in particular the kinetic consideration of the initiation and termination processes, seemed, at first sight, compatible with a free radical mechanism. There was an initial acceleration period and a post-polymerization effect, which could hardly be explained except by a radical mechanism. On the other hand, the propagation rate of the so-called "stationary-rate-regime", which is first power dependent on the dose-rate, was explained by assuming a hindered termination process (3).

To the above example of the radical polymerization, one can contrast the radiation-induced polymerization of gaseous isobutene, which proceeds by an ionic mechanism (4, 5). However, some experimental observations are common to both systems, *iso*-C_4H_8 and C_2H_3Cl. An example is the increase in the rate of polymerization with dose-rate according to a first order relation, which was invoked by Okamoto *et al.* (4) as an argument for the ionic polymerization process in isobutene. Recently Williams *et al.* (6) showed that a termination involving a transfer of the active species to an impurity or a scavenger, such that the reaction product is nonpropagating, will give a first power dependence on the dose-rate, and the mechanism will apply indistinguishably to ionic or radical polymer chain propagation. In the gas phase the role of such impurities or scavengers may be filled by the numerous radiation-induced decomposition products, which are sometimes formed with relatively high yields. This, together with the observation (7) of continuous acceleration of the propagation-rate of radiation-induced polymerization of vinyl chloride in the presence of an electric field, and of the action of nitric oxide, which even at relative important concentrations (~ 7 mol%) does not completely stop the polymerization, led us to reconsider some of our previous conclusions, and to give special attention to the possibility of some ionic mechanisms. Recent work on ion–molecule reactions shows the existence of some short chain reactions in the gaseous vinyl chloride (8, 9), although it seems doubtful to associate ionic propagation measured at 10^{-2} Torr and polymer formation at pressures of several hundred Torr.

Therefore we have carried out new experiments on the radiation-induced polymerization of gaseous vinyl chloride in order to obtain a better understanding of the mechanisms responsible for the polymer formation. The approach was twofold: measurement of the rate of polymerization in the presence of suitable additives, some of them being recognized as ionic scavengers (NH_3) or electron capturers (SF_6), and characterization of the polymer by its chain length and composition.

Experimental

The experimental device was the same as that described previously (3), with modifications to allow precise mea-measurements of the polymerization-rate at the very beginning and at the end of the irradiation. Essentially, the experimental device is a manostat composed of an irradiation cell, F, a mercury manometer with an electrical control, M, and a calibrated container, C, whose volume can be adjusted by a controlled admission of mercury, Fig. 1. The changes in the volume are transposed into electrical signals by a variable resistance connected to the container. In the present work the irradiation cell was a 1 l stainless steel or glass cylindrical vessel with its principal axis horizontal. As before (3), the X-rays

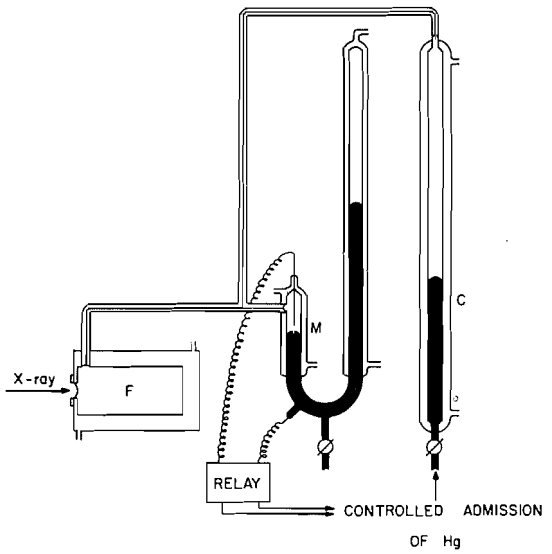

FIG. 1. The experimental design.

from a "Machlett OEG 60" tube penetrate horizontally into the irradiation cell through a thin aluminum window (0.06 mm thick, 22 mm diameter). In this way the polymer falls to the bottom and is outside the directly irradiated volume. The sensitivity of the manostat at 1 atm corresponds to the pressure change resulting from a variation of temperature of less than 0.01 °C. The whole manostat was therefore placed in a thermostatic bath whose temperature could be kept constant within 0.02 °C. The compensation of the pressure changes could be recorded automatically both by expansion and by contraction of the volume. Such recording is very useful when measuring the volume changes at the beginning of the experiments when the gas expands by absorption of the energy from X-rays. In this way, the induction periods, if any, could be accurately observed.

Each irradiation experiment was carried out on a freshly prepared mixture of the monomer and the additive. When a series of irradiation experiments of vinyl chloride with increasing quantities of a particular additive was finished, the irradiation cell was demounted and thoroughly cleaned. The solid polymer from some series of experiments was collected and used for further studies. In order to obtain reproducible results (because of the slow establishment of the adsorption equilibrium), gases freshly admitted to the irradiation cell were always kept several hours (usually over-night) at the temperature of the thermostatic bath before the beginning of the irradiation.

Vinyl chloride from Matheson Company was purified by trap-to-trap distillation at the temperature of liquid nitrogen and stored in a 6 l container from which it was taken for irradiation experiments. The only impurity detected by gas chromatography was C_2HCl in quantities less than 10 p.p.m. Oxygen was prepared by pyrolysis of analytical grade $KMnO_4$. Nitric oxide from Matheson was purified further by the method of Forst and Rice (10). Other additives, SF_6, NH_3, CH_3NH_2, HCl, and C_2H_2, obtained from Matheson Company, were purified by trap-to-trap distillation at −185 °C and distilled water was previously degassed by the thawing–freezing technique before its mixing with the monomer.

The dose-rate was estimated from the $P\Delta V$ measurements at the pressure and the temperature of the experiment and at the very beginning of the irradiation. The absorption of the X-rays by the gas and the walls increases instantaneously the temperature inside the irradiation cell (a few tenths of a degree depending upon the intensity of X-ray and pressure of the gas), and the corresponding increase of the volume was recorded. It was impossible to establish the ratio of the energy absorbed by the gas and by the walls, therefore only an approximate value of the dose-rate could be calculated by comparison with $G(—C_2H_3Cl)$ published by Herman and Hupin (3); in the present study it was around 2.8×10^{17} eV g^{-1} min^{-1}. The total dose absorbed ranged between 10^{19} and 10^{20} eV, which allowed the maximum conversion of the monomer to be maintained under 1.5%.

The infrared spectrum of the solid polymer in KBr was taken on a Perkin–Elmer 621 spectrophotometer. The molecular weight distribution was determined by gel permeation chromatography (Waters Associates Inc.). The lack of suitable poly(vinyl chloride) standards of low molecular weight (< 20 000) forced us to calibrate our polymer samples against polystyrene standards. However, the calibration curves for higher molecular weights (> 50 000) from polystyrene and poly(vinyl chloride) standards coincide; hence we assume that the error in molecular weight determination against polystyrene standards is small. The polymer was dissolved in tetrahydrofuran.

Results

The radiation-induced polymerizations were conducted at constant pressure, 77 ± 0.3 cm Hg, and constant temperature, 19.8 ± 0.02 °C. In some experiments the X-ray intensity was varied in order to measure the dependence on the dose-rate. In all experiments the polymerization started immediately the X-rays were switched on and the rate of the monomer disappearance was constant during the whole time of irradiation. At the end of irradiation the pressure dropped suddenly as the gas cooled and this corresponded on the recorded curve to a rapid decrease of the volume, but we did not notice any slow exponential decrease of the volume which could be attributed to the post-polymerization. These two facts, (*a*) the constant rate of monomer disappearance over the whole time of irradiation and (*b*) the apparent lack of a post-polymerization, are in contradiction with what has already been published (3). The negative temperature coefficient of the polymerization-rate was again

For personal use only.

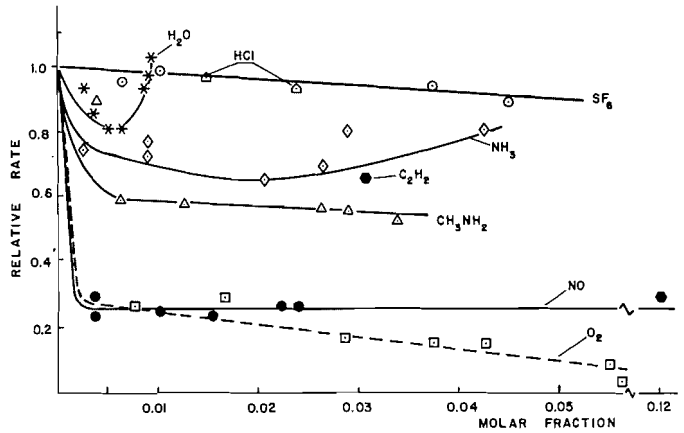

FIG. 2. Relative polymerization-rates of gaseous vinyl chloride mixed with various additives, irradiated by X-rays.

noted, in agreement with other works (11, 12). However, the polymerization-rate of the pure vinyl chloride depends on the condition of the surface; it increases (*ca.* 10%) when the surface of the cell is coated with previously deposited poly(vinyl chloride). This surface effect, operating either for stainless steel or glass walls, is responsible for the poor reproducibility of the polymerization-rate for pure C_2H_3Cl in a freshly cleaned irradiation cell.

The decrease of the volume during radiation-induced polymerization is taken as a measure of the polymer formation. This is in fact a lower limit, because one should take into account the increase of the number of molecules within the system due to the accumulation of the decomposition products resulting from radiolysis. However, in the conditions of the present experiments the total yield of the decomposition products is less than 3% of the $G(-C_2H_3Cl) \sim 500$ of the monomer disappearance. Hence, we can assume that within 2% the rate of monomer consumption represents the polymerization. The effect of increasing quantities of NO, O_2, H_2, NH_3, CH_3NH_2, SF_6, HCl, and C_2H_2 on the polymerization-rate of vinyl chloride is shown in Fig. 2. Nitric oxide and oxygen were used as radical scavengers, whereas ammonia, methylamine and SF_6 were added as ion or electron interceptors. The mean value of the rate of disappearance of the pure monomer is 6.4 μmol/min for either glass or stainless steel cells coated with the deposit of the polymer. Oxygen and nitric oxide have the most pronounced effect on the rate; amounts as small as $\sim 2 \times 10^{-3}$ mole-fraction are sufficient to decrease by $\sim 75\%$ the initial polymerization-rate. After this sharp decrease of polymerization-rate, further additions of O_2 or NO have different effects; increasing amounts of oxygen slowly diminish the rate of polymerization of the monomer, whereas NO does not further alter the attained rate. The action of CH_3NH_2 and NH_3 are less pronounced; they decrease the rate by ~ 40 and $\sim 31\%$, respectively. It is worthwhile to record that with increasing amounts of ammonia the polymerization-rate increases slightly. This effect is much more pronounced in the presence of water vapor. Here the polymerization-rate passes through a minimum at $\sim 7 \times 10^{-3}$ mole-fraction of H_2O and then increases rapidly to values which are higher than the polymerization-rate of pure vinyl chloride. The action of SF_6, which is added to C_2H_3Cl as competitor for electron capture, is weak, but noticeable. During the radiolysis of C_2H_3Cl the main decomposition products are HCl and C_2H_2 and their yields per 100 eV of absorbed energy are around 10, and 1.5, respectively (13). In two experiments we added small amounts of HCl (Fig. 1) to verify if the polymerization is retarded by this compound. The results indicate that HCl has the same effect as SF_6. On the other hand a molar fraction of $\sim 3 \times 10^{-2}$ of acetylene diminishes by $\sim 35\%$ the polymerization-rate (Fig. 2). In order to obtain more information, we carried on some experiments in which equal quantities of SF_6 and NH_3 were mixed at the same time with C_2H_3Cl. For the system SF_6 (0.028) + NH_3 (0.025) the relative polymerization-rate dropped to 0.61,

while for the mixture SF_6 (0.052) + NH_3 (0.048 mole-fraction) the relative rate was 0.69.

In the present study, the polymerization-rate, V, for pure vinyl chloride can be represented by the following expression

$$V = k\,P^{1.2}\,I^{1.07}$$

where I stands for X-ray intensity. This expression agrees in respect to the intensity dependence with a similar one obtained by Herman and Hupin (3) for the "regime rate" of polymerization. The presence of additives diminishes the value of the exponent of the intensity factor to around 0.83 ± 0.05, and seems to be relatively independent of the nature of the additive.

The infrared (i.r.) spectrum of the pure poly(vinyl chloride) resembles that described by Krimm (14), but in addition there is always a weak band at 1720 cm^{-1}. This absorption band is characteristic of the carbonyl group, $R-\overset{\overset{O}{\|}}{C}-R$, especially if a halogen atom is linked to an adjacent carbon (15). During radiolysis of the pure vinyl chloride the formation of a carbonyl group in the polymer is impossible; neither the traces of oxygen adsorbed on the metallic walls nor on the glass walls of the irradiation cell could contribute to such an extent to the 1720 cm^{-1} band. The only plausible explanation of the origin of this band is the instantaneous oxidation of free bonds of the polymer when the cell is opened for removing the products and cleaning. This agrees with the observation of Hupin (7), that the oxygen is adsorbed after irradiation by the freshly formed polymer. The i.r. spectrum of poly(vinyl chloride) formed in irradiated C_2H_3Cl + H_2O also has the 1720 cm^{-1} weak band of the carbonyl group. In the case of vinyl chloride irradiated in the presence of O_2, the i.r. spectrum of the polymer shows a very strong 1720 cm^{-1} band. The polymer i.r. spectra of C_2H_3Cl irradiated in the presence of NH_3 or SF_6 indicate some bands characteristic of the N, or S and F atoms, respectively. In the case of the polymer formed in the presence of ammonia there are medium intensity absorption bands at 3150 and 3050 cm^{-1}, which might be assigned to $-NH_2$ and —NH stretching of amides (16). There is another strong band at 1408 cm^{-1}, but its assignment is uncertain. The system C_2H_3Cl + SF_6 gives a red polymer, whose i.r. spectrum shows additional bands at 820, 840, and 870 cm^{-1}, at which the assignment is uncertain, but which most probably belong to the —C—S—F group. The i.r. spectra of polymers of both systems, C_2H_3Cl + NH_3 and C_2H_3Cl + SF_6 show also a very weak carbonyl group band at 1720 cm^{-1}, which means that in these systems some free bonds persist after irradiation.

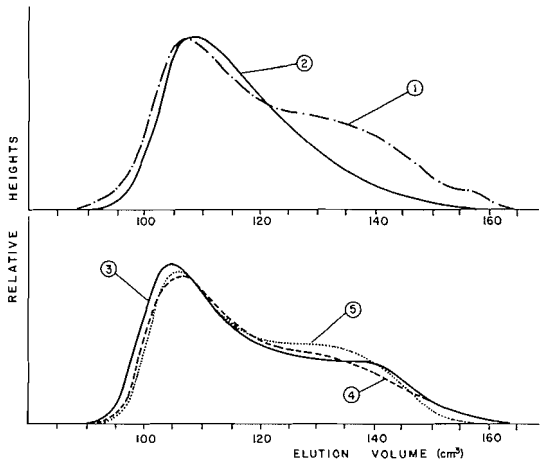

FIG. 3. Gel permeation chromatograms of poly(vinyl chloride) formed from pure C_2H_3Cl and its mixture with various additives. (*1*), pure C_2H_3Cl irradiated by X-rays; (*2*), pure C_2H_3Cl irradiated by β-rays; (*3*), C_2H_3Cl + H_2O; (*4*), C_2H_3Cl + SF_6; (*5*), C_2H_3Cl + NH_3.

Much information can be obtained from analysis of the polymer by gel permeation chromatography (g.p.c.). Figure 3 shows the shape of the g.p.c. chromatograms for polymers formed during irradiation of pure vinyl chloride or the mixtures with additives. In Table 1 are represented the number average, $\overline{M}_n$, and the weight average, $\overline{M}_w$, molecular weight calculated by the method of Smith (17) as modified by Chen (18). The values of $\overline{M}_n$ obtained by the g.p.c. method are comparable with those already published (3) which were established by a cryoscopic method. The ration $\overline{M}_w/\overline{M}_n$ defines the polydispersity index of the polymeric material (column 5 of Table 1). For comparison we include the results of polymerization of pure gaseous C_2H_3Cl by 0.54 MeV β-rays from a ^{90}Sr source (curve 2 in Fig. 3). It can be seen that in the latter case the $\overline{M}_n$ is higher by a factor ~ 2 and consequently the polydispersity index is lower. Obviously the reason for that is the reduced tailing of the low molecular weight polymer compared to the

TABLE 1. Molecular weights calculated from g.p.c. distribution curves

poly(vinyl chloride) formed in X-ray irradiation (curve 1 in Fig. 3). The g.p.c. chromatograms are very much alike for the polymers formed by X-ray irradiation of both pure C_2H_3Cl and with added scavengers. All of them show a flat broad component spread over low molecular weights as far as the trimer and dimer. The low molecular weight component is only slightly related to the nature of the additive. Only ammonia shows an effect, the amount of the low molecular weight component increasing relative to the high molecular weight polymer (Fig. 3 and Table 1).

Table 2 gives the results of the chemical analysis of the solid polymer.

Discussion

Criticism of The Previous Work

The results of the present studies disagree on several points with the previous data by Herman and Hupin (3). In contrast to (3) we do not find any evidence for an initial acceleration of the polymerization-rate, and a relatively important post-polymerization. The absence of the first effect can easily be explained by the improved design of the automatic regulator of the manostat. The post-polymerization effect in (3) was confused with the establishment of the adsorption equilibrium. In fact, there must be a small post-polymerization, as shown by the fixation of O_2 on free bonds of the polymer when opening the cell but this effect was overestimated in (3). We have already stressed that the adsorption equilibrium is reached very slowly. Now, as soon as the X-rays impinge on the walls a desorption occurs which is reversed when irradiation is stopped. It is this readsorption which was erroneously taken as a post-polymerization. Therefore, the hypothesis of an important hindered termination process of the polymerization (3) cannot be retained and another explanation of the observed phenomena must be sought.

Present Studies

We shall start with the study of the solid polymer, because it indicates some important aspects of the polymerization processes. The g.p.c. chromatograms show a high polydispersity index either for the polymer prepared from pure vinyl chloride, or for mixtures of C_2H_3Cl with additives (Table 1). Even if the polydispersity index tends to be overstated by the g.p.c. method (18), the shape of the chromatograms suggests that we are dealing with a polymer formed in more than one process. The peak corresponding to ~ 110 cm^3 of eluted volume (Fig. 3) results most probably from one process, while the broad shoulder on the right side of the peak arises from another process. Huang and Westlake (19) were able to show for the γ-ray induced polymerization of liquid styrene at low temperatures, that a bimodal molecular weight distribution corresponds to two different polymerization processes.

The comparison of the molecular weight distribution curves of the polymer formed in β-ray irradiation (curve 2) with that of the polymer formed in the X-ray experiment (curve 1) is particularly interesting. The curve 2 is unimodal and the broad shoulder (which exists on all chromatograms of polymer formed in X-ray experiments) has disappeared. Now, the initiation and the propagation mechanisms of polymerization are the same for both β- and X-ray irradiation. Therefore, the hypothesis that the component corresponding to ~ 110 cm^3 results from radical mechanisms and the broad shoulder from ionic processes (or vice-versa) cannot be accepted, because molecular weight distribution curves should be practically the same for both kinds of radiation. However, there are two other possible explanations: (*a*) the intensity effect and (*b*), irradiation of the polymer during the time it takes to fall to the bottom of the irradiation cell. The intensity of the X-ray source being about 4 orders of magnitude higher than our ^{90}Sr β-ray irradiation facilities, there is an increased probability of termination of polymeric chains by primary radicals. In this case one expects that the molecular weight distribution would conserve the shape of curve 2, but might be shifted toward lower molecular weight, *i.e.* to higher elution volume. Figure 2 shows that this is not the case and, therefore, the intensity alone cannot explain the existence of the broad shoulder component characteristic of X-ray irradiations. It seems that the hypothesis of irradiation of the polymer is the best answer. The mass-absorption coefficient of X-rays by the solid polymer being much higher that that of the gaseous monomer (roughly in the ratio of densities of solid poly(vinyl chloride) to gaseous C_2H_3Cl) the probability of X-ray absorption by the polymer is quite high and leads to the formation of free sites, which can initiate lateral chains on an isolated linear polymer. Indeed, poly(vinyl chloride) is known to cross-link under ionizing radiation (20). At the same molecular weight a branched polymer has a smaller average dimension than a linear macromolecule and it will be eluted with lower molecular weight linear polymers, and should be found in the tail of the molecular weight distribution curve. This hypothesis is strengthened by the fact that at room temperature the polymer does not dissolve entirely in a mild solvent, such as *o*-dichlorobenzene, suggesting that some branched material is present after irradiation. Obviously, β-ray induced polymerization cannot behave in a similar way. If the assumption is correct, it implies an underestimation by the g.p.c. method of the number average molecular weight, $\overline{M}_n$ and the average degree of polymerization, $\overline{\text{d.p.}}$, and explains the deviation between the present measurements (Table 1) and the previously reported value, $\overline{\text{d.p.}} = 18.2$ (3).

The i.r. spectra and the chemical analysis of the polymers formed from C_2H_3Cl mixed with SF_6, NH_3, or H_2O, show in each case fragments of the additive incorporated into the polymer chain. None of these additives can initiate polymerization, therefore, their presence in the polymer can only proceed from chain transfer. If this is correct and assuming one only additive fragment per macromolecule, it is possible to calculate the average degree of polymerization from chemical analysis data. The following values are found: $\overline{\text{d.p.}} \approx 25$ for the $C_2H_3C + SF_6$ system, $\overline{\text{d.p.}} \approx 22$ for $C_2H_3Cl + H_2O$, and $\overline{\text{d.p.}} \approx 15$ for $C_2H_3Cl + NH_3$. These confirm, in general, the average degree of polymerization measured by the g.p.c. and cryoscopic methods. In the case of the mixture of vinyl chloride with ammonia the $\overline{\text{d.p.}}$ seems low. It is possible that in this case there is, on the average, more than one nitrogen atom per macromolecule and it might indicate that ammonia reacts with poly(vinyl chloride) in different processes.

The additives used in this study can intervene in three different ways: (*a*) scavenging action of free radicals, (*b*) interception of positive or negative (electrons) ions, and (*c*) chain transfer process. In the last case one can distinguish between an active chain transfer and a deactivating chain transfer. We have already assumed that additives are acting in a chain transfer as well as in their characteristic scavenging role. The addition of less than 0.005 molar fraction of oxygen or nitric oxide has a very pronounced effect, the relative polymerization-rate being reduced by $\sim 75\%$. The possibility of charge transfer between parent ion, $C_2H_3Cl^+$ (ionization potential, i.p. = 10.0 eV) (21) and oxygen (i.p. = 12.07 eV) (22, 23) must be ruled out; it follows then that the observed decrease of the rate results from radical processes. In the case of NO (i.p. = 9.25 eV) (23) a charge transfer from the vinyl chloride ion is possible, in principle, but there is no evidence for it when a comparison is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

made to the scavenging action of oxygen (Fig. 2). Therefore, we assume that at the pressure of *ca.* 77 cm Hg about 25% of the polymerization is accounted for by a non-radical mechanism. A further addition of O_2 to the system influences the rate of this non-radical part of polymerization, while NO has no effect (Fig. 2). The reason for this is the oxygen induced decomposition of C_2H_3Cl which gives an important increase in HCl formation, which in turn acts as a retarder of the polymerization, (13). Apparently, NO does not decompose the monomer, but instead it reacts efficiently with Cl atoms to form nitrosyl chloride (7).

If some ionic species are precursors or initiators of polymerization, then the addition of SF_6 would compete for thermal electrons, and we would expect to observe an initial rapid decrease of the polymerization-rate followed by a plateau when all electrons of interest are scavenged. Such behavior is not observed. There is only a slow steady decrease of the relative polymerization-rate with increasing concentration of SF_6 (Fig. 2). There is still the possibility that the polymer electron-attachment coefficient is much higher than that of the SF_6. Lee (24) showed that the greater the number of Cl atoms substituted to the alkyl group the higher the probability of electron attachment. No matter what the electron-attachment process is, it seems that the action of SF_6 is not related to the anionic polymerization of gaseous C_2H_3Cl. Moreover, experiments with irradiation of $C_2H_3Cl + NH_3 + SF_6$ systems suggest that SF_6 is acting as a neutral species and not as a negative ion, because the polymerization-rate in such systems decreases by an amount which is the sum of the independent action of each of the additives alone. We assume, therefore, that the steady slow decrease of the rate with increasing additive concentration results from a deactivating chain transfer. This is partly confirmed by the chemical analysis and the i.r. spectra of the polymer.

It is important to note that HCl acts exactly in the same manner as SF_6, and we assume that here we are also dealing with a deactivating chain transfer process. At atmospheric pressure $G(HCl) \sim 10$ in γ-ray irradiated gaseous vinyl chloride (13) and, assuming that this value is approximately the same for 50 kV X-ray irradiation, the accumulation of HCl within the system might have a non-negligible effect on polymerization as a chain transfer agent. The next important radiolysis product of gaseous C_2H_3Cl is acetylene, $G(C_2H_2) \sim 1.5$. In Fig. 2 we see that the addition of 0.03 molar fraction of C_2H_2 decreases the polymerization-rate by around 35%, which is high compared to the $\sim 6\%$ decrease by a similar amount of HCl. Acetylene is known to be a deactivating chain transfer agent (25) and its retarding action suggests that it behaves in the same manner in the present system. The combined actions of C_2H_2 and HCl as deactivating chain transfer agents are most probably the reason for the low degree of polymerization of vinyl chloride in the gas phase, and they may be considered as limiting the polymerization-rate in the absence of all other additives.

In contrast to isobutene (4) the evidence from the use of additives such as ammonia or methylamine is not conclusively in favor of a cationic polymerization. The charge exchange reaction between vinyl chloride ion and ammonia (i.p. = 10.15 eV)(26) is possible if the parent ion has a small energy excess of around 0.2 eV. However, charge transfer processes of this kind might be much slower than the bimolecular reaction between $C_2H_3Cl^+$ and the monomer for which the rate constant is around 1×10^{-11} cm^3 molecule^{-1} s^{-1} (8). Therefore, the initial drop of the relative polymerization-rate with addition of small quantities of NH_3 is probably due to interception of radical species able to initiate polymerization. In the case of methylamine (i.p. = 8.97 eV) (27) a charge transfer process from the $C_2H_3Cl^+$ is much more favored than with NH_3. A contribution from such a process might be included in the initial rapid decrease of the rate, which is substantially higher than that for the $C_2H_3Cl + NH_3$ system. After the initial rapid drop of the rates in the presence of NH_3 or CH_3NH_2, more of these additives induces a slow decrease of the polymerization (Fig. 2) which we attribute to a deactivating chain transfer. In the case of the $C_2H_3Cl + NH_3$ system an increase of the polymerization-rate can be noticed beginning at 0.025 molar fraction of NH_3. A tentative explanation of this might be the consumption of HCl by NH_3 in the reaction for formation of ammonium chloride. The increase of polymerization-rate by NH_3 is also seen during irradiation of vinyl bromide (25), and we account for this effect by the interception of HBr, which is a powerful deactivating chain transfer agent. The $C_2H_3Cl + H_2O$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

system shows effects, which might be linked with the hydration of ionic species and HCl removal. However, we are unable, for the time being, to give any evidence for such processes.

Chain transfer will lead to retardation of polymerization if the radical product of the transfer reaction has a low reactivity towards the monomer. A kinetic scheme for such retarded polymerization in the present case is given below, in which M, S, P_r represent monomer, additive (retarder), and polymer, and $R_i^{\cdot}$, $R_p^{\cdot}$, and $R_b^{\cdot}$ initial, and propagating, linear and branched radicals (and ions), respectively.

$$[1a] \qquad M \xrightarrow{\text{X-ray}} R_i^{\cdot}$$

$$[1b] \qquad R_i^{\cdot} + S \rightarrow RS^{\cdot} \text{ (inactive)}$$

$$[1c] \qquad R_i^{\cdot} + M \rightarrow R_{i+1}^{\cdot}$$

$$[1d] \qquad R_p^{\cdot} + M \rightarrow R_{p+1}^{\cdot}$$

$$[1e] \qquad R_p^{\cdot} + S \rightarrow P_r + S'^{\cdot} \text{ (inactive)}$$

$$[1f] \qquad P_r \xrightarrow{\text{X-ray}} R_b^{\cdot}$$

$$[1c'] \qquad R_b^{\cdot} + M \rightarrow R_{b+1}^{\cdot}$$

$$[1e'] \qquad R_b^{\cdot} + S \rightarrow P_r + S'^{\cdot} \text{ (inactive)}$$

$$[1g] \qquad R_p^{\cdot} + R_s^{\cdot} \rightarrow P_{p+s} \text{ or } P_p + P_s$$

$$[1h] \qquad R_p^{\cdot} + S^{\cdot} \rightarrow P_p$$

The reaction 1*b* is operating only in systems where additives are mixed with the monomer. In particular the rate dependence on intensity of irradiation is affected by this reaction. A rigorous treatment of scheme 1 without the initiation by irradiated polymer [1*f*] was given by Kice (28). Subsequently, Allen *et al.* (29) and Jenkins (30) used a similar treatment. The kinetic expression for the propagation-rate is quite cumbersome and its use is limited to special experimental conditions. Due to the further complexity in introducing the propagation by activated polymer [1*f*], we do not try to establish a quantitative expression for the propagation-rate. We assume that in the absence of any additives, the role of the retarder S is played by C_2H_2 and HCl. On the other hand, additives such as NH_3 or CH_3NH_2, besides their retarding action, scavenge the $Cl^{\cdot}$ atoms which result from the decomposition of the excited C_2H_3Cl or C_2H_4Cl molecules. The latter molecule results from the addition of H atoms to the double bond of the monomer (31). In our opinion the $Cl^{\cdot}$ atoms are responsible in part for the initiation of the polymerization. Such initiation is in competition, of course, with the formation of the HCl.

This work was made possible through the financial assistance of the National Research Council of Canada. The authors are indebted to Miss H. R. Chen for illuminating discussions and to Dr. R. Lanthier for PVC standards used in the g.p.c. calibration. We are also grateful to Mr. F. Bouchard and Mr. G. Marier for technical assistance.

Substituent Effects on the Orientation of Diels–Alder Reactions. II

CIRILL SCHMIDT,[1,2] S. D. SABNIS,[2,3] EDITH SCHMIDT, AND D. K. TAYLOR
Department of Chemistry, University of Prince Edward Island, Charlottetown, Prince Edward Island

Received July 22, 1970

The competitive ortho directing (c.o.d.) influence of a 1-methoxy group and a 4-methyl was studied in the Diels–Alder addition of 1-methoxy-1,3-pentadiene (**1**) to 2,6-dimethylbenzoquinone (**2**). It was found that the c.o.d. influence of a terminally located methoxy is stronger than the effect of a terminal methyl group in the diene since only adduct **3** could be isolated. The influence of non-terminal substituents compared to terminal substituents in the diene appears to be insignificant. This was demonstrated by obtaining only adduct **5** from the addition of 3-ethoxy-1,3-pentadiene (**4**) with 2,6-dimethylbenzoquinone (**2**). The following order of c.o.d. influence was suggested in the diene relative to a methyl group in the dienophile $OCH_3 > CH_3 > H$.

Canadian Journal of Chemistry, 49, 371 (1971)

Recently a novel approach was initiated to investigate the mechanism of Diels–Alder reactions by determining the ratios of the two possible adducts III and IV formed from 1,4-unsymmetrically disubstituted dienes I and 2,6-disubstituted quinones II, eq. 1 (1). Such an experimental design allows a convenient variation of electronic density at the four carbon atoms involved in the formation of the two σ bonds. The following order of ortho[4] orienting influence was suggested by varying the substituents in the diene (X and Y) relative to a methyl in the dienophile ($Z = CH_3$) as defined by eq. 1 (1).

The purpose of the present communication was to extend this study to the internal competition between an alkoxy and a methyl group at the two terminal positions of a diene. It was found previously that a terminal acetoxy group is approximately four times more powerful as an ortho orientor than a terminal methyl group (1). Since the methoxy group is a more efficient mesomeric electron donor than an acetoxy group, it was of interest to examine the reaction of 1-methoxy-1,3-pentadiene (**1**) with 2,6-dimethylbenzoquinone (**2**), eq. 2.

Another aspect of the present study was to inquire about the influence of an alkoxy group at a terminal position in comparison to the effect of the same group when located at a non-terminal position. Thus the addition of 2-ethoxy-1,3-pentadiene (**4**) with 2,6-dimethylbenzoquinone (**2**) was studied, eq. 3.

Results and Discussion

(a) The Reaction of 1-Methoxy-1,3-pentadiene (1) with 2,6-Dimethylbenzoquinone (2)

The desired diene **1** was obtained by the catalytic pyrolysis of 1,1,3-trimethoxy-pentane (**7**) using a continuous flow system, eq. 4. The methoxy acetal was prepared from the readily available 2-penten-1-al (**6**) (2) by the standard procedure (3). In spite of numerous attempts, the yield of the pyrolitic reaction could not be improved beyond 20% by us under a variety of conditions.

Diene **1** appeared to be homogeneous in v.p.c. and had the appropriate mass and spectroscopic properties. It is assumed that diene **1** possessed a *trans,trans* geometry since it participated in the Diels–Alder reaction without difficulty. The addition of diene **1** to quinone **2** led to the isolation of the crystalline adduct **3** in a 60% yield based on quinone **2**. The components were reacted in benzene at 120° in a sealed tube for 24 h. In refluxing benzene the reaction did not proceed to a significant extent. Its structure follows from its spectroscopic properties, especially its 100 MHz n.m.r. spectrum. The one-proton doublet situated at (τ) 6.15, $J = 5$ Hz is assigned to the hydrogen at C-1, whereas a second, clearly defined doublet at 6.83, ($J = 8$ Hz, 1H) is assigned to the proton at C-4*a*. Had this compound had the alternative orientation corresponding to **8**, the signal at 6.15 should have been a triplet.

The remainder of the clearly resolved n.m.r. signals is in agreement with the proposed structure. Our attempts had been unsuccessful to detect any trace of the alternatively oriented adduct **8** or **9** which could have been formed by the elimination of methanol from adduct **8**. The cross conjugated compound **9** was encountered while studying the addition of 1-acetoxy-1,3-pentadiene (1). The stereochemistry of adduct **3** is assigned in compliance with the vast number of known diene additions (4).

It can therefore be concluded that a terminal methoxy group is a more powerful ortho orientor than a terminal methyl group relative to a methyl group in the dienophile.

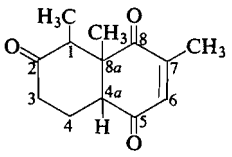
(b) The Reaction of 3-Ethoxy-1,3-pentadiene (4) with 2,6-Dimethylbenzoquinone (2)

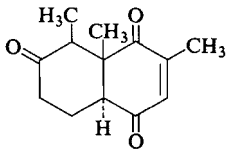
The readily available diene **4** (3) was reacted with 2,6-dimethylbenzoquinone (**2**) in refluxing benzene for 24 h. Only one adduct, **5**, was isolated in 70% yield as an oil, having the appropriate spectroscopic properties. The enol–ether **5** was hydrolyzed with aqueous acetic acid at room temperature furnishing the crystalline unsaturated triketone **10**, m.p. 110–112°, in 80% yield.

The 100 MHz n.m.r. spectrum of **10** reveals the structure of adduct **5**. A one proton triplet centered at 7.02 could be assigned to the hydrogen at C-4*a*. This proton, α to a ketone, should be therefore adjacent to a methylene group.

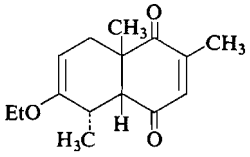
Had the unsaturated triketone **10** been derived from the alternatively oriented Diels–Alder adduct **12** → **13**, the one-proton signal located at 7.02 should have been a doublet. It should be pointed out that the signal at 7.02 (1H) cannot be due to the hydrogen at C-1 in compound **10** since this signal should have appeared as a quadruplet. Furthermore the same signal cannot be attributed to the hydrogen at C-4 in the alternatively oriented triketone **13** because this should have appeared



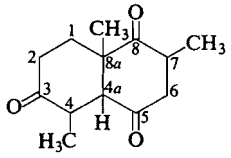
10



11



12



13

as a multiplet. This assignment was further confirmed by a decoupling experiment. Decoupling at the 1-methyl doublet position 8.8, $J = 7$ Hz, 3H did not affect the one proton triplet at 7.02.

When the unsaturated triketone **10** was heated at 100 °C for 3 h it isomerized to the crystalline **11** melting at 145°. Although the i.r. spectra of **10** and **11** are identical, their n.m.r. spectra are markedly different. In the case of the low melting compound **10**, the methyl signals appeared at 8.52, (s, 3H, angular methyl), 8.80 (d, 3H, $J = 7$ Hz, 1-methyl), and at 7.97 (s, 3H, 7-methyl). The respective signals for **11** appeared at 8.87 (s, 3H, angular methyl), 9.25 (d, 3H, 1-methyl), and at 7.96 (s, 3H, 7-methyl). These data suggest that these two compounds are *cis–trans* isomers with respect to the ring junction.

On examination of Dreiding models it can be seen that the angular methyl group of **10** is located in the deshielding zone of C-8 keto group. Accordingly, the same group in **11** should be shielded. The secondary 1-methyl group exhibited a considerable (0.45 p.p.m.) change in its n.m.r. signal. Since, however, the latter group is likely to be influenced by the anisotropies of two keto groups (at C-2 and -8) it would be unjustified to comment on the stereochemistry of the 1-methyl group on this basis. Tentatively the secondary methyl group is assumed to be equatorial in **10** and **11**. The stereochemistry of adduct **5** is assigned in accordance with the *endo–cis* addition rules (4).

It appears therefore that a terminal methyl group is a significantly better ortho orientor than a hydrogen. Furthermore a 3-alkoxy group has no influence on the outcome of orientation in comparison to terminal substituents in the diene.

It is well-known that the addition of 2-substituted dienes to an unsymmetric dienophile leads to a high para/meta isomer ratio (5). If such an orienting influence had been operational in this case, adduct **12** should have been formed in preference to the exclusively formed compound **5**. This finding is in agreement with the large number of cases studied (4). Nevertheless it was of interest to ascertain the overwhelming influence of terminal substituents compared to the effect of non-terminal groups at the inception of these investigations.

From the two Diels–Alder additions studied it can be concluded that the ortho directing influence of terminal substituents follows the order: $OCH_3 > CH_3 > H$.

The study of further critically chosen Diels–Alder additions is in progress.

It is believed that a knowledge of orientation preferences will lead to a better understanding of the mechanism of Diels–Alder reactions.

Experimental[5]

1,1,3-Trimethoxy-pentane (7)

A solution of 1 l of absolute methyl alcohol and 250 ml of trimethyl orthoformate was acidified with 0.5 ml of absolute methyl alcohol which was previously saturated with dry hydrochloric acid gas. To this solution 265 g of 2-pentene-1-al (2) was dripped in at 5° in 1 h. The reaction mixture was allowed to stand for 24 h. The solution was neutralized with sodium methylate dissolved in methyl alcohol (universal indicator paper). The excess methanol and a part of the trimethyl orthoformate were distilled off at atmospheric pressure using a Vigreux column while the temperature rose to approximately 100°. The residue was fractionated at 100 mm Hg. After discarding 25 ml of forefraction, 260 g of product was collected at 79–83° corresponding to a 50% yield. The residue was not distillable at this pressure. Mass spectrum (70 eV) *m/e*: 162 (molecular ion), 147 (base peak); i.r. (CCl_4) 2950, 1460, 1380, 1100 cm^{-1}; u.v. end absorption; n.m.r. ($CDCl_3$) τ 9.07 (t, 3, CH_3—CH_2), 8.38 (m, 2, CH_3—CH_2—), 7.82 (m, 2, CH_2 at C-2), 6.77 (s, 3, CH_3O), 5.69 (m, 1, C*H*—OCH_3 at C-3), 4.64 (t, 1, C*H*—$(OCH_3)_2$).

[5]All melting points were taken on a Fisher–Johns melting point apparatus and are uncorrected. The elemental analyses were carried out by Pascher Mikroanalytical Laboratorium, Bonn, West Germany, and Schwarzhopf Mikroanalytical Laboratory, Woodside, N.Y. The i.r. spectra were recorded on a Perkin–Elmer Model 137B infracord spectrophotometer. The u.v. spectrograms were taken on a Coleman Hitachi Model 124 double-beam grating spectrophotometer. The n.m.r. spectra were recorded on a Varian Associates 56.4 MHz spectrophotometer. The mass spectra were obtained with a Hitachi Perkin–Elmer Model RMS-4 spectrometer.

1-Methoxy-1,3-pentadiene (1)

One hundred grams of 1,1,3-trimethoxy-pentane (7) was dripped into a pyrolyzer at 300° in 45 min using dry nitrogen as the carrier gas. The pyrolyzer consisted of a 35 cm long pyrex tube (diameter 12 mm) which was heated with a coil of Nichrome wire regulated with a powerstat. The catalyst was prepared by soaking pyrex glass wool in a saturated solution of potassium bisulfate and heating at 400° in an oven.

The products were collected in two consecutive Dry Ice – acetone cooled traps which contained pentane and 5% sodium bicarbonate solution. The pentane solution of the products was washed four times with saline then dried with magnesium sulfate. The pentane was removed by atmospheric distillation, then the residue (60 g) was fractionated. After collecting 30 g of forefraction 18 g of the product was distilled at 122°/760 mm Hg. This fraction was further purified with the help of preparative gas chromatography furnishing 11 g of diene **1** (18.5%).[6] Several attempts were made to improve the yield with $KHSO_4$ and NaH_2PO_4 as catalysts at various temperatures without success. Mass spectrum (70 eV) *m/e* 98 (parent peak), 77 (base peak); i.r. (CCl_4) 2950, 1630, 1250 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 237 mμ (ε 20 000); n.m.r. cis-1,4,4a,5,8,8a-Hexahydro-1α-methoxy-4α,7,8,8aβ-trimethyl-5,8-dioxonaphthalene (3)

A solution of 1 g of 1-methoxy-1,3-pentadiene and 1 g of 2,6-dimethylbenzoquinone in 5 ml of benzene was heated at 120° for 18 h in a sealed tube. After evaporating the benzene, the residue was subjected to vacuum distillation at 0.1 mm Hg. The unreacted quinone (390 mg) sublimed at 70°. The brown residue was then chromatographed on silica gel plates by developing with benzene–ether (9:1). Besides some starting material (53 mg) one product (586 mg) was isolated in crystalline form corresponding to a 60% yield based on the amount of consumed quinone. It was recrystallized from benzene–pentane, m.p. 72–73 °C. Mass spectrum (70 eV) *m/e* 234 (parent peak), 159 (base peak); i.r. (CCl_4) 2900, 1690, 1630, 1100 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 242 mμ (ε 10 500); n.m.r. cis-1,4,4a,5,8,8a-Hexahydro-2-ethoxy-1α,7,8aβ-trimethyl-5,8-dioxonaphthalene (5)

A solution of 14 g of 3-ethoxy-1,3-pentadiene (**4**) (3) and 8 g of 2,6-dimethylbenzoquinone (**2**) in 100 ml of dry benzene was refluxed under anhydrous conditions for 24 h. After evaporating the benzene and a part of the diene by distilling at atmospheric pressure the brown residue was fractionated *in vacuo*. The unreacted quinone (1.5 g) was recovered by sublimation then 8.45 g of adduct **5** was collected at 114–120°/0.2–0.35 mm Hg corresponding to a 70% yield based on the amount of consumed quinone. The residue of distillation amounted to about 1 g. The oily product appeared homogeneous in t.l.c. and v.p.c.; i.r. (CCl_4) 2900, 1680, 1625, 1450, 1170 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 242 mμ (ε 11 500); n.m.r. (CCl_4) τ 8.89 (d, 3, J = 7 Hz, 1-methyl), 8.7 (t, 3, CH_3—CH_2O—), 8.62 (s, 3, angular methyl), 8.00 (s, 3, 7-methyl), 6.3 (q, 2, CH_3—CH_2O—), 5.63 (m, 1, olefinic at C-3), 3.30 (s, 1, olefinic at C-6). Adduct **5** was analyzed in terms of crystalline triketones **10** and **11**.

cis-1,2,3,4,4a,5,8,8a-Octahydro-1α,7,8aβ-trimethyl-2,5,8-trioxonaphthalene (10)

A solution of 10 g of enol ether **5** in 120 ml of acetic acid–water (3:1) was allowed to stand at room temperature for 3 h. After the removal of solvents *in vacuo* the orange colored residue was recrystallized from ether, furnishing 6.5 g (73%) of triketone **10**, m.p. 110–112°; i.r. ($CHCl_3$) 2900, 1715, 1680, 1625, 1200 cm^{-1}; u.v.$_{max}$ (95% C_2H_5OH) 242 mμ (ε 11 500); n.m.r. ($CDCl_3$) τ 8.8 (d, 3, J = 7 Hz, 1-methyl), 8.52 (s, 3, angular methyl), 7.97 (s, 3, 7-methyl), 7.02 (t, 1, proton at C-4*a*), 3.35 (s, 1, olefinic).

The Photolysis in Acidic Aqueous Solutions of the Monooxalato-bisethylenediamine Chromium(III) Cation and the Bisoxalatomonoethylenediamine Chromate(III) Anion: Photolysis Modes and Quantum Yields

A. D. KIRK, K. C. MOSS, AND J. G. VALENTIN
Department of Chemistry, University of Victoria, Victoria, British Columbia

Received August 17, 1970

The photolysis reactions of the complex ions $[Cr(en)_2ox]^+$ and $[Cren(ox)_2]^-$ have been studied in the p*H* range $1 \rightarrow 3$ and at temperatures from 0 to 25 °C. It has been found that both ions photoaquate to a monodentate protonated ethylenediamine complex which then undergoes further aquation thermally with loss of the ethylenediamine ligand. Quantum yields for these aquations were measured for irradiation into the ligand field bands, the values obtained being 0.18 and 0.02, respectively. The results are discussed in terms of known empirical correlations for Cr(III) complexes. Assuming these reactions may occur from the $^4T_{2g}$ state as precursor, arguments are presented that the correlation between quantum yield and ΔE may depend on mixing of the $^4T_{2g}$ and ^2E_g states, and its effect on the intersystem crossing rate constant.

Canadian Journal of Chemistry, 49, 375 (1971)

Introduction

During the last decade there has been a growing interest in the solution photochemistry and the luminescence of complex ions. For some metals, patterns of behavior have begun to emerge and some empirical correlations have been noted. Both subjects have recently been reviewed (1–4).

Perhaps the most suitable transition metal complexes for these studies are those of Cr(III), since they are often thermally substitution inert, their photoreactions are uncomplicated by redox processes, they have well-defined and understood spectroscopic states, and they have well-understood luminescence behavior (5). The main limitations on research on Cr(III) complexes are difficulties of preparation of many of the compounds with two or more different ligands, the thermal instability in solution of some, and the difficulties of analysis and identification, particularly of closely related isomers.

Previous work on the photolysis of Cr(III) complexes has suggested that the complexes with O_h symmetry show quantum yields that generally decrease together with ΔE, the spacing between the $^4T_{2g} \leftarrow {}^4A_{2g}$ and $^2E_g \leftarrow {}^4A_{2g}$ absorption band maxima (6, 7) or, as is roughly equivalent, the average field strength of the ligands (referred to as the ΔE correlation). For non-O_h chromium(III) complexes Adamson (8) has suggested that the mode of photoaquation can be predicted from the rules.

"(*1*) Consider the six ligands to lie in pairs at the ends of three mutually perpendicular axes. That axis having the smallest average crystal field will be the one labilized, and the total quantum yield will be about that for an O_h complex of the same average field.

(*2*) If the labilized axis contains two different ligands, then the ligand of greater field strength preferentially aquates. This may be a type of *trans* effect.

(*3*) The discrimination implied by rules *1* and *2* will occur to a greater extent if it is the L_1 rather than the L_2 band that is irradiated."

The present work comprises a study of the photochemistry of the pair of complex ions $[Cr(en)_2ox]^+$ and $[Cren(ox)_2]^-$. Together with the ion $[Cr(en)_3]^{3+}$ studied by Schläfer and Geiss (9), and the ion $[Cr(ox)_3]^{3-}$ studied by Spees and Adamson (10), and Porter *et al.* (11), these comprise a series of ions for which the validity of the ΔE correlation for progressive substitution of one ligand by another may be examined. It was also hoped that studies of the mode of photolysis would give information on the validity of Adamson's Rules for these ions.

Previous work on $[Cr(ox)_3]^{3-}$ placed an upper limit of 10^{-3} on the photoaquation yield for this complex, although a wavelength-independent yield of 0.08 was found for photoracemization. Schläfer and Geiss showed that $[Cr(en)_3]^{3+}$ underwent photoaquation with a wavelength independent quantum yield of 0.37. No photoracemization yield was reported although racemization was found in the thermal reaction (15*b*). The reaction was followed both by spectropho-

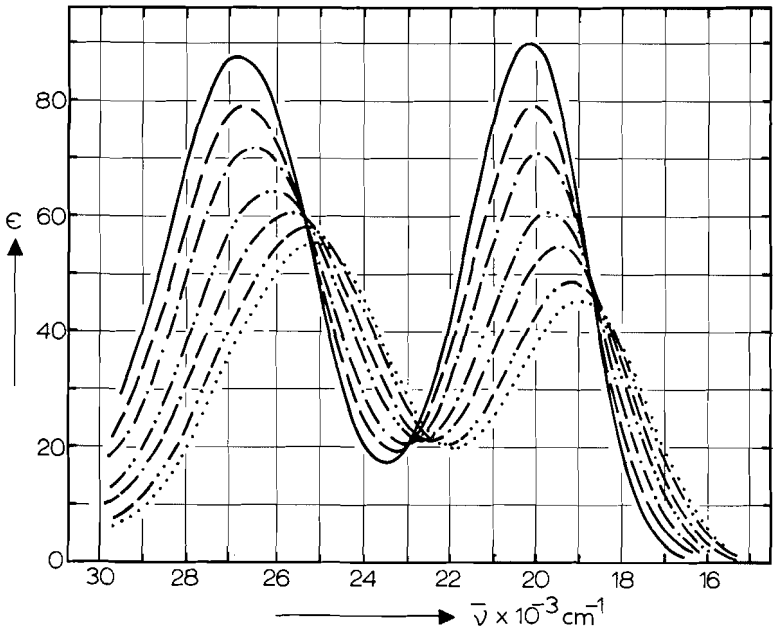

FIG. 1. Spectral changes in the photolysis of $[Cr(en)_2ox]^+$. pH = 1.0, temperature = 25 °C.

tometry and by the pH change during photolysis. The conclusion reached by these authors was that the initial product of the photoreaction was the monodentate protonated ethylenediamine complex $[Cr(en)_2(enH)(H_2O)]^{4+}$ (complexes containing this ligand will hereafter be referred to as enH complexes) which then underwent thermal aquation to give the product $[Cr(en)_2(H_2O)_2]^{3+}$, stated to be predominantly *cis*. The intermediate species was not, however, isolated from the solution and of its properties, only the calculated extinction coefficients at the photolysis wavelengths were obtained. Other workers have reported relatively stable complexes containing monodentate protonated ethylenediamine (12), ethylenetriamine (13), and recently oxalate (14). Background information to this study was also provided by the previous studies of the thermal aquations of $[Cr(en)_3]^{3+}$ (15), *cis*-$[Cr(en)_2(H_2O)_2]^{3+}$ (16), and $[Cren(ox)_2]^-$ (17).

Results

The Photolysis Modes of $[Cr(en)_2ox]^+$ and $[Cren(ox)_2]^-$

Both of these complexes were observed to undergo thermal aquation with loss of ethylenediamine (17) in acid solution at room temperature, the rate being faster for $[Cren(ox)_2]^-$. On photolysis with light corresponding to absorption either in the $^4T_{2g} \leftarrow {}^4A_{2g}$ and $^4T_{1g} \leftarrow {}^4A_{2g}$ ligand field bands (pseudo O_h symmetry), similar but recognizably different spectral changes were observed. Neither for the photochemical nor for the thermal reactions of either complex was any free oxalate observed in the reacted solutions.

The spectral changes on photolysis, Figs. 1 and 2, showed that for both complexes ethylenediamine aquation was occurring, but the disappearance of the isosbestic points after the initial reaction clearly showed that secondary processes were occurring. When slightly acid solutions were photolyzed (pH 2 → 3) the pH was observed to rise, and post-irradiation proton uptake also occurred. Thin-layer chromatography of the photolyzed solutions (18) showed the presence of $[Cren(H_2O)_2ox]^+$ and $[Cr(H_2O)_2(ox)_2]^-$ as products of the two photoreactions.

The above results were rationalized when the thermally unstable species $[Cren(enH)(H_2O)ox]^{2+}$ and $[Cr(enH)(H_2O)(ox)_2]^0$ were isolated from the respective photolyzed solutions by ion-exchange chromatography at 0 °C. $[Cr(enH)(H_2O)(ox)_2]^0$ was also isolated in smaller amounts from thermally reacted solutions of $[Cr(en)(ox)_2]^-$.

No evidence was found for any other type of

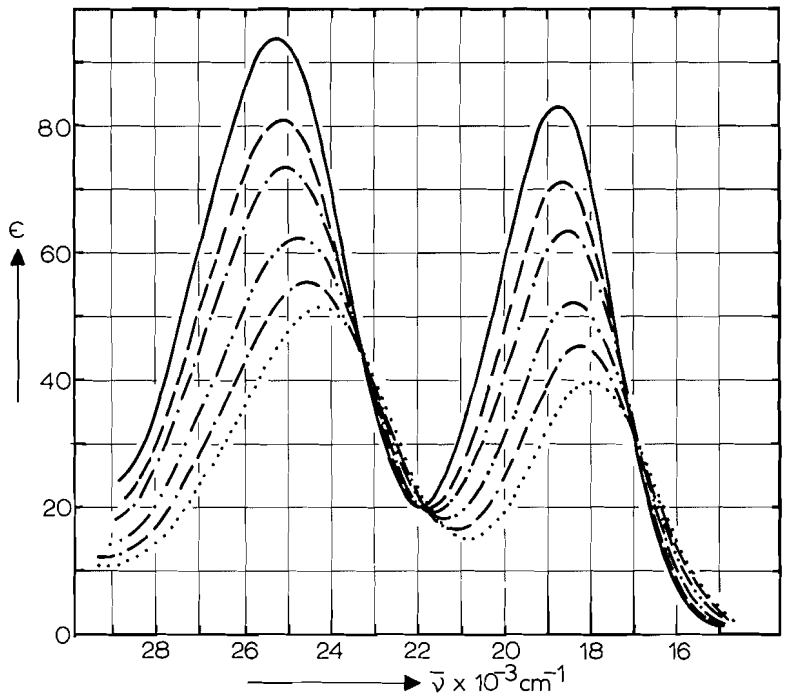

FIG. 2. Spectral changes in the photolysis of $[Cren(ox)_2]^-$. pH = 1.0, temperature = 25 °C.

photoreaction, although, as is discussed later, photoracemization remains a possibility. Thus at pH < 4, and provided conditions are chosen to minimize any secondary photolysis, the modes of the thermal and photochemical reactions can be written,

$$[1] \quad [Cr(en)_2ox]^+_{aq} + H^+ \xrightarrow[k_1]{\phi_1} [Cr(en)(enH)(H_2O)ox]^{2+}_{aq}$$

$$[2] \quad [Cr(en)(enH)(H_2O)ox]^{2+}_{aq} + H^+ \xrightarrow[k_2]{} [Cren(H_2O)_2ox]^+_{aq} + enH_2^{2+}$$

$$[3] \quad [Cren(ox)_2]^-_{aq} + H^+ \xrightarrow[k_3]{\phi_2} [Cr(enH)(H_2O)(ox)_2]^0_{aq}$$

$$[4] \quad [Cr(enH)(H_2O)(ox)_2]^0_{aq} + H^+ \xrightarrow[k_4]{} [Cr(H_2O)_2(ox)_2]^-_{aq} + enH_2^{2+}$$

$[Cr(en)(enH)(H_2O)ox]^{2+}$ Spectrum and Thermal Aquation

This compound was separated from the reaction solution by chromatography on Rexyn 102 at 0 °C, eluted by 10^{-2} M HCl after the other complexes present had been eluted with 10^{-3} M HCl. In Fig. 3 the absorption spectrum of this enH complex is compared with the species $[Cr(en)_2ox]^+$ and $[Cr(en)(H_2O)_2ox]^+$. It is seen, as is expected from ligand field theory and analogy with the ammine complexes, that the spectrum is intermediate both in regard to wavelengths of the band maxima and extinction coefficients. This is entirely consistent with the replacement of one $-NH_2$ group of the ethylenediamine ligand by water. The extinction coefficients were obtained by chromium analysis on the eluted fraction. In addition, the spectrum is very similar to that obtained by calculation (see caption to Fig. 3) from the spectral changes in a rapid photolysis at high intensity.

Spectrophotometric attempts to measure the rate of thermal aquation of the enH complex at pH 1.0 and 21 °C did not yield precise values, due to the thermal instability of the product $[Cren(H_2O)_2ox]^+$, but the order of magnitude of k_2

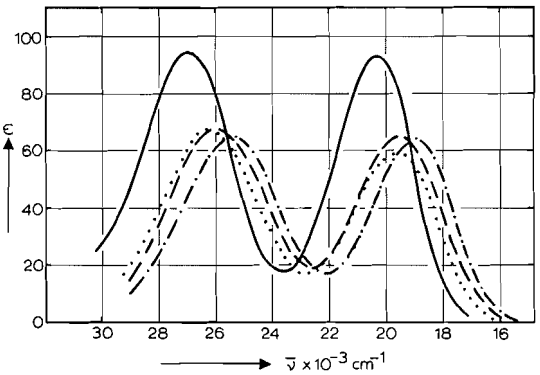

FIG. 3. Comparison of spectra of $[Cr(en)_2ox]^+$ (—) and (·-·-·) $[Cren(H_2O)_2(ox)]^+$ with the product (---) of $[Cr(en)_2ox]^+$ photolysis at p*H* 2 and 0 °C.
This figure also shows the spectrum of the product, (···), calculated as follows. With the full visible light from the lamp to give high intensity, $[Cr(en)_2ox]^+$ was photolyzed and the extent of its decomposition measured from the p*H* change assuming reaction to the monodentate enH complex. The spectrum was then calculated from the final observed spectrum assuming that $[Cr(en)(enH)(H_2O)(ox)]^{2+}$ was the sole product complex.

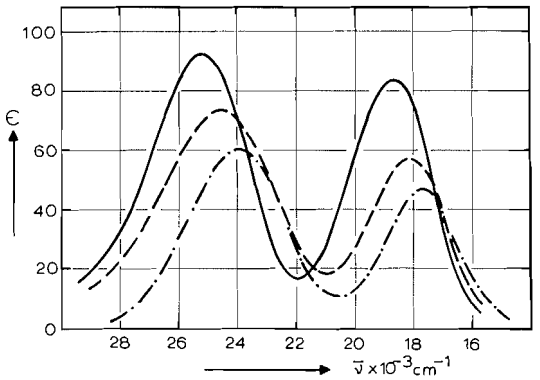

FIG. 4. Comparison of spectra of $[Cren(ox)_2]^-$ (—) and $[Cr(H_2O)_2(ox)_2]^-$ (·-·-·) with the product (---) of $[Cren(ox)_2]^-$ photolysis at p*H* 2.0 and 0 °C.

was $1.0 \rightarrow 5.0 \times 10^{-5}$ s^{-1}. Furthermore, none of this enH complex could be isolated by ion exchange chromatography from the thermal reaction. This is consistent with our observations that $k_2 > k_1$. The rough value $k_1 = 0.5 \times 10^{-5}$ s^{-1} was calculated from the spectral changes in the thermal reaction on the assumption that the thermal reaction leads directly to the bisaquo complex and free ethylenediamine. To our knowledge, no complete kinetic study of the thermal aquation of $[Cr(en)_2ox]^+$ has been carried out, probably due to this complication of $[Cren(H_2O)_2ox]^+$ instability, so no precise comparisons are possible.[1]

$[Cr(enH)(H_2O)(ox)_2]^0$ Spectrum and Thermal Aquation

The complex $[Cr(enH)(H_2O)(ox)_2]^0$ was separated from the reaction solution by chromatography on Dowex 1-X8, eluted with 10^{-3} *M* $NaClO_4$ at 0 °C. Figure 4 shows that the spectrum is again intermediate to the starting material and the bisaquo complex, as to be expected for the replacement of one $—NH_2$ group of the ethylenediamine ligand by water.

This enH complex showed, however, a more complex time-dependence of its absorption spectrum. As the solution warmed to 21 °C in the spectrophotometer cell, and before the onset of aquation to yield free enH_2^{2+} and the bisaquo complex (a process easily recognizable by the band shifts to the red and the slight lowering of the extinction coefficients), a rapid spectral change was observed. This consisted of a rise of about 33% in the extinction coefficients of the bands, without shifts in the wavelengths of the maxima. (Simple temperature dependence of the extinction coefficients was excluded as a cause.) Constant temperature measurements at 0 °C gave a first order rate constant of about 7×10^{-5} s^{-1} for the process at this temperature. On the basis of the nature of the spectral change and the value of the rate constant found, we consider the process to be a *cis/trans* equilibration of the reaction product $[Cr(enH)(H_2O)(ox)_2]^0$.

By analogy with the spectra of known *cis/trans* pairs the increase in extinction coefficients suggests that the initial product is predominantly in the *trans* configuration. This conclusion requires that the photoaquation reaction proceeds predominantly with stereochemical change. This finding may support Schläfer and Wasgestian's results with $[Cr(NH_3)_5Cl]^{2+}$ (28) should future work confirm the *cis* configuration of the product $[Cr(NH_3)_4(H_2O)Cl]^{2+}$ reported there.[2]

[1]Subsequent to submission of this manuscript, the authors became aware of such a study which confirms our conclusions and our values of k_1 and k_2 (31).

[2]This *cis* configuration has recently been confirmed by Bulzani (32).

§Average of 3 runs; pH = 1.0, T = 25 °C.

Kinetic analysis of the spectral changes subsequent to this *trans* to *cis* equilibration yields a value of 0.94×10^{-5} s^{-1} for the first order rate constant k_4 at 21.5 °C and p*H* 2. This result is in excellent agreement with that of Schläfer and co-workers who obtained $k_4 = 1.0 \times 10^{-5}$ s^{-1} at 20.0 °C and p*H* 1.1 from a kinetic analysis of the thermal aquation of $[Cren(ox)_2]^-$ (17).

Quantum Yields of the Photoaquation Reactions

Having identified the reaction modes, and having the spectra of all the complexes involved, it became possible to measure the quantum yields of photoaquation by means of either the proton uptake or the spectral changes. Because the latter were small, the more precise values are generally obtained by the first method. Mainly due to the relatively low light intensities obtainable when using interference filters to produce monochromatic radiation, in both complexes significant corrections had to be made for thermal reaction during the photolysis. These corrections ranged from 10 to 40% for the bisethylenediamine–monooxalato complex and from 30 to 200% for the monoethylenediamine–bisoxalato complex, depending on the temperature of the experiment. Despite these large magnitudes the quantum yields were satisfactorily consistent, but the statistical uncertainty in the quantum yields is consequently large.

The results are tabulated in Table 1, which includes for comparison those yields obtained by the spectrophotometric methods. The agreement between the two methods is satisfactory. Within ±10% uncertainty, the data reveal no trends suggesting a large temperature variation of quantum yield for either complex, and no variations with p*H*. It appears from the results for $[Cr(en)_2ox]^+$ that there may be some effect of wavelength, the quantum yield perhaps being somewhat larger in the $^4T_{1g} \leftarrow {}^4A_{2g}$ band. More reliable data on these questions would demand much greater experimental precision. For the purpose of the ensuing discussion it will be taken that the bisethylenediamine–monooxalato complex has a constant photoaquation quantum yield under these conditions of 0.18, while the quantum yield of the monoethylenediamine–bisoxalato complex is a constant value of about 0.02. Table 1 shows also the maximum quantum yields for any free oxalate production from the two complexes.

No experiments were carried out to investigate any photoracemization processes in these complexes. Such measurements would be extremely difficult. In particular one would wish to separate the changes in rotation arising from the photo-

For personal use only.

aquation process from those due to true inversion of configuration. Even were that possible, one could then not unequivocally assign any such rotation to a particular mechanism, such as thermal re-chelation of monodentate oxalate intermediates to the starting materials.

Discussion

For the bisethylenediamine–monooxalato complex the photoaquation mode is entirely ethylenediamine and is therefore the same as the rate-controlling first step in the thermal reaction. As stated, our measurements of the rate of the latter suggest that for the thermal process at 21 °C, $k_1 < k_2$ so that the intermediate enH complex can not be present in large amounts in the thermal reaction. As shown, however, the relatively stable compound is obtained easily by photolysis, with $\phi = 0.18$.

We recognize that the absence of free oxalate in the photolyzed solution does not eliminate the possibility of oxalate photolysis to give an intermediate of structure $[Cr(en)_2(H_2O)(oxH)]^{2+}$. (Experiments with solutions of $[Cr(H_2O)_2(ox)(oxH)]^0$ prepared according to Chang (14) showed no reaction in the test for oxalate.) However, such a process would result in the take-up of protons without observable spectral changes (since ox^{2-} and H_2O have equivalent ligand field strengths) and the quantum yields measured by the two methods (pH and spectrophotometric) would be in disagreement, the pH quantum yield being higher by the amount of any such oxalate aquation. For $[Cr(en)_2ox]^+$ such a disagreement is not observed. In addition, were such an intermediate reasonably stable at 0 °C, one would have expected to find it in the chromatographic separations. That such an intermediate is likely to be stable is suggested by the findings of Chang (14) for the complexes $[Cr(H_2O)_2(ox)(oxH)]^0$ and $[Cr(H_2O)_2mal(malH)]^0$ (mal = malonate).

The possibility remains of an additional primary process occurring, whereby a monodentate oxalate intermediate is initially produced but instead of protonating re-chelates to the original complex. Such a process might be thought detectable by photoracemization studies but we have not attempted them because of the difficulty of such experiments for a complex which also photoaquates, and the ambiguities of interpretation pointed to earlier.

Similar arguments can be made for the monoethylenediamine bisoxalate complex. The quantum yield data allow some possibility of a small oxH product yield but nevertheless the chromatographic evidence is against the presence of such a species. Again the yield of oxalate aquation allowable by the data may be small due to immediate thermal re-chelation of a monodentate species.

Because of the ambiguity created by possible re-chelation of primary products, discussions of the photolysis modes in terms of Adamson's rules are not really justified. For the bisethylenediamine compound the reaction mode is the same as for the thermal reaction and is consistent with Adamson's rules. For $[Cren(ox)_2]^-$ the only certain process observed is the same as the thermal reaction but is not the oxalate aquation predicted by Adamson's rules. However, it appears that the low quantum yields of oxalate aquation in all these complexes may be determined by strong bonding between Cr(III) and the bidentate oxalate ion. The example serves to illustrate the importance of purely chemical factors in influencing the overall reaction mode of excited states.

Consideration of the overall photoaquation yields for the series of complexes from $[Cr(en)_3]^{3+}$ to $[Cr(ox)_3]^{3-}$ supports the ΔE correlation for progressive ligand exchange. The only other series of O_h complexes for which similar information is available is the $[Cr(NH_3)_x(H_2O)_{6-x}]^{3+}$ series (6), and there, although it may be of minor significance, no measurements of water exchange were made.

It has been previously suggested that the ΔE correlation has its origin in thermal back reaction from the doublet state shortening the lifetime of this supposedly photochemically active state (6). Schläfer has suggested alternatively that it is due to some inherent property of the states themselves (7). Now recent work by Porter (19) shows that at least for reineckate ion the quartet state may be photochemically active, as had been earlier suggested by Adamson (8). This suggests the possibility of a more direct reason for the ΔE correlation, residing in reaction from quartet states.

Figure 5 shows the typical idealized energy level diagram for an O_h Cr(III) complex and defines rate constants for various radiative and non-radiative processes. Assuming that some

For personal use only.

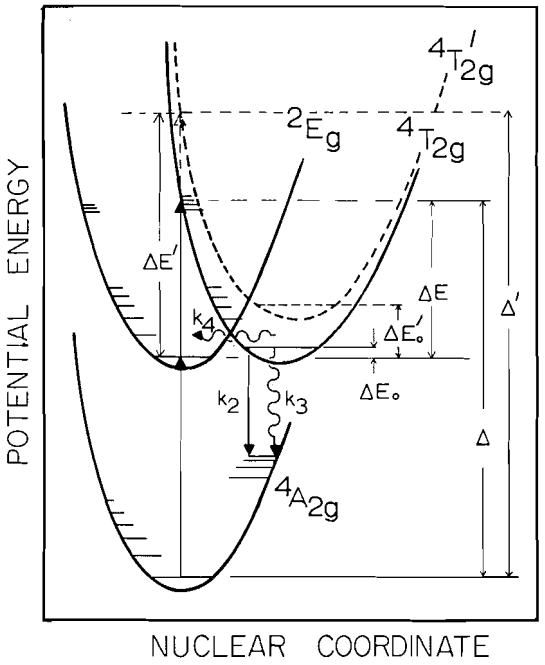

FIG. 5. Potential energy diagram for a Cr(III) complex ion. The rate constants shown are for radiative transition of $^4T_{2g}$ to the ground state, k_2; non-radiative transition of $^4T_{2g}$ to the ground state, k_3; and intersystem crossing from $^4T_{2g}$ to ^2E_g, k_4. The diagram also shows diagrammatically the relation between ΔE_0, ΔE, and Δ, the primed values being for the $^4T_{2g}$ state of a complex with a larger Δ value.

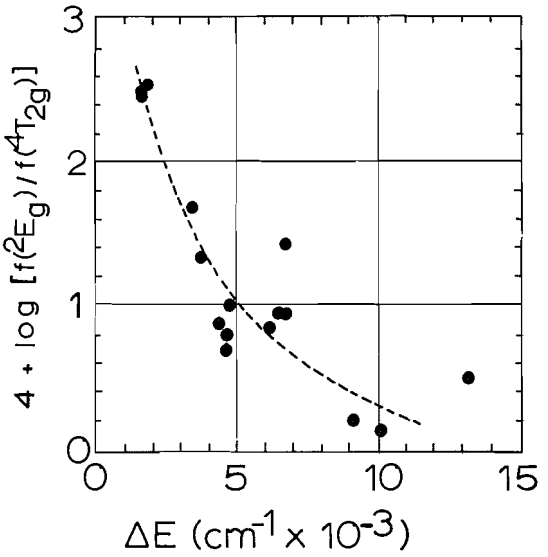

FIG. 6. Plot of $\log_{10} f(^2E_g \leftarrow {}^4A_{2g})/f(^4T_{2g} \leftarrow {}^4A_{2g})$ *vs.* ΔE, $\Delta E = E(^4T_{2g} \leftarrow {}^4A_{2g}) - E(^2E_g \leftarrow {}^4A_{2g})$. The ratio of the oscillator strengths of the $^2E_g \leftarrow {}^4A_{2g}$ and $^4T_{2g} - {}^4A_{2g}$ transitions has been taken as a measure of the extent of mixing of the $^4T_{2g}$ and ^2E_g states by spin–orbit coupling. The plot demonstrates a crude correlation of the extent of such mixing with ΔE.

fraction a, of the rate constant k_3 represents photochemical reaction from the $^4T_{2g}$ state as precursor, then the quantum yield of reaction is

$$\phi_r = a.k_3/(k_2 + k_3 + k_4)$$

It is clear from this expression that if arguments can be presented to suggest that k_4 increases rapidly as ΔE decreases, while at the same time, a, k_2, and k_3 have values insensitive to ΔE, then the decrease in ϕ_r with ΔE can be rationalized.

That k_4 does increase with decreasing ΔE can be supported both theoretically and in terms of indirect experimental evidence. From the theory of radiationless transitions one may relate k_4, the intersystem crossing rate constant, to the first order mixing of the pure $^4T_{2g}$ and ^2E_g states by spin–orbit coupling. Thus its magnitude will depend inversely on the square of the energy difference ΔE_0 between the zeroth levels of these states (20). As we have tried to show in Fig. 5, this ΔE_0 should increase together with $\Delta E = E(^4T_{2g}) - E(^2E_g)$ as Δ increases.

Unfortunately not enough data on intersystem crossing rates in Cr(III) complexes is available to make a direct test of this correlation possible. However, the process discussed here parallels the radiative transition $^2E_g \leftarrow {}^4A_{2g}$, which in first order theory borrows its intensity from the $^4T_{2g} \leftarrow {}^4A_{2g}$ transition by the same mixing of the states $^4T_{2g}$ and ^2E_g. Thus indirect support is obtained when one views the plot in Fig. 6, based on data from Table 2, of $\log f(^2E_g \leftarrow {}^4A_{2g})/f(^4T_{2g} \leftarrow {}^4A_{2g})$ *vs.* ΔE. The plot supports the contention that the extent of mixing of the two states is an inverse function of ΔE. Since there is no theoretical or experimental reason to propose a dependence of a, k_2, or k_3 on ΔE, it is therefore reasonable to ascribe the variation of ϕ_r with ΔE to the variation of k_4. As ambiguous direct support for the foregoing thesis we quote the recent work of Webb and Patterson (21), who find that for three Cr(III) complexes, $(k_3 + k_4)$, the total rate constant for non-radiative removal of $^4T_{2g}$ states increases with decreasing ΔE.

To obtain the further correlation of ϕ with Δ one must correlate Δ and ΔE. This does not appear at first sight likely since ΔE may be approximately written

§From ref. 9.

$$\Delta = \Delta - 9B - 3C$$

$$\Delta - 21B; \text{ if } C = 4B$$

where B and C are the Racah parameters.

However, an examination of the data for some complexes in Table 2 shows very good correlation between ΔE and Δ. Thus either the ratio C/B or the values of B and C generally vary in a compensatory manner with Δ. Table 2 shows that on the basis of the presently limited data on the photochemistry of octahedral Cr complexes, the correlation of Δ or ΔE with the quantum yield of reaction is good. Exceptions appear to be hexocyanochromate(III) and other complexes such as the trisphenanthroline complex where π bonding may stabilize the complexes.

Experimental

(A) Preparations

$K[Cren(ox)_2].2H_2O$ was prepared as described by Schläfer *et al.* (17)

Anal. Calcd. for $K[Cren(ox)_2].2H_2O$: Cr, 14.3; C, 19.8; H, 3.3; N, 7.7. Found: Cr, 14.8; C, 20.5; H, 3.2; N, 7.9.

$[Cr(en)_2ox]Cl.H_2O$ was prepared as described by Bushra and Johnson (22).

Anal. Calcd. for $[Cr(en)_2ox]Cl.H_2O$: Cr, 16.6; C, 23.0; H, 5.8; N, 17.8. Found: Cr, 16.4; C, 23.3; H, 6.2; N, 17.8.

$[Cren(H_2O)_2ox]Br.H_2O$ was prepared as described by Werner (23).

Anal. Calcd. for $[Cren(H_2O)_2ox]Br.H_2O$: Cr, 15.6; C, 14.4; H, 4.2; N, 8.4. Found: Cr, 15.6; C, 14.3; H, 4.1; N, 8.4.

$[Cren(enH)(H_2O)ox]^{2+}$ or $[Cr(enH)(H_2O)(ox)_2]^0$ were prepared by photolyzing acidic solutions of $[Cr(en)_2ox]Cl$ or $K[Cren(ox)_2]$, respectively, at 0 °C, with visible light and separating the photolysis products by chromatography.

(B) Solutions

All photolysis solutions were prepared at the run temperature in semi-darkness. For spectrophotometric determinations 1.0×10^{-2} M solutions of complex at pH 1.0 were used. In addition, the $[Cren(ox)_2]^-$ solutions were 0.15 M in ClO_4^- and $[Cr(en)_2ox]^+$ solutions were 0.10 M in Cl^-. For pH runs 1.0×10^{-2} M solutions of complex at pH 3.0 were used. All solutions for pH runs were 0.10 M in KCl.

(C) Photolysis Apparatus

A P.E.K. 1000 W A-H6 water-cooled high pressure mercury lamp was used as a light source. A Calflex-C heat reflecting filter together with filtraflex B-20 interference filters (Rolyn Corp.) were used for wavelength selection. The 400 nm filter had a half-band-width of 5 nm and the 540 nm filter, 7 nm.

The photolysis cell was positioned in a constant temperature bath (±0.1 °C) equipped with a double quartz window to admit the light beam. The face of the photolysis cell was masked to eliminate the possibility of any cell wall effects of the type reported by Lee and Seliger (24).

(D) Actinometry

2.0×10^{-2} M solutions of $K[Cr(NH_3)_2(NCS)_4]$ at its natural pH were used as chemical actinometers (25). In the spectrophotometric runs the actinometer cell was placed directly behind the sample cell so that intensity

monitoring was integral for the transmitted light. In the p*H* runs about 8% of the filtered light beam was reflected by a 45° quartz window on to a photocell. The output of the photocell was used to monitor the intensity of the lamp during each run. The photocell was calibrated at the two wavelengths used with 2.0×10^{-2} *M* solutions of $K[Cr(NH_3)_2(NCS)_4]$.

(E) Chromatography

Thin-layer chromatographic separations of $[Cren(H_2O)_2ox]^+$ from $[Cr(en)_2ox]^+$ and $[Cr(H_2O)_2(ox)_2]^-$ from $[Cren(ox)_2]^-$ have been previously described (18).

Ion exchange column chromatography on a jacketed column at 0 °C was used for separation of the components of the photolysis solutions. On Rexyn 102, $[Cr(en)_2ox]^+$ and $[Cr(en)(H_2O)_2ox]^+$ eluted first with 10^{-3} *M* hydrochloric acid, after which $[Cr(en)(enH)(H_2O)(ox)]^{2+}$ eluted with 10^{-2} *M* hydrochloric acid. On Dowex 1-X8 $[Cr(enH)(H_2O)(ox)_2]$ eluted first with 10^{-3} *M* sodium perchlorate, followed by $[Cren(ox)_2]^-$ and finally $[Cr(H_2O)_2(ox)_2]^-$.

The extinction coefficients of the enH complexes were found by measuring the absorbance spectra of the separated components and then analyzing the solutions for Cr(III) as described below (Section I).

(G) Spectrophotometric Determination of Thermal Kinetics

The thermal aquation rates of the monodentate protonated ethylenediamine complexes were found by observing spectral changes at constant temperature. The complexes were separated from the photolysis solution by ion exchange chromatography and the time dependence of their spectrum followed using an Unicam SP-700 ultraviolet–visible spectrophotometer equipped with a constant temperature cell compartment.

(H) Oxalate Analysis

All analyses for free oxalate in the photolysis solutions were made using the method of Buriel-Marti *et al.* (26) with the following modification: 4 ml of the Fe(III) salicylate solution was pipetted into a 10 ml volumetric flask and 3 ml of the photosolution added. The solution was made up to 10 ml and the absorbance read at 19 500 cm^{-1}. The method was calibrated by adding to the reagent 3 ml aliquots of 2.0×10^{-2} *M* $K[Cren(ox)_2].2H_2O$ containing known amounts of free oxalate.

The Fe(III) salicylate reagent gave a negative response when tested with a monodentate oxalate complex. Equal excesses of $[Cr(H_2O)_2(oxH)(ox)]^0$ (13) and potassium oxalate were added to separate solutions of the Fe(III) salicylate reagent. The potassium oxalate completely decolorized the Fe(III) salicylate reagent indicating a positive test for oxalate. The $[Cr(H_2O)_2(oxH)ox]^0$ produced no color change other than that due to dilution.

(I) Chromium Analysis

All Cr(III) analyses were made using an alkaline peroxide oxidation technique. The solution to be analyzed was made alkaline with ammonia and a small excess of H_2O_2 was added. The solution was heated on a steam bath for 20 min, additional ammonia being added to ensure alkalinity. The solution was then diluted to a known volume, the absorbance of the resulting $[CrO_4]^-$ measured at 373 nm and compared to a previously prepared calibration curve for $K[CrO_4]$.

The authors are grateful for the financial support of the National Research Council of Canada and the University of Victoria Faculty Research Fund by grants-in-aid of research (A.D.K and K.C.M) and for an NRCC Bursary (J.G.V).

Biosynthesis of Lobinaline[1, 2]

R. N. GUPTA AND IAN D. SPENSER
Department of Chemistry, McMaster University, Hamilton, Ontario

Received July 9, 1970

The biosynthesis of lobinaline (**1**) in intact plants of *Lobelia cardinalis* L. was studied by tracer methods. The incorporation data are consistent with the view that the alkaloid is formed by dimerization of α-phenacylpiperidine (**3**), whose piperidine nucleus is derived from lysine via a nonsymmetrical intermediate, and whose sidechain originates, as an intact C_6–C_2 unit, from phenylalanine via cinnamic acid.

Introduction

The cardinal flower, *Lobelia cardinalis* L., so called for its brilliant scarlet bloom, is one of the more spectacular North American wild flowers. Lobinaline (**1**), the major alkaloid of this plant species, was isolated by Manske (2) in 1938. Its structure was determined some 30 years later (3, 4, 5).

Visual dissection of its nucleus (dotted line) leads to two fragments, C_6–C_2–C_5N, whose skeleton corresponds to that of some simpler Lobelia alkaloids, 8-phenylnorlobelol (**4**) (6) and 8-phenyllobelol (**5**) (6), which occur in *Lobelia inflata*. Even though such monomeric structures have not hitherto been found in *L. cardinalis*, the hypothesis is biogenetically attractive, that the lobinaline skeleton originates by dimerization of a suitably functionalized C_6–C_2–C_5N monomer. Indeed, such a suggestion was made (7) long before the structure of lobinaline had been established.

The origin of the C_6–C_2–C_5N alkaloids of *Lobelia inflata* has not been investigated. However, the biosynthesis of sedamine (**5**), a base which differs from 8-phenyllobelol only in the configuration at C-2′, has been studied in *Sedum acre* (1, 8, 9). It was established that the piperidine nucleus of sedamine arises from lysine via a nonsymmetrical intermediate, and that the C_6–C_2 sidechain is derived as an intact unit from phenylalanine (Scheme 1).

The objectives of the present study of lobinaline biosynthesis were to identify primary precursors and to test whether the alkaloid does indeed originate by dimerization of a monomer related to sedamine, such as α-phenacylpiperidine (**3**).

Methods and Results

In 11 tracer experiments, specifically labelled samples of phenylalanine, cinnamic acid, benzoic acid, lysine, and α-phenacylpiperidine were administered by the wick method to intact plants of *Lobelia cardinalis* L. when these were in full bloom. In each experiment lobinaline (**1**) was extracted from the aerial parts of the plants and was purified to constant radioactivity as the *N*-acetyl derivative (**2**). The details of these experiments are recorded in Table 1.

The labelled samples of acetyllobinaline (**2**) obtained from individual feeding experiments were degraded, by reactions described in the Experimental section, into the degradation products shown in Scheme 2. The specific activities of the degradation products are listed in Tables 2, 4, and 6 (indicated limits are standard deviation of the mean).

The samples of acetyllobinaline derived from 3-^{14}C-phenylalanine (expt. 2) and 3-^{14}C-cinnamic acid (expt. 5) yielded *p*-nitrobenzoic acid whose specific activity was half that of the intact alkaloid, and whose label was confined to the carboxyl carbon (*i.e.* C-5 and/or C-7 of lobinaline) (*p*-nitrobenzoic acid minus *p*-nitroaniline) (Table 2). The acetyllobinaline derived from the sample of 2,3-$^{14}C_2$-phenylalanine of known isotope distribution (see Experimental) (expt. 3) yielded *p*-nitrobenzoic acid whose specific activity, relative to that of the intact alkaloid, corresponded to the fraction of radioactivity at C-3 of the doubly labelled precursor (Table 3).

Activity from 2-^{14}C-phenylalanine (expt. 1) and from 2-^{14}C-cinnamic acid (expt. 4) was also

incorporated into lobinaline. These samples of the alkaloid were not degraded, since all attempts to develop reactions suitable for extracting the presumed labelled centers, C-6 and -8, were unsuccessful. Acetyllobinaline isolated after administration of carboxyl-^{14}C-benzoic acid (expt. 6) was essentially inactive.

Radioactivity from 6-^{14}C-lysine (expts. 7 and 8) was recovered in the degradation fragments derived from the heterocyclic nuclei of lobinaline. Succinic acid, β-alanine, and a mixture of β-alanine and *N*-methyl-β-alanine, each showed a specific activity corresponding to approximately half that of the intact alkaloid (Table 4).

The same fragments, isolated from the acetyllobinaline from 2-^{14}C-lysine (expt. 9), were devoid of radioactivity, as was the formaldehyde (C-2) obtained from this sample of the alkaloid (Table 4).

The activity of the formaldehyde (C-2) obtained in an early experiment from 6-^{14}C-lysine-derived acetyllobinaline corresponded to one

quarter of the activity of the intact alkaloid (expt. 7). Modification of the degradation procedure in more recent work (expt. 8) led to formaldehyde containing 40% of the total activity. This discrepancy is discussed below.

Acetyllobinaline, obtained from the experiment with 6-^{3}H,2-^{14}C-lysine (expt. 10), showed a $^3H/^{14}C$ ratio identical with that of the doubly labelled precursor. The $^3H/^{14}C$ ratio of the pipecolic acid, isolated from the same plants, was approximately 20% higher (Table 5).

The distribution of radioactivity within the acetyllobinaline derived from 6-^{14}C-α-phenacylpiperidine (expt. 11) (Table 6) was similar to that of the alkaloid sample derived from 6-^{14}C-lysine (expt. 8).

Discussion

Lysine and phenylalanine, the primary metabolites which supply the skeleton of sedamine (**5**) also serve as precursors of lobinaline (**1**). The mode of incorporation of each of these substrates into sedamine (Scheme 1) was deduced unequivocally on the basis of a chemical degradation which permitted isolation of individual carbon atoms in such a way that the total activity of the intact alkaloid was accounted for in terms of activity at individual sites (8). Chemical degradation of lobinaline, on the other hand, was only partial. Due to the inertness of the alkaloid towards a wide variety of reagents (*cf.* ref. 3), sustained attempts to devise reactions capable of yielding degradation products representing C-6, -8, -8*a*, and -2′ failed to give useful results. Even though the interpretation of some of the incorporation data therefore rests on indirect argument, the conclusions are, for the most part, unambiguous.

The results of the experiments with phenylpropanoid precursors (expts. 1–5) are consistent with the view that an intact C_6–C_2 unit, derived from phenylalanine, is incorporated into each of the two "halves" of lobinaline, in analogy with the mode of entry of the phenylalanine-derived fragment into sedamine (Scheme 1).

Label from 3-^{14}C-phenylalanine (expt. 2) and from 3-^{14}C-cinnamic acid (expt. 5) is confined to the carboxyl group of the degradation product, *p*-nitrobenzoic acid, whose specific activity was half that of lobinaline in both experiments (Table 2).

Lobinaline contains two *C*-phenyl groups. *Provided that the yield of p-nitrobenzoic acid derived from each of these two moieties is equal*, isolation of a sample of this acid, with a specific activity half that of the original lobinaline, accounts for the total activity of the alkaloid and indicates that either one or both of the two

C_6–C_1 units are specifically derived from phenylalanine. The relative specific activity of the two units is not necessarily the same, but distribution of activity must be such that the relationship, relative specific activity at C-5 plus relative specific activity at C-7 equals 100, is obeyed. However, the two *C*-phenyl moieties of lobinaline lie in different chemical environments. There is therefore no *a priori* reason why *p*-nitrobenzoic acid should arise at the same rate from the two sites. Since oxidation of lobinaline is not necessarily complete, it is more likely that the two sites produce different amounts of degradation product, and that these yields differ somewhat from experiment to experiment. *If on oxidation each of the two sites yields a different quantity of p-nitrobenzoic acid*, the resultant product will have a specific activity corresponding to half that of the intact alkaloid either purely fortuitously,[3] or only if each of the two sites, C-5 and -7, contains one half of the total activity of the original lobinaline.

Even though we incline towards the last mentioned interpretation of the results, the other possibilities cannot be entirely ruled out on the basis of the present results.[4]

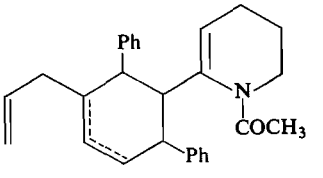
[3]Thus, *e.g.*, *p*-nitrobenzoic acid of the observed specific activity would be obtained from a sample of lobinaline containing 10% of its activity at C-5 and 60% at C-7, provided that four times as much *p*-nitrobenzoic acid is contributed to the final product by C-7 as is supplied by C-5. Under such circumstances the total activity of the intact alkaloid is not accounted for in the *p*-nitrobenzoic acid.

[4]Mention should be made of an attempt, albeit unsuccessful, to show by means of mass-spectroscopy whether both or only one of the phenyl nuclei of lobinaline had acquired label. A major mass-spectrometric fragment (*m/e* 186) of lobinaline has been related to a segment of the molecule (5), which happens to correspond to one of the two "biogenetic halves" of lobinaline. Mass spectrometry of labelled lobinaline, obtained from a feeding experiment with [ring $^2H_5$]-phenylalanine, should demonstrate whether the molecular ion of lobinaline was accompanied by a signal M + 10 or M + 5, and whether the fragment, *m/e* 186, was accompanied by a corresponding fragment, *m/e* 191. A feeding experiment with [ring $^2H_5$]phenylalanine was carried out but the deuterium content of the lobinaline which was isolated was too low to yield the desired information (*cf.* footnote 7).

The remaining ambiguity might have been dispelled, had we succeeded in perfecting degradations of lobinaline, capable of isolating C-6 and/or C-8, the presumed centers of activity in lobinaline derived from 2-^{14}C-phenylalanine (expt. 1) and 2-^{14}C-cinnamic acid (expt. 4). Attempts to isolate α-picolinic acid, whose carboxyl group would have represented C-6, by aromatization of the piperideine nucleus followed by oxidation (3), failed to yield more than traces of the desired product. Equally futile were attempts to gain access to C-8, as the 2-carboxyl group of quinolinic acid, by demethylation of lobinaline (3) followed by dehydrogenation (3) and oxidation. Another possible approach to C-8, exhaustive methylation at N-1, which led, via **6** and **7** (*cf.* ref. 5), to a neutral methine, *m/e* 473, presumably **8** (two possible positions of the double bond shown by dotted lines), was also abandoned because of low yields.

Even though specific incorporation of label from 2-^{14}C-phenylalanine and 2-^{14}C-cinnamic acid into the predicted sites of lobinaline was therefore not demonstrated, the results of two further experiments are, nevertheless, consistent with the view that intact C_6–C_2 units derived from phenylalanine are incorporated into the alkaloid.

The labelling pattern established by partial degradation (Table 2), within the lobinaline obtained from plants to which intermolecularly labelled 2,3-$^{14}C_2$-phenylalanine of known distribution of radioactivity was administered (expt. 3), was found to correspond to that of the precursor (Table 3). Such a numerical relation-



8

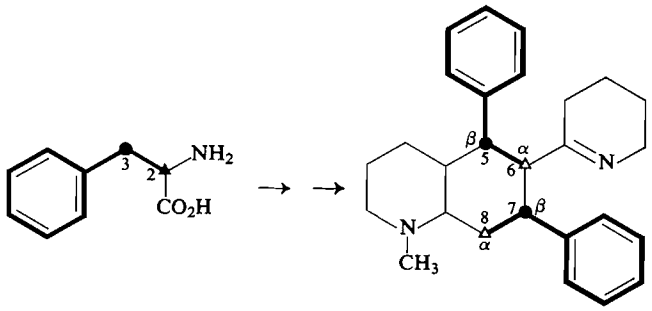

SCHEME 3. Incorporation into lobinaline of an intact C_6–C_2 unit derived from phenylalanine.

ship is as demanded by the hypothesis that intact C_6–C_2 units are incorporated and is most unlikely to be coincidental. The lack of incorporation of a C_6–C_1 precursor (expt. 6) is also consistent with this view.

Even though not entirely conclusive, the weight of evidence from expts. 1–6 favors the conclusion that, as in the case of sedamine, intact C_6–C_2 units supply the predicted moieties of lobinaline (Scheme 3).

The results of the experiments with labelled lysine (expts. 7–10) demonstrate that, in analogy with the biosynthesis of sedamine (8), a C_5N unit, derived from lysine by way of a nonsymmetrical intermediate, is incorporated into the piperidine nucleus of each of the two "halves" of lobinaline, and that each of the two "halves" of the molecule contains one half of the total activity (Table 4).

An early degradation result (July 1966) appeared to lead to a different conclusion. Formaldehyde, generated by ozonolysis of the Hofmann degradation product **7** (in the presence of unchanged lobinaline, see Experimental) obtained from lobinaline derived from 6-^{14}C-lysine, contained one quarter of the activity of the intact alkaloid (expt. 7, Table 4). This result demonstrated non-random entry of label from lysine into the alkaloid. Since it was presumed that the formaldehyde was derived solely from C-2 of lobinaline, the result appeared to indicate that four of the carbon atoms of the alkaloid were labelled. On this basis it might have been tempting to infer that the four labelled centers were C-2, -8*a*, -2′, and -6′, and that lysine had been incorporated into each of the two "halves" of lobinaline via a symmetrical intermediate. To provide further evidence in support of such an inference, confirmatory results had to be generated. At that time none of the crucial carbon atoms, other than C-2, were accessible. Evidence was sought in another way. If lysine had indeed entered by way of a symmetrical intermediate and activity from 6-^{14}C-lysine was distributed equally over four sites of lobinaline, it was an essential corollary that the same four sites would be labelled analogously when 2-^{14}C-lysine served as the precursor. Yet the formaldehyde derived from a sample of lobinaline isolated from the feeding experiment with 2-^{14}C-lysine (expt. 9) was completely inactive (Table 4). The earlier inference, that two symmetrical C_5N units had entered lobinaline, thus became untenable, since incorporation of the lysine-derived unit into ring A had clearly taken place in a non-symmetrical manner. The results might be plausibly interpreted to mean that the two "halves" of lobinaline were unequally labelled, and that they were therefore derived from related but unequal precursor units (10).

It became increasingly obvious that compelling evidence on the mode of incorporation of lysine into lobinaline would emerge only if the resistance of the molecule to degradation could be broken and degradation fragments could be obtained from each of the two hetero-rings, accounting for the total activity of the intact alkaloid. Success appeared assured when, on careful oxidation of lobinaline, a mixture of amino acids was obtained, from which β-alanine, contaminated with a little *N*-methyl-β-alanine, was isolated as the major component (Scheme 2). The specific activity of this mixture, obtained from the lobinaline derived from 6-^{14}C-lysine (expt. 7, Table 4), was half of that of the original alkaloid.

This result can be interpreted in a variety of ways, on the basis of arguments analogous to those adduced in the interpretation of the data obtained in the experiment with 3-^{14}C-phenylalanine, above. The most likely, though by no means the only, explanation of the activity pattern found in the amino acid mixture was that each of the components of the mixture, β-alanine and *N*-methyl-β-alanine, were equally labelled, presumably at the C-atoms derived, respectively, from C-6′ and -2 of the original alkaloid, and that the two "halves" of lobinaline contained equal activity. This inference, which was supported by the observation that succinic acid obtained in the same degradation also showed a specific activity corresponding to one half that of the alkaloid, was in direct contradiction to the earlier result, that formaldehyde (thought to be derived solely from C-2) showed only one quarter of the initial activity. This result thus became suspect. The mode of incorporation of 6-^{14}C-lysine into lobinaline was therefore reinvestigated (expt. 8).

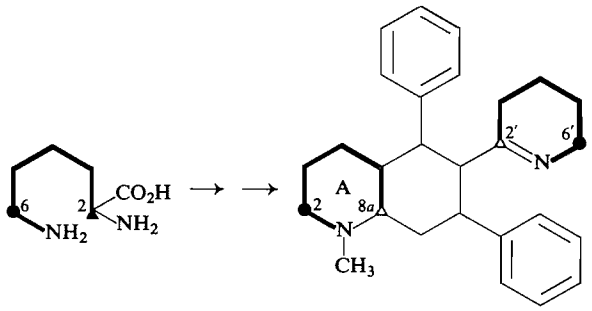
Succinic acid, and the mixture of the *N*-dinitrophenyl derivatives of β-alanine and *N*-methyl-β-alanine, obtained from the oxidation of this sample of lobinaline, again contained approximately one half of the activity of the intact alkaloid. So did a pure sample of *N*-dinitrophenyl-β-alanine, obtained by oxidation of the corresponding lobinaline methohydroxide (**6**) (Scheme 2). Since β-alanine represents C-6′, -5′, -4′, of the piperideine nucleus of lobinaline,[5] it follows that this fragment contains one half of the total activity of the alkaloid, presumably[6] at C-6′.

The other half of the activity of the intact alkaloid would be expected to reside at C-2. This carbon is contained in the degradation fragment, *N*-methyl-β-alanine. Since the specific activity of the mixture of β-alanine and *N*-methyl-β-alanine and that of β-alanine corresponded to approximately one half that of the intact alkaloid, *N*-methyl-β-alanine must also contain approximately one half the original activity. This activity is presumably contained at C-2, the carbon which is the source of the formaldehyde obtained on degradation. Yet, in the earlier experiment with 6-^{14}C-lysine (expt. 7), this formaldehyde had contained one quarter, rather than one half of the total activity. A modified procedure for the ozonolysis of the Hofmann product involving shorter exposure to ozonized oxygen yielded formaldehyde which contained approximately 40, and not 25%, of the activity of the original alkaloid. It must be concluded that in the course of the oxidation formaldehyde is generated not only from C-2, but also from one of the *N*-methyl groups of the methine base **7** or of the contaminating acetyllobinaline, presumably by way of the corresponding *N*-oxides. The inactive formaldehyde so produced then causes lowering of the specific activity of the formaldehyde derived from C-2. This contamination with inactive formaldehyde can be minimized but cannot be entirely prevented. Analogous findings in the course of the osmium tetroxide–periodate oxidation of a similarly ^{14}C-labelled Hofmann product have recently been reported (11).

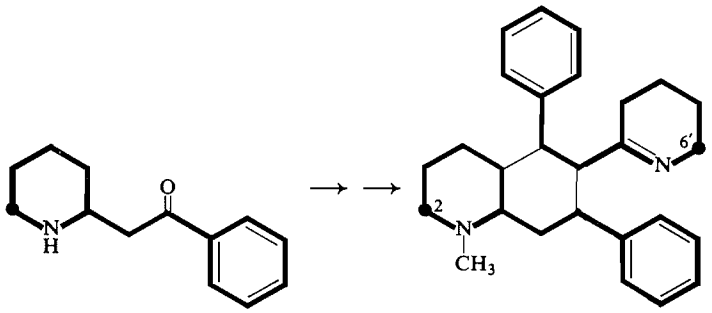
The evidence from expts. 7–9 indicates that activity from ^{14}C-lysine is equally divided between the two "halves" of lobinaline, and that the two heterocyclic rings are derived from lysine via a non-symmetrical intermediate (Scheme 4). Non-symmetrical incorporation of lysine is confirmed by the result of the experiment with 6-^{3}H,2-^{14}C-lysine (expt. 10). The ^{3}H/^{14}C ratio of this doubly labelled precursor was maintained in lobinaline (Table 5), indicating that loss of tritium relative to carbon had not occurred in the course of biosynthesis. Symmetrical incorporation of a lysine-derived precursor would have

[5]The possibility cannot be excluded, however, that β-alanine may originate also from ring A (C-2, -3, -4) of lobinaline, as a consequence of oxidative demethylation.

[6]Further degradation of the β-alanine was precluded by lack of material.



SCHEME 4. Incorporation into lobinaline of a C_5N unit derived from lysine.



3

SCHEME 5. Incorporation into lobinaline of α-phenacylpiperidine.

placed C-6 of lysine at C-2′, as well as at C-6′ of lobinaline. Since C-2′ does not carry a hydrogen atom, such symmetrical incorporation would have demanded loss of tritium, relative to ^{14}C.

Incorporation of lysine, as well as of phenylalanine, into lobinaline, thus takes place in complete analogy with the entry of the two substrates into sedamine. Furthermore, it appears that the lysine-derived C_5N unit and the phenylalanine-derived C_6–C_2 unit enter both "halves" of lobinaline at the same rate, since in every experiment in which a degradation was performed, approximately half of the activity of the intact alkaloid was recovered in fragments representing each of the two "halves" of lobinaline.

The evidence is thus entirely consistent with the notion that lobinaline is, from the point of view of its biosynthesis, a modified dimer of a C_6–C_2–C_5N unit, related to sedamine.

A final experiment strengthened this view. 6-^{14}C-α-Phenacylpiperidine (3) (12) was administered to *L. cardinalis* (expt. 11). Partial degradation of the highly radioactive lobinaline which was isolated indicated, within the limitations of the degradation procedures discussed earlier, that both "halves" of the molecule were labelled at the predicted sites (C-2 and -6′) (Scheme 5), and that each of these sites carried one half of the activity of the precursor[7] (Table 6). The hypothesis that lobinaline originates from a monomer unit related to α-phenacylpiperidine demands exactly such a distribution of activity. The results here reported support this hypothesis.

Experimental

Isolation of Lobinaline

The dried aerial parts[8] of *Lobelia cardinalis* L. (40 g) were powdered in a blender (Osterizer Galaxie 10), the powder was moistened with aqueous ammonia (2 *M*, 25 ml), the mixture was allowed to stand for 1 h, and was continuously extracted with ether for 36 h. The ether extract was then extracted with hydrochloric acid (2 *M*, 5 × 5 ml). The acid extract was repeatedly washed with ether (10 ml portions), until the ether extract was no

An attempt to demonstrate, by mass-spectrometry, incorporation of ^{15}N from ^{15}N-α-phenacylpiperidine (prepared (*cf.* ref. 12) from ε-^{15}N-DL-lysine) failed to yield conclusive results. The ^{15}N content of the lobinaline which was obtained was too low for direct mass-spectrometric demonstration of heavy species.

[8]Preliminary experiments showed that the roots of the plant contained negligible amounts of the alkaloid.

longer colored. The acid solution was made strongly alkaline by addition of potassium hydroxide solution (10% w/v), and the basic components were extracted into hexane (5 × 30 ml). The combined hexane extract was dried (sodium sulfate) and the solvent evaporated, yielding crude lobinaline as a dark semicrystalline solid. Attempted purification of lobinaline by chromatography on alumina and crystallization as the hydrochloride (5) or the free base (3) was accompanied by significant losses of material.

Purification was achieved by conversion to acetyllobinaline. The crude product was refluxed with acetic anhydride for 5 min and solvent was evaporated *in vacuo*. The residue was dissolved in water, the aqueous solution was washed with ether and made alkaline by addition of aqueous potassium hydroxide (10% w/v). The mixture was extracted with ether (3 × 20 ml), the ether extracts were dried, solvent was evaporated, and the residue was recrystallized from hexane and sublimed at 190–200° and 3×10^{-3} mm. Acetyllobinaline (350 mg), m.p. 158–159°, was obtained (mass spectrum *m/e* 428). Reported m.p. 159–160° (3).

p-Nitrobenzoic Acid by the Oxidation of Acetyllobinaline

A mixture of acetyllobinaline (175 mg) and concentrated nitric acid (5 ml) was heated on the steam bath until nitric acid had evaporated. The residue was dissolved in sodium hydroxide solution (5% w/v, 10 ml), finely powdered potassium permanganate (1.2 g) was added, and the mixture heated overnight with continuous stirring. The mixture was cooled and acidified with dilute sulfuric acid, a stream of sulfur dioxide was passed through, and the solution was then extracted with ether. The ether extract was washed with water, dried, and evaporated. The residue was crystallized from aqueous methanol and sublimed at 120–125° and 5×10^{-3} mm, yielding a crystalline solid (40 mg), m.p. 239–240°, mass spectrum *m/e* 167, identical (mixture m.p., i.r. spectrum) with an authentic sample of *p*-nitrobenzoic acid.

p-Nitroaniline from p-Nitrobenzoic Acid (13)

p-Nitrobenzoic acid (50 mg) was dissolved in chloroform (5 ml), and a mixture of oleum (10%, 2.5 ml) and concentrated sulfuric acid (0.5 ml) was added, followed by sodium azide (5 mg). The mixture was refluxed 3 h with rapid stirring, cooled, and poured onto crushed ice (25 g). The chloroform layer was separated and rejected. The aqueous layer was made alkaline with sodium hydroxide (1 *M*) and extracted with ether (3 × 10 ml). The ether layer was washed with water, dried, and the solvent was evaporated. The residue was sublimed at 130–140° and 3×10^{-3} mm, yielding *p*-nitroaniline (25 mg) melting at 147–148°.

Hofmann Degradation of Acetyllobinaline

Acetyllobinaline (200 mg) was dissolved in dry acetone (4 ml), methyl iodide (2 ml) was added, and the mixture was allowed to stand 48 h at room temperature, and was then evaporated to dryness, yielding a foamy residue which did not crystallize. The residue was repeatedly triturated with ether, and the ether extracts containing unreacted acetyllobinaline were decanted. The residue was dissolved in hot aqueous methanol (50% v/v) and freshly precipitated silver oxide (300 mg) was added. The mixture was allowed to stand 4 h in the dark, solid was filtered off, the filtrate and washings were combined, solid potassium hydroxide (1 g) was added, and the solvent was evaporated.

Basic components were recovered from the residue by high vacuum sublimation at 190–200° and 5×10^{-3} mm. The sublimate was a mixture of unchanged acetyllobinaline (~70%) and the methine base (7) (~30%). In a pilot experiment the latter was separated by the general method described for the purification of methine bases derived from *trans*-decahydroquinoline systems (14). The mixture was refluxed 6 h with a solution containing acetic anhydride (2.5 ml) and glacial acetic acid (2.5 ml). The solvents were then evaporated, the residue was dissolved in water, and the solution made alkaline with potassium hydroxide (1 *M*), and was extracted with ether to remove unreacted acetyllobinaline. The aqueous layer was saturated with potassium iodide and extracted with chloroform, and the solvent evaporated. A quaternary salt, presumably 9 (*cf.* ref. 14) (n.m.r. spectrum: *C*-methyl, doublet, centered at 1.6 p.p.m.) remained. It was dissolved in hot water, freshly precipitated silver oxide was added, and the hot solution was left for 2 h in the dark. Solid was filtered off, the solution was evaporated, and the residue was heated *in vacuo*. The methine base 7 (*cf.* ref. 5) sublimed at 150–180° and 3×10^{-3} mm as a gummy mass which did not crystallize (mass spectrum, molecular ion *m/e* 442).

This separation was not used in the degradation of labelled samples. The mixed crude bases were dissolved in a mixture of ethyl acetate (3 ml) and acetic acid (2 ml). The solution was cooled in ice/salt mixture and ozonized oxygen was passed, in early experiments for 15 min, and in more recent runs for less than 5 min. The solution was then diluted with water (40 ml), zinc dust (50 mg) was added, and the mixture was concentrated until 25 ml distillate had been collected.

5,5-Dimethyl-1,3-cyclohexanedione (dimedone) (25 mg) was added to the distillate which was then allowed to stand at room temperature overnight. Formaldehyde dimethone (10 mg), which crystallized when the solution was concentrated, was recrystallized from aqueous methanol, and after sublimation at 120–140° and 3×10^{-3} mm melted at 186–187°.

The reaction mixture remaining after removal of formaldehyde by distillation was made alkaline by addition of aqueous sodium hydroxide (1 *M*), and was then extracted with ether. The ether extract was dried, solvent was evaporated, and water (20 ml) and powdered potassium permanganate (1 g) were added to the residue. The mixture was heated 24 h under reflux with constant stirring. The mixture was cooled and acidified (1 *M* sulfuric acid) and sulfur dioxide was passed until all manganese dioxide had dissolved. The solution was extracted with ether (3 × 10 ml), the extract was washed with water (1 ml), dried and evaporated, the residue was sublimed at 60° and 5×10^{-3} mm, and the sublimate was crystallized from aqueous methanol. Resublimation yielded benzoic acid (10 mg), m.p. 120–121°.

β-*Alanine from Acetyllobinaline*

(a) Chromic Acid Oxidation of Acetyllobinaline

Acetyllobinaline (200 mg) was suspended in aqueous sulfuric acid (5 ml, 30% v/v) and the mixture was refluxed for 1 h with continuous stirring. Chromic acid (1 g) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

water (1.5 ml) was then added and refluxing was continued for 36 h with stirring.

Excess chromic acid was destroyed by addition of a few drops of methanol and the mixture was continuously extracted with ether for 24 h. The ether extract was worked-up for succinic acid, the residue was diluted with water (100 ml), and worked-up for amino acids.

The ether layer was extracted with water (5 × 1 ml), the aqueous extract was washed with ether (2 ml) and was then evaporated to dryness. The residue was sublimed at 110–130° and 5×10^{-3} mm, yielding succinic acid (5 mg), m.p. 181–182°, identical with an authentic sample.

The aqueous solution containing the residue remaining after extraction of the chromic acid oxidation mixture with ether was heated on the steam bath and neutralized (p*H* 6–7) by addition of hot barium hydroxide solution. After 1 h the mixture was filtered, the precipitate was washed with hot water (3 × 10 ml), and the combined filtrate and washings were concentrated, treated with charcoal and filtered. Sodium carbonate (25 mg) and methanolic 2,4-dinitrofluorobenzene (10% v/v, 1 ml) was added, and the mixture was allowed to stand at room temperature with occasional stirring. The solution whose p*H* was still above p*H* 8 was extracted with ether, and the extract discarded. The solution was then acidified with hydrochloric acid (2 *M*) and was extracted with ether. The ether extract was dried, solvent was evaporated under reduced pressure, and the residue was heated at 80° and 3×10^{-3} mm to remove 2,4-dinitrophenol by sublimation. The deep yellow residue was dissolved in chloroform (0.5 ml) and the solution was applied to two plates (20 × 20 cm) coated with silica gel (2 mm thickness). Development with benzene/pyridine/acetic acid 80:20:2 (15) led to the appearance of three well separated major bands, whose R_f value corresponded to those of authentic samples of the *N*-dinitrophenyl derivatives of glycine (R_f 0.28), β-alanine (R_f 0.72), and γ-aminobutyric acid (R_f 0.82). A minor band of higher R_f value was not identified.

The band corresponding to *N*-dinitrophenyl-β-alanine was scraped off the plate and eluted thoroughly with methanol. The methanol was evaporated, the residue was dissolved in hydrochloric acid (1 ml, 1 *M*) and the solution extracted with ether (3 × 5 ml). The ether extract was washed with water (1 ml) and dried (sodium sulfate), the solvent evaporated, and the residue sublimed at 150–160° and 3×10^{-3} mm.

The sublimate did not crystallize. Its mass spectrum showed, in addition to the expected molecular ion of *N*-dinitrophenyl-β-alanine, *m/e* 255, a signal at *m/e* 269, presumably due to *N*-dinitrophenyl-*N*-methyl-β-alanine. The sublimate was esterified by treatment with diazomethane in ether. The n.m.r. spectrum of the product in deuterochloroform showed a singlet (3.03 p.p.m.) characteristic for *N*-methyl. The mixture of the *N*-dinitrophenyl derivatives of β-alanine and *N*-methyl-β-alanine, or of their methyl esters, resisted all attempts at separation by thin layer, column, or gas–liquid chromatography.

(b) Chromic Acid Oxidation of Acetyllobinaline Methohydroxide

Methyl iodide (2 ml) was added to a solution of acetyllobinaline (300 mg) in acetone (2 ml), the mixture was allowed to stand 48 h at room temperature and was then evaporated to dryness. The residue was triturated with ether to remove unreacted acetyllobinaline. The residue was dissolved in hot aqueous methanol (5 ml, 50% v/v), freshly precipitated silver oxide (400 mg) was added, and the mixture was kept in the dark for 4 h. Solid was filtered off and washed with hot water (2 × 5 ml), and filtrate and washings were combined and evaporated, yielding a residue which was dissolved in aqueous sulfuric acid (5 ml, 30% v/v) and refluxed 1 h with continuous stirring. Chromic acid (1 g) in water (1.5 ml) was then added and refluxing was continued for 36 h with stirring.

Further work-up of the reaction mixture was as described in the case of the direct chromic acid oxidation of acetyllobinaline, above. Succinic acid was isolated from the ether soluble fraction of the oxidation mixture. Amino acids, present in the aqueous layer, were converted into their *N*-dinitrophenyl derivatives, which were separated by thin layer chromatography, as described above. Three major bands were again observed.

The band corresponding to *N*-dinitrophenyl-β-alanine was scraped off the plate and eluted thoroughly with methanol. The methanol was evaporated, the residue was dissolved in dilute hydrochloric acid, and the solution extracted with ether. The ether extract was washed with a little water, the solution was dried (sodium sulfate), the solvent was evaporated and the residue sublimed at 150–160° and 3×10^{-3} mm, yielding *N*-dinitrophenyl-β-alanine (10 mg), m.p. 142–144° (reported m.p. 145–146° (16)), which was further purified by crystallization from a mixture of methanol and ether, followed by resublimation (mass spectrum, molecular ion *m/e* 255).

N-2,4-Dinitrophenyl Derivatives

Authentic samples of the *N*-dinitrophenyl derivatives of ω-amino acids, which were required for comparison with the samples derived from acetyllobinaline, were obtained as follows.

N-Dinitrophenylglycine, N-Dinitrophenyl-β-alanine, and N-Dinitrophenyl-γ-aminobutyric Acid

These samples were commercial products (Sigma Chemical Co.).

N-Dinitrophenyl-N-methyl-β-alanine

3-Methylaminopropionitrile (420 mg, Aldrich Chemical Co.) was dissolved in methanol (5 ml), and sodium hydroxide (1 *M*, 5.2 ml) was added. The mixture was refluxed 6 h, the solvents were then evaporated and the residue triturated with ether to remove unchanged nitrile or amide. The residue was then dissolved in water (5 ml) and the solution was brought to p*H* 10 by addition of a few drops of 1 *M* hydrochloric acid. Methanolic 2,4-dinitrofluorobenzene (10% v/v, 5 ml) was added and the mixture was allowed to stand 2 h at room temperature with occasional shaking. Water was added, the solution was extracted with ether, and the ether extract rejected. The aqueous solution was acidified and extracted with ether, the ether extract was washed with water, dried over anhydrous sodium sulfate, and concentrated. *N-Dinitrophenyl-N-methyl-β-alanine* crystallized spontaneously, and was further purified by sublimation at 5×10^{-3} mm and 130–140°, m.p. 142–143°. Mass spectrum, molecular ion *m/e* 269.

Anal. Calcd. for $C_{10}H_{11}N_3O_6$: C, 44.61; H, 4.12; N, 15.61. Found: C, 44.45; H, 4.05; N, 15.37.

N-Dinitrophenyl-N-methyl-γ-aminobutyric Acid

A mixture of *N*-methyl-2-pyrrolidone (500 mg, Aldrich Chemical Co.) and concentrated hydrochloric acid (2 ml) was refluxed 4 h. The solution was evaporated to dryness and the residue was repeatedly extracted with ether to remove unchanged starting material, and was then recrystallized from methanol/ether (17). The *N*-methyl-γ-aminobutyric acid hydrochloride so obtained was converted, by the standard procedure outlined above, into *N-dinitrophenyl-N-methyl-γ-aminobutyric acid*, m.p. 104–105°, after recrystallization from aqueous methanol. Mass spectrum, molecular ion *m/e* 283.

Anal. Calcd. for $C_{11}H_{13}N_3O_6$: C, 46.64; H, 4.63; N, 14.84. Found: C, 46.87; H, 4.57; N, 14.74.

Methyl Esters of N-Dinitrophenyl-ω-amino Acids (cf. ref. 18)

The *N*-dinitrophenyl-ω-amino acid (20 mg) was dissolved in methanol (5 ml), a solution of diazomethane in ether was added, and the mixture was allowed to stand at room temperature overnight. Solvents were evaporated under reduced pressure and the dark red oily residue was dissolved in chloroform (0.5 ml) and applied to a column (1 × 10 cm) packed with neutral alumina, activity I. The product was eluted with benzene, the eluate was concentrated to dryness, and the residue crystallized from methanol and sublimed at $\sim 10^{-3}$ mm.

The following esters were prepared:

Methyl 3-[2,4-dinitrophenylamino]propionate (methyl ester of *N*-dinitrophenyl-β-alanine) m.p. 97°; mass spectrum, molecular ion *m/e* 269.

Anal. Calcd. for $C_{10}H_{11}N_3O_6$: C, 44.61; H, 4.12; N, 15.61. Found: C, 44.49; H, 3.98; N, 15.46.

Methyl 4-[2,4-dinitrophenylamino]butyrate (methyl ester of *N*-dinitrophenyl-γ-aminobutyric acid) m.p. 52°; mass spectrum, molecular ion *m/e* 283.

Anal. Calcd. for $C_{11}H_{13}N_3O_6$: C, 46.64; H, 4.63; N, 14.84. Found: C, 46.43; H, 4.60; N, 15.07.

Methyl 3-[N-2,4-dinitrophenyl-N-methylamino]propionate (methyl ester of *N*-dinitrophenyl-*N*-methyl-β-alanine) m.p. 103°; mass spectrum, molecular ion *m/e* 283, n.m.r. spectrum, *N*-methyl, singlet 3.03 p.p.m.

Anal. Calcd. for $C_{11}H_{13}N_3O_6$: C, 46.64; H, 4.63; N, 14.84. Found: C, 46.77; H, 4.71; N, 15.04.

Methyl 4-[N-2,4-dinitrophenyl-N-methylamino]butyrate (methyl ester of *N*-dinitrophenyl-*N*-methyl-γ-aminobutyric acid) oily, mass spectrum, molecular ion *m/e* 297.

Administration of Labelled Compounds to Lobelia cardinalis

Plants of *Lobelia cardinalis* L. were obtained from Sheridan's Nursery, Port Credit, Ontario. Plants in full bloom were used in all feeding experiments. The labelled compound was dissolved in distilled water (10 ml), and equal portions of the solution were administered to individual plants by aspiration into the stem through a cotton wick. In most experiments the plants were kept in contact with tracer for 3 days. The labelled compounds which were administered to the plants in separate experiments are listed in Table 1.

The sample of doubly labelled phenylalanine (expt. 3) was prepared by mixing [2-^{14}C]-DL-phenylalanine (Nuclear Research Chemicals Inc., 9.3 mg, total activity $(4.75 \pm 0.17) \times 10^7$ c.p.m., specific activity $(0.84 \pm 0.03) \times 10^9$ c.p.m. mmol^{-1}) and [3-^{14}C]-DL-phenylalanine (New England Nuclear, 3.7 mg, total activity $(6.07 \pm 0.22) \times 10^7$ c.p.m., specific activity $(2.71 \pm 0.10) \times 10^9$ c.p.m. mmol^{-1}). This gave intermolecularly labelled [2,3-$^{14}C_2$]-DL-phenylalanine (13.0 mg, total activity $(10.82 \pm 0.28) \times 10^7$ c.p.m., specific activity $(13.73 \pm 0.34) \times 10^8$ c.p.m. mmol^{-1}), with a specific activity at C-2 of $(6.03 \pm 0.22) \times 10^8$ c.p.m. mmol^{-1} ($43.9 \pm 1.9\%$) and a specific activity at C-3 of $(7.70 \pm 0.27) \times 10^8$ c.p.m. mmol^{-1} ($56.1 \pm 2.4\%$).

The sample of doubly labelled lysine (expt. 10) was prepared by mixing [2-^{14}C]-DL-lysine (Tracerlab, 14.5 mg, nominal total activity 0.1 mCi) and [6-^{3}H]-DL-lysine (New England Nuclear, 0.021 mg, nominal total activity 0.8 mCi. The ^{3}H/^{14}C ratio of the sample (Table 5) was determined by liquid scintillation counting.

The sample of [6-^{14}C]-α-phenacylpiperidine (expt. 11) was prepared from [6-^{14}C]-DL-lysine (Commissariat à l'Énergie Atomique, France) by the method described in an earlier paper (12).

Isolation of Labelled Lobinaline and Pipecolic acid from L. cardinalis

Labelled lobinaline was isolated from the dried stems and leaves of the plants used in each of the 11 tracer experiments. Chemical and radiochemical yields are summarized in Table 1.

Radioactive pipecolic acid was isolated by carrier dilution from plants of *L. cardinalis* to which 6-^{3}H,2-^{14}C-DL-lysine had been administered. The dried plant material was first extracted with ether to isolate lobinaline (see above), and was then further extracted with methanol (12 h). Solvent was evaporated, and unlabelled pipecolic acid (250 mg) was added to the residue which was then extracted with water (5 × 5 ml). Pipecolic acid was then re-isolated by a method described in an earlier publication (19).

Determination of Radioactivity

Radioactivity was assayed, on samples of finite thickness on aluminum planchettes, with a gas-flow system (Model 4342, Nuclear Chicago). The usual corrections for background and self-absorption were applied. The counting efficiency for ^{14}C was approximately 30%. For plating, a 1% solution of collodion in dimethylformamide was used as the solvent. In the cases of benzoic and *p*-nitrobenzoic acid, a drop of a 5% solution of sodium hydroxide in 50% aqueous methanol was added to prevent loss by evaporation.

The ^{3}H/^{14}C ratios were measured by liquid scintillation counting (Mark I liquid scintillation computer, Model 6860, Nuclear Chicago). Activity due to ^{3}H and ^{14}C was determined simultaneously, by external standardization counting with ^{133}Ba. Samples were dissolved in methanol or methanol–water and the solution was dispersed in a solution of Liquifluor (Nuclear Chicago) diluted 25 times with toluene. Duplicate samples of each compound were counted under comparable conditions of quenching. For highly quenched samples the confidence limits of the quench correction curves were ±5%.

Confidence limits shown in the Tables are standard deviation of the mean.

We are greatly indebted to Dr. M. M. Robison, CIBA Pharmaceutical Company, Summit, New Jersey, for a most generous sample of lobinaline. This investigation was supported by a grant from the National Research Council of Canada.

Polarographic Observations of some Iron Organometallic Compounds in Acetonitrile

J. H. BRECKENRIDGE,[1] H. W. VANDENBORN, AND W. E. HARRIS
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received[2] August 29, 1969

Polarography in acetonitrile is useful for the study of the electrochemical behavior of organometallic compounds because acetonitrile is a suitable solvent for this class of compounds and provides a wide potential range over which their electrochemical behavior can be investigated. This inquiry was undertaken to enhance the understanding of the chemistry of these compounds. The polarographic behavior of three related iron compounds was studied and attempts were made to identify the products of the electrochemical reactions.

Canadian Journal of Chemistry, 49, 398 (1971)

Experimental

Reagent-grade acetonitrile was purified by distillation from sodium hydride followed by distillation from phosphorous pentoxide. Tetraethyl ammonium perchlorate was prepared according to ref. 1, recrystallized four times from water, and dried over phosphorous pentoxide.

The purified acetonitrile was stored in a glass container under helium and was metered into a polarographic cell with a Metrohm piston buret through a glass and teflon system. Oxygen was removed from the acetonitrile by bubbling helium previously saturated with acetonitrile through it.

Polarograms were obtained by using a three-electrode system and a Metrohm Polarecord equipped with an infrared (i.r.) compensator. The supporting electrolyte, tetraethyl ammonium perchlorate, was used at a concentration of 0.05 *M*. The reference electrode was a Ag/0.01 *M* $AgNO_3$ electrode in acetonitrile. The reference electrode was isolated from the solution by a small piece of porous glass sealed in glass tubing with silicone rubber cement (G.E. Silicone Seal). The working counter electrode was a platinum wire sealed in glass. The polarographic cells were flat-bottom glass tubes about 7 cm long and 2.8 cm in diameter. The supporting electrolyte and compound were weighed into the cell, then the cell was flushed with helium and a known volume of acetonitrile metered into it.

The same apparatus was also used to control the potential of a mercury-pool electrode for coulometric measurements. The solution was stirred with a magnetic stirrer. The counter working electrode was isolated behind two glass frits. Electrical connection between the working counter electrode and the solution was maintained through acetonitrile saturated with electrolyte (approximately 0.5 *M*). The total corrent passed was determined with the aid of a hydrazine coulometer (2).

Infrared spectra were determined with 1-mm KBr cells and a Perkin–Elmer 337 infrared spectrophotometer. Spectra in the far i.r. were obtained with Nujol mulls, polyethylene cells, and a Beckman IR-11 spectrophotometer.

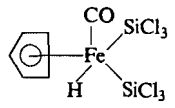
[2]Revision received September 3, 1970.

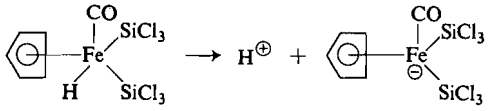
Polarographic Results

The polarographic behavior of cyclopentadienecarbonylhydridobis(trichlorosilyl)iron (**1**) in



1

acetonitrile was examined. This compound is known (3) to ionize in acetonitrile according to the equation



In the polarogram for this compound shown in Fig. 1*A* two waves with half-wave potentials of about −1.5 and −2.4 V are evident. The diffusion current for both these waves is a linear function of concentration. The diffusion current for the first wave decreases as the electrolyte concentration is increased, whereas the diffusion current for the second increases as the concentration is increased. This behavior is consistent with the theory that the first wave is due to the reduction of a positive species and the second, to a negative species.

A graph of potential against log $i/(i_d - i)$ for the first and second waves had slopes of −0.13 and −0.14 V. This suggests that the polarographic reductions at the electrode were not reversible.

Coulometric measurements indicate that the first wave is a one-electron reduction (the experimental value for n was found to be 0.99). Decom-

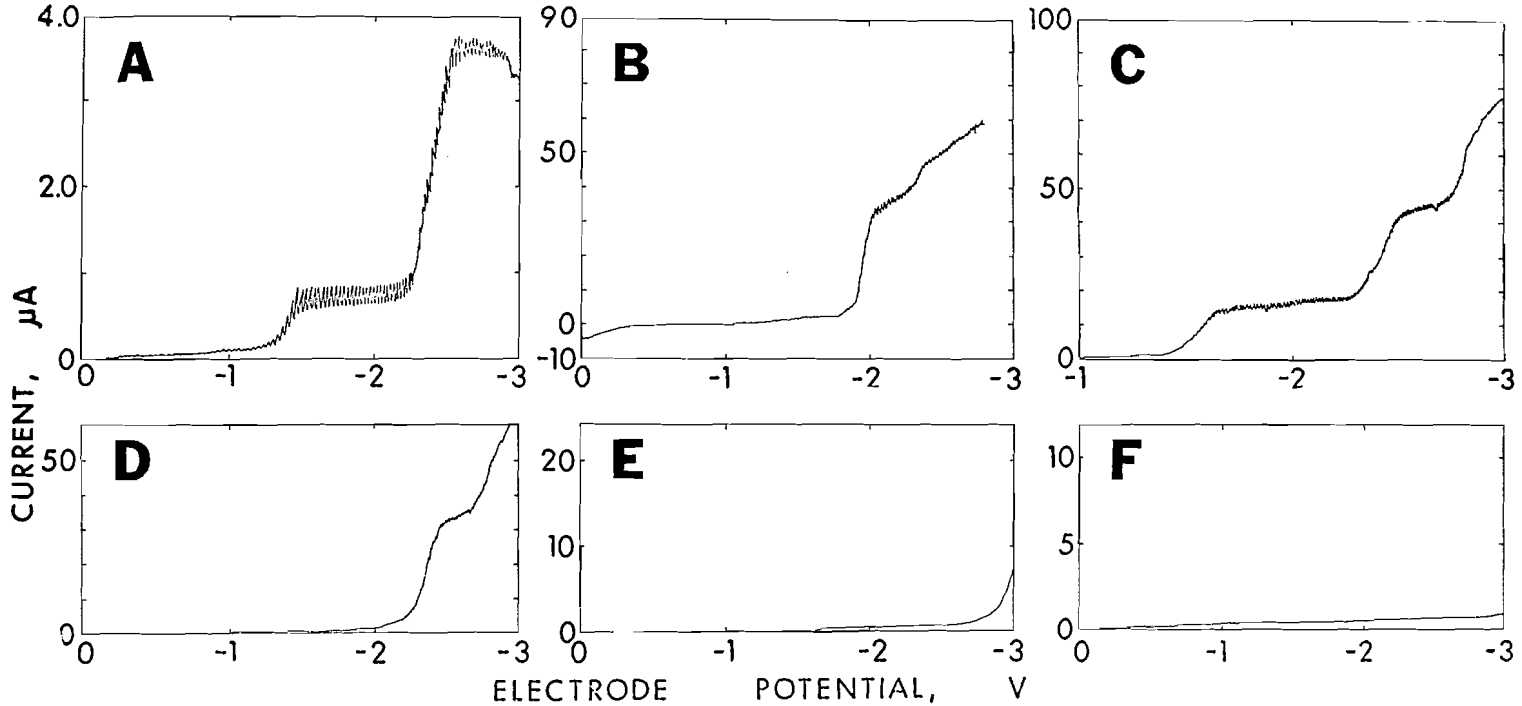

FIG. 1. Polarograms taken in acetonitrile with 0.05 *M* tetraethylammonium perchlorate with a Ag/0.01 *M* $AgNO_3$ reference electrode. *A*, compound **1**; *B*, compound **3**; *C*, compound **3** after ½ h of coulometric reduction at −2.05 V; *D*, compound **3** at end of coulometric reduction at −2.05 V; *E*, compound **3** at end of coulometric reduction at −2.6 V; *F*, background current of acetonitrile with 0.05 *M* Et_4NClO_4.

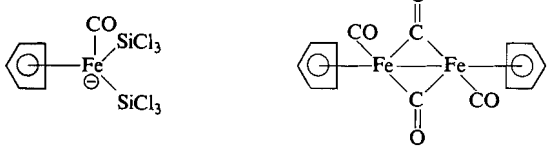
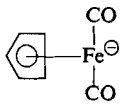
position occurred during the coulometric reduction at −2.4 V, but relatively large values for the number of electrons were signified from the approximate data obtained. Estimates based on the Ilkovic equation and the diffusion currents at known concentrations indicated a value for n of about 6 or 7 for the second wave.

On the basis of the polarographic and coulometric evidence it seems reasonable to conclude that the first wave results from a reduction of a solvated proton and the second from reduction of the ion

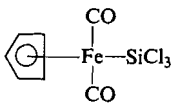


2

Bis(dicarbonylcyclopentadienyliron) (**2**) yielded a single well-defined polarographic wave with a half-wave potential of −1.84 V. The diffusion current was a linear function of concentration and the number of electrons was equal to two. The product of the reduction was not the expected ion



One product, a fine black powder exceedingly high in iron, was presumably iron. The other product was most likely the cyclopentadienyl ion. As demonstrated by Fig. 1*B*, a typical polarogram for cyclopentadienedicarbonyltrichlorosilyliron



3

(**3**) has two polarographic waves. The first wave has a half-wave potential of −1.93 V. The second, which is poorly defined, has a half-wave potential of about −2.4 V. The magnitude of the second wave is a linear function of concentration, whereas the diffusion current for the first wave becomes less than linear at higher concentrations. Plots of diffusion current against the square root of the height of the mercury column indicated that both waves were diffusion-controlled. For the first wave typical coulometric values for n were 2.2 and for the second about 0.9; these values were reproducible to about 5%. During coulometric runs on the first polarographic wave the reduction current did not decline exponentially, as one would expect, but increased for about the first half hour. This unusual behavior was attributed to the formation and reduction of hydrogen chloride (see below).

Figure 1*C* shows a polarogram taken 30 min after beginning a coulometric reduction at a potential of −2.05 V (the top of the first polarographic wave). Only a small fraction of the original wave at −1.93 V remains, and now a well-defined wave exists at −2.4 V and a completely new wave has appeared at −1.4 V.

The new wave at −1.4 V was found to be due to a volatile chlorine compound that could be removed from the solution by passing helium through it. The condensed gas coming out of the cell (acetonitrile together with the volatile compound) tested positively for chloride. The half-wave potential agrees with that reported for hydrogen chloride (4) and hydrogen chloride can be blown out of an acetonitrile solution (4). From these observations it was concluded that the compound was hydrogen chloride.

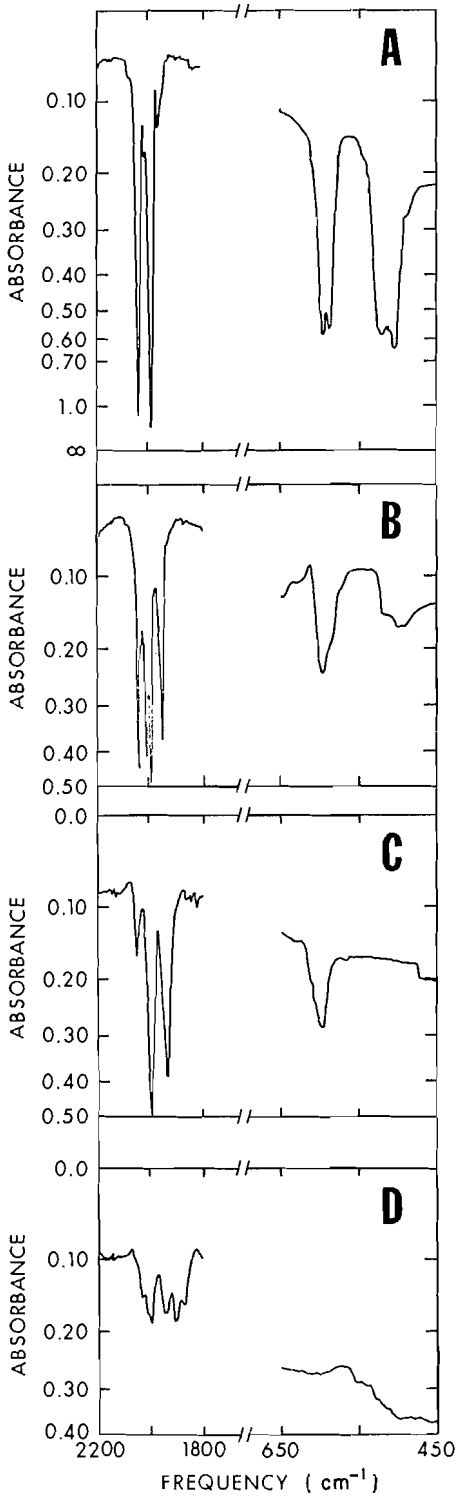
Chloride ions yield a well-developed anodic wave in acetonitrile. This wave was used to determine whether or not chloride is released during the electrolysis of **3**. It was found that about two chloride ions (probably one from direct electrochemical reduction and subsequently another by chemical reaction of the reduction product to form hydrogen chloride) are released during coulometric reduction at −2.05 V and an additional chloride is released during the coulometric reduction at −2.4 V. Coulometric reduction at the half-wave potential −1.95 V gave the same results as for reduction at −2.05 V.

Infrared Examination of the Products of Coulometric Reduction

The changes in the infrared spectrum of **3** during its coulometric reduction were obtained by examining the solution at regular intervals. Compound **3** has carbonyl frequencies at 2040 and 1990 cm^{-1} in acetonitrile as solvent. These frequencies are virtually identical to those reported by Jetz and Graham (5) with hexane as solvent. The trichlorosilyl group gives two doublets, at 595 and 586 cm^{-1} and at 520 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



505 cm^{-1} (Fig. 2*A*). After ½ h of coulometry one of the trichlorosilyl doublets became a shoulder on a single new peak at 600 cm^{-1}, and the other became a small broad peak. At the end of the coulometric reduction at −2.05 V only the new peak at 600 cm^{-1} remained (Fig. 2*C*). If the coulometric reduction was continued at a higher voltage, *i.e.*, at −2.6 V, which is in the region of the diffusion current for the second wave, further changes in the spectrum could be observed. The intensity of the carbonyl peaks at 2010 and 1950 cm^{-1} decreased, and the trichlorosilyl peak at 600 cm^{-1} disappeared (Fig. 2*D*).

Compound **3** was also examined spectroscopically in the far infrared region. A peak was observed at 304 cm^{-1}. After coulometric reduction at −2.05 V this peak split into two new peaks at 350 and 280 cm^{-1}. These two peaks disappeared after the coulometric reduction was continued at the higher voltage of −2.6 V. No assignments for these absorption bands are suggested at this time.

The $SiCl_2$ and $SiCl_3$ groups are known (6) to give two peaks, in the regions of 450–530 and 540–600 cm^{-1}. The SiCl group, however, gives only one peak, in the region of 460–660 cm^{-1}. From these infrared and polarographic observations it seems reasonable to conclude that the polarographic wave with half-wave potential at −1.93 V for compound **3** results from the electrochemical removal of a chlorine atom attached to the silicon and the reduction of hydrogen chloride, which is formed by a chemical reaction that removes the second chlorine from the silicon atom. The effect of the loss of the two chlorine atoms is to cause a downward shift in the carbonyl peaks. The single new peak at 600 cm^{-1} suggests that one chlorine atom remains attached to the silicon atom after coulometric reduction at −2.05 V. The disappearance of the peak at 600 cm^{-1} after further reduction at −2.6 V suggests that the polarographic wave with half-wave potential −2.4 V results from the removal of the remaining chlorine atom. Removal of this last chlorine atom probably results in some decomposition of the product because the intensity of the carbonyl peaks decreased. At this stage the

FIG. 2. Infrared spectra of compound **3** taken at intervals during coulometric reduction. *A*, before any reduction; *B*, after ½ h of reduction of −2.05 V; *C*, end of coulometric reduction at −2.05 V; *D*, end of coulometric reduction at −2.6 V.

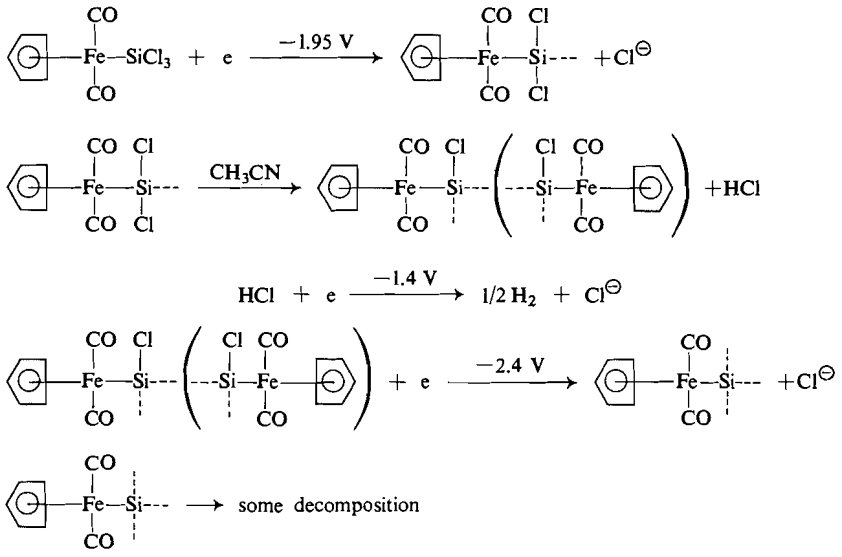


FIG. 3. Possible mechanism and suggested products formed during reduction of compound **3**.

solution was a clear bright orange with no precipitate present.

On the basis of the experimental observations it seems reasonable that in all three of the compounds **1**, **2**, and **3**, each cyclopentadiene and chloride ion can accept one electron during electroreduction. The electroreductions of **1** and **2** seem straightforward; the reduction of **3**, however, is complicated by side reactions because the number of electrons was not a whole number. The source of hydrogen to form hydrogen chloride as a product of the electroreduction of **3** is probably acetonitrile. Traces of water are not involved here because the water content of the acetonitrile was negligibly low. If 1 to 2% of water was added to the acetonitrile, hydrogen chloride was not formed as one of the products of electroreduction at −2.05 V and the number of electrons, *n*, remained at 2. Also in the presence of a small amount of water there was little or slow hydrolysis of the trichlorosilane groups. After coulometric reduction of **3** at −2.6 V, an irreversible polarographic wave at highly negative potentials still remained (Fig. 1*D*). At potentials more negative than −2.6 V coulometric reduction leads to decomposition of the compound, and a fine black suspension was obtained as product.

Figure 3 proposes a possible mechanism for the electroreduction. The overall reaction at −1.95 V is consistent with infrared evidence and the chloride content of the solution after coulometry. It is suggested that the initial product of the reduction may further react to form a new compound with an Si—Si bond. Compound **2** can be ruled out as a possible product of the reduction at −2.4 V because of its incompatible spectral and electrochemical characteristics.

We wish to thank W. Jetz, who synthesized and donated the iron compounds essential to this study.

Addition of Iodonium Nitrate to Unsaturated Hydrocarbons

U. E. DINER
Research Council of Alberta,[1] *Edmonton 7, Alberta*

AND

J. W. LOWN
Department of Chemistry, University of Alberta, Edmonton 7, Alberta

Received August 25, 1970

Iodonium nitrate in chloroform–pyridine at room temperature undergoes a *trans* stereospecific electrophilic addition to alkenes to form (*i*) iodoaliphatic nitrate esters, (*ii*) iodoalkane pyridinium nitrates, or (*iii*) alkene pyridinium iodides depending on the substrate. The addition is sensitive to steric hindrance effects and anti-Markovnikov addition is commonly encountered. In similar additions to conjugated dienes 1,2-additions in a Markovnikov fashion to form 1:1 adducts of type (*ii*) are the rule. Terminal acetylenes give alkynyl iodides in fair yield.

Canadian Journal of Chemistry, 49, 403 (1971)

Investigations of the scope and mechanism of addition of pseudo-halogens (iodine isocyanate, iodonium azide, nitrosyl acetates, *N,N*-dichlorourethan) have attracted considerable attention and have proved of synthetic utility in the preparation of aziridines and β-halocarbamates (1–7).

In a preliminary communication we reported the addition of iodonium nitrate (generated *in situ* by the reaction of iodine chloride with silver nitrate in chloroform–pyridine solution) to some monoolefins, a reaction which gave (*i*) iodoaliphatic nitrate esters, (*ii*) iodoalkane pyridinium nitrates, or (*iii*) alkene pyridinium iodides depending on the substrate (8). These reactions extended the range of known pseudo-halogen additions and complemented the recent report by Hassner *et al.* of the reaction of nitryl iodide with alkenes (9).

In a continuation of our investigations we report reactions of iodonium nitrate with (*a*) dienes, conjugated and unconjugated, cyclic and acyclic; (*b*) acetylenic compounds; and we provide further details of the reactions with (*c*) acyclic and cyclic alkenes, terminally and nonterminally unsaturated.

Reactions with Acyclic Terminal Alkenes

Simple alkenes upon reaction with iodonium nitrate gave only products of the type shown in eq. 1. Only in the case of 1-hexene however was

[1] $\text{>C=C<} + (\text{I·2Py})^{+}\text{NO}_3^{-} \xrightarrow[\text{Pyridine}]{\text{CHCl}_3} \text{>C(ONO}_2\text{)—C(I)<}$

the adduct predicted from considerations of carbonium ion stability (*i.e.* corresponding to Markovnikov addition) the sole product in the reaction, when 1-iodo-2-hexanol nitrate was produced in 83% yield. This and similar structures were confirmed by zinc–copper couple reduction, followed by treatment of the resulting iodohydrin with lithium aluminum hydride (procedure A, see eq. 2). The alcohol produced was identical with an authentic sample of 2-hexanol.

[2] 
Steric factors appear to play an important role directing the approach of the nitrate ion to the initially formed iodonium ion in the case of 3,4-dimethyl-1-hexene leading to a mixture of 70% Markovnikov and 30% anti-Markovnikov[2] addition (see Table 4). In the assignment of structures to these and similar products in this study by n.m.r. spectroscopy it was observed that methine protons alpha to an ONO_2 group absorb in the range 4.8–5.4 δ, whereas protons alpha to an iodo function absorb in the range 4.0–5.0 δ (10). Fowler *et al.* have shown that methylene protons alpha to an iodo function absorb at 3.0–3.5 δ (11). In our work methylene hydrogens alpha to

[1]Research Council of Alberta Contribution No. 498.

[2]In our previous communication the reported figures were 40% Markovnikov and 60% anti-Markovnikov. That was the ratio observed after distillation of the crude oil. Repetition of the experiment, and careful distillation to avoid loss and decomposition of material produced a mixture with the composition indicated above. The influence of the methyl groups is still apparent with the formation of 30% of the product derived from steric effects.

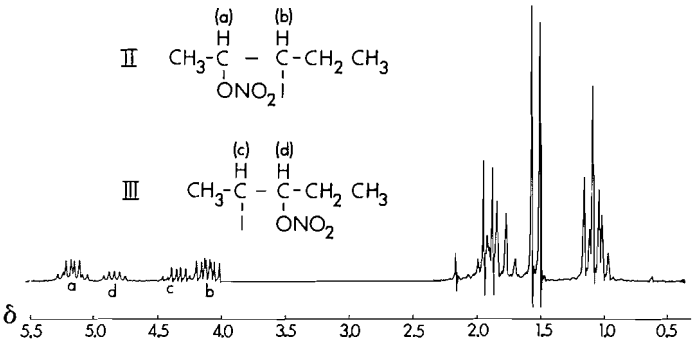

FIG. 1. The n.m.r. spectrum of 3-iodo-2-pentanol (II) and 2-iodo-3-pentanol (III) nitrates (isomeric mixture in $CDCl_3$ (100 MHz).

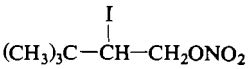
an iodo group absorbed close to 3.5 δ. For example, the n.m.r. spectrum of 1-iodo-2-hexanol nitrate showed δ ($CDCl_3$): 0.7–1.2 (m, 9H, CH_3, 3(CH_2)), 3.35 (d, 2H, CH_2I), and 4.9 (m, 1H, $CHONO_2$).

In the case of 3,3-dimethyl-1-butene steric hindrance by the *tert*-butyl group to the approach of the nitrate ion is the overriding factor and the ester with the nitrate group at the primary position **1** is the only product obtained as clearly demonstrated by the n.m.r. spectrum. Procedure A produced pure 3,3-dimethylbutan-1-ol as shown by the n.m.r. spectrum and comparison of its g.l.c. retention time with that of an authentic sample.

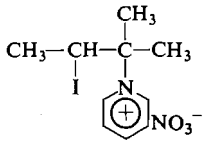


1

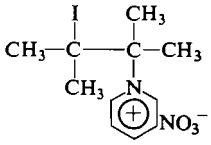
Reactions with Acyclic Non-terminal Alkenes

cis-2-Pentene afforded a mixture of 3-iodo-2-pentanol and 2-iodo-3-pentanol nitrates in a 70:30 ratio as shown by the n.m.r. spectrum (Fig. 1) corresponding to a preferential attack by the nitrate ion at the less hindered carbon of the iodonium ion intermediate. The assignments in the n.m.r. spectrum made on the basis of the empirical chemical shift observations mentioned above are shown in Fig. 1. The structural assignments were confirmed by hydrogenolysis of the isomeric iodopentanol nitrates by (*a*) zinc–copper in acetic acid or (*b*) electrolytic reduction in a buffer at p*H* 4.7 at −0.9 V *vs.* saturated calomel electrode at a mercury cathode. Reduction of the iodohydrins with lithium aluminum hydride produced a mixture of the corresponding 2-pentanol and 3-pentanol, the composition of which (70:30) was determined by g.l.c. by comparison with mixtures of authentic 2-pentanol and 3-pentanol.

When iodonium nitrate in chloroform–pyridine was added to more highly substituted olefins, in addition to the expected iodonitrate ester, the formation of iodopyridinium salts was observed. 2-Methyl-2-butene gave *N*-[2-(2-methyl-3-iodo) butyl]pyridinium nitrate (**2**) in 75% yield and 2,3-dimethyl-2-butene gave the analogous iodopyridinium nitrate **3** in 47% yield. As can be seen in Table 5 the chemical shift of methyl groups α to the pyridinium and iodine groups is very similar.



2



3

In the case of **3** for example, the starting olefin presented a sharp signal in the n.m.r. spectrum at δ 1.6. The iodo pyridinium nitrate (**3**) on the other hand showed two sharp signals at δ 2.08 and 2.05.

The analogous addition of bromonium nitrate to 2-methyl-2-butene gave as the major product the bromonitrate ester **4** together with only a small yield of the corresponding bromopyridinium nitrate **5**.[3] With ethyl vinyl ether, another example in which the carbonium ion involved is considerably stabilized, the pyridine competes successfully (12) with the nitrate ion for the

[3]It may be noted that when I is replaced by Br, the chemical shift of the α methyl group moves upfield about 0.3 p.p.m. *N*-[2-(2-Methyl-3-bromo)butyl]pyridinium nitrate, prepared with bromonium nitrate in a similar way, showed in the n.m.r. δ [$(CD_3)SO$]: 1.6 (d, 3H, J = 7 Hz, CH_3—C—Br); 1.82(s, 6H, $(CH_3)_2$—C—N^+); and 4.9 (q, 1H, J = 7 Hz, CH—Br). The separation between the two sets of methyl groups was now very clear, the methyl group α to the bromine atom being 0.22 p.p.m. upfield from the —CH_3 groups α to the pyridinium group.

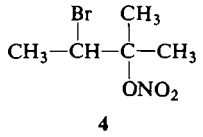
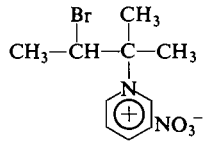
iodonium ion giving *N*-[1-(1-ethoxy-2-iodo)ethyl]pyridinium nitrate as the exclusive product.



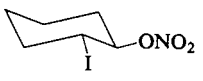
4



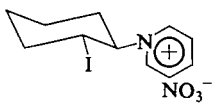
5

Reactions with Cyclic Monounsaturated Compounds

Addition of iodonium nitrate to cyclic olefins allows an examination of the stereochemistry of the reaction. Cyclohexene gave two products the first of which, the iodoalkane nitrate obtained in 50–60% yield showed in the n.m.r. the following significant absorptions, 4.17 (m, 8 lines, 1H, C*H*—I, $J_{1,2} = 10$, $J_{2,3a} = 9$, $J_{2,3e} = 5$ Hz); 5.15 (m, 8 lines, 1H, *C*HONO$_2$, $J_{1,2} = 10$, $J_{1,6a} = 9$, $J_{1,6e} = 5$ Hz) which demonstrates a *trans* stereospecific addition leading to a *trans* diequatorial conformation **6**. Closely related electrophilic additions to alkenes have been demonstrated to be *trans* stereospecific (11, 13). This conformation



6



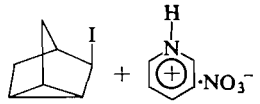
7

was insensitive to changes in solvent polarity ($CDCl_3$, CCl_4, C_6H_6, CD_3CN) (14). In this reaction the corresponding iodo pyridinium salt **7** was obtained in 40% yield. The n.m.r. spectrum showed δ [$(CD_3)_2SO$]: 4.9 (m, 2H, C*H*I and C*H*—N^+), 2.5 (m, 4H, —CH_2—CHI and CH_2—CH—N^+), and 2.1 (m, 4H, 2(CH_2)). The signals corresponding to the pyridinium ring appeared at δ 8.35, 8.8, and 9.35 as three multiplets integrating in the ratio of 2:1:2.

Similarly cyclopentene reacted with iodonium nitrate to give 2-iodo-cyclopentanol nitrate in 54% yield and *N*-(2-iodocyclopentyl)pyridinium nitrate in 43% yield.

Norbornene gave the expected iodonitrate ester **8** in approximately 60% yield. However no iodopyridinium salt was produced. Instead, the nortricyclanyl iodide **9** was formed in 40% yield together with a corresponding amount of the pyridinium nitrate (see eq. 3). Even after several distillations **8** and **9** could not be obtained analytically pure. However the n.m.r. and mass spectra were consistent with the structures proposed. Reduction of **8** by procedure A afforded norborneol consisting of 90% of the *endo* isomer and 10% of the *exo* isomer, the n.m.r. spectrum and g.l.c. retention times of which corresponded to those of authentic samples.

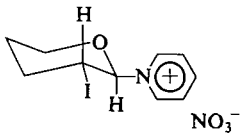
[3] 
8



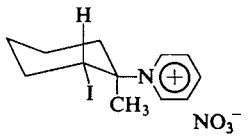
9

The n.m.r. of **9** was consistent with the structure proposed; δ ($CDCl_3$): 3.8 (s, 1H, *C*HI); 2 (m, 2H, 2—*CH*); and 1.4 (m, 6H, 2(CH_2), 2—*CH*). It compared well with the n.m.r. of authentic nortricyclanyl-bromide.

Reaction with 2,3-dihydropyran produced *trans*-equatorial *N*-(3-iodo-tetrahydropyranosyl) pyridinium nitrate (**10**), the n.m.r. spectrum of which (anomeric proton) δ in $(CD_3)_2SO$, 6.38 (d, 1H, $J_{1,2} = 10$Hz) closely resembles that of similar substances reported by Lemieux and Morgan (15). In contrast to the case of cyclohexene



10



11

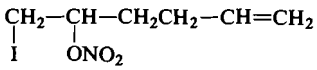
the corresponding iodonitrate ester could not be isolated, in keeping with the finding that compounds which give rise to very stable carbonium ion intermediates react preferentially to give the iodopyridinium nitrate salts. This is demonstrated by contrasting the reaction of cyclohexene (*vide supra*) with that of 1-methylcyclohexene in which the only isolable product was the *N*-[1-(1-methyl-2-iodocyclohexyl)]pyridinium nitrate (**11**) in 25% yield. The fact that the pyridinium group becomes attached to the more highly substituted carbon on an olefinic bond was established by an X-ray crystallographic study of *N*-[2-(2-methyl-3-iodobutyl)]pyridinium nitrate (**2**) formed from 2-methyl-2-butene which showed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the pyridinium ring attached to the tertiary carbon (16). A complete report on the structure determination will be published elsewhere.

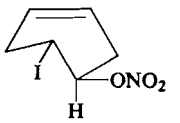
Reactions with Unconjugated Dienes

In all cases upon reaction of an unconjugated diene with 1 equiv of iodonium nitrate only one double bond reacted, giving the iodoalkene nitrate ester and/or the iodoalkene pyridinium nitrate depending on the degree of substitution in the substrate. For example 1,5-hexadiene gave a 1:1 adduct with the characteristic n.m.r. absorption for the $-CH_2I$ and $CHONO_2$ groups: 2.0 (m, 4H, 2(CH_2), 3.35 (d, 2H, CH_2I), 5.15 (m, 3H, $=CH_2$ and $CHONO_2$), and 5.6 (m, 1H, =CH). Accordingly structure **12** was assigned to

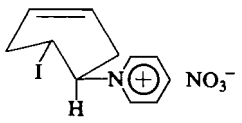


12

this product, corresponding to Markovnikov addition. 1,4-Cyclohexadiene behaved in a similar way to other unconjugated alkenes and gave 5-iodocyclohexene-4-ol nitrate **13** in 27% yield and *N*-[4-(5-iodocyclohexenyl)]pyridinium nitrate **14** in 24% yield. Reaction of 4-vinylcyclohexene

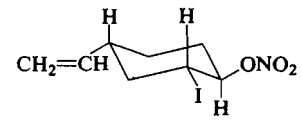


13

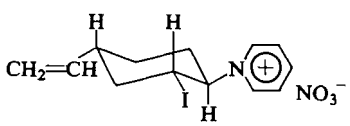


14

with iodonium nitrate allows an examination of competition in the electrophilic addition to acyclic and cyclic alkenes within the same model. The products proved to be the iodonitrate ester **15** in 25% yield and the iodopyridinium salt **16** in 27% yield corresponding exclusively to addition in the ring. The alternative structure for **15** in which addition takes place to the vinyl group may be immediately excluded because of the absence in 3.5–3.0 δ region of the n.m.r. spectrum of a signal characteristic of $-CH_2I$. The comparable alternative structure for **16** may also be excluded because in no case in additions to a monosubstituted alkene has a pyridinium compound been observed in significant amounts (see above).[4] It should be noted that the positions of the iodine and nitrate groups in **15** and the iodine and pyridinium groups in **16** on the 1–2 cyclohexane bond cannot be assigned unambiguously. The marked preference for electrophilic additions in this case to the cyclic olefinic bond may be ascribed to the greater stability of the resulting iodonium ion.

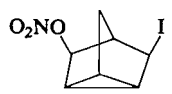


15

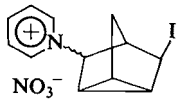


16

Reaction of norbornadiene with iodonium nitrate produced two products corresponding to cross-ring interaction, *i.e.* tricyclo [2.2.1.$0^{2,6}$]-3-iodoheptan-5-ol nitrate **17** (in 64% yield after distillation) and the corresponding iodopyridinium salt **18**, *N*-[3-(5-iodonortricyclanyl)]pyridinium

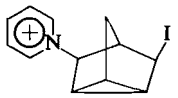


17

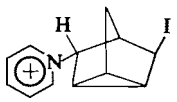


18

nitrate in 10% yield. The n.m.r. spectrum of **17** showed no olefinic protons and was consistent with a tricyclane structure. The structure of **17** was confirmed by reduction with zinc–copper couple in acetic acid at room temperature followed by reduction with zinc dust in acetic acid to nortricyclanol as verified by comparison with an authentic sample (17). It may be noted that reduction could not be effected using procedure A in this particular example. Examination of the n.m.r. spectrum of **18** showed it to consist of a mixture of two isomers **18***a* and *b*, the former



18*a*



18*b*

having the same configuration as that of the major product **17**. The above reaction resembles the addition of iodine isocyanate to 5-methylenenorbornene reported by Hassner and coworkers (18) and also resembles products obtained by Grimwood and Swern (19).

[4]In the case of 3,4-dimethylhex-1-ene and 3,3-dimethylbut-1-ene a very small amount of pyridinium salts was observed and isolated. This will be discussed in a subsequent publication.

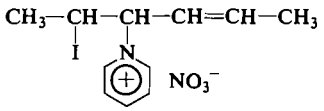
For personal use only.

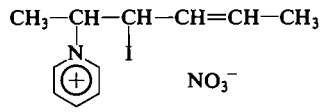
Reactions with Conjugated Dienes

In all the examples studied of addition to conjugated dienes only the iodopyridinium salts were obtained and they corresponded exclusively to 1,2-addition of one equivalent of iodonium nitrate. In these cases the carbonium ion involved is allylic and the sole formation of the pyridinium salt is consistent with the observation that this is the major type of product obtained when a stable carbonium ion is involved as observed in the case of monoolefins discussed above.

2,4-Hexadiene produced a 70% yield of *N*-[4-(5-iodo-2-hexenyl)]pyridinium nitrate (**19**). The



19

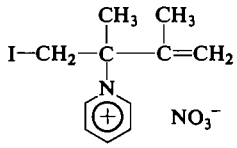


20

possibility of a 1,4-addition was discounted since the n.m.r. spectrum showed two well-separated doublets at δ 2.0 and 1.75 with $J = 7$ and 5 Hz respectively, corresponding to two methyl groups in quite different environments, whereas other model compounds show that methyl groups alpha to an iodo group have similar chemical shifts to methyl groups alpha to a pyridinium group.

The n.m.r. spectrum is consistent with either the Markovnikov structure **19** or the anti-Markovnikov structure **20**. However structure **19** is preferred from mechanistic considerations since the pyridine would be expected to attack the more stable allylic cationic center.

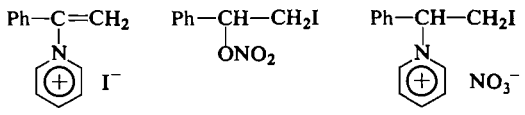
2,3-Dimethyl-1,3-butadiene afforded *N*-[3-(4-iodo-2,3-dimethyl)butenyl]pyridinium nitrate **21** in 62% yield. The n.m.r. spectrum of the product



21

was again consistent with a 1,2-addition because it showed an AB quartet characteristic of the terminal vinylic protons centered at 5.28 and 5.41 δ. The former is assigned to the proton *cisoid* to the methyl group because of further long range coupling to the methyl group (20).

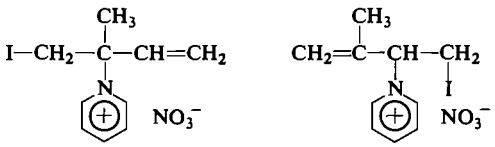
Styrene falls naturally in this group and gave two products, *N*-[1-(1-phenylethenyl)]-pyridinium iodide (**22**) as the major product in 75–80% yield together with 10% of the iodonitrate ester **23**. Compound **23** could not be isolated analytically



22 **23** **24**

pure, because it suffers extensive decomposition when distilled. However n.m.r. and mass spectrometry evidence was consistent with the assigned structure. Treatment of **23** with an excess of pyridine at room temperature afforded **22** in good yield, presumably by way of pyridine-catalyzed elimination of hydrogen iodide from the intermediate **24**. This suggests but does not prove that the pyridinium salts like **22** described in this study are formed by nucleophilic displacement of the nitrate ion by pyridine from the corresponding initially formed iodo-nitrate esters.

Isoprene also gave an iodopyridinium salt **25** as the only isolable product in 30% yield. In this particular reaction a considerable amount of tars were produced and the salt obtained was difficult to crystallize.



25*a* **25*b***

The n.m.r. spectrum, Fig. 2, showed an ABB′ system for the vinylic protons clearly demonstrating the marked preference for 1,2-addition. The n.m.r. spectrum similarly confirms **25*a*** and eliminates **25*b*** for this sample. In only one instance was this pure isomer obtained. Further runs produced a mixture of **25*a*** and *b* in the ratio of 70:30. The n.m.r. spectrum of **25*b*** was similar to that of **25*a*** except for an ICH_2 absorption at δ 4.42 and a CH_3 absorption at δ 2.07.

Similarly 1,3-cyclohexadiene gave the pyridinium salt **26** in 60% yield. The reasons for the marked preference for 1,2-additions in the case of conjugated dienes are not clear at this time.

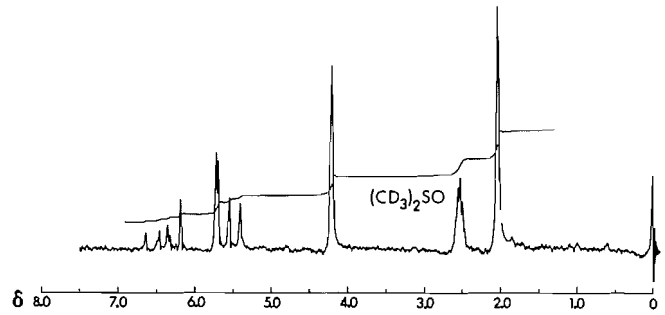


FIG. 2. The n.m.r. spectrum of **25***a* in $(CD_3)_2SO$ (60 MHz).

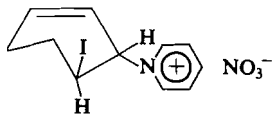
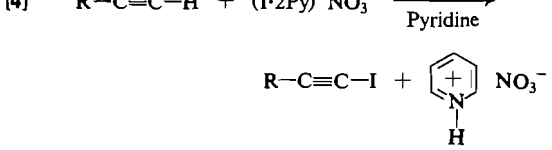


26

Reactions with Acetylenic Compounds

As expected, non-terminal acetylenes were unreactive towards electrophilic addition of iodonium nitrate. However terminal acetylenes reacted readily to give alkynyl iodides according to eq. 4.



[4] $R-C\equiv C-H + (I\cdot 2Py)^+NO_3^- \xrightarrow[\text{Pyridine}]{CHCl_3} R-C\equiv C-I +$ pyridinium NO_3^-

Pyridinium nitrate was obtained in stoichiometric quantity indicating complete replacement of the acidic proton of the acetylene. Some tar formation took place with a consequent decrease in yield of product. The structures of the iodoacetylenes were fully consistent with the analytical and spectral data. The chemistry of this class of compounds has recently been reviewed (21). The terminal iodo compounds produced in this way are summarized in Table 1.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The i.r. spectra were recorded on a Perkin–Elmer model 221 spectrophotometer. The n.m.r spectra were recorded on Varian A-60 and A-100 analytical spectrometers. The spectra were measured on approximately 10–15% (w/v) solutions in $CDCl_3$ or $(CD_3)_2SO$ with tetramethylsilane as a standard. Line positions are reported in p.p.m. from the reference. Mass spectra were obtained with a Perkin–Elmer model 270 gas chromatograph–mass spectrometer. The ionization energy, in general, was 70 eV.

The g.l.c. analyses were performed with an F and M model 700 gas chromatograph; various columns packed with polar and non-polar liquid phases were used to check the chromatograms obtained.

General Procedure for the Reaction of Iodonium Nitrate with Unsaturated Hydrocarbons

Silver nitrate, 6.8 g, (0.04 mol) was dissolved in a mixture of 30 ml of chloroform and 15 ml of reagent grade pyridine. Iodine monochloride, 6.5 g (0.04 mol), in 15 ml of chloroform, was added dropwise to the stirred solution. The silver chloride produced was filtered off and washed with 10 ml of pyridine, and 0.04 mol of the olefin added at once to the yellow filtrate. The mixture was stirred at room temperature for 3 h. Then ether was added to the solution, the oily precipitate (if any), collected, and the ethereal solution evaporated in a rotary evaporator. The oil obtained after evaporation was distilled, the product obtained being the iodo-nitrate ester.

The precipitate which was insoluble in ether was washed several times with ether, whereupon it became a solid. The following procedure (B) was found satisfactory

TABLE 1. Iodoacetylene compounds

	Alkynyl iodide

for these compounds. This solid was dissolved in a beaker in a small amount of a 50:50 mixture of ethanol – isopropyl alcohol. Ether was added until the solution became slightly cloudy. This beaker was then placed inside a bigger one, containing a small amount of ether. This bigger beaker was covered with Saran wrap, sealed with an elastic band wrapped around, and finally put in the refrigerator. The crystals obtained, (iodo pyridinium salt) were filtered off, washed with ether, and dried. In a few instances, when the iodo pyridinium salt was difficult to purify and very dark in color (contamination with iodine and tarry materials), the purification was carried out by chromatography on silica gel, eluting with $CHCl_3$, 5% CH_3OH in $CHCl_3$ (v/v), 10% CH_3OH in $CHCl_3$ (v/v), and 30% CH_3OH in $CHCl_3$ (v/v), the iodo pyridinium salt being collected with the last mixture of solvents.

The analytical and spectral data for the iodoaliphatic nitrate esters, and iodoalkane pyridinium nitrate salts thus obtained are summarized in Tables 2–5.

Formation of the Iodo Alkynes

The procedure was similar to that explained above. Addition of ether to the reaction mixture resulted in the precipitation of an equivalent amount of pyridinium nitrate that was filtered off. The remaining liquid was evaporated in the rotary evaporator and the residual oil distilled.

General Procedure for the Electrolytic Reduction of the Iodo-nitrate Esters

The iodo-nitrate ester (0.02 mol) was dissolved in 75 ml of acetate buffer, p*H* 4.7, and 175 ml of isopropyl alcohol. This solution was electrolyzed at −0.9 V *vs.* saturated calomel electrode over a period of 16 h, after which time there was no more material reducible at −0.9 V.

Then the solution was poured into water, extracted with ether, the ether extract washed with dilute sodium bicarbonate solution, dried ($MgSO_4$), and evaporated. The residual oil was distilled and the collected iodohydrin, without further purification, reduced with lithium aluminum hydride.

General Procedure for the Zinc–Copper Couple Reductions

The iodo-nitrate ester (6 mmol) was added dropwise to a stirred mixture of 1.5 g of zinc–copper couple (Alfa Inorganics) in 25 ml of acetic acid at room temperature,[5] and left stirring overnight. Then, the solid was filtered off, the liquid poured into a mixture of ether–water and solid sodium bicarbonate added in portions until the solution was completely neutralized. The ether layer was removed, the aqueous layer extracted with more ether, the two ethereal portions combined, then dried ($MgSO_4$) and evaporated. The resulting liquid (about 90% pure by g.l.c.) showed no covalent nitrate absorption in the i.r. spectrum but the presence of the OH group. Without further purification it was then reduced with excess lithium aluminum hydride and the resulting alcohols identified by comparison of their retention times and i.r. and n.m.r. spectra with those of authentic samples.

Reduction of the Tricyclo [2.2.1.$0^{2,6}$]-3-iodopentan-5-ol with Zinc Dust in Acetic Acid – Ether

The iodo alcohol (1.7 g) was dissolved in 10 ml of ether and 10 ml of acetic acid. Zinc dust (1 g) was added and the reaction mixture refluxed overnight, allowed to cool, filtered, and poured into a mixture of ether–water. Solid sodium bicarbonate was added in portions until the solution was completely neutralized. The ether layer was washed with water saturated with sodium chloride, dried, and evaporated. The residual oil (0.84 g) proved it to be a mixture of 90% of nortricyclanol and 10% nortricyclyl acetate by g.l.c. (17). This mixture was then dissolved in methanol containing a small amount of sodium methoxide, refluxed for 5 h, and the solvent evaporated. The residue was taken up with petroleum ether (b.p. 40–60°), the petroleum ether washed with water, dried ($MgSO_4$), and evaporated. Pure nortricyclanol (0.4 g, 50% yield) was obtained, identical with an authentic sample.

Preparation of the N-[2-(2-Methyl-3-bromo)butyl)]-pyridinium Nitrate ***5*** *and the Corresponding Bromo-nitrate Ester* ***4***

The procedure and molar quantities was similar to that used for the preparation of the iodo pyridinium salts, except that bromine was used instead of iodine chloride. After the addition of ether to the reaction mixture, no oily precipitate was observed. The organic liquid was then concentrated in a rotary evaporator and 7 g of a brown oil was obtained that separated into two layers. These two phases were separated, and the upper layer (5.3 g) was placed in the refrigerator for 3 days. A few crystals formed, which were filtered off and the residual liquid distilled. Three grams of product **4** were obtained (35% yield), b.p. 30 °C at 0.3 mm.

Anal. Calcd. for $C_5H_{10}NO_3Br$: C, 28.32; H, 4.75; N, 6.60. Found: C, 28.43; H, 4.93; N, 6.47.

The n.m.r. of **8** showed δ ($CDCl_3$): 4.7 (q, 1H, *CH*—Br, J = 7 Hz); 1.65—1.77 (s, d, 9H, $3CH_3$).

The second layer produced 120 mg of crystals upon cooling that were combined with the first crop. Recrystallization was performed according to procedure B and 100 mg of **5** were obtained.

Anal. Calcd. for $C_{10}H_{15}N_2O_3Br$: C, 41.25; H, 5.19; N, 9.62. Found: C, 40.83; H, 5.27; N, 9.20.

*Purification of N-[1-(1-Phenylethenyl)]pyridinium Iodide (****22****)*

The crude crystalline product was dark and contaminated with considerable amounts of pyridinium nitrate which were difficult to remove by the recrystallization procedure described above. Therefore 1 g of the crude material was dissolved in H_2O (10 ml) and 0.5 g of solid potassium carbonate added. The aqueous solution was extracted with ether, the ether discarded, and the solution acidified to p*H* = 7 with dilute nitric acid. The aqueous layer was evaporated to dryness *in vacuo* and the residual solid taken up in ethanol. The ethanol solution was concentrated *in vacuo* and 0.42 g of pure **22** obtained, m.p. 155–158°.

Anal. Calcd. for $C_{13}H_{12}NI$: C, 50.50; H, 3.91; N, 4.53. Found: C, 50.10; H, 3.71; N, 4.31.

[5]If the preparation is done on a larger scale, it is advisable to cool the reaction mixture in an ice bath.

Theory of Ionic Conduction in Solids Based on the Homogeneous Generation of Defect Pairs and Its Application to Anodic Oxidation

M. J. DIGNAM AND D. F. TAYLOR
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received August 19, 1970

The theory for ionic conduction in solids based upon the homogeneous, field-assisted generation of defect pairs is developed in a general, three dimensional form, and its range of applicability is examined. At high field strengths the equations reduce to those of the so-called high field Frenkel defect theory, proposed originally by Bean, Fisher, and Vermilyea. At low field strengths, the steady-state expression reduces to the well-known conduction equation derived originally by Mott for ionic conduction in the alkali halides. At intermediate field strengths, more complicated relationships obtain. The homogeneous generation of defect pairs, whether field or current assisted, is shown to be inapplicable as a mechanism for the high field anodic oxidation of the valve metals, since either type of theory predicts unacceptable behavior for the mean free path of the mobile defects. Any such conduction mechanism can be acceptable only for the case of thick films ($\gg 10^4$ Å).

Canadian Journal of Chemistry, 49, 416 (1971)

Introduction

In 1956, Bean, Fisher, and Vermilyea (1) proposed a theory to account for the complex kinetics of formation of anodic oxide films on the valve metals (principally Ta, Al, Nb). The theory was subsequently clarified in certain details, first by Dewald (2) in 1957, and then by Young (3) in 1959. It was Young who named it the high field Frenkel defect theory. The essential features of this theory are summarized in the following paragraph.

The applied electric field is assumed to act on lattice cations in the oxide film reducing the activation energy for the formation of Frenkel defects (interstitial cations and cation vacancies). The interstitial cations so generated are assumed to move in the direction of the applied field, which acts to reduce the activation energy for the transport motion as well as that for defect formation. The vacancies, assumed immobile, function as traps for the mobile interstitials, and are assigned a characteristic capture cross-section for this recombination process. Under conditions of constant field strength and temperature, a steady-state concentration of defect pairs is ultimately established in which the rate of field-assisted generation of defect pairs is equal to the rate of their recombination. Under these steady-state conditions, the ion current density is a function of the field strength alone for a given temperature. On changing the current density or field strength suddenly, however, the concentration of defect pairs adjusts slowly, and the approach toward a new steady-state condition produces field or ion-current transients.

This theory has been shown to account for the functional form of many of the data pertaining to the anodic oxidation of the valve metals. However, it fails to account for both the form of the observed constant field transients and the transport number data (4, 5).

The purpose of this paper is twofold: first, to derive from the basic model proposed by Bean *et al.* more general ionic conduction equations, and second, to show that this model cannot be applied to valve metal anodic oxidation.

Field Assisted Generation of Defect Pairs

In order to simplify the problem somewhat, it is assumed at the outset that the positions occupied by the lattice cations (from which the Frenkel defects are generated) represent centers of symmetry in the solid, at least with respect to the potential energy surface for displacement of these lattice cations. From elementary rate theory, the probability that a given lattice cation will enter an interstitial position along a path within the infinitesimal solid angle $\sin\theta d\theta d\phi$, where θ is the polar angle and ϕ the longitudinal angle (normal spherical polar coordinates) is given by $\nu_{\theta,\phi} \exp[-U_{\theta,\phi}(E_{\theta,\phi})/kT] \sin\theta d\theta d\phi$ where $E_{\theta,\phi}$ is the component of the electric field in the (θ,ϕ) direction, $U_{\theta,\phi}(E_{\theta,\phi})$ is the net activation energy in this direction, and $\nu_{\theta,\phi}$ is the corresponding frequency factor. The direct functional dependence of $U_{\theta,\phi}$ on (θ,ϕ) and the functional form of $\nu_{\theta,\phi}$ will reflect the structural symmetry. Thus in this case, where the origin is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

assumed to be a center of symmetry,

$$\nu_{\theta,\phi} = \nu_{\pi-\theta,\phi+\pi}$$

and

$$U_{\theta,\phi}(E_{\theta,\phi}) = U_{\pi-\theta,\phi+\pi}(-E_{\pi-\theta,\phi+\pi})$$

Taking $\theta = 0$ as the direction of the applied field, the total probability of lattice dissociation in any direction, P_+, is given by

$$[1]\quad P_+ = \int_{-1}^{1}\int_{0}^{2\pi} \nu_{x,\phi} \exp\left[-U_{x,\phi}(Ex)/kT\right] d\phi\, dx$$

where E is the electric field strength and $x \equiv \cos\theta$. This integral can be expressed as the sum of two integrals for $-1 \leqslant x \leqslant 0$ and $0 \leqslant x \leqslant 1$. If the limits of integration on the first of these two terms are changed to (0, 1) by substituting $-x$ for x, on applying the symmetry conditions in the form

$$\nu_{-x,\phi} = \nu_{x,\phi+\pi}$$

and

$$U_{-x,\phi}(-Ex) = U_{x,\phi+\pi}(-Ex)$$

one obtains

$$[2]\quad P_+ = \int_{0}^{1}\int_{0}^{2\pi} \nu_{x,\phi} \exp\left[-U_{x,\phi}(Ex)/kT\right] d\phi\, dx + \int_{0}^{1}\int_{0}^{2\pi} \nu_{x,\phi+\pi} \exp\left[-U_{x,\phi+\pi}(-Ex)/kT\right] \times d\phi\, dx$$

Since $\nu_{x,\phi}$ and $U_{x,\phi}$ (Ex) must be periodic functions of ϕ of period 2π or a sub-multiple of 2π, the integrals in eq. 2 differ only in the sign of the parameter E. Making the substitution

$$[3]\quad \nu_1 \exp\left[-W_1(E)/kT\right] = \int_{0}^{1}\int_{0}^{2\pi} \nu_{x,\phi} \exp\left[-U_{x,\phi}(Ex)/kT\right] d\phi\, dx$$

where ν_1 is the weighted mean value of $\nu_{x,\phi}$, the weighting factor being $\exp\left[-U_{x,\phi}(Ex)/kT\right]$, and $\exp\left[-W_1(E)/kT\right]$ is the mean value of $\exp\left[-U_{x,\phi}(Ex)/kT\right]$, eq. 2 becomes

$$[4]\quad P_+ = \nu_1\left[\exp\left[-W_1(E)/kT\right] + \exp\left[-W_1(-E)/kT\right]\right]$$

As $U_{x,\phi}(Ex)$ will in general be a polynomial function of Ex (6), and most likely also somewhat temperature dependent, no significant increase in function complexity is introduced through the averaging process of eq. 3. In fact, one would expect that for any given E, $U_{x,\phi}(Ex)$ would display one or more pronounced minima on variation of (x,ϕ), the number depending on the rotational symmetry order of the structure about the $x = 1$ ($\theta = 0$) axis (specified by the direction of the field). In this case, W_1 would reflect very closely the function $U_{x,\phi}$ at the minima. Setting W_1 equal to $U_{x,\phi}$ at the minimum or saddle point, and ν_1 equal to $\nu_{x,\phi}$ at the same point, corresponds to the usual approximation made in treating thermally activated kinetic processes.

The rate of formation of defect pairs per unit volume, dn_+/dt, can now be written in the form

$$[5]\quad dn_+/dt = (N-n)\nu_1\left\{\exp\left[-W_1(E)/kT\right] + \exp\left[-W_1(-E)/kT\right\}\right.$$

where N is the number of cation lattice positions per unit volume and n the number of cation vacancies.

Ion Flux and Defect Recombination

Proceeding in a manner exactly analogous to that of the section above, the flux density of ions in a direction within the solid angle $\sin\theta d\theta d\phi$ is given by

$$[6]\quad d^2J_{\theta,\phi} = ma_{\theta,\phi}\nu_{\theta,\phi}{}^1 \exp\left[-U_{\theta,\phi}{}^1(E\cos\theta)/kT\right] \sin\theta d\theta d\phi$$

where m is the number of interstitial cations per unit volume, and $a_{\theta,\phi}$ is the mean distance travelled in the (θ,ϕ) direction per activation. Assuming as before that the interstitial positions are centers of symmetry, the net flux in the direction of the field, J, is given by

$$[7]\quad J = m\int_{0}^{1}\int_{0}^{2\pi} xa_{x,\phi}\nu_{x,\phi}{}^1\{\exp\left[-U_{x,\phi}{}^1(Ex)/kT\right] - \exp\left[-U_{x,\phi}{}^1(-Ex)/kT\right]\} d\phi\, dx$$

Upon making the substitution

$$[8]\quad \nu_2 \exp\left[-W_2(E)/kT\right] = \int_{0}^{1}\int_{0}^{2\pi} xa_{x,\phi}\nu_{x,\phi}{}^1 \exp\left[-U_{x,\phi}{}^1(Ex)/kT\right] d\phi\, dx$$

eq. 7 becomes

$$[9] \qquad J = ma\nu_2\{\exp[-W_2(E)/kT] - \exp[-W_2(-E)/kT]\}$$

where $a\nu_2$ is the weighted mean value of $a_{x,\phi}\nu_{x,\phi}{}^1$, the weighting factor being $x \exp[-U_{x,\phi}{}^1(Ex)/kT]$, and $\exp[-W_2(E)/kT]$ is the mean value of $x \exp[-U_{x,\phi}{}^1(Ex)/kT]$.

Defining $\sigma_{x,\phi}(E)$ as the capture cross-section of a cation vacancy for an interstitial moving in the (x,ϕ) direction, the rate of recombination of defect pairs per unit volume within the solid angle $\sin\theta d\theta d\phi$ is given by $n\sigma_{x,\phi}(E)d^2J_{x,\phi}$ provided the vacancies are immobile. On substituting from eq. 6, integrating over all values of (x,ϕ), and applying the symmetry condition, the total rate of recombination of defect pairs per unit volume is obtained as

$$[10] \quad (dn_-/dt) = mn\int_0^1\int_0^{2\pi}\sigma_{x,\phi}(E)a_{x,\phi}\nu_{x,\phi}{}^1\{\exp[-U_{x,\phi}{}^1(Ex)/kT] + \exp[-U_{x,\phi}{}^1(-Ex)/kT]\}\,d\phi\,dx$$

Defining σ through eq. 11

$$[11] \qquad \sigma a\nu_2 \exp[-W_2(E)/kT] = \int_0^1\int_0^{2\pi}\sigma_{x,\phi}(E)a_{x,\phi}\nu_{x,\phi}{}^1 \exp[-U_{x,\phi}{}^1(Ex)/kT]\,d\phi\,dx$$

eq. 10 becomes

$$[12] \qquad dn_-/dt = mn\sigma a\nu_2\{\exp[-W_2(E)/kT] + \exp[-W_2(-E)/kT]\}$$

By solving for σ from eqs. 11 and 8, it can be seen that this parameter is the weighted mean value of $\sigma_{x,\phi}(E)/|x|$, the weighting function being $|x|a_{x,\phi}\nu_{x,\phi}{}^1 \exp[-U_{x,\phi}{}^1(E|x|)/kT]$. For values of E which are not too small, the weighting function will be a maximum for $|x|$ close to one, and fall off rapidly with decreasing $|x|$. Under these conditions, σ will be very nearly the capture cross-section for motion in the field direction. As a direct result of the coulombic attraction between the defect pairs, $\sigma_{x,\phi}(E)$ would be expected to depend somewhat on both field strength and temperature. Even in the absence of such dependence, however, σ should show a field and temperature dependence introduced through the averaging procedure. This effect should be small compared to the temperature and field variation inherent in $\sigma_{x,\phi}(E)$.

Steady-State Ionic Conduction

For specimens sufficiently thick that space charge effects may be neglected (7), under steady-state conditions $n = m$ and $dn_+/dt = dn_-/dt$ so that from eqs. 5 and 12

$$[13] \qquad n^2 = \frac{(N-n)\nu_1}{\sigma\nu_2 a}\,\frac{e^{-W_1(E)/kT} + e^{-W_1(-E)/kT}}{e^{-W_2(E)/kT} + e^{-W_2(-E)/kT}}$$

$W_j(E), j = 1$ or 2, may be represented by the following expression (6)

$$[14] \qquad W_j(E) = \phi_j\left[1 - \frac{\mu_j{}^*E}{\phi_j} + \frac{1}{C_j}\left(\frac{\mu_j{}^*E}{\phi_j}\right)^2 + \cdots\right]$$

where ϕ_j is the zero field activation energy, $\mu_j{}^*$ the activation dipole in the limit of low field strength, and C_j a dimensionless constant.

(I) Very High Field Strengths

For $(\mu_j{}^*E/kT) \gg 1, j = 1, 2$, eq. 13 reduces to

$$[15] \qquad n^2 = \frac{(N-n)\nu_1}{\sigma\nu_2 a}\,e^{-[(W_1(E)-W_2(E))/kT]}$$

and from eq. 9

$$[16] \qquad i = nqa\nu_2\,e^{-W_2(E)/kT}$$

where i is the ion current density and q the charge on the mobile ion. Elimination of n from eqs. 15 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

16 leads to the following steady-state equation for high field ionic conduction, provided $N \gg n$

$$[17] \qquad i = q\left(\frac{N\nu_1\nu_2 a}{\sigma}\right)^{\frac{1}{2}} e^{-[W_1(E)+W_2(E)]/2kT}$$

If terms of order 3 or higher in the field strength are ignored, eq. 17 may be written as

$$[18] \qquad i = q\left(\frac{N\nu_1\nu_2 a}{\sigma}\right)^{\frac{1}{2}} e^{-\phi/kT} e^{[(\mu^*E/kT)(1-\mu^*E/C\phi)]}$$

where $\mu^* = (\mu_1^* + \mu_2^*)/2$, $\phi = (\phi_1 + \phi_2)/2$ and

$$\frac{1}{C} = \frac{1}{2C_1}\frac{(\mu_1^*/\mu^*)^2}{(\phi_1/\phi)} + \frac{1}{2C_2}\frac{(\mu_2^*/\mu^*)^2}{(\phi_2/\phi)}$$

Equation 18 is essentially the same as that proposed by Bean *et al.* (1), except for the inclusion of the quadratic field term.

(II) Intermediate Field Strengths

For $\phi_j \gg \mu_j^* E \gtrsim kT, j = 1, 2$, the quadratic field term is negligible and eqs. 13 and 14 reduce to

$$[19] \qquad n^2 = \frac{(N-n)\nu_1}{\sigma\nu_2 a} e^{-(\phi_1-\phi_2)/kT}\frac{\cosh(\mu_1^* E/kT)}{\cosh(\mu_2^* E/kT)}$$

and eqs. 9 and 14 can be combined to give

$$[20] \qquad i = 2nqa\nu_2 \sinh(\mu_2^* E/kT) e^{-\phi_2/kT}$$

so that when n is eliminated (assuming $N \gg n$)

$$[21] \qquad i = 2q\left(\frac{N\nu_1\nu_2 a}{\sigma}\right)^{\frac{1}{2}} e^{-(\phi_1+\phi_2)/2kT} \sinh\left(\frac{\mu_2^* E}{kT}\right)\left[\frac{\cosh(\mu_1^* E/kT)}{\cosh(\mu_2^* E/kT)}\right]^{\frac{1}{2}}$$

(III) Low Field Strengths

For $\mu_j^* E/kT \ll 1$, eqs. 19 and 21 reduce to

$$[22] \qquad n^2 = \frac{(N-n)\nu_1}{\sigma\nu_2 a} e^{-(\phi_1-\phi_2)/kT}$$

$$[23] \qquad i = 2nqa\left(\frac{\mu_2^* E}{kT}\right) e^{-\phi_2/kT}$$

hence

$$[24] \qquad i = 2q\left(\frac{N\nu_1\nu_2 a}{\sigma}\right)^{\frac{1}{2}}\frac{\mu_2^* E}{kT} e^{-(\phi_1+\phi_2)/2kT}$$

It is interesting to note that for low field strengths, n is independent of field strength, hence the defects must be generated by thermal activation alone. Thus at low field strength, n will be equal to the equilibrium value, and

$$[25] \qquad K_d = \frac{n^2}{N(N-n)} = \frac{\nu_1}{\sigma\nu_2 aN} e^{-(\phi_1-\phi_2)/kT}$$

where K_d is the equilibrium constant for the formation of defect pairs. Since

$$[26] \qquad \left[\frac{\partial(k \ln K_d)}{\partial(1/T)}\right]_V = -\Delta U_d^0$$

where ΔU_d^0 is the standard internal energy of formation of a defect pair, and since $\sigma, \nu_1, \nu_2, a, \phi_1$, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ϕ_2 may be considered essentially temperature independent under conditions of constant volume,

[27] $$\phi_1 - \phi_2 = \Delta U_d^0$$

Noting that $kT \ln K_d = -\Delta A_d^0 = -\Delta U_d^0 + T\Delta S_d^0$ and that $\mu_2^* = qa/2$ (6, 8), a combination of eqs. 24, 25, and 27 leads to

[28] $$i = (\nu_2 N q^2 a^2/kT) E \exp[\Delta S_d^\circ/2k] \exp\{-[(\Delta V_d^\circ/2) + \phi_2]\}$$

This expression is the same as that obtained by Mott and Gurney (9) for low field ionic conduction in the alkali halides, except that in that case, N is the concentration of ion pairs in the crystal and ΔS_d^0 and ΔU_d^0 refer to the formation of Schottky defects at constant volume.

Turning briefly once again to ionic conduction under conditions of very high field strengths, it should be emphasized that the equations which have been derived in the previous sections are equivalent to those of Bean, Fisher, and Vermilyea (1) not only for the steady-state, but for transient situations as well. Upon making the assumption that the film is electrically neutral ($m = n$), the ion-current density is given by eq. 9 as

[29] $$i = qna\nu_2 \, e^{-W_2(E)/kT}$$

and an expression for the net rate of formation of defect pairs per unit volume can be obtained from eqs. 5, 9, and 12

[30] $$\frac{dn}{dt} = (N - n)\nu_1 \, e^{-W_1(E)/kT} - \frac{n\sigma i}{q}$$

Except for the inclusion of a quadratic field term in $W_j(E)$, $j = 1, 2$, eqs. 29 and 30 are identical to those given by Dewald (2) to describe the transient behavior of anodic oxide films on valve metals.

Mean Free Path of Mobile Defects

For any conduction model in which the mobile defects are generated within the transport medium, motion in the direction of the field can be characterized by a mean free path, λ. The net flux of defects is simply the product of their rate of formation and the mean distance travelled by each defect in the field direction before annihilation. Hence λ is related to J and (dn_+/dt) through the equation

[31] $$J = \lambda (dn_+/dt)$$

For high field conditions in which ionic motion against the field direction can be ignored, the rate of defect annihilation is simply given by

[32] $$(dn_-/dt) = n\sigma J$$

where n is the volume concentration of trapping sites and σ their capture cross-sectional area. Combining eqs. 31 and 32 gives

[33] $$\lambda = \frac{1}{n\sigma}\left(\frac{dn_-}{dt} \Big/ \frac{dn_+}{dt}\right)$$

which for the conditions $(dn_+/dt = dn_-/dt)$ reduces to the familiar relation for the steady-state mean free path

[34] $$\lambda_s = 1/n\sigma$$

Equations 31 to 34 are valid, independent of the particular mechanism of formation of the mobile defects so long as they are generated homogeneously throughout the transport medium. Equations 9 and 12 yield eq. 32 in the high field limit, and elimination of λ from eqs. 31 and 34 combined with eqs. 5 and 15 gives eq. 17, as expected.

(I) Steady-State Conditions

For the particular case of high field generation of defect pairs, eqs. 15 and 34 combine to give

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[35] $$\lambda_s = \left(\frac{\nu_2 a}{N\nu_1\sigma}\right)^{\frac{1}{2}} e^{[W_1(E)-W_2(E)]/2kT}$$

Recalling that $\phi = (\phi_1 + \phi_2)/2$, λ_s can be expressed as

[36] $$\lambda_s = \left(\frac{\nu_2 a}{N\nu_1\sigma}\right)^{\frac{1}{2}} e^{-[(\mu_1^{*2}/C_1\phi_1)-(\mu_2^{*2}/C_2\phi_2)]E^2/2kT} e^{(\phi-\phi_2)/kT} e^{-(\beta_s-\beta_2)E}$$

where $W_1(E)$ and $W_2(E)$ have been expanded according to eq. 14, and

[37] $$\beta_2 = -\frac{1}{kT}\left(\frac{\partial W_2(E)}{\partial E}\right)_T$$

$$\beta_s = -\frac{1}{2kT}\left[\frac{\partial[W_1(E) + W_2(E)]}{\partial E}\right]_T$$

The coefficient of E^2 in eq. 36 is small, and E is a very slowly changing function of i. This exponential factor is therefore essentially constant over a wide range of current densities and will subsequently be represented by the symbol A.

In the same way eq. 17 becomes

[38] $$i = i_0 e^{-\phi/kT} e^{\beta_s E}$$

where i_0 is again essentially constant and is given by

[39] $$i_0 = q\left[\frac{N\nu_1\nu_2 a}{\sigma}\right]^{\frac{1}{2}} e^{[(\mu_1^{*2}/C_1\phi_1)+(\mu_2^{*2}/C_2\phi_2)]E^2/2kT}$$

Thus a steady-state expression for the mean free path which does not depend explicitly on E can be obtained from eqs. 36 and 38

[40] $$\lambda_s = \left(\frac{\nu_2 a}{N\nu_1\sigma}\right)^{\frac{1}{2}} A\left[\exp\left[\frac{\phi(\beta_2/\beta_s) - \phi_2}{kT}\right]\right]\left[\frac{i_0}{i}\right]^{(\beta_s-\beta_2)/\beta_s}$$

From a consideration of the physical system, λ_s cannot be smaller than one jump distance, nor as large as one-half the film thickness; *i.e.*

[41] $$X/2 > \lambda_s \gtrsim 3 \text{ Å}$$

Since an equation of the form of [17] fits steady-state data for anodic film formation on tantalum, a typical valve metal, for films at least as thin as a few hundred Å, and over a substantial range of temperature and field strength (10), it is clear that the following conditions must hold

[42] $$(\beta_s - \beta_2)/\beta_s \ll 1$$

$$[\phi(\beta_2/\beta_s) - \phi_2]/kT \ll 1$$

otherwise λ_s would be a rapidly varying function of current density and temperature, and this is precluded by condition 41. For example, if the high field Frenkel defect theory (or essentially this theory involving other defect pairs) were correct then β_s and β_2 would correspond to the steady-state and transient differential field coefficients defined in [43]

[43] $$\beta_s = \frac{\partial \ln i}{\partial E}\left(\text{limit } \frac{dE}{dt} \to 0\right)$$

$$\beta_2 = \frac{\partial \ln i}{\partial E}\left(\text{limit } \frac{dE}{dt} \text{ large}\right)$$

For the anodic oxidation of tantalum, β_s/β_2 is approximately equal to 3 (6) so that from eq. 40 λ_s is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

proportional to the current density to the power $-2/3$. Young's data for tantalum (10) shows adherence to the conduction equation for a film 600 Å in thickness over a three decade range in current density. This corresponds to a two decade range in the steady-state mean free path, and from [41] such a range in λ_s for $X = 600$ Å is only just possible. However, for the equations derived on the basis of homogeneous generation of defect pairs to be a good approximation, the steady-state mean free path must in fact be substantially less than $X/2$, otherwise it will not be controlled entirely by kinetic phenomena within the film, but will be greatly influenced by the film thickness. Accordingly, for a film 600 Å thick, λ_s must be between about 3 and 30 Å for the high field homogeneous generation theory to be valid. To account for the data, however, λ_s must vary by a factor of 10^2, so that on this basis alone the high field Frenkel defect theory (or a modified form of it involving other defect pairs) may be ruled out as a possible mechanism.

Young has proposed a model for high field ionic conduction in valve metals in which the mobile defects are generated by an avalanche mechanism, homogeneously, and at a rate proportional to J^2 (11). This gives, with condition 41, the result $\lambda \propto 1/J$ for both steady-state and transient conditions, which requires that λ_s vary by a factor of 10^3 for a film 600 Å thick, a totally impossible condition. Indeed it is highly improbable that any conduction mechanism based on homogeneous generation of defects, and involving a defect concentration dependent on E and/or J, will satisfy condition 41 within the accessible range of experimental conditions for films even as thick as 10^4 Å.

Further evidence against the applicability of this class of mechanism to the valve – metal oxide system can be found in the series of galvanostatic transient measurements carried out by Tvarusko on very thin (10–100 Å) films of tantalum oxide (12). Chemically polished tantalum wires were anodized galvanostatically in a 1% H_3PO_4 aqueous electrolyte at current densities of 0.4 and 4 $\mu A/cm^2$ for various but very short periods of time before the current was doubled. The voltage "overshoots" observed were similar in all respects to those obtained by Dewald with much thicker (> 200 Å) tantalum oxide films formed in dilute sulfuric acid (2). Upon analysis, it was found that the excess field values (2) were independent of film thickness even for the thinnest films, and in fact these values were almost identical to those of Dewald. All calculations led to the conclusion that the situation in very thin films of the order of 10–20 Å is not essentially different from that in thicker films. To be consistent with the theory of high field generation of defect pairs, arguing as above, these data require that the steady-state mean free path vary by a factor of $(20)^{2/3} \simeq 7.4$ for a film 10–20 Å thick. Similarly, for Young's avalanche theory, λ_s must be assumed to vary by a factor of 20. In both cases, the requirement is at variance with condition 41.

(II) Transient Conditions (Constant Current)

Ignoring charging currents, the ratio of λ just before to that just after the abrupt increase in cell current in the experiments described above is given from eqs. 32 and 33 as

$$\frac{\lambda_1}{\lambda_m} \simeq \left(\frac{J_1}{J_2}\right)\left(\frac{dn_+}{dt}\right)_m \Big/ \left(\frac{dn_+}{dt}\right)_1 \qquad [44]$$

since n cannot change instantaneously.

In actual fact, the ion flux cannot be switched instantly from J_1 to J_2, primarily on account of charging current transients. These are much faster than ion current transients for the valve – metal oxide systems, so that the approximation made in eq. 44 will be a good one for these systems. Referring specifically to the high field theory of defect generation, the corresponding fields can be related through eqs. 17, 37, and 43 giving

$$E_m - E_1 \simeq (1/\beta_2) \ln (J_2/J_1) \qquad [45]$$

and from eqs. 5 and 37 the ratio of the volume rates of defect generation is obtained as

$$\left(\frac{dn_+}{dt}\right)_m \Big/ \left(\frac{dn_+}{dt}\right)_1 \simeq e^{(2\beta_s - \beta_2)(E_m - E_1)} \qquad [46]$$

Thus for this special case of galvanostatic field transients and the tantalum–oxide system,

$$[47] \qquad \frac{\lambda_m}{\lambda_1} \simeq \left(\frac{i_1}{i_2}\right)^{2[(\beta_s-\beta_2)/\beta_2]} \simeq \left(\frac{i_1}{i_2}\right)^4$$

The corresponding equation for Young's avalanche theory is

$$[48] \qquad \lambda_m/\lambda_1 = i_1/i_2$$

Equation 47 predicts that for a voltage overshoot experiment in which the current density is doubled, the transient mean free path should vary by a factor of 16. Dewald's data for thicker films ($\sim$ 300 Å) produce an even more surprising result, since he found that the observed phenomena were independent of the ratio (i_2/i_1) for values of this ratio as high as 40. From eq. 47, this would correspond to a reduction in the transient mean free path by a factor of approximately 4×10^{-7}! If λ as well as λ_s were assumed to satisfy the inequality, [41], the above result would clearly rule out the high field theory even for very thick films. We are not in general entitled to make this assumption, however, since under conditions in which λ is time dependent, it can no longer be identified with the mean distance travelled by a mobile defect in one lifetime. Thus, although eq. 31 defines λ unambiguously for both steady-state and transient conditions, λ can only be interpreted as a true mean free path for conditions in which λ is time independent. The arguments presented here against both the theory involving the high field generation of defect pairs and that involving an avalanche mechanism must therefore rest on the behavior predicted for λ_s. On this basis alone, both theories show gross internal contradictions when examined against the data.

The situation is essentially unaltered if allowance is made for motion of the other member of the defect pair. Generation of the defects is of course unaffected, but an equation corresponding to eq. 9 must be introduced to describe the motion of the oppositely charged species in the reverse direction. There will be characteristic a_3, ν_3, and W_3 terms for this motion, and these parameters will not in general be equal to a_2, ν_2, and W_2. In fact, it is highly unlikely that the two activation energies for defect transport will be similar enough to allow a significant contribution from both sources. The capture cross-section for the recombination process will remain unchanged, but the increase in relative velocity must be taken into account by using the vectorial difference of the two fluxes in equations such as eq. 32. The conduction equations of the previous section must become correspondingly more complicated, and a second mean free path is required. However, the mean free path as defined and discussed in this section is simply the sum of those required in the more complicated theory involving dual modes of charge transport, and consequently the arguments presented against rate control through the field or current assisted homogeneous generation of defects are generally valid.

Summary

The so-called high field Frenkel defect theory for ionic conduction in solids has been extended to a more general form, and its range of applicability has been examined. Expressions have been derived for conduction under high-, intermediate-, and low-field conditions. These equations were found to coincide with those derived previously by other authors for the high and low field cases. The homogeneous field-assisted generation of defect pairs was shown to be inapplicable as a mechanism for the anodic oxidation of a typical valve metal, tantalum. Irreconcilable contradictions arose when the predictions of such a theory regarding the steady-state mean free path of the mobile defects were examined against experimental data. In a similar manner the mechanism for defect generation by an ionic avalanche process controlled by the current was shown to be unacceptable under the same circumstances.

In so far as high field ionic conduction through thin films ($\lesssim 10^4$ Å) is concerned, it is highly improbable that the concentration of mobile defects is controlled by homogeneous generation within the film. If for some accessible temperature and current density the conditions for homogeneous generation should fortuitously be met, altering the current density or temperature by a relatively small amount would almost certainly alter the predicted steady-state mean free path to lie outside its permitted range. It must be concluded that any conduction mechanism based on the homogeneous generation of

defects where the concentration of these defects is directly dependent on E and/or i can be justified only for the case of relatively thick ($\gg 10^4$ Å) films.

Structure of Lycoctamone and its Analogues[1,2]

M. H. Benn,[3] J. D. Connolly,[3] O. E. Edwards, L. Marion, and Z. Stojanac[3]

Biochemistry Laboratory, National Research Council of Canada, Ottawa, Canada

Received June 22, 1970

The lactams derived from the lycoctonine family of diterpenoid alkaloids undergo acid-catalyzed dehydration of the *vic*-glycol system to produce pinacolones. More vigorous acid treatment converts these to 'lycoctamone' analogues, which are now shown to be α,β unsaturated aldehydes containing in addition an inert allylic alcohol system. Proof of structure and a mechanism for the formation of these compounds involving bond migration and fission are presented. A steric driving force for the reaction leading to these compounds is suggested. Lycoctamone and its analogues are of potential value in the stepwise degradation of the lycoctonine skeleton for biosynthetic studies.

The structure and stereochemistry illustrated in **1** was established for the alkaloid lycoctonine[4] by X-ray crystallography (1). Most of the previously described chemistry was soon shown to be consistent with this structure (2–7). However, the nature of one intriguing transformation product, 'lycoctamone' (8), eluded us until p.m.r. observations corrected misconceptions about the functional groups.

Mild acid treatment of the lactam **2** (R = OH) derived from lycoctonine gave the pinacolic dehydration product anhydrooxolycoctonine[5] (**3**, R_1 = OH, R_2 = OCH_3) (Scheme 1). More vigorous treatment with acid converted both **2** and **3** to lycoctamone (8). This compound was still a δ lactam (ν_{max} 1610 cm^{-1}) and contained one readily-acetylated and one hindered hydroxyl, and two methoxyl groups. Spectral evidence (λ_{max} 245 (ε 10 000) and 310 mμ ε 160); ν_{max} 1661 cm^{-1}) and catalytic hydrogenation disclosed the presence of an α,β unsaturated carbonyl system in lycoctamone.

The primary hydroxyl group was not involved in the formation of lycoctamone, since 18-*O*-methyl-oxolycoctonine (**4**) and 18-deoxy-oxolycoctonine (**5**) which have no oxygen on that carbon, gave exactly parallel products.

Both 18-*O*-methyl-6-demethoxyoxolycoctonine (**6**) and oxodelpheline (**7**) (6) gave lycoctamone analogues with the loss of $C_2H_8O_2$. This is the same loss as for the conversion of oxolycoctonine to lycoctamone, hence the function on C-6 is not involved in the reaction.

Since 1-deoxyoxodelcosine (**8**) gave a lycoctamone analogue with loss of CH_6O_2, the hydroxyl on C-14 is involved but the function on C-1 is not. The participation of the C-14 function was confirmed when oxobrowniine (**9**), was treated with acid. Again loss of CH_6O_2 was observed giving the precise analogue (brownamone) of lycoctamone. By elimination we conclude that the other *O*-methyl group lost in formation of the lycoctamones was on C-16.

The fact that the pinacolic dehydration product **3** gave lycoctamone at least as efficiently as the parent glycol oxolycoctonine, and that this was true also of anhydro compounds (pinacones) corresponding to **4** and **6**, suggested that the molecule of water lost in formation of the lycoctamones came from the glycol and that the anhydro compounds (pinacones) were intermediate in the reaction.

It had been concluded earlier (8) that lycoctamone was a trisubstituted α,β unsaturated ketone (ν_{max} 246 mμ) and that it contained only one double bond. Analysis of its n.m.r. spectrum has shown both these conclusions to be incorrect.

The presence of an aldehyde function was indicated by a one-hydrogen singlet at τ 0.25 in the spectrum of lycoctamone and a comparable signal in the spectra of all the analogues which were studied. In the spectra of the dihydro derivatives, in which the conjugated double bond was reduced, the aldehyde proton resonated at τ 0.50 and as expected the signal was now a doublet

SCHEME 1

with J = 3Hz. The alcohols (lycoctamols) derived by sodium borohydride reduction of the aldehyde function of 18-deoxylycoctamone and des(oxymethylene)lycoctamone (**16**) had a broad ($w_{1/2}$ = 4 Hz) two-hydrogen singlet at τ 5.85, shifted downfield on esterification. Finally, the presence of the weak i.r. band at 2730 cm^{-1}, a positive Angeli–Remini test for aldehyde, a positive hydrogen sulfide – sodium pentacyanoammine ferroate (9) test for an α,β unsaturated aldehyde, and dehydration of the oxime of 18-deoxylycoctamone to a nitrile confirmed that lycoctamone and its analogues were α,β unsaturated aldehydes.

Inspection of the n.m.r. spectrum of lycoctamone[6] revealed the presence of three vinyl hydrogens. A broad ($w_{1/2}$ = 6 Hz) one-hydrogen signal near τ 3.4 in lycoctamone was shifted upfield to near τ 4.6 in the products of sodium borohydride reduction of the aldehyde function (lycoctamol). Hence this arises from a β hydrogen of an α,β unsaturated aldehyde system in lycoctamone. In accord with this the signal was absent in dihydrolycoctamone. A second double bond was indicated by a pair of one-hydrogen singlets at τ 4.68 and 4.73 in the spectrum of lycoctamone, and nearly identical signals in that of the other lycoctamone analogues. This pair of signals was absent in tetrahydrolycoctam, in which both double bonds had been reduced and the aldehyde oxygen removed by hydrogenolysis. The double bond carrying these protons was resistant to hydrogenation. An indication of the nature of this double bond came from the i.r. spectra of lycoctamone. A medium-intensity band appeared quite consistently near 910 cm^{-1}; this and a weak band near 3100 cm^{-1} suggested that it was an exocyclic methylene group. The n.m.r. signals for the two vinyl hydrogens asso-

[6]The following comments about lycoctamone spectra apply to the analogues derived from compounds **4** to **9** as well.

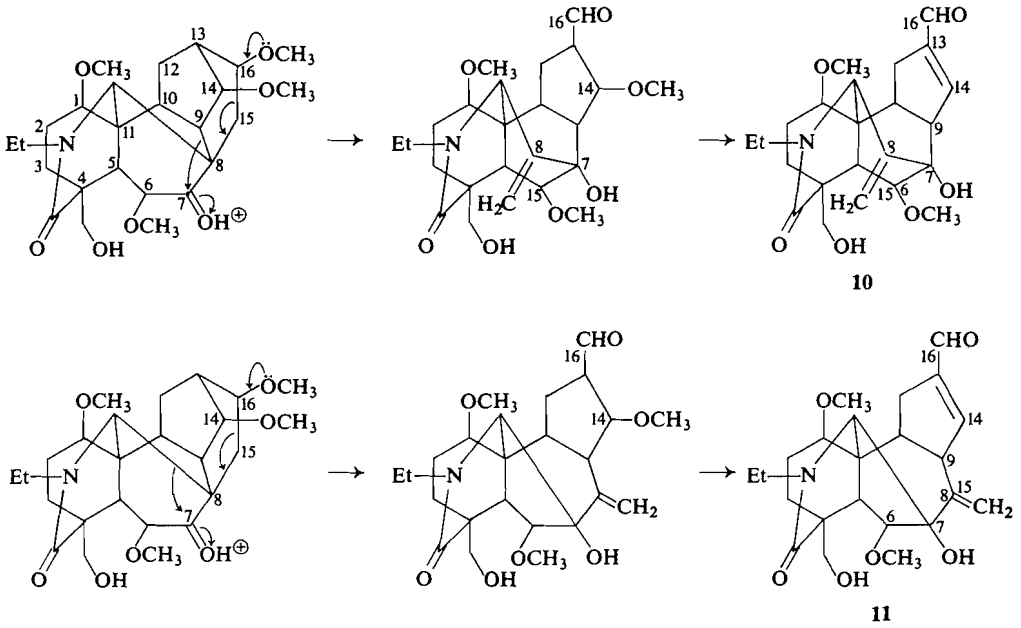

SCHEME 2

ciated with it were at rather low field for non-conjugated terminal methylene (τ 5.4), but did not exclude this possibility.[7]

The u.v. maximum of lycoctamone was at long wavelength (*ca.* 245 mμ) for an unsaturated aldehyde, but was not far from that of cyclopent-1-enal (ν_{max} 238 mμ). The i.r. peak for the carbonyl of cyclopent-1-enal (ν_{max} ($CHCl_3$) 1675 cm^{-1}) was at a low wave number, similar

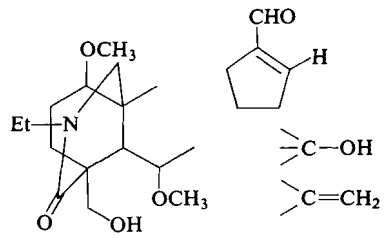

FIG. 1. Suggested systems contained in the lycoctamone analogues.

to that of lycoctamone. In addition the aldehyde hydrogen of cyclopent-1-enals gave n.m.r. signals near τ 0.28 (*cf.* lycoctamone at τ 0.25), at significantly lower field than that of cyclohex-1-enal (τ 0.66) and other conjugated unsaturated aldehydes (10).[8] We hence tentatively concluded that the lycoctamone analogues contained the systems illustrated in Fig. 1.

On the assumption that anhydrolycoctonam (2) was an intermediate in the formation of lycoctamone, mechanistic considerations (Scheme 2) led to postulation of two alternative structures, **10** and **11**, for lycoctamone, both of which contained the required functional groups. It seemed unlikely that **11** would have survived the acid reaction conditions and the subsequent basic hydrolysis of the monoacetate since there is no obvious reason why the terminal double bond would not move into conjugation. In addition the marked inertness of the isolated double bond to catalytic hydrogenation and osmylation (see below) are not accounted for by **11**. The three dimensional representation of **10**, however, (see **12**) shows the terminal methylene to be markedly shielded by other rings. Hence **10** ≡ **12** was a good working hypothesis for the structure of lycoctamone. The proximity of the terminal methylene group and the double bond of the cyclopentenal system is illustrated in more detail in **13**. The overlap of π orbitals could possibly

[7]The action of ozone on lycoctamone and dihydrolycoctamone (conjugated olefin reduced) in chloroform gave formaldehyde. However, the diagnostic value of these observations was made very uncertain when it was shown that delcosine gave formaldehyde under these conditions. Presumably oxidation of methoxy groups to formaldehyde takes place.

[8]We thank Professor J. B. Stothers for informing us of his observations prior to publication.

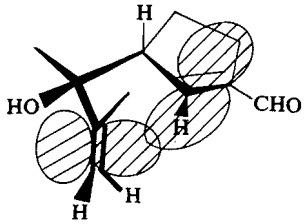
12



13

account for the bathochromic shift of the $\pi \rightarrow \pi^*$ absorption in lycoctamone relative to cyclopentenal ($\Delta\lambda = +7$ mμ) since the positive charge on C-14 would thereby be delocalized.

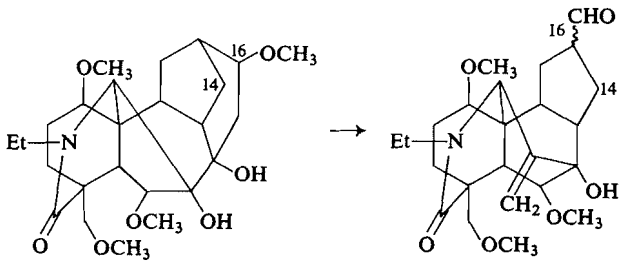
A test of the plausibility of structures **10** or **11** was provided by treating 14-deoxyoxobrowniine (**14**) with acid. As expected, pinacolic dehydration product and a mixture of non-conjugated aldehydes (dihydrobrownamones) (ν_{max} ($CHCl_3$) 2730 and 1720 cm^{-1}, n.m.r. signals around τ 0.5) were produced. The aldehydes were sensitive, and decomposed on attempts to separate them by repeated chromatography. This prevented precise correlation with the dihydrobrownamone produced by catalytic hydrogenation of brownamone. However, the analysis and spectral evidence indicated that they were the C-13 epimers of structure **15** (Scheme 3) if lycoctamone was correctly represented by **10**.

With structure **10** as a working hypothesis, an effort was made to establish the structure of lycoctamone and its analogues. First, attempts were made to prove the presence of the cyclopentenal system and the presence of a terminal methylene group and associated tertiary allylic alcohol. Later, attempts were made to interrelate these two sets of functions.

Des(oxymethylene)lycoctamone (**16**) was reduced over palladium to the dihydro compound **17** (Scheme 4). This was converted to the methyl ketone **18** by methyl magnesium iodide and subsequent oxidation. Trifluoroperacetic acid oxidation of **18**, followed by alkaline hydrolysis of the product and oxidation of the resulting secondary alcohol gave an epoxy ketone **19**. This had ν_{max} ($CHCl_3$) 1730 cm^{-1} which did not convincingly demonstrate its cyclopentanone character. The low frequency could however be rationalized if the epoxide had the most likely configuration illustrated in **19**. The unshared electrons on the oxide oxygen would be close enough to reduce the restoring force in a polarizing vibration of the C=O group, and so lower the cyclopentanone carbonyl stretching frequency.

A second sequence of steps gave more rigorous proof of the cyclopentenal system. Wolff–Kishner reduction of deoxymethylene lycoctamone gave under varying conditions three olefins.

The terminal olefin **20** was the major product of the reduction when performed at 180°. Relatively pure olefin **21** was obtained by conversion of the aldehyde to the ethylene thioketal, followed by Raney-nickel desulfurization. Wolff–Kishner reduction at 200° produced all three olefins, and at 220° **22** became a major product. Further, when a mixture of the three olefins was heated at 220° with potassium hydroxide in



14 15

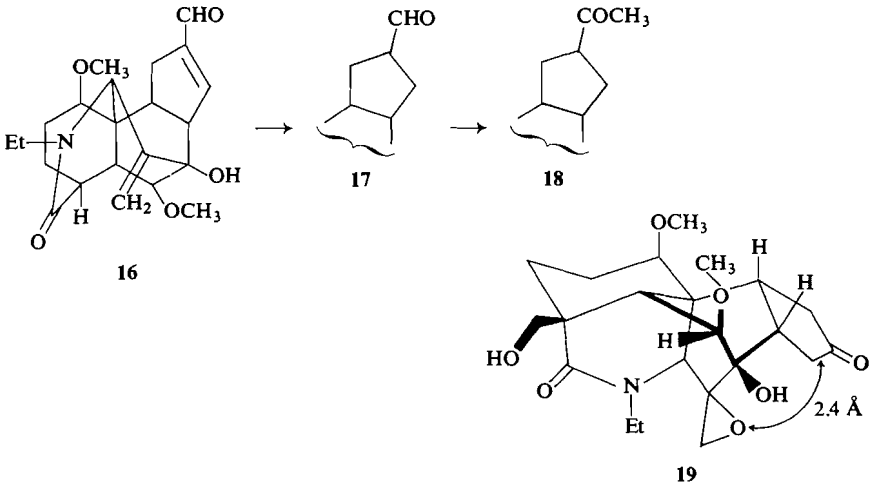
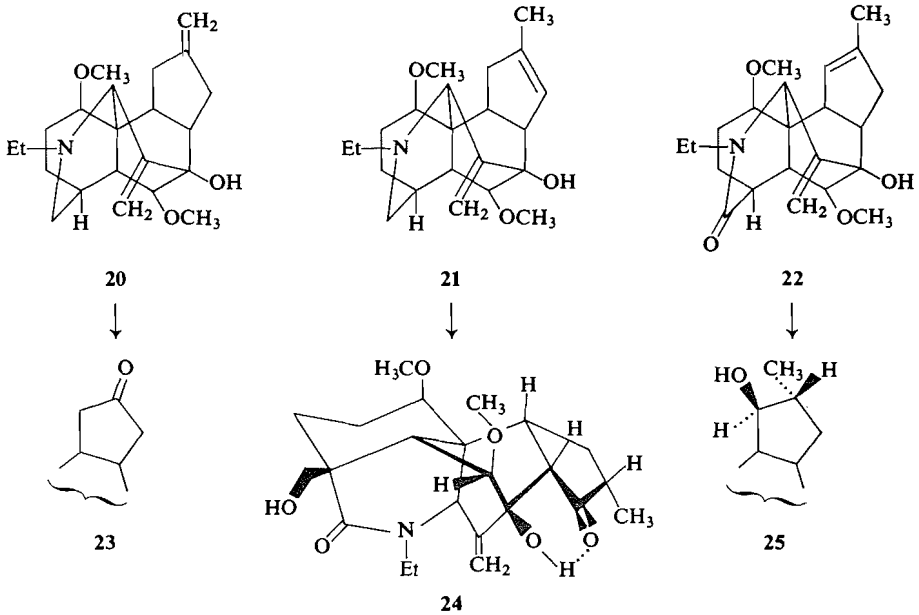


SCHEME 4

triethyleneglycol, **20** and **21** were converted almost completely into **22**. The illustrated structures (Scheme 5) account beautifully for the chemistry of these olefins. Oxidation of **20** gave a ketone **23** with ν_{max} (CCl_4) 1742 cm^{-1}, finally confirming the cyclopentenal character of lycoctamone. Hydroboration of **21** and **22** gave alcohols but only the one form **21** could be readily oxidized to a ketone. This ketone was internally hydrogen bonded (ν_{max} (CCl_4) 3420 and 1718 cm^{-1} at high dilution) in perfect accord with structure **24**.

The n.m.r. spectrum of olefin **22** showed the presence of one vinyl hydrogen (in addition to those of the terminal methylene). Hence the hydroboration product should be the secondary alcohol **25**. Both the isomerization of **21** to **22** and the resistance of alcohol **25** to oxidation can be accounted for on steric grounds. In olefin **21**, repulsive interaction of the 17, 1α and 12α hy-



SCHEME 5

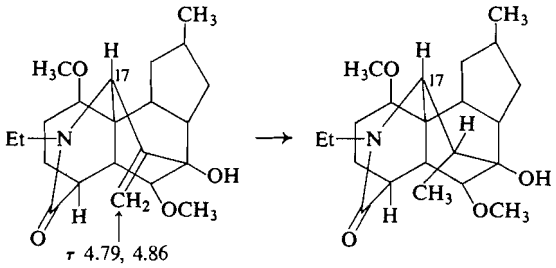
A B C

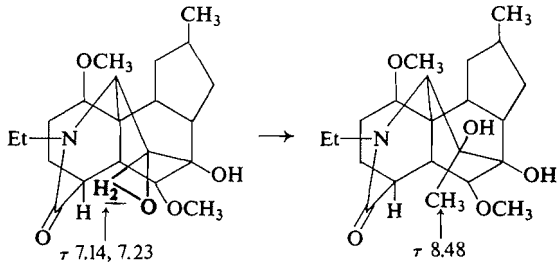
drogens is marked (in a Courtauld model the hydrogen atoms nearly touch, *i.e.* the inter-hydrogen distance is *ca.* 2 Å) (see **A**). In addition the vinyl hydrogen and 7-hydroxyl are eclipsed. These interactions are relieved on isomerization to **22** (see **B**). The hydroboration product **25** has the 12α-hydrogen very encumbered (see **C**) and relatively inaccessible to the base required to complete chromic acid oxidation (11).



26 **27**

SCHEME 6

In order to simplify study of the hindered terminal double bond of the lycoctamones, the cyclopentenal system was converted by hydrogenolysis over palladium in acetic acid to the methylcyclopentane. The product from lycoctamone, dihydrolycoctam, was inert to osmium tetroxide – sodium periodate combination. However, both it and des(oxymethylene)dihydrolycoctam (**26**) still gave vinyl hydrogen signals in their n.m.r. spectra. Des(oxymethylene)dihydrolycoctam could be hydrogenated further over platinum in ethanol to a saturated lactam **27** (tetrahydrodes(oxymethylene)lycoctam) (Scheme 6). The increased complexity of the signals above τ 8.5 in the n.m.r. spectrum of the fully hydrogenated product suggested that a new methyl group had been produced but the integrated intensities were not decisive. In a further set of reactions, **26** was converted to the epoxide **28** using trifluoroperacetic acid. Analysis, the change in chemical shift of the methylene hydrogens shown on the figures in Scheme 7, and the further chemical reactions of **28** were consistent with this formulation. Vigorous lithium aluminum hydride reduction of **28** gave a basic diol,



28 **29**

SCHEME 7

which could be oxidized by permanganate to the lactam **29**. The new methyl group gave a sharp signal at τ 8.48 as expected. The diol took up 1.3 mol of lead tetraacetate in 2 h giving a mixture of ketones and an ester (ν_{max} 1710 and 1745 cm^{-1}). The n.m.r. spectrum of the mixture showed the presence of an acetoxy group (τ 7.52) and two methyl ketone groups (epimers?) at τ 7.89 and 8.00. The diketone was not isolated in a pure state however since internal aldol condensations and/or epimerizations rapidly converted it to a mixture. One compound was isolated from this mixture and found to have the composition and physical properties expected for the internal aldol-condensation product **30**. The presence of extra low-field hydrogen signals (one-hydrogen doublet entered at τ 5.94, J = 9 Hz), corresponding to a hydrogen on C-6, excludes aldol condensation onto this carbon.

The presence and environment of the allyl alcohol thus corresponds exactly to that in structure **10**.

A spin decoupling study of the n.m.r. spectrum of des(oxymethylene)lycoctamone gave results in agreement with structure **16**. A broad ($w_{1/2}$ 5 Hz)

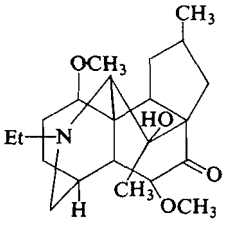
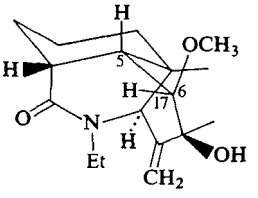
one-hydrogen signal at τ 5.76 should correspond to the hydrogen on C-17. A doublet at τ 6.75 and 6.80 seemed likely to arise from the hydrogen on C-6. Irradiation at τ 8.14 collapsed the doublet to a singlet and sharpened the signal at τ 5.78. This is consistent with resonance of the 5-hydrogen at τ 8.14. Long range W plan coupling with the 17-hydrogen (J = 3 Hz) is to be expected (12) (see formula **31**).

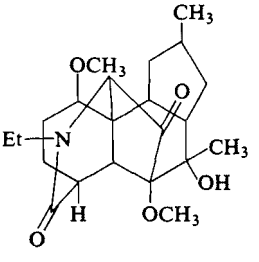


30

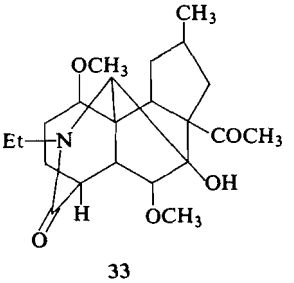


31

Attempts to directly relate the functions on the cyclopentane ring to the allyl alcohol system failed. However the internal hydrogen bonding observed for ketone **24** not only provides evidence for the assumed relationship, but it is incompatible with a corresponding ketone derived from structure **11**. In addition, the hydrogen on C-17 in dihydrodes(oxymethylene)lycoctam (**26**) was at τ 5.88. In the tetrahydro derivative **27** this hydrogen resonated at τ 6.40 close to that for des(oxymethylene)oxolycoctonine itself (τ 6.30). This large chemical shift is consistent with the allylic relation between the 17-hydrogen and the double bond as in **10**, but cannot be accounted for on the basis of structure **11**. In addition, the spectra of the aldol condensation product **30** (ν_{max} 1716 cm^{-1}; a three-hydrogen singlet at τ 8.42) are accounted for by this structure but not with the alternative ones **32** or **33** corresponding to structure **11**. In particular, the carbonyl stretching frequency of aldols similar to **32** was around 1742 cm^{-1} (des(oxymethylene)-iso compound) (3, 13), and a methyl ketone



32



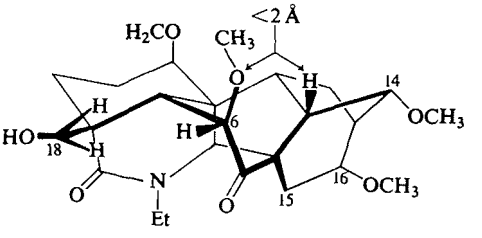
33

function as in **33** has its methyl signal near τ 7.85.

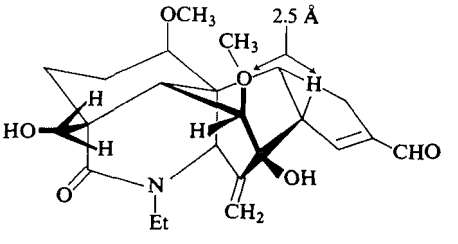
In view of the above evidence and the arguments advanced earlier about the expected instability of **11**, we conclude that lycoctamone has structure **10**.

The driving force for the unusual and deep-seated change leading to lycoctamone would seem to be steric in origin since the primary fission product has no obvious electronic stabilization. A likely possibility for the driving force was relief of the repulsive interactions of the 1,3-diaxial oxygen substituents at C-14 and -16. However, this is not a dominant factor since 14-deoxyoxobrowniine (**14**) underwent the reaction with facility.

Notable relief of repulsive interactions between substituents on C-18 and the 6-hydrogen and between the 6-methoxyl and the 9-hydrogen is illustrated in the transition from the anhydro



34



35

compound **34** to lycoctamone **35**. As expected if these interactions provided much of the driving force for the reaction, replacement of the 4-substituent by hydrogen (des(oxymethylene)oxylycoctonine) makes the reaction much more difficult. Very little unsaturated aldehyde was produced under the usual acid conditions, but in 5 h, at room temperature in concentrated sulfuric acid, approximately 50% of des(oxymethylene)lycoctamone was produced. The removal of the 6-methoxyl group (18-*O*-methyl-6-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

demethoxyanhydrooxolycoctonine, **3**, R_1 = OCH_3, R_2 = H) made the reaction even more sluggish. After 5 h in concentrated sulfuric acid only 25% of lycoctamone analogue was produced. The fragmentation must be well advanced in the transition state so that relief of the abovementioned interactions is felt. Both Dreiding and Courtauld models demonstrate that considerable angle distortion of bonds exists in the anhydro compounds. This can be noticed readily if the 15–16 bond is coupled last. It is likely that some of the driving force for the rearrangement to the lycoctamones also arises from this strain.

It is, at first sight, surprising to find an allyl alcohol as product of an acid-catalyzed reaction. However because of the bridgehead position of the allylic hydroxyl, the only likely course of further reaction would be protonation of the terminal methylene followed by rearrangement to a methyl ketone. The fact that this takes place slowly, if at all, we attribute to the proximity of the methylene group to the more basic amide and α,β unsaturated aldehyde systems which must compete successfully for available protons.

The lycoctamone analogues are potentially very valuable in studies of biosynthesis of the lycoctonine family of diterpenoid alkaloids, since labelling on C-18 and -19 could readily be examined.

Experimental

The i.r. spectra were taken on a Perkin–Elmer model 21 prism spectrometer, and are of Nujol mulls unless otherwise specified. The n.m.r. spectra were obtained on Varian HA-60 and A-60 instruments in deuterochloroform unless specified, with tetramethylsilane as internal standard unless otherwise indicated. Rotations were in absolute ethanol unless the solvent is given. Chromatography was on Woelm neutral alumina and t.l.c. on silica gel plates.

Lycoctamone

This gave positive Angeli–Rimini and Tollens tests for aldehyde, and a positive test for an α,β unsaturated aldehyde (9). Weak bands at 2720 (—CHO) and 3090 cm^{-1} (=CH_2) were present in the i.r. spectrum of a carbon tetrachloride solution of lycoctamone acetate. The n.m.r. spectrum of lycoctamone ($CDCl_3$) had a sharp one-hydrogen signal at τ 0.25 (CHO), a broad one-hydrogen signal centered at τ 3.24 (HC=C—C=O), two one-hydrogen signals at τ 4.68 and 4.73 (=CH_2), and two methoxyl signals at τ 6.28 and 6.54.

Dihydrolycoctamone

Lycoctamone (135 mg) was added to 20 ml of 95% ethanol containing 20 mg of palladium black presaturated with hydrogen. In 25 min, uptake of hydrogen ceased (6.94 ml at N.T.P., 1.17 mol). The product crystallized from a concentrated acetone solution, m.p. 125–128°. It had only end absorption in the u.v., and ν_{max} ($CHCl_3$) 1615 and 1721 cm^{-1}. It gave positive Tollens and Angeli–Rimini tests but a negative test for α,β unsaturated aldehyde (9). Its n.m.r. spectrum had a one-hydrogen doublet at −134 Hz from solvent chloroform (J = 4 Hz) and two one-hydrogen singlets at +113 and +119 Hz from the chloroform signal.

Anal. Calcd. for $C_{23}H_{33}NO_6 \cdot 2H_2O$: C, 60.64; H, 8.19. Found: C, 60.25; H, 7.81.

Parent ion at *m/e* 419, Calcd. for $C_{23}H_{33}NO_6$: 419

Dihydrolycoctamone monoacetate, prepared by reduction of lycoctamone acetate as above had m.p. 190–194°.

Anal. Calcd. for $C_{25}H_{35}NO_7$: C, 65.05; H, 7.64. Found: C, 64.94; H, 7.63.

Attempted Oxidation of Dihydrolycoctam

A solution of 80 mg of dihydrolycoctam (8) and 30 mg of osmium tetroxide in 3 ml of 80% acetic acid – 20% water was left for 1 h at room temperature. To this was added 100 mg of sodium paraperiodate in 10 ml of 80% acetic acid. After 5 h at room temperature the solvent was removed *in vacuo*, the residue dissolved in methylene chloride, and acid removed by extracting with sodium carbonate solutions. The neutral product (80 mg) had an n.m.r. spectrum nearly identical to that of dihydrolycoctamone. A trace of carbonyl-containing product was indicated by a band at 1700 cm^{-1}.

Ozonolysis of Dihydrolycoctamone

A stream of ozonized oxygen was bubbled into a solution of 5 mg of dihydrolycoctamone in 7 ml of chloroform for 10 min. The chloroform was then evaporated *in vacuo* and the residue taken up in 4 ml of water. Steam distillation was carried out until 5 ml of distillate collected. This gave a rich violet color with chromatropic acid reagent. A blank with reagents was negative.

Ozonolysis of Delcosine

Ozonized oxygen was bubbled for 15 min into a solution of 20 ml of delcosine in 8 ml of acetic acid. After addition of 8 ml of water, the mixture was steam distilled. The distillate gave the characteristic violet color with chromatropic acid reagent.

18-O-Methyllycoctamone

A solution of 80 mg of 18-*O*-methylanhydrooxolycoctonine (14) in 1.5 ml of acetic acid containing 0.2% sulfuric acid was heated for 2 h at 115°. The cooled mixture was added to 5 ml of ice-water, and the resulting solution made alkaline with ammonia. Extraction with chloroform gave 80 mg of product, which was adsorbed from benzene onto 2 g of neutral alumina, activity III. Benzene eluted 14 mg of amorphous material, then benzene–chloroform mixtures eluted 62 mg which crystallized from acetone. After recrystallization and sublimation at 180°, 5×10^{-4} mm, the product had m.p. 227–228°, and λ_{max} 245 mμ (ε 12 000).

Anal. Calcd. for $C_{24}H_{33}NO_6$: C, 66.80; H, 7.71; 3 OCH_3, 21.57. Found: C, 66.52; H, 7.45; OCH_3, 21.98.

The compound gave n.m.r. signals at τ 0.05 (1H), 3.22 (1H), a two-hydrogen pair at τ 4.7 and 4.73, and three three-hydrogen signals at τ 6.28, 6.50, and 6.59.

For personal use only.

18-O-Methyl-6-demethoxylycoctamone

18-*O*-Methyl-6-demethoxyanhydrolycoctonam (14) (69 mg) was dissolved in 1 ml of concentrated sulfuric acid, the solution left for 5 h at room temperature, then poured onto crushed ice. The aqueous solution was made alkaline using concentrated ammonium hydroxide, then the product extracted into chloroform. The 45 mg of readily extracted product was adsorbed from benzene onto 1 g of alumina, activity II. Benzene (30 ml) eluted 16 mg of undesired product. Benzene–chloroform (3:1, 10 ml) eluted 9 mg of an approximately 3:7 mixture of starting material and desired product, and a further 10 ml of solvent eluted 9 mg of the lycoctamone analogue. The compound was sublimed at 195°, 1×10^{-3} mm. It then had ν_{max} 3380, 1682, and 926 cm^{-1}. It melted over a wide range, mainly 235–243°.

Anal. Calcd. for $C_{23}H_{31}NO_5$ (mol. wt. 401): 2 OCH_3, 15.29. Found (parent ion at *m/e* 401 with an impurity at *m/e* 415): OCH_3, 16.93, 16.88.

The yield estimated from the i.r. maximum was approximately 21%. Prolonging the time of reaction to 20 h reduced the yield to approximately 11%.

18-Deoxyoxolycoctonine (5)

The yield was markedly improved over the previous report (15). 18-deoxylycoctonine (1.03 g) in 5 ml of dry pyridine was added to a mixture of 800 mg of chromium trioxide in 12 ml of pyridine. The reaction mixture was shaken overnight, concentrated to half-volume under reduced pressure (bath at 45°), then poured onto 50 ml of crushed ice. After acidification with 3 *N* sulfuric acid, remaining oxidizing agent was reduced by bubbling in sulfur dioxide. The product was extracted into chloroform (6 × 25 ml). The chloroform layer, after washing with water then drying over sodium sulfate, was evaporated, leaving 860 mg of glassy residue. This was adsorbed from benzene onto 10 g of neutral alumina, activity II. Benzene and benzene–chloroform eluted 860 mg of product which crystallized from acetone–hexane to give 703 mg of colorless prisms, m.p. 166–169°.

18-Deoxylycoctamone

A solution of 758 mg of 18-deoxyoxolycoctonine (5) in 10 ml of 0.2% sulfuric acid in acetic acid was heated at 115° for 1.5 h. The sulfuric acid was neutralized by addition of sodium carbonate, then the bulk of the acetic acid evaporated under reduced pressure. The residue was taken up in water, the product extracted into chloroform and this solution washed free of acid with sodium carbonate solution. The product recovered from the chloroform was adsorbed from benzene onto 16 g of alumina, activity III. Benzene (50 ml) and benzene–chloroform (1:1) eluted 12 mg which was discarded. Benzene–chloroform (1:1, 80 ml) and benzene–chloroform (1:3, 60 ml) eluted 658 mg which yielded 204 mg of deoxylycoctamone. Rechromatography of the mother liquor on 6.6 g of alumina activity IV gave more product. The eluates with benzene and benzene–chloroform (1:1) crystallized, yielding a further 170 mg of 18-deoxylycoctamone. After recrystallization from acetone it melted at 240–244°, and had $[\alpha]_D$ + 361° (*c*, 2.3 in $CHCl_3$), λ_{max} 244 (ε 16 600), 308 mμ (ε 288), and ν_{max} 3600, 3500, 3300, 1671, and 1620 cm^{-1}.

Anal. Calcd. for $C_{23}H_{31}NO_5 \cdot H_2O$: C, 65.85; H, 7.94. Found: C, 66.10; H, 7.60.

The compound had n.m.r. signals at −282 (1H, sharp), −115 (1H, broad), −32 (1H), and −28 (1H) Hz relative to external water.

When 172 mg of 18-deoxyoxolycoctonine was dissolved in 1.5 ml of concentrated sulfuric acid and the solution left at room temperature for 5 h, the product contained no starting material or anhydro compound. Chromatography on alumina enabled isolation of 59 mg of 18-desoxylycoctamone.

Oxime: m.p. 255–260°, λ_{max} 244 mμ, (ε 13 800).

Anal. Calcd. for $C_{23}H_{32}N_2O_5$: N, 6.73. Found: N, 6.65.

The oxime was dehydrated by 1 h refluxing with acetic anyhydride, giving a 50% yield of crude nitrile (ν_{max} 2120 cm^{-1}) after chromatography on alumina. After recrystallization from acetone–hexane the nitrile had m.p. 235–238°, ν_{max} 2240 cm^{-1}.

Anal. Calcd. for $C_{23}H_{30}N_2O_4$: C, 69.32; H, 7.59; N, 7.03. Found: C, 69.31; H, 7.47; N, 7.05.

18-Deoxylycoctamol

A solution of 80 mg of 18-deoxylycoctamone and 80 mg of sodium borohydride in 5 ml of methanol was left at room temperature for 45 min. Fifteen milliliters of 2 *N* sulfuric acid were added, and the product extracted into chloroform. After removal of the chloroform the 80 mg of glassy residue was taken up in acetone–hexane. It crystallized in the form of small prisms m.p. 205–210°. After two recrystallizations from this solvent mixture it had m.p. 230–232°. It had only strong end absorption in the u.v., and ν_{max} 3430, 3360, 1123, and 908 cm^{-1}. Its n.m.r. spectrum had vinyl hydrogen signals at 112 Hz (broad one-hydrogen singlet), and a poorly resolved doublet centered at 128 Hz (two hydrogens). It had a two-hydrogen signal at 190 Hz attributable to a $—CH_2OH$ group (all chemical shifts relative to internal chloroform).

Brownamone

Oxobrowniine (16), m.p. 165–168° (600 mg) was dissolved in 20 ml of 0.2% (v/v) sulfuric acid in acetic acid. The solution was heated in a bath held between 115 and 123° for 2.5 h, then concentrated to small volume under reduced pressure. After addition of 10 ml of water it was adjusted to p*H* 8 using 4% sodium carbonate solution. Thorough extraction with methylene chloride gave 660 mg of product. This was hydrolyzed by 25 min refluxing with 50 ml of 5% potassium hydroxide in 50% aqueous methanol, giving 581 mg of hydrolysate. This was adsorbed from benzene onto 17 g of neutral alumina, activity III. Benzene (90 ml), chloroform in benzene (50 ml 10%, 50 ml 20%) eluted 35 mg of ketonic material. Chloroform in benzene (30–50%) eluted 158 mg of pure brownamone and 70 mg of less pure material. The estimated total yield was 208 mg (39%). The product had m.p. 222–230° with some crystals remaining until 240°; ν_{max} (Nujol) 3400, 1678, 1616, 934 cm^{-1} and λ_{max} 244 mμ, (ε 11 900). Its n.m.r. spectrum had signals at τ 0.25 (1H singlet), 3.34 (1H, $w_{1/2}$ 5 Hz), 4.81 (1H), 4.87 (1H), 5.80 (1H doublet, J = 3.5 Hz), 6.36 (3H), 6.59 (3H), 6.68 (3H), 8.87 (3H triplet, J = 7 Hz).

Anal. Calcd. for $C_{24}H_{33}O_6N$: C, 66.80; H, 7.71. Found: C, 66.89; H, 7.62.

*14-Deoxyoxobrowniine (**14**)*

14-Dehydrooxobrowniine (16) m.p. 167–171° (979 mg) was dissolved in 25 ml of triethylene glycol and 7 ml of 95% hydrazine. The solution was heated at 140° for 1 h, 4 g of potassium hydroxide was cautiously added, then the bath temperature raised during 40 min to 190°. The bath was maintained at 190–200° for 4 h, then at 200–210° for 1 h. After cooling, the mixture was diluted with 35 ml of water and extracted repeatedly with methylene chloride. The 923 mg of white froth remaining after removal of the methylene chloride was adsorbed from benzene on 18.5 g of neutral alumina, activity III. Benzene, benzene–chloroform, and chloroform eluted 650 mg of nearly pure 14-deoxyoxobrowniine which, however, did not crystallize. After distillation at 200°, 5×10^{-4} mm, it had ν_{max} 1615 cm^{-1}.

Anal. Calcd. for $C_{25}H_{39}O_7N$: C, 64.49; H, 8.44. Found: C, 64.64; H, 8.63.

*Dihydrobrownamone (**15**)*

A solution of 234 mg of 14-deoxyoxobrowniine in 20 ml of 0.2% (v/v) sulfuric acid in glacial acetic acid was heated at 115° for 100 min. The bulk of the acetic acid was evaporated under reduced pressure, the residue taken up in 5 ml of water, then sufficient solid sodium carbonate added to bring the p*H* to 8. Thorough extraction with methylene chloride gave 203 mg of product. This was hydrolyzed by 30 min reflux with 5% potassium hydroxide in 50% aqueous methanol. The 165 mg of hydrolysate was adsorbed on 3.3 g of grade III neutral alumina. Benzene (50 ml) eluted 10 mg of ketonic material. Chloroform in benzene (1:4 to 3:1) eluted the desired product (90 mg) with some contamination at both ends. The estimated total yield of dihydrobrownamone was 79 mg (31%). After recrystallization from ether–pentane the compound had m.p. 146–156°, ν_{max} ($CHCl_3$) 3570, 3420, 2730, 1720 and 1630 cm^{-1}. Its n.m.r. spectrum had three signals at τ 0.43, 0.52, and 0.57 (—CHO), two one-hydrogen signals at τ 6.28 and 6.40 (=CH_2), and a split six-hydrogen signal at τ 6.67 (two methoxyl groups). Attempts to separate the aldehyde epimers by further chromatography resulted in destruction of the sensitive compound. The compound was dried 2 h at 100° *in vacuo*.

Anal. Calcd. for $C_{24}H_{35}O_8N$: C, 66.49; H, 8.14. Found: C, 66.28; H, 8.09.

The action of 12 *N* sulfuric acid at 100° for 2 h on 14-deoxyoxobrowniine gave a mixture containing pinacolic dehydration product and dihydrobrownamone. The yield of the latter was estimated by i.r. spectroscopy to be approximately 30%.

*1-Deoxyoxodelcosine (**8**)*

One gram of 1-dehydrooxodelcosine (17), m.p. 225–227°, was added to a mixture of 25 ml of triethylene glycol and 10 ml of hydrazine. After 70 min heating at 140°, potassium hydroxide (4 g) was added cautiously. The temperature was raised to 190° during 1 h, excess hydrazine being swept out of the condenser by dry nitrogen. The bath temperature was maintained at 185–190° for 4 h. The cooled reaction mixture was then diluted with 30 ml of water and the product extracted into methylene chloride. The methylene chloride layers were washed with water, dried, and distilled, giving 875 mg of product. This was adsorbed from benzene onto 18 g of alumina, activity III. Benzene (50 ml) eluted a fore-run of 15 mg. Chloroform (100 ml) eluted 750 mg of quite pure 1-deoxyoxodelcosine. This was rechromatographed on 15 g of alumina, activity III. Chloroform (150 ml) eluted 688 mg of product which crystallized readily. After three recrystallizations from benzene–hexane it melted at 225–235°. It appeared to be strongly hydrated, and only slowly lost water on drying. After 2 h at 110°, 1×10^{-2} mm, it gave a low carbon value.

Anal. Calcd. for $C_{24}H_{32}O_7N$: C, 63.83; H, 8.26. Found: C, 62.72; H, 8.13.

*Action of Sulfuric Acid on **8***

1-Deoxyoxodelcosine (208 mg) was dissolved in 4 ml of concentrated sulfuric acid at room temperature. After 5 h crushed ice was added, the solution made alkaline with saturated sodium carbonate solution, and the product extracted into chloroform. The 83 mg of froth recovered from the chloroform was adsorbed from benzene on 1.7 g of alumina, activity III. The benzene eluates (30 ml) were discarded. Benzene–chloroform (15 ml, 1:1) eluted 30 mg of the desired product. After crystallization from benzene–hexane it lost solvent at 95° with partial melting, resolidified, and melted at 154–157°. After 24 h drying over P_2O_5 under 1×10^{-2} mm it was analyzed.

Anal. Calcd. for $C_{23}H_{31}O_5N$: C, 68.80; H, 7.78. Found: C, 69.18; H, 7.59.

The compound had ν_{max} 3340, 2730, 1683, 1616, and 935 cm^{-1}, and λ_{max} 243 mμ, (ε 10 600). The yield of the α,β unsaturated aldehyde was estimated spectroscopically to be 22%.

The yield of unsaturated aldehyde when 1-deoxyoxodelcosine was heated for 3 h at 100° in 12 *N* sulfuric acid was estimated spectroscopically to be 12%.

*Des(oxymethylene)lycoctamone (**16**)*

Des(oxymethylene)lycoctonam (15) (1.01 g) was dissolved with stirring in 8 ml of concentrated sulfuric acid. After 5 h at room temperature the solution was poured onto crushed ice, and the product extracted into methylene chloride. The organic layers were washed free of acid using sodium carbonate solution, dried, and distilled, giving 706 mg of froth. This was adsorbed from benzene on 14 g of alumina, activity III. Benzene, and benzene–chloroform (1:1) eluted fairly pure des(oxymethylene)-lycoctamone. After recrystallization from acetone–hexane this gave 330 mg, m.p. 198–201° (237–241° in an evacuated capillary); $[\alpha]_D$ + 288° (*c*, 1.04). It had ν_{max} 246 mμ, (ε 10 700) and ν_{max} 3380, 1675, 1621, and 913 cm^{-1}.

Anal. Calcd. for $C_{22}H_{29}NO_5$: C, 68.19; H, 7.54; 2 OCH_3, 16.02. Found: C, 68.68; H, 7.67; OCH_3, 15.89.

Its n.m.r. spectrum had signals at τ 0.27 (1H), 3.37 (1H), 4.80 (1H), 4.87 (1H), 5.76 (1H), 6.50 (OCH_3), 6.68 (OCH_3), a one-hydrogen doublet (?) centered at 6.79 (J = 3.5 Hz), and a triplet centered at 8.89 (J = 7 Hz) (N—C_2H_5).

Treatment of des(oxymethylene)lycoctonam with 0.1% sulfuric acid in acetic acid at 110° for 1.5 h gave a product which had no maximum at 246 mμ.

*Dihydrodes(oxymethylene)lycoctamone (**17**)*

When hydrogenated over presaturated 30% palladium-on-charcoal in ethanol des(oxymethylene)lycoctamone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

absorbed consistently 1.2 mol of hydrogen. Chromatography of the product on neutral alumina, activity IV, gave a very readily (20% benzene in chloroform) eluted hydrogenolysis product, followed by a mixture of two dihydro products. The yield of the latter was approximately 81%. The mixture had m.p. 125–137° after recrystallization from acetone–ether–hexane; $[\alpha]_D$ 116° (*c*, 1.14 in chloroform).

Anal. Calcd. for $C_{22}H_{31}O_5N$: C, 67.84; H, 8.02. Found: C, 68.01; H, 8.22.

Hydrogenation of des(oxymethylene)lycoctamone over palladium black gave 1.05–1.17 mol uptake. The dihydro compound from this reduction had m.p. 125–128° after recrystallization from acetone–pentane. It had ν_{max} ($CHCl_3$) 1720 and 1605 cm^{-1} and only end absorption in the u.v.

Methyl Carbinols from Dihydrodes(oxymethylene)lycoctamone (17)

Dihydrodes(oxymethylene)lycoctamone mixture (272 mg) in dry ether–chloroform mixture was added to an excess of methyl magnesium iodide in ether. The mixture was refluxed for 3 h, then left overnight at room temperature. The excess reagent was decomposed with dilute sulfuric acid, and the product extracted into chloroform. This mixture (300 mg) was chromatographed on neutral alumina, activity IV. After a weakly adsorbed fore-run, carbinol 1 was eluted with 50% chloroform–benzene giving 45 mg, m.p. 179–182°, $[\alpha]_D$ 112° (*c*, 0.9).

Anal. Calcd. for $C_{23}H_{35}O_5N$: C, 68.12; H, 8.70. Found: C, 68.02; H, 8.52.

Elution with chloroform and methanol in chloroform gave carbinol 2, 100 mg, m.p. 190–192°, $[\alpha]_D$ 109° (*c*, 1.28).

Anal. Calcd. for $C_{23}H_{35}O_5N{\cdot}H_2O$: C, 65.22; H, 8.81. Found: C, 66.23; H, 8.10.

Mol. wt. Calcd. for $C_{23}H_{35}O_5N$: 405. Parent ion at *m/e* 405.

Methyl Ketone 18

The mixture of methyl carbinols (72 mg) was left for 15 h in excess chromium trioxide – pyridine at room temperature, dilute sulfuric acid was added, and sulfur dioxide bubbled in until a clear green solution was obtained. This was extracted with chloroform to give 65 mg of product. The t.l.c. showed the presence of two similar products, whose ratio was not noticeably changed by 2 h exposure to potassium hydroxide in methanol. The mixture was chromatographed on grade IV neutral alumina, giving 57 mg of readily-eluted methyl ketones. The middle fractions crystallized from ether–hexane giving 23 mg, m.p. 149–151°, $[\alpha]_D$ 100° (*c*, 1.2); ν_{max} 1700, 1620 cm^{-1}.

Anal. Calcd. for $C_{23}H_{33}O_5N$: C, 68.46; H, 8.24. Found: C, 68.31; H, 8.09.

The mother liquors and the other ketone-rich fractions gave nearly identical i.r. spectra, so were combined for Baeyer–Villiger oxidation.

Epoxy Diol

A mixture of the methyl ketones (**18**) (254 mg) was treated with excess trifluoroperacetic acid in methylene chloride, the solution refluxed for 1 h, then left at room temperature for 3–4 h. Aqueous sodium sulfite was added, then the methylene chloride layer separated and washed with sodium carbonate solution. The product was hydrolyzed by 1 h refluxing with potassium hydroxide in ethanol. After removal of the alcohol under reduced pressure the residue was taken up in dilute acid and extracted with chloroform, giving 156 mg of product. This gave two main spots on t.l.c. Concentration of the aqueous layers followed by further extraction gave 50 mg of more polar products. The main product was chromatographed on alumina, activity IV. The least polar compound, eluted with benzene–chloroform mixtures and chloroform, crystallized readily from chloroform–ether giving 70 mg, m.p. 232–235°, $[\alpha]_D$ 62 (*c*, 0.98), ν_{max} ($CHCl_3$) 1625 cm^{-1}. Its n.m.r. spectrum had a 1H signal near τ 5.8 superimposed on the *N*-ethyl quartet (CHOH), a 1H singlet at τ 6.09 (C-15 hydrogen) and two 1H singlets at τ 7.2 and 7.3 (H_2C C).

Anal. Calcd. for $C_{21}H_{31}O_6N$: C, 64.10; H, 7.94. Found: C, 64.23; H, 7.69.

The second major product was not obtained pure.

Epoxy Ketol 19

Crystalline epoxy diol (21 mg) was left overnight with 25 mg of chromium trioxide in pyridine. The 21 mg of product had a weak carbonyl peak near 1725 cm^{-1} in carbon tetrachloride. The t.l.c. showed the presence of considerable unchanged alcohol. Repetition of the oxidation on the mixture increased the carbonyl intensity; however unchanged alcohol was still present and semi-crystalline, but not completely pure, ketone was obtained. Oxidation of the epoxy diol with chromium trioxide in acetic acid or Kiliani reagent gave mixtures of carbonyl compounds, probably because of opening of the epoxide ring.

Olefin 20

Des(oxymethylene)lycoctamone (320 mg) in ethylene glycol (10 ml) and hydrazine hydrate (10 ml) was heated at 120° for 1 h. Potassium hydroxide (900 mg) was added and the reaction temperature raised to 180–190° for 4 h. The solution was cooled, acidified with 6 *N* hydrochloric acid, and extracted with chloroform. The product (316 mg) crystallized on standing. Its n.m.r. spectrum showed the presence of a large proportion of the exocyclic olefin **20**. The t.l.c. showed mainly one spot which was resolved into three on silica–$AgNO_3$ plates. The main spot was the one with the lowest R_f, corresponding to the exocyclic olefin **20**, while the other spots corresponded to olefins **21** and **22**. After recrystallization from chloroform–acetone, 140 mg of nearly pure **20** was obtained (m.p. 212–216°). A second recrystallization from the same solvent gave a sample with m.p. 222–224°, $[\alpha]_D$ 142° (*c*, 1.06 in chloroform).

Anal. Calcd. for $C_{22}H_{31}O_4N$: C, 70.75; H, 8.37. Found: C, 70.96; H, 8.57. The sample had ν_{max} (Nujol) 3300, 1622 cm^{-1} and gave n.m.r. signal at τ 4.6 (1H), 4.75 (1H), and 5.26 (2H).

Olefin 21

Des(oxymethylene)lycoctamone (70 mg) was dissolved in a chloroform–ether mixture, then ethane dithiol (0.2 ml) and redistilled BF_3 etherate (0.2 ml) added. The reaction mixture was left at room temperature for 2 h. Excess aqueous sodium hydroxide (4 *N*) was added and the solution extracted with ether. The ether extract was washed with 4 *N* aqueous NaOH, then with water. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

product (70 mg) crystallized from $CHCl_3$–ether–hexane; m.p. 182–184°; $[\alpha]_D$ +244° (*c*, 0.8 in $CHCl_3$).

Anal. Calcd. for $C_{24}H_{33}NO_4S_2$: C, 62.19; H, 7.18. Found: C, 61.95; H, 7.43.

Thioketal (45 mg) in acetone was refluxed for 6 h with excess deactivated Ni(R). The Ni(R) was filtered off and washed six times with hot acetone. The product (30 mg) crystallized on standing and was purified by preparative t.l.c. It was recrystallized from $CHCl_3$–ether–hexane, m.p. 171–173°; $[\alpha]_D$ +213° (*c*, 0.55 in $CHCl_3$).

Anal. Calcd. for $C_{22}H_{31}NO_4$: C, 70.75; H, 8.37. Found: C, 70.98; H, 8.71.

The n.m.r. spectrum of the product had a strong signal at τ 8.30 (CH_3—C=C). The t.l.c. on silica gel – silver nitrate showed the presence of a small amount of olefin **22**, with olefin **21** as the main product.

High Temperature Wolff–Kishner Reduction (Olefin 22)

Des(oxymethylene)lycoctamone (100 mg) in ethylene glycol (5 ml) and hydrazine hydrate (4 ml) was heated for 1½ h. Potassium hydroxide (400 mg) was added and the reaction mixture heated at 220° for 4 h. Work-up as usual yielded crystalline material (95 mg). The t.l.c. on silica gel – silver nitrate showed this to be a mixture of all three olefins as before but with an increased amount of the least polar one (**22**).

The mixture (95 mg) was heated in ethylene glycol (5 ml) with KOH (2.5 g) for 2 h at 220°. The product was a yellow oil (60 mg) and showed two shots on an ordinary plate. Separation by preparative t.l.c. yielded two crystalline fractions, the less polar being the required olefin fraction (40 mg). The more polar (20 mg) compound had no vinyl proton signals in its n.m.r. spectrum and was set aside (this was also formed to some extent in the gentler Wolff–Kishner reduction). The olefin fractions were shown by t.l.c. on a silica gel – silver nitrate plate to be almost pure olefin **22**. This crystallized from acetone–ether–hexane mixture, and had m.p. 176–186°. After one recrystallization it had m.p. 186–189° and $[\alpha]_D$ +52° (*c*, 1.02 in $CHCl_3$).

Anal. Calcd. for $C_{22}H_{31}NO_4$: C, 70.75; H, 8.37. Found: C, 70.36; H, 8.82. The n.m.r. spectrum showed signals at τ 4.52 (1H), 4.65 (1H), 4.95 (1H) and 8.39 (3H).

A mixture of olefins from Wolff–Kishner reduction at 180° was shaken with H_2 in ethanol over 10% palladium-on-charcoal; approximately 1 mol of H_2 was taken up in 3 min. The product crystallized spontaneously and on silica gel – silver nitrate plates showed mainly one spot with none of the olefins remaining. It crystallized from $CHCl_3$–ether–hexane to give m.p. 185–192°. Its n.m.r. spectrum still contained the signals for the exocyclic methylene group (C-18) and was indistinguishable from that of dihydrodes(oxymethylene)lycoctam.

Oxidation of Olefin 20

The exocyclic olefin (30 mg) in ether (3 ml) and pyridine (3 ml) was treated with OsO_4 (3 mg) overnight at room temperature. The osmate ester was destroyed by stirring with aqueous sodium bisulfite for 20 min. The crude diol (25 mg) obtained by extraction with $CHCl_3$ was dissolved in MeOH (5 ml) and treated with sodium periodate (30 mg) in water at 5° for 3 h. Water was added and the solution extracted with $CHCl_3$ to yield crude ketone **23** (20 mg) which crystallized from an acetone–ether–hexane mixture giving 10 mg with m.p. 224–228° and $[\alpha]_D$ +141° (*c*, 0.69 in $CHCl_3$).

Anal. Calcd. for $C_{21}H_{29}NO_5$: C, 67,18; H, 7.79. Found: C, 67.61; H, 8.00. The ketone had ν_{max} (CCl_3) 1742 (cyclopentanone) and 1647 cm^{-1} (lactam) and n.m.r. peaks at τ 4.52 (1H) and 4.77 (1H) (exocyclic methylene).

Ketone 24

Olefin **21** (140 mg) contaminated with some olefin **19** was treated with excess diborane in tetrahydrofuran under nitrogen for 12 h. After removal of the solvent the residue was refluxed for 5 min with ethanol containing hydrogen peroxide and potassium hydroxide. The product was contaminated with "polymeric" material, but was purified by chromatography on alumina (activity III). The more readily eluted alcohol **25** (25 mg, m.p. 217–223°) was followed by the desired alcohol from **21**. This appeared to be a mixture of stereoisomers due to attack of diborane on both sides of the ring. It crystallized from acetone–hexane as rods, m.p. 150–166°, ν_{max} (CCl_4) 3650, 3530, and 1643 cm^{-1}. After sublimation it analyzed for a hemi-hydrate.

Anal. Calcd. for $C_{22}H_{33}NO_5 \cdot \frac{1}{2}H_2O$: C, 65.97; H, 8.56. Found: C, 65.66; H, 8.76.

The alcohols from **21** were oxidized with pyridine – chromium trioxide complex. A benzene solution of the product was filtered through a short column of alumina, activity III. The material recovered from the benzene crystallized but was apparently a mixture of epimers with m.p. 145–158°. After recrystallization from acetone–hexane and sublimation, a fraction with m.p. 161–165.5° was obtained. The bulk of the product analyzed correctly for ketone **24**.

Anal. Calcd. for $C_{22}H_{31}O_5N$: C, 67.84; H, 8.02. Found: C, 67.74; H, 7.94.

The ketone had ν_{max} (CCl_4) 3420, 1735 (shoulder), 1724, and 1645 cm^{-1}, unchanged at higher dilution. Its n.m.r. spectrum contained the two-hydrogen signal characteristic of the exocyclic methylene group.

Alcohol 25

Olefin **22** (m.p. 187–190°, 120 mg) was hydrated as described for olefin **21**. After one recrystallization from alcohol and two from acetone–hexane, alcohol **25** separated as prisms, m.p. 223–224°, $[\alpha]_D$ 124° (*c*, 0.77). It had ν_{max} ($CHCl_3$) 3560, 3440 and 1630 cm^{-1}. It was sublimed for analysis.

Anal. Calcd. for $C_{22}H_{33}O_5N$: C, 67.49; H, 8.50. Found: C, 67.24; H, 8.66.

The n.m.r. spectrum showed signals at δ 4.62 and 4.75 (>C=CH_2), 5.7 (d, OH), 5.82 (1H), 6.53 (OCH_3), 6.60 (OCH_3), 6.79, 6.85 (d?, 2H), 7.56 (OH), 8.87 (3H triplet, J = 7 Hz) and 8.97 and 9.04 (3H doublet). Another sample with identical rotation and i.r. and n.m.r. spectra melted at 233–236°.

The alcohol was only acetylated to a small extent after 16 h at room temperature in 1:1 acetic anhydride – pyridine mixture. It was inert to chromium trioxide – pyridine and potassium dichromate in acetic acid. Jones reagent (19) in acetone at room temperature produced some ketone (ν_{max} ($CHCl_3$) 1726 cm^{-1}) but much of the alcohol was converted to acids.

Dihydrodes(oxymethylene)lycoctam (26)

When hydrogenated over 30% palladium-on-charcoal in acetic acid, des(oxymethylene)lycoctamone took up 1.8 mol of hydrogen. The product gave mainly one spot on t.l.c. with R_f identical to the minor product from the reduction over platinum in acetic acid (see below). Chromatography on alumina, activity IV, gave pure material as the first eluted substance. When recrystallized from chloroform–hexane it had m.p. 189–195°; $[\alpha]_D$ 130° (*c*, 0.71). Its n.m.r. spectrum had the pair of one-hydrogen singlets at τ 4.70 and 4.75 characteristic of the exocyclic methylene group, and a new methyl doublet centered at τ 9.05 (J = 5 Hz). The hydrogen on C-15 gave a sharp singlet at τ 5.88. After sublimation it had m.p. 203–206°; ν_{max} (CCl_4) 3545, 1641 cm^{-1}.

Anal. Calcd. for $C_{22}H_{33}O_4N$: C, 70.37; H, 8.86. Found: C, 71.67; H, 8.72.

Hydrogenation of the dihydro compound over platinum in acetic acid gave a product with R_f on t.l.c. identical with that of tetrahydrodes(oxymethylene)lycoctam.

Tetrahydrodes(oxymethylene)lycoctam (27)

Des(oxymethylene)lycoctamone (130 mg) in acetic acid was shaken for 15 h with Adam's platinum catalyst and hydrogen. The product gave two main spots on t.l.c. A repetition of the hydrogenation resulted in a small uptake of hydrogen and some reduction in intensity of the spot with higher R_f. The products were separated by chromatography on alumina into two hydrogenolysis products and a more polar mixture presumably having primary alcohol functions. The least polar compound still had vinyl hydrogens in its n.m.r. spectrum and had ν_{max} 910 cm^{-1} (=CH_2) (see dihydrodes(oxymethylene)lycoctam).

The second product eluted (57 mg) had m.p. 208–214° after sublimation and $[\alpha]_D$ 24° (*c*, 0.82).

Anal. Calcd. for $C_{22}H_{35}O_4N$: C, 69.99; H, 9.35; N, 3.71. Found: C, 70.29; H, 9.10; N, 3.91.

Its n.m.r. spectrum had no vinyl hydrogen signals. The hydrogen on C-15 now gave a broad ($w_{1/2}$ Hz) singlet at τ 6.40.

Epoxy Compound 28

Dihydrodes(oxymethylene)lycoctam (20 mg) was treated with excess trifluoroperacetic acid in methylene chloride in the presence of sodium dihydrogen phosphate. The reaction mixture was stirred for 30 min, refluxed for 1 h then stirred for 4 h at room temperature. The excess peracid was reduced by aqueous sodium sulfite and the organic layer washed free of acid using aqueous sodium carbonate. The product gave one main spot on t.l.c. Chromatography on grade IV alumina gave 8 mg of crystals, m.p. 200–205°, $[\alpha]_D$ 75° (*c*, 0.91). This was sublimed for analysis.

Anal. Calcd. for $C_{22}H_{33}O_5N$: C, 67.49; H, 8.50. Found: C, 67.52; H, 8.41. The n.m.r. spectrum showed a quartet centered at τ 5.75, J = 7 Hz (N—CH_2—CH_3), a doublet at τ 6.1 (J = 3.5 Hz, 15-H), τ 6.51 and 6.69 (two OCH_3), and two 1H singlets at τ 7.14 and 7.22 (hydrogens on C-18).

Reduction of the Epoxy Compound 28

A solution of 330 mg of epoxide in 20 ml of dry dioxan containing *ca.* 1 g of lithium aluminum hydride in suspension was refluxed for 17 h. The product was separated into basic (310 mg) and neutral (18 mg) components. The base gave two spots on t.l.c. The more polar of the two was obtained nearly free of the less polar by chromatography on alumina, activity IV (eluted with benzene and chloroform). After sublimation, the dihydroxy base melted at 189–190°.

Anal. Calcd. for $C_{22}H_{37}O_4N$: C, 69.62; H, 9.83. Found: C, 69.67; H, 9.29.

Permanganate Oxidation of the Dihydroxy Base

A solution of 220 mg of the base in a mixture of 10 ml of acetone, 5 ml of acetic acid, and 1 ml of water was oxidized by addition of 540 mg of potassium permanganate over a period of 3 h. The neutral product (210 mg) was chromatographed on alumina, activity III. Chloroform and methanol in chloroform eluted 98 mg of **29** which crystallized from acetone as square prisms, m.p. 210–218° (47 mg).

Anal. Calcd. for $C_{22}H_{35}O_5N$: C, 67.14; H, 8.97. Found: C, 67.23; H, 8.96. It had ν_{max} ($CHCl_3$) 1625 cm^{-1} and $[\alpha]_D$ +21° (*c*, 0.63 in $CHCl_3$). Its n.m.r. spectrum had a 2H quartet at τ 5.70, a one-hydrogen doublet at 6.23 (J = 2 Hz, C-15 hydrogen), methoxyl signals at τ 6.60 and 6.71, and a new methyl singlet at τ 8.48.

The other more readily eluted neutral products (using up to 70% chloroform in benzene) were not characterized, but contained the *N*-acetyl compound (ν_{max} 1670 cm^{-1}), a second lactam (ν_{max} 1630 cm^{-1}), and probably the desethyl lactam.

Lead Tetraacetate Oxidation of 29

Compound **29** in a saturated solution of lead tetraacetate in acetic acid (1 mg of **29** per ml) reduced 0.68 mol of oxidant in 40 min, 1.26 mol in 2 h, and 1.46 mol in 20 h. Preparative oxidations were run under these conditions for 1.5 h. The n.m.r. spectrum of the crude product had a signal at τ 5.40 (N—CHC=O), and sharp signals at τ 7.52, 7.89, and 8.00. The product (200 mg) chromatographed on alumina, activity III. Only the early eluate (40–60% chloroform in benzene) crystallized, giving 30 mg. After sublimation this melted at 140–146° and had $[\alpha]_D$ −5° (*c*, 1.3 in $CHCl_3$) and ν_{max} ($CHCl_3$) 1716, 1627 cm^{-1}.

Anal. Calcd. for $C_{22}H_{33}O_5N$: C, 67.49; H, 8.50. Found: C, 67.30; H, 8.27.

The n.m.r. spectrum showed signals at τ 5.95 (15-hydrogen), a doublet at τ 5.88 and 6.10, two three-hydrogen signals at τ 6.43 and 6.70, and a three-hydrogen signal at τ 8.42. This agrees with structure **30**.

We thank Dr. K. H. Palmer, who first prepared 18-deoxylycoctamone, Mr. R. Lauzon for i.r. spectra, Mr. H. Seguin for microanalyses, and Mr. M. Lesage and Mr. J. Nicholson for n.m.r. spectra.

Secondary Kinetic Isotope Effects in Bimolecular Nucleophilic Substitutions. IV. The Temperature Dependence of the Deuterium Effect for the Reaction of *N,N*-Dimethyl-d_6-aniline and Methyl *p*-toluenesulfonate. Correlation of Isotope Effects on Activation Parameters[1,2]

K. T. Leffek and A. F. Matheson[3]
Chemistry Department, Dalhousie University, Halifax, Nova Scotia

Received August 27, 1970

The temperature dependence of the isotope effect for the reaction of dimethylaniline and dimethyl-d_6-aniline with methyl *p*-toluenesulfonate in nitrobenzene solvent has been measured, yielding the result, $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}) = -134 \pm 30$ cal mole^{-1}, $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger}) = -0.15 \pm 0.09$ cal mol^{-1} degree^{-1}.

This result has been compared with 15 other temperature dependence studies by plotting $\Delta\Delta H^{\ddagger}$ per D atom *vs.* $T\Delta\Delta S^{\ddagger}$ per D atom. The points fall on two clearly separated straight lines. A similar correlation is found for a plot of $\Delta\Delta G^{\ddagger}$ per D atom *vs.* $\Delta\Delta H^{\ddagger}$ per D atom.

The significance of the correlation is discussed and a possible rationalization, in terms of mechanism and particularly the role of the solvent is given.

Canadian Journal of Chemistry, 49, 439 (1971)

Introduction

Kaplan and Thornton (1) have studied the effect of deuterium substitution for the methyl hydrogens of *N,N*-dimethylaniline on the rate of the quaternization reaction of the amine with methyl *p*-toluenesulfonate in nitrobenzene solvent at 51°. From frequency change considerations and force constant model calculations, they concluded that steric interactions yielded the most satisfactory explanation of their results. This implies that the isotope effect is a rate change brought about primarily by a difference between the enthalpies of activation for the normal and deuterated species, rather than a difference between the entropies of activation. The only temperature dependence study of a secondary deuterium isotope effect on this type of reaction was carried out by Leffek and MacLean (2) who found that the rate change resulting from the deuteration of methyl iodide in its reaction with 2-picoline in benzene was due entirely to an entropy effect. It seemed of interest, therefore, to carry out a temperature dependence study on the isotope effect for *N,N*-dimethyl-d_6-aniline and methyl *p*-toluenesulfonate.

[1]Presented in part at the International Conference on the Mechanisms of Reactions in Solution at the University of Kent at Canterbury, England, July 20–24, 1970.

[2]Based on a thesis submitted by A. F. Matheson in partial fulfillment of the requirements for the degree of Doctor of Philosophy at Dalhousie University, 1969.

[3]Present address: Uniroyal Research Centre, Guelph, Ontario.

Results and Discussion

Since the isotope effect measured by Kaplan and Thornton (1) at 51° was about 12% ($k_H/k_D = 0.88_3$), it was necessary to determine the rate ratio over a wide temperature range in order to be sure that a small change in the rate ratio with temperature would be detected. Table 1 shows the rate constants for the reaction of dimethylaniline and its deuterated analogue with methyl *p*-toluenesulfonate in nitrobenzene solution over a range of temperatures from 30 to 120°. The value reported by Kaplan and Thornton (1) is included and was used together with the present results to calculate the activation parameter differences by the least squares method. Equation 1 yielded $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}) = -134 \pm 30$ cal mol^{-1} and $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger}) = -0.15 \pm 0.09$ cal mol^{-1} deg^{-1}.

$$[1] \quad \ln \frac{k_H}{k_D} = \frac{(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})}{RT} - \frac{(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})}{R}$$

The isotope effect is seen to be mainly an enthalpy effect, supporting the interpretation offered by Kaplan and Thornton (1) and also the argument presented earlier by Brown and McDonald (3), that nonbonded interactions play a major role in the inverse effects found for Menschutkin reactions where the positions of isotopic substitution are in the tertiary amine. The zero-point

energy approximation predicts an increase in the separation of the vibrational zero-point energy levels between the normal and deuterated molecules on attainment of the transition state, when the positions of isotopic substitution experience a more crowded environment, *i.e.* $E_D - E_H$ ($=\Delta\Delta H^{\ddagger}$) is negative. Such a situation holds in the present reaction if the initial aniline is considered to consist of an almost planar, trigonal conformation about the central nitrogen atom. Spectroscopic and theoretical evidence in support of this assumption is available (4, 5). In the transition state, the change towards a tetrahedral structure about the nitrogen atom will bring the methyl (deuteromethyl) groups into closer proximity with one another, with an accompanying increase in deformation frequencies. Kaplan and Thornton's i.r. assignments (1) for the normal and deuterated anilines and the corresponding product quaternary ammonium salts appear to indicate that the stretching frequencies are affected to only a minor degree.

Correlation of Isotope Effects on Activation Parameters

A major problem in the study of secondary deuterium isotope effects lies in the lack of understanding of the relative variations in the isotope effects on the enthalpy and entropy of activation. Individual cases have been explained in terms of physical-organic concepts (6) or in theoretical terms (7), but no general correlations have been made. For this reason a plot of $\Delta\Delta H^{\ddagger}$ ($=\Delta H_D{}^{\ddagger} - \Delta H_H{}^{\ddagger}$) per D atom *vs.* $T\Delta\Delta S^{\ddagger}$ per D atom was made as shown in Fig. 1, from the data available in the literature, which are summarized in Table 2. The value of T was selected as 300 °K. The use of $T\Delta\Delta S^{\ddagger}$ rather than the entropy of activation which Leffler used (8) allows a direct comparison of the contributions from the enthalpy and entropy of activation to the free energy of activation isotope effect. The selected reactions all involve relatively straight-forward nucleophilic substitution at a saturated carbon atom, for which the temperature dependence study has been made using at least three different temperatures. Reactions in which σ–π overlap with the forming carbonium ion have been postulated (9) and reactions involving free radical formation (10), have not been included.

A clear separation of reactions under consideration is seen in Fig. 1, which are labelled

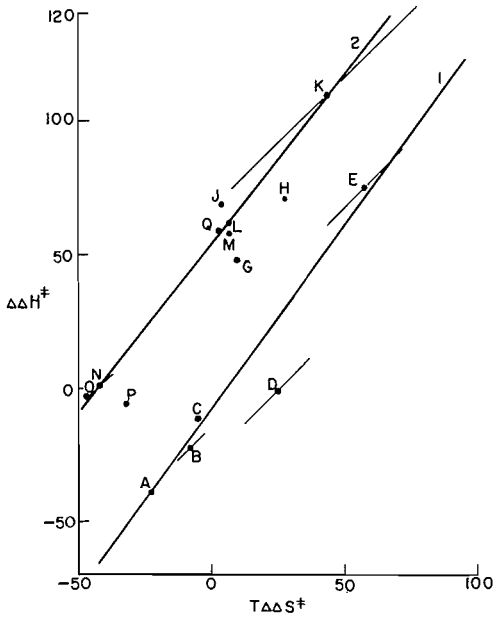

FIG. 1. Correlation of the enthalpy and entropy contributions to the secondary deuterium isotope effect at 300 °K for nucleophilic substitution reactions at saturated carbon. The letters refer to the reactions in Table 2.

series 1 and series 2 for the set with the lower $\Delta\Delta H^{\ddagger}$ and the set with the higher $\Delta\Delta H^{\ddagger}$, respectively.

Before considering these linear free energy relationships further, it is necessary to examine their meaningfulness. Leffler has intensively studied the relationship between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for selected reaction series of structurally similar substrates and demonstrated that for many such systems an isokinetic relationship (8)

$$\delta\Delta H^{\ddagger} = \beta\,\delta\Delta S^{\ddagger}$$

holds where β is a constant with the dimensions of absolute temperature. Leffler and Grunwald (11) and several others (12–15) have considered the possibility that the linear relationship between enthalpy and entropy of activation may be accounted for solely in terms of experimental error, since $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are not independent parameters so that an error in one yields a corresponding error in the other (16). This leads to an error contour about a given point which is not the usual circle but an elongated ellipse with the long axis inclined to the entropy co-ordinate at a slope equal to the mean experimental temperature (11). Thus an error in $\Delta H^{\ddagger}$ will only displace a given point along the correlation line and will not produce a set of scattered points. These observations may give rise to doubts concerning the meaningfulness of $\Delta H^{\ddagger}$ *vs.* $\Delta S^{\ddagger}$ plots in which all the points fall on a single straight line, but they cannot account for the separation of a correlation into two parallel lines.

In Fig. 1, the circles indicate only the position of the experimental points, but some error limits are illustrated as lines through certain points. In

the examples showing error limits, the limits are those obtained as standard deviations in $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ by application of the usual least squares treatment to a series of rate ratios measured at a series of different temperatures. Wiberg (16) has warned that in these circumstances it is the maximum error which should be considered, but this is rather difficult to estimate in an objective manner. Therefore, the objective standard deviation is shown which may be multiplied by 2 or 3 to estimate the maximum error.

Exner (14) has shown that apart from the problem of large errors in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, a purely random set of rate constants measured at two different temperatures will yield activation parameters which show a correlation coefficient of 0.998. Exner demonstrated that meaningful correlations may be established between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ indirectly by plotting log k at one temperature against log k at a second temperature, or by plotting the activation energy against log k. The latter test has been applied to the present case by plotting $\Delta\Delta H^{\ddagger}$ against $\Delta\Delta G^{\ddagger}$ and is shown in Fig. 2. The scales of both Figs. 1 and 2 exclude reaction F (Table 2) but this point is so far removed from the others that it could be correlated with either or both series of reactions. Thus, it is concluded that a genuine compensatory effect between $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ exists irrespective of the position of deuteration. This emphasizes the unitary nature of secondary deuterium isotope effects with respect to the site of isotope substitution and demonstrates the triviality of the division of the effects into α-, β-effects, etc. Such a classification is useful, but should not be allowed to obscure the fact that the rate changes which result upon isotopic substitution come about through changes in vibrational frequencies of the molecule and that these changes are merely interpreted by attaching names to them such as hyperconjugation, induction, steric effects, etc.

The validity of the zero-point energy approximation, which assumes that $\Delta\Delta H^{\ddagger}$ is the major contributor to $\Delta\Delta G^{\ddagger}$ and hence to the rate ratio, is clarified by the correlation in Fig. 1. The slopes of approximately 1.3 show that $\Delta\Delta H^{\ddagger}$ increases more rapidly than does the compensating $T\Delta\Delta S^{\ddagger}$ term within each series. The series 1 line passes very close to the origin (at $T\Delta\Delta S^{\ddagger} = 0, \Delta\Delta G^{\ddagger} \cong -7$ cal mol^{-1}), so that $\Delta\Delta H^{\ddagger}$ provides the larger contribution to $\Delta\Delta G^{\ddagger}$ for all but the very small normal and inverse isotope effects. However, since the series 2 line does not pass through the origin, the $T\Delta\Delta S^{\ddagger}$ term is approximately equal to or larger than the $\Delta\Delta H^{\ddagger}$ contribution, for $\Delta\Delta G^{\ddagger}$ values ranging from approximately -40 to $+40$ cal mol^{-1} per D atom. The corresponding rate changes for such isotope effects can be large for molecules containing several deuterium atoms, *e.g.* the solvolysis of isopropyl-β-d_6 compounds in water (points labelled N, O, and P in Fig. 1) exhibit rate ratios of about 1.3–1.5 (6).

Although the two sets of reactions do not correspond to their molecularity (*i.e.* S_N2 or S_N1), the reactions of series 1 are predominantly S_N2 and most of those of series 2 have considerable S_N1 character. However, a more distinct difference between the two series is that one set consists exclusively of solvolytic reactions while the other contains non-solvolytic reactions. Thus, the most obvious external source of the shift from series 1 to series 2 is the solvent and its behavior on passage from the ground state to the transition state, which, in the majority of the latter cases, involves a reaction center with a degree of electron deficiency. Therefore, it is proposed that the distinction between the two series is engendered by a more effective increase in solvation on passage to the transition state for the reactions in series 2 compared to those in series 1, because of the vulnerability of their carbon centers to solvent approach.

It is of interest to consider to what extent an unsolvated model for the reactions is capable of explaining the separation of the two series. A simple approach is to consider the separation as an entropy shift, *i.e.* series 2 is characterized by more negative $T\Delta\Delta S^{\ddagger}$ terms than series 1. Wolfsberg and Stern (17) have carried out theoretical calculations starting from general eq. 2 in which the symbols have their standard

$$[2]\quad k_H/k_D = \left[\frac{M_D}{M_H}\cdot\frac{M_H^{\ddagger}}{M_D^{\ddagger}}\right]^{3/2}\left[\frac{\Pi I_D}{\Pi I_H}\cdot\frac{\Pi I_H^{\ddagger}}{\Pi I_D^{\ddagger}}\right]^{1/2} \times \prod^{3N-6}\frac{e^{-\frac{1}{2}h\nu_D/kT}}{e^{-\frac{1}{2}h\nu_H/kT}}\cdot\prod^{3N^{\ddagger}-7}\frac{e^{-\frac{1}{2}h\nu_H^{\ddagger}/kT}}{e^{-\frac{1}{2}h\nu_D^{\ddagger}/kT}} \times \prod^{3N-6}\frac{(1-e^{-h\nu_D/kT})^{-1}}{(1-e^{-h\nu_H/kT})^{-1}} \times \prod^{3N^{\ddagger}-7}\frac{(1-e^{-h\nu_H^{\ddagger}/kT})^{-1}}{(1-e^{-h\nu_D^{\ddagger}/kT})^{-1}}$$

meanings (17). Following Wolfsberg and Stern, eq. 2 may be abbreviated to eq. 3 where MMI

$$[3]\quad k_H/k_D = (\mathrm{MMI}) \times (\mathrm{ZPE}) \times (\mathrm{EXC})$$

TABLE 3. Calculated $\Delta\Delta S^{\ddagger}$ contributions from mass and moment of inertia changes for trigonal transition states

C–Y distance (Å)	C–X distance (Å)	Mass of X (a.w.u.)	$\Delta\Delta S_I{}^{\ddagger}$	$\Delta\Delta S_M{}^{\ddagger}$ (cal mol^{-1} deg^{-1})	$\Delta\Delta S_{MMI}{}^{\ddagger}$
2.5	1.5	120.5	−0.440	−0.031	−0.471
2.5	2.5	120.5	−0.443	−0.031	−0.474
2.5	3.5	120.5	−0.443	−0.031	−0.474
2.5	2.5	60.25	−0.438	−0.020	−0.458
2.5	2.5	120.5	−0.443	−0.031	−0.474
2.5	2.5	180.75	−0.442	−0.037	−0.479
—	—	—	+0.927	+0.479	+1.406

represents the mass, moment of inertia term of eq. 2, ZPE, the zero-point energy term, and EXC, the excitation of vibrations term. If the EXC is approximated to unity

$$[4] \qquad k_H/k_D = (\text{MMI}) \times (\text{ZPE})$$

or

$$[5] \qquad \ln k_H/k_D = \ln (\text{MMI}) + \ln (\text{ZPE})$$

When eq. 5 is compared to eq. 1 the entropy contribution to the isotope effect

$$\Delta\Delta S^{\ddagger} = -R \ln (\text{MMI})$$

or

$$[6] \quad \Delta\Delta S^{\ddagger}{}_{MMI} = -\frac{R}{2} \ln \left[\frac{\Pi I_D \, \Pi I_H{}^{\ddagger}}{\Pi I_H \, \Pi I_D{}^{\ddagger}}\right] - \frac{3R}{2} \ln \left[\frac{M_D \, M_H{}^{\ddagger}}{M_H \, M_D{}^{\ddagger}}\right]$$

Thus $\Delta\Delta S_{MMI}{}^{\ddagger}$ can be estimated from the geometry of a model reaction and the assumed geometry for the corresponding transition state. Wolfsberg and Stern have made such calculations for a variety of models (17), two of which have been developed here. The basic S_N2 reaction between a nucleophile X and a substrate CH_3Y has been considered, in which the C—Y bond distance is taken as 2.00 Å and the atomic weight of Y as 120.5, *i.e.* CH_3Y is similar to CH_3I. The substrate was treated as tetrahedral and the transition state as a trigonal bipyramid, with $X\hat{C}Y = 180°$ and $H\hat{C}H = 120°$. Table 3 shows the effect of varying the transition state structure and it may be seen that altering the mass of the attacking nucleophile X and its distance from the carbon atom have very little effect on $\Delta\Delta S_{MMI}{}^{\ddagger}$, which remains virtually constant at -0.47 cal mol^{-1} deg^{-1}.

In contrast to this, the last line of Table 3 shows that a hypothetical transition state consisting of a trigonal CH_3 group unassociated with either X or Y yields a $\Delta\Delta S_{MMI}{}^{\ddagger}$ of $+1.41$ cal mol^{-1} deg^{-1}. This is one extreme of the range of possible transition states for S_N1 reactions, the other being the tetrahedral CH_3Y, identical to the initial state which gives an (MMI) of unity (17) and, therefore, $\Delta\Delta S_{MMI}{}^{\ddagger}$ equal to zero.

These calculations show that S_N1 reactions should exhibit a positive $\Delta\Delta S^{\ddagger}$ provided that the approximation (EXC) = 1 is valid, which may not always be the case (17). Nevertheless, in semi-quantitative terms, $\Delta\Delta S^{\ddagger}$ would be expected to correlate with mechanism.

Inspection of Table 2 and Fig. 1 reveals that negative $T\Delta\Delta S^{\ddagger}$ terms are found in series 1 for those reactions which are S_N2 with the exception of that for reaction D, which does not fall on the line. In series 2, the most negative entropy terms are found for the three *sec*-propyl compounds studied, although both primary and tertiary compounds are seen to yield positive entropy terms. There is no doubt that solvation effects will modify the predictions of Table 3 to a marked degree, especially in the solvolytic reactions, so the agreement between the experimental values and those of Table 3 is no worse than is to be expected. It is concluded that the unsolvated model, although useful in itself, is insufficient to fully account for the separation of the reactions into two series.

Experimental

Materials

N,N-Dimethylaniline was refluxed with acetic anhydride in a 2:1 ratio by weight for 3 h, then distilled at atmospheric pressure (26). The amine was then fractionally redistilled under vacuum and the middle fraction was collected and stored in an opaque container over calcium hydride and under nitrogen.

N,N-Dimethyl-d_6-aniline was prepared via trimethyl-d_9 phenylammonium iodide as described by Kaplan and Thornton (1). The deuterium source was methyl-d_3 iodide from Merck, Sharpe and Dohme of Canada, Ltd. The

overall yield was about 75%. An n.m.r. spectrum of a neat sample of product showed no signal for the methyl hydrogens and a mass spectrometric analysis gave 96.7% of d_6 product and 3.3% of d_5 product.

Commercial methyl tosylate was distilled *in vacuo* and the middle cut retained.

Trimethylphenylammonium tosylate was prepared by refluxing an equimolar mixture of methyl tosylate and *N,N*-dimethylaniline in benzene for 1 h. The reaction mixture was then stoppered and allowed to stand overnight. The white product was washed with anhydrous ether, twice recrystallized from isopropanol and stored under vacuum over phosphorus pentoxide. The yield was 75%, m.p. 160–161° (lit. (1) 160–161°).

Nitrobenzene solvent was dried over anhydrous calcium sulfate and distilled at atmospheric pressure, boiling range 210.5–211°.

Kinetic Measurements

The reaction rates were measured by following the change in conductivity with time using a Wayne–Kerr Universal bridge, model B 221 and cells manufactured by LKB—Producter AB (Sweden) of about 5 ml capacity and cell constant approximately 0.1 cm^{-1}. The oil filled constant temperature baths maintain the quoted temperatures to $\pm 0.01°$ at the lower temperatures and $\pm 0.02°$ at the higher temperatures.

The cells were washed with acetone, water, and acetone again and dried by a stream of nitrogen for 2 min before use. Calibration curves were obtained for concentration *vs.* conductivity of trimethylphenylammonium tosylate at each temperature. A stock solution of tosylate was prepared by weight and the conductances determined for a series of ten diluted solutions. The dilutions were made using the mechanical titrimeter built by Martin *et al.* (27), which had been calibrated by Kulin (28). Two of the calibration curves are illustrated in Fig. 3. The calibration curves obtained with undeuterated trimethylphenylammonium tosylate were also applied to the deuterated analogue, assuming that the isotope effect on the conductivity was negligible. This was checked experimentally and found to be true for the salt *N*-methyl-d_3-pyridinium iodide.

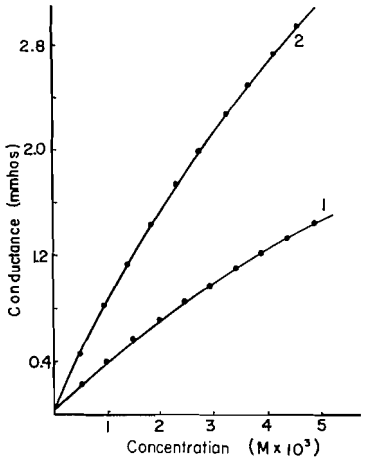

FIG. 3. Calibration graphs of concentration *vs.* conductance for trimethylphenylammonium tosylate in nitrobenzene. Curve 1 at 40° and curve 2 at 120°.

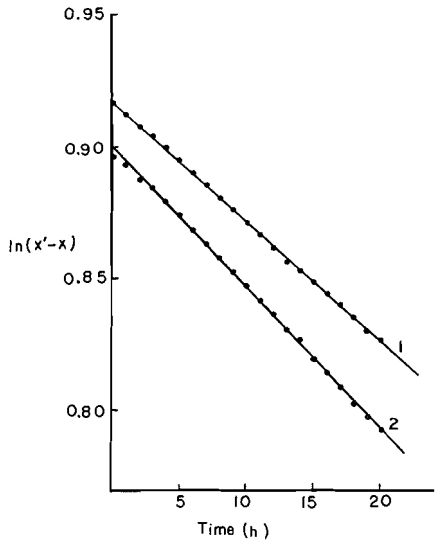

FIG. 4. Guggenheim plots for the reactions of dimethylaniline (1) and dimethyl-d_6-aniline (2) with methyl tosylate at 40° in nitrobenzene.

The kinetic runs were carried out under pseudo–first order conditions with initial concentrations of methyl tosylate and *N,N*-dimethylaniline approximately 0.1 and 3×10^{-3} *M* respectively. The first order rate constants were calculated by the Guggenheim method (29) by a least squares method applied to 21 conductivity readings made in each of the first and third half-lives of the reaction. Second order rate constants were found by division of the first order constant by the initial methyl tosylate concentration, corrected for solvent expansion to the appropriate temperature. Two runs are illustrated in Fig. 4.

The authors are grateful for financial support by the National Research Council of Canada and, specifically, for an NRCC Studentship to A.F.M. The loan of the mechanical titrimeter by Dr. R. E. Robertson, University of Calgary, Calgary, Alberta (formerly of NRCC, Ottawa), is also gratefully acknowledged.

Cinétique de l'oxydation du sous-oxyde de carbone en phase gazeuse

JEAN LEBEL[1] ET CYRIAS OUELLET
Département de Chimie, Université Laval, Québec 10, Québec

Reçu le 10 juillet 1970

Nous avons étudié la combustion lente et explosive du sous-oxyde de carbone, par la méthode statique, à des pressions inférieures à 500 mm Hg et à des températures de 560 à 680 °C. La réaction se fait en deux temps, [*a*] et [*b*]. La réaction *b* étant inhibée par C_3O_2. L'oxydation lente [*a*] est suivie

[*a*] $$C_3O_2 + 2O_2 = 2CO + CO_2 + O_2$$

[*b*] $$2CO + O_2 = 2CO_2$$

de l'oxydation [*b*] explosive ou lente selon que l'on est en-dessous ou au-dessus de la limite supérieure d'explosion du système $CO–O_2$. Au-dessus d'une autre limite de pression, le mélange $C_3O_2–O_2$ explose sans retard. La présence de H_2O accélère la réaction *a* et abaisse les limites d'explosion. L'oxydation lente a une énergie d'activation globale de 34 kcal/mol. Nous proposons une chaîne propagée par

$$C_3O_2 + O = C_2O + CO_2$$

$$C_2O + O_2 = 2CO + O$$

et ramifiée selon

$$CO_2^* + O_2 = CO_2 + O + O$$

dans une chaîne énergétique responsable de l'explosion.

The slow and the explosive combustion of carbon suboxide has been studied by the static method at pressures below 500 mm Hg and temperatures ranging from 560 to 680 °C. Reaction occurs in two distinct phases, [*a*] and [*b*], where [*b*] is inhibited by C_3O_2. The slow oxidation [*a*] is followed by

[*a*] $$C_3O_2 + 2O_2 = 2CO + CO_2 + O_2$$

[*b*] $$2CO + O_2 = 2CO_2$$

oxidation [*b*] which is explosive at the lower pressures but slow above the upper pressure limit for $CO–O_2$. Above another, higher pressure limit, the $C_3O_2–O_2$ mixture explodes without delay. Water accelerates reaction *a* and lowers the pressure limits. Reaction *a* shows an over-all activation energy of 34 kcal/mol. We suggest that chain propagation takes place according to

$$C_3O_2 + O = C_2O + CO_2$$

$$C_2O + O_2 = 2CO + O$$

and that an energy chain leads to the branching reaction

$$CO_2^* + O_2 = CO_2 + O + O$$

responsible for explosion.

Canadian Journal of Chemistry, **49**, 447 (1971)

Introduction

On connaît peu de choses sur la combustion du sous-oxyde de carbone. Clusius et Huber (1) ont montré que ce composé brûle avec une flamme bleue dans l'air sec et avec une flamme jaunâtre et fuligineuse dans l'air humide; ils ont aussi déterminé les limites d'allumage par étincelle de mélanges de plusieurs compositions. von Weyssenhoff *et al.* (2) ont trouvé qu'à la température ordinaire, le sous-oxyde ne réagit pas avec l'oxygène moléculaire, mais qu'il réagit lentement avec l'ozone et très rapidement avec l'oxygène atomique selon deux mécanismes donnant l'un 3 CO et l'autre CO_2 et le radical C_2O. La réaction du sous-oxyde avec l'oxygène atomique et celles de C_2O avec l'oxygène moléculaire et avec quelques autres composés ont été étudiées en détail par Liuti *et al.* (3), Williamson et Bayes (4), et Willis et Bayes (5). Lebel *et al.* (6) ont mis en évidence l'inhibition de l'explosion du système $CO–O_2$ par le sous-oxyde.

Nous avons entrepris une étude systématique de l'oxydation du sous-oxyde par l'oxygène moléculaire à hautes températures et des rapports entre cette réaction et l'oxydation du

[1]Adresse actuelle: Centre d'études universitaires, Rimouski, Québec.

monoxyde de carbone. Dans nos expériences, nous avons pris soin d'éviter la polymérisation et la présence de composés hydrogénés.

Méthode expérimentale

La réaction a été étudiée par la méthode statique dans un cylindre en Vycor de 22 × 4.5 cm dont la température était maintenue constante et uniforme à ±1 °C près dans un four. Environ 30 min avant chaque expérience, on introduisait les quantités désirées de sous-oxyde et d'oxygène dans un ballon auxiliaire en évitant que ces gaz ne soient contaminés par de la vapeur de mercure. On détendait rapidement la quantité voulue de ce mélange dans le réacteur, où sa pression était mesurée par un capteur électro-magnétique de marque Pace (modèle P7) et enregistrée au cours de la réaction. Entre les expériences, on maintenait dans le réacteur chaud un vide de l'ordre de 10^{-4} mm durant au moins 30 min.

On préparait le sous-oxyde de carbone par déshydratation de l'acide malonique selon la technique de Long *et al.* (7) telle que modifiée par Batchelor *et al.* (8). Après l'avoir redistillé plusieurs fois, on le conservait à −196 °C à l'obscurité pour l'empêcher de se polymériser. On contrôlait sa pureté en prenant le spectre i.r., le spectre de masses et des chromatogrammes; d'après ces essais, les quantités d'anhydride carbonique et d'acide acétique étaient dans tous les cas nettement inférieures à 0.1%. L'oxygène employé était de marque Ohio pour fins médicales. Nous croyons que nos mélanges réactionnels étaient "secs", c'est-à-dire exempts d'impuretés hydrogénées, puisque l'addition de petites quantités d'eau affectait de façon disproportionnée les limites d'explosion, comme on le verra plus loin.

Pour analyser les gaz durant la réaction, on aspirait un échantillon dans une boucle d'où il était entraîné par un flux d'hélium dans un chromatographe de marque F & M, modèle 700, le tout à la température de la chambre. Sur tamis moléculaire 5 Å, on séparait l'oxygène et le monoxyde de carbone avec des temps de retention respectifs de 4.8 et 16.5 min. Le sous-oxyde de carbone et l'anhydride carbonique étaient séparés sur brique pilée contenant 23% d'Apiezon M, selon les indications de Hirt et Palmer (9), avec des temps de retention respectifs de 9.2 et 3.5 min dans nos colonnes.

Résultats

(a) Comportement général et limites d'explosion

Bien que l'oxydation complète du sous-oxyde en anhydride carbonique ne comporte aucune variation de pression, la réaction débute dans tous les cas par une augmentation de pression. Selon la température, la composition du mélange et la pression, cette variation de pression suit l'un des cours illustrés sur la fig. 1. Il s'agit, dans ce cas, d'une famille de réactions, à 653 °C, de mélanges contenant tous du sous-oxyde à la même pression initiale de 24.6 mm Hg, mais de l'oxygène à différentes pressions initiales. En

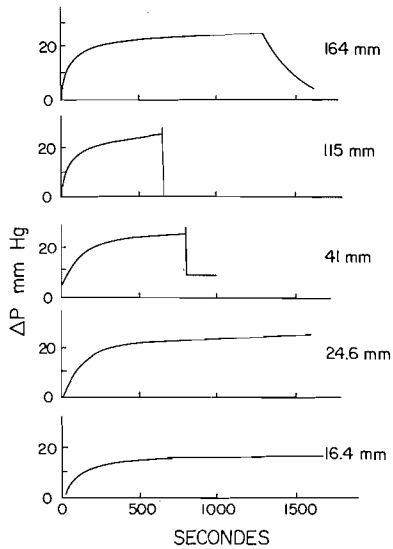

FIG. 1. Variations de pression au cours de réactions à 653 °C de mélanges où la pression initiale de C_3O_2 est de 24.6 mm Hg, celle d'oxygène étant inscrite vis-à-vis chaque courbe.

examinant de bas en haut les courbes de cette figure, on voit que si la pression initiale de l'oxygène ne dépasse pas celle du sous-oxyde, la pression totale atteint un plateau et reste stationnaire. S'il y a un excès d'oxygène, la montée de pression est suivie d'une explosion accompagnée d'une lueur bleuâtre. Avec un grand excès d'oxygène. l'augmentation de pression se termine par une baisse lente qui débute soudainement. Tout se passe comme si la réaction s'effectuait en deux temps, l'étape

$$[1] \qquad C_3O_2 + 2O_2 = 2CO + CO_2 + O_2$$

devant se terminer avant que ne débute la suivante:

$$[2] \qquad 2CO + O_2 = 2CO_2$$

En effet, sur la courbe du bas, on voit que la hausse de pression est égale à la pression initiale d'oxygène, 16.4 mm, qui limite l'étendue de la réaction 1. Sur la courbe suivante les deux réactifs ont la même pression initiale de 24.6 mm et la réaction 1 est complète, se soldant par un accroissement de pression de 24.6 mm, c'est-à-dire que $\Delta P_f = P_0(C_3O_2)$. La troisième courbe est obtenue en présence d'un excès modéré d'oxygène. Dès que la réaction 1 est terminée avec $\Delta P_f = 24.6$ mm, le mélange CO–O_2 explose, mais il ne reste pas assez d'oxygène pour

que la combustion soit complète. Sur la courbe suivante, $P_0(O_2) > 2P_0(C_3O_2)$, on trouve encore $\Delta P_f = 24.6$ mm, et dans ce cas la combustion explosive de CO, réaction 2, est complète et la pression du système revient à sa valeur initiale. Si l'on accroît encore la pression d'oxygène, on atteint une région où la combustion du monoxyde par l'oxygène en excès est une réaction lente qui débute soudainement; on se trouve au-dessus de la limite supérieure d'explosion du mélange CO–O_2. On voit donc que les réactions 1 et 2 constituent deux étapes bien distinctes, la deuxième n'étant franchie qu'après la disparition pratiquement complète du sous-oxyde. Ce dernier est un inhibiteur puissant (6, 10).

Il est intéressant de noter la ressemblance entre nos résultats et ceux de James et Laffitte (11) et de Cusin et James (12) sur la combustion du cyanogène. Cette réaction se fait aussi en deux étapes, la première étant une accumulation de monoxyde selon

$$(CN)_2 + 2O_2 = 2CO + N_2 + O_2$$

suivie de sa combustion explosive.

Enfin, il existe une pression au-dessus de laquelle l'allure de la réaction change radicalement. L'accroissement de pression, au lieu de débuter à une vitesse maximum pour aller vers un plateau, prend une allure autoaccélérée comme dans les courbes de la fig. 2 et dégénère en explosion après un temps très bref qui se confond avec la période d'échauffement des gaz.

La fig. 3 représente les régions où l'on observe ces divers types de réaction avec des mélanges de composition $1C_3O_2:2O_2$. La région A est celle où l'on obtient des explosions à long retard attribuables à la combustion [2] du monoxyde accumulé durant l'étape 1. Dans la région B, la combustion à long retard du monoxyde est lente. La région C est celle où le mélange C_3O_2–O_2 explose sans retard. Sans préjuger des

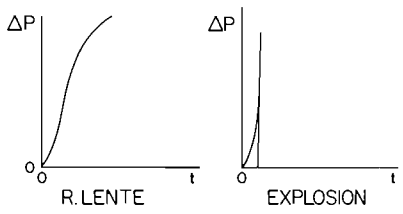

FIG. 2. Allures de la variation initiale de pression au voisinage de la limite d'explosion.

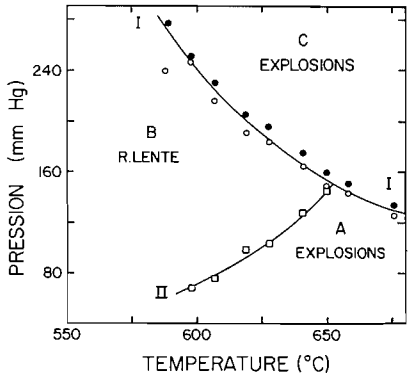

FIG. 3. Domaines de réactions lentes et d'explosions pour un mélange de composition $1C_3O_2:2O_2$.

mécanismes de ces types de réaction, nous appelons la courbe I (fig. 3) limite inférieure d'explosion du mélange C_3O_2–O_2 et la courbe II limite supérieure d'explosion du mélange CO–O_2–CO_2 provenant de l'étape [1]. On voit que ces deux limites se recoupent à 653 °C pour le mélange de composition $1CO_3O_2:2O_2$.

Si l'on porte les logarithmes des pressions limites contre $1/T$, on obtient les droites de la fig. 4 représentant la limite inférieure d'explosion du sous-oxyde et la limite supérieure d'explosion du monoxyde en présence du CO_2 provenant de la réaction 1.

Les limites représentées sur la fig. 3 sont celles de mélanges $1C_3O_2:2O_2$. Les changements de composition entraînent des déplacements importants de ces limites; nous en avons noté, mais n'en avons pas fait une étude systématique.

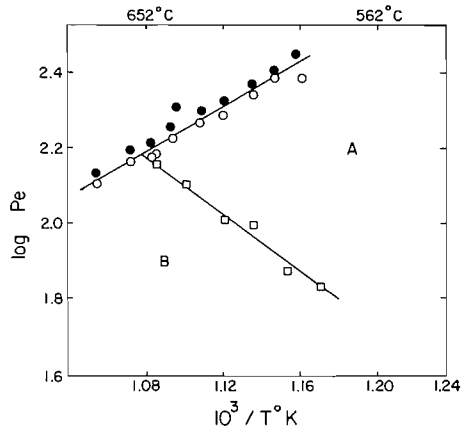

FIG. 4. Droites d'Arrhénius tirées des limites de la fig. 3.

Ces effets de composition expliquent que certains de nos résultats semblent, à première vue, être en désaccord avec les données de la fig. 3. Par exemple, la réaction représentée au sommet de la fig. 1 s'effectuant à 653 °C à une pression totale de 188.6 mm Hg, serait une explosion immédiate si le mélange avait la composition 1:2. D'autre part, ces déplacements de limites ont rétréci le champ de certaines séries d'expériences à composition variable.

Il est reconnu que l'addition de composés hydrogénés affecte les limites d'explosion de mélanges $CO–O_2$ (13) si ces derniers sont suffisamment secs. Nous avons d'abord remarqué que des traces d'hydrogène accélèrent la combustion lente du sous-oxyde et abaissent sa limite inférieure d'explosion. Nous avons aussi ajouté de l'eau et avons constaté que 1 mm d'eau exerçait un effet égal à celui de 12 mm. Pour des raisons de commodité, nous avons travaillé en présence d'une pression partielle d'eau égale à 5 mm, introduite dans le réacteur avant le mélange $1C_3O_2:2O_2$. On retrouve, dans ces conditions, des courbes de pression de mêmes allures que celles de la fig. 1, mais fortement accélérées, et les limites d'explosions sont abaissées de quelque 100 °C et 100 mm, comme on le constate en comparant la fig. 5 à la fig. 3. On voit, en particulier que la limite d'explosion que nous croyons être la limite supérieure du système $CO–O_2$ est largement décalée vers les basses températures, phénomène déjà connu (13). Il est remarquable que par sa position et par son apparence de rebroussement à 575 °C, cette limite semble s'apparenter à la deuxième limite d'explosion du système $H_2–O_2$ dans la région où celle-ci s'incurve vers la troisième limite. Il

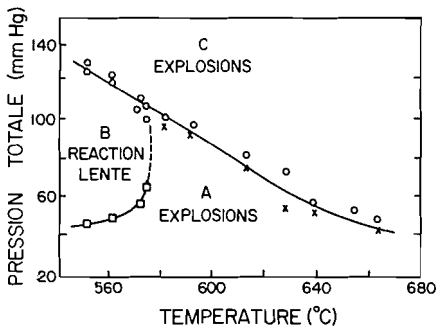

FIG. 5. Domaines de réactions lentes et d'explosions pour un mélange $1C_3O_2:2O_2$ en présence de 5 mm Hg de H_2O.

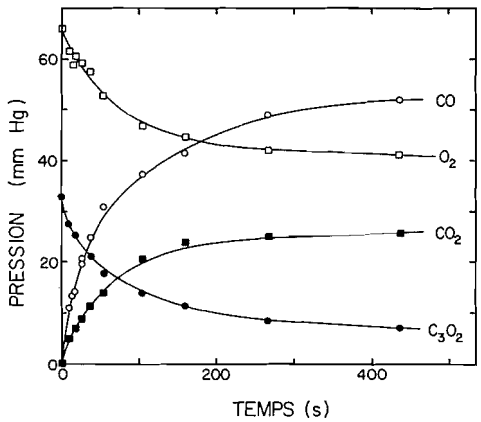

FIG. 6. Variations des pressions partielles durant l'oxydation à 632 °C d'un mélange $1C_3O_2:2O_2$ de pression initiale 99.8 mm Hg.

n'est pas impossible, étant donné que des atomes d'oxygène sont produits dans la chaîne d'oxydation de C_3O_2, qu'un nouveau mode de ramification tel que

$$CO + O + H_2O = CO_2 + H + OH$$

entre en jeu (14).

(b) Cinétique de la réaction lente

Cette section contient la description des résultats cinétiques obtenus sur la réaction 1, l'oxydation lente du sous-oxyde de carbone. Les résultats se rapportant à l'oxydation lente du monoxyde de carbone au-dessus de sa limite supérieure d'explosion seront décrits dans un autre article (15).

La fig. 6 montre l'évolution des espèces chimiques durant l'oxydation lente à 632 °C d'un mélange $1C_3O_2:2O_2$ de pression initiale $P_0 =$ 99.8 mm Hg. Cette réaction est l'une de celles qui sont suivies d'une combustion explosive du monoxyde de carbone par l'oxygène résiduel. Des familles de courbes semblables à celle-ci ont été obtenues par chromatographie à partir d'échantillons de mélanges gazeux à 632, 645, 652, et 671 °C. Dans tous ces cas et à tous instants durant ces réactions, les produits étaient dans un rapport de concentrations constant: $(CO)/(CO_2) = 2.0$ à la précision des mesures près. De plus, les variations de pression totale et partielles obéissaient à l'éq. 3, ce qui vérifie

$$[3] \quad \Delta P = -\Delta P_{C_3O_2} = -\Delta P_{O_2} = +\Delta P_{CO_2} = +0.5\Delta P_{CO}$$

TABLEAU 1. Variation de la vitesse initiale V_0 en fonction de la pression initiale P_0 de C_3O_2; $\theta = 631$ °C, P_0 de $O_2 = 162$ mm Hg

P_0 (mm)	P_0^2 (mm^2)	V_0 (mm s^{-1})	P_0^2/V_0
28.2	795	1.43	555
15.3	235	0.417	562
9.2	85	0.129	660
4.7	22	0.0513	430
3.9	15.2	0.0242	620

que cette première phase de phénomène est uniquement l'oxydation du sous-oxyde suivant l'éq. 1, et en particulier qu'il ne se forme pas d'autre produit, par exemple un polymère qui se déposerait dans la canalisation près du réacteur.

Ces constatations nous ont permis d'utiliser les mesures de pression pour l'étude de la cinétique de la réaction lente [1].

Nous avons d'abord mesuré les valeurs $V_0 = (dP/dt)_0$ des taux initiaux d'accroissement de pression en prenant les pentes à l'origine. On voit au tableau 1 que V_0 varie comme le carré de la pression partielle initiale de C_3O_2 dans une série de réactions à 631 °C où la pression initiale de O_2 était partout de 162 mm Hg. Pour la série de réactions à 653 °C du tableau 2, la pression initiale de C_3O_2 est de 24.6 mm Hg et l'on voit que V_0 varie comme la racine carrée de la pression initiale de O_2. Une autre série de réactions à 653 °C à composition initiale constante $1C_3O_2{:}2O_2$ a montré que V_0 varie comme la pression initiale à la puissance 2.5. On peut donc écrire, pour nos mélanges "secs", l'éq. 4. En

$$[4] \qquad -d(C_3O_2)/dt = k(C_3O_2)^2(O_2)^{1/2}$$

désignant les pressions partielles initiales par $A = P_0(C_3O_2)$ et $B = P_0(O_2)$ et en tenant

TABLEAU 2. Variation de la vitesse initiale V_0 en fonction de la pression initiale P_0 de O_2; $\theta = 653$ °C, P_0 de $C_3O_2 = 24.6$ mm Hg

P_0 (mm)	$P_0^{1/2}$ (mm$^{1/2}$)	V_0 (mm s^{-1})	$P_0^{1/2}/V_0$
164	12.8	0.537	23.8
115	10.7	0.448	24.0
49.2	7.0	0.323	21.8
41.0	6.4	0.311	20.5
32.8	5.7	0.233	24.5
24.6	4.9	0.222	22.4
16.4	4.0	0.171	23.6
8.2	2.8	0.113	25.4

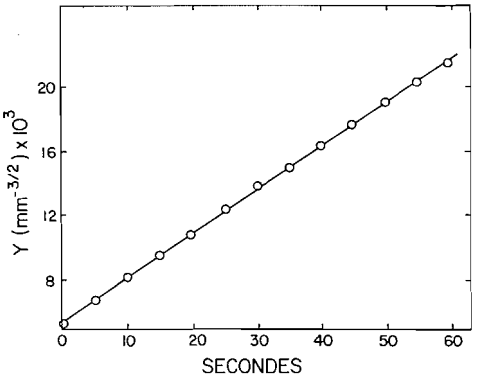

FIG. 7. Représentation de l'éq. 5 d'après les données obtenues lors de la réaction à 652 °C d'un mélange $1C_3O_2{:}2O_2$ de pression initiale 66 mm Hg.

compte de l'éq. 3, on écrit [4] sous la forme

$$d(\Delta P)/dt = k'(A - \Delta P)^2(B - \Delta P)^{1/2}$$

Dans le cas où l'oxygène est en excès, $(B > A)$, l'intégration donne l'éq. 5. Sur la fig. 7, on a

$$[5] \quad \frac{1}{B-A}\left[\frac{(B-\Delta P)^{1/2}}{(A-\Delta P)} - \frac{1}{2}\left(\frac{2.3}{(B-A)^{1/2}} \times \log\frac{(B-\Delta P)^{1/2}+(B-A)^{1/2}}{(B-\Delta P)^{1/2}-(B-A)^{1/2}}\right)\right] = k't$$

porté les valeurs du membre de gauche de cette équation (désigné par la lettre Y) en regard du temps, en insérant les valeurs de ΔP et de t obtenues lors d'une réaction à 652 °C avec un mélange où $A = 22$ et $B = 44$ mm Hg, soit $(1C_3O_2{:}2O_2)$. On voit que l'éq. 5 est bien vérifiée durant une bonne partie de la réaction; il en est ainsi quelles que soient les valeurs relatives de A et de B. Au-delà d'environ 60% de conversion, la droite s'incurve vers le bas, ce que nous attribuons à l'influence des produits. La pente de cette droite est la valeur de k'. Dans le cas de la réaction de la fig. 6, nous obtenons $k' = 2.7 \times 10^{-4}$ mm Hg$^{-3/2}$ s^{-1}. Plus loin, nous remplacerons k' par k (l/mol)$^{3/2}$ s^{-1}.

Il faut noter que l'ordre global de 2.5 a été obtenu dans tous les cas où notre mélange était "sec". Avec des mélanges moins purs (contenant probablement des traces d'eau ou d'acide acétique) l'ordre global devenait égal à 2, l'ordre par rapport au sous-oxyde s'abaissant à 1.5 tandis que l'ordre par rapport à l'oxygène restait de 0.5.

Nous avons calculé l'énergie d'activation

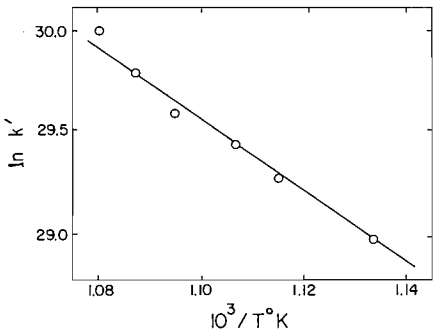

FIG. 8. Droite d'Arrhénius obtenue à partir des valeurs k' de l'éq. 5.

globale de deux façons. D'après les vitesses initiales $V_0 = (dP/dt)_0$ à différentes températures, on obtient $E = 33$ kcal/mol. D'autre part, nous avons pris les valeurs de k' d'après l'éq. 5 pour des réactions à différentes températures et en avons tiré les valeurs de la constante k de l'éq. 4 en termes des concentrations, par conversion des unités et corrections pour l'effet de température. La droite d'Arrhénius de la fig. 8, où k est exprimée en $(l/mol)^{3/2}\ s^{-1}$, nous a donné $E = 35$ kcal/mol. Incidemment, la concordance entre ces deux valeurs confirme la validité de l'éq. 5. Pour le facteur préexponentiel A dans $k = Ae^{-E/RT}$, on obtient la valeur $A = 2.3 \times 10^{21}\ (l/mol)^{3/2}\ s^{-1}$.

(c) Effets d'additifs et de surface

Les effets d'additifs sont très variés (10). L'argon n'affecte pas la vitesse initiale V_0, mais abrège la période d'induction τ de l'explosion, donc favorise l'explosion de $CO–O_2$ en présence d'une petite concentration résiduelle de C_3O_2. L'addition de CO_2 n'affecte pas non plus V_0, mais retarde l'explosion de $CO–O_2$. Par exemple, dans une réaction à 653 °C où $P_0(C_3O_2 + 3O_2) =$ 196 mm Hg, l'addition de 49 mm Hg de CO_2 a porté la période d'induction τ de 1163 à 1763 s. L'effet de l'addition de CO au mélange $C_3O_2–O_2$ initial est complexe; ce gaz abaisse la limite d'explosion de $C_3O_2–O_2$, accroît légèrement la vitesse initiale V_0 d'oxydation de C_3O_2 et abrège la période d'induction τ de l'explosion de $CO–O_2$, comme le montre le tableau 3. De plus, en présence de quantités importantes de CO, l'ordre de la réaction relatif à C_3O_2 passe de 2.0 à 1.5. Enfin, un effet inattendu: en présence de CO, l'augmentation de la concentration initiale de C_3O_2 entraîne un accroissement de la

TABLEAU 3. Effets de l'addition de CO à un mélange initial où $P_0(C_3O_2) = 32.8$, $P_0(O_2) = 164$ mm Hg, et $\theta = 631$ °C

$P_0(CO)$ (mm)	V_0 (mm s^{-1})	τ (s)
0.0	1.43	980
13.4	1.62	538
20.2	1.74	581
27.3	2.10	571
40.6	2.27	402
50.6	1.99	221

vitesse initiale V_0 mais aussi un prolongement important de la période d'induction τ, tandis qu'en l'absence de CO, la période τ est d'autant plus courte que la vitesse initiale est plus grande. Ceci s'explique si l'on considère que durant la réaction 1, CO s'accumule et C_3O_2 s'épuise jusqu'à ce que le rapport $(CO)/(C_3O_2)$ atteigne la valeur critique à laquelle il y a explosion. Ainsi, l'addition de CO hâte l'explosion et l'addition de C_3O_2 la retarde. Les divers effets de l'addition de H_2O ont été décrits plus haut.

L'addition de NO_2 inhibe fortement l'oxydation de C_3O_2, comme le montre la fig. 9. Il est difficile de dire si l'effet observé est attribuable à NO ou à NO_2, ce dernier étant fortement dissocié à 661 °C, car on se trouve ici en présence d'un excès d'oxygène. On sait (4) qu'à 25 °C, NO réagit sur le radical C_2O 135 fois plus vite que l'oxygène moléculaire. Il est donc vraisemblable qu'il agisse comme capteur de C_2O dans la chaîne d'oxydation de C_3O_2, tandis qu'il a peu d'effet sur celle de CO.

Pour étudier l'influence du rapport surface/-volume, nous avons utilisé trois cylindres de Vycor identiques de 4.5 × 22 cm, l'un vide, les

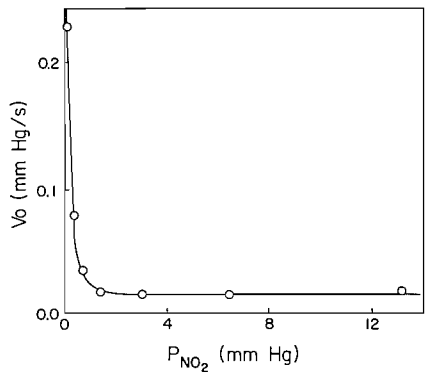

FIG. 9. Inhibition par NO_2 de l'oxydation lente de C_3O_2.

autres contenant des tubes de Vycor courts. Les rapports obtenus étaient respectivement S/V = 1.1, 3.2, 5.0 cm^{-1}. Une série d'expériences (10) à des pressions allant de 12 à 130 mm de mélanges $1C_3O_2$:$2O_2$ à 661 °C ont montré que la vitesse initiale V_0 décroît quand S/V croît, la vitesse variant grosso-modo comme la racine carrée du diamètre. De plus, l'ordre global de la réaction pour chacun des réacteurs passe de 2.4 pour S/V = 1.1 cm^{-1}, à 2.0 pour S/V = 3.2 cm^{-1}, et à 1.8 pour S/V = 5.0 cm^{-1}. La limite inférieure d'explosion d'un mélange $1C_3O_2$:$2O_2$ à 671 °C est passée de 130 mm Hg dans le réacteur ordinaire de S/V = 1.1 cm^{-1} à 250 mm Hg dans celui de S/V = 3.2 cm^{-1}, l'explosion devenant immédiate et violente.

Discussion

Nous proposons le schéma réactionnel 1 ci-dessous.

		$\Delta H°$ 1000 °K kcal/mol
[i]	$C_3O_2 + O_2 + M \rightarrow 3CO + O + M$	4
[i']	$C_3O_2 \xrightarrow{\text{paroi}} C_2O + CO$	86
[6]	$C_3O_2 + O \rightarrow C_2O + CO_2$	−42
[7]	$C_2O + O_2 \rightarrow 2CO + O$	−82
[8]	$CO + O \rightarrow CO_2^*$	12
[9]	$CO_2^* + CO \rightarrow CO_2 + CO^*$	−2
[10]	$CO^* + O_2 \rightarrow CO_2 + O$	−146
[11]	$CO_2^* + O_2 \rightarrow CO_2 + O + O$	−19
[12]	$C_2O + O_2 \rightarrow CO_2 + CO$	−211
[13]	$C_3O_2 + O \rightarrow 3CO$	−117
[14]	$C_2O + CO \rightarrow C_3O_2$	−86
[15]	$O \xrightarrow{\text{paroi}}$	
[16]	$C_2O \xrightarrow{\text{paroi}}$	

SCHEMA 1

Les enthalpies de ces réactions ont été obtenues à partir des données de Kybett *et al.* (16) sur C_3O_2 et de celles de Willis et Bayes (5) et de Becker et Bayes (17) sur le radical C_2O, et converties à 1000 °K. Pour les enthalpies de formation à 1000 °K, nous adoptons $\Delta H_f^0(C_3O_2)$ = −10 kcal/mol et $\Delta H_f^0(C_2O)$ = 98 kcal/mol. La pyrolyse de C_3O_2, [i'], doit être affectée d'une variation d'enthalpie de 86 kcal/mol. D'autre part on a trouvé (18, 19) pour la pyrolyse homogène, des énergies d'activation de 56 et de 61 kcal/mol. Pour expliquer nos résultats, nous supposons que la pyrolyse de C_3O_2 sur la paroi est beaucoup plus importante que celle en phase gazeuse dans les conditions de nos expériences. Nous avons calculé pour notre réaction 1 ΔH_1^0 = −127 kcal/mol, de sorte que l'effet d'auto-échauffement n'intervient probablement pas aux vitesses ordinaires, mais contribue sans doute à déclencher l'explosion.

(a) L'oxydation lente

Au début de l'oxydation lente de C_3O_2 selon [1], il n'y a pas encore de CO dans le système. Il se forme du CO et du CO_2 par le cycle des réactions de propagation [6] et [7]. Le fait que les produits restent dans la proportion $(CO)/(CO_2)$ = 2 jusqu'à la disparition quasi complète de C_3O_2 signifie que C_3O_2 est un capteur d'atomes O beaucoup plus efficace que CO ($k_6 \gg k_8$). Dès qu'il ne reste plus de C_3O_2, les atomes O deviennent disponibles pour attaquer le CO suivant la chaîne énergétique des réactions 8 à 11. Cette vue simplifiée d'un mécanisme "tout ou rien" est justifiée parce que le début de l'oxydation de CO se manifeste toujours par une cassure nette de la courbe de pression et aussi parce que les analyses de quelques échantillons prélevés quelques secondes avant cette cassure n'on révélé que des traces de C_3O_2.

Les ordres apparents de 2 relatif à C_3O_2 et 1/2 relatif à O_2 [4], ainsi que l'abaissement de ces ordres par l'augmentation du rapport surface/volume, nous ont conduits à admettre que l'initiation résulte de deux réactions: une oxydation homogène par choc triple, [i] et une pyrolyse hétérogène [i']. De plus, nous postulons des terminaisons homogènes [12], [13], et [14] et hétérogène [15] et [16]. Les concentrations des atomes O et des radicaux C_2O sont infimes au cours de la réaction lente; c'est pourquoi nous n'avons pas inclus, parmi les modes de terminaison, leurs recombinaisons dont les taux seraient négligeables par rapport à ceux des réactions 12, 13, et 14. D'autre part, comme les terminaisons hétérogènes sont toutes linéaires, elles n'affectent pas l'ordre de la réaction, mais seulement la vitesse et les limites d'explosion. Nous les avons omises pour simplifier le calcul des états stationnaires.

Si les deux modes d'initiation [i] et [i'] sont

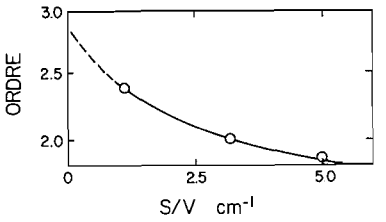

FIG. 10. Variation de l'ordre global de l'oxydation lente en fonction du rapport surface/volume.

importants, on doit s'attendre à ce que les ordres, en particulier l'ordre global de la réaction, dépendent de la valeur du rapport surface/volume, comme nous l'avons déjà constaté. Les ordres que nous avons observés expérimentalement dans nos trois réacteurs sont représentés sur la fig. 10 en fonction de S/V. L'ordre tend vers $n = 3$ pour un réacteur hypothétique à $S/V = 0$ (absence de parois), c'est-à-dire dans le cas d'une initiation purement homogène.

Incluons les deux modes d'initiations, négligeons les terminaisons sur la paroi et posons $k_7 \gg k_{12}$ (puisque $(CO)/(CO_2) = 2$ reste constant). La concentration stationnaire des atomes d'oxygène s'écrit alors

$$(O)_{stat.} = \frac{k_i k_6 (O_2)(M) + k_i' k_7}{k_7 k_{13} + k_{12} k_6}$$

La constance du rapport 2 des produits implique aussi que $k_6 \gg k_{13}$, de sorte que la dest truction de C_3O_2 dans l'oxydation lente espratiquement attribuable à la seule réaction 6 et donne l'éq. 17. En l'absence d'initiation hétérogène, le terme $k_i'(C_3O_2)$ serait nul et l'ordre apparent serait $n = 3$, comme pour le cas $S/V = 0$ sur la fig. 10. Par contre, pour des

$$[17] \quad \frac{-d(C_3O_2)}{dt} = \frac{k_7 k_6}{k_7 k_{13} k_{12} k_{16}} \times [k_i(C_3O_2)(O_2)(M) + k_i'(C_3O_2)]$$

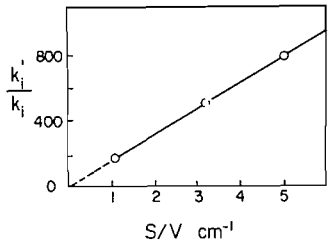

FIG. 11. Importances relatives des réactions d'initiation [i] et [i'] en fonction du rapport surface/volume.

valeurs élevées de S/V, le terme $k_i'(C_3O_2)$ prédominerait et l'ordre tendrait vers $n = 1$, comme l'indique la même figure. Pour préciser cette prédiction qualitative, nous avons calculé les valeurs du rapport k_i'/k_i pour lesquelles une courbe $\log V_0$ *vs.* $\log P_0$ (où V_0 = vitesse initiale et P_0 = pression totale initiale) donne les ordres $n = 2.4$, 2.0, et 1.8 obtenus expérimentalement dans nos trois réacteurs. Ces valeurs sont $k_i'/k_i = 180$, 550, et 850 respectivement. La validité de ce calcul est confirmée par la fig. 11, où l'on voit que l'importance de l'initiation hétérogène (k_i') est proportionnelle à S/V et, en particulier, que $k_i' \to 0$ quand $S/V \to 0$.

(b) Les explosions

Nous avons distingué deux sortes d'explosion: l'explosion retardée du mélange CO–O_2–CO_2, qui correspond à la région A de la fig. 3; et l'explosion immédiate du mélange C_3O_2–O_2, qui correspond à la région C. Dans l'un et l'autre cas, l'explosion résulte d'une accélération de la réaction par la ramification [11] ce qui implique que le mécanisme dominant est la chaîne énergétique des réactions 8 à 11.

Dans le cas de l'explosion retardée, les facteurs qui empêchent la réaction de s'auto-accélérer sont la capture des atomes O par C_3O_2 selon [6] et [10], mais aussi la désactivation de CO_2* et de CO* par le CO_2 présent, effet que nous n'avons pas inscrit dans notre schéma, et peut être aussi la recombinaison homogène [14] étudiée par Palmer et Cross (20), tant qu'il reste un peu de C_3O_2.

L'explosion du mélange C_3O_2–O_2 doit faire intervenir l'ensemble des chaînes radicalaire et énergétique. La limite inférieure dépendra du taux net de production d'atomes O, qui peut s'écrire

$$d(O)/dt = -k_8(CO)(O) + k_{10}(CO^*)(O_2) + 2k_{11}(CO_2^*)(O_2) - k_6(C_3O_2)(O) + k_7(C_2O)(O_2) - k_{15}(O)$$

En remplaçant dans cette équation (CO*), (CO_2*), et (C_2O) par leurs concentrations stationnaires, on obtient l'expression du facteur net de ramification, [18]. Dans le membre de

$$[18] \quad \phi = \frac{k_{11} k_{13} (CO)(O_2)}{k_9(CO) + k_{11}(O_2)} - \frac{k_6(C_3O_2)[k_{14}(CO) + k_{16}]}{k_7(O_2) + k_{10}(CO) + k_{16}} - k_{15}$$

droite de cette équation, le premier et le troisième termes, pris seuls, donnent la valeur de ϕ pour la combustion de système $CO–O_2$. Le deuxième terme, qui est négatif, exprime l'action inhibitrice de C_3O_2 sur l'oxydation de CO.

Durant l'oxydation lente de C_3O_2, le deuxième terme décroît à mesure que C_3O_2 disparaît par les réactions 6 et 7, en même temps que le premier terme croît à mesure qu'il se forme du CO. La valeur de ϕ devient de moins en moins négative et atteint $\phi \simeq 0$, valeur critique à laquelle le mélange explose. Il se peut d'ailleurs qu'à certaines températures et compositions, la somme du premier et troisième termes reste négative après la disparition du deuxième; dans ce cas le CO s'oxyde lentement. L'équation 18 montre que la limite d'explosion dépend des concentrations d'une façon compliquée. On peut cependant dire que le deuxième terme n'influe pas sur la limite d'une explosion retardée, puisqu'il s'annule, $(C_3O_2) = 0$, avant qu'elle ne se produise.

Aux pressions et températures les plus élevées, il se peut que l'oxydation lente du C_3O_2 soit auto-accélérée, vraisemblablement par auto-échauffement. Dans ce cas, la décroissance du deuxième terme serait accélérée et, fournissant le CO, provoquerait une croissance accélérée du premier terme. L'effet thermique aidant, le système s'acheminerait rapidement vers $\phi = 0$ et l'explosion, qui serait celle d'un mélange $CO–O_2$. Ce serait le cas de la limite inférieure d'explosion du système $C_3O_2–O_2$ (courbe I de la fig. 3). En réalité, cette appellation désignerait un état de choses où l'explosion de $CO–O_2$ est atteinte sans retard.

Il est possible que les deux sortes d'explosion soient attribuables à la même réaction de ramification [11]. Si l'on désigne par B, l'énergie d'activation de cette réaction, on peut exprimer les coefficients de température des limites inférieure et supérieure d'explosion par les équations

$$P_{\text{inf.}} = C/d\, e^{B/2RT}$$

$$P_{\text{sup.}} = C'\, e^{-(B-E)/RT}$$

où C et C' sont des constantes, d est le diamètre du réacteur, E est l'énergie d'activation d'une terminaison homogène, et B, l'énergie d'activation de la réaction de ramification. Les pentes des droites de la fig. 4 nous donnent les valeurs expérimentales $B/2 = 14$ kcal/mol pour la limite inférieure d'explosion de $C_3O_2–O_2$ et $B - E = 24$ kcal/mol pour la limite supérieure d'explosion de $CO–O_2$. Donc, pour $C_3O_2–O_2$, $B = 28$ kcal/mol, ce qui est en accord avec la valeur citée par Dainton (21) $B > 25$ kcal/mol pour $CO–O_2$ et représente probablement l'énergie d'activation de la ramification [11]. Pour la limite supérieure d'explosion de $CO–O_2$, nous arrivons à la même valeur $B = 28$ kcal/mol en attribuant à la recombinaison la valeur plausible $E = 4$ kcal/mol. Il semble donc que les explosions des systèmes $C_3O_2–O_2$ et $CO–O_2$ impliquent le même processus de ramification [11]. Rappelons que la limite inférieure d'explosion du système $C_3O_2–O_2$ est très sensible au rapport surface/volume, ce qui implique des terminaisons hétérogènes importantes, malgré la pression relativement élevée, et sans doute aussi un gradient de température résultant de l'oxydation rapide de C_3O_2. Dans ces conditions, il n'est pas invraisemblable que la limite inférieure d'explosion du système $CO–O_2$ en présence d'un inhibiteur puissant (C_3O_2) se situe à une pression supérieure à celle de la limite supérieure d'explosion du système $CO–O_2$ non inhibé.

Proton Magnetic Resonance Studies of Ionic Solvation in Ion-Exchange Resins. Part II

H. D. SHARMA[1] AND N. SUBRAMANIAN
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received July 7, 1970

The proton magnetic resonance spectra of anion-exchange resin Dowex AG1 of various crosslinkages ranging from X1 to X10 in the F^-, Cl^-, Br^-, I^-, NO_3^-, and ClO_4^- forms have been recorded and the values of the molal chemical shift, $\delta^0_{X^-}$, are found to be -0.035, 0.026 (assumed), 0.035, 0.045, 0.037, and 0.058 p.p.m./mol, respectively, for the anions. These values are generally lower compared to those observed in corresponding aqueous solutions, indicating that ion–solvent interactions are similar in both the resin matrix and the aqueous solution but there is probably increased ion association in the resin phase. The effective hydration numbers have been deduced from the temperature dependence measurements of proton chemical shifts for the alkali-metal ions and for a few anions in various crosslinkages of Dowex AG 50W and Dowex AG1 resins. The values of the hydration number decrease as the crosslinkage increases for the alkali-metal ions. The decrease in the hydration number at high crosslinkage is attributed to ion association in the resin phase. The reversal of selectivity in K^+/Cs^+ system below X16 in the sulfonated resin is explained on the basis of decrease in the hydration of K^+ form of resin compared to that of Cs^+ form, consistent with the experimental observations. The electrostatic interactions between the counterion and fixed group and ions and solvent in the resin phase have been discussed in the light of the proposed models.

Canadian Journal of Chemistry, 49, 457 (1971)

Introduction

A considerable body of experimental data has been obtained in connection with equilibria and kinetics in ion-exchange resin (1–3). Several models have been proposed to interpret and to predict the selectivity of ions when in equilibrium with their respective solutions. The model proposed by Gregor pictures the ion-exchanger as consisting of two parts, an un-crosslinked polyelectrolyte with solvent and the cross linking. Selectivity for an ion is considered to arise primarily because of differences in the partial molal volumes of the counterions in the resin phase (4). The other models rely on the electrostatic interactions between the counterion and the fixed group and the ion–solvent interactions (5–7). In all these models ion-pair formation and ionic hydration is recognized as of key importance to explain the observed swelling pressures and selectivity of ions under a variety of conditions. An excellent review has been presented by Reichenberg and Diamond and Whitney in ref. 2. However, there is very little direct experimental evidence to support or disprove the basic assumptions on which the models are based. Glueckauf and Kitt obtained the hydration numbers of cations in the resin phase by a method based on thermodynamical considerations (8).

Nuclear magnetic resonance (n.m.r.) has proved to be a versatile technique in studying ionic solvation in aqueous and non-aqueous solutions of electrolytes (9–11). More recent studies in this connection concern the determination of solvation numbers of ions in solution (12–16). Of these, two approaches are particularly suitable for aqueous solutions of alkali and alkaline earth salts, *viz.*, (*a*) effect of concentration (17) and (*b*) effect of temperature (14–16) on the proton chemical shift of water. The n.m.r. spectra of suspensions of ion-exchange resins should shed light on the structure of the "internal electrolyte solution". This has been verified by the investigations of Gordon (18) and Choppin and co-workers (19). It has been shown by us that the effect of ion concentration and temperature on the chemical shifts of interior water can be conveniently studied in a quantitative manner in sulfonated cation-exchange resins (20). The "effective hydration numbers" for alkali-metal ions were calculated from the temperature dependence of the chemical shift. Recently, similar results have been reported by Creekmore and Reilley (21). We have extended these studies to both anion- and cation-exchange resins of various cross linkages and ionic forms. The hydration numbers calculated from the experimental results have been discussed in terms of the "models" to rationalize the observed selectivity coefficients for ions.

Experimental

All the resins used in this work were procured from Bio-Rad Laboratories, Richmond, California. Dowex AG 50W (X1 to X16) cation-exchange resins (with sulfonate anion on a polystyrene lattice) were obtained in the H^+ form while the anion-exchanger Dowex AG1 (X1 to X10) (with quaternary ammonium group on a polystyrene lattice) and Bio-Rex 9 (with pyridinium group on a polystyrene lattice) were in their Cl^- form. After necessary conditioning, these were converted to the required ionic forms by the column method. Special care was taken to ensure complete conversion and removal of all excess of the electrolyte used in the process. Bio-Rex 63 (a cation-exchange resin with phosphonate anion on a polystyrene lattice) and Bio-Rex 70 (another cation-exchange resin with carboxylate anion on an acrylic lattice), supplied in the Na^+ form, were used as such after conditioning. 200–400 mesh beads were used throughout except for Dowex AG 50W (X1) and Dowex AG1 (X1) resins where only 50–100 mesh was available. However, the bead size, while affecting the signal width, had little effect on the observed chemical shift (20).

Water contents of the resins in their various ionic forms and crosslinkages were determined by the Karl Fischer technique. This method has been shown to be very rapid and reliable for both cation- (22) and anion- (23) exchange resins and yields values of water contents with an accuracy of $\pm 2\%$.

The capacities of cation-exchange resins were determined as described previously (20). For the anionic resins, the capacities were found in the chloride form as follows (24). A given weight of the air-dried resin of known water content was transferred to a column. A very large excess of 0.5 *N* KNO_3 solution was passed through the column and the concentration of the liberated chloride ions in the effluent was estimated by Mohr titration. Doubly distilled, deionized water was used throughout and the salts were all of the highest purity commercially available.

The proton magnetic resonance (p.m.r.) spectra of aqueous suspensions of resins were recorded on a Varian A-60 spectrometer. The temperature of the sample was controlled with a Varian V-6040 temperature controller. The details of the spectral measurements are given in our earlier paper (20).

Results

The p.m.r. spectrum of a well-settled aqueous suspension of an ion-exchange resin usually consists of two signals arising from water protons inside and outside the resin environment (18). Compared to pure water and solutions of diamagnetic salts, the line widths are larger due to susceptibility considerations and heterogeniety of the resin phase (18). The chemical shift between the external and internal water peaks is defined, as before, by $\delta = \Delta\nu/60$ (p.p.m.), where $\Delta\nu = (\nu_{ext\,H_2O} - \nu_{int\,H_2O})$ c.p.s. *i.e.*, a positive value of δ would mean that the internal water peak is upfield with respect to the external water peak. The p.m.r. spectra of aqueous suspensions of Dowex AG1 (X1 to X10) in the F^-, Cl^-, Br^-, I^-, NO_3^-, and ClO_4^- forms were recorded at 25 °C. If the chemical shifts of the internal and external water protons were very close, the overlapping peaks were resolved by a hybrid analog-digital computer routine using an IBM 360/44 computer. The observed δ values are plotted against the ionic molalities, *m*, in Fig. 1.

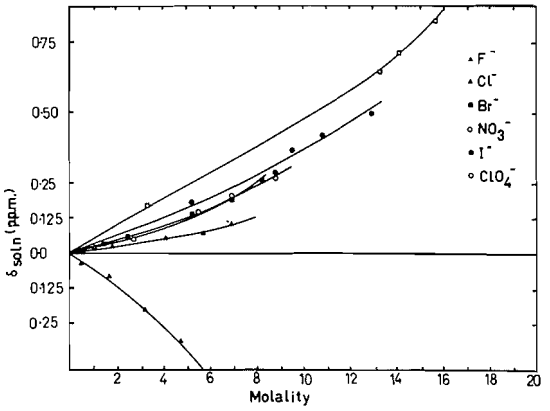

FIG. 1. Chemical shift as a function of ionic concentration for Dowex AG1 resin at 25 °C.

The influence of temperature on the proton chemical shift of internal water, δ_{soln}, was studied in Dowex AG 50W resins of crosslinkage 4, 8, and 16 in the Na^+, K^+, Rb^+, Cs^+, and NH_4^+ forms. Similar temperature–shift data were also obtained for a few anionic forms of Dowex AG1. The change in the observed δ values with increase in temperature for the NH_4^+ form of Dowex AG 50W (X8) is shown in Fig. 2 as a typical case.

For each ionic form, the δ_{soln} value at a given temperature with respect to gaseous ethane, δ_{soln}^{ethane}, was evaluated from the experimental δ values and by following the procedure described previously (20). The coefficient, $\delta_{soln}^{ethane}/dT$ (p.p.m./°C), was then obtained as the slope of a least square plot of δ_{soln}^{ethane} *vs.* temperature (Table 1). For the ClO_4^- form, the temperature studies could not be carried out beyond 40 °C. When heated to 50 °C and above, irreversible decomposition of the resin sets in as was indicated by irreproducible δ values.

Discussion

Susceptibility Corrections

In the p.m.r. studies of aqueous solutions, it

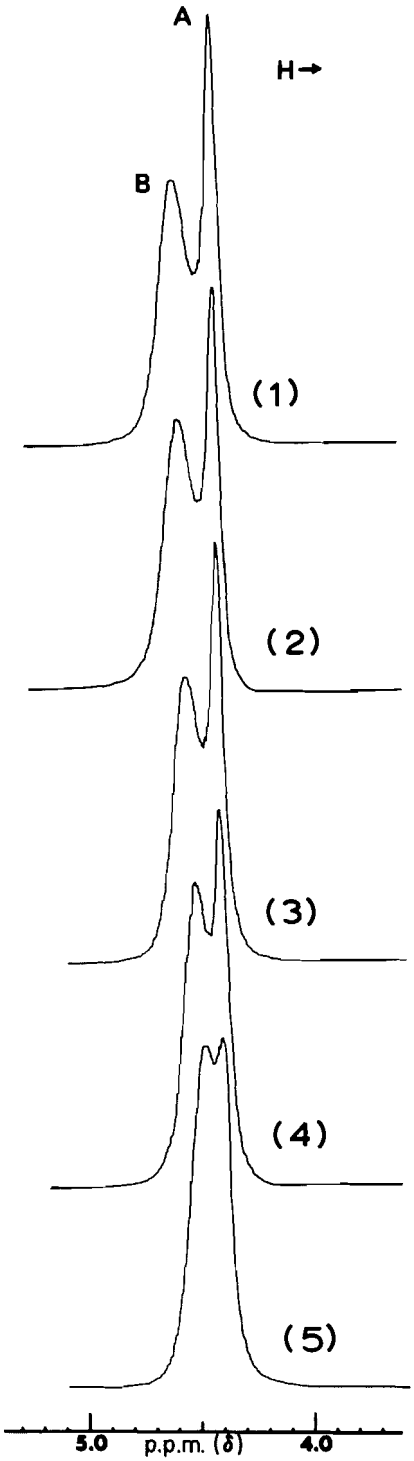

FIG. 2. Effect of temperature on the proton magnetic resonance spectrum of a suspension of AG 50W (X8) (200–400 mesh) resin in the NH_4^+ form: (*1*) 15 °C, (*2*) 25 °C, (*3*) 32 °C, (*4*) 40 °C, and (*5*) 50 °C; *A*, "internal" water peak; *B*, "external" water peak.

was found necessary to correct for the bulk diamagnetic susceptibility contributions from the ionic species present (17, 25). In the resin system, additional contribution can be expected from the organic part of the resin particle. It was seen by us, however, that when the spectra of sulfonated cation-exchangers were recorded without allowing the resin beads in the n.m.r. tube to settle down, a third line appeared as a shoulder on the high field side of the "external" water line (20). The very sharp third resonance line was assigned to the protons of the "bulk" water. A similar observation was made with the anion-exchanger as well. The spectra of well-shaken suspensions of AG1 resin in the F^- and ClO_4^- forms are reproduced in Fig. 3.

It is significant that, for a given ionic form and crosslinkage, δ is independent of the bead size (20). On the other hand, the shift between "bulk" and "external" water, whose value varies from 2 to 10 c.p.s., is found to be a function of the nature of the counterion (being maximum for Cs^+), the crosslinkage and the size (and, therefore, the density) of the resin. This latter shift is a result of susceptibility effects. Whereas the bulk water molecules are farther removed from the resin, the external water is actually held as a tightly bound sheath around the resin surface. The rate of exchange between the two kinds of water is lower than the n.m.r. time scale (17). While considering the δ values, it is therefore reasonable to assume that there is, so to speak, a built-in susceptibility correction in the system and to omit any further such correction. The fact that the resin beads are spherical provides additional justification for neglecting the susceptibility effect (26, 27).

Factors Influencing the Chemical Shift

In order to interpret the observed δ values, we need to consider the effect of (*a*) the organic matrix, (*b*) the fixed ionic group, and (*c*) the counterion on the structure of the internal water. The nature and concentration of the counterion strongly influence the position of the internal water proton signal, but the contribution from the other two factors still remains uncertain.

TABLE 1. Effective hydration numbers of Dowex AG 50W and Dowex AG1 resins in various ionic forms and crosslinkages

Resin	Ionic form	Cross-linkage	Ionic molality (m)	$d\delta_{soln}^{ethane}/dT$ (p.p.m./°C)	h (±0.5–1.0)

*Values from previous work, ref. 20. Values in parentheses from ref. 16.

(a) The Organic Matrix

Gordon has reported a high field shift of the resonance signal of carbon-bound protons present inside the cation- and anion-exchange resins (18). He attributes this effect to the diamagnetic anisotropy of the polystyrene matrix. According to Gordon (18) and Choppin and co-workers (19), similar high field shift of resonance line is likely also for water protons. However, it can be seen from Fig. 1 that as $m \to 0$, $\delta \to 0$; *i.e.*, at zero ionic concentration, internal and external water protons have identical chemical shifts. A similar observation was made earlier for the cation-exchange resins (20). If the matrix does in fact shift the interior water line upfield, extrapolation to $m = 0$ would have resulted in a positive intercept. Since this is not observed for the several ionic forms investigated, it can be concluded that, for hydroxylic protons, matrix contribution from anomalous magnetic susceptibility to the experimentally observed δ value is negligible.

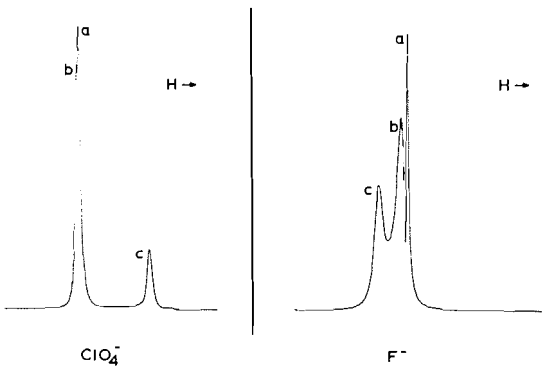

FIG. 3. Proton magnetic resonance spectra of suspensions of ClO_4^- and F^- forms of Dowex AG1 (X8) (200–400 mesh) in water (without allowing the resin particles to settle down): (*a*) "bulk water", (*b*) "external" water, and (*c*) "internal" water signals.

(b) The Fixed Ionic Group

It has been suggested that the ion attached to the resin matrix may not affect the water proton

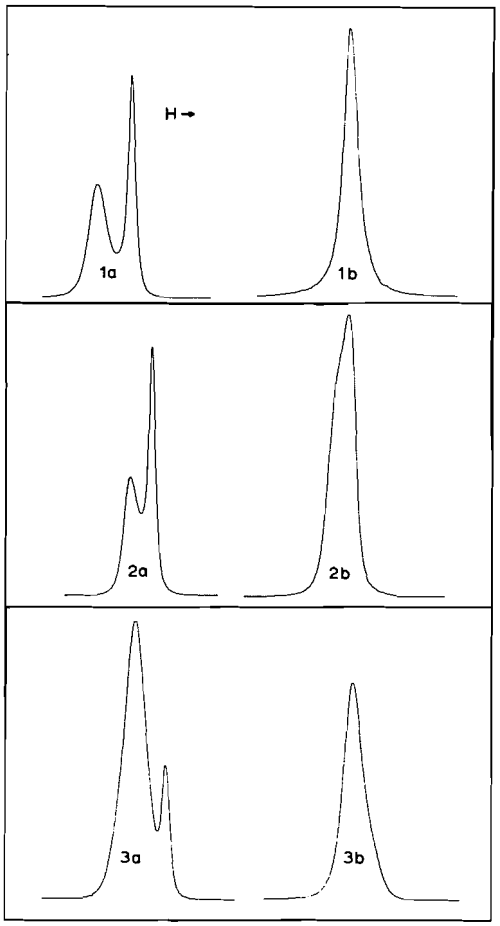

FIG. 4. Comparison of p.m.r. spectra of ion-exchange resins with different fixed ionic groups: (*1a*) Dowex AG 50W (X8), Na^+ and (*1b*) Bio-Rex 63, Na^+; (*2a*) Dowex AG 50W (X8), Na^+ and (*2b*) Bio-Rex 70, Na^+; (*3a*) Dowex AG1 (X1), I^- and (*3b*) Bio-Rex 9, I^-.

shift (28). If it were indeed so, the ion-exchange system should offer an excellent means of determining the "absolute" shift characteristic of the counterion, since, as mentioned above, the observed shifts are free from the matrix and susceptibility effects. With a view to examining the influence of the fixed ionic function, the p.m.r. spectra of the following pairs of resins were recorded (Fig. 4): (*i*) Na^+ form of Dowex AG 50W (X8) ($m = 5.26$) and Bio-Rex 63 ($m = 4.8$); (*ii*) Na^+ form of Dowex AG 50W (X4) ($m = 3.25$) and Bio-Rex 70 ($m = 3.3$), and (*iii*) I^- form of Dowex AG1 (X1) ($m = 5.2$) and Bio-Rex 9 ($m = 6.2$). The observed dissimilarity in values for each pair of resins may be due to the difference in the $\delta^0_{X^-}$ value characteristic of the fixed ion and/or due to the difference in the extent of ion association between the fixed group and the counterion. The contribution towards δ from these two factors cannot be separated particularly in weak acid and weak base resins.

Concentration Dependence of δ for Anion-exchange Resins

The variation of δ with the ionic concentration in the resin phase has already been considered for the cation-exchange resins (20). The shift data were analyzed following Hindman's treatment of water proton chemical shift in aqueous solutions of uni–uni electrolytes (17). The same procedure is followed for the anion-exchange resins. It is assumed that the experimentally observed δ values can be related to the molality of the resin salt according to the equation

$$[1] \qquad \delta = \delta^0_{salt}(m) + B(m)^2$$

where, δ^0_{salt} is δ/m as $m \to 0$ and B, a constant, depends on the nature of the salt. At infinite dilution, δ^0_{salt} can be considered to be the sum of $\delta^0_{M^+}$ and $\delta^0_{X^-}$, the cationic and anionic molal shifts, respectively. The δ^0_{salt} values were evaluated for the halide, nitrate, and perchlorate ions in Dowex AG1 resin from least square plots of δ *vs.* m and are reported in Table 2.

Hindman (17) reported a value of 0.026 p.p.m./mol for Cl^- in aqueous solutions, based on the scale $\delta^0_{NH_4^+} = 0$. Since the $\delta^0_{M^+}$ values in the resin were obtained earlier using the same scale, and since our purpose is to compare the molal shifts observed in the two systems, we assume, for consistency, that $\delta^0_{Cl^-} = 0.026$ p.p.m./mol in the resin. If there is ion-pair formation in the Cl^- form this value is expected to be lower. The experimentally observed value of δ^0_{salt} for the Cl^- form of Dowex AG1 is 0.008 p.p.m./mol. Consequently, the quaternary ammonium cation of the resin is assigned a $\delta^0_{M^+}$ value of -0.018 p.p.m./mol. Based on this value, $\delta^0_{X^-}$ were obtained for the other anions.

The anion molal shifts in the resin are compared with those found in aqueous solution in Table 2. The signs and the order of the shifts are seen to be identical in the two systems, while $|\delta^0|$ values are uniformly lower in the resin phase, thus complementing earlier observations on the molal shifts for the cations (20). $\delta^0_{X^-}$ values for Br^- and NO_3^- ions in the resin are close to the corresponding values in aqueous solution within the limits of experimental error. The larger

TABLE 2. Comparison of molal chemical shifts for anions in ion-exchange resin and in aqueous solution at 25 °C

Anion	Molal shift (p.p.m.) Ion-exchange δ^0_{salt}	Ion-exchange $\delta^0_{X^-}$	Aqueous solution $\delta^0_{X^-}$ (Hindman, ref. 17)
F^-	−0.053	−0.035	−0.075
Cl^-	0.008	0.026 (assumed)	0.026*
Br^-	0.017	0.035	0.053
I^-	0.027	0.045	0.069
NO_3^-	0.019	0.037	0.046
ClO_4^-	0.040	0.058	0.091

*Value based on $\delta^0_{NH_4^+} = 0$ scale.

differences in the case of I^- and ClO_4^- ions may very well be due to error resulting from extrapolation. The aqueous solution values for these ions have been computed from δ–m plots for NaI and NH_4ClO_4 solutions in the concentration region 0–4.5 and 0–2 m, respectively. On the other hand, the lowest concentration limit attainable in the resin is 5.2 m for I^- and 3.3 m for ClO_4^-.

Amongst the anions, the largest difference in the $\delta^0_{X^-}$ value is observed for F^-. This resembles a similar observation made with the H^+ form of the cation-exchange resin, for which $|\delta^0_{ion\text{-}ex} - \delta^0_{aq.\ soln}|$ was found to be maximum (20). In these two cases, ion-pair formation in the resin matrix is very likely as a result of the small ionic size. ^{19}F chemical shifts in the resin have been interpreted recently as indicating possible association of F^- with the resin ion (21).

Differences in the magnitude of the two sets of molal chemical shifts are only to be expected in view of the additional factors encountered in the resin system. The enormous osmotic pressure present within the resin bead, the physical presence of the intertwining hydrocarbon matrix and the immobility of the fixed ion will affect, in some way, the structure of the internal water. Considering these additional effects, there appears to be a similarity in the magnitude of the ionic molal shifts. This can be taken to indicate that either the various extraneous effects cancel each other or the electrostatic interactions of ions with water and between themselves predominantly influence the observed chemical shift of the water protons. Finally, the result that resin $|\delta^0|$ values are consistently lower for both cations and anions as compared to the ones in homogeneous aqueous solutions may be regarded as evidence of enhanced ion–ion interactions.

Effect of Temperature

Malinowski *et al.* have deduced "effective hydration numbers" for electrolytes from the results of change of proton chemical shift with temperature in aqueous solutions (14–16). By assuming that the chemical shift of water molecules hydrating the ions is not influenced by change in temperature, they have related the effective hydration number, h, to the rate of change of δ with temperature in pure water and in solution. In the present work, the temperature coefficient data obtained for some cation- and anion-exchange resins listed in Table 1 are likewise treated. The "effective hydration numbers" so obtained are included in Table 1. Values of h from our earlier work (20) and those reported independently by Creekmore and Reilley (21) are also included in the Table for comparison.

If indeed $\delta^0_{NH_4^+} = 0$, as assumed previously (17), it is satisfactory to set $d\delta_{NH_4^+}/dT$ equal to zero, or, in effect, $h_{NH_4^+} = 0$ (this may not be correct, but NH_4^+ ion does not perturb the water structure and therefore the p.m.r. signal remains unaffected (17)). For ammonium resinates, the observed hydration numbers can thus be assigned to the fixed sulfonate group (Table 1). From these values and the equation (15)

$$[2] \qquad h = n_+h_+ + n_-h_-$$

the values of h_+ for H^+ and the alkali-metal ions can be evaluated. The number of moles of cations and anions formed when one mole of salt dissociates, n_+ and n_-, are both unity for all cases

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

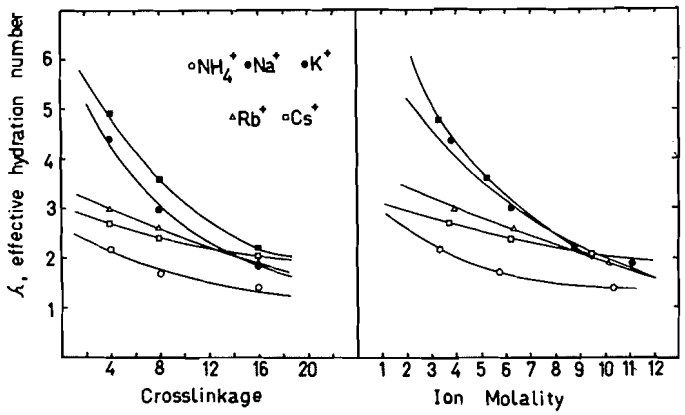

FIG. 5. Effective hydration numbers of ammonium and alkali metal resinates as (*a*) function of crosslinkage (*b*) function of molality in Dowex AG 50W resin.

considered here. It can be seen that the average values of h_+ when extrapolated to resin of crosslinkage of 0 (Fig. 5) (linear extrapolation is strictly not valid. The values of h for resin of crosslinkage 2 could not be determined since Δv is very small), are nearly equal to the ones found in aqueous solutions (Table 3). The h_+ values for Na^+, K^+, and Rb^+ decrease as the crosslinkage of the resin increases. It is inconceivable that the hydration number of Na^+ can be ~ 1 in resin of X16 when "free solvent" is present in the resin matrix. We attribute the lowering of hydration numbers of the above mentioned ions to increased ion association in the resin phase. Further evidence for ion association is derived from the fact that if the hydration number does not change with concentration of the electrolyte, then the $\delta_{soln}{}^{ethane}$ *vs.* temperature lines for all concentrations of the electrolyte should converge to a fixed point (14). It can be seen from Fig. 6 that the lines for all the crosslinkages meet at one point for Cs^+ form and not for Na^+ form. Creekmore and Reilley have reported an increase in ^{23}Na line width with increase in crosslinkage (21), which has also been interpreted in terms of ion association of Na^+ with the fixed group in the resin matrix. Our preliminary experiment with Cs^+ form of resin of crosslinkage 12 indicates that the ^{133}Cs n.m.r. signal is clearly observable and the line width is ~ 500 Hz. This may be indicative of the fact that the solvation of Cs^+ ions is not affected significantly in the resin phase with change in crosslinkage from 4 to 16. Since there is evidence for ion association in the resin phase for Na^+ with the fixed group, the hydration number as shown in Table 1, cannot be assigned to individual ions but they can be considered as number of molecules of water associated with the counterion and the fixed group (resinate) together. The effect of hydration of resinates on ion-exchange selectivity will be discussed later.

The comments on the hydration numbers for the anions in the anion-exchange resin are of a similar nature. It is assumed that the hydration number for the fixed quaternary ammonium ion

is zero (16) and that the hydration numbers obtained by the temperature dependence of the chemical shift (Table 1) are due to counterions. As expected, the hydration numbers for the anions are lower compared to those for the cations. The observations of Creekmore and Reilley (21) on the n.m.r. signal of ^{19}F in the resin phase indicate considerable ion association of the counterion with the fixed group inside the resin matrix. The hydration numbers follow the order $ClO_4^- < I^- < Br^- \leqslant NO_3^- < F^-$. The variation of h values with increasing crosslinkage is less pronounced.

Ionic Hydration and Ion-exchange Selectivity

The molal selectivity coefficient $K_{B/A}$ for two competing univalent ions A and B can be depicted by (1)

$$[3] \quad \ln K_{B/A} = \ln (\bar{\gamma}_A/\bar{\gamma}_B) + \ln (\gamma_B/\gamma_A) + (\pi/RT)(v_A - v_B)$$

where $\bar{\gamma}$ and γ are the mean activity coefficients of ions denoted by the subscript in the resin and aqueous phases, respectively. π = swelling pressure, and v = partial molar volume of ions. In a dilute solution γ_A and γ_B approach unity and thus can be neglected. $\bar{\gamma}_A$ and $\bar{\gamma}_B$ for ions cannot be determined by any direct method. According to Gregor's postulates, the activity coefficient of ions in the resin phase can be related to the solvation of the counterion and the fixed group and to the swelling pressure as follows

$$[4] \quad \ln K_{B/A} = (\pi/RT)(\bar{v}_A - \bar{v}_B)$$

where $\bar{v}_A$ and $\bar{v}_B$ are the hydrated molar volumes of ions in the resin phase. If the rationale behind the Malinowski's method is correct, we can estimate the partial molar volumes of the ions from their respective hydration numbers. For low crosslinked resin $\bar{v}$ follows the order $Na^+ > K^+ > Rb^+ > Cs^+$ and hence we obtain the selectivity sequence of ions as $Cs^+ > Rb^+ > K^+ > Na^+$. For Dowex AG 50W X16, the hydration number of counterions follows the order $Rb^+ < K^+ < Cs^+ < Na^+$. $\bar{v}$ will be in the order $Cs^+ > Rb^+ > K^+ \geqslant Na^+$ if effective radii of the cations are taken into account for estimating the $\bar{v}$ values. The selectivity sequence will then be $Na^+ \geqslant K^+ > Rb^+ > Cs^+$, which is contrary to the experimental observations (2). However, if we consider the hydrated volume of the resinate (experimental evidence exists for ion association), $\bar{v}$ perhaps follows the order $Rb^+ > K^+ > Cs^+ > Na^+$ (radius of cation has much less influence on $\bar{v}$), and hence the observed selectivity sequence can be predicted. Moreover, the reversal in the selectivity of Cs^+ and K^+ (2) *i.e.* change in sign of $\ln K_{Cs/K}$ at crosslinkage of 15 can be predicted from Fig. 5. The selectivity sequences predicted by Eisenman (7) from his observations on the electrode glasses of varying composition can also be predicted from the degree of hydration of the resinates, *i.e.* the predicted selectivity sequences for the alkali-metal ions for the sulfonated resins are $Cs^+ > Rb^+ > K^+ > Na^+$, below X12; $Rb^+ > Cs^+ > K^+ > Na^+$ from X12–X14; and $Rb^+ > K^+ > Cs^+ > Na^+$ from X15–X20.

Similarly, from Table 1, the selectivity sequence for the anions in Dowex AG1 can be predicted as $ClO_4^- > I^- > Br^- \sim NO_3^- > F^-$, which is the observed sequence (2).

Gregor's theory presents a simplified approach towards the interpretation of ion-exchange equi-

libria. Its applicability has been demonstrated by modifying the concept of hydrated volume of ions inside the resin phase and not counterion alone. As stated earlier, Gregor considered the solvation of both the fixed group and the counterion. This is the first time that some experimental results have been obtained to demonstrate the applicability of the theory. Unfortunately, the selectivity sequences for ions other than alkali-metal ions can hardly be rationalized, for example $\bar{v}$ for NH_4^+ is lower than that of Cs^+ and thus NH_4^+ should be preferred in the resin phase which is contrary to the experimental observations. Similarly the sequences for alkyl ammonium ions cannot be rationalized. It probably fails to account for the selectivity of large, poorly solvated ions.

A mechanistic approach based on ion–ion and ion–solvent interactions in the resin phase has been suggested (5–7). These interactions are considered to be electrostatic in nature for a fixed grouping of low field (sulfonic acid or quaternary ammonium groups). Hydration of ions is recognized as of key importance in terms of energetics rather than hydrated volume. For complete discussion of the ion-exchange selectivity we refer to articles by Reichenberg and Diamond and Whitney in ref. 2. The selectivity coefficient is related to the net free energy change in the ion-exchange equilibrium when the resin is in contact with solution of ions A and B.
Thus

$$[5] \quad \ln K_{B/A} = -\Delta G_{B/A}{}^0/RT = -(1/RT)[(\overline{\Delta G}_h{}^B - \overline{\Delta G}_h{}^A) - (\Delta G_h{}^B - \Delta G_h{}^A) + (\overline{\Delta G}_{el}{}^B - \overline{\Delta G}_{el}{}^A)]$$

where $\overline{\Delta G}_h$ and ΔG_h are free energy of hydration of the ions depicted by superscripts in the resin and aqueous phase respectively. $\overline{\Delta G}_{el}$ is electrostatic free energy of ion interacting with the fixed group. Our experimental observations indicate that large changes in ΔG values are involved even for alkali-metal ions when they are taken up into the resin phase from dilute solutions. The subject of ion hydration and ion pairing has been treated extensively (29–31) but there is no satisfactory theoretical treatment to calculate the free energy change for these equilibria wherein the dielectric constant of the medium is not known. The selectivity coefficients can only be predicted qualitatively. However, it is difficult to rationalize the selectivity of large ions in resins of low crosslinkage. Recent observations of Zundel from infrared (i.r.) spectra of polystyrenesulfonic acid of 5% crosslinkage indicate that large ions can form a lattice type structure inside the resin matrix (32). The electrostatic free energy is further lowered (Madelung factor). This type of structure is formed if the fixed groups are separated by appropriate distance. If they are too close together, the lattice type of structure cannot exist and thus a reversal in selectivity is expected. The lattice type structure can also permit larger "free water" content in the matrix. Polyvalent ions similarly orient themselves in the resin matrix to maximize the electrostatic free energy (32). The ion-exchange selectivity depends not only on hydration of ions but also on the orientation of counterion with respect to the fixed groups and the polarizability of ions (specific interactions). Zundel has further shown from i.r. spectra that the ions like Ag^+, Tl^{3+}, Hf^{4+} have greater interaction with the fixed groups.

The total water content of the resin in a given ionic form can be regarded as the sum of "bound" and "free" water molecules (1)

$$[6] \quad H_2O_{(t)} = H_2O_{(b)} + H_2O_{(f)}$$

all quantities referring to 1 g resin in H^+ form. Since $H_2O_{(b)}$ is given by $(h \times Q \times 18/1000)$ where Q is the capacity in meq/g, and knowing $H_2O_{(t)}$, it is possible to determine $H_2O_{(f)}$. The amounts of "free" water calculated in this way for Dowex AG 50W in some alkali-metal forms are found in Table 4. It is surprising to note that the free water is almost constant for a given crosslinkage of resin for alkali-metal ion forms. The free water is probably present to minimize the repulsion between the fixed group. The concept of "free" water has some bearing on the mobility of ions in the resin phase. It is indeed postulated that "free" water aids the transport of ions in the matrix.

Finally, mention should be made of the apparent anomalous behavior of the resin in H^+ and F^- forms. In both these cases, increase in ion molality results in an increase of hydration number. Kaminsky observed anomalous temperature effects on the viscosity of aqueous solutions of structure-forming ions like Li^+ and Mg^{2+} and attributed this to the long range ordering of water molecules (33). It is also interesting to note that temperature effect on

TABLE 4. Total, bound, and free water in Dowex AG 50W resins of different ionic forms and crosslinkages

proton chemical shifts yields lower values of h for LiCl and $MgCl_2$ as compared to CsCl and $CaCl_2$, respectively (16). It appears that this technique for the determination of hydration number generally tends to give rather unexpected values for structure-forming ions. It is likely that the cause for these deviations can be traced to the assumptions involved in the derivation of the relationship of temperature dependence of the chemical shift. More experimental evidence in both aqueous and resin systems (for the structure forming ions) is necessary before any definite conclusion can be drawn.

Conclusions

Proton magnetic resonance can be effectively used as a probe to investigate the perturbations of the internal water structure in the ion-exchange resins caused by the matrix and the fixed and counterions. The concentration–chemical shift and temperature–chemical shift data obtained lend themselves to reasonable quantitative treatments similar to those employed by Hindman and Malinowski in the study of aqueous electrolyte solutions. Insight into ion–water, ion–ion, and water–water interactions might be gained by comparing such parameters as δ^0_{ion} and h in the two systems. Experimental evidence up to this point seems to support the original concept of ion-exchange resins as concentrated aqueous electrolyte (34). Further, it is hoped that a knowledge of the parameters such as those reported in this work might prove useful in interpreting the experimentally observed ionic selectivities, rate of uptake of ions etc., in the ion-exchange resin.

The Crystal Structure of $KIO_3.HIO_3$

LILIAN Y. Y. CHAN AND F. W. B. EINSTEIN
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received June 11, 1970

The crystal structure of potassium hydrogen di-iodate (bi-iodate) $KIO_3.HIO_3$ was determined from three dimensional X-ray data collected by counter methods. The structure was refined by full-matrix least-squares techniques to a conventional R factor of 5.0% for the 1392 observed reflexions. The salt crystallizes in the monoclinic space group $P2_1/c$ with eight formula units in a cell of dimension $a = 7.028(1)$ Å, $b = 8.203(1)$ Å, $c = 21.841(3)$ Å, $\beta = 98.03(1)°$.

The iodate units are all basically pyramidal; weak interionic I—O contacts complete a very distorted octahedral environment around three iodine atoms. There is a capped octahedral (7-coordinate) environment around the remaining iodine atom. The I—O bonds are in the range 1.75–1.82 Å and the I—OH bonds are 1.91 and 1.95 Å; variations in length can be correlated with differences in the degree of involvement in (*a*) hydrogen bonding and (*b*) interaction with adjacent iodine atoms.

Canadian Journal of Chemistry, 49, 468 (1971)

Introduction

The crystal structure of α-iodic acid, HIO_3, was studied by Rogers and Helmholz (1) and was found to contain pyramidal IO_3 groups. Later, a neutron diffraction study by Garrett (2) showed the hydrogen bonding in the structure to consist of infinite chains of the type, ...H—IO_3...H—IO_3...H—IO_3. It was also pointed out (1) that three more distant oxygen atoms completed a distorted octahedron around the central iodine atom. Dasent and Waddington (3) studied the infrared spectra of a number of iodates; among them potassium hydrogen di-iodate, $KIO_3.HIO_3$. It was found that for this compound, the spectrum was complex and the bands could not be assigned satisfactorily from a simple structural model. They concluded therefore that two types of iodate groups were present. We have carried out an X-ray crystal structure analysis of $KIO_3.HIO_3$ in order to ascertain firstly the nature of the hydrogen bonding and secondly to examine the differences in the iodate groups including the interactions between oxygen and iodine atoms of neighboring iodate ions.

Experimental

Colorless potassium hydrogen di-iodate crystals were obtained by crystallizing equimolar quantities of HIO_3 and KIO_3 from hot water. Weissenberg photographs of the zones *h*0*l*, *h*1*l*, *h*2*l* using CrK_α radiation, together with precession photographs of the zones *hk*0, 0*kl* and several other general *hkl* zones using MoK_α radiation, showed systematic absences for *h*0*l*: $l = 2n + 1$ and 0*k*0: $k = 2n + 1$. This combined with the Laue group, 2/*m*, indicated unambiguously the space group $P2_1/c$.

Crystal Data

$KIO_3.HIO_3$

Monoclinic, f.w. = 390, space group $P2_1/c$ with $a = 7.028(1)$, $b = 8.203(1)$, $c = 21.841(3)$ Å, $\beta = 98.03(1)°$ and $V = 1246.8$ Å^3. $D_m = 4.17(10)$ g/cm^3 (Berman density balance determination), $D_x = 4.16$ g/cm^3, $Z = 8$, $F(000) = 1392$, $\mu(MoK_\alpha) = 108.7$ cm^{-1}.

All data were collected using a plate-shaped crystal fragment of dimensions 0.54 × 0.19 × 0.05 mm mounted with the *b* axis (the direction of greatest elongation) parallel to Φ. The largest crystal face was the {100}; the remaining faces were not identified on account of the irregular crystal shape. Cell constants were determined by applying a least-squares fit to 30 general high angle reflexions. $MoK_{\alpha1}$, $K_{\alpha2}$, and K_β measurements were used in three independent refinements whose results did not differ significantly. The values quoted were that based on $MoK_{\alpha2}$, $\lambda = 0.713543$ Å, at 22 °C. The numbers in parentheses are the least-squares estimated standard errors.

Reflexion intensities for the unique set of data were manually measured with Niobium-filtered MoK_z radiation, $\lambda = 0.7107$ Å, using a scintillation detector with pulse-height analysis. Measurements were made using a 1.2° takeoff angle with a symmetrical θ–2θ scan of 1.6° width (carried out at a rate of 4°/min). Background counts of 12 s were measured at both scan limits. Of the 1644 intensities recorded in the range $0° < 2\theta < 45°$, 1392 were above 2σ and were considered as observed reflexions. ($\sigma = \sqrt{N}$ where N is the scan count plus the total of both background counts.) Three standard reflexions were measured every 3 h and retained a constancy within 1% over the entire data collection. Coincidence losses were checked by measurement of outstanding reflexions together with some of intermediate intensities at lower incident beam strength; since a constant relationship was found, no coincidence losses were assumed. An experimental absorption curve in Φ was determined at $\chi = 90°$; the intensity varied symmetrically about $\Phi = 0$. Approximate absorption corrections were applied to the intensity data according to this experimental curve and then Lorentz and polarization

factors were applied to give structure factors in the usual manner.

Structure Determination

The density and space group requirements could only be met by having eight formula units per unit cell, each asymmetric unit consisting of two formula units. From the unsharpened three-dimensional Patterson function it was possible to assign positions for four independent iodine atoms. These atomic coordinates, with isotropic temperature factors of 2.0 Å^2, were used to phase the structure factors. One cycle of full-matrix least-squares refinement of these atomic positions and individual isotropic temperature factors was carried out. The function minimized was $\Sigma\omega(|F_o| - |F_c|)^2$ where ω was chosen to be unity. The conventional R-factor (defined as $(\Sigma|F_o| - |F_c|)/\Sigma|F_o|$) dropped from 0.49 to 0.30. A three-dimensional electron-density map was computed from which two potassium atomic positions were located. Two cycles of least-squares refinement on these atomic positions and isotropic temperature factors brought the R-factor down to 0.20. At this point, an electron density difference map revealed twelve oxygen atoms around the iodine atoms and in one cycle of least-squares refinement the agreement improved to 0.132.

An examination of the structure factors F_o and F_c at this stage showed that the experimental absorption curve applied was too severe and it was modified to be less so. The R-factor improved spectacularly to 0.071. After two cycles of full-matrix least-squares refinement varying all isotropic and coordinate parameters, the agreement was 0.058. At this point, some of the low angle reflexions appeared to be affected by extinction. An isotropic extinction parameter E_c was introduced such that the following expression was minimized by the least-squares procedure

$$\sum \omega \left(F_o - \frac{F_c}{1 + E_c \times I} \right)^2$$

where I is the uncorrected intensity and $\omega = 1$. (The final value of E_c was 0.0000841(53).) The R-factor dropped to 0.054, while all the temperature factors were held isotropic. An electron density difference map showed as its largest feature that all four iodine atoms were moving anisotropically. Two cycles of least-squares refinement including anisotropic temperature factors for the four iodine atoms brought the value of R down to 0.050 and showed further shifts negligible. Whilst the anisotropic thermal motion and extinction parameters might well contain errors due to the approximate absorption corrections, the values obtained were physically reasonable. The improvement obtained from introducing these variables was sufficiently large to justify them on Hamilton's criterion (4). Until completion of the refinement, $\omega = 1$ had been used throughout. This choice was justified on the basis of an examination of trends for $\Sigma\omega\Delta^2/n$ as a function of $\sin\theta/\lambda$ and $|F_o|$, where $\Delta = |F_o| - |F_c|$ and n = total number of reflexions. For the final cycle, ω was given a constant value (0.1307) such

*Anisotropic thermal parameter used for iodine atoms (Å)^2 × 10^4.

†These values were obtained from $\beta_{ij} = 2\pi^2 b_i b_j U_{ij}$ where β_{ij} appear as a temperature effect through $\exp[-(\beta_{11}h^2 + 2\beta_{12}hk + \ldots)]$ in the structure factor expression and b_i are the reciprocal lattice vectors.

that the error of fit, $[\Sigma\omega(|F_o| - |F_c|)^2/(N_o - N_v)]^{\frac{1}{2}}$, where $(N_o - N_v)$ = number of observations − number of variables, was 1.00. This gave 'correct' standard errors for the coordinate and temperature parameters as absolute weights were used.

An electron density difference map computed after the refinement was complete showed no positive peaks greater than 0.7 e/Å^3 though a negative trough of −1.2 e/Å^3 was found.

The scattering factors used throughout including anomalous scattering for iodine and potassium atoms, were taken from the "International Tables for X-ray Crystallography" (5).

The major programs used were our modifications of the NRCC Data Reduction Program, the University of Canterbury (New Zealand) versions of ORFLS, ORFFE, and FORDAP. Calculations were carried out at the Simon Fraser University Computing Centre on an IBM 360/50.

Table 1 gives the final atomic parameters. The least-squares estimated standard errors are listed in parentheses. Table 2 lists the relevant interatomic distances and angles, the standard errors in parentheses include errors from cell dimensions and those estimated from the variance–covariance matrix calculated during the last cycle of least-squares refinement. Table 3 lists the $|F_o|$ and F_c for each measured reflexion where $|F_c| = |\sqrt{A^2 + B^2}|$ and F_c has the sign of A since, in general, B is small. Accidentally unobserved reflexions are indicated as negative $|F_o|$ and were given the value of $\sigma/2$. Figure 1 shows the packing of the ions within the unit cell viewed down the a^* axis.

Structure Description and Discussion

(I) Environment of the Iodine Atoms

For each of the iodine atoms, there are three oxygen atoms at a distance of ~1.8 Å from the central iodine atom, forming a distorted pyramidal arrangement. The I—O bond lengths vary from 1.753 to 1.952 Å.

In addition to these expected covalent bonds, there are extensive oxygen–iodine contacts ranging from 2.4 to 3.4 Å between neighboring iodate ions. Iodine atoms are found to have two types of environment.

(a) Distorted Octahedron

Around I(*1*), I(*3*), and I(*4*), there are three short I—O contacts of ~1.8 Å as well as three long I...O contacts of ~2.6 Å for I(*3*) and I(*4*) and ~3.0 Å for I(*1*). These six oxygen atoms form a distorted octahedron about the central iodine atom. A similar environment around the iodine atom is also found in αHIO_3 (1).

(b) Distorted Capped-Octahedron

Each iodate group, based on I(*2*), has in addition to the three covalently bonded oxygen atoms, four more distant contacts (~3.0 Å)

TABLE 2. Interatomic distances and angles

(*a*) I—O bond distances

Predicted formal bond order	Contacts	Observed bond length (Å)	Average length (Å)*

forming a distorted capped-octahedron around the iodine atom. Two of these weaker contacts are provided from a crystallographically equivalent (centro-symmetrically related) iodate I(*2*) ion. The remaining two arise from oxygen atoms of other independent iodate ions.

(II) Description of K^+ Ion Environment

Each potassium ion has eight near-neighboring oxygen atoms, K^+—O being 2.67–3.04 Å. Each ion has a similar environment which can best be described as a distorted square antiprism.

(III) Crystal Packing

The overall structure may be considered to consist of $(IO_3...HIO_3...HIO_3)^-$, $(IO_3...IO_3)^{2-}$, and K^+ ions packed together electrostatically. Rogers and Helmholz (1) had originally interpreted the structure of αHIO_3 as being held together by bifurcated hydrogen bonds. Later, Wells (6) re-examined the structure and concluded that it was better described as infinite $HIO_3...HIO_3...$ chains; this model was confirmed by Garrett's (2) neutron diffraction work. $KIO_3.HIO_3$ may be regarded as containing a fragment of this chain, which suggests that chains of this type have some inherent stability.

The packing density of oxygen atoms in $KIO_3.HIO_3$ is less than those found for other structures containing the iodate ion. The volume per oxygen atom is 26.0 $Å^3$ compared with 21.8 in ceric iodate monohydrate (7), 20.8 in HIO_3, 24.7 in sodium iodate, and about 16 in a closest packed oxygen structure. The oxygen atoms in $KIO_3.HIO_3$ do not form a closest packed arrangement, a result which is hardly surprising.

The Covalent I—O Bonds

The twelve independent I—O bonds (range 1.75 to 1.95 Å) show two significantly longer I—O bonds, namely I(*5*)—O(*42*) = 1.952 and I(*3*)—O(*32*) = 1.911 Å. These can reasonably be expected to be the hydroxylic oxygen atoms (the final electron density difference map showed peaks in suitable positions for hydrogen atoms but these peaks were no larger than other spurious non-atomic peaks). Further support for this interpretation is provided by the distances of O(*42*)—O(*32*) = 2.708 and O(*42*)—O(*11*) = 2.731 Å. These are fully consistent with the O—H stretching frequency in the infrared spectrum (3) which would predict an OH...O length of 2.7 Å on the basis of existing empirical correlations (8, 9). Also from these I—O and O—O distances, one concludes that O(*42*) acts both as a hydrogen bond donor and acceptor, whereas O(*32*) acts as hydrogen bond donor alone. The interatomic angles in Table 2*d* show reasonable agreement with this conclusion.

The I—O bonds of order 1 in O_2I—OH are significantly different from those of formal bond order $1\frac{2}{3}$ (in the IO_3^-, 1.80 Å) which do not, however, differ significantly from those of bond order 2 (in the HIO_3 molecule, 1.78 Å). Two factors are likely to mask these fractional differences between multiple bonds, firstly involvement as hydrogen bond acceptors, and secondly, variations in the weak donation of the oxygen atoms lone pair of electrons to an adjacent iodine atom's empty d orbitals. The latter effect may well be a crucial one in this structure, since the high effective charge on the iodine atom makes it strongly electrophilic.

The Weak I—O Interactions

The relatively high charge (5+) and electronegative environment of the iodine atom may be responsible for contraction of the d orbitals allowing them to provide suitable overlap with the oxygen p orbitals, as pointed out by Mitchell (10). This would provide an explanation of the extensive, weak I--O interactions found in $KIO_3.HIO_3$; in addition, for the XO_3^- species, one would expect acceptor strength to decrease in the series X = I, Br, Cl, as I is the most polarizable and thus has the highest effective positive charge.

It is worthwhile comparing the weak I—O interactions between the IO_3^- and the HIO_3 species listed in Table 2. In the IO_3^- ions

(involving I(*1*) and I(*2*)), the average I...O distances are invariably longer than those for the HIO_3 molecules (I(*3*) and I(*4*)). These differences may be explained in terms of the negative charge of the IO_3^- ion being more localized on the iodine atom than in the case for the HIO_3 molecule. Hence, the negative oxygen atoms would find it easier to approach, and donate, to the vacant empty 5d orbitals of the more electropositive iodine atom in HIO_3.

We propose that the lone pair on the iodine atom is situated in between the longer I—O contacts in the case of the distorted octahedral environment. If such is the case, one would not expect a head-on approach of an oxygen atom directly towards a lone pair position as is found in a regular capped octahedron. In fact, the approach of the distorted capped oxygen atom O(*31*) to I(*2*) is considerably displaced towards one side of the triangle formed by O(*21*)′, O(*22*)′, and O(*13*). This suggests that the lone pair of I(*2*) in the I(*2*)–I(*2*) dimer has more s character than the other iodine atoms.

The thermal motion for the different atoms in $KIO_3.HIO_3$ is in general low, even after approximate absorption corrections have been made. None of the iodine atoms show markedly anisotropic motion and in the absence of any sound physical model to base corrections on, we have used interatomic distances uncorrected for anisotropic thermal movement. The corrections would be small in any event, and susceptible to the errors in our treatment of absorption. The small amount of thermal motion may be attributed to the ionic nature of the crystals together with the hydrogen bonding giving a stable 3-dimensional structure. It is also consistent with the hardness and difficulty in cleaving crystals.

Note added in proof

Dr. K. Rieckhoff and Mr. R. Ninnis have kindly examined a sample of $KIO_3 \cdot HIO_3$ and have detected a strong second harmonic effect indicating that, as in the parent structures KIO_3 and HIO_3, a crystallographic center of symmetry is lacking. This result is in agreement with the piezoelectric effect recently reported (11). It might be expected that the deviations from centrosymmetry arise mainly through the hydrogen bonding.

We wish to thank Dr. D. G. Tuck of this Department for suggesting the problem and for his interest in its solution. We are grateful to Dr. F. R. Ahmed and Dr. B. R. Penfold who kindly supplied their computer programs. Our thanks are also due to the National Research Council of Canada as without their financial support this work could not have been carried out.

The Raman Spectra of the Chlorofluorosilanes in the Gaseous, Liquid, and Solid State; Anomalous ^{35}Cl, ^{37}Cl Isotope Intensity Effects in the Splitting of the Totally Symmetrical SiCl Stretching Mode in $SiCl_3F$ and $SiCl_2F_2$

K. HAMADA,[1] G. A. OZIN, AND E. A. ROBINSON

University of Toronto, Lash Miller Chemical Laboratories and Erindale College, Toronto 181, Ontario

Received July 17, 1970

The Raman spectra of the chlorofluorosilanes are reported in their various phases together with vibrational assignments of the normal modes. The ^{35}Cl–^{37}Cl isotope lines of the totally symmetrical SiCl stretching modes in $SiCl_3F$ and $SiCl_2F_2$ were partially resolved in the solid and liquid phases and their intensities were found to be approximately normal in the liquid state but may show deviations in the solid state. Possible reasons for this behavior are discussed and the results are compared with similar effects observed for CCl_3F and $CHCl_3$.

Introduction

One of the advantages of laser Raman spectroscopy is that highly reactive or hygroscopic materials can be studied in all-glass cells and in certain favorable cases in all three phases. A change in structure with phase is thus easily detected and, by studying the species in the gas phase, spectra can be obtained free from interfering effects that often make the spectra of solids and liquids difficult to interpret.

Using argon-ion and krypton-ion laser excitation we have been able to obtain excellent quality spectra in the gas, liquid, and solid phases for most of the chlorofluorosilanes; the vibrational data for which has previously been incomplete (1, 2). As far as can be certain the Raman spectra of $SiCl_2F_2$ and $SiClF_3$ have not been previously reported and our gas phase data for SiF_4, $SiClF_3$, $SiCl_2F_2$, and $SiCl_3F$ are new.

Experimental

The chlorofluorosilanes were prepared according to the method of Booth and Swinehart (3) through a Swartz type reaction. Silicon tetrachloride was partially fluorinated using antimony trifluoride with antimony pentachloride as a catalyst, and the chlorofluorosilanes were separated by means of trap-to-trap distillation and low temperature fractionation. The separate fractions were found to be sufficiently pure for spectroscopic examination as the peak intensities of impurity bands, were always less than 5% of the strongest band in the fraction under investigation. Raman spectra were recorded on a Spex 1401 spectrometer using a Carson argon ion laser (2 W at 4880 or 5145 Å) or krypton-ion laser (200 mW at 5682 or 6471 Å) for excitation. For measurements at low temperature the cell used was similar to that previously described (5).

Results and Discussion

The vibrational modes for the tetrahedral molecules SiF_4 (T_d), $SiClF_3$ (C_{3v}), $SiCl_2F_2$ (C_{2v}), and $SiCl_3F$ (C_{3v}) are such that all modes are expected to be Raman active.

The Raman spectra of the chlorofluorosilanes are shown in Tables 1, 2, and 3 together with polarization data for the liquids and gases. The vibrational assignments are straightforward for $SiCl_3F$ and $SiClF_3$ by analogy with the recently published liquid phase Raman spectra of the bromofluorosilanes (4) and are also shown in Tables 1, 2, and 3. In the case of $SiCl_2F_2$ some ambiguity lies in the assignment of the three low frequency deformations of symmetry type b_1, b_2, and a_2 but the two a_1 type deformations in $SiCl_2F_2$ are easily identified since their lines will be polarized and the symmetrical SiF_2 deformation is expected to be at a higher frequency than the corresponding $SiCl_2$ deformation.

In the spectrum of $SiCl_3F$ three doublets occur at 946 and 935, 640 and 620, and 476 and 467 cm^{-1}, respectively, all of which may be interpreted as due to Fermi resonance. Thus, for example, in the solid phase 946 (a_1) is in resonance with 2×467 ($a_1 \times a_1 = a_1$), 640 (e) is in resonance with $467 + 168$ ($a_1 \times e = e$), and 467 (a_1) is in resonance with 2×238 ($a_1 \times a_1 = a_1$).

An interesting feature of the present study relates to the ^{35}Cl, ^{37}Cl isotope splitting, an effect well known for ν_1 of the tetrahedral MCl_4 species (M = C, Si, Ge, Sn, Ti, and P), ν_1 of planar

BCl_3, ν_5 of $CHCl_3$, and ν_1 of Si_2Cl_6 (5). The observed intensities of the component lines constituting the multiplets are generally found to be in satisfactory agreement with those theoretically predicted from the abundances of the chlorine isotopes; however, in one or two cases, notably in solid $CHCl_3$ (−196 °C), anomalous isotope intensities have been observed (6).

The calculations of isotope intensities are generally based on the first order approximation that the intensity of a line associated with a particular isotope arrangement is proportional to the probability of forming that molecular arrangement. For example, the chlorine isotope splitting of the SiCl totally symmetrical stretching mode in Si_2Cl_6 has been observed (5); five of the expected seven components were observed at −196 °C and their intensities found to be in satisfactory agreement with those predicted on the above model. The remaining two were expected to be too weak to be detected.

In the present study we have observed the chlorine isotope splitting for solid $SiCl_3F$ and $SiCl_2F_2$ at −196 °C, and for the liquids at 25 °C. The Raman data are consistent with the expected symmetries (C_{3v} and C_{2v}, respectively) in both the solid and liquid phases and the observed frequencies and gross intensities remain essentially

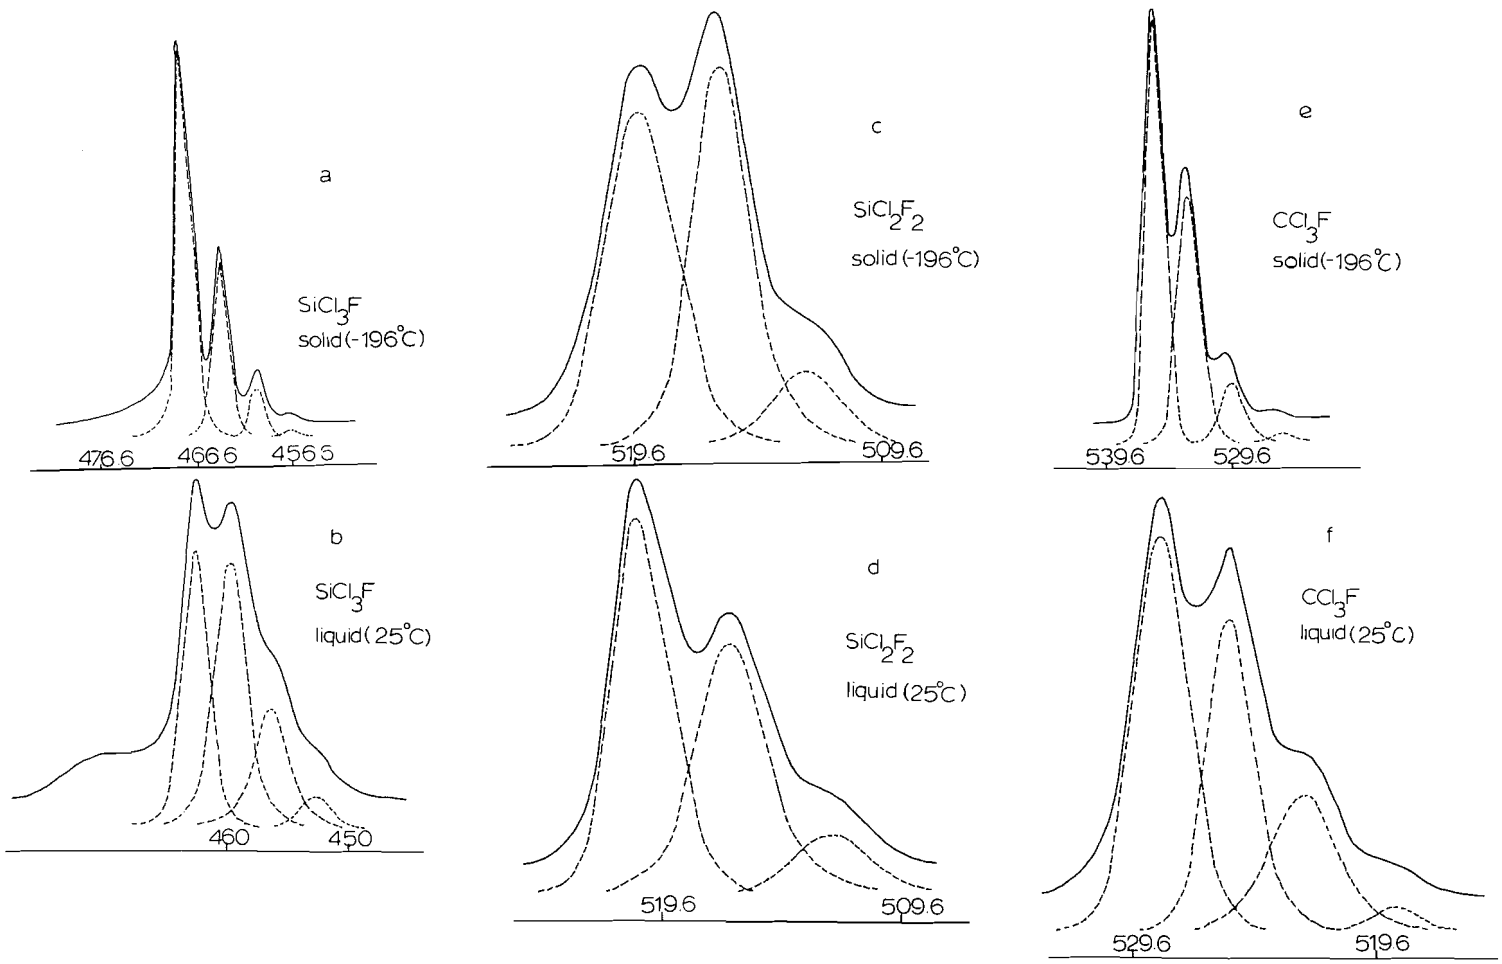

FIG. 1. ^{35}Cl, ^{37}Cl isotope splitting in the a_1 MCl stretching mode of (*a*) solid $SiCl_3F$ (−196 °C), (*b*) liquid $SiCl_3F$ (25 °C), (*c*) solid $SiCl_2F_2$ (−196 °C), (*d*) liquid $SiCl_2F_2$ (25 °C), (*e*) solid CCl_3F (−196 °C), and (*f*) liquid CCl_3F (25 °C).

TABLE 4. Correlation of a C_{3v} molecule through the site symmetry C_s and into the crystal $D_{2h}{}^{16}$

C_{3v} (Free molecule 4 in unit cell)	C_s (Site symmetry) [Correlating about $\sigma(\times z)$]	$D_{2h}{}^{16}$ (Unit cell)
$4\times a_1$	$4a'$	$a_g+b_{2g}+b_{1u}+b_{3u}$
$4\times e$	$4a'$	$a_g+b_{2g}+b_{1u}+b_{3u}$
	$4a''$	$b_{1g}+b_{3g}+a_u+b_{2u}$

unchanged between phases. However, the chlorine isotope lines for the a_1 SiCl stretching modes in $SiCl_3F$ and $SiCl_2F_2$ are found to be approximately normal in the liquids but show deviations in the solids. The observed intensities are shown in Fig. 1, together with the individual peaks obtained by use of a Dupont curve resolver.

In the case of $SiCl_3F$ (*cf.* CCl_3F), the solid state intensities clearly show deviations (Fig. 1*a*) from the theoretical values 28.8:28.2:19.2:1.0. However, the liquid state intensities for the species $Si^{35}Cl_3F$, $Si^{35}Cl_2{}^{37}ClF$, $Si^{35}Cl^{37}Cl_2F$, and $Si^{37}Cl_3F$ are approximately in agreement with the theory (Fig. 1*b*). It is interesting to note that the isotope component intensity ratios in solid $CHCl_3$ (5), $SiCl_3F$, and CCl_3F (Fig. 1*a* and 1*e*) for the symmetrical MCl stretching modes, are all *closely similar.*

If the crystal structures of CCl_3F and $SiCl_3F$ are isomorphous with that of the known structure of crystalline $CHCl_3$ ($P_{nma}[D_{2h}{}^{16}]$), with four molecules in the primitive unit cell (7), then correlation splitting of the a_1 MCl stretching mode to give similar intensities of the isotopic components is reasonable. The anomalous intensities of the isotope components in CCl_3F and $SiCl_3F$ can then be attributed to an unresolved factor group splitting. For site symmetry C_s the correlation shown in Table 4 would be expected.

In the case of $SiCl_2F_2$ the three predicted components of the totally symmetrical stretching mode due to the isotope species $Si^{35}Cl_2F_2$, $Si^{35}Cl^{37}ClF_2$, and $Si^{37}Cl_2F_2$ were partially resolved. The expected intensity ratios 9.40:6.13:1.00 were approximately observed in the liquid phase (Fig. 1*d*) but again the ratios of the intensities in the solid state (Fig. 1*c*) were anomalous. These probably result from a similar phenomenon to that described for solid $SiCl_3F$ and solid CCl_3F, that is, unresolved factor group splitting.

The authors are grateful to the Defence Research Board of Canada and the National Research Council of Canada for financial support.

Synthesis and Structure of 3-Methyl-1-phenyl-4-sulfhydrylbenzylidene-5-thiopyrazolone

R. F. LANGLER
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received August 25, 1970

The synthesis of 3-methyl-1-phenyl-4-sulfhydrylbenzylidene-5-thiopyrazolone (**4**) is reported. It is a potential sequestering agent as well as a new example of a β-dithiocarbonyl compound. The structure of **4** is unambiguously established by conversion to 4-benzoyl-3-methyl-1-phenyl-5-pyrazolethiol (**3**).

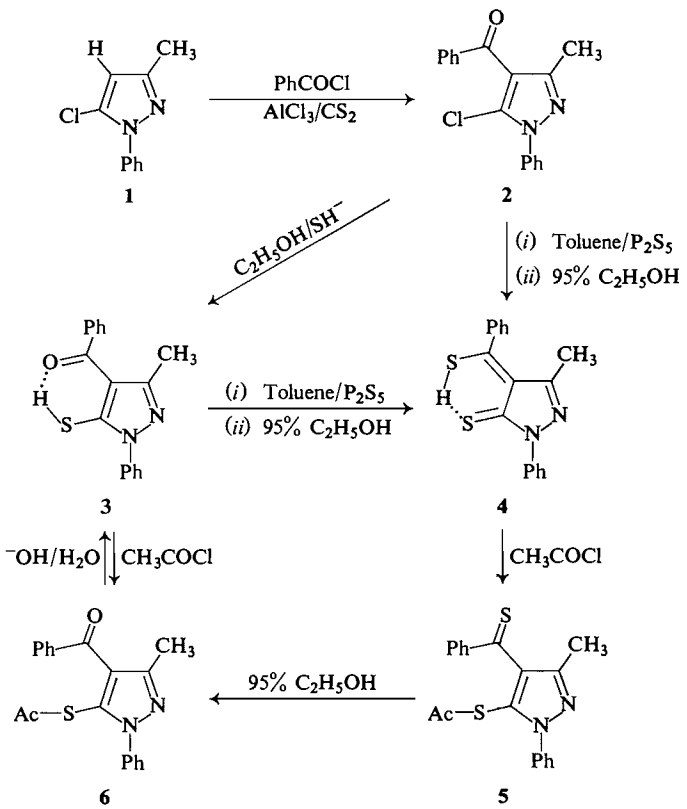
Canadian Journal of Chemistry, **49**, 481 (1971)

In recent years, there has been an increasing interest in the application of sulfur-containing ligands to trace-metal analysis. A number of successful syntheses of both monothio (1–4) and dithio analogs (5–7) of the β-dicarbonyl chromophore have been reported. I now report the preparation of a new β-dithiocarbonyl system.

A 4-acyl pyrazole substrate was selected because of the well established value of these systems as sequestering agents (8, 9).

Treatment of 4-benzoyl-5-chloro-3-methyl-1-phenylpyrazole (**2**) or 4-benzoyl-3-methyl-1-phenyl-5-pyrazolethiol (**3**) with phosphorus pentasulfide in hot toluene gives 3-methyl-1-phenyl-4-sulfhydrylbenzylidene-5-thiopyrazolone (**4**) in 10 and 15% yields respectively (see Scheme 1).

The i.r. spectrum of **4** exhibits a broad, weak absorption band at 2400 cm^{-1} which does not change upon dilution, in accord with an intramolecularly H-bonded thiol. The n.m.r. spectrum displays a sharp singlet at -0.1 τ (1H) which is



SCHEME 1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

readily removed from the spectrum when the sample is shaken with D_2O, thus further substantiating the thiol moiety. Also evident in the n.m.r. are a broad signal centered at 2.4 τ (10H) and a singlet at 8.2 τ (3H) assigned to the two phenyl rings and the C-3 methyl group respectively.

The high resolution mass spectrum of **4** shows the molecular ion at *m/e* 310.0586 ($C_{17}H_{14}N_2S_2$) and an abundant ion at *m/e* 121.0113 (C_7H_5S) in agreement with a thiobenzoyl group. Other abundant ions occur at *m/e* 309 ($M^{\cdot+}$-H), 277 ($M^{\cdot+}$-SH), 105 (PhN_2^+), 77 ($C_6H_5^+$), and 51 ($C_4H_3^+$) all of which were determined at low resolution. The loss of a hydrogen radical ($M^{\cdot+}$-1) and an ·SH radical ($M^{\cdot+}$-33) from the molecular ion are processes observed in the mass spectrum of enethiolphenone **3** and have been observed in other enethiol systems (1).

The u.v. spectrum of **4** exhibits maxima at 235 (ε 15 900), 310 (ε 5600), and 538 nm (ε 228), the latter of which shifts to 450 nm (ε 3480), in the presence of dilute sodium hydroxide. Hopefully, this base-induced hypsochromic shift will prove useful in characterizing other β-dithiocarbonyl compounds. No analogous shift is observed in the u.v. spectrum of enethiolphenone **3**.

When the red crystalline dithiopyrazole **4** is refluxed in acetyl chloride, the blue, oily monoacetate **5** is obtained. Its i.r. spectrum displays an intense enethiolacetate carbonyl bond (4) at 1720 cm^{-1}. The n.m.r. spectrum of this dithioacetate exhibits two sharp singlets (3H each) at 7.9 and 7.8 τ confirming monoacetylation.

The mass spectrum of the acetylated dithio adduct **5** does not show a molecular ion but is essentially identical to that of **4** with an additional ion at *m/e* 43 (CH_3CO^+). The u.v. spectrum displays maxima at 595 (ε 100), 310 (ε 10 000), and 232 nm (ε 20 000).

By momentarily refluxing the dithioacetate **5** in 95% ethanol a quantitative conversion to the colorless crystalline monothioacetate **6** is accomplished. The i.r. spectrum of **6** shows intense absorption bands at 1720 and 1660 cm^{-1} in agreement with enethiolacetate and enaminophenone functions respectively. The n.m.r. spectrum exhibits two methyl singlets at 7.9 and 7.7 τ. A high resolution mass spectrum established the molecular ion as 336.0929 a.m.u. ($C_{19}H_{16}N_2O_2S$) showing no ion at *m/e* 121 and displaying abundant ions at *m/e* 105 ($C_7H_5O^+$, $C_6H_5N_2^+$) and 43 (CH_3CO^+). The mass spectrum of **6** is essentially identical to that of **3** with an additional ion at *m/e* 43.

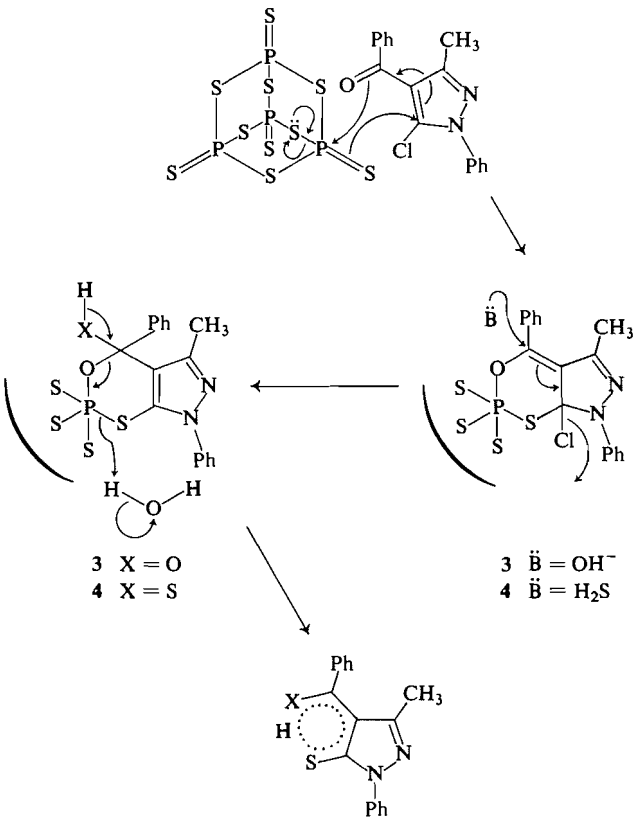
Since the instability of thioketones is well established (10), the mild hydrolysis of **5** to **6** lends chemical support to the formulation of **5** as a thiophenone.

The monothio acetate **6** may also be conveniently prepared by treating **3** with acetyl chloride, thus unambiguously establishing the skeleta of **6**, **5**, and **4** and conclusively establishing **4** as the desired dithioketo system.

The facile conversion of the monothioacetate **6** to the enethiolphenone **3** in dilute aqueous sodium hydroxide provides chemical evidence for the formulation of **6** (and therefore **5**) as an *S*-acetate, since this functional group is particularly unstable to base (11).

The n.m.r. resonance positions of the C-3 methyl group in the chlorophenone **2**, the enethiolphenone **3**, and the dithiopyrazole **4** are 7.5, 7.9, and 8.2 τ respectively. This can be interpreted to indicate progressively decreasing π-electron density along the C_4—C_5 bond of the pyrazole nucleus, thereby resulting in progressively lesser deshielding of the C-3 methyl group by the π-system of the ring. Hence, I have formulated the dithiopyrazole as tautomer **4**. Such a formulation is in accord with expectation. Tautomeric forms involving a thiophenone are essentially precluded by the instability of thioketones (10). Further, thioamides are generally quite stable (12) and the resonance energy of the pyrazole nucleus appears to be rather small (9) so that the ring itself provides little energy for enolization of the thiolactam thiocarbonyl.

If the residue from the reaction of chlorophenone **2** with phosphorus pentasulfide is recrystallized from 95% ethanol, excess reagent is hydrolyzed, generating H_2S *in situ*, and red crystals of **4** are obtained in 10% yield. If, however, the residue is washed with several aliquots of 2½% sodium hydroxide solution, no dithiopyrazole **4** is obtained but the enethiolphenone **3** is isolated from the wash solution in 10% yield. Since dissolution of pure dithiopyrazole **4** in aqueous sodium hydroxide does not result in the formation of any enethiolphenone **3**, it is reasonable to propose that some intermediate is formed between P_2S_5 and chlorophenone **2**, which is then decomposed upon work-up to give products



SCHEME 2

dependent upon the nucleophiles present in solution. A proposed mechanism is depicted in formula Scheme 2.

Experimental

General

The i.r. spectra were recorded on a Baird Associates Model 4-55 Double-beam spectrophotometer. The mass spectra were determined with a Bell and Howell/CEC 21-110B spectrometer. The n.m.r. spectra were obtained on a Varian A-60 instrument using TMS as internal standard. The u.v. spectra were recorded using a Coleman Model 124 Hitachi Double Beam spectrophotometer. Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. The t.l.c. was carried out on plates of silica gel G (A. G. Merck).

Preparation of 4-Benzoyl-5-chloro-3-methyl-1-phenylpyrazole (2)

The chlorophenone **2** is prepared as described by Michaelis and Rojahn (13) from the chloropyrazole **1** (14). The preparation requires reflux of the appropriate compounds (*vide* formula Scheme 1), in CS_2 for 18 h. If the procedure is modified by allowing the CS_2 to evaporate after refluxing for 15 min, and heating the dry reaction mixture for 5–6 h at 70 °C, the yield, after basification and ether extraction, is 83% as opposed to the reported yield of 65–70%.

Preparation of 3-Methyl-1-phenyl-4-sulfhydrylbenzylidene-5-thiopyrazolone (4)

Purified phosphorus pentasulfide[1] (10 g) (15) and either 4-benzoyl-5-chloro-3-methyl-1-phenylpyrazole (**2**) or 4-benzoyl-3-methyl-1-phenyl-5-pyrazolethiol (**3**) (6 g) (16, 17) were heated in distilled toluene (50 ml) for 3.5 h at 100 °C. The toluene was decanted, evaporated, and the residue recrystallized from 95% ethanol (25 ml). Red needles (650 mg) were obtained after recrystallization to constant m.p. (128–130 °C). The product was homogeneous on t.l.c. (R_F, 0.45) using benzene as eluant. The i.r. bands were present ($CHCl_3$) 2400 and 1600 cm^{-1}; λ_{max} (EtOH) 235 (ε 15 900), 310 (ε 5600) and 538 nm (ε 228). The n.mr. spectrum ($CDCl_3$) showed signals at τ −0.1 (1H, D_2O exchangeable), 2.4 (10H), and 8.2 (3H). The high resolution mass spectrum confirmed the formula as $C_{17}H_{14}N_2S_2$ (molecular ion *m/e* 310.0586).

Preparation of 5-Mercaptoacetyl-3-methyl-1-phenyl-4-thiobenzoylpyrazole (5)

The dithiopyrazole **4** (100 mg) was refluxed in freshly

[1]Reagent grade CS_2 should be used for the preparation of purified P_2S_5 as described in this reference.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

distilled acetyl chloride (10 ml) for 1 h. The acetyl chloride was evaporated to give the blue, oily dithioacetate **5**. This oil exhibited two spots on t.l.c. The major spot (R_F, 0.60) using chloroform for elution was due to **5**. The secondary spot proved to be identical with authentic **6** when double spotted. The i.r. bands ($CHCl_3$) were present at 1720 and 1600 cm^{-1}; λ_{max} (EtOH) 232 (ε 20 000), 310 (ε 10 000) and 595 nm (ε 100).

The n.m.r. spectrum ($CDCl_3$) showed signals at τ 2.3 (10H), 7.8 (3H), and 7.9 (3H).

Preparation of 4-Benzoyl-5-mercaptoacetyl-3-methyl-1-phenylpyrazole (6)

Enethiolphenone **3** (100 mg) was refluxed in freshly distilled acetyl chloride (10 ml) for 1 h. Evaporation of the acetyl chloride, and recrystallization of the residue from benzene/low boiling petroleum ether gave colorless crystals (m.p. 114–115 °C).

The recrystallized product was homogeneous on t.l.c. (R_F, 0.45), using chloroform as eluant. The i.r. bands were present ($CHCl_3$) at 1720, 1660, and 1600 cm^{-1}; λ_{max} (EtOH) 210 (ε 22 000), 260 (ε 16 000) and 270 nm (ε 10 000). The n.m.r. spectrum ($CDCl_3$) displayed signals at τ 2.4 (10H), 7.7 (3H), and 7.9 (3H). The high resolution mass spectrum confirmed the formula as $C_{19}H_{16}N_2O_2S$ (molecular ion *m/e* 336.0929).

Hydrolysis of 5

5-Mercaptoacetyl-3-methyl-1-phenyl-4-thiobenzoylpyrazole (**5**) (44 mg) was heated in boiling 95% ethanol for 2 min. The ethanol was evaporated and the residue recrystallized from benzene/low boiling petroleum ether to give **6** (40 mg). Identity with authentic **6** (*vide supra*) was established by t.l.c., n.m.r., i.r., and a mass spectrum. No depression of m.p. was observed when the sample was admixed with authentic **6**.

Basic Hydrolysis of 6

4-Benzoyl-5-mercaptoacetyl-3-methyl-1-phenylpyrazole (**6**) (52 mg) was added to a solution of methanol (2 ml) – 2½% aqueous sodium hydroxide (8 ml) and the solution gently refluxed. As solid **6** dissolved, the solution turned yellow. After 1 h the solution was acidified and extracted with ether. The ether (dried over $MgSO_4$) was evaporated to give crude enethiolphenone **3** (42 mg).

After recrystallization from 95% ethanol, identity was established with authentic **3** by mixed m.p., t.l.c. and n.m.r. spectra.

It is a pleasure to express my sincere gratitude to Dr. D. E. Ryan, who initiated and supported this research, and to Dr. C. A. Armour for his interest and encouragement. Special thanks are extended to both Mr. D. J. Embree, who obtained the mass spectra, using the mass spectrometric facilities of the Atlantic Regional Laboratories of the National Research Council of Canada, Halifax, and to Dr. D. L. Hooper of Dalhousie University who ran the n.m.r. spectra.

Dibenzo[*a*,*d*]cycloheptene and Related Compounds. III.[1] The Synthesis of Some Analogues of Methadone Containing the Dihydrodibenzo[*a*,*d*]cycloheptene and the Tetrahydrodibenzo[*a*,*d*]cyclooctene Ring Systems

D. E. HORNING AND J. M. MUCHOWSKI[2]
Bristol Laboratories of Canada, Candiac, Quebec

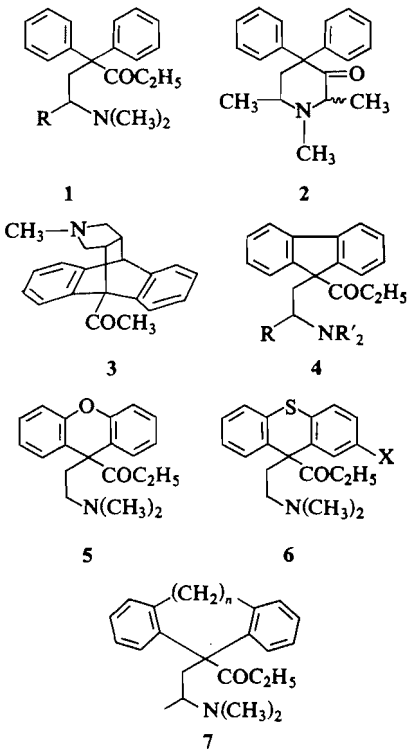
Received July 6, 1970

The synthesis and spectral properties of some two- and three-carbon ortho-bridged analogues of the analgesic methadone are described. These compounds were devoid of analgesic activity.

Canadian Journal of Chemistry, 49, 485 (1971)

Methadone (**1**, R = CH_3), a clinically useful narcotic analgesic (2), was first prepared by Bockmuhl and Ehrhart (3) during the second World War. Although considerable effort has been devoted to structural modification of this molecule (3–6; see especially ref. 4, pp. 969–986), most of the synthetic activity has been confined to the preparation of conformationally flexible open chain systems much like methadone itself. Structures **2** (7), **3** (8), **4** (ref. 4, pp. 985–986, and refs. 9, 10), **5** (11), and **6** (12) represent notable departures from this trend.[3]

We wished to prepare analogues of **1** in which the mobility of the aliphatic portion of the molecule was essentially unaltered, but wherein the rotational freedom of the phenyl groups was intermediate between that of methadone and structures **3**–**6**. A study of Dreiding models indicated that the two- and three-carbon ortho-bridged compounds **7** (n = 2, 3) were capable of adopting several conformations in which the angle between the planes of the aromatic rings closely resembled that observable in a number of the conformations readily accessible to methadone. The preparation of **7** (n = 2, 3) for evaluation as analgesics therefore was of considerable interest, and the synthesis of these compounds was achieved in the manner described in Scheme 1.

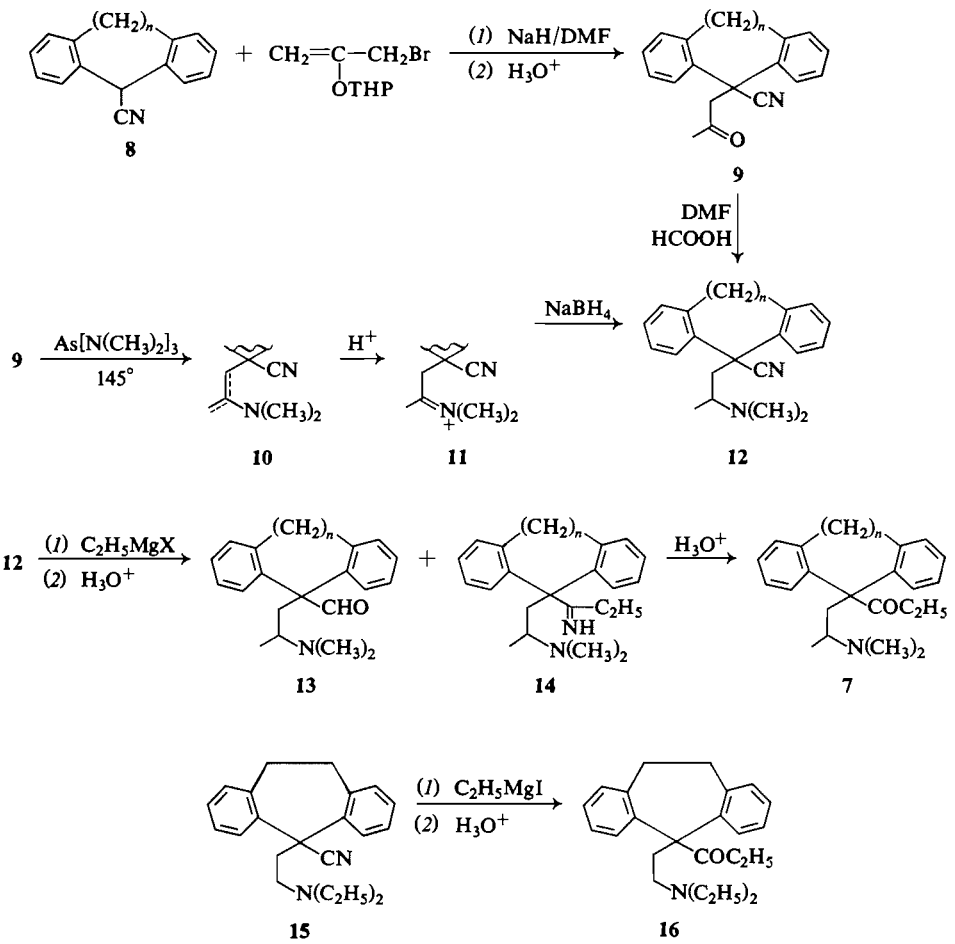


The alkylation of the cyanides **8** with 3-bromo-2-(tetrahydropyran-2-yloxy)-propene (THP = tetrahydropyran-2-yl), generated *in situ* (13), followed by acidic hydrolysis of the intermediate enol ethers, produced the keto nitriles **9**, which in turn were converted to the methadone-type nitriles **12** by a Leuckart reaction[4] with dimethylformamide and formic acid. The transformation

[1]For Part II see ref. 1.

[2]To whom enquiries concerning this paper should be addressed.

[3]Compound **2** was said (7) to be "quite toxic" and did not exhibit "promising analgesic activity", **3** had 1/20 of the activity of morphine (1/25 methadone) in mice on subcutaneous administration (8), **4** (R = R′ = CH_3) was described (9) as showing "slight analgesia at 0.5–5 mg/kg", **5** was reported (11) to possess "1/5 of the analgesic activity of morphine (1/6 methadone) when used on experimental animals", and **6** (X=H, Cl) was not active (12) in mice or rats at 10 mg/kg (subcutaneous).



SCHEME 1

of **9** to **12** could also be effected[4] by the borohydride reduction of the quaternary imminium tosylates **11** derived from the corresponding enamines **10** and anhydrous *p*-toluenesulfonic acid. These enamines were obtained when the keto nitriles **9** and *tris*-dimethylamino arsine were heated together at 145°. When the nitriles **12** were treated with an excess of an ethyl Grignard reagent at 90°, mixtures of the reduction products **13** and the expected imines **14** were produced in both cases. The relative proportions of these products depended on the ethyl halide which was used for the preparation of the Grignard reagent; for example, with **12** ($n = 2$), ethylmagnesium iodide gave approximately equal amounts of the aldehyde and the imine, while ethylmagnesium bromide produced a 2:1 imine–aldehyde mixture. While the reduction of hindered nitriles to aldehydes by secondary and tertiary Grignard reagents is known (14), the reaction does not appear to have been described for primary Grignard reagents. The increase in the proportion of the aldehyde **13** ($n = 2$) when ethylmagnesium iodide was substituted for ethylmagnesium bromide is comparable to that observed for the reduction of ketones to the corresponding alcohols by Grignard reagents (15). The behavior of the nitrile **12** ($n = 3$) was atypical in the sense that the relative amount of the aldehyde was greater for ethylmagnesium bromide. The hydrolysis of the imines **14** to the ketones **7** was accomplished under relatively mild conditions (*e.g.* see ref. 17) by heating an aqueous solution of the hydro-

[4]When this work was nearing completion, a patent was issued (16) which described the application of essentially identical synthetic approaches to methadone-type nitriles.

bromide salts at reflux temperature for *ca.* 2.5 days.

One example, **16**, of a compound related to normethadone (**1**, R = H) was prepared from the known (18) nitrile **15** and ethylmagnesium iodide.

The yields and physical constants of some of the above compounds are contained in Table 1, the n.m.r. and i.r. spectral data are compiled in Tables 2 and 3.

On the basis of physical and chemical evidence, Casy ((19) and refs. therein) proposed that the favored conformation of methadone and its salts in solution was probably represented by structure **17**. The non-equivalence of the *N*-methyl

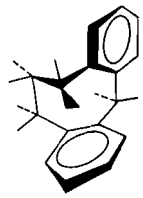
19



20

groups in the n.m.r. spectrum of methadone salts and the high field n.m.r. absorption of the secondary methyl group (in comparison to that of the corresponding nitrile for example; see Table 3) in methadone and its salts were consistent with this proposal.

An examination of Dreiding models of the seven- and eight-membered analogues of methadone (**7**, $n = 2, 3$) showed that the acyclic portions of these molecules could readily adopt a chair-like conformation virtually identical to that of methadone.[5] Furthermore, the flexible tetrahydrodibenzo[*a*,*d*]cyclooctene system in **7** ($n = 3$) could assume conformations varying from the favorable with aryl planes intersecting at 110° (*i.e.* **19**), to the relatively unfavorable with nearly (within 25°) bisecting aryl planes (*i.e.* **20**). On the other hand, the comparatively rigid dihydrodibenzo[*a*,*d*]cycloheptene system of **7** ($n = 2$) adopted a boat-like conformation (*i.e.* **18**)[6] with the aryl planes tilted about 60° from coplanarity.

One of the more salient observations to be made from the data shown in Table 3 was the similarity of the n.m.r. spectra of methadone free base and the eight-membered analogue **7** ($n = 3$). In addition, hydrochloride salt formation in this compound resulted in the anticipated downfield shift and non-equivalence of the *N*-methyl groups like that observed for methadone. In contrast to methadone, however, the chemical shift of the secondary methyl group[7] was not significantly altered on salt formation. This indicated that the expected deshielding was compensated for by an increase in aromatic shielding, perhaps as a result of a decrease in the conformational mobility of the acyclic portion of the molecule (see below). The non-equivalence of the *N*-methyl groups[8] and the unchanged chemical shift of the secondary methyl group in the salt, both were in support of a strong hydrogen bond between the carbonyl oxygen atom and the protonated amino group, probably in a conformation similar to that depicted by **17**.

The n.m.r. spectra of the seven-membered compound (**7**, $n = 2$) and methadone free base also showed similarities, but the *N*-dimethyl group was much more shielded than for methadone. Salt formation again produced the expected downfield shift of the *N*-dimethyl group but in this case the non-equivalence ($\Delta = 17$ Hz) of the *N*-methyl groups was much more dramatic. In addition, as for methadone, protonation of the dimethylamino group resulted in a concomitant deshielding of the secondary methyl hydrogens, but the magnitude of this shielding was larger than for methadone. The high field position of the *N*-dimethyl group in the base and the salt was interesting and was evidence for a conformation in which both *N*-methyl groups were specially shielded by the aromatic features of the molecule. This observation when viewed in conjunction with the high field position of the secondary

[5]The acyclic portions of the xanthene and thioxanthene compounds, **5** and **6**, and normethadone (**1**, $R = CH_3$) had about the same conformational mobility, but the aryl groups in **1** were restricted to within 35 ° of coplanarity.

[6]Two identical boat conformers, which differed only in the relative dispositions of the 5-substituents, were possible.

[7]The secondary methyl groups for several of the compounds listed in Tables 2 and 3 did not appear as simple doublets separated by J_{H-CH_3} (*e.g.* see footnotes ¶ and §§, Table 2). This phenomenon was probably due to virtual coupling (20) between the secondary methyl group and the β-methylene function. In these cases, the J_{H-CH_3} coupling constants should be viewed as being very approximate.

[8]A referee has pointed out that the non-equivalence of the *N*-methyl groups in the salts of methadone and **7** ($n = 2, 3$) is dependant on the proximity of the dimethylammonium group to an asymmetric carbon, and conformational preferences, and that pronounced chemical differences are evidence for marked conformational preferences (see ref. 21). In this connection, it is worth noting that salts of methadone nitrile do not show non-equivalent *N*-methyl groups. Further, the evidence for an intramolecular hydrogen bond in a conformation such as **17** for methadone salts is based on reactivity and i.r. data (see (19) and refs. therein), and pk_a measurements (23*b*), in addition to the n.m.r. studies cited above. Lastly, the above conformation is found in crystalline methadone hydrobromide as shown by X-ray data (see (19) and refs. therein).

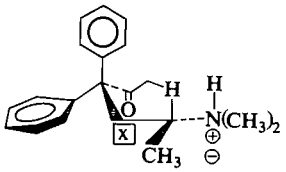
methyl group (lower than methadone, but still shielded in comparison to the nitrile **12** (n = 2)), make it unlikely that **7** (n = 2) and methadone possess similar conformations.

Any apparent conformational similarities between **7** (n = 2, 3) and methadone were not mirrored by their physiological activities in laboratory animals (mice) since neither the seven- nor the eight-membered analogues had detectable analgesic activity (Eddy hot plate test) at dose levels of 150 and 50 mg/kg by the oral and subcutaneous route respectively.[9]

Portoghese has proposed (22, 23) that **21** may represent the manner in which methadone interacts with the "analgesic receptor" (⊖ represents an anionic site; ⊠ denotes an H-bonding proton donor dipole). Compounds **3–7**, and **16** clearly cannot adopt a conformation with bisected aryl planes as in **21** although **7** (n = 3) could approach



21

it. The lack of analgesic activity in compounds **7** (n = 2, 3) and **16** would seem to be consistent with the existence of such a conformation (*i.e.* **21**) at the receptor level.[10]

Experimental

The melting points were determined in a Gallenkamp melting point apparatus and are not corrected.

A solution of anhydrous *p*-toluenesulfonic acid was prepared by distilling off the benzene–water azeotrope from a benzene solution of *p*-toluenesulfonic acid monohydrate. The acid concentration was determined by titration of an aliquot with standard sodium hydroxide solution (phenolphthalein).

5-Cyano-10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene (**8**, n = 2) and 12-cyano-5,6,7,12-tetrahydrodibenzo[*a*,*d*]-cyclooctene (**8**, n = 3) were prepared according to a published procedure (1).

The term "carbonate solution" used throughout the Experimental section refers to an aqueous solution of sodium carbonate (200 g/l).

*5-Cyano-5-acetonyl-10,11-dihydrodibenzo[a,d] cycloheptene (**9**, n = 2)*

A 60% dispersion of sodium hydride in mineral oil (2.00 g, 50 mmol) was freed of the carrier with hexane, covered with DMF (50 ml), and cooled to 0°. A solution of 1,3-dibromo-2-(tetrahydropyran-2-yloxy)propane (9.0 g, 30 mmol (13)) in dry DMF (10 ml) was added all at once and the cooling bath was removed. At 10°, hydrogen evolution became vigorous; the temperature was not allowed to exceed 25°. After 45 min, when gas evolution had become slow, the mixture was cooled to 0° or less, and the solid nitrile (**8**, n = 2; 4.38 g, 20 mmol) was added portion-wise while maintaining the temperature at 0°. The cooling bath was removed, and after 3.5 h at room temperature the solution was poured into a large volume of water. The product was extracted into benzene, the extract was dried over sodium sulfate and evaporated *in vacuo*. The oily enol ether was taken up in a solution consisting of methanol (180 ml) and 10% hydrochloric acid (20 ml), and heated at reflux temperature for 1 h. The solution was evaporated to a small volume *in vacuo* the residue was diluted with a large volume of water and the product was extracted into dichloromethane. The extract was dried over sodium sulfate, the solvent was removed *in vacuo* and the residue was crystallized from 2-propanol. The yield of product, m.p. 155–157°, was 4.07–4.51 g (74–82%). On recrystallization this material melted at 157–158°, resolidified, and then melted again at 161–162°.

*12-Cyano-12-acetonyl-5,6,7,12-tetrahydrodibenzo-[a,d]cyclooctene (**9**, n = 3)*

This compound, prepared in the same way as the corresponding seven-membered compound, was obtained in 66–77% yield.

*5-Cyano-5-(2-dimethylamino)propyl-10,11-dihydrodibenzo[a,d]cycloheptene (**12**, n = 2)*

(1) Leuckart Method

The ketone (2.75 g, 10 mmol), DMF (40 ml), and 90% formic acid (2 ml), were heated together at 190° in a stainless steel bomb for 42 h. The cooled solution was diluted with water, made alkaline with carbonate solution, and then extracted with benzene. The benzene phase was alternately extracted with 10% hydrochloric acid and water, dried over sodium sulfate, and evaporated *in vacuo*. The solid residue was crystallized from 2-propanol to give the recovered ketone, m.p. 156–157° then 160–161° (706–980 mg). The combined aqueous and acid extract from above was made alkaline with carbonate solution and the product was extracted into dichloromethane. The extract was dried over sodium sulfate and evaporated *in vacuo* giving an oil (1.53–1.84 g, 78–82% based on ketone consumed) which crystallized on standing. It was sufficiently pure to be used directly in the Grignard reaction. The acid oxalate, prepared in the manner described below, had m.p. 150–152°.

*(2) Borohydride Reduction of the Quaternary Imminium Tosylate **11** (n = 2)*

A mixture of the ketone (10 mmol) and *tris*-dimethylaminoarsine ((24); 2 ml, 2.25 g, 10.8 mmol) was heated

[9]The compounds were administered orally as dispersions (Tween) in water and subcutaneously as aqueous solutions of the non-crystalline hydrochloride salts. The activities were double checked to exclude possible animal variations. Compound **16** was inactive at an oral dose of 150 mg/kg.

[10]On the other hand, the significant activity shown by **3** and **5** is an enigma which will probably have to be accounted for in terms of some other mode of substrate–receptor interaction. It would also be of interest to determine if the thioxanthene compounds **6** (inactive at 10 mg/kg) had analgesic activity at the dose levels at which compounds **3** and **5** were reported to be active (10–40 mg/kg).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

briefly at 200° to form a melt, and the melt was then placed in an oil bath at 145° until the evolution of dimethylamine was complete (10 min). To the cooled glass was added dry benzene (50 ml) and the mixture was stirred to effect solution of the enamine (i.r. 1614 cm^{-1} (neat)). To the stirred mixture was added a solution of anhydrous *p*-toluenesulfonic acid in benzene (75 ml; 6 mg/ml). After 1.5 h the solvent was removed *in vacuo*, dry DMF (75 ml) was added to the residue, and the mixture was cooled to 0° with stirring. Sodium borohydride (1.5 g) was added portionwise, and then stirring was continued at 0° for 0.5 h. The mixture was poured into ice-water containing some salt, this was shaken with benzene, filtered through Celite to break the emulsion, and the organic phase was separated and combined with a benzene extract of the aqueous phase. The extract was washed well with water, dried over sodium sulfate, and the solvent was removed *in vacuo*. The residual amine borane (i.r., 2375 cm^{-1}(neat)) was dissolved in 75% acetic acid (200 ml) containing 10% hydrochloric acid (2 ml), and the solution was heated on a steam bath for 2.5 h. The solvent was removed *in vacuo*, the residue was diluted with water, made basic with carbonate solution, and extracted with benzene. The organic phase was extracted with 10% hydrochloric acid, the acid phase was made alkaline with carbonate solution, and the liberated base was extracted into dichloromethane. The extract was dried over sodium sulfate and evaporated *in vacuo* leaving an oil (1.61–1.92 g, 53–63% yield) which usually crystallized on standing. It was further purified by conversion to the acid oxalate in 2-propanol. The yield of this salt, m.p. 149–152° was 40–49% based on the starting ketone. The pure base could be recovered from the oxalate in greater than 95% yield.

*12-Cyano-12-(2-dimethylamino)propyl-5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene (**12**, n = 3)*

(a) Method 1

The Leuckart reaction was carried out in the same way as for the seven-membered ketone, however it was necessary to purify the cyano amine by dry column chromatography (25) on neutral alumina [Fluka, activity II, ratio of alumina to compound = 200 (by weight), elution solvent, 1% methanol in chloroform (v/v)] to free it of a more polar impurity. The yield of the pure amine was 14% based on starting material taken or 26% based on unrecovered starting material.

(b) Method 2

The reaction was carried out precisely as for the seven-membered compound except that the crude product was purified by dry column chromatography (neutral alumina, activity II) to remove two more polar side products. The column was developed with 2% methanol in chloroform. The amine, m.p. 75–77°, identical to that prepared by method 1, was obtained in 25–32% yield.

*5-Formyl-5-(2-dimethylamino)propyl-10,11-dihydrodibenzo[a,d]cycloheptene (**13**, n = 2) and 5-Propionyl-5-(2-dimethylamino)propyl-10,11-dihydrodibenzo[a,d]cycloheptene (**7**, n = 2)*

The cyano amine (**12**, $n = 2$) was reacted with 2 molar equiv. of ethylmagnesium bromide exactly as described by Attenburrow *et al.* (26). The reaction mixture was decomposed with 20% hydrobromic acid, and the acid phase was made alkaline with carbonate solution and extracted with dichloromethane. The extract was dried over sodium sulfate and evaporated *in vacuo* leaving an oil (2.3 g from 2.26 g of the nitrile) which was taken up in 20% hydrobromic acid (50 ml). Magnesium chloride hexahydrate (10 g) was added and after 12 h the solid was collected by filtration. It was immediately slurried in carbonate solution, and the liberated base was extracted into dichloromethane. The extract was dried over sodium sulfate and evaporated *in vacuo* leaving the crude crystalline aldehyde. This material was sublimed at 90°/0.005 mm to give the pure aldehyde m.p. 92–93° (410 mg, 18%). When ethylmagnesium iodide was used the yield of this product was 25%.

The acidic filtrate from above was made alkaline with carbonate solution and extracted with dichloromethane. The usual manipulations gave the imine (**14**, $n = 2$, i.r., 1640 cm^{-1}(neat), 1.41 g) which contained a trace of the aldehyde as shown by i.r. spectroscopy. Hydrogen bromide gas was bubbled through an ethereal solution of this mixture, the whole was evaporated *in vacuo*, and the residue was taken up in water (300 ml) and heated at reflux temperature for 48–66 h. The solution was made alkaline with carbonate solution and the liberated base was extracted into dichloromethane. After the usual work-up, the oily base was evaporatively distilled at 140–150°/0.005 mm to give a viscous oil (1.00 g, 41%). When ethylmagnesium iodide was used the yield of this base was 25%. We were not able to prepare any crystalline derivatives of this compound (*e.g.* oxalate, hydrochloride, hydrobromide, tartarate, etc.). For n.m.r. purposes, the hydrochloride was prepared by the addition of a dichloromethane solution of the base to a three-fold excess of dry hydrogen chloride in the same solvent. The solution was evaporated to dryness *in vacuo*, dichloromethane was added to the residue, and the solvent was again removed. This process was repeated two additional times and the solid foam thus obtained was dried *in vacuo* over calcium chloride for 12 h.

*12-Formyl-12-(2-dimethylamino)propyl-5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene (**13**, n = 3) and 12-Propionyl-12-(2-dimethylamino)propyl-5,6,7,12-tetrahydrodibenzo[a,d]cyclooctene (**7**, n = 3)*

The Grignard reaction on the nitrile was carried out as for the corresponding seven-membered compound. The aldehyde–imine mixture was easily separated by dry column chromatography on neutral alumina (activity II) using 2% methanol in chloroform as the eluant. When ethylmagnesium iodide was used the yield of the oily aldehyde (i.r. 1723 cm^{-1}(neat)) was 26%. The aldehyde was not characterized further. The crude imine was produced in 38% yield (i.r. 1638 cm^{-1}(neat)). If ethylmagnesium bromide was used the yield of the aldehyde rose to 42% while that of imine dropped to 31%.

The imine was hydrolyzed in the usual manner. The crude product was evaporatively distilled at 150°/0.005 mm to give 15–27% of the pure ketone (based on starting nitrile). This base also did not give any crystalline salts with the usual acids. The hydrochloride salt (solid foam) was prepared in the same way as described for the seven-membered compound above.

*5-Cyano-5-diethylaminoethyl-10,11-dihydrodibenzo-[a,d]cycloheptene (**15**)*

This compound was prepared by the dropwise addition

of a toluene solution of *N,N*-diethyl-2-chloroethylamine to a solution of the nitrile (**8**, $n = 2$) in *t*-butanol containing sodium *t*-butoxide. The pure amino nitrile (80% yield) had physical constants in agreement with those reported by Davis *et al.* (18).

*5-Propionyl-5-diethylaminoethyl-10,11-dihydrodibenzo[a,d]cycloheptene (**16**)*

The reaction of **15** with ethylmagnesium iodide was carried out exactly as described by Attenburrow *et al.* (26) with the exception that the decomposition of the Grignard reaction mixture was carried out with 20% hydrobromic acid. The base was evaporatively distilled at 140–150°/0.01 mm to give a clear viscous oil (50% yield).

We thank Dr. T. Conway of these laboratories, and Professor B. Belleau of the University of Ottawa, Ottawa, Canada, for invaluable discussions concerning several aspects of this paper. We wish to thank Dr. R. Berman and J. C. Vigeant of the Pharmacology Division of these laboratories for making the mouse activity data on compounds 7, ($n = 2, 3$) and **16** available to us. The n.m.r. spectra were recorded by G. Lacasse whose efforts in this regard are gratefully acknowledged.

Oligoribonucleotide Synthesis. II.[1] Preparation of 2′-*O*-tetrahydropyranyl Derivatives of Adenosine and Cytidine Necessary for Insertion in Stepwise Synthesis

THOMAS NEILSON AND EVA S. WERSTIUK
Department of Biochemistry, McMaster University, Hamilton, Ontario

Received July 30, 1970

The syntheses of N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**2**) and N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**11**) and their corresponding 5′-*O*-*p*-methoxytrityl derivatives, **3** and **12** respectively, are described. Compounds **2**, **3**, **11**, and **12** are the protected derivatives of adenosine and cytidine required for insertion into a new oligoribonucleotide synthesis. Compound **2** was prepared from the known 2′-*O*-tetrahydropyranyladenosine by perbenzoylation followed by de-*O*-benzoylation. Compound **11** is prepared from cytidine by the following sequence: orthoacetate protection of the 2′- and 3′-hydroxyls; benzoylation of the 5′- and N^4-positions; orthoacetate ring opening provided a mixture of the 2′- and 3′-monoacetates from which the major, 3′-*O*-acetyl-N^4,5′-*O*-dibenzoylcytidine (**7**) was isolated; dihydropyran treatment on the 2′-hydroxyl of **7** and subsequent selective deacylation studies were carried out. Specific de-*O*-acylation gave **11**.

Canadian Journal of Chemistry, 49, 493 (1971)

Synthesis of oligoribonucleotides of defined length and sequence is essential for the investigation of the many remaining problems surrounding the phenomenon of protein synthesis, in particular, the nature of transfer RNA binding sites in aminoacyl synthetases and ribosomes. Although enzymic synthesis can supply a few oligonucleotides of this type, at present only chemical synthesis is potentially capable of supplying all possible combinations. Additional advantages inherent in chemical synthesis stem from its ready extension to the preparation of analogues, for example, changing the bases of any given sequence, say one at a time.

No synthetic material longer than a triribonucleotide has been made by purely chemical means following the preparation of the 64 triplets by Lohrmann *et al.* (2). Their approach was relatively laborious and tended to be inefficient resulting often in yields of a few o.d. units. Two developments however, have encouraged further interest in this general area.

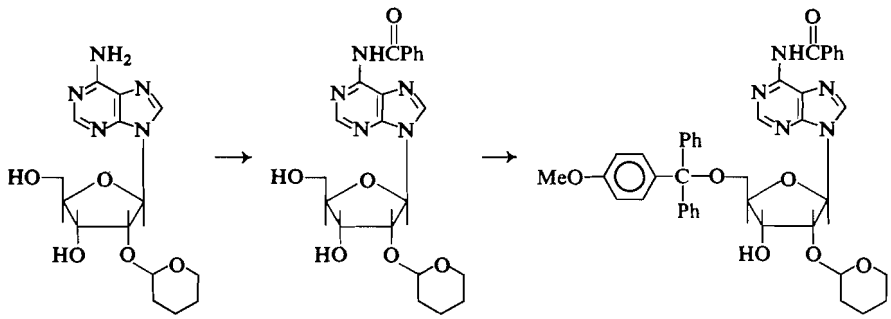
(*a*) Ready solubility of tertiary phosphates in non-polar solvents means that relatively large quantities of intermediates can be handled by silica gel chromatography (3–5). Consequently the slower DEAE–cellulose chromatographic procedures can be by-passed, at least until after the various protecting groups have been removed late in overall synthesis.

(*b*) Removal of the *O*-tetrahydropyranyl grouping can be accomplished using mild mineral acid (p*H* 2) (6) with negligible isomerization of the diphosphate ester linkage. Consequently certain acid-labile protecting groups can also be used to protect the hydroxyl groups of the ribofuranoside ring.

A new stepwise oligoribonucleotide synthesis incorporating these salient features has been developed (1) and its relative convenience illustrated by the synthesis of uridyl[3′–5′]uridyl[3′–5′]uridine (UpUpU) from 2′-*O*-tetrahydropyranyluridine. To show the general nature of this synthetic procedure, 2′-*O*-tetrahydropyranyl derivatives of adenosine, cytidine, and guanosine must be available to allow preparation of oligonucleotides of any sequence. Although the uracil base requires no protection, the amino groups of adenine, cytosine, and guanine must be protected to ensure efficient 3′–5′ diphosphate coupling. *N*-Aroyl groups, in particular *N*-benzoyl and anisoyl, are most often used for this purpose.

In this communication we describe the synthesis of protected intermediates, N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**2**) and N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**11**) and their corresponding 5′-*O*-*p*-methoxytrityl derivatives, **3** and **12** (the latter pair destined to become the precursors of the 5′-terminal nucleoside unit of an oligoribonucleotide). Subsequent stepwise incorporation of these compounds into a linear sequence by diphosphate coupling will provide synthesis of protected oligoribonucleotides

[1]For part 1 see ref. 1.



1 2 3

containing any predetermined sequence of uridine, adenosine, and cytidine.

2′-*O*-Tetrahydropyranyladenosine (**1**) was prepared by the method of Griffin *et al.* (6). The better crystallizing lower R_F diastereoisomer was used in subsequent conversions to ensure complete and specific blocking of the 2′-position of adenosine. This will guarantee high fidelity in all future 3′–5′ internucleotidic linkages.

Benzoylation of **1** in pyridine followed by careful de-*O*-benzoylation (7) gave N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (**2**) in 87% yield as a solid foam. Treatment of **2** with 1 equiv of *p*-anisylchlorodiphenylmethane in pyridine gave the expected N^6-benzoyl-5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranyladenosine (**3**) in 88% yield.

Treatment of 2′,3′-*O*-methoxyethylidenecytidine (**5**) (8) with benzoyl chloride in pyridine gave N^4,5′-*O*-dibenzoyl-2′,3′-*O*-methoxyethylidenecytidine (**6**) in 95% yield over two steps from cytidine (4). Treatment with 5% acetic acid opened the cyclic orthoacetate ring system to give a mixture of the 3′- and 2′-*O*-acetyl derivatives, **7** and **8**. The p.m.r. data indicated an approximate 3:1 mixture of the isomers. Fractional crystallization gave 3′-*O*-acetyl-N^4,5′-*O*-dibenzoylcytidine in 35% yield. The p.m.r. data of the 3′-*O*-acetate, **7**, agreed with the empirical rules established by Fromageot *et al.* (9).

Deacylation studies on **7** showed that it was possible to remove the protecting groups selectively. Half-saturated methanolic ammonia treatment for 2.5 h at ambient temperature gave 85% yield of the N^4,5′-*O*-dibenzoylcytidine (**9**). Sodium hydroxide (0.5 *N*) treatment on **7** in ethanol–pyridine solution gave N^4-benzoylcytidine in 57% yield. Prolonged methanolic ammonia exposure on **7** for 2 days at ambient temperature gave cytidine (**4**) in 69% yield. Such mild conditions for the removal of an *N*-benzamido group should prove useful in an oligoribonucleotide deblocking procedure.

Reaction of **7** with dihydropyran and *p*-toluenesulfonic acid in anhydrous dioxan gave the corresponding 2′-*O*-tetrahydropyranyl derivative which on immediate de-*O*-acylation using methanolic ammonia, gave a diastereoisomeric mixture of N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**11**). Silica gel column chromatography separated this mixture into low R_F (high melting) and high R_F (low melting) components in 30 and 34% yields respectively. Treatment of **11** (low R_F) with 1 equiv of *p*-anisylchlorodiphenylmethane in anhydrous pyridine gave the expected N^4-benzoyl-5′-*O*-methoxytrityl-2′-*O*- tetrahydropyranylcytidine (**12**) in 96% yield.

A further check on exclusive 2′-*O*-tetrahydropyranyl substitution of cytidine was provided by preparing **11** from 3′-*O*-acetyl-N^4-benzoyl-5′-*O*-methoxyacetylcytidine (**15**). The isolation of **15** and its 2′-isomer **16** as crystalline solids has been reported (10), thorough p.m.r. and chemical studies on this pair being carried out to ascertain their substitution pattern. Unfortunately no preparative data exist for these compounds and so **15** was prepared in the following manner.

Cytidine (**4**) was converted to its N^4-benzoyl derivative **10** in 59% yield by reaction of benzoic anhydride in methanol. Trimethyl orthoacetate treatment of **10** in anhydrous acidic conditions gave N^4-benzoyl-2′,3′-*O*-methoxyethylidinecytidine (**13**) as a glass in 90% yield. Reaction of **13** with methoxyacetic acid[2] activated by triiso-

[2]This constitutes a convenient general method for esterification as it uses the more stable and more readily available free carboxylic acids rather than their corresponding acid chlorides or anhydrides.

propylbenzenesulfonyl chloride in pyridine gave the corresponding 5′-*O*-methoxyacetate (**14**) as a solid foam. Orthoacetate ring opening of **14** using aqueous 5% acetic acid solution gave the expected mixture of 2′- and 3′-*O*-acetate isomers **15** and **16** in 33% yield over the last two steps. Fractional crystallization of this mixture gave a sample of pure 3′-*O*-acetate (**15**). Condensation of **15** with dihydropyran and subsequent methanolic ammonia treatment gave a diastereoisomeric mixture of N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (**11**) which on silica gel column chromatography gave identical samples of the components obtained by the route described above.

Thus, suitably protected intermediates are available for insertion into the stepwise synthesis (1). Work describing the triphosphate coupling reactions and subsequent deblocking procedures to give oligoribonucleotides of predetermined sequence and length is in progress.

Experimental

Melting points were taken on a Gallenkamp hot-block melting point apparatus and are uncorrected. The p.m.r. spectra were recorded on a Varian T60 spectrometer in 10–15% (w/v) DMSO-d_6 – D_2O solutions, and line positions are reported in p.p.m. from the reference (TMS). Mass spectra were determined on an Associated Electrical Industries MS-9 double focusing high resolution mass spectrometer. Silica gel (Baker Analyzed Reagent) was used for column chromatography; and Analtech prescored silica gel plates were employed for t.l.c. The plates were developed in 5 or 10% methanol in methylene chloride mixtures.

N^6-Benzoyl-2′-O-tetrahydropyranyladenosine (2)

The lower R_F component of the diastereoisomeric mixture of 2′-*O*-tetrahydropyranyladenosine (**1**) was prepared from adenosine (6). Compound **1** (1 g) was dissolved in anhydrous pyridine (10 ml) and the solution cooled to 0°. Benzoyl chloride (2 ml) was added dropwise, the reaction mixture stirred for 2 h, and then allowed to return to ambient temperature whereupon pyridine hydrochloride separated. The use of t.l.c. in 5% CH_3OH–CH_2Cl_2 showed the reaction to be complete (R_F 0.1 → 0.9). Ice (2–3 g) was added and the quenching allowed to proceed for 20 min. The mixture was poured into water (100 ml) and the solution extracted with methylene chloride (3 × 50 ml). The combined extracts were washed with water (2 × 50 ml) and evaporated *in vacuo* to give an oil. The crude tribenzoate was dissolved in a solution mixture of ethanol (15 ml) and pyridine (8 ml). A sodium hydroxide (2*N*) solution (16 ml) and additional ethanol (16 ml) were added. The de-*O*-benzoylation was allowed to proceed for *only* 5 min, then Dowex-50 resin (pyridinium form) was added to the reaction mixture until the solution p*H* was approximately 7. The t.l.c. in 5% CH_3OH–CH_2Cl_2 showed complete conversion (R_F 0.9 → 0.3). The resin was removed by filtration and the filtrate was reduced to a third of its volume by evaporation *in vacuo* whereupon it was extracted by methylene chloride (4 × 20 ml). The combined extracts were washed with water (2 × 25 ml) and evaporated *in vacuo* to a solid foam, the last traces of pyridine being removed by co-distillation *in vacuo* with toluene (2 × 20 ml). This foam was subjected to silica gel column chromatography and N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine was obtained as a solid foam (1.13 g, 87%) upon elution with 2% CH_3OH–CH_2Cl_2. Crystallization could not be effected but the material was sufficiently pure for further conversions.

The p.m.r. spectrum showed signals (δ TMS) at 8.82 and 8.78 (2H, 2 singlets; 2 and 8 protons of adenine); 7.95 (2H, multiplet; *o*-benzoate protons); 7.55 (3H, multiplet; other benzoate protons); 6.26 (1H, doublet $J \sim 6$ Hz; 1′-anomeric proton); 4.88 (1H, triplet $J \sim 5$ Hz; 3′-sugar proton); 4.73 (1H, singlet; THP acetal proton); 4.42 and 4.11 (1H each, multiplets; 2′- and 4′-sugar protons); 3.72 (4H, multiplet; *O*-methylene of THP and 5′-sugar protons); and 1.60 p.p.m. (6H, multiplet; *C*-methylene THP protons).

Anal. Calcd. for $C_{22}H_{25}N_5O_6$ (mol. wt. 455.46): N, 15.3. Found: N, 14.7. The mass spectrum of N^6-benzoyl-2′-*O*-tetrahydropyranyladenosine (recorded at 250–260°, probe 1) showed a strong M^+ peak at 455 *m/e*; and further peaks at 426 (M-29, loss of CHO); 351 (M-104, loss of C_6H_5CO—); 266 (M-189, loss of C_6H_5CO— and THP); 136, 135 (M-319, and M-320 respectively, loss of C_6H_5CO—, THP and ribose).

N^6-Benzoyl-5′-O-p-methoxytrityl-2′-O-tetrahydropyranyladenosine (3)

N^6-Benzoyl-2′-*O*-tetrahydropyranyladenosine (280 mg) was dissolved in anhydrous pyridine (2 ml) and methylene chloride (10 ml). *p*-Anisylchlorodiphenylmethane (280 mg, 1.1 equiv) was added and the reaction mixture was sealed and left overnight in the dark at ambient temperature. The t.l.c. in 5% CH_3OH–CH_2Cl_2 showed the reaction was complete (R_F 0.3 → 0.9). The reaction was quenched with ethanol (2 ml) and poured into water (25 ml). The mixture was extracted with methylene chloride (3 × 25 ml). The combined extracts were washed with water (3 × 25 ml) and evaporated *in vacuo* to a gum, the last traces of pyridine being removed by co-distillation *in vacuo* with toluene (2 × 20 ml). Column chromatography on silica gel was applied. Elution with 1% CH_3OH–CH_2Cl_2 gave the desired 5′-*O*-monotrityl material as a solid foam (390 mg, 88%) which was sufficiently pure for oligonucleotide coupling reactions. The p.m.r. spectrum showed signals (δ TMS) at 8.20 and 8.12 (2H, 2 singlets; 2 and 8 protons of adenine); 7.65 (2H, multiplet; *o*-benzoate protons); 7.15 (3H, multiplet; other benzoate protons); 6.90 (14H, multiplet; trityl aromatic protons); 5.95 (1H, doublet $J \sim 5$ Hz; 1′-anomeric proton); 4.80 (1H, triplet $J \sim 4$ Hz; 3′-sugar proton); 4.57 (1H, singlet; THP acetal proton); 4.41 and 4.11 (1H each, multiplets; 2′- and 4′-sugar protons); 3.62 (4H, multiplet; *O*-methylene of THP and 5′-sugar protons); 3.41 (3H, singlet; MeO of *p*-methoxytrityl); and 1.6 p.p.m. (6H, broad multiplet; *C*-methylenes of THP).

2′,3′-O-Methoxyethylidenecytidine (5)

This compound was prepared in 95% yield as described

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(8) and was used in the next reaction without further purification.

*N^4-5′-O-Dibenzoyl-2′,3′-O-methoxyethylidenecytidine (**6**)*

Benzoyl chloride (2.5 ml, 0.021 mol) was added dropwise, with stirring to a cooled (ice) solution of 2′,3′-*O*-methoxyethylidenecytidine (**5**) (2.95 g, 0.01 mol) in anhydrous pyridine (30 ml). When the addition was completed, the reaction mixture was allowed to warm up to room temperature and stirred for a further 1 h. The t.l.c. indicated complete conversion into a product of R_F: 0.85 in 10% CH_3OH–CH_2Cl_2. Water was then added (1 ml) and stirring continued for a further 1 h. The reaction mixture was then concentrated *in vacuo* to *ca.* 10 ml, dilute triethylammonium bicarbonate buffer (p*H* 7.5) was added (25 ml), and the product extracted repeatedly with chloroform (3 × 25 ml). The combined organic extracts were washed, dried (Na_2SO_4), and evaporated to dryness *in vacuo*. The pale yellow glass (4.34 g, 86%, R_F: 0.85 in 10% CH_3OH–CH_2Cl_2) was used in the next reaction without further purification.

*3′-O-Acetyl-N^4-5′-O-dibenzoylcytidine (**7**)*

A mixture of N^4-5′-*O*-dibenzoyl-2′,3′-*O*-methoxyethylidenecytidine (**6**) (4.34 g, 0.0086 mol) and 5% acetic acid (50 ml) was stirred at room temperature. After 30 min t.l.c. indicated the presence of products of R_F: 0.89, 0.80, and 0.66 in 10% CH_3OH–CH_2Cl_2. The reaction mixture was then repeatedly extracted with methylene chloride (4 × 25 ml), the combined organic extracts were washed, dried (Na_2SO_4), and evaporated *in vacuo*. The colorless glass (4.08 g) was purified by chromatography on silica gel (60 g) in methylene chloride. Elution with 2% methanol – methylene chloride (400 ml) and 2.5% methanol – methylene chloride mixtures (400 ml) gave a mixture of **7** and **8** (1.85 g, 44% yield, R_F: 0.66 in 10% CH_3OH–CH_2Cl_2).

Pure 3′-*O*-acetyl-N^4-5′-*O*-dibenzoylcytidine (**7**), 1.48 g, 35% yield of m.p. 192–194°, was obtained by crystallization from absolute ethanol (50 ml). The p.m.r. spectrum showed signals (δ TMS) at 8.28–7.28 (12H, multiplet, two C_6H_5CO—, and 6-, 5-cytidine protons); 5.90 (1H, doublet, $J \sim 5$ Hz; 1′-anomeric proton); 5.12 (1H, triplet; 2′-sugar proton) and at 2.1 p.p.m. (3H, sharp singlet; —$COCH_3$ protons).

Anal. Calcd. for $C_{25}H_{23}N_3O_8$ (mol. wt. 492.46): C, 60.85; H, 4.70; N, 8.52. Found: C, 60.36; H, 4.71; N, 8.26.

Concentration of the mother liquor to a small volume yielded a *ca.* 1:1 mixture of N^4-benzoyl-2′(3′)-*O*-acetates **8** and **7** respectively of m.p. 177–185°. The p.m.r. spectrum showed signals (δ TMS) at 5.99 (1H, two doublets of the 1′-anomeric protons of **7** and **8** superimposed); 5.48 and 5.23 (1H, two triplets of 2′-proton of **7** and 3′-proton of **8** superimposed); and at 2.18 and 2.15 p.p.m. (3H, two sharp singlets; of 3′-$COCH_3$ protons of **7** and 2′-$COCH_3$ protons of **8** respectively).

*N^4-Benzoyl-2′-O-tetrahydropyranylcytidine (**11**)*

(*a*) A solution of *p*-toluenesulfonic acid monohydrate (0.86 g, 4.3 mmol) in dry dioxan (15 ml) containing molecular sieves (0.25 g) was cooled in ice until solidified. Dihydropyran (5.24 g, 6.0 ml; 0.062 mol) was then added dropwise with stirring, followed by a suspension of 3′-*O*-acetyl-N^4-5′-*O*-dibenzoylcytidine (3.0 g, m.p. 190–192°; 0.06 mol, R_F: 0.62 in 10% CH_3OH–CH_2Cl_2) in dry dioxan (15.0 ml). The reaction mixture was then allowed to warm up to room temperature (*ca.* 10 min) and kept at this temperature with continued stirring. After 2 h t.l.c. indicated complete conversion into products of R_F: 0.84 and 0.73 in 10% CH_3OH–CH_2Cl_2. The colorless solution was then cooled in ice and neutralized with concentrated ammonia. The precipitated ammonium tosylate was filtered off, washed well with methylene chloride, and the combined filtrate and washings evaporated *in vacuo*. The yellow oil (3.2 g) obtained was suspended in a mixture of ethanol (30 ml) and pyridine (15 ml), and 50% ethanolic sodium hydroxide (containing 15 ml 2 *N* NaOH and 15 ml absolute ethanol) was added with stirring, and the reaction mixture set aside at room temperature. After 5 min t.l.c. indicated two products of R_F: 0.69 and 0.61 in 10% CH_3OH–CH_2Cl_2 in about 1:1 proportion. The p*H* of the solution was then adjusted to 7.0 with Dowex 50W-X8 resin (pyridinium form). The resin was then filtered off, washed well with methylene chloride – ethanol, and the combined filtrate and washings evaporated *in vacuo*. The resulting mixture of diastereoisomers was separated on silica gel (40 g) in methylene chloride. Elution with 3% methanol – methylene chloride mixture (400 ml) yielded 0.88 g (34.1%) of the low m.p. diastereoisomer of R_F: 0.61 in 10% CH_3OH–CH_2Cl_2. Continued elution with 4% methanol – methylene chloride mixture (200 ml) gave 0.46 g (17.8%) of a mixture of the two diastereoisomers R_F: 0.61 and 0.54 in 10% CH_3OH–CH_2Cl_2. Finally, the high m.p. isomer of R_F: 0.54 (0.41 g, 15.5%) was obtained on elution with 4.0–4.5% methanol – methylene chloride mixtures (200 + 400 ml). The mixture of diastereoisomers (0.46 g; R_F: 0.61 and 0.54 in 10% CH_3OH–CH_2Cl_2) was rechromatographed on silica gel (15 g) to yield further 0.38 g (14.5%) of the high m.p. diastereoisomer of R_F: 0.54. An analytically pure sample of m.p. 162–164°, R_F: 0.61 was prepared by crystallization from methylene chloride – hexane. Its p.m.r. spectrum showed signals (δ TMS) at 8.05–7.25 (6H, multiplet, C_6H_5CO—, and 5-cytidine proton); 5.85 (1H, singlet, 1′-anomeric proton); 5.02 (1H, singlet, acetal proton of THP); 3.78 (4H, —O—CH_2— protons of THP and 5′-sugar protons); and a broad peak at 1.6 p.p.m. (6H, multiplet, THP protons).

Anal. Calcd. for $C_{21}H_{25}N_3O_7$ (mol. wt. 431.43): C, 58.46; H, 5.84; N, 9.74. Found: C, 58.33; H, 5.61; N, 9.27.

Crystallization from methylene chloride – hexane provided an analytical sample of m.p. 194–196° of the other isomer of R_F: 0.54 (Reese reported (11) m.p. 195–197°). Its p.m.r. spectrum showed signals (δ TMS) at 8.45 (1H, doublet, $J \sim 8$ Hz; 6-cytidine proton); 8.08–7.2 (6H, multiplet, C_6H_5CO—, and 5-cytidine proton); 6.03 (1H, doublet, $J \sim 4$ Hz; 1′-anomeric proton); 4.80 (1H, singlet, acetal proton of THP); and a broad peak at 1.58 p.p.m. (6H, multiplet, THP protons).

Anal. Calcd. for $C_{21}H_{25}N_3O_7$ (mol. wt. 431.43): C, 58.46; H, 5.84; N, 9.74. Found: C, 58.55; H, 5.82; N, 8.94.

(*b*) A solution of *p*-toluenesulfonic acid monohydrate (142 mg, 0.75 mmol) in dry dioxan (5 ml) containing molecular sieves (0.05 g) was cooled in ice till solidified.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Dihydropyran (0.92 g, 1 ml, 1.1 mmol) was then added dropwise with stirring, followed by a suspension of 3′-*O*-acetyl-N^4-benzoyl-5′-*O*-methoxyacetylcytidine (**15**) (0.461 g, 1.0 mmol; m.p. 95–97° R_F: 0.69 in 10% CH_3OH–CH_2Cl_2) in dry dioxan (2.5 ml). The reaction mixture was then allowed to warm up to ambient temperature (*ca.* 10 min) and maintained with continued stirring. After 3.5 h, t.l.c. indicated complete conversion into products of R_F: 0.93 and 0.86 in 10% CH_3OH–CH_2Cl_2. The colorless solution was then cooled in ice, neutralized with concentrated ammonia, the precipitated ammonium tosylate filtered off, and washed well with methylene chloride and the combined filtrate and washings evaporated *in vacuo*. The yellow oil obtained was suspended in a mixture of ethanol(5.0 ml) – pyridine(2.5 ml), 50% ethanolic sodium hydroxide (containing 2.5 ml 2 N NaOH and 2.5 ml absolute ethanol) was added with stirring, and the reaction mixture set aside at room temperature. After 5 min, t.l.c. indicated two products of R_F: 0.69 and 0.61 in 10% CH_3OH–CH_2Cl_2. The p*H* of the solution was then adjusted to 7.0 with Dowex 50W-X8 resin (pyridinium form). The resin was then filtered off, washed well with methylene chloride – ethanol, and the combined filtrate and washings evaporated *in vacuo*. The resulting colorless glass (0.4 g) was purified by chromatography on silica gel (15 g) in methylene chloride. Elution with 3% methanol – methylene chloride mixture (200 ml) first yielded pure N^4-benzoyl-2′-*O*-tetrahydropyranylcytidine (62 mg, 14%; R_F: 0.61); then some mixture (0.044 g, R_F: 0.69 and 0.61). The second diastereoisomer (0.161 g, 37%; R_F: 0.61) was obtained on further elution with 4% methanol – methylene chloride mixture (200 ml). An analytical sample of m.p. 193–195°, R_F: 0.61 was obtained by crystallization from methylene chloride – hexane. The p.m.r. spectrum was identical with that of a sample obtained from the N^4-5′-*O*-dibenzoyl-3′-*O*-acetylcytidine (**7**) prepared previously (*a*).

*N^4-Benzoyl-5′-O-p-methoxytrityl-2′-O-tetrahydropyranylcytidine (**12**)*

N^4-Benzoyl-2′-*O*-tetrahydropyranylcytidine (**11**) (107 mg, 0.25 mmol; m.p. 193–195°; R_F: 0.54 in 10% CH_3OH–CH_2Cl_2) was evaporated from anhydrous pyridine (2 × 10 ml) and finally its volume reduced to *ca.* 3 ml. *p*-Anisylchlorodiphenylmethane (90 mg, 0.27 mmol; 1.1 equiv) was added and the reaction mixture set aside at room temperature in the dark. After 16 h t.l.c. indicated the presence of a product of R_F: 0.73 and some starting material of R_F: 0.51 in 10% CH_3OH–CH_2Cl_2. Further amount of the reagent (45 mg, 0.13 mmol) was then added, and the reaction allowed to continue till completed (*ca.* 2–3 days). Absolute ethanol (5 ml) was then added, and the mixture evaporated *in vacuo*. The resulting oil was dissolved in methylene chloride, washed with water, and evaporated to dryness *in vacuo*. The last traces of pyridine were removed by co-distillation with toluene (2 × 5 ml). The colorless glass (280 mg) obtained was purified by chromatography on silica gel (12 g) in methylene chloride. Elution with 1–2% methanol – methylene chloride mixtures (200 + 200 ml) yielded N^4-benzoyl-5′-*O*-*p*-methoxytrityl-2′-*O*-tetrahydropyranylcytidine (**12**) (170 mg, 96%) (R_F: 0.73 in 10% CH_3OH–CH_2Cl_2). The p.m.r. spectrum showed signals (δ TMS) at 8.35–6.85 (21H, multiplet, C_6H_5CO—, 6-, and 5-cytidine protons; and *p*-methoxytrityl protons); 6.10 (1H, doublet $J \sim 2$ Hz; 1′-anomeric proton); 4.98 (1H, broad singlet, acetal proton of THP); 3.68 (3H, sharp singlet; OCH_3); and 1.62 p.p.m. (6H, broad multiplet; THP protons).

*Selective De-O-acylation of 3′-O-Acetyl-N^4-5′-O-dibenzoylcytidine (**7**)*

*(a) N^4-Benzoylcytidine (**10**)*

To a stirred suspension of 3′-*O*-acetyl-N^4-5′-*O*-dibenzoylcytidine (**7**) (200 mg, 0.4 mmol, m.p. 188–190°, R_F: 0.62 in 10% CH_3OH–CH_2Cl_2) in ethanol (1.0 ml) and pyridine (0.5 ml), 50% ethanolic sodium hydroxide (containing 0.5 ml of 2 *N* NaOH and 0.5 ml of absolute ethanol) was added at room temperature. The clear solution obtained was stirred for 5 min, when t.l.c. indicated complete conversion into a product of R_F: 0.16 in 10% CH_3OH–CH_2Cl_2. The p*H* of the solution was then adjusted to 7.0 with Dowex 50W-X8 resin (pyridinium form), the resin was filtered off, washed well with methanol – methylene chloride, and the combined filtrate and washings evaporated *in vacuo*. The white crystals of N^4-benzoylcytidine (**10**) (82 mg, 57%) had m.p. 220–222° (dec.) R_F: 0.16 in 10% CH_3OH–CH_2Cl_2; lit. m.p. 219–220° (12).

The p.m.r. spectrum showed signals (δ TMS) at 8.55 (1H, doublet, $J \sim 8$ Hz; 6-cytidine proton); 7.35 (1H, doublet, $J \sim 8$ Hz; 5-cytidine proton); 8.15–7.40 (5H, multiplet, C_6H_5CO—); and 5.90 p.p.m. (1H, doublet, $J \sim 3$ Hz; 1′-anomeric proton). N^4-Benzoylcytidine (**10**) was also prepared from cytidine by selective benzoylation.

A mixture of cytidine (5.0 g, 0.02 mol) in methanol (250 ml) and benzoic anhydride (1.0 g, 4.4 mmol) was heated under reflux. Further portions of benzoic anhydride (5 × 1 g, 0.022 mol) were added at *ca.* 1 h intervals. After the addition was completed (total added 6.0 g, 0.026 mol) the reaction mixture was cooled, and the precipitated N^4-benzoylcytidine (1.77 g, R_F: 0.16 in 10% CH_3OH–CH_2Cl_2) was filtered off. The t.l.c. indicated still some unreacted starting material (R_F: at origin in 10% CH_3OH–CH_2Cl_2), so the filtrate was concentrated *in vacuo* to *ca.* 150 ml, and was again heated under reflux with further portions of benzoic anhydride (3 × 1 g, 1.3 mmol). On cooling further 2.33 g of product (R_F: 0.16 in 10% CH_3OH–CH_2Cl_2) was filtered off. Total obtained: 4.1 g, m.p. 220–222° (dec.) 59%. The sample of N^4-benzoylcytidine (**10**) was identical with that obtained above (*a*) from (**7**) as confirmed by its p.m.r. spectrum.

*(b) N^4-5′-O-dibenzoylcytidine (**9**)*

3′-*O*-Acetyl-N^4-5′-*O*-dibenzoylcytidine (**7**) (200 mg, 0.4 mmol; m.p. 188–190°, R_F: 0.62 in 10% CH_3OH–CH_2Cl_2) was suspended in dilute methanolic ammonia (4 ml, prepared by diluting saturated (at 20°) methanolic ammonia with an equal volume of methanol) and stirred at room temperature. After 2.5 h t.l.c. indicated complete conversion into a product of R_F: 0.46 in 10% CH_3OH–CH_2Cl_2. The reaction mixture was then evaporated *in vacuo*, and the product crystallized from ethanol. N^4-5′-*O*-Dibenzoylcytidine was obtained (150 mg, 85%; m.p. 193–195°, R_F: 0.46 in 10% CH_3OH–CH_2Cl_2; lit. m.p. 186–190° (8)). Its p.m.r. spectrum showed signals (δ

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

TMS) at 8.3–7.25 (12H, multiplet, 6-, and 5-cytidine protons, and *two* C_6H_5CO— protons); 5.95 (1H, doublet, $J \sim 2$ Hz; 1′-anomeric proton); and 4.85 and 4.25 p.p.m. (5H, 2 multiplets, sugar protons).

(c) Cytidine (4)

3′-*O*-Acetyl-N^4-5′-*O*-dibenzoylcytidine (**7**) (100 mg, 0.2 mmol; m.p. 188–190°, R_F: 0.62 in 10% CH_3OH–CH_2Cl_2) was suspended in dilute methanolic ammonia (4 ml, prepared by diluting saturated (at 20°) methanolic ammonia with an equal volume of methanol) and stirred at room temperature. After 40 h t.l.c. indicated complete conversion into a product of R_F: at the origin in 10% CH_3OH–CH_2Cl_2. The reaction mixture was then evaporated to dryness *in vacuo* and triturated with ether (3 × 5 ml), and the residue crystallized from ethanol. The cytidine (**4**) obtained (33 mg, 69%; m.p. 210–212°, R_F, at origin in 10% CH_3OH–CH_2Cl_2) was identical with that of an authentic sample.

N^4-Benzoyl-2′,3′-O-methoxyethylidenecytidine (13)

A mixture of N^4-benzoylcytidine (5.2 g, 0.015 mol), *p*-toluenesulfonic acid monohydrate (0.70 g, 3.7 mmol; 0.25 equiv) and trimethyl orthoacetate (12.5 ml) was stirred at room temperature. After 2.5 h t.l.c. indicated complete conversion into a product of R_F: 0.72 in 10% CH_3OH–CH_2Cl_2. The reaction mixture was then cooled, and neutralized with concentrated ammonia solution, then chloroform was added (50 ml), and the precipitated ammonium tosylate filtered off. The precipitate was washed well with chloroform (3 × 25 ml), and the combined organic solutions evaporated *in vacuo*. The yellow glass obtained (5.0 g, 90%) had R_F: 0.70 in 10% and 0.48 in 5% CH_3OH–CH_2Cl_2. This material was used for the next reaction without any further purification.

3′-O-Acetyl-N^4-benzoyl-5′-O-methoxyacetylcytidine (15)

Methoxyacetic acid (1.15 g, 12.5 mmol) was evaporated from anhydrous pyridine (2 × 25 ml), and finally its volume reduced to *ca.* 10 ml. The solution was sealed under nitrogen, tri-isopropylbenzenesulfonyl chloride (3.5 g, 12.5 mmol) added, and the reaction mixture allowed to stand at room temperature for 1 h. N^4-Benzoyl-2′,3′-*O*-methoxyethylidenecytidine (**13**) (5.0 g, 12.5 mmol) was evaporated from anhydrous pyridine (2 × 25 ml), and finally its volume reduced to *ca.* 10 ml. This solution was added to the methoxyacetic acid – TPS complex (prepared above) and the reaction mixture set aside at room temperature. After 4 h t.l.c. indicated *ca.* 90% conversion into a product of R_F: 0.84 in 5% CH_3OH—CH_2Cl_2. A small piece of ice was then added to the mixture, and stirring continued for a further 1 h. The reaction mixture was then poured into ice-water (50 ml) and repeatedly extracted with methylene chloride (6 × 30 ml). The combined organic extracts were washed and evaporated *in vacuo* to give N^4-benzoyl-5′-*O*-methoxyacetyl-2′,3′-*O*-methoxyethylidenecytidine (**14**) as a cream colored glass (8.0 g). Crude (**14**) (8.0 g) was treated with 5% acetic acid (100 ml), and the mixture stirred at room temperature. After 16 h t.l.c. indicated complete conversion into products R_F: 0.59, and 0.48 in 5% CH_3OH—CH_2Cl_2. The reaction mixture was then repeatedly extracted with methylene chloride (6 × 40 ml). The combined organic extracts were washed, dried (Na_2SO_4), and evaporated *in vacuo*. The colorless glass obtained (8.5 g) was purified by chromatography on silica gel (100 g) in methylene chloride. Elution with 2% methanol – methylene chloride mixture (300 ml) yielded a mixture, (0.6 g, R_F: 0.59, and 0.48 in 5% CH_3OH–CH_2Cl_2). The required 2′(3′)-*O*-acetyl-N^4-benzoyl-5′-*O*-methoxyacetylcytidine (1.9 g, 33.0%, R_F: 0.48 in 5% CH_3OH–CH_2Cl_2) was obtained on elution with 2.5% methanol – methylene chloride mixture (600 ml). Further material (0.58 g, R_F: 0.25 in 5% CH_3OH–CH_2Cl_2) tentatively identified as N^4-benzoyl-2′(3′)-*O*-acetylcytidine by its p.m.r. spectrum, was obtained by washing the column with 3% methanol – methylene chloride (300 ml). The pure 3′-*O*-acetyl-N^4-benzoyl-5′-*O*-methoxyacetylcytidine (**15**) was obtained by repeated crystallization from absolute ethanol – small amount of methylene chloride. The pure 3′-acetate had m.p. 95–97° (lit. m.p. 99–100° (10)). The p.m.r. spectrum showed signals (δ TMS) at 8.2–7.25 (7H, multiplet; 6-, and 5-cytidine protons; and C_6H_5CO— protons); 5.90 (1H, doublet; $J \sim 4$ Hz, 1′-anomeric proton); 5.30 and 4.28 (3H, two multiplets, sugar protons); 3.25 (3H, sharp singlet, CH_3O— protons); and 2.08 p.p.m. (3H, sharp singlet, —$COCH_3$ protons).

Pure 2′-*O*-acetyl-N^4-benzoyl-5′-*O*-methoxyacetylcytidine of m.p. 146–148° (lit. m.p. 155–157° (10)) was also obtained by repeated crystallization from absolute ethanol – trace of methylene chloride.

Attempts to record the mass spectra of cytidine derivatives **10**, **7**, **15**, and the two diastereoisomers of **11** were unsuccessful. The high temperatures (above 280°, probe 3.5) required for volatilization of these compounds gave only decomposition products.

Bicyclo[2.2.1]heptyl phosphonates. III.[1] Radical Addition of Dimethyl Phosphonate to Norbornadiene

HENRY J. CALLOT[2] AND CLAUDE BENEZRA
Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received August 26, 1970

Radical addition of dimethyl phosphonate to norbornadiene was found to give four main compounds **2**, **3**, **4**, and **5** whose structures have been demonstrated by chemical and spectroscopical methods. Particularly noteworthy is the formation of norbornene phosphonate derivatives in addition to the nortricyclene derivatives.

L'addition radicalaire du phosphonate de diméthyle sur le norbornadiène conduit à quatre produits principaux **2**, **3**, **4**, et **5** dont les structures ont été démontrées par spectroscopie et par voie chimique. Il est intéressant de noter la formation de dérivés du norbornène phosphonate à côté des dérivés nortricycliques.

The course of radical addition to norbornadiene (**1**) depends on the nature of the attacking species (1, 2). Generally nortricyclene derivatives are obtained. Only sulfur (1, 2) or silicon (3) radicals lead to some norbornenyl compounds. Among several radicals (generated from aldehydes, CCl_4, RSH, $(EtO)_2PHO$, etc.), Trecker and Henry (2) found that only mercaptans were able to give norbornene adducts. Since phosphorus, as sulfur and silicon, is also a third-row element, we felt that phosphorus radicals might also give norbornene adducts. Trecker and Henry (2) have reported that addition of phosphorus radicals to norbornadiene gives only nortricyclene products. However these authors investigated only the volatile fraction. In order to test our hypothesis (possible formation of norbornene derivatives with phosphorus radicals) we decided to study in detail the addition of dimethylphosphonate to norbornadiene in the presence of benzoyl peroxide.

Results and Discussion

Addition of dimethylphosphonate to norbornadiene (**1**) affords four compounds **2**, **3**, **4**, and **5**, the latter two being obtained as an inseparable mixture.

The first product is assigned the nortricyclene structure **2** on the following grounds. The n.m.r. spectrum shows no olefinic protons. A doublet centered at 3.71 p.p.m.[3] is assignable to the methoxy groups and H-4 appears as a broad singlet at 2.21 p.p.m. The proton appearing at 2.06 p.p.m. as part of an AB quartet shows a large H–H coupling (11 Hz) compatible, in such a system, only with a geminal relationship. This proton is probably H-7 since among the protons of the nortricyclene only H-7 *syn* to the dimethyl phosphonate group is likely to be deshielded. The signal corresponding to H-3, α to phosphorus, is a broad doublet centered at 1.81 p.p.m. (J_{PCH} = 9 Hz) collapsing to a broad singlet by phosphorus decoupling.

The i.r. spectrum of compound **2** is consistent with a nortricyclyl structure since it shows absorptions at 807 and 3040 cm^{-1} (4, 5). The i.r. spectroscopy technique in this case is not useful since peaks at 807 and 3050 cm^{-1} are also found in the i.r. spectrum of dimethyl *exo*-5-norbornenyl-2-phosphonate (**6**) (6), a possible reaction product which is formed when an excess olefin is used (see below).

The mass spectrum of the nortricyclene phosphonate **2** which will be discussed in detail elsewhere (7) confirms the assigned structure: the base peak at *m/e* 92 and the strong parent ion at *m/e* 202 are typical of nortricyclene derivatives (8).

Chemical evidence for the proposed structure was gained from two cyclopropane ring opening reactions. The first one was the reaction of compound **2** with boiling concentrated HCl to give, after methylation, chloro-**7** and hydroxy-**8** derivatives. Compound **2** was unexpectedly resistant to the classical treatment with an HCl

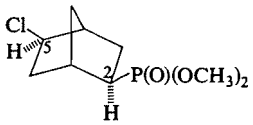
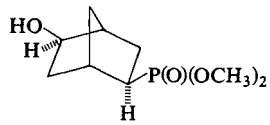
saturated solution in methylene chloride (9); starting material was recovered after 48 h.

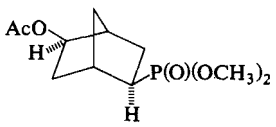
The n.m.r. spectrum of **7** showed a double doublet centered at 3.89 p.p.m. assignable to H-5 on the carbon bearing the chlorine atom.



7



8



9

This pattern is characteristic of an *endo* proton in the bicyclo[2.2.1]heptane system (10), which leaves the *exo* configuration for Cl. *exo*-Configuration for the $(MeO)_2P(O)$ group stems from the existence of a *ca.* 6 Hz spin–spin coupling between ^{31}P and H-1 (11). The absence of coupling between phosphorus and the low field hydrogen (—C*H*Cl), as confirmed by phosphorus decoupling experiments, rules out the possibility of an attack of Cl^- at C-2 in compound **2**.

Structure **7** is confirmed by dehydrochlorination with tert-BuOK in DMSO, a reaction known to proceed without skeletal rearrangement (12), followed by an acidification of the reaction mixture and diazomethane treatment of the resulting phosphonic acid. This base treatment was incomplete and an inseparable mixture of the expected dimethyl *exo*-5-norbornenyl-2-phosphonate (**6**) and of the starting material was recovered. Nevertheless, it was possible to estimate the percentage of norbornene derivative by n.m.r. and a spectrum of a mixture prepared with the calculated proportions of **7** and **6** was superimposable to the n.m.r. of the products of base treatment.

The second product of the $HCl–H_2O$ treatment of the nortricyclene phosphonate followed by methylation is a hydroxyphosphonate, **8**, which was acetylated to **9**. The *exo* orientation for the OAc group (and therefore for OH) is apparent from the double doublet displayed by H-5 as discussed above; the phosphorus again has the same *exo* configuration as in **7**. The alcohol probably results from a direct attack by H_2O on the protonated cyclopropane. Compounds **8** and **9** could also be obtained on treatment of **2** with an acetic acid – sulfuric acid mixture, followed by esterification.

Three other compounds **3**, **4**, and **5** were isolated from the high-boiling fraction. Compound **3** was shown, by combustion analysis, to be a 2:1 adduct (diene:phosphonate). Structure **3** is tentatively assigned to this product. The n.m.r. spectrum shows one dimethylphosphonate

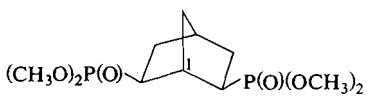
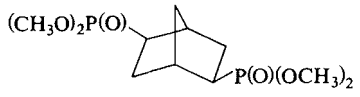
group for two bicyclo [2.2.1]heptyl moieties and *no* olefinic protons. The *exo,exo* junction of the two tricyclic moieties seems reasonable since radical additions to norbornenes generally give mainly *exo* derivatives (13) (except in the case of silicon radicals (3)). The part of the mass spectrum of compound **3** below *m/e* 110 is quite similar to that of the 1:1 adduct **2**. Particularly characteristic of the nortricyclene phosphonate system seem to be the *m/e* 92 and 91 peaks which probably correspond to a nortricyclyl cation (having or not having the nortricyclene skeleton) which has lost one or two hydrogens. The other peaks at *m/e* 79, 66, and 65 are often found in nortricyclene derivatives (8). Finally, as expected from a tricyclic structure, the parent ion [294] is very strong (73% of the base peak 91). The presence of a telomer compound such as **3** is not surprising (14) and their existence was suggested by Trecker and Henry (2) but no isolation was attempted.



4



5

Compounds **4** and **5** are isolated as an inseparable mixture. The structures arise from the examination of their n.m.r. and mass spectra. On the basis of symmetry, it is possible to predict that the two bridgehead protons in structure **4** should be very different and that H-1 should appear as a broad triplet. In structure **5**, the two bridgehead hydrogens play the same role *vs.* the two phosphonate groups and should give a broad doublet, provided the two $(CH_3O)_2P(O)$ groups are *exo* (11). In agreement with the above, the n.m.r. spectrum of the mixture of **4** and **5** showed a doublet and a triplet at 2.57 and 2.97 p.p.m. respectively; these collapse to broad singlets on ^{31}P decoupling. The presence of the parent ion in the mass spectrum confirms the assigned structure.

The structure of diphosphonates **4** and **5** was further proven by their independent preparation through addition of dimethyl phosphonate to the *exo* norbornene derivative **6**. Exactly the same mixture of **4** and **5** is obtained.

Formation of compounds **4** and **5** is of significance and confirms the expectation that phosphorus radicals are able to give norbornene derivatives. Compounds **4** and **5** probably arise from a radical addition to the intermediate dimethyl *exo*-5-norbornenyl-2-phosphonate (**6**) (see Scheme 1). There is competition for the initially formed radical **10** between ring closure, to give the nortricyclyl radical **11** and hydrogen transfer to give the intermediate norbornene derivative **6** which leads to **4** + **5**. The 1:1 ratio of the two compounds is in favor of a statistical attack on the double bond of **6** by dimethyl phosphonate radical.

The intermediacy of dimethyl *exo*-5-norbornenyl-2-phosphonate (**6**) has been confirmed by a radical addition of dimethyl phosphonate to norbornene performed with an excess amount of olefin.[4] The n.m.r. spectrum of the product showed the presence of both **6** and **2**. A mixture of **6** and **2** prepared with authentic samples in the same proportions (3:7) showed n.m.r. and i.r. spectra superimposable to those of the reaction product.

The results of this study confirm that the major products of radical additions to norbornadiene (see Table 1 for product distribution) have a nortricyclene structure (2). It is however of interest to note that formation of norbornene phosphonate and norbornene derivatives does occur. Thus far only silicon and sulfur radicals have been shown to give such products.

Experimental

The n.m.r. spectra were run on a HA-100 Varian Spectrometer in deuterochloroform solutions, chemical shifts are given in δ p.p.m. values with TMS as internal

[4]A referee has pointed out that the decrease in the amount of dimethyl phosphonate used should result in the increase of the ratio nortricyclyl/norbornene adducts (or at least this ratio should remain constant) as was shown in a kinetic study by Cristol *et al.* (1) on radical addition of thiols to norbornadiene. However the isolation techniques of the two experiments are too different to be compared. In the first one (excess phosphonate) the norbornene derivatives are isolated from the high-boiling fraction followed by a chromatography; in the second one (excess olefin) the norbornene phosphonate **6** is isolated by distillation together with the nortricyclyl phosphonate **2**. In the first experiment the yield of diphosphonates **4** and **5** could well be higher than the one indicated in the experimental part and corresponding to the isolated product. In our opinion neither the isolation techniques nor the overall yields are comparable (52.5% total yield in the first experiment, 20% only in the second) and only allow *qualitative* conclusions to be drawn.

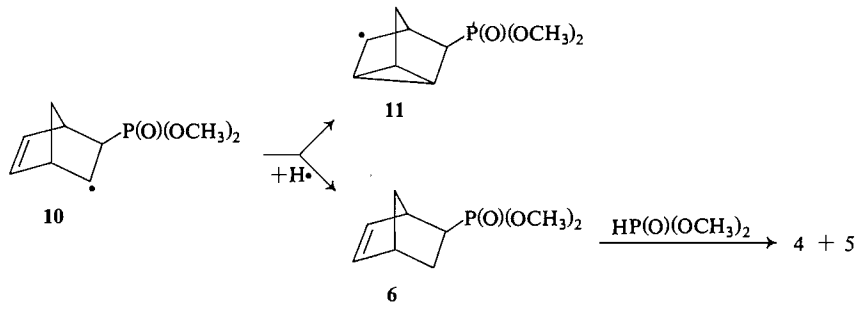


TABLE 1. Products distribution (radical addition to norbornadiene)

reference. The i.r. spectra were all consistent with the proposed structure and showed P=O (1250 cm^{-1}) and P—O—C (1050 cm^{-1}) absorptions. Dimethyl phosphonate and norbornadiene were purchased from Aldrich Company. Mass spectra were recorded on a Hitachi–Perkin–Elmer RMU-6D spectrometer at 70 eV.

Addition of Dimethyl Phosphonate to Norbornadiene (1)

To a boiling solution of norbornadiene (37 g) in dimethyl phosphonate (88 g) was added benzoyl peroxide (2 g) over a 1.5 h period. The reaction mixture was distilled yielding (after a forerun containing both starting materials) two fractions, b.p. 100–150° and 150–225°/10 Torr, and leaving a dark residue (not investigated). The first fraction (35.4 g) was redistilled to give a colorless oil (30 g; 37% from norbornadiene), b.p. 120–123°/10 Torr: compound **2**.

Anal. Calcd. for $C_9H_{15}O_3P$: C, 53.47; H, 7.43; P, 15.35. Found: C, 53.33; H, 7.26; P, 15.40.

The n.m.r.: 3.71 (*d*, 6H, OCH_3, J_{PH} = 8 Hz); 2.21 (broad s, 1H, H-4); 2.06 (*d*, part of an AB quartet, 1H, H-7, J_{AB} = 11 Hz); 1.81 (*d*, 1H, H-3, J_{PH} = 9 Hz); *ca.* 1.25 (m, 6H).[5]

[5]Although most of these assignments agree with Trecker and Henry's (2) for the n.m.r. spectrum of the diethyl ester analog of **2** (within the experimental errors, and considering that their spectrum was taken in CCl_4), these authors describe *two* singlets (assigned to H-4 and -2) and *one* doublet (assigned to H-3) whereas there actually are *one* singlet (H-4) and *two* doublets (probably H-7 and -3, as shown by ^{31}P decoupling). A spectrum of compound **2** was taken in CCl_4 solution at 60 MHz (on a T-60 Varian Spectrometer) and the same pattern (one *s*, H-4, two *d*, H-7 and -3) was found. There is no reason why **2** and its diethyl ester analog (2) should show different absorptions for protons H-4, -7, and -3.

Mass Spectrum: *m/e* 202 (M^+; 53%); 137 (18%), 111 (37%), 110 (45%), 93 (29%), 92 (100%), 91 (70%), 79 (26%), 77 (20%), 65 (18%).

The higher boiling fraction (25 g) was chromatographed on silica gel. Elution with acetone gave successively an oily fraction (1.5 g) showing no P—O—CH_3 resonance (n.m.r.), followed by monophosphonates (9.1 g) and diphosphonates (9.5 g; 7.5% from norbornadiene). Rechromatography of the monophosphonates on silica gel (5 to 20% acetone in carbon tetrachloride) afforded compound **3** (5.1 g; 8.5% from norbornadiene) and some **2** (2.5 g; total yield of **2**: 40%). Compound **3** was purified by microdistillation (130°/0.4 Torr).

Anal. Calcd. for $C_{16}H_{23}O_3P$: C, 65.31; H, 7.82; P, 10.54. Found: C, 64.93; H, 7.66; P, 10.42.

The n.m.r.: 3.71 (*d*, 6H, OCH_3, J_{PH} = 10.5 Hz); complex multiplet 0.8–2.15 (17 H).

Mass Spectrum: *m/e*: 294 (M^+; 74%), 184 (47%), 137 (76%), 124 (66%), 110 (38%), 105 (52%), 92 (36%), 91 (100%), 79 (60%), 77 (48%).

The diphosphonates **4** and **5** were purified by microdistillation (145°/0.25 Torr) and analyzed as a mixture.

Anal. Calcd. for $C_{11}H_{22}O_6P_2$: C, 42.31; H, 7.05; P, 19.87. Found: C, 42.27; H, 7.28; P, 19.77.

Mass Spectrum: *m/e* 312 (M^+; 19%), 203 (19%), 176 (52%), 175 (100%), 174 (12%), 137 (52%), 110 (20%), 93 (15%), 91 (12%), 79 (15%).

Reaction of 2 with Acids

(a) Hydrochloric Acid

A mixture of **2** (1.6 g) and concentrated hydrochloric acid (25 ml) was refluxed for 4 h. The excess acid was evacuated under vacuum and the resulting colorless oil (1.5 g) crystallized slowly. Part of this crude phosphonic acid mixture (1 g) was dissolved in methanol (5 ml) and treated with excess diazomethane in ether. Distillation of solvent followed by chromatography on silica gel (eluent: acetone–CCl_4 mixtures) gave chloride **7** (620 mg, 53%), an oily mixture (30 mg; not further investigated) and alcohol **8** (110 mg, 10%). Compound **7** was purified by microdistillation (120°/15 Torr).

Anal. Calcd. for $C_9H_{16}ClO_3P$: C, 45.28; H, 6.75; P, 13.00; Cl, 14.88. Found: C, 44.99; H, 6.80; P, 12.71; Cl, 15.30.

The n.m.r.: 3.85 (*d* of *d*, 1H, C*H*Cl, J_{HH} 4 and 6.5 Hz); 3.73 and 3.71 (2*d*, 6H, unequivalent OCH_3, J_{PH} = 10.5 Hz); 2.61 (H-1, broad *m*, J_{PH} *ca.* 6 Hz); 2.53 (H-4, *s*).

Mass Spectrum: *m/e* 238 and 240 (M^+, 4 and 13%),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

203 (61%), 175 (32%), 137 (100%), 110 (99%), 109 (36%), 93 (38%), 91 (29%), 80 (38%), 79 (69%).

Alcohol **8** (100 mg) was acetylated in acetic anhydride (0.5 ml)/pyridine (0.5 ml) at room temperature. After standing 5 h, the excess reagents were vacuum distilled (50°/0.2 Torr) yielding the acetate **9** as a colorless oil (105 mg), purified by microdistillation (90°/0.1 Torr).

Anal. Calcd. for $C_{11}H_{19}O_5P$: C, 50.38; H, 7.31; P, 11.83. Found: C, 50.29; H, 7.34; P, 12.01.

The n.m.r.: 4.62 (H-5, *d* of *d*, J_{HH} = 3.5 and 7.5 Hz); 3.74 and 3.72 (2*d*, unequivalent OCH_3, J_{PH} = 10.5 Hz); 2.57 (H-1, broad *s*, J_{PH} *ca.* 6 Hz); 2.40 (H-4); 1.99 (CH_3, *s*).

Mass Spectrum: *m/e* 262 (M^+, 7%), 220 (20%), 202 (19%), 179 (21%), 137 (100%), 124 (19%), 111 (27%), 110 (40%), 109 (61%), 79 (34%).

(b) Acetic acid/sulfuric acid

A solution of **2** (1 g) in acetic acid (20 ml) containing 5 drops of concentrated sulfuric acid, was refluxed for 19 h. Evacuation of acetic acid left a colorless oil, which was dissolved in methanol (50 ml) and left standing for 5 days. Treatment of the resulting solution with excess diazomethane in ether and chromatography on silica gel (carbon tetrachloride – acetone) gave successively acetate **9** (350 mg; 27%), a mixture (190 mg; not investigated), and alcohol **8** (300 mg; 27.5%). Compounds **8** and **9** were identified (i.r., n.m.r., t.l.c.) with the compounds described above.

Dehydrochlorination of Dimethyl exo-5-Chlorobicyclo-[2.2.1]-exo-2-phosphonate (7)

Chloride **7** (100 mg) in anhydrous DMSO (4 ml) was treated with potassium *t*-butoxide (300 mg) in a N_2 atmosphere for 24 h at room temperature. Water (5 ml) was added and the solvent removed (35°/0.05 Torr). The dry solid was dissolved in water (10 ml) treated with HCl and extracted with chloroform (3 × 10 ml). After drying on sodium sulfate and evacuating the solvent, the resulting oil was dissolved in methanol (5 ml) and treated with excess diazomethane. The residue (50 mg), after removal of the solvents, was found to be a mixture of starting material (60–65%) and unsaturated compound **6** (35–40%) by comparing i.r. and n.m.r. spectra of authentic samples.

Preparation of 4 + 5 from 6

A solution of **6** (0.5 g) in dimethyl phosphonate (1 g) was heated at 100° and benzoyl peroxide (40 mg) added over 10 min. Chromatography of the mixture (silica gel; ether–methanol) gave some unreacted dimethyl phosphonate followed by the diphosphonates (650 mg; 84%) as mixture, identified (i.r., n.m.r.) with the sample described above.

Reaction of Dimethyl Phosphonate with Excess Norbornadiene

To a boiling mixture of norbornadiene (46 g; 0.5 mol) and dimethyl phosphonate (27.5 g, 0.25 mol) was added benzoyl peroxide (1 g) during 0.5 h. The mixture was distilled under reduced pressure. After a forerun (10 ml) of dimethyl phosphonate, a fraction, b.p. 92–99°/0.15 Torr (10.5 g), was collected and identified as a mixture of **2** and **6** (7/3) by comparison with n.m.r. and i.r. spectra of authentic samples. The viscous residue left in the distillation flask was not further investigated.

Support of this work by the National Research Council of Canada is gratefully acknowledged.

Model Calculations on the Energy Levels of Diatomic Anharmonic Oscillators: Relation to Hydrogen Bonding[1]

A. FOLDES[2] AND C. SANDORFY
Département de Chimie, Université de Montréal, Montréal, Québec

Received September 14, 1970

Vibrational frequencies and anharmonicity constants for diatomic anharmonic oscillators are obtained by model calculations based on the conventional potential function

$$V = \tfrac{1}{2}k_2q^2 + k_3q^3 + k_4q^4 + \cdots$$

and assumed values of the potential constants. Values obtained from formulas derived from second order perturbation theory are compared with those obtained by diagonalization of a 20 by 20 perturbational matrix. Various sets of potential constants are studied and the range of validity of the second order approximations is determined. An attempt is made to correlate the observed anharmonic behavior of vibrations affected by hydrogen bonding with the results of these model calculations.

In cases of strong perturbations the inapplicability of second order perturbation theory precludes the calculation of the potential constants from the experimentally determined anharmonicity constants. These cannot be deduced from a simple series of overtone frequencies.

Canadian Journal of Chemistry, **49**, 505 (1971)

Introduction

In previous publications from this laboratory, the influence of hydrogen bonding and solvent effects on the anharmonicity of diatomic vibrators have been examined (1–6). It was found that hydrogen bonding has a profound influence on anharmonicity; and, furthermore, that different hydrogen bonds showed different, characteristic anharmonic behavior. Thus O—H···O bond formation in alcohols increased the anharmonicity constant obtained from the fundamental and first overtone frequencies of the OH stretching vibration by a factor of about two; but the same quantity decreased when deduced from the frequencies of the first and second overtones. On the other hand, N—H stretching vibrations in secondary amines showed first a decrease, and then an increase to about the same value as that found for free NH bonds.

Both cases involve a breakdown of second order (Morse curve) approximations, since in this approximation

$$[1]\quad X_{12} \equiv \nu_{01} - \nu_{02}/2 = \nu_{02}/2 - \nu_{03}/3 \equiv X_{23}$$

An alternative way of stating this is that if we use two anharmonicity constants but still within the framework of second order perturbation theory, then

$$[2]\quad X_{123} \equiv \nu_{01} - \tfrac{1}{2}\nu_{02} - 4.5\ Y_{123}$$

$$[3]\quad Y_{123} \equiv \frac{1}{2}\left(\nu_{02} - \nu_{01} - \frac{\nu_{03}}{3}\right)$$

the value of Y_{123} must be very much smaller than X_{123} for the approximation to be valid. (Here ν_{01}, ν_{02}, ν_{03}, $\cdots$ denote the frequencies of the fundamental and the first-, second-, $\cdots$ etc., overtones.) A large value of Y_{123} implies that $X_{12} \neq X_{23}$. (See refs. 3 and 6.)

It would be very useful to be able to compute potential constants from experimentally determined anharmonicity constants in order to gain an insight into the nature of the potential surface controlling the vibrations of hydrogen bonded systems. However, this is not, in general, possible. The dependence of the latter on the former is complex, and the degree of the complexity increases rapidly if we exceed approximations to the second order. We therefore decided to make some model calculations in the reverse order; *i.e.* values of potential constants were assumed and frequencies were calculated.

The aim of these calculations was to determine the approximate magnitudes of the various constants beyond which the second order perturbation method loses its validity; and if possible, to find sets of potential constants which reproduce the observed anharmonic behavior of hydrogen bonded systems.

Calculations

We take the conventional expression for the potential,

$$[4] \qquad V = \tfrac{1}{2}k_2q^2 + k_3q^3 + k_4q^4 + \cdots$$

where the harmonic, cubic, quartic, $\cdots$ potential constants are in cm^{-1}, and q is a dimensionless normal coordinate for a diatomic molecule or a group frequency which is supposed to be perfectly localized in a bond. The Hamiltonian of the system is then

$$[5] \qquad H \equiv \left[\tfrac{1}{2}k_2\left(\frac{p^2}{\hbar} + q^2\right)\right] + k_3q^3 + k_4q^4 + \cdots$$

where the expression in brackets is the energy of the unperturbed system, and the kinetic part is taken to be unaffected by the perturbation. In the perturbation calculation, the perturbed wave functions are, as usual, considered to be expanded in terms of the harmonic oscillator wave functions, and the matrix of the Hamiltonian is then computed. The non-zero terms of p^2, q^2, q^3, and q^4 have been tabulated by Barchewitz (7) and by Buckingham (8); those for q^5 and q^6 have been given by us in a previous publication (3). Using these we have constructed the matrix of the Hamiltonian as in Table 1[1] wherein $q_{vv'}{}^n$ denotes the matrix element of the nth power of the normal coordinate for two harmonic oscillator wave functions characterized by vibrational quantum numbers v and v'; and we have computed the matrix elements numerically for v and $v' = 0$ to 20 and $n = 3$ to 6. These are given in extenso in the Appendix,[1] since they are useful in actual calculations. We have effected the diagonalization of such 20×20 matrices with assumed values of the potential constants on a CDC-3400 Computer, using the subroutine "HDIAG" due to Corbato and Merwin (9) and given by Wiberg (10).

The results are presented in Tables 2, 3,[1] and 4.[1] Under the heading M.C. are the results obtained with the complete 20×20 matrices for the wave numbers of the fundamentals and the first, second, and third overtones. In column 1 are the results obtained by a conventional second order perturbation treatment.

$$[6] \qquad E_v = E_v{}^0 + H'_{vv'} - \sum_{v=v'} \frac{H'_{vv'}{}^2}{E_{v'}{}^0 - E_v{}^0}$$

where $E_v{}^0$ is the unperturbed energy and $H' = k_3q^3 + k_4q^4$, the perturbation. Only the diagonal term of q^4 contributes to the first order, and only the off-diagonal terms of q^3 contribute to the second order perturbation corrections.

Under column 2 are the results of a calculation in which second order perturbation formulas are used, but in which the off-diagonal terms of q^4 are also included; whilst column 3 lists the results obtained under the further inclusion of terms in q^5 and q^6. Approximations 2 and 3 do not correspond to a well defined order of perturbation, but we were interested to know the effect on the results of the additional terms. We also computed the anharmonicity constants X_{123} and Y_{123} from eqs. 2 and 3 using the frequencies obtained by the different approximations.

Results and Discussion

In Table 2 the assumed harmonic frequency was $\omega_e = k_2 = 3800\ cm^{-1}$, and the constants k_3, k_4, k_5, k_6 are related to each other by a factor f multiplying the preceding constant. f was varied from 0.01 to 0.15. In Tables 3[1] and 4[1] the values assumed for ω_e were 3600 and 2700 cm^{-1}, respectively.

These tables require little comment. The most interesting is the comparison between columns "1" and "M.C.", since these contain the frequencies and anharmonicity constants obtained from simple second order perturbation theory and the complete 20×20 matrices where the terms of the successive potential constants up to k_6 were included. It is immediately apparent that the results are almost identical until $f = 0.05$. Significant deviations occur for $f = 0.075$, and from $f = 0.10$ the results of the second order calculation are quite unreliable.

As a "rule of thumb" we might say that if $f \geqslant 0.075$, *i.e.*, if $k_3 \geqslant 0.075\,k_2$, then second order perturbation formulas lead to erroneous results.

The inclusion of the off-diagonal terms of q^4 (column "2") has little effect; but it may be useful since it enables us to introduce the anharmonicity constants W and Y into the expression of the vibrational term values

$$G_v = \omega_e(v + \tfrac{1}{2}) - (v + \tfrac{1}{2})W - (v + \tfrac{1}{2})^2X - (v + \tfrac{1}{2})^3Y - (v + \tfrac{1}{2})^4Z$$

As expected, the inclusion of quintic and sextic

terms into the second order formulas leads to obvious errors (column "3").

In order to observe the behavior of the anharmonicity constants for less regular sets of potential constants we examined four more cases. The results are shown in Figs. 1 to 4. In these figures the solid curves give X_{123} and Y_{123} values computed from the frequencies given by the complete secular determinant; whereas the dashed lines were obtained through approximation 2. The numerical values of X_{123} are different according to the approximation used; but the general trend is the same.

In Fig. 1, $k_2 \equiv \omega_e = 3800\ \text{cm}^{-1}$, k_4 is kept at the constant, small value $9.5\ \text{cm}^{-1}$ (0.25% of k_2) and k_3 is varied from 1 to 5% of k_2. It is seen that under these circumstances Y_{123} varies little but X_{123} increases gradually from about -12 to $+22\ \text{cm}^{-1}$.

In Fig. 2, k_2 is still $3800\ \text{cm}^{-1}$, k_3 is held at the large, constant value $190\ \text{cm}^{-1}$ (5% of k_2) and k_4 is varied from 0 to 5% of k_2. Y_{123} still shows little variation, but X_{123} decreases sharply (from about 30 to $-230\ \text{cm}^{-1}$) when k_4 increases. This is a particularly important diagram since it shows how a large k_4 can make the anharmonicity constants low or even negative while the vibration is actually very anharmonic (*cf.* the case of amines (1, 3, 6, 11)). In Fig. 3, $k_4 = 19\ \text{cm}^{-1}$ is fixed and k_3 varies between 0 and 10%. In this case X_{123} increases until k_3 reaches a value of about 8% of k_2 and then it starts to decrease. Y_{123} remains nearly unchanged until the same point; and from there it increases sharply. Figure 4 illustrates the case of an even higher k_3, $380\ \text{cm}^{-1}$ with k_4 varying between 0 and 10%. X_{123} diminishes with increasing k_4 whereas Y_{123} first decreases and then increases. We repeated these calculations including values of k_5 and k_6 up to $38\ \text{cm}^{-1}$. This produces changes in the numerical results, but does not affect the qualitative aspect of the problem.

We have also studied a few cases with $k_3 = k_5 = 0$ corresponding to symmetrical hydrogen bonds (Table 5). Negative values are obtained for X_{123}; and Y_{123} remains small except for very high values of k_4 (the last section of Table 5). The full secular equation gives lower values for Y_{123} than the simpler approximations. (A small value was given to k_6 in these calculations.) The

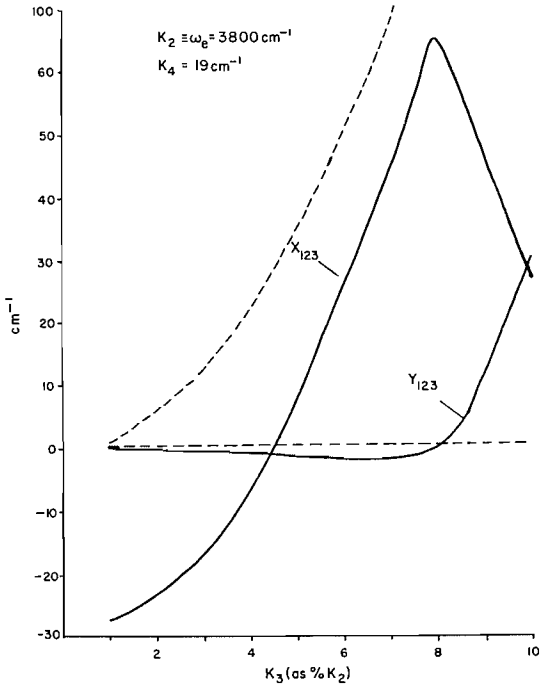

FIG. 3. Anharmonicity constants as functions of k_3. Solid lines, values obtained by diagonalizing the complete perturbation matrix; dashed lines, by second order perturbation formulas ($k_4 = 19\ cm^{-1}$).

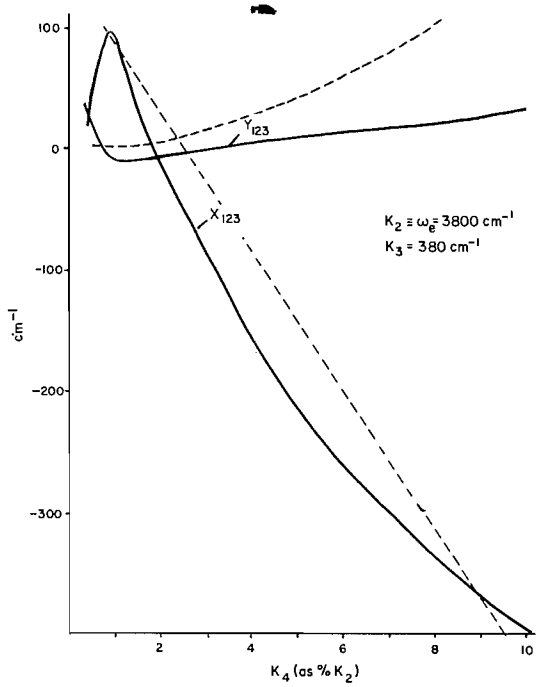

FIG. 4. Anharmonicity constants as functions of k_4. Solid lines, values obtained by diagonalizing the complete perturbation matrix; dashed lines, by second order perturbation formulas ($k_3 = 380\ cm^{-1}$).

first, third, $\cdots$ overtones are forbidden in this case, and the even order overtones diverge. This is substantiated by the frequencies of the fundamental and the second overtones of the antisymmetric stretching vibration of the $(FHF)^-$ ion determined by Coté and Thompson (12, 13).

Conclusion

It has been shown that vibrational frequencies and anharmonicity constants obtained from the usual potential function

$$V = \tfrac{1}{2}k_2q^2 + k_3q^3 + k_4q^4 + \cdots$$

using second order perturbation theory approximate reasonably closely those obtained by a diagonalization of the complete perturbational secular determinant in cases where k_3 does not exceed about 7.5% of k_2 (or Y_{123} no greater than about 5 cm^{-1}) and in which similar ratios apply between k_3, k_4 and the subsequent higher potential constants. Even this applies only when the k_3, k_4, $\cdots$ decrease regularly in this order. With less regular choices or larger values of the anharmonic potential constants the applicability of second order formulas becomes doubtful. In general, increasing k_3 values make X_{123} increase; while increasing k_4 values decrease X_{123} and increase Y_{123}. According to our previous work, the first corresponds to the case of the OH stretching vibrations of self-associated alcohols, and the second to the case of self-associated secondary amines and many other hydrogen bonded NH groups.

Externally unperturbed molecules or molecules only slightly perturbed by solvent effects usually constitute "regular" cases where second order perturbation theory can be considered reliable.

In cases of stronger perturbations, especially hydrogen bonding, the disappointing conclusion is that inapplicability of second-order perturbation theory precludes any simple calculation of the potential constants from the experimentally determined anharmonicity constants. On the other hand the changes observed in the values of the anharmonicity constants together with the model calculations presented in this paper provide an insight into the corresponding trends in the values of the potential constants.

Magnetic and Spectral Studies on Cobalt(II) Fluorosulfate

J. M. TAYLOR AND R. C. THOMPSON
Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received September 2, 1970

The magnetic moment of cobalt(II) fluorosulfate has been measured over the temperature range 312 to 120 °K and the results agree with theory for cobalt(II) in a regular octahedral ligand environment with λ equal to the free-ion value and no reduction in the magnetic moment due to electron delocalization. From its electronic spectrum, values of the ligand-field parameters Dq and B are estimated to be 765 and 860 cm^{-1}, respectively. The infrared spectrum shows no distortion of the fluorosulfate groups from C_{3v} symmetry.

Canadian Journal of Chemistry, 49, 511 (1971)

Introduction

Several transition-metal fluorosulfates have been prepared previously by heterogeneous displacement reactions in fluorosulfuric acid (1, 2). Because of their insolubility in fluorosulfuric acid the compounds are obtained as microcrystalline powders and as yet no structural determinations by single crystal X-ray methods have been reported. In view of their lack of volatility and insolubility in fluorosulfuric acid it seems likely that these compounds are highly polymeric. On the basis, largely, of room-temperature magnetic moments Edwards *et al.* (3) suggested that the metal ions are in an octahedral environment of oxygen atoms; for the fluorosulfates of divalent transition metals this would require each anion to be three-coordinate. The most likely form of coordination by the fluorosulfate ion, FSO_3^-, would be via the three oxygen atoms and a plausible structure would be a layer type of structure (4) in which each fluorosulfate group acts as a tridentate bridge between three different metal ions.

In the work described here the magnetic and spectral properties of cobalt(II) fluorosulfate are examined in an attempt to obtain more information on bonding and on distortions from regular stereochemistry in this compound.

Experimental

Cobalt(II) fluorosulfate was prepared by the reaction of anhydrous cobalt(II) *m*-bromobenzoate with fluorosulfuric acid. The carboxylic acid salt was obtained by reacting sodium *m*-bromobenzoate with an excess of cobalt(II) chloride hexahydrate in water, followed by drying the precipitate under reduced pressure at about 70 °C (5). Fluorosulfuric acid was doubly distilled directly into a reaction flask equipped with a magnetic stirrer and containing finely powdered cobalt(II) *m*-bromobenzoate. The reaction was instantaneous and exothermic yielding a pale pink, insoluble product. The product was vacuum filtered, washed several times in the vacuum filtration apparatus with freshly distilled fluorosulfuric acid (to ensure removal of *m*-bromobenzoic acid), and finally pumped dry. During all these manipulations, care was taken to avoid hydrolysis by atmospheric moisture and the vacuum filtrations and washings were carried out in a manner analogous to that described previously for the preparation of anhydrous chlorosulfates (6). The product was stored in a vacuum desiccator over phosphoric oxide. Cobalt was determined by EDTA titration and fluorine and sulfur analyses were obtained in the A. Bernhardt microanalytical laboratories.

Anal. Calcd. for $CoS_2O_6F_2$: Co, 22.93; S, 24.95; F, 14.78. Found: Co, 22.6; S, 24.79; F, 14.53.

Magnetic susceptibilities were determined, at a field strength of approximately 4,500 G, using the Gouy apparatus described previously (7). A measurement of the magnetic susceptibility at room temperature and a field of approximately 7 000 G gave no evidence for dependence of the susceptibility on field strength. Calibration was achieved using $HgCo(CNS)_4$ (8). Diamagnetic corrections of 12.8×10^{-6} for Co^{2+} and 40.1×10^{-6} (c.g.s.u.) for SO_3F^- (this value obtained by assuming the correction for SO_3F^- will be the same as that for the isoelectronic SO_4^{2-} ion) were made (9).

Infrared spectra in Nujol were obtained using a Perkin–Elmer model 457 spectrophotometer with the sample contained between AgCl and KBr plates.

Electronic spectra were obtained on a powdered sample (diffuse reflectance) using a Bausch and Lomb Spectronic 600 spectrophotometer and on a sample mulled in hexachlorobutadiene using a Cary model 14 spectrophotometer.

Results and Discussion

Vibrational Spectrum

The infrared spectrum of cobalt(II) fluorosulfate shows six bands corresponding to the six

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

fundamental modes of vibration of a fluorosulfate group possessing C_{3v} symmetry. The frequencies (cm^{-1}) observed, with assignments according to Goubeau and Milne (2), are as follows: 1265, $\nu_4(E)$; 1109, $\nu_1(A_1)$; 850, $\nu_2(A_1)$; 610, $\nu_5(E)$; 568, $\nu_3(A_1)$; 420, $\nu_6(E)$. The strongest band is ν_4 and the remaining bands have medium intensities. Any significant reduction in the symmetry of the fluorosulfate group from C_{3v} would cause a splitting of the doubly degenerate E modes. Although ν_4 is a fairly broad band the other two E modes, ν_5 and ν_6 are sharp single bands with no evidence of splitting. Within the limitation of resolution of the instrument used ($\sim 3\ cm^{-1}$) there is no evidence for a lowering of symmetry below C_{3v}.

In its more ionic salts such as those of the larger alkali metals, where cation–anion interactions are relatively weak, the fluorosulfate ion retains C_{3v} symmetry (2, 10, 11). However, in compounds of the bivalent transition metals, interaction of the fluorosulfate ions with the metal ions would be expected to be sufficiently important to alter the vibrational frequencies of the fluorosulfate group. Indeed the frequencies observed for cobalt(II) fluorosulfate are significantly shifted from those in the alkali metal salts. In particular a shift in ν_2 to high frequencies has been shown to be a sensitive test of increased cation–anion interaction (11) and in the cobalt compound it is shifted by about 110 cm^{-1} from the value observed in the potassium salt. The maintenance of C_{3v} symmetry by the fluorosulfate ions in cobalt(II) fluorosulfate in the presence of significant cation–anion interaction indicates that all three oxygens are involved in coordination in an equivalent manner to cobalt ions. One can now assume, for the moment, octahedral coordination of the cobalt ions resulting in a CoO_6 skeleton, not significantly distorted from O_h symmetry. This situation is also indicated by the magnetic susceptibility data discussed below. Support for the arguments used here comes from the observation by Goubeau and Milne (2) that in copper(II) fluorosulfate, the fluorosulfate ions are reduced in symmetry from C_{3v} to C_s. As discussed by these authors, the CuO_6 octahedron is probably distorted with four short Cu—O distances in a square plane and two longer Cu—O distances. It follows then that two of the oxygen atoms in each fluorosulfate ion are closer to copper ions, and thus interact more with the metal ions than the other oxygen atom resulting in the observed reduction in symmetry.

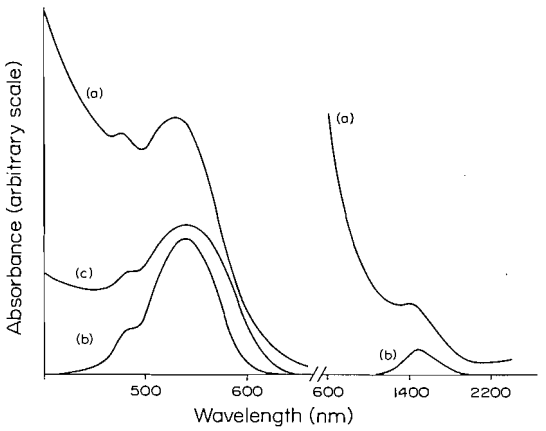

FIG. 1. Electronic spectrum of cobalt(II) fluorosulfate. *a*, hexachlorobutadiene mull; *b*, hexachlorobutadiene mull spectrum corrected for background; *c*, diffuse reflectance.

Electron Spectrum

The electronic spectrum of cobalt(II) fluorosulfate is shown in Fig. 1. The diffuse reflectance spectrum (curve *c*) agrees with that reported by Edwards *et al.* (3) with the exception that our instrument did not have the range required to observe the band at 13 500 cm^{-1} reported by the previous authors. The hexachlorobutadiene mull spectrum (curve *a*) gave a strong background, due presumably to light scattering from the sample, which increased with decreasing wavelength. Subtraction of this background from the spectrum yielded curve *b* in Fig. 1. In view of the excellent agreement between curve *b* and the diffuse reflectance spectrum in the visible region, we feel the procedure used of subtracting the background from the mull spectrum is valid.

Two principal bands are observed in the electronic spectrum at 1500 nm (6670 cm^{-1}) and 540 nm (18 500 cm^{-1}) with a shoulder on the latter band at approximately 480 nm (20 600 cm^{-1}). Assuming a ligand environment of O_h symmetry about Co^{2+} we assign the band ν_1 at 6670 cm^{-1} to the transition $^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$ and the band ν_3 at 18 500 cm^{-1} to the transition $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$. The third ligand field band, ν_2, corresponding to the transition $^4T_{1g}(F) \rightarrow {}^4A_{2g}(F)$ is formally a two-electron transfer and is usually observed, if at all, as a weak band in the spectra of octahedral cobalt(II) complexes. This transition

probably occurs beyond the range of the instrument we used to obtain the diffuse reflectance spectrum and may correspond to the band observed by Edwards *et al.* at 13 500 cm^{-1}. The intense background of the mull spectrum would make observation of a weak band very difficult. The shoulder which appears at 20 600 cm^{-1} on the principal visible band is a common feature of the spectra of octahedral cobalt(II) complexes and its origin has been the subject of considerable discussion. It cannot be assigned to the ν_2 transition since, as discussed by Lever and Ogden (12) this transition should not occur at a frequency more than 2.2 times greater than the ν_1 frequency. It is also unlikely that it is a component of the ν_3 band arising through lowering of the symmetry from O_h, since the magnetic susceptibility results (to be discussed later) indicate that there is no significant distortion of the ligand environment about the cobalt ion. Following the previous work of Ferguson *et al.* (13), we therefore tentatively assign the shoulder to an enhanced spin-forbidden transition.

Initial estimates of the ligand field parameters Dq and B were obtained from the measured ν_3/ν_1 ratio using the appropriate transition energy ratio and Tanabe–Sugano diagrams as described by Lever (14). Final values of 765 cm^{-1} for Dq and 860 cm^{-1} for B were determined by an iterative fit to the expressions for the energies of the $^4T_{1g}(F)$, $^4T_{2g}(F)$, and $^4T_{1g}(P)$ levels given in p. 183 of ref. 14. Using these values the calculated frequency of ν_2 is 14 300 cm^{-1}, in approximate agreement with the band observed by Edwards *et al.* at 13 500 cm^{-1}.

It is instructive to compare the results obtained here for cobalt(II) fluorosulfate with those reported previously for cobalt(II) chloride. The overall spectra are very similar (13). The values of Dq and B for $CoCl_2$ are 764 and 775 cm^{-1} (p. 324 of ref. 14). This places the SO_3F^- ion at the same position as the Cl^- ion in the spectrochemical series for octahedral cobalt(II) but lower than the Cl^- ion (less reduction in the interelectron repulsion parameter B) in the nephelauxetic series.

Magnetic Properties

Magnetic susceptibility data for cobalt(II) fluorosulfate are given in Table 1. The theoretical expression for the magnetic moment of spin-free cobalt(II) complexes in a regular octahedral ligand field, ignoring the effects of electron delocalization, is (15),

$$[1]\quad \mu_{eff}^2 = \frac{3\left[\frac{7(3-A)^2}{5} + \frac{12(2+A)^2}{25Ax} + \left(\frac{2(11-2A)^2}{45} + \frac{176(2+A)^2}{675Ax}\right)\exp\left(\frac{-5Ax}{2}\right) + \left(\frac{(5+A)^2}{9} - \frac{20(2+A)^2}{27Ax}\right)\exp(-4Ax)\right]}{3 + 2\exp\left(\frac{-5Ax}{2}\right) + \exp(-4Ax)}$$

The quantity $x = \lambda/kT$ where λ is the spin–orbit coupling constant. The parameter A allows for the admixture of the higher lying $^4T_{1g}(P)$ into the ground $T_{1g}(F)$ term by the primary cubic field and may be obtained from a knowledge of the parameters Dq and B (16). From the values of Dq and B determined in the present work A is calculated to be 1.43 for cobalt(II) fluorosulfate. Using this value for A and the value -170 cm^{-1} for λ (the free ion spin–orbit coupling constant for Co^{2+} is -172 cm^{-1}), theoretical magnetic moments were calculated at each temperature studied and these are recorded in the last column of Table 1. Although there is some scatter in the experimental magnetic moments at the lower temperatures, in general the agreement between experimental and calculated values is good.

Figgis *et al.* have examined in some detail the effects of electron delocalization and low symmetry ligand fields on the magnetic properties of complexes with $^4T_{1g}$ ground terms (16). These authors tabulate theoretical magnetic moments calculated from expressions which involve two additional parameters: k, the orbital reduction factor, which allows for a reduction in the orbital contribution to the magnetic moment due to electron delocalization ($k = 1$ for no electron delocalization and is otherwise less than unity), and Δ, the axial ligand-field component, which is the magnitude of splitting of the ground term by

*Calculated from eq. 1.

fields of axial symmetry. Equation 1 corresponds to the situation where $k = 1$ and $\Delta = 0$. Attempts to fit our experimental magnetic moments with those tabulated by Figgis *et al.* for other values of k or Δ gave only poorer agreement with theory. The accuracy to which the parameters k, λ, and Δ may be determined by this method warrants some comment. Examining the effects of variations in these parameters on the calculated magnetic moments and considering an experimental uncertainty in the measured magnetic moments of about ± 0.03 at room temperature to about ± 0.05 at the lower temperatures, it is apparent that a reduction of either k or λ up to about 5% from the values 1.0 and -170 cm^{-1} respectively would be difficult to detect. Moreover, the calculated magnetic moments are relatively insensitive to small distortions from octahedral symmetry. The data do indicate, however, that a distortion giving rise to a splitting of the ground term by more than about 300 cm^{-1} is unlikely.

Since the fluorosulfate ion is the anion of a very strong acid (17, 18) it would be expected to exhibit a rather high degree of ionic character in its bonds to transition metals. Consistent with this is the relatively low position of the fluorosulfate ion in the nephelauxetic series as mentioned in the previous section. Values of the parameters k and λ as deduced here from magnetic susceptibility data should give some measure of the degree of metal–ligand covalent bonding, since strong covalent bonding should reduce k below unity and λ below the free-ion value (16). The values of these parameters for cobalt(II) fluorosulfate would appear to be consistent with relatively weak covalent interactions in this compound. It has been pointed out previously (16, 19), however, that a direct correlation between k and λ values and the degree of covalent bonding is not always possible and, indeed, values of these parameters do not as yet provide a sound basis on which to decide the degree of covalent bonding.

The financial support of the National Research Council of Canada is gratefully acknowledged. The authors also thank Mr. C. T. Wong for technical assistance.

Nuclear magnetic resonance measurements upon polymerizing methyl methacrylate solutions show that a significant proportion of the solute molecules (naphthalene, phenanthrene) remain untrapped when the material becomes solid (60–30% residual unsaturation), complete rigid trapping of the solute occurring only as the unsaturation present is reduced to near zero.

Phosphorescence measurements show increasing phosphorescence from solid polymethylmethacrylate containing phenanthrene as the residual unsaturation in the polymer is reduced from about 4% to zero, which is attributed to the gradual immobilization of an increasing fraction of the solute molecules as the unsaturation is reduced. Methyl isobutyrate reduces the phosphorescence from solutions of phenanthrene in polymethylmethacrylate at room temperature, but polymer solutions containing methyl isobutyrate and those containing residual unsaturation phosphoresce strongly at 77 °K.

L'étude par r.m.n. de la polymérisation des solutions de méthacrylate de méthyle indique qu'une proportion significative des molecules solutées (naphthalène, phenanthrène) n'est pas capteé lorsque le matériel se solidifie (60–30% de monomère résiduel). Le soluté est complètement et rigidement capté seulement lorsque le montant de monomère résiduel approche le valeur de zéro.

L'intensité de la phosphorescence d'échantillons de polyméthacrylate de méthyle solide contenant de la phenanthrène augmente lorsque le monomère résiduel dans le polymère est réduit de 4% à 0%. Ceci est attribué à l'immobilisation graduel d'une plus grande fraction de molecules de soluté lorsque le degré de saturation est diminué. L'isobutyrate de méthyle diminue l'intensité de phosphorescence d'une échantillon de polyméthacrylate de méthyle à température ambiante. Mais, les échantillons contenant l'isobutyrate de méthyle aussi bien que ceux contenant le monomère résiduel sont fortement phosphorescents à la température 77 °K.

Canadian Journal of Chemistry, **49**, 515 (1971)

Triplet states of certain aromatic hydrocarbons and *N*-heterocyclic compounds show an initial, unexpected, non-exponential decay in thermally polymerized polymethylmethacrylate (PMMA) containing residual unsaturation (1–15% of the unsaturation originally present in the monomer); the decay becomes essentially exponential as the triplet population falls (1). The ratio of non-exponential to exponential decay is increased by warming the polymer or by incorporating methyl isobutyrate during polymerization but is reduced if the polymer is first annealed at 80–100 °C for periods up to about 48 h (further annealing has relatively little effect). The non-exponential decay was attributed to diffusion-controlled quenching reactions occurring in low-viscosity regions in the solid polymer; it was suggested that the viscosity in such regions would be reduced by incorporating a low-viscosity solvent (*e.g.* methyl isobutyrate) in the polymer or (temporarily) by warming the polymer, while thermal annealing would reduce the proportion of low-viscosity material present by leading to more complete polymerization. The present experiments were carried out to determine whether the solutes used were in fact mobile in "solid" polymethylmethacrylate containing residual unsaturation. They consist of two parts: an investigation of the simultaneous loss of monomer and of solute (naphthalene, phenanthrene) mobility in polymerizing methyl methacrylate by nuclear magnetic resonance

spectroscopy (n.m.r.), and an investigation of the effect of thermal annealing upon the quenching of phenanthrene phosphorescence in PMMA glasses containing no added quencher and in glasses containing iodine or uranyl nitrate. In both studies the unsaturation present was monitored by the infrared absorption at 1621 nm.

Experimental

Methyl methacrylate (Eastman Organic Chemicals) was rapidly distilled twice immediately before use. The remaining materials were reagent grade and used as supplied.

Nuclear magnetic resonance spectra were recorded with a Varian T-60 n.m.r. spectrometer operating in the "auto" mode; integrals were measured without the sample spinning in order to eliminate spinning sidebands from overlapping regions of interest. All solutions studied were freshly prepared and sealed in 5 mm Pyrex n.m.r. tubes; air-free samples were sealed under vacuum but were not exhaustively degassed.

Phosphorescence measurements were made on right-angled prisms (approx. 12 × 12 × 50 mm) cut from material prepared by thermal polymerization of methyl methacrylate solutions at 80 °C for 12–20 h; solutions were not degassed since during polymerization any oxygen present is converted to a form that is not an efficient phosphorescence quencher (1), although completed samples were stored *in vacuo* to reduce oxygen diffusion into the polymer. Iodine added prior to polymerization was converted to (colorless) organic iodide during the polymerization. Total emission spectra (fluorescence, 300–450 nm; phosphorescence, 450–600 nm) were recorded at room temperature with an Aminco-Bowman spectrophotofluorometer (model 4-8202) using 340 nm exciting light. Polymer samples were annealed in baths at 80 or 100 °C for periods up to 20 h and then cooled to room temperature before making spectral measurements.

Unsaturation present in the samples was estimated from their absorption at 1621 nm (2), determined with a Cary 14 recording spectrophotometer, compared with that of a freshly distilled sample of methyl methacrylate of the same dimensions; no allowance was made for the reduction in volume (~21%) which occurs upon polymerization (concentrations referred to in this paper are those of the solutes in methyl methacrylate prior to polymerization).

Results

Figure 1 shows the effect of heating a 1 *M* solution of naphthalene in methyl methacrylate at 80 °C upon the methyl methacrylate concentration (determined from the $=CH_2$ n.m.r. absorption at *ca.* τ 4.6), the concentration of "mobile polymer" (determined from the CH_3 n.m.r. absorption at *ca.* τ 9.1 normalized to methyl methacrylate), the "mobile naphthalene" concentration (determined from the n.m.r. absorption at *ca.* τ 2.8), and the concentration of unsaturation (determined from the absorption at 1621 nm). During polymerization the liquid became progressively more viscous, gelled, and finally contracted sufficiently to pull away from the walls of the container. The points labelled "gel" and "solid" in Figs. 1 and 2 are approximations and correspond to the times at which the liquid became too viscous to flow in the 5 mm diameter tube and at which the material contracted from the walls of the tube, respectively. The fine structure of the n.m.r. spectra was lost only after the material had become solid and no significant n.m.r. absorption was observed with samples which had been heated longer than 20–25 h at 80 °C. Similar results were obtained

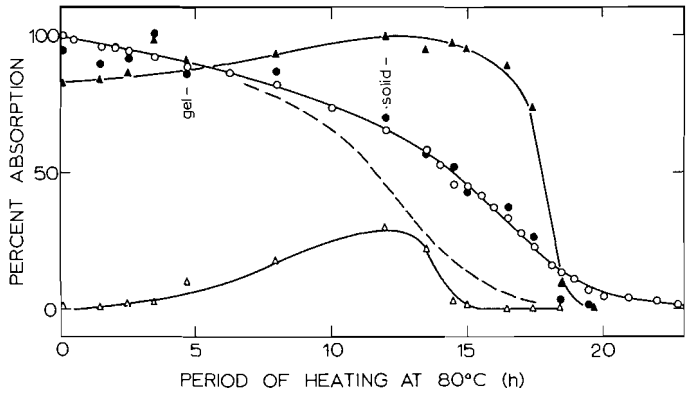

FIG. 1. Effect upon 1 *M* naphthalene in methyl methacrylate of heating at 80 °C *in vacuo*. ▲, naphthalene n.m.r. absorption; △, methyl methacrylate detected as polymer (n.m.r.); ●, methyl methacrylate remaining (n.m.r.); ○, unsaturation remaining (1621 nm absorption); ----, unsaturation remaining, air-saturated solution (1621 nm absorption).

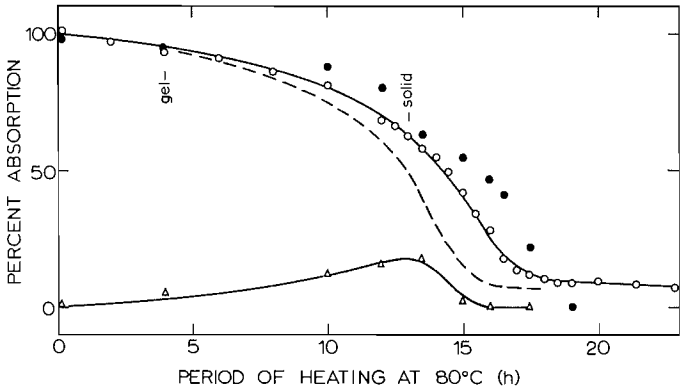

FIG. 2. Effect upon 10^{-3} *M* phenanthrene in methyl methacrylate of heating at 80 °C *in vacuo*. △, methyl methacrylate detected as polymer (n.m.r.); ●, methyl methacrylate remaining (n.m.r.); ○, unsaturation remaining (1621 nm absorption); ----, unsaturation remaining, air-saturated solution (1621 nm absorption).

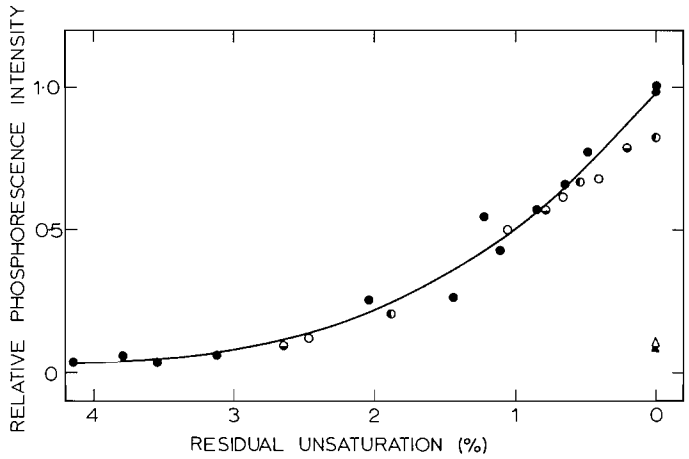

FIG. 3. Relative phosphorescence intensity of polymethylmethacrylate containing 10^{-3} *M* phenanthrene and the following additives: ●, none; ◐, 1.7×10^{-6} *M* iodine; ◒, 10^{-4} *M* iodine; ○, 3×10^{-4} *M* iodine; ▲, 10% methyl isobutyrate; △, 10% methyl isobutyrate + 10^{-4} *M* iodine.

with 10^{-3} *M* solutions of phenanthrene in methyl methacrylate (Fig. 2) although the concentration of phenanthrene was too low for useful measurements of "mobile solute" concentration to be made; the phenanthrene appeared to retard the loss of unsaturation (measured by the 1621 nm absorption) once the concentration of unsaturation had fallen below 10% of the initial value, this effect was very marked with *M* phenanthrene solutions but was not found with any of the other solutes examined. The broken curves in Figs. 1 and 2 show the effect upon the concentration of unsaturation of heating solutions in the presence of air. Infrared and n.m.r. measurements were also made on air-saturated methyl methacrylate solutions containing 1 *M* naphthalene, 1 *M* benzene, and 0.5 *M* benzene + 0.5 *M* methyl isobutyrate, respectively. No significant differences were observed between these experiments and the results depicted in Figs. 1 and 2; the n.m.r. absorption of the benzene and the methyl isobutyrate disappeared at approximately the same rate in the solution containing both of these solutes and the sample showed no measurable n.m.r. absorption after 20 h at 80 °C. An apparent increase in solute concentration, determined from the solute n.m.r. absorption, as the solutions solidify (*e.g.* Fig. 1) is attributed to the contraction that takes place at this point.

Figure 3 illustrates the effect upon phenanthrene phosphorescence intensity at 463 and

496 nm (the plotted points are averages of the intensities at these two wavelengths) of annealing polymethylmethacrylate containing 10^{-3} *M* phenanthrene alone and with organic iodide ($\sim 10^{-6}$ or $\sim 10^{-4}$ *M*) formed by the addition of iodine to the monomer prior to polymerization. The observed phosphorescence intensities are expressed relative to the intensity of a PMMA sample containing 10^{-3} *M* phenanthrene and essentially free of residual unsaturation used as a standard. Small differences ($\pm 4\%$) between individual samples have been allowed for by assuming that the intensity of the fluorescence (at 366 nm) from each sample should be the same (it is independent of the amount of unsaturation present) and normalizing the observed emission spectra to the fluorescence of the standard sample. Polymer samples containing 1 *M* (10% by weight) methyl isobutyrate and 10^{-3} *M* phenanthrene, alone or with the addition of 10^{-4} *M* iodide, had no residual unsaturation detectable by adsorption at 1621 nm after thermal polymerization at 80 °C for 18 h and showed relative phosphorescence intensities about 10% of that of the standard (Fig. 3). These samples and others containing several percent residual unsaturation, all of which showed relatively low phosphorescence intensities at room temperature, phosphoresced strongly when cooled to 77 °K. No quantitative measurements were made at 77 °K.

Discussion

The n.m.r. studies on polymerizing methyl methacrylate containing relatively large amounts of naphthalene (Fig. 1), benzene, and methyl isobutyrate show that polymerization proceeds with the build-up of polymer which becomes immobilized (the polymer-CH_3 n.m.r. absorption broadens and then disappears) as the gelled material contracts and solidifies. However, rigid trapping of the solute only occurs at a rather later stage in the polymerization, and samples containing 10–20% residual unsaturation still contain appreciable amounts of "mobile" solute which appears to be trapped in liquid regions between the polymer chains. Thus the suggestion (1) that PMMA with this degree of residual unsaturation may allow some solute mobility appears to be substantiated. The n.m.r. experiments indicate that some solute molecules have freedom of movement when the polymer contains less than 5% residual unsaturation, although broadening of the n.m.r. spectra make quantitative measurements difficult in this region. Phosphorescence studies were therefore used to investigate solute mobility at low concentrations of residual unsaturation and at low solute concentrations comparable to those used (10^{-6} to 10^{-2} *M*) in the original triplet decay experiments (1).

Triplet quenching occurs rapidly in liquid solutions and is generally attributed to diffusion controlled processes that are restricted in the solid state. Thus liquid solutions of phenanthrene in methyl methacrylate, with or without added quencher, do not phosphoresce although solid solutions of phenanthrene in PMMA do. The present experiments show that the phosphorescence intensity from solutions of phenanthrene in PMMA increases as the residual unsaturation is reduced from about 4% to zero, consistent with the postulates (1) that in this region some solute molecules are still mobile and quenching occurs as a consequence of this, and that solute mobility (and quenching) will be reduced as polymerization becomes more complete (as indicated by the reduction in residual unsaturation). The experiments give no indication of the nature of the quenching species, although it was shown earlier (1) that the unsaturated material present, by itself, does not produce any marked quenching. The addition of iodine, an efficient phosphorescence quencher, to the system has little effect (Fig. 3), suggesting that the availability of quenching species is not a decisive factor. Quenching experiments with uranyl nitrate (10^{-6} or 10^{-4} *M*), which would probably concentrate in the liquid regions of the polymer to a greater extent than iodine, gave results almost identical to those obtained using iodine (Fig. 3).

Polymer samples containing phenanthrene and methyl isobutyrate, but no residual unsaturation, show marked quenching (Fig. 3), consistent with the suggestion that methyl isobutyrate forms low viscosity regions in the polymer in which quenching can occur (however, absence of any n.m.r. absorption characteristic of methyl isobutyrate in PMMA containing this ester but no residual unsaturation indicates that any such regions are small and that movement within them is restricted). The marked increase in phosphorescence from samples containing methyl iso-

butyrate or residual unsaturation when the temperature is lowered to 77 °K is also consistent with solute motion within the solid polymer since any such motion would be reduced as the temperature is lowered.

On the Existence of Five-Coordinate Titanium(IV) Acetylacetonates

C. E. Holloway and A. E. Sentek
Department of Chemistry, York University, Downsview, Ontario

Received July 3, 1970

Monomeric trialkoxy(acetylacetonato)titanium(IV) compounds postulated as five coordinate complexes, are shown to be mixtures of well-established four and six coordinate derivatives. A structure is suggested for the dimeric species.

Canadian Journal of Chemistry, **49**, 519 (1971)

Introduction

The preparation of a number of compounds of the general formula $TiX_3(acac)$, where X is an alkoxy or halide group and acac is chelated acetylacetone, was described several years ago (1). Molecular weight determinations at the time, and also in a later study by other investigators (2) suggested an equilibrium between monomer and dimer dependent upon the bulk of the X group. In particular, when X is the highly branched *iso*-propoxy or *sec*-butoxy group the complexes were found to be monomeric. In less sterically hindered systems the metal atom would be expected to expand its coordination number to six by oligomer formation via bridging alkoxy groups (3). The monomeric derivatives, having a chelated acetylacetonato group (1) should afford examples of five-coordinated titanium(IV). As such they would provide convenient models for investigating ligand exchange processes which are believed to involve five-coordinated intermediates. However, attempts to isolate a monomeric species using highly branched alkoxy groups have failed, and the present results show that such compounds cannot be prepared by the literature methods. Instead, the so-called five coordinate complexes are actually 1:1 mixtures of the more familiar six- and four-coordinated derivatives already known. The former is the bis-acetylacetonato complex, $TiX_2(acac)_2$, and the latter unreacted starting material TiX_4.

Experimental

The *tert*-butoxy and *iso*-propoxy derivatives were prepared by the prescribed method (2) and after pumping under vacuum at room temperature for 24 h gave the correct metal analyses for the mono-acetylacetonato complexes. Metal analysis was carried out gravimetrically (2). The ratio of acetylacetone to alkoxide protons was determined by integration of the proton magnetic resonance (p.m.r.) spectra (5). Two types of alkoxy group were observed in the ratio 1:2 and one type of acetylacetone undergoing intramolecular exchange. The alkoxy to acetylacetone ratio was 3.0:1.0.

The trichloro derivative, $TiCl_3(acac)$, was prepared by the literature method (2) and also by the dropwise addition of $TiCl_4$ to $TiCl_2(acac)_2$ in a 1:1 mole ratio in benzene solution. The dark red crystals were filtered under dry nitrogen and dried *in vacuo*. Satisfactory metal and chloride analyses were carried out gravimetrically (2).

Infrared spectra were obtained on Perkin–Elmer 225 and a Beckmann IR-12 spectrometers using liquid films or mulls in KBr cells. Nuclear magnetic resonance data were obtained on a Varian A-60 instrument at normal operating temperature, using TMS as an internal reference.

Results and Discussion

The *tert*-butoxy and *iso*-propoxy derivatives are pale yellow liquids. Since previous preparations (2) yielded a compound of the correct stoichiometry, no further purification steps have been reported. The p.m.r. spectra of these complexes are shown in Table 1 together with spectra for the starting material, TiX_4 (4), and the bis-acetylacetonato derivative (5) under similar solvent conditions. The estimated rates of exchange

butyrate or residual unsaturation when the temperature is lowered to 77 °K is also consistent with solute motion within the solid polymer since any such motion would be reduced as the temperature is lowered.

On the Existence of Five-Coordinate Titanium(IV) Acetylacetonates

C. E. Holloway and A. E. Sentek
Department of Chemistry, York University, Downsview, Ontario

Received July 3, 1970

Monomeric trialkoxy(acetylacetonato)titanium(IV) compounds postulated as five coordinate complexes, are shown to be mixtures of well-established four and six coordinate derivatives. A structure is suggested for the dimeric species.

Canadian Journal of Chemistry, **49**, 519 (1971)

Introduction

The preparation of a number of compounds of the general formula $TiX_3(acac)$, where X is an alkoxy or halide group and acac is chelated acetylacetone, was described several years ago (1). Molecular weight determinations at the time, and also in a later study by other investigators (2) suggested an equilibrium between monomer and dimer dependent upon the bulk of the X group. In particular, when X is the highly branched *iso*-propoxy or *sec*-butoxy group the complexes were found to be monomeric. In less sterically hindered systems the metal atom would be expected to expand its coordination number to six by oligomer formation via bridging alkoxy groups (3). The monomeric derivatives, having a chelated acetylacetonato group (1) should afford examples of five-coordinated titanium(IV). As such they would provide convenient models for investigating ligand exchange processes which are believed to involve five-coordinated intermediates. However, attempts to isolate a monomeric species using highly branched alkoxy groups have failed, and the present results show that such compounds cannot be prepared by the literature methods. Instead, the so-called five coordinate complexes are actually 1:1 mixtures of the more familiar six- and four-coordinated derivatives already known. The former is the bis-acetylacetonato complex, $TiX_2(acac)_2$, and the latter unreacted starting material TiX_4.

Experimental

The *tert*-butoxy and *iso*-propoxy derivatives were prepared by the prescribed method (2) and after pumping under vacuum at room temperature for 24 h gave the correct metal analyses for the mono-acetylacetonato complexes. Metal analysis was carried out gravimetrically (2). The ratio of acetylacetone to alkoxide protons was determined by integration of the proton magnetic resonance (p.m.r.) spectra (5). Two types of alkoxy group were observed in the ratio 1:2 and one type of acetylacetone undergoing intramolecular exchange. The alkoxy to acetylacetone ratio was 3.0:1.0.

The trichloro derivative, $TiCl_3(acac)$, was prepared by the literature method (2) and also by the dropwise addition of $TiCl_4$ to $TiCl_2(acac)_2$ in a 1:1 mole ratio in benzene solution. The dark red crystals were filtered under dry nitrogen and dried *in vacuo*. Satisfactory metal and chloride analyses were carried out gravimetrically (2).

Infrared spectra were obtained on Perkin–Elmer 225 and a Beckmann IR-12 spectrometers using liquid films or mulls in KBr cells. Nuclear magnetic resonance data were obtained on a Varian A-60 instrument at normal operating temperature, using TMS as an internal reference.

Results and Discussion

The *tert*-butoxy and *iso*-propoxy derivatives are pale yellow liquids. Since previous preparations (2) yielded a compound of the correct stoichiometry, no further purification steps have been reported. The p.m.r. spectra of these complexes are shown in Table 1 together with spectra for the starting material, TiX_4 (4), and the bis-acetylacetonato derivative (5) under similar solvent conditions. The estimated rates of exchange

of acetylacetone methyl sites, based on line shape, are included for comparison. The unimolecular nature of the exchange process was shown by the concentration independence of the methyl line shape. In the case of the *tert*-butoxy derivative the two resonances of equal area indicate two methyl environments per acetylacetone. This is also true of the *iso*-propoxy derivative at low temperature. The close coincidence of the data suggested that the complexes might be mixtures of the bis-acetylacetonato complex and parent alkoxide. A striking difference in the α-proton shifts of alkoxy groups bonded to titanium in different coordination states has been documented elsewhere (6). The infrared spectra from 380 to 4000 cm^{-1} (Table 2) also show the same coincidence (5, 7) and support such an interpretation. Previously reported infrared data for the bis-acetylacetonato complexes (8) are incomplete due to interference from the solvent CS_2, which could not be eliminated by the use of balanced cells. The alternative explanation requires dimer formation with bridging alkoxy groups, which is contrary to the reported molecular weight data.

Careful fractionation of the materials *in vacuo* (0.001 mm Hg) yielded two distinct fractions, in each case with no residue. The first fraction, at a bath temperature between 65–70 °C, was readily identified by n.m.r. and metal analysis as the colorless monomeric tetraalkoxide. The second fraction, at 120–130 °C was the pale yellow bis-acetylacetonato complex. The boiling point of the first fraction is lower than the temperature (75–80 °C) at which the reactants are initially refluxed, hence any ligand scrambling due to heating can be assumed to have taken place during the first steps of the preparation. The similarity of the boiling points of the first fraction and that of the free tetraalkoxide suggests that any association between the two components of the mixture is very weak, consistent with previous molecular weight data. It therefore seems certain that the complexes $TiX_3(acac)$ have not yet been prepared, the primary products of the preparative reaction being the parent compound and its disubstituted derivative.

A feasible explanation for this is that substitution by acetylacetone is more rapid for the second alkoxy group than for the first.

$$[1] \quad TiX_4 + Hacac \xrightarrow{\text{slow}} TiX_3(acac) + HX$$

$$[2] \quad TiX_3(acac) + Hacac \xrightarrow{\text{fast}} TiX_2(acac)_2 + HX$$

This can be understood in terms of reduced steric hindrance to S_N2 attack by which the reaction most likely proceeds. The bis-acetylacetonato complex thus formed can then act as a Lewis base towards the unreacted TiX_4 via lone pairs of electrons of its alkoxy or halide groups. The structure of the dimeric species would be as shown in reaction 3, there being no need to postulate coordination numbers other than 4 and 6 for the titanium atoms in the resulting equilibrium.

With the present two alkoxy derivatives the equilibrium is expected to lie very much to the left. In less sterically hindered derivatives, such as methoxide and ethoxide, the equilibrium would lie more to the right. However, in these cases the parent alkoxide is itself polymerized (3) and a more complicated situation obtains. These cases are being studied further.

Support for the dimer structure (Fig. 1) is

[3] 
afforded by the nature and behavior of trichloro(acetylacetonato)titanium. During the preparation it is fairly evident from color changes that some $TiCl_2(acac)_2$ is initially formed. This is also evident from the alternative preparation in which the insoluble trichloro complex is immediately precipitated on mixing benzene solutions of $TiCl_4$ and $TiCl_2(acac)_2$ at room temperature. The infrared spectra of the Chloro complexes are given in Table 2. The spectra have several interesting differences in both the acetylacetonato and metal–chlorine regions. It is observed (8) that in the $TiX_2(acac)_2$ complexes the band associated with metal–oxygen stretching of the acetylacetonato group moves to higher energy as the X groups become more electro-
